Oxford University Press is a department of the University of Oxford.
It furthers the University's objective of excellence in research, scholarship,
and education by publishing worldwide. Oxford is a registered trade mark of
Oxford University Press in the UK and in certain other countries

First Edition published in 2002

Second Edition published in 2011

Third Edition published in 2022

Impression: 1

Preface

It is now over a hundred and seventy years since Arnold Berthold demonstrated that endocrine glands convey their effects via the bloodstream and a hundred and ten years since the word 'hormone' was coined by Ernest Starling. Amazingly, it is just under a hundred years since one of the nascent specialty's most spectacular Nobel Prize-winning triumphs, the purification and use of insulin to transform Type I diabetes from a rapidly fatal wasting disease of childhood into a manageable chronic condition. Similarly, seventy years ago the Nobel Prize recognised the life-saving impact of glucocorticoids both for patients with adrenal insufficiency and as immunosuppressive therapy for chronic inflammatory disease. Since then endocrinology has continued to ride the crest of a wave of technological advances, most prominent recently in areas such as molecular genetics, imaging, immunotherapy and rational drug design.

The first edition of the *Oxford Textbook of Endocrinology & Diabetes* was published in 2002. The landscape of endocrine disease has evolved enormously since then, driven largely by burgeoning obesity and by population ageing. The spectrum of endocrinology has been further broadened by the increasing use of immunomodulatory therapies with endocrine complications, evolving patterns of recreational drug use impacting endocrine systems, and widespread exposure to endocrine disrupting chemicals. The therapeutic armamentarium of the endocrinologist has also expanded at pace, not only through development of novel small molecule and biological therapies, but also through step changes in e-technology and their application to chronic disease management and "precision" medicine.

We now comprehensively update the second edition of the *Textbook* published in 2012. The expanded first part of the book is devoted to overview chapters focusing on principles underpinning the science and practice of endocrinology. Elsewhere, other sections have also been enlarged to capture exciting developments in subspeciality practice, with separate sections now devoted to endocrine disease in pregnancy and transgender endocrinology.

The diabetes section has been extensively reorganised to reflect rapid advances in understanding the molecular pathogenesis of diabetes, step changes in the sophistication of technologies used for metabolic monitoring and insulin delivery, and innovations in immunotherapy, behaviour-focused and cell-based therapies. New chapters are devoted to current urgent responses to diabetes as a public health and economic challenge.

Fascination in the science underlying endocrinology continues to endure, and clinical endocrinologists have an ever more sophisticated ability to transform the length and quality of life of those with hormone-related diseases. This book aims both to illuminate the emerging scientific concepts that underlie endocrinology, and to provide an accessible and authoritative account of cutting edge endocrine practice.

We are very grateful indeed to our national and international colleagues who have kindly, expertly and cerebrally contributed to all sections. We are proud of this *magnum opus* and thank them sincerely for their significant efforts.

We also thank Claire Brankin, James Oates and Helen Liepman from Oxford University Press who have expertly and efficiently guided us through this whole process.

This book should be available to every endocrinologist, trainee and researcher and we hope that it provides as much enjoyment and intellectual satisfaction in the reading as it did in putting it together.

John A.H. Wass
Wiebke Arlt
Robert K. Semple

Contents

Volume 1

SECTION 4
Parathyroid, Calcium and Bone Metabolism Disorders

Section editor: John Bilezikian

SECTION 5
Adrenal Diseases

Section editor: Wiebke Arlt

Volume 2

SECTION 7
Disorders of Growth, and Development and Transition

Section editor: Peter Clayton

SECTION 8
Female Reproductive Endocrine Disorders

Section editor: Bulent Okan Yildiz

SECTION 9
Endocrine Disorders of Pregnancy

Section editors: Kristien Boelaert and Cathy Williamson

SECTION 10
Male Reproductive Endocrine Disorders

Section editors: Frederick Wu and Mathis Grossmann

Symbols and Abbreviations

AAS	androgenic anabolic steroids
AC	adenylate cyclase (*also* arachnoid cysts)
ACE	American College of Endocrinology
ACE	angiotensin-converting enzyme
ACTH	adrenocorticotrophic hormone
AD	autosomal dominant
ADH	autosomal dominant hypocalcaemia
ADIS	agonist-driven insertional signalling
ADT	androgen deprivation therapy
AF	atrial fibrillation
AGHDA	assessment of GH deficiency in adults
AgRP	agouti-related peptide
AHA	Anterior hypothalamic area
AHO	Albright's hereditary osteodystrophy
AI	alcohol-induced (*also* aromatase inhibitors)
AIDS	acquired immunodeficiency syndrome
AIDS	advanced HIV disease
AIP	aryl hydrocarbon receptor-interacting protein
AIRE	autoimmune regulator
AKAP	A-kinase-anchoring proteins
ALS	acid-labile subunit
ALSPAC	Avon Longitudinal Study of Parents and Children
ANCA	antineutrophil cytoplasmic antibodies
ANF	atrial natriuretic factor
AP	anterior pituitary
APECED	autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy
APT	aggressive pituitary tumours
AR	androgen receptor
ARC	arcuate nucleus
ARE	androgen response elements
ART	assisted reproduction technologies
ASD	autism spectrum disorders
ATA	American Thyroid Association
ATD	antithyroid drug
ATMA	antithyroid microsomal antibody
ATOR	Australian thyroid-associated orbitopathy research
AVP	arginine-vasopressin (*also* antidiuretic hormone)
BMAD	bone mineral apparent density
BMD	bone mineral density
BMI	body mass index
BP	blood pressure
BST	bed nucleus of the stria terminalis
CAH	congenital adrenal hyperplasia
CAIS	complete androgen insensitivity syndrome
CAPTEM	capecitabine and temozolomide
CART	cocaine- and amphetamine-related transcript
CAS	clinical activity score
CAS	Court of Arbitration for Sport
CaSR	calcium-sensing receptor
CBG	corticosteroid-binding globulin
CBG	cortisol-binding globulin
CC	clivus chordoma (*also* clomiphene citrate)
CCCR	calcium-to-creatinine clearance ratio
CCH	central congenital hypothyroidism
CDI	central diabetes insipidus
CDK	cyclin-dependent kinase
CDP	constitutional delay of puberty
CE	calcium excretion
CEA	carcinoembryonic antigen
CG	chorionic gonadotrophin
CGTT	clinical genetics think tank
CH	cavernous haemangiomas (*also* congenital hypopituitarism)
CHH	congenital hypogonadotropic hypogonadism
CIRCI	critical illness-related corticosteroid insufficiency
CKD	chronic kidney disease
CLIP	corticotropin-like intermediate peptide
CLOCK	circadian locomotor output cycles kaput
CME	clathrin-mediated endocytosis
CNS	central nervous system
CNV	copy number variant
COPD	chronic obstructive pulmonary disease
CPAP	continuous positive airway pressure
CPHD	combined pituitary hormone deficiency
CPI	checkpoint inhibitors
CRE	CAMP-response elements
CREB	CAMP-Response Element Binding
CREB	cyclic AMP-response element binding
CRH	corticotropin-releasing hormone
CRP	C-reactive protein
CRPC	castration-resistant prostate cancer
CSF	cerebrospinal fluid
CSHI	continuous subcutaneous hydrocortisone infusion
CSM	cavernous sinus meningiomas
CT	computed tomography
DA	dopamine agonists
DAA	direct-acting antivirals
DALY	disability-adjusted life year
DBD	DNA-binding domain
DCV	dense-cored vesicles
DDT	dichloro-diphenyl-trichloroethane

DEXA	dual-energy X-ray absorptiometry
DHAES	dehydroepiandrosterone sulphate
DI	diabetes insipidus
DMD	Duchenne muscular dystrophy
DMH	dorsomedial hypothalamus
DON	dysthyroid optic neuropathy
DS	diaphragma sellae
DSA	digital subtraction angiography
DSD	disorder of sex development
dSPZ	dorsal subparaventricular zone
DXA	dual-energy X-ray absorptiometry
ED	endocrine disruptor (*also* erectile dysfunction)
EDC	endocrine disrupting compounds
EGF	epidermal growth factor
EGFR	epidermal growth factor receptor
ELISA	enzyme-linked immunosorbent assay
EMA	European Medicines Agency
EMAS	European Male Ageing Study
ENIGI	European Network for the Investigation of Gender Incongruence
EPP	ectopic posterior pituitary
EQA	external quality assurance
ER	endoplasmic reticulum
ERR	excess relative risk
ESE	European Society of Endocrinology
ESPGHAN	European Society of Paediatric Gastroenterology, Hepatology and Nutrition
ESPR	European Society of Paediatric Research
ESR	erythrocyte sedimentation rate
ESRD	end stage renal disease
ETA	European Thyroid Association
EUGOGO	European Group on Graves' Orbitopathy
FAP	familial amyloidotic polyneuropathy
FDA	US Food and Drug Administration
FDH	familial dysalbuminaemic hyperthyroxinaemia
FEO	food-entrainable oscillator
FHH	familial hypocalciuric hypercalcaemia
FHPP	familial hypokalaemic periodic paralysis
FIH	familial isolated hyperparathyroidism
FISH	fluorescent *in situ* hybridization
FN	follicular neoplasm
FNA	fine-needle aspiration
FNAB	fine-needle aspiration biopsy
FSH	follicle-stimulating hormone
GABA	gamma aminobutyric acid
GAD	glutamic acid decarboxylase
GAH	gender-affirming hormones
GBD	gracile bone dysplasia
GD	gender dysphoria (*also* Graves' disease)
GDNF	glial cell-derived neurotrophic factor
GDR	German Democratic Republic
GFR	glomerular filtration rate
GH	growth hormone
GHBP	growth hormone-binding protein
GHD	growth hormone deficiency
GHR	growth hormone receptor
GHRH	growth hormone-releasing hormone
GHS	growth hormone secretagogues
GK	Gamma Knife
GNAS	guanine nucleotide-binding protein G(S)
GnRH	gonadotropin-releasing hormone
GO	Graves' orbitopathy
GPCR	G-protein-coupled receptor
GREAT	Graves' Recurrent Events After Therapy
GRP	gastrin-releasing peptide
GTR	gross total resection
GTV	gross tumour volume
GWAS	genome-wide association studies
H&E	haematoxylin & eosin
HCG	human chorionic gonadotropin
HDL	high-density lipoprotein
HDR	hypoparathyroidism, deafness, and renal
HGPIN	high-grade prostatic intraepithelial neoplasia
HH	hypogonadotropic hypogonadism (*also* hypothalamic hamartoma)
HIF	hypoxia-inducing factor
HIV	human immunodeficiency virus
HLA	human leukocyte antigen
HOMA	homeostasis model assessment
HOS	hypo-osmotic swelling
HP	hypothalamo–pituitary
HPA	hypothalamic–pituitary–adrenal
HPF	high power field
HPT	hypothalamic-pituitary-testicular
HPT	hypothalamic–pituitary–thyroid
HPV	human papilloma virus
HRE	hormone response element
HRT	hormone replacement therapy
HSP	heat shock protein
HT	Hashimoto's thyroiditis
HyOb	hypothalamic obesity
IAD	isolated ACTH deficiency
IAPP	islet amyloid polypeptide
ICSI	intracytoplasmic sperm injection
ICU	intensive care unit
IDD	iodine deficiency disorders
IGF	insulin-like growth factor
IGF-1	insulin-like growth factor 1
IGF1R	insulin-like growth factor 1 receptor
IGHC	integrated growth hormone concentration
IGT	impaired glucose tolerance
IHH	idiopathic hypothalamic hypogonadism
IIH	idiopathic infantile hypercalcaemia
IJV	internal jugular vein
ILP	interstitial laser photocoagulation
IMRT	intensity-modulated radiotherapy
INSR	insulin receptor
IOC	International Olympic Committee
IOM	Institute of Medicine
IPEX	immunodysregulation polyendocrinopathy enteropathy X-linked
IPSC	induced pluripotent stem cells
IQ	intelligence quotient
IR	insulin resistance
IRAE	immune-related adverse effects
IRD	inner ring deiodination

ISE	ion-specific electrode
ISRS	International Stereotactic Radiosurgery Society
ITT	insulin tolerance test
IUI	intrauterine insemination
IVF	*in-vitro* fertilization
JNK	Jun N-terminal kinase
KS	Kallmann syndrome (*also* Klinefelter syndrome)
LAR	long-acting release
LATS	long-acting thyroid stimulator
LBD	ligand-binding domain
LC	liquid chromatography
LC	locus coeruleus
LCH	Langerhans cell histiocytosis
LDL	low-density lipoprotein
LDT	laterodorsal tegmental nucleus
LEPR	leptin receptor
LGBT	lesbian, gay, bisexual, and transgender
LH	luteinizing hormone
LHA	lateral hypothalamic area
LHRH	luteinizing hormone-releasing hormone
LIF	leukaemia inhibitory factor
LINAC	linear accelerator
LN	lymph node
LOH	local osteolytic hypercalcaemia
LOH	loss of heterozygosity
LS	Lugol's solution
LS	Lynch syndrome
LVMI	left ventricular mass index
MACE	major adverse cardiovascular events
MAI	mycobacterium avium intracellulare
MAP	mitogen-activated protein
MAPK	mitogen-activated protein kinase
MC2R	melanocortin-2 receptor
MCH	melanin-concentrating hormone
MCT	monocarboxylate transporter
MDD	major depressive disorder
MDT	multidisciplinary team
MEN	multiple endocrine neoplasia
MES	mineralocorticoid excess syndrome
MFB	medial forebrain bundle
MFS	metastasis-free survival
MHC	major histocompatibility complex
MHRA	Medicines and Healthcare products Regulatory Agency
MI	myocardial infarction
MIF	migration inhibition factor
MIP	minimally invasive parathyroidectomy
MMI	methyl-mercapto-imidazole
MMSE	Mini-Mental State Examination
MNG	multinodular goitre
MPB	male pattern baldness
MPN	medial preoptic nucleus
MPO	medial preoptic area
MR	magnetic resonance
MRI	magnetic resonance imaging
MSH	melanocyte-stimulating hormone
MTC	medullary thyroid cancer
MTC	medullary thyroid carcinoma
MTP	mitochondrial trifunctional protein
NAFLD	non-alcoholic fatty liver disease
NCD	non-communicable diseases
NCRP	National Council of Radiation Protection
NEFA	non-esterified fatty acids
NFPA	non-functioning pituitary adenomas
NGS	next generation sequencing
NHL	non-Hodgkin's lymphoma
NICE	National Institute for Clinical Excellence
NLS	nuclear localization sequence
NNRTI	non-nucleoside reverse transcriptase inhibitor
NOD	non-obese diabetic
NOGG	National Osteoporosis Guideline Group
NRTI	nucleoside reverse transcriptase inhibitors
NTCP	Na-taurocholate cotransporting polypeptide
NTD	N-terminal domain
NTD	N-terminal transcriptional regulation domain
NTE	neuropathy target esterase
NTG	non-toxic goitre
NTI	non-thyroidal illness
NYHA	New York Heart Association
OAR	organ at risk
OATP	organic anion transporting polypeptide
ODS	osmotic demyelination syndrome
OF	orbital fibroblasts
OGTT	oral glucose tolerance test
OHG	optico-hypothalamic gliomas
OI	osteogenesis imperfecta
OIS	oncogene-included senescence
ONH	optic nerve hypoplasia
OPG	optic pathway gliomas
OR	odds ratio
ORD	outer ring deiodination
OS	overall survival
OSA	obstructive sleep apnoea
OXT	oxytocin
PA	pituitary adenomas
PASS	pheochromocytoma of the adrenal gland scaled score
PC	pituitary carcinoma (*also* prohormone convertase)
PCB	polychlorinated biphenyls
PCOS	polycystic ovary syndrome
PCR	polymerase chain reaction
PCS	petroclival chondrosarcomas
PDX	patient-derived xenograft
PEARS	Parathyroid Epidemiology and Audit Research Study
PEG	polyethylene glycol
PET	positron emission tomography
PeVN	periventricular nucleus
PFS	progression-free survival
PH	pleckstrin homology
PI	protease inhibitor
PIA	proliferative inflammatory atrophy
PIC	pars intermedia cysts
PIN	prostatic intraepithelial neoplasia
PLAP	placental alkaline phosphatase
PPT	pedunculopontine tegmental nucleus
PREGO	presentation of Graves' orbitopathy

PROTAC	PROteolysis TArgeting Chimera
PRRT	peptide receptor radionuclide therapy
PRV	planning risk volume
PSA	prostate-specific antigen
PSIS	pituitary stalk interruption syndrome
PSMA	prostate-specific membrane antigen
PTC	papillary thyroid carcinoma
PTH	parathyroid hormone
PTHrP	parathyroid hormone-related protein
PTM	post-translational modification
PTPR	papillary tumours of the pineal region
PTSD	post-traumatic stress disorder
PTTG	pituitary tumour-transforming gene
PTV	planning target volume
PVH	periventricular hypothalamus
PVN	paraventricular nucleus
QC	quality control
QoL	quality of life
RAAS	renin angiotensin aldosterone system
RANKL	RANK ligand
RCC	Rathke's cleft cysts
RCOG	Royal College of Obstetrics and Gynaecology
RCT	randomized clinical trial
REM	rapid eye movement
REMS	risk evaluation and mitigation strategy
RL	RAS-like
RNI	reference nutrient intake
RR	relative risk
RRM	RNA recognition motifs
RS	radiosurgery
RTH	resistance to thyroid hormone
RTK	receptor tyrosine kinases
RXR	retinoid X receptor
SAH	subarachnoid haemorrhage
SCCM	Society of Critical Care Medicine
SCN	suprachiasmatic nucleus
SD	standard deviation
SDR	spontaneous dwarf rats
SDS	standard deviation score
SE	spin echo
SERM	selective oestrogen receptor modulator
SGK	serum glucocorticoid-regulated kinase
SH	subclinical hyperthyroidism
SHBG	sex-hormone-binding globulin
SIADH	syndrome of inappropriate antidiuretic hormone
SIBO	small intestinal bacterial overgrowth
SINE	selective inhibitors of nuclear export
SMR	standardized mortality ratio
SNP	single-nucleotide polymorphism
SOCS	suppressor of cytokine signalling
SOD	septo-optic dysplasia
SON	supraoptic nucleus
SPECT	single photon emission computed tomography
SRIF	somatotropin release inhibiting factor
SRL	somatostatin receptor ligands
SRS	sex reassignment surgery
SSA	senile systematic amyloidosis
SSRI	selective serotonin reuptake inhibitors
SST	short synacthen test
StAR	steroidogenic acute regulatory
SWS	slow-wave sleep
TAO	thyroid-associated orbitopathy
TBI	traumatic brain injury
TBS	trabecular bone score
TC	thyroid cancer
TCR	T-cell receptor
TDF	Tenofovir disoproxil fumarate
TED	thyroid eye disease
TGCC	testicular germ cell cancer
TGF	transforming growth factor
TH	thyroid hormone
THDP	thyroid hormone distributor protein
THR	thyroid hormone receptor
TKI	tyrosine kinase inhibitor
TMC	total motile count
TMD	transmembrane domains
TMN	tuberomammillary nucleus
TPP	thyrotoxic periodic paralysis
TR	thyroid hormone receptor
TR	thyroid receptor
TRH	thyrotropin-releasing hormone
TRT	testosterone replacement therapy
TSH	thyroid-stimulating hormone
TSHR	thyroid-stimulating hormone receptor
TSM	tuberculum sellae meningioma
TSS	transcriptional start site
TSS	transsphenoidal surgery
TVDT	tumour volume doubling time
UFC	urine-free cortisol
USI	universal salt iodization
VDDR	vitamin D-dependent rickets
VDR	vitamin D receptor
VEGF	vascular endothelial growth factor
VEGFR	vascular endothelial growth factor receptor
VEP	visual evoked potential
VFA	vertebral fracture assessment
VIP	vasoactive intestinal peptide
VLPO	ventrolateral preoptic area
VMH	ventromedial hypothalamus
VMN	ventromedial nucleus
vSPZ	ventral subparaventricular zone
VTA	ventral tegmental area
WADA	World Anti-Doping Agency
WBS	whole-body scan
WGS	whole genome sequencing
WHO	World Health Organization
WHR	waist/hip ratio
WT	Wilm's tumour
XLH	X-linked hypophosphataemia

SECTION 1

Principles of Basic and Clinical Endocrinology

1.1

Endocrine Practice Fundamentals

Lynn Loriaux

Introduction

The 'essential' theme of the physician's life is the commitment to expend time in a focused effort to improve the life of patients (πάσχειν—paskhein—to suffer, sufferer). This is a tall order. Many forces come to bear in the effort, forces that can hinder or facilitate the process. Understanding these forces is essential for the complete physician: fear, trust, knowledge, and threat.

Fear

It is not an exaggeration to say that all people fear the doctor. It starts in childhood when going to see the doctor meant pain and separation. It is still that way. How can we manage fear?

In my transition between the Brigham Hospital and the National Institutes of Health (NIH), I had decided that medicine has too many shibboleths, like the white coat, which frighten people. I decided that I would dress like any average person at work. I began to wear a Pendleton shirt in place of the white coat. Nobody seemed to care. A few months later a head nurse corralled me and dragged me into the clean utility room.

'What is the matter with you?' she asked.
'I am not sure. What do you think?'
'Your patients are afraid of you!' she said.
'What? They are not!'
'You don't look like a doctor. You look like a cowboy. Where are you from anyway?'
'New Mexico.'
'That explains it. Get rid of that shirt, get some white ones and sport jacket.'
I did what she said.

A month later, walking down the hall, she took my arm and said, 'your patients are not afraid of you now. And neither are we!'

Michael DeBakey, the famous heart surgeon, used patient expectations to fight fear in a different way. He wore only green scrub suits, everywhere he went. His scrubs were monogrammed, MED. He always wore a scrub hat and had a mask around his neck. When patients met him, it was like an audience with St. Peter or Gandhi. Fear melted into adoration. Comfort filled the room. His patients had no fear and did better than the other doctor's patients. Fear is everpresent. The best doctors learn to manage it for the good of their patients. Calling their name in the waiting room is a good start.

Trust

Without trust there could be no Western medicine. It is the bedrock of the physician–patient interaction.

It begins in the waiting room, sometimes at the bedside. The physician's eye meets the patient's eye and thus begins an association based on mutual trust and an unspoken commitment to work together to find more hours of tolerable life than would have happened without the encounter. There is a trade of some of the physician's 'good hours' for some of the patient's 'bad' ones. Both are energized by a 2500-year record of spectacular success in Western medicine. There is nothing else in life quite like this covenant. It occurs no place else in human experience. A 'hand off' of some of the labours of suffering in return for some of the burdens of uncertainty. In its train comes trust and hope.

At the core of the physician patient relationship is the Oath of Hippocrates. The patient knows that the physician will always work in the patients' best interest and can be trusted with nakedness of the flesh and nakedness of the soul. Short of catastrophe, this covenant will endure.

The physician washes hands. In this gesture the physician demonstrates a commitment to the health of the patient and to their own health. It happens at every meeting that requires touch. The barrier to touch is breached. The pulse and respirations are counted and temperature is estimated. There is an assessment of anxiety, depression, indifference, pain, and sorrow. 'What brings you here?' It is the last open-ended question the physician will ask.

One night, many years ago, I was closing the admitting clinic doors when I saw a small middle-aged woman sitting in the corner wrapped in a care worn coat of wool.

'Why are you still here?' I asked.
'To see the doctor,' she said.
'How long have you been here?' I asked.
'A long time. Nobody called me in.'
'Did you register?'
'No. They could see me.'

The nurses were in no mood for another patient, but they did their duty and got her in a gown and in an examining room. I could find nothing on physical examination. She was tired, five children, abusive husband, not enough money. I told her I could find nothing to worry about. Maybe some iron pills.

'That is all right doctor,' she said. 'I will be fine. I have iron pills at home.'
She got up to dress and I said, 'When was your last pelvic examination?'
She stopped and looked at me for what seemed a long time.
'It has been years,' she said.
'We should do one now,' I said.
The nurses were seething.
She said, 'All right.'
I left the room and the nurses set up a pelvic tray and got her into the stirrups.
When I returned, large tears were running down her cheeks.
'What is wrong?' I asked. 'Are you afraid?'
'No. I am not afraid.'
'Should we go ahead?'
'Yes.' The tears rolled on.

Before I could start the examination, I found that her vulva would not admit the entrance of even a single finger. Her pelvis was filled with an ovarian cancer that would be obvious to any physician contemplating a pelvic examination. No one had ever looked. I got up and moved to the head of the table.

'How long has it been like this?'
'A while,' she said.
'No other doctors have examined you?'
'No. They always said everything was all right down there. I just needed iron and vitamins. It did seem to help.' She wept.

She died of ovarian cancer not too many weeks hence. She knew she was sick and she was reasonably sure of what the problem was, but she trusted the doctors. If they could find nothing wrong, nothing was wrong. It gave her some relief from fear until she could tolerate it no longer and then she would go to a different doctor. She reasoned that any competent doctor would find the problem. Not so. Fear of the truth.

A complete physical examination is the single most important thing the physician can do for the patient. William Osler famously said, 'It is the responsibility of the consultant to perform the rectal examination.'

Knowledge—Docere—To Teach

Hippocrates spends the first third of the oath clarifying who can be a physician and the ever-present obligation to teach. In this case, the physician teaches the patient. Patient understanding is essential for success.

The physician explains the examination that is about to occur. When it is clear that the patient understands, the patient sits on the examination table, the physician stands up and turns the computer off. It will not be turned on again until the patients leaves. The process begins with an examination of the hair. The physician explains to the patient that in this kind of specialty examination, a thorough physical examination is of utmost importance. For completeness sake, it is helpful if the patient will get into a hospital gown. They almost never say no. This is the best time to ask if the patient would like to have a nurse with us during the examination. A family member cannot play this role. The physician steps out of the room while the patient changes into the gown. This is the time to update the medication list and verify what the patient actually is taking. It is the third most important activity of the day.

The physician must be able to see all of the patient, physically and mentally. The lemma is that 'nothing can be between the patient and the stethoscope but air'. Patients want a thorough physical examination, but they fear it. Something serious could be found bringing an end to the façade. The patient is at the point of maximum vulnerability.

There is the focused examination. The sprained ankle. There is the complete examination—head to toe. And then, there is the effective examination. The physician looks and sees, listens and hears, and touches and feels. Every patient knows intuitively what an effective examination is. Every patient deserves an effective examination, even if incomplete. At the end of the examination, the patient is asked to change back into their street clothes.

While the patient changes, the physician slips into the hall and jots down the important findings. Re-entering the examination room, the patient is asked if they would like anybody to join us in the discussion of the findings. It is important that another person participates. There is always more than one person can remember, much less understand.

After discussing the findings, you explore your plans to verify the 'working diagnosis'. You discuss various options you might use in case the first plan doesn't work out. Laboratory tests are sure to play an important role in this discussion. The physician must understand the tests that are likely to be used. The physician must know the dangers of the test, the normal ranges, the sensitivity and specificity, the positive and negative predictive values, the effect of 'time of day', fasting or fed, what medications or foods can affect the accuracy and precision of the test, how much blood will be drawn? One of the most egregious examples of the damage that ignoring laboratory details can cause is the saga of the 1 mcg Cosyntropin® stimulation test. In the early 1990s a group of investigators became interested in finding the smallest dose of Cosyntropin® that could effect secretion of cortisol from the adrenal glands. The usual dose of Cosyntropin® in this test is 250 mcg given intravenously. These investigators examined doses of 0.6, 0.8, 1.0, and 250 mcg of Cosyntropin®. They examined these doses in a group of ten normal volunteers with blood drawn at 30 minutes. The resultant data were not normally distributed so that the mean and standard deviation could not be calculated. However, the response of cortisone to the 1 mcg dose was identical to the 250 mcg dose. The investigators proposed that because of this finding the 1 mcg test could be interpreted using the 250 mcg standard curve. The Cortrosyn test performed in a test

with normally distributed data, however, shows that almost 50% of subjects are 'abnormal'. The diagnosis of a mild form of adrenal insufficiency was made. Subjects that failed this test were told that they had adrenal insufficiency and most were treated with cortisol. When the studies were repeated in assays providing a normal data distribution, all of the tested volunteers were normal. The 1 mcg test has been abandoned. The point is, that when you understand the tests that you use, this kind of disaster will not occur. You must understand all of the hormonal measurements and the provocative tests that you use on a day-by-day basis.

'Where will I find the time to do all of these things?' you ask. You will create the time by asking no open-ended questions.

Threat

Job Satisfaction

Physician job satisfaction is always highest at the beginning of a new job. As time goes by, most of the reasons that induced the physician to accept the job will change. If the change is good, it is soon forgotten. When the change is bad, it is never forgotten and frequently comes to mind. Most problems are related to patient volume, pay, patient satisfaction, and assigned clerical duties.

Patient Volume

Physicians lost control over their work volume years ago. The volume is now regulated by business people. They know how to 'optimize' your time, how to 'trim' your product. However, they do not know how to put these changes into effect.

Currently, most endocrine practices look like this: consultants see all urgent cases in the day the consultation is received. Non-urgent consultations must be seen in 3 weeks. The full patient load is seven clinics a week. Hospital-attending duties are usually added on without supplemental pay. Most practices schedule new patients with two return visits. The first visit is the diagnostic visit. The second visit is the planning visit, and the third visit is the discharge visit. The clinic sessions are usually three new patients in the morning and six return patients in the afternoon. This means that there will be alternation of six clinics per week with eight clinics per week, giving an average load of seven clinics a week. Necessary paperwork such as the electronic medical record fills the remaining time. It is never enough. This results in doing chart work from home. The workload from home never ever goes down. It continually goes up. This problem is tethered to patient volume, and can be approached from that direction, but with great difficulty. Dogma prevails.

Problems with compensation are almost always caused by failure of the 'compensation plan' to keep pace with changes in the value of the 'dollar'. Money doubles every 10 years. Compensation plans never double every 10 years. At 5 years, the physician is 'seeing' more patients for less money than when the job was negotiated. The doctor will be forced to ask for a raise. The 'compensation boss' will first try to convince you that the 'bonus' feature of the compensation plan will retain your income in a competitive range. Changes in the bonus calculation, however, will ensure that equity can never occur. The vehicle is usually an emergency tax that is essential for the 'health of the institution'. You will always be short unless you negotiate a new job in a new place at great cost. If you do, the cycle begins anew.

Next, the patient satisfaction survey. Like all great hospitals and clinics, your great institution will expect 100% patient satisfaction, and is proud of it!! The problem is that the expectation and the highest possible grade are the same, guaranteeing that no physician will ever meet the expectation of 100%. If a physician does get 100% patient satisfaction more than a few times, that physician is almost certainly pandering to patients, giving them what they want, instead of what they need. Never go to that physician, nor refer any of your patients in that direction. These doctors are usually 'the apple in the eye of the CFO' [chief financial officer]. They meet all the targets, even when it is mathematically impossible. They can be dangerous doctors, even lethal.

There was a time when business people worked for the doctors. They were charged with making medicine more profitable. Physicians paid their wages. Sometime around 1968–1969, and the advent of Medicare and Medicaid, business people were hired to manage the money, and in a few years, the doctors worked for the business people. Things have never been the same. They want us to treat every patient the same and to pay all of the doctors the same salaries, surgeons at the top, and cognitive specialist at the bottom. Now, we work for them. The quality of medicine has deteriorated. At some point in the future, the structure will collapse, and we will have a chance to rebuild along the principles of patient-centred care. We will have to move fast. They are not afraid. They believe we will not leave the bedside and hence ignore the struggle. They are right. Hope for the best!

You may attribute most of this to the 'ravings of an old man'. True, but most of the recommendations were made when I was much younger. They have survived, especially the no 'open-ended questions', and the '100% satisfaction' doctor. If all fails to help with your particular problem, there is this:

'Never be the first, nor the last, to use a new medication or technique!' If you can remember this, and do it, you will probably be alright.

1.2

Hormones and Receptors

Fundamental Considerations

John W. Funder

Background

The original endocrine physiologists viewed hormones as responses to homoeostatic challenge, any signal a call to arms; the word is thus derived from the classical Greek ωρμαειν—'to arouse'. In the twenty-first century a hormone is a molecule—small or large, protein or lipid—secreted in a regulated fashion from one organ and acting on another. The definition is firmly based on the anatomy of the seventeenth century, the histology of the nineteenth, and the physiology of the twentieth. It has been shaped by convention and clinical specialization: gut hormones are the marches between endocrinology and gastroenterology, and the adrenal medulla the territory of the cardiovascular physician. It has been refined by concepts of paracrine—where the secretion of one cell type in a tissue acts on another cell type in the same tissue—and autocrine, where a particular cell type both secretes and responds to a particular signal. Inherent in the concepts of paracrine and autocrine are that the signal is not secreted into blood or lymph, to be distributed more or less throughout the body, but is made locally to act locally. A very good example of a signalling system with both paracrine and autocrine activities is the neuronal synapse.

Inherent in the concept of the signal is that of a receptor: a signal without a receptor is the sound of one hand clapping. Inherent in the concept of a receptor are two functions: that of being able to discriminate between different signals, and to propagate the signal by activating cell membrane or intracellular signal transduction pathways. Discrimination by a receptor between different circulating potential signals is, in the first instance, a function of the likelihood of a particular signal being able to interact with the receptor, for a period of time sufficient to alter the confirmation of the receptor and thus to trigger propagation. This interaction is commonly referred to as binding, and thus the circulating hormone as a ligand (that which is bound). If the structures of ligand and receptors are such that the initial interaction is followed by formation of strong intermolecular bonds between the two, lessening the possibility of dissociation and the receptor returning to an unliganded state, the receptor is said to have high affinity for the ligand (and vice versa). If the binding is followed by propagation of the 'appropriate' signal the ligand is classified as an agonist, or active hormone; if a molecule occupies the binding site on the receptor but does not so alter its structure as to propagate a signal, it is often called a hormone antagonist (and, more accurately, a receptor antagonist). In the past couple of decades, the concepts of 'agonist' and 'antagonist' have needed to be refined, as noted subsequently in this chapter.

Hormones and Receptors: Binding

In symbols, the reversible interaction between hormone and receptor can be simply written as follows;

$$[H] \cdot [R] \underset{}{\overset{K_1}{\rightleftharpoons}} [HR] \qquad \text{(Equation 1)}$$

where [H] is the concentration of hormone, [R] the concentration of empty or unliganded receptor, and [HR] the concentration of occupied receptor (i.e. hormone-receptor complexes). The forward (to the right by convention) or association reaction is equally a function of hormone and receptor concentrations; the association rate constant [K_1] is a reflection of the likeliness of apposition/goodness of fit of hormone and receptor, reflecting their structures plus extrinsic factors such as temperature, ionic strength of the milieu, and unstirred layers (close to the receptor, where hormone is less likely to diffuse). The actual rate of the forward reaction is thus

multifactorial, a function of the rate constant, the concentration of hormone, and the concentration of receptor, or

$$\text{foreword rate (or on-rate)} = K_{-1}[H][R]. \qquad \text{(Equation 2)}$$

The dissociation of hormone-receptor complexes [HR] is driven by one thing, and one thing only, the dissociation rate constant [K_{-1}], a measure of the inherent probability of the two entities falling apart, under particular conditions of temperature, ionic strength, and so on. The actual rate of dissociation is thus the product of K_{-1}, the dissociation rate constant, and the concentration of hormone-receptor complexes, or

$$\text{reverse rate}\left(\text{or off-rate}\right) = K_{-1}[HR]. \qquad \text{(Equation 3)}$$

At equilibrium, by definition, the rates of the forward and reverse reactions are equal, i.e. for every molecule of hormone that associates with a receptor molecule, a preformed hormone-receptor complex dissociates, or

$$K_1[H][R] = K_{-1}[HR]. \qquad \text{(Equation 4)}$$

By simple rearrangement, this can be rewritten as

$$\frac{K_{-1}}{K_1} = \frac{[H][R]}{[HR]}. \qquad \text{(Equation 5)}$$

The quotient of the two rates constants (K_{-1}/K_1) is termed the dissociation constant or K_d; its reverse (K_1/K_{-1}) is the less commonly used K_a or association constant of the reaction. The key outcome of all this relatively simple mathematics is to put a value on K_d, as a measure of affinity, or overall probability of the hormone-receptor complex being in existence, as follows:

$$K_d = \frac{K_{-1}}{K_1} = \frac{[H][R]}{[HR]}. \qquad \text{(Equation 6)}$$

If we were to choose a concentration of hormone which would half saturate the receptors, then [R] would equal [HR]. Under such circumstances the two terms can be cancelled in Equation 6, and

$$K_d = [H], \qquad \text{(Equation 7)}$$

where K_d equals [H], the hormone concentration at which half maximal receptor occupancy is achieved, and which has the dimensions of concentration, that is, molar.

From Equations 1 to 7 there are a number of things that flow. First, in a simple binding system the dissociation of hormone from receptor is not accelerated by addition of excess hormone. What this does, when, for instance, 1000-fold non-radioactive hormone is added to a system containing tracer hormone-receptor complexes, is to operationally prevent (i.e. dilute 1000-fold) reassociation of tracer to receptor. Under such conditions then, the disappearance of tracer–receptor complexes over time thus provides an accurate estimate of the dissociation rate. There are receptors that oligomerize: in such circumstances binding of ligand can increase or decrease the affinity of the other binding sites for hormone, termed positive and negative cooperativity, respectively. Dissociation of bound tracer, for instance, is accelerated in systems displaying negative cooperativity.

Secondly, dissociation constants can only be derived from equilibrium studies, that is, those in which the rates of forward and backward reactions are equal. The association rate constant and dissociation rate constant are often very different, and are constant for a given set of physical circumstances; the actual rates of association and dissociation are determined by not just these constants, but also by the concentration of reactants, as noted earlier. Where this concept of equilibrium comes into play is in situations where binding is covalent, or essentially irreversible; under such circumstances Scatchard analysis, for example, is inappropriate for determining K_d. A practical case in point is triamcinolone acetonide (TA), a powerful synthetic glucocorticoid in clinical use, which (in contrast with dexamethasone or the physiological glucocorticoids) requires approximately 24 h to come into equilibrium in glucocorticoid receptor binding systems *in vitro* at 4 C; exposure for shorter time points will consistently underestimate the affinity of TA for the glucocorticoid receptor. Third, different binding systems respond differently to changes in physical conditions. Cortisol, for example, binds transcortin with an order of magnitude higher affinity at 4°C than at 37°C, across a number of species, and shows clear differences in transcortin binding at physiologically relevant temperatures. In contrast, cortisol binding to glucocorticoid receptors is not particularly temperature dependent, but if anything is of a higher affinity at physiological than at lower temperatures.

Finally, there is the inherent bias of endocrinology, that of seeing high-affinity binding as good ('binds well to the receptor . . .'), and lower affinity binding as less good ('binds poorly . . .'). The underpinnings of this bias are twofold, one theoretical and the other practical. Practically, particularly in often unstable broken cell preparations, the absence of high-affinity binding equates to experimental failure, a powerful driver of emotive language. Even if no experiment ever failed, however, an endocrinologist's bias is to regard high-affinity binding as good, for the following reason. The higher the affinity the lower the concentration of signal required to half-maximally occupy, and, other things being equal, activate the 'cognate' receptor. There are two consequences of this, one of which appears to be biologically sound, the other less so. The latter is a notion of economy; that it is better for an organ to make less rather than more signal, in that it poses less of a demand on precursors and metabolism. This is experientially not the case; every molecule of thyroglobulin, with a molecular weight in excess of 600 000 yields 4–16 molecules of thyroxine, at first sight an example of conspicuous biological extravagance. The other concept underlying the bias has more biological purchase, in that the higher the concentration required to activate cognate receptors, the more likely is the hormone to cross-react with other receptors, acting as an agonist or antagonist, and thus reducing the specificity of the signalling system. It is, of course, entirely possible that there have evolved circumstances in which such 'cross-reactivity' may reflect physiology, and that our bias is Ockham's razor cutting too close to the bone: on the whole, however, such a degree of cautious reductionism appears justified.

Hormones and Neurotransmitters

In contrast with the previous discussion, if we take a broader biological view that low-affinity binding can be 'good'—for example, when it enables rolling of platelets or leucocytes on endothelium, giving them time to 'sniff the wind' in terms of damage or inflammation. It is also not only advantageous, but functionally required, within the nervous system where low-affinity binding of signal to receptor is a necessity for the time constants of neurotransmission.

When the electrical impulse underlying nerve conduction is translated into a chemical signal at a synapse or neuroeffector junction, minute quantaties of neurotransmitter are released. Because the space into which the neurotransmitter is released is even more minute, the concentration of neurotransmitter becomes very high, so that receptors are rapidly occupied and activated. To achieve this, the 'on-rate' of neurotransmitter-receptor binding must be very rapid; and the off-rate (in contrast with hormone-receptor interactions) must also be very rapid, to enable the receptor to return to ground zero. Signal is rapidly cleared by reuptake, diffusion, and metabolism, so that quantal release of signal is followed essentially stochastically by a single response.

To achieve this rapid-onset-rapid-offset binding and activation by neurotransmitters, receptors have to be low affinity, to allow the time constants that characterize neurotransmission. The nervous system does it by mass, 'brute-forcing' occupancy of low-affinity receptors, with a restricted spatial distribution of the mass of signal to allow the very high concentrations required, and very efficient mechanisms of rapidly reducing signal concentration. Reflecting this difference, hormones have time constants of minutes, hours, and days compared with the nervous system's milliseconds; the endocrine system sacrifices time to allow its signals to be distributed all over the body, to 'arouse' the diversity of cells that express receptors to which the particular signal can bind. Its signals are broadcast like radio, in contrast with the nervous system landline telephone network.

One striking anthropomorphic illustration of this difference may be worth a thousand words of theoretical justification [1]. First, picture a hummingbird in the *National Geographic*, its wings still blurred despite shutter speeds of 1/500 or 1/1000 of a second. If acetylcholine had the same high affinity for its receptors at the neuromuscular junction as progesterone has for progesterone receptors, then a hummingbird could beat its wings twice a minute—aerodynamically challenging and clearly no evolutionary advantage. Even less of an evolutionary advantage accrues if progesterone receptors had the same affinity for progesterone as cholinergic receptors for acetylcholine. Unless the efficiency of steroidogenesis were vastly improved, the placenta would need to be considerably larger: to maintain plasma progesterone at the levels required, other things equal, it would need to be the size of a 14 cubic foot refrigerator. Other evolutionary considerations would be the 9 months of somnolence that such levels of progesterone would almost certainly produce, difficult to reconcile with the additional 25 000 calories per day required to maintain the requisite levels of progesterone biosynthesis required.

Mineralocorticoid Receptors: A Case Study

We have mercifully evolved otherwise, and evolution has exploited a range of interactions between signals and receptors in terms of growth, development, homoeostasis, and cognition. Sometimes we can second-guess nature, perhaps to our own disadvantage in terms of realizing our own physiology.

One example, within the author's area of experience, is that of the mineralocorticoid receptor. Mineralocorticoid hormones were defined in 1961 by Jean Crabbé as promoting unidirectional transepithelial sodium transport [2], a definition that has stood the test of time. The principal mineralocorticoid hormone, aldosterone, is secreted from the zona glomerulosa of the adrenal cortex in response to elevated plasma potassium concentrations, increased levels of angiotensin II, or acutely, adrenocorticotropic hormone (ACTH). In response to sodium deficiency, volume depletion, or potassium loading, aldosterone incontestably acts via mineralocorticoid receptor in kidney and colon, salivary gland and sweat gland to retain sodium, and excrete potassium thus acting as a classic homoeostatic hormone. And yet . . .

When human mineralocorticoid receptors were first cloned [3], the highest levels of mRNA were found in the hippocampus, not a classical site of aldosterone action, and recapitulating earlier binding studies on rat tissue extracts [4]. Second, in both studies, mineralocorticoid receptors were shown to have equivalent affinity for the physiological glucocorticoids (cortisol, corticosterone) as for aldosterone, raising obvious questions of how aldosterone ever occupies epithelial mineralocorticoid receptors, given the orders of magnitude for higher circulating concentrations of glucocorticoids.

The answer to this question appears to be the coexpression, in epithelial tissues, of the enzyme 11β-hydroxysteroid dehydrogenase [5, 6], which converts cortisol and corticosterone to their inactive 11-keto metabolites cortisone/11-dehydrocorticosterone. Aldosterone is not similarly metabolized, because its signature aldehyde group at C18 cyclizes with the hydroxyl at C11, forming a stable hemiacetal which is not susceptible to enzyme attack by 11β-hydroxysteroid dehydrogenase 2.

The enzyme is expressed at high abundance in aldosterone target cells ($3–4 \times 10^6$ molecules/cell), and its operation—by metabolizing glucocorticoids and clearly by other mechanisms [7, 8]—appears sufficient to confer aldosterone selectivity on the epithelial mineralocorticoid receptor. When it is congenitally deficient, as in the autosomal recessive syndrome of apparent mineralocorticoid excess [9], cortisol activates epithelial mineralocorticoid receptors, leading to uncontrolled sodium retention and severe hypertension.

The enzyme 11β-hydroxysteroid dehydrogenase 2 is not found in non-epithelial tissues in which mineralocorticoid receptors are expressed at high (hippocampus) or modest (heart) abundance, and which aldosterone thus has little chance of occupying. An inescapable corollary of the last sentence is that such mineralocorticoid receptors are physiologically high-affinity glucocorticoid receptors.

A second, quite different mechanism modulating the activity of mineralocorticoid receptors has recently been demonstrated [10]. Classically, mineralocorticoid receptors were believed to be confined to principal cells in the tubule; in 2013 Shibata and his colleagues

showed that renal intercalated cells also express mineralocorticoid receptors, normally held inactive by phosphorylation of serine 843 in the ligand binding site. In volume depletion, however, angiotensin dephosphorylates the receptors, which can then be activated by aldosterone or by cortisol. Their response to glucocorticoid underpins the difference between the aldosterone synthase null mouse and the mineralocorticoid receptor mouse [11]. The latter does not survive sodium restriction [12], whereas the former does [13]. Although a complete tissue scan is yet to be done, to date this mechanism appears confined to the renal intercalated cell.

Hormones and Receptors: Evolutionary Considerations

In the syndrome of glucocorticoid remediable aldosteronism ([14]: now termed familial hyperaldosteronism type-1), aldosterone is secreted primarily in response to adrenocorticotrophic hormone (ACTH), with aldosterone synthase activity expressed throughout the adrenal cortex. The underlying genetic defect is a chimeric gene in which the 5′ end of the gene for 11β-hydroxylase is fused with the 3′ end of the gene coding for aldosterone synthase. This can happen because the two parent genes lie next to one another, on chromosome 8, and because they are 94% identical in terms of nucleotide sequence. What the condition reflects is the product of an unequal crossing over at meiosis in an ancestral gamete, reflecting the relatively small misalignment required (gene proximity) and the possibility of realignment (sequence homology). In evolutionary terms, however, what the condition illustrates is the probability that the two genes (for 11β-hydroxylase and aldosterone synthase) share a relatively recent ancestor, and that their degree of identity and juxtaposition represent a relatively recent gene duplication event. Compare this with the gene coding for the mineralocorticoid receptor (chromosome 4) and the glucocorticoid receptor (chromosome 5).

Mineralocorticoid receptors and glucocorticoid receptors have one area of high (about 90%) sequence identity, the DNA-binding domain, and another of considerable homology, the ligand binding domain, with 57% identity: the majority of the two molecules, including major activation domains, have minimal (less than 15%) identity. It would thus appear that the mineralocorticoid receptor and glucocorticoid receptor are rather more evolutionarily distant than are the enzymes 11β-hydroxylase and aldosterone synthase. Although classically mineralocorticoid and glucocorticoid receptors were thought to share a common immediate 'corticoid' receptor ancestor [15], more recently evidence has emerged for mineralocorticoid receptors being the first of the mineralocorticoid/glucocorticoid/androgen/progestin receptor subfamily to branch off [16].

In evolutionary terms aldosterone is thus a Johnny-come-lately, pressed into service as organisms became amphibious, to activate a pre-existing high-affinity glucocorticoid receptor (which we now term the mineralocorticoid receptor). Mineralocorticoid receptor selectivity in epithelial aldosterone target tissues is produced by coexpression of the enzyme 11β-hydroxysteroid dehydrogenase 2 at high abundance, and the integrity of a system for Na^+ retention out of seawater obtained by the expression of aldosterone synthase being yoked to surrogates of Na^+ deficiency (angiotensin II, K^+) rather than primarily to the brain hormone ACTH. To call aldosterone the cognate ligand for mineralocorticoid receptor—and the ascription 'mineralocorticoid receptor' itself—is thus understandable in terms of our historical knowledge of aldosterone, but it fails to recognize the previous, and current, physiological roles for mineralocorticoid receptors net of aldosterone. The rainbow trout, for instance, does not synthesize aldosterone. In an attempt to clone rainbow trout androgen receptors, an rtMR sequence was identified, related to rtGR but with much higher identity with mammalian mineralocorticoid receptors [17]. Its physiologic role(s), like the pathophysiologic roles of mammalian non-epithelial mineralocorticoid receptors, await exploration.

A final fundamental consideration might thus be as follows. There are currently 49 members of the extended steroid/thyroid/retinoid/orphan receptor superfamily of ligand activated transcription factors in the human genome, evidence for enormous evolutionary scope and flexibility. One might thus be pardoned for asking why a 'specific' mineralocorticoid receptor did not evolve, responsive to a ligand with levels inversely related to Na^+ status, rather than the complicated system of highly reactive C18 aldehyde groups and epithelial 11β-hydroxysteroid dehydrogenase 2. This is in fact an impertinent question, bluntly put this way: what is the appropriate question to ask, is where is the evolutionary gain in the system developing as it did?

Receptor Activation, Receptor Blockade

For aldosterone and mineralocorticoid receptors, the past decade has provided more questions than answers. Among the latter, for the hormone, is the acceptance that aldosterone can have both genomic and acute, non-genomic effects [18], and that most but probably not all such rapid effects are via the classic mineralocorticoid receptor [19]. In addition, there is now general consensus that the syndrome of primary aldosteronism represents ≥ 10% of all 'essential hypertension' [20], and that such patients show higher cardiovascular morbidity and mortality than age-, sex-, and blood pressure-matched patients with essential hypertension [21]. For the receptor, the RALES, EPHESUS, and 4E trials [22–24] have shown the beneficial effects of mineralocorticoid receptor blockade in heart failure and essential hypertension. The functions and roles of non-epithelial mineralocorticoid receptors, constitutively (90–99%) occupied by glucocorticoids, have hardly begun to be properly addressed. The mechanisms whereby the physiological glucocorticoids show bivalent activity when bound to mineralocorticoid receptors—normally antagonist, but agonist (in the sense of mimicking aldosterone) in the context of redox change (11β-hydroxysteroid dehydrogenase 2 blockade, reactive oxygen species generation [7, 8]) similarly remain to be established.

In fact, the terms agonist and antagonist need to be seen for what they are—effector definitions, like that proposed for mineralocorticoids almost half a century ago by Jean Crabbé. For most hormone-receptor systems, the last 20 years has seen the growing emergence of tissue selective agents, agonist in some organs, antagonist is others. While most microarray analyses have provided a formidable list of genes, expression of which is doubled or halved by a classical agonist, similar lists can be complied for classical antagonists. Some classical antagonists (e.g. spironolactone for epithelial

mineralocorticoid receptors), demonstrate inverse agonist activity in experimental myocardial infarction [25]. Aldosterone and cortisol aggravate the infarct area; spironolactone at low (EC50 3–5 nm) concentration reduces the infarct area, in the absence of any other steroid.

Spironolactone thus has its 'antagonist' effects in the context of cardiac damage not just by competing with agonist steroids for occupancy of mineralocorticoid receptors, but by inducing expression of protective genes and lowering that of proapoptotic genes. It does this at relatively low concentrations, evidence that not all mineralocorticoid receptors, or even a majority, need to be occupied for such an effect. Even before the advent of microarray, it was clear that the effects on enzyme induction, for example, in cultured cells could show distinct dose–response curves, evidence for maximal effects on some readouts at submaximal receptor occupancy. This has not been widely incorporated into consideration of the clinical roles of aldosterone and mineralocorticoid receptors. An example of the former is the demonstration that relatively mild elevations of aldosterone in primary aldosteronism, which would have minimal incremental effects on non-epithelial receptor occupancy, are accompanied by demonstrable cardiovascular damage [26], even in the absence of an elevated blood pressure [27], compared with age-, sex-, and blood pressure-matched controls. An example of the latter would appear to be the otherwise curiously low dose (x = 26 mg/day) of spironolactone which, when added to standard care, produced a remarkable 30% improvement in survival, and 35% lower hospital admission rate, in the RALES trial [22].

ENV0I

Given the achievements of the human genome project, we are faced with a mass of information of daunting proportions. This brief chapter has attempted to raise questions, and thus help shape the mindsets of those who face the exciting but very challenging task of reconciling the enormity of information with the demands of clinical endocrinology, from individual patients through populations. For a chance of success, we need a degree of comfort with the underlying mathematics, the biology, and as best we can guess from the historical record, the evolution.

1.3

Molecular Aspects of Hormone Regulation

Kenneth Siddle and Gemma V. Brierley

Introduction

Hormones are chemically and structurally diverse. Most are either small proteins (e.g. insulin, glucagon), shorter peptides derived from precursor proteins (e.g. CRH, melanocortins), cholesterol-derived steroids (e.g. testosterone, cortisol), amino acid derivatives (e.g. catecholamines, thyroid hormones), or fatty acid derivatives (e.g. eicosanoids). All bind highly selective or specific receptors, either on the surface, in the cytoplasm, or in the nucleus of target cells to elicit biological responses. Hormone receptors enable cells to receive information and to process, decode, and respond to that information. Decades of research has established that information is transmitted from many hormone receptors via signalling 'cascades' of sequential enzymic reactions, giving rise to the widespread notion of 'signalling pathways'. It has progressively become clear, however, that specific biological effects often do not arise solely through linear information transfer, but rather involve complex interactions among multiple pathways, so that many responses are better understood in terms of signalling 'networks'. Distinct biological outcomes result from integration of protein–protein interactions, modulation of enzymatic activity, sometimes generating 'second messengers', multiple post-translational protein modifications including phosphorylation, and changes in RNA and protein biosynthesis. These processes are all subject to temporal, spatial, and threshold constraints. Similar mechanisms govern the actions of growth and differentiation factors and cytokines that act in a paracrine or autocrine manner. This chapter gives a brief overview of molecular mechanisms involved in cellular responses to hormones, using examples to illustrate the underlying principles and complexities (see **Box 1.3.1**).

Classes of Hormone Receptor

Nuclear Hormone Receptors

Steroid and thyroid hormones, which are lipophilic, cross cell membranes by passive diffusion, by facilitated diffusion via membrane-bound transport proteins, or by other mechanisms which continue to be elucidated. Once inside target cells, they bind intracellular receptors. These are either constitutively located within the nucleus (e.g. thyroid hormone receptors) or translocated to the nucleus following hormone binding in the cytosol (e.g. sex hormone receptors). This class of receptors serve as ligand-activated transcription factors, acting in concert with other proteins that include so-called corepressors and coactivators. Receptors bind via zinc-finger motifs to hormone response elements (HREs) within enhancer and promoter regions of genes. Ligand binding causes a conformational change that alters the repertoire of proteins interacting with the receptor to drive gene transcription. The pattern of gene expression that ensues is not stereotyped, with different hormones or ligands regulating distinct but overlapping sets of genes even when acting on the same receptor in the same cell. Cellular context is also important, with differential expression of the proteins that interact with receptors, and differential accessibility of HREs due to chromatin conformation modulating transcriptional responses to receptor activation. Although the direct transcriptional actions of nuclear hormone receptors bound to HREs are best studied, they are also capable of indirect actions that do not require the receptors themselves to be DNA bound, but are mediated through interactions with other transcription factors. Nuclear hormone receptors may also exert fast-acting non-genomic actions via initiation of second messenger cascades similar to those discussed next for cell surface receptors.

Subclassification of Nuclear Receptors

Nuclear hormone receptors are grouped into subtypes based on cellular location, internal structure of cognate HREs, and mechanism of their action on gene transcription. Type I hormone receptors, such as those for androgens and oestrogens, reside in the cytoplasm,

Box 1.3.1 'Call out' box

Glucose transporter 4 (GLUT4) storage vesicle (GSV): insulin-responsive storage and transport vesicle containing glucose transporter 4 protein.

GTPases: proteins that switch between GTP-bound active form to GDP-bound inactive form by hydrolysis of GTP via their intrinsic GTPase activity.

GTPase-activating proteins (GAPs): enzymes that inactivate GTPases by catalysing GTP hydrolysis.

Guanine nucleotide exchange factors (GEFs): enzymes that activate GTPases by catalysing GDP release followed by GTP binding.

Histones: proteins that package DNA into chromatin.

Histone acetyltransferase (HAT): enzyme that transfers acetyl groups to histones to relax the structure of chromatin.

Histone deacetylase (HDAC): enzyme that removes acetyl groups from histones to condense chromatin.

Hormone response element (HRE): a short sequence of DNA that binds specific nuclear hormone receptors.

Nuclear localization sequence (NLS): an amino acid sequence within a protein that identifies the protein for import into the nucleus.

Phosphatase: enzyme that catalyses the removal of phosphate groups from proteins.

Phosphotyrosine-binding (PTB) domain: protein domain that binds phosphorylated tyrosine residues in proteins.

Pleckstrin homology (PH) domain: protein domain that (usually) binds phosphoinositol lipids within membranes.

(Protein) kinase: enzyme that catalyses the transfer of phosphate groups to serine, threonine, or tyrosine residues on proteins.

Src homology 2 (SH2) domain: protein domain that binds phosphorylated tyrosine residues in proteins and differs from PTB domains.

where they are sequestered by binding to chaperone proteins. Ligand binding by a type I receptor causes conformational changes within the receptor leading to its dissociation from the chaperone protein and subsequent homodimerization. This produces further conformational changes exposing a nuclear localization sequence (NLS) that permits entry into the nucleus. Hormone-bound type I receptors in the nucleus bind palindromic inverted repeat HREs and associate with multiprotein complexes called transcriptional coactivators to increase target gene transcription [1]. Type III hormone receptors function similarly to type I receptors, but recognize HREs with a directly repeated sequence.

Type II hormone receptors reside within the nucleus bound to HREs with direct repeat sequences, usually as heterodimers with the retinoid X receptor (RXR). The spacing between the HRE direct repeats confers receptor specificity [2]. Unliganded type II hormone receptors, including thyroid hormone receptors (THR), are bound to HREs near the transcriptional start site (TSS) of target genes (e.g. growth hormone, GH) and act as transcriptional repressors in the basal state through association with multiprotein corepressor complexes (Figure 1.3.1). These corepressor complexes include histone deacetylases that remove acetyl side groups from histones, favouring chromatin condensation, limiting transcription factor access, and repressing transcription [2]. Binding of T_3 to THR promotes dissociation of the corepressor complex and recruitment of a coactivator complex. This opposes the action of corepressor complexes, favouring acetylation of histones and thus access to the TSS for core transcription factors and RNA polymerase (Figure 1.3.1).

Cell Surface Hormone Receptors

Protein, peptide, catecholamine, and some eicosanoid hormones, in contrast to steroid hormones, elicit cellular responses by binding to and activating receptors on the cell surface. Ligand binding to a receptor induces a conformational change in the receptor that transmits information across the plasma membrane lipid bilayer to the intracellular portion of the receptor, ultimately initiating relays of intracellular signals, or signalling 'cascades'. Termination of such

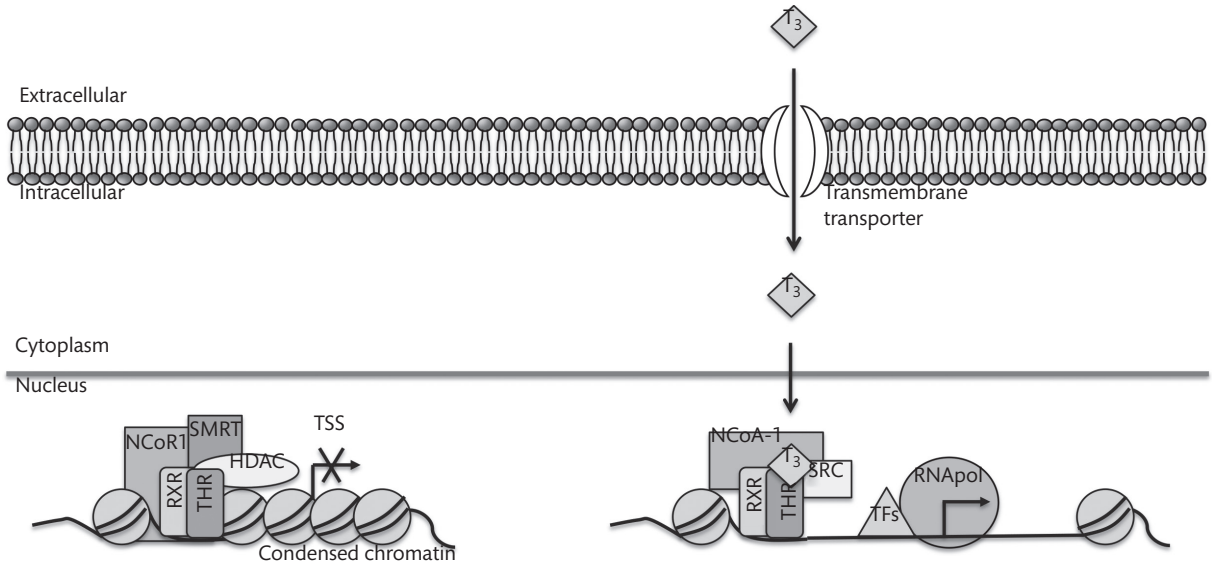

Figure 1.3.1 Triiodothyronine (T_3)-mediated regulation of growth hormone gene transcription. T_3 binds the thyroid hormone receptor THR in the nucleus where it is bound to the hormone-responsive element in a heterodimer with RXR. This changes the conformation of THR allowing coactivators to bind, remodelling surrounding chromatin to allow transcription factors (TFs) and RNA polymerase to access the transcriptional start site (TSS) and leading in turn to expression of target genes such as GH. NCoR1, nuclear receptor corepressor-1; SMRT, silencing mediator for retinoid and thyroid receptor (SMRT); HDAC, histone deacetylases; SRC, steroid-receptor coactivator family; NCoA-1, nuclear coactivator 1 (NCoA-1).

signalling is essential if the receptor is to continue to serve a useful information transfer function, and so signalling is almost invariably transient, being terminated by enzymatic reactions and/or internalization of the activated receptor into the endosomal/lysosomal system. Cell surface receptors have diverse mechanisms of action, but these usually involve either the generation of intracellular small molecule 'second messengers', or the activation of protein kinase activity acting on intracellular substrates. This section will give an overview of the principles and general paradigms underlying intracellular signalling networks before focusing on the receptor families.

Covalent Modifications in Signalling Cascades

One major mechanism whereby activation of a hormone receptor propagates signalling inside a cell is through sequential activation of enzymes through their covalent modification. The most common and best studied such modification is phosphorylation, or addition of a phosphate group by kinase enzymes to amino acids with suitably receptive side chains, namely serine, threonine, or tyrosine. This often induces a conformational change that either disrupts or creates protein–protein interactions, or may create a new protein binding site without major conformational change, which in turn leads to activation of the target enzyme or transcription factors. Often, a sequence of several enzymes in a signalling cascade, each activating the next one specifically, serves to amplify the initial signal within the cell, and also provides multiple points for regulation and modulation of the response.

Although phosphorylation is the best studied so-called post-translational modification (PTM) in hormone signalling pathways, many other forms of PTM of target proteins are also important. These include other chemical modifications such as acylation, methylation, and acetylation. For example, the covalent modification of histones by methylation and acetylation is involved in the epigenetic regulation of gene expression by both altering chromatin structure and allowing the recruitment of other histone modifiers. Other PTMs are protein based and involve the attachment of the 76 amino acid protein ubiquitin in a process known as ubiquitylation. This can be extended to form polyubiquitin chains and the ubiquitin within these chains can be further modified by small ubiquitin-like (Ubl) modifier (SUMO) family proteins, acetylation, and phosphorylation to create a diverse signalling cipher known as the 'ubiquitin code'. The biological outcomes of ubiquitin signalling are many and various and affect almost all aspects of cell biology [3].

Second Messengers in Signal Transduction

As well as transferring information directly through the action of enzymes on protein substrates to alter their function, hormone signalling pathways also commonly rely on activation of enzymes that generate diffusible small molecules, or 'second messengers' that can either be cytosolic or membrane-anchored. These can exert effects on distant cellular components, or, conversely, can bind target proteins and thus concentrate them locally, close to substrate or targets. Second messengers are rapidly generated or released in response to extracellular signals and serve to relay and amplify the message. They are now known to come in many forms, including not only cyclic nucleotides (e.g. cAMP, cGMP) or ions (e.g. calcium, magnesium) acting within the cytosol, but also membrane-associated lipids or lipid-derived molecules. In non-stimulated cells second messenger concentrations are extremely low, but they are produced rapidly in response to receptor activation, binding and altering target proteins within the cell to propagate signalling [4]. As for all signalling processes, mechanisms must exist to extinguish the signal. In the case of second messengers this is usually through enzyme-mediated metabolism of organic second messengers, or sequestration of ionic messengers in membrane-bound organelles.

Cyclic Nucleotide Second Messengers

In the 1960s, Earl Sutherland first elucidated the role of 3'–5'-cyclic adenosine monophosphate (cAMP) as the 'second messenger' of catecholamine action (adrenaline/epinephrine itself being viewed as the first messenger), a breakthrough of such significance that Sutherland was awarded the 1971 Nobel Prize in Physiology or Medicine 'for his discoveries concerning the mechanisms of the action of hormones'. Membrane-bound adenylyl cyclases, which synthesize cAMP in response to activation, are particularly important in transmitting signals from the G-protein-coupled class of cell membrane receptors described next.

The major target protein of cAMP is protein kinase A (PKA), which through its kinase activity can then phosphorylate downstream targets (Figure 1.3.2). Many different proteins are substrates for PKA, and ensuring that the correct target is phosphorylated at the right time in response to the physiologically appropriate signal is governed both by the monomers constituting the PKA heterotetramer and by A-kinase-anchoring proteins (AKAPs) that function as scaffolds to anchor PKA to subcellular structures [4]. The phosphodiesterase family of enzymes play a critical role in modulating the duration and amplitude of signalling by cAMP (and cGMP, which has also been shown to have a second messenger role in distinct signalling pathways) by catalysing the hydrolysis of these two second messengers. Tissue-specific expression and discrete subcellular location of various phosphodiesterase family members allows tight control of compartmentalized gradients of cAMP and cGMP hence regulating their signalling pathways and downstream biological effects. Phosphodiesterases have thus been exploited pharmacologically for therapeutic effect and the development of drugs that target individual subfamilies has improved tolerability and efficacy of treatments for Cushing's disease, erectile dysfunction, asthma, and heart disease [5].

Lipid Second Messengers

Several types of membrane phospholipid serve as important substrates for generation of second messengers. Glycerophospholipids anchored on the cytoplasmic face of the cell membrane can be hydrolysed by phospholipase D and phospholipase C (PLC) to generate the second messengers, phosphatidic acid and diacylglycerol (DAG), respectively [4]. When phosphatidylinositol 4,5-bisphosphate (PIP_2) is hydrolysed by PLC in response to receptor activation, DAG remains in the cell membrane while the polar head group inositol trisphosphate (IP_3) is released into the cytosol. There it binds IP_3 receptors on organelles resulting in the release of calcium (itself a second messenger) into the cytosol (Figure 1.3.2). IP_3 can be further phosphorylated to IP_4 which activates chloride channels, and IP_6 which may have a role in apoptosis [4]. DAG acts as a second messenger to target a family of enzymes known collectively as protein

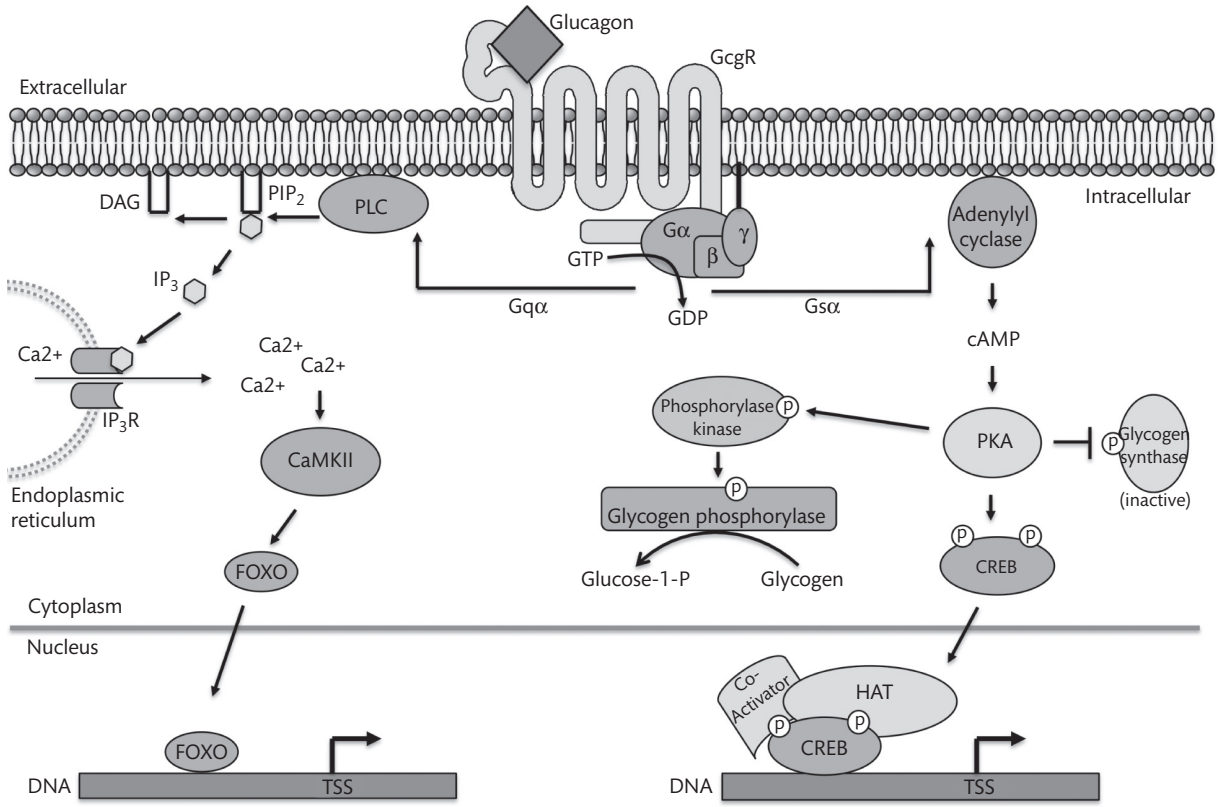

Figure 1.3.2 Glucagon signalling via its G-protein-coupled receptor. Glucagon signals via a GPCR (GCGR) that associates with either Gsα or Gqα heterotrimeric G-proteins. This activates pathways leading to transcription of genes involved in glycogenolysis and gluconeogenesis. Glucagon signalling also stimulates enzymatic changes that regulate glycogenolysis and the generation of glucose.

kinase C (PKC). Some PKC isoenzymes require both DAG and calcium for activation, giving rise to a level of specificity as PKC can transduce signals that trigger selective hydrolysis of PIP_2 due to the release of calcium caused by IP_3 mobilization. Other isoenzymes of PKC can be activated by DAG alone, while so-called atypical PKC isoenzymes do not respond to DAG or calcium. Signalling by PKC is terminated by the phosphorylation of DAG by DAG kinase which removes the second messenger [4].

Plasma-membrane-associated PIP_2 can also be phosphorylated by phosphoinositide 3-kinase (PI3K) to produce the second messenger phosphatidylinositol (3,4,5)-triphosphate (PIP_3), which is key in the PI3K-AKT signalling pathway. This is triggered by many receptor tyrosine kinases (RTKs) such as the insulin and IGF1 receptors (Figure 1.3.3). Activation of PI3K leads to conversion of PIP_2 to PIP_3. PIP_3 in turn provides a docking site for AKT and other effector proteins, serving to drive their localization to desired sites of action at the plasma membrane.

Calcium as a Second Messenger

In direct response to receptor activation, or as a consequence of second messenger action, calcium can rapidly enter the cytoplasm via activation of channels and transporters either at the cell surface or on organelles with a high internal calcium concentration. Calcium itself acts as a second (or third!) messenger and can rapidly propagate signals by regulating targets either by direct binding or by modulating calcium sensors and calcium-sensitive enzymes [4]. For example, as one component of glucagon signalling (Figure 1.3.2), in addition to activation of adenylate cyclase, PLC is activated and cleaves phosphatidylinositol 4,5-bisphosphate (PIP_2) generating IP_3 and DAG. IP_3 then acts on the IP_3 receptor calcium channel on the endoplasmic reticulum resulting in an increase in Ca^{2+} in the cytoplasm and activation of the Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII). Downstream of CaMKII activation, the transcription factor FoxO is phosphorylated and translocated to the nucleus where it can stimulate expression of genes involved in hepatic glucose production [6]. Cells actively maintain gradients of calcium across lipid membranes and when calcium channels are opened, rapid diffusion of calcium down these gradients generates spatiotemporal waves and oscillations which, coupled to the subcellular organization of the calcium signalling machinery, allows for a vast array of signals to be encoded and propagated. Calcium actions are terminated by pumping calcium out of the cell or back into subcellular organelles [4].

Types of Plasma Membrane Hormone Receptor

G-Protein-Coupled Receptors

G-protein-coupled receptors (GPCRs) are a large family of proteins (numbering as many as 800 in mammals). They share core sequence and structural similarity, but the family has evolved to be activated by a myriad of different ligands including light-sensitive compounds, odorant chemicals, pheromones, and neurotransmitters as well as hormones. Hormones of clinical importance that bind

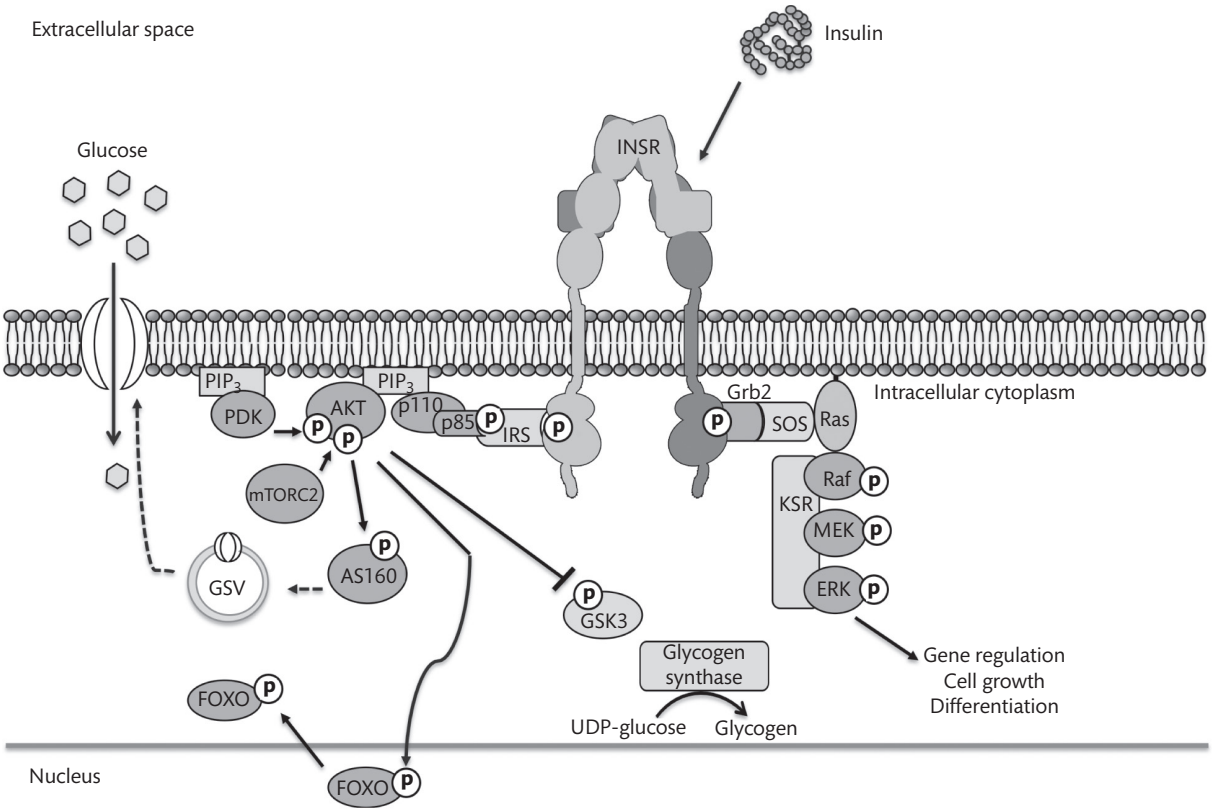

Figure 1.3.3 Signalling pathways downstream from insulin receptor activation. Insulin stimulates activation of both PI3K/AKT and Ras/ERK pathways resulting in a broad range of cellular outcomes including effects on glucose uptake and metabolism, protein synthesis, cell growth and differentiation, and prevention of apoptosis.

GPCRs include catecholamines, glucagon, ACTH, PTH, TSH, FSH, LH, and β-hCG, among many others. GPCRs are also the largest family of proteins targeted by approved drugs. All GPCRs include seven transmembrane regions between an extracellular N-terminal domain and a cytosolic C-terminal segment. Extracellular ligand binding causes a conformational change, reconfiguring the cytoplasmic loops to bind and activate a heterotrimeric G-protein complex that is responsible for signal transduction [7]. GPCRs are also capable of transactivating both RTKs and serine/threonine receptor kinases, providing one of many mechanisms of 'crosstalk' with other signalling pathways [7].

G proteins constitute one of the most important families of signalling proteins. Martin Rodbell and Alfred Gilman shared the 1994 Nobel Prize in Physiology or Medicine 'for their discovery of G-proteins and the role of these proteins in signal transduction in cells'. G-protein complexes comprise α, β, and γ subunits, for each of which multiple isoforms exist. Function is defined primarily by the Gα subunit. The combination of G-protein subunits determines which receptor the complex couples to, the second messenger generated, and the downstream effectors activated, allowing the cell to integrate information from a variety of extracellular stimuli. Stimulatory G protein (Gs_α) activates adenylyl cyclase, which generates the second messenger 3'–5'-cyclic adenosine monophosphate (cAMP), while inhibitory G protein (Gi_α) inhibits adenylyl cyclase. Gq_α activates phospholipase C (PLC), resulting in generation of inositol trisphosphate (IP_3) and diacylglycerol (DAG) as second messengers (Figure 1.3.2). Signalling from G_α is terminated by its intrinsic GTPase, which hydrolyses G_α-bound guanosine triphosphate (GTP) to guanosine diphosphate (GDP). This enables reassociation of G_α to $G\beta\boldsymbol{\gamma}$ [7]. GTP hydrolysis is enhanced by a variety of GTPase-activating proteins (GAPs), and nucleotide exchange is enhanced by Guanine nucleotide exchange factors (GEFs). Both these types of proteins serve as important sites of regulation of the action of many hormones. GPCR signalling is also regulated by the β-arrestin family of proteins. β-arrestins were initially identified for their role in switching off GPCR signalling by desensitizing the receptors and facilitating their internalization and recycling. More recently, β-arrestins have been shown to have wider roles in GPCR signalling, acting both as signal transducers by controlling phosphorylation of intracellular targets and as scaffold proteins for the recruitment of signalling cascades (such as ERK), thereby prolonging signalling by GPCRs internalized to the endosomes [8].

β-arrestins also play a key role in the 'signalling bias' shown by both natural ligands and pharmacological compounds that can act not only as full agonists and antagonists, but also as partial and inverse agonists by way of multidimensional allosteric or orthosteric interactions with the GPCR. Such 'signalling bias' is being exploited for therapeutic benefit as some ligands/compounds preferentially activate classical G-protein-dependent signal transductions, whereas others demonstrate preferential activation of β-arrestin mediated signalling. This allows selective control of pathway activation to minimize potential side effects [8].

Receptor Tyrosine Kinases

RTKs bind many important peptide hormones and growth factors. RTK ligand-binding domains reside in the extracellular portion of the receptor, a transmembrane domain spans the plasma membrane, and the intracellular portion of the receptor contains the tyrosine kinase domain. RTKs are commonly expressed at the cell surface as monomers that undergo dimerization upon binding of bivalent ligands which cross-links monomers to form active complexes [9]. Exceptions are the insulin receptor (INSR) and the closely related type I insulin-like growth factor receptor (IGF1R), which exist at the cell surface as preformed dimers, within which ligand binding causes conformational changes and activation currently best described by a 'harmonic oscillator' model [10].

While precise signalling mechanisms differ for the various members of the RTK family, ligand binding and the resulting conformational changes generally trigger the release of autoinhibition within the tyrosine kinase domain, resulting in activation of the RTK [9]. This leads to autophosphorylation of tyrosine residues in receptors themselves and on separate substrate proteins (e.g. INSR substrates, IRS-1 and IRS-2), which provide docking sites for adaptor proteins that recognize phosphotyrosines within specific sequence contexts. Docking and sometimes phosphorylation of these adaptor molecules propagates signalling cascades responsible for diverse cellular responses. For example, the effects that insulin exerts on glucose metabolism, cell growth, and differentiation are mediated mostly by signalling pathways involving phosphoinositide 3-kinase/AKT (PI3K/AKT) and mitogen-activated protein kinase/extracellular signal-related kinase (MAPK/ERK) [11], which are initiated by recruitment of regulatory subunits or proteins to IRSs (**Figure 1.3.3**). Generation of PIP_3 by PI3K leads to membrane binding of AKT and its colocalization with phosphoinositide-dependent kinase I (PDKI), also recruited to the cytoplasmic face of the cell membrane by PIP_3, and the mammalian target of rapamycin complex 2 (mTORC2). These phosphorylate and activate AKT, a kinase that in turn phosphorylates an array of substrates with important metabolic and growth-related functions [12]. Multiple enzymes contribute to the termination of RTK signalling, including protein tyrosine phosphatases (PTPs) that dephosphorylate INSR and IRS proteins, the phosphatase and tensin homologue (PTEN) that dephosphorylates PIP_3 and the protein phosphatases PHLPP and PP2A that dephosphorylate AKT.

Other Receptors and Signalling Pathways

In contrast to the RTKs and PS/TRKs (discussed next), cytokine-type cell surface receptors lack intrinsic kinase activity, instead associating with members of the intracellular Janus kinase (JAK) family to propagate signalling. The cytokine family includes a diverse array of proteins including growth hormone, leptin, interferons, chemokines, adipokines, lymphokines, and tumour necrosis factors with endocrine, paracrine, and autocrine actions. Ligand binding to cytokine receptors induces conformational changes favouring recruitment and activation of the associated JAK leading to phosphorylation of proteins called signal transducers and activators of transcription (STAT) [13]. Like the other cell surface receptors, a key mechanism for modulating cytokine signalling at the cell surface is internalization of the receptor upon ligand binding. Together with subsequent recycling back to the cell surface or degradation of the receptor, this modulates receptor availability to ligand. Cytokine receptor signalling is negatively regulated intracellularly by Src homology 2 domain-containing PTPs (SHPs) and the suppressor of cytokine signalling (SOCS) family of proteins [14].

The protein serine/threonine receptor kinases (PS/TRKs) respond to members of the superfamily of ligands that include the transforming growth factor beta family (TGFβ), bone morphogenic proteins (BMPs), activins, and growth and differentiation factors (GDFs) which have diverse roles in embryonic development and tissue homeostasis, the immune system, and cancer, as well as endocrine regulation of adipose tissue metabolic functions. Ligand binding causes the formation of a heterotetrameric complex of two different PS/TRKs (type I and type II receptors) resulting in an interaction where the type II receptor phosphorylates and activates the type I receptor allowing signal transduction via the phosphorylation of serine or threonine residues on target downstream signalling substrates [15]. The best-known pathway downstream from PS/TRKs involves the Smad family of transcription factors, although other signal transduction pathways such as ERK and c-Jun N-terminal kinase (JNK) can be activated, for example, in response to TGFβ [15].

Information Coding in Signalling Networks

For all the multitude of different cell surface receptors, the repertoire of signalling cascades initiated in response to receptor activation is relatively limited. Despite this they mediate a broad spectrum of cellular outcomes, and yet individual receptors produce distinct responses. Many mechanisms exist to permit such specificity of information transfer. Important factors include the cellular context of receptor expression, positive and negative crosstalk among signalling pathways, and feedback regulation within pathways. Spatial and temporal factors including subcellular localization and regulated intracellular trafficking of signalling components, cytoskeletal arrangements, and differential utilization of 'scaffold' and adaptor proteins are also critical. Such determinants of signalling specificity are discussed briefly next.

Hormone Receptor Signalling: 'Cascades' or 'Networks'?

Although hormone signalling pathways are commonly schematized as distinct, simple, and linear, this is a gross simplification. Feedback both within and between different pathways is a major feature of signalling. Negative feedback from later stages of a pathway to proximal steps is one prevalent mechanism which means that activation of a pathway inevitably leads, with a time delay, to its downregulation [16]. Positive feedback loops also exist within some signalling cascades, however, that can stabilize and amplify signals [17]. Many examples of both positive and negative feedback between distinct pathways also exist. The collective dynamics of such positive/negative feedback loops and oscillations in enzyme on/off states can affect the timescale and magnitude of biological responses. Sophisticated modern techniques, most involving mass spectroscopy, are beginning to define temporal complexity of signalling in response to different hormones; however, understanding how different types of

information are encoded remains limited. A complete account of the richness of information transmitted by hormone action will require further integration of such temporal considerations with the subcellular spatial localization of signalling molecules. Only once this considerable computational feat is achieved may it be possible to understand the diverse biological outcomes achieved with such a limited number of signalling pathways [17].

Selective Receptor Modulation and Biased Agonism

Hormone receptor signalling is sometimes viewed, for simplicity, as binary, with receptors acting essentially as 'switches' to trigger a stereotyped cellular response. However, as the preceding discussion has indicated, hormone receptor signalling is much more complex. Responses to hormones are usually graded, and at different levels of hormone stimulation responses may qualitatively vary, as different arms of the downstream pathway may require different degrees of stimulation to activate. Signalling responses are also context dependent, in part due to the accessory proteins that function with hormone receptors to modulate selectivity or to direct downstream responses. This is true of both nuclear hormone receptors and cell surface receptors. For example, the biased agonism of GPCRs depends on the context of the allosteric or orthosteric interactions of a particular ligand of a GPCR that lead to either preferential activation of G-protein-dependent signalling or preferential β-arrestin mediated signalling [8]. Biased signalling can also be observed with the receptors of the insulin-like growth factor (IGF) system and their various affinities for the IGFs and insulin, which is further complicated by the variety of hybrid receptors that can form between the IGF1R, INSR-A, and INSR-B isoforms [12]. Understanding the biophysical, structural, and pharmacological biology of receptors, their mechanism of actions and how these relate to distinct signalling outcomes has enabled the development of therapeutics that capitalize on selective pathway activation to minimize potential side effects and/or selectively target one target tissue over another. A prime example is the failed contraceptive tamoxifen, which is a selective oestrogen receptor modulator (SERM) and has mixed agonist and antagonist properties depending on tissue of action. Tamoxifen is used to treat breast cancer and has beneficial effects in postmenopausal women on bone mineral density and serum lipids, but also increases the risk of development of endometrial cancer due to its oestrogen receptor (ER) agonist activity in the uterus [18].

Spatial Regulation of Intracellular Signalling

Another mechanism which can serve to diversify biological outcomes, even using the same signalling process, is the localization of machinery involved to specific parts of the cell. This commonly involves so-called scaffold proteins which essentially serve to tether, orientate, and coordinate allosteric control of partner molecules, providing a flexible means of signalling regulation [19]. Scaffold proteins can either mediate linear signalling down a pathway or provide a branching point for diversification of the signal. An example of linear signalling can be observed with the kinase suppressor of Ras (KSR) scaffold protein that helps to tether and activate components of the Ras-Raf-MEK-ERK signalling pathway downstream of RTK activation, by facilitating the assembly of a multiprotein complex that brings the downstream substrates in close proximity to their upstream activators (Figure 1.3.3) [19, 20]. Scaffold proteins are themselves subject to regulation by PTMs such as phosphorylation, which can be either stimulatory or inhibitory to enable or block protein–protein or protein–lipid interactions that sequester the signalling molecules to distinct subcellular locations (such as the effect of AKAP scaffold proteins on PKA as discussed in the section on cAMP second messengers), or ubiquitination which targets substrates for proteosomal degradation [19]. Scaffold proteins are also pivotal in coordinating feedback loops involving phosphatases that are important for temporal dynamics and the termination of signalling pathways [17]. Not only do scaffold proteins function to integrate signalling networks arising from hormonal activation of cell surface receptors, they are also involved in the coordination of sequential passing of some type I and III steroid hormone receptors across their chaperone proteins prior to translocation to the nucleus [20].

Receptor Endocytosis and Signal Termination

Common to both GPCR and RTK signalling is that receptor activation at the cell surface is followed by endocytosis. The consequent decrease in cell surface expression helps prevent excessive downstream signal activation by attenuating the strength and duration of signalling or by providing a shift in the dose-response relationship between ligand and receptor such that a greater concentration of ligand is required to produce a cellular response [21]. Internalized receptors are trafficked through the endosomal/lysosomal pathway and this process is not only critical for the termination of signalling via receptor sequestration and degradation, but also allows recruitment of specific signalling components in different compartments. For example, full activation of the extracellular signal-regulated kinases (ERK1/2) by RTKs requires internalization of the receptor and complexing with scaffold proteins in the late endosome [21]. In contrast, full activation of AKT can occur at the plasma membrane prior to receptor internalization [21]. Similarly, GPCRs are capable of sustained signalling within endosomes that affects recruitment of downstream mediators [22].

Activated receptors generally undergo clathrin-mediated endocytosis (CME) [23] either by direct interaction with the adaptor complex AP2 (RTKs) or via interactions with β-arrestins (GPCRs). Ubiquitination can also target receptors for internalization and the level of receptor ubiquitination in endosomes affects recycling back to the plasma membrane or trafficking to the lysosomes for degradation [21]. Receptors that are internalized by clathrin-independent endocytosis may be degraded more rapidly than those that undergo CME, suggesting another level by which trafficking routes can influence cellular signalling. Various signalling kinases also have an effect on endosomal sorting and trafficking to lysosomes to reduce receptor recycling and terminate signalling [21, 22].

Hormone Resistance

Primary endocrine disorders may broadly be classified into those featuring loss or dysregulation of hormone production, and others featuring an abnormality of hormone action, most commonly hormone resistance. Hormone resistance as a clinical phenomenon has been recognized for many years, notably through the work of

Table 1.3.1 Genetic forms of hormone resistance

Examples of hormone resistance caused by hormone receptor mutations			
Gene	**Hormone**	**Receptor type**	**Syndrome**
INSR	Insulin	Receptor tyrosine kinase	Severe insulin resistance
IGF1R	IGF-1	Receptor tyrosine kinase	Short stature
GHR	Growth hormone	Cytokine	Laron dwarfism
LEPR	Leptin	Cytokine	Severe early onset obesity
GNRHR	GnRH	G-protein-coupled	Hypogonadotropic hypogonadism
TSHR	TSH	G-protein-coupled	Congenital hypothyroidism
MC2R	ACTH	G-protein-coupled	Glucocorticoid deficiency
THRB	Thyroid hormone	Nuclear receptor	Thyroid hormone resistance
AR	Androgens	Nuclear receptor	Androgen insensitivity
Examples of hormone resistance caused by mutations in signalling molecules downstream from hormone receptors*			
Gene	**Function of gene product**		**Syndrome**
PIK3R1	Regulatory subunit of phosphatidylinositide 3-kinase (PI3K)		SHORT syndrome (including short stature and insulin resistance)
GNAS	Stimulatory G protein coupled to many peptide hormone receptors		Pseudohypoparathyroidism
STAT5B	Transcription factor activated downstream from some cytokine receptors		Growth hormone resistance with immunodeficiency

* Examples of hormone resistance caused by loss-of-function mutations. Syndromes due to defects in signalling molecules are often more complex than those involving receptor defects due to sharing of signalling pathways. ACTH, adrenocorticotropic hormone; AR, androgen receptor; GHR, growth hormone receptor; GNAS guanine nucleotide-binding protein G(S); GnRH, gonadotropin releasing hormone; GNRHR, gonadotropin releasing hormone receptor; IGF-1, insulin-like growth factor 1; IGF1R, insulin-like growth factor 1 receptor; INSR, insulin receptor; LEPR, leptin receptor; MC2R, melanocortin-2 receptor; PIK3R1, phosphatidylinositol 3-kinase regulatory subunit alpha; SHORT, short stature, hyperextensibility, hernia, ocular depression, Rieger anomaly, and teething delay; STAT5B, signal transducer and activator of transcription 5B; THRB, thyroid hormone receptor beta; TSH, thyroid stimulating hormone; TSHR, thyroid stimulating hormone receptor.

Harold Himsworth on insulin in the 1930s, and the work of Fuller Albright on PTH in the 1940s. In the molecular genetic era, as the genes encoding components of signalling pathways have been identified, so the precise molecular bases of some forms of hormone resistance have been identified. Many of these lie in the receptor itself, while others lie in receptor signalling pathways downstream from the receptor (Table 1.3.1). For some truly pandemic conditions such as insulin resistance, however, the precise defect is imprecisely identified, and appears not, in general, to be due to single gene defects of insulin action. For other disorders, such as obesity, the very nature and existence of leptin resistance continues to be debated.

It follows from consideration of the complexity of receptor action that some forms of primary hormone resistance are not simply classifiable as loss of hormone action, but rather reflect selective loss of some aspects of hormone intracellular signalling. Depending on the feedback loops that regulate a pathway, this means that compensatory high levels of hormone may paradoxically drive unimpaired aspects of receptor signalling, and this may lead to clinical disease. Common insulin resistance may provide one such example, with significant evidence suggesting that some aspects of the 'insulin resistance syndrome' are actually driven by high levels of insulin signalling in some tissues, driven by hyperinsulinaemia. Disentangling perturbations of complex signalling networks is a major challenge for current efforts to understand many common endocrine disorders.

Conclusion

Methodological and conceptual advances over the last 40 years have provided major insight into the molecular mechanisms of hormone action. The anatomy of intracellular signalling networks has been revealed, and new insights gained into how cells decode, process, and respond to multiple external stimuli utilizing only a limited repertoire of signalling pathways. The concept of temporal and spatial compartmentalization influencing signalling network specificity is now established, however, much is still to be learned about the mechanisms that couple external stimuli to their intracellular 'roadmap' to a specific biological outcome. Integrating the computational methodologies of systems biology with biochemical experimentation [24] will be required to further enhance understanding of signalling specificity, and to enable more refined endocrine interventions, for example, in the form of selective receptor modulators, for human disease.

Endocrinology and Evolution

Lessons from Comparative Endocrinology

Janine A. Danks and Samantha J. Richardson

Introduction

Comparative endocrinology is the study of endocrine glands and hormones in different animal species. It is undergoing a renaissance driven by rapid technological advances facilitating, for example, DNA/RNA sequencing, profiling of DNA methylation and protein interactomes, and genome editing with CRISPR. Until relatively recently, characterization of hormones in 'lower' vertebrates relied upon biological assays and protein chemistry, whereas now genes are readily revealed in whole genome sequences, and specific antibodies and other reagents for sensitive assays can rapidly be developed, enabling revealing physiological experiments.

Endocrinology traditionally used animal species including many lower vertebrates. Comparative endocrinology became distinct only in the last 50 years as endocrinologists concentrated on rodents as their preferred model. In 1933, Riddle demonstrated that an avian pituitary factor promoting growth of the pigeon crop-sac was identical to a mammalian pituitary factor earlier found to initiate and maintain milk secretion. Riddle called this avian factor prolactin and the crop-sac response provided a sensitive assay for human prolactin detection in pituitary extracts. Pigeon prolactin was the first pituitary hormone to be crystallized and purified in 1937, leading to purification of mammalian prolactin. Prolactin has many roles in lower vertebrates, including a vital role as a hypercalcaemic factor in fish.

This chapter will focus on two paradigmatic examples of the value of comparative endocrinology. Calcium regulating factors including parathyroid hormone (PTH), parathyroid hormone-related protein (PTHrP) and stanniocalcin (STC) will first be considered, followed by THs (which have identical structures in all vertebrates from fish to humans) and transthyretin (a thyroid hormone distributor in blood and cerebrospinal fluid). Both groups of hormones are essential for human life during development and in adulthood, and pivotal insights have been gained from non-mammalian vertebrates.

Calcium Regulation

Regulation of calcium concentration in intracellular (c.0.1μmol/L) and extracellular compartments is fundamental in vertebrate physiology. Calcium regulation in body fluids demarcates invertebrates and vertebrates: marine invertebrates have plasma calcium concentrations around 10 mmol/L, close to the concentration in the environment. Primitive marine vertebrates (cyclostomes) have plasma calcium levels of 5 mmol/L in the same environment, and most cartilaginous and bony fish, regardless of environment, have

plasma calcium levels around 2 mmol/L, similar to mammals. Most aquatic vertebrates are less dependent on the skeleton as a calcium source, as the aquatic environment provides an inexhaustible calcium supply.

Fish use their scales instead of their skeleton as a rapidly accessible calcium store. In contrast, terrestrial vertebrates have skeletons serving both as a physical support and calcium reservoir. Dietary calcium supply is episodic, so calcium reserves must be labile and dynamic. All vertebrates possess several essential factors with complex interrelated actions controlling circulating ionic calcium.

Calcium Regulating Factors in 'Lower' Vertebrates

The major difference in calcium control between 'lower' and tetrapod vertebrates is the presence of the parathyroid gland and its product, PTH. A distinct parathyroid gland first appeared in amphibians, but no comparable gland has been observed in fish. PTH is critical for calcium homeostasis at all stages of tetrapod development, interacting with calcitonin and 1,25-dihydroxyvitamin D_3. PTH elevates serum calcium by causing calcium release from bone and inhibition of renal calcium excretion.

PTH

Despite the absence of a parathyroid gland, several reports describe an immunoreactive PTH-like protein in fish, detected by antisera raised against the mid-molecule portion of bovine PTH [1]. PTH-like immunoreactivity was demonstrated in brain and pituitary of goldfish and platyfish, the pituitary of eel and cod, and the plasma of trout and goldfish. Problems with these studies included insufficient controls and poor characterization of antibodies, however. Physiological studies by Parsons *et al.* [2] predicted a rapidly acting hypercalcaemic factor in cod pituitary with a PTH-like N-terminus, however existence of a fish PTH homologue was unproven until 2003, when a *PTH* gene was identified from the *Fugu rubripes* genome [3]. *Fugu* PTH has low overall homology with human PTH (32%) and *Fugu* PTH(1–34) has only 56% identity with human PTH(1–34), however *Fugu* PTH(1–34) was found to have *in vitro* biological activity resembling that of human PTH(1–34). A second *Fugu PTH* gene was later identified that is not present in the human genome, suggesting a gene duplication in bony fish. There are now three PTH genes in zebrafish [4], chicken and *Xenopus* [5], but the third PTH gene is absent in eutherian mammals, which generally have fewer chromosomes (e.g. 39 in chickens vs. 23 in humans).

Subsequent studies have identified two *PTH* genes in the elephant shark (*Callorhinchus milii*) [6]. The elephant shark is among the most ancient cartilaginous fish, the oldest living group of jawed vertebrates (approximately 450 million years old) (Figure 1.4.1). Its genome has been termed the 'reference vertebrate genome' as initial studies have shown it to resemble the human genome more than those of other fish (e.g. *Fugu* or zebrafish) [7]. The two elephant shark PTH proteins have different biological activity and the gene encoding elephant shark *PTH2* does not exist in other fish or humans [6].

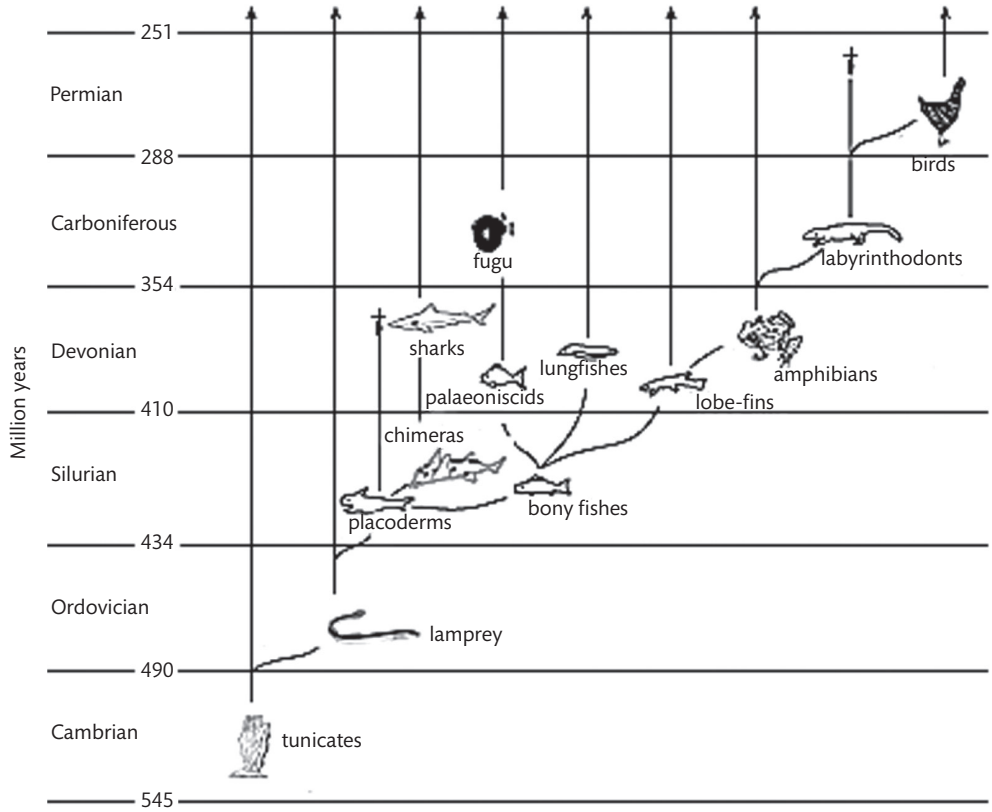

Figure 1.4.1 Classification of chordates, including tunicates and lower vertebrates, in relation to phylogenetic origins and palaeontological periods.

PTHrP

The earliest reports of PTH-like immunoreactivity in fish prompted studies in the early 1990s [8] demonstrating immunoreactive PTHrP in tissues including the pituitary as well as in the circulation of a marine bony fish. PTHrP is highly homologous to the N-terminus of PTH and may be the factor predicted by Parsons *et al.* [2] in cod pituitary. PTHrP was first isolated from human tumours [1, 9, 10] and identified as a factor causing humoral hypercalcaemia of malignancy (HHM), acting via the classical PTH receptor (PTH1R) in bone and kidney. PTH and PTHrP bind the receptor with different affinities. They share sequence homology only in the N-terminal, notably in the 1–34 region, with 8 of the first 13 amino acids being identical. The N-terminus of PTH and PTHrP are required for PTH1R binding. Subsequent studies indicated that PTHrP is synthesized in many normal adult and embryonic mammalian tissues, implying numerous potential functions, many autocrine or paracrine [1].

The *PTHrP* and *PTH* Genes

The *PTHrP* gene is more complex than the *PTH* gene (Figure 1.4.2). Rat and chicken *PTHrP* genes comprise five exons encoding a protein of 139 or 141 amino acids (Figure 1.4.2), while the human *PTHrP gene* has nine exons and encodes at least three isoforms of 139, 141 and 173 amino acids [1]. The *Fugu PTHrP* gene, in contrast, has only three exons, like the *PTH* gene. The *PTH* gene is conserved among these species, generating proteins of 84 or 88 amino acids. The increasing complexity and number of protein products of the *PTHrP* gene from birds to humans may reflect increasing numbers of roles for PTHrP through evolution. Indeed, *PTHrP* may be the original gene and *PTH* the copy. This is supported by the highly conserved gene structure of *PTH*, and the single encoded protein, suggesting a role(s) unchanged through evolution.

Duplication of the *PTHrP* and *PTH* Genes

The gene for human *PTHrP* is on chromosome 12 while the *PTH* gene is located on chromosome 11. The *PTH* and *PTHrP* genes are considered paralogous. That is, they have arisen through duplication of a single ancestral gene within a species [11]. This is opposed to orthologous genes, which are found in different species but have diverged from their common ancestral gene during speciation and separate evolution. This divergence has been documented for other gene families with members on both chromosomes 11 and 12, including the insulin-like growth factors, the aromatic amino acid hydroxylases, lactate dehydrogenases and the *Ras* gene family (Table 1.4.1). All these genes map to the same regions of these two chromosomes, suggesting a single duplication event. Chromosome 12 appears moreover to have a central position in the human genome [11], indicating that it might be a primordial chromosome. The genes on this chromosome may thus have a long evolutionary history.

The duplication event that generated two members of the PTH family may have been one of two tetraploidization events occurring between invertebrates and vertebrates [12]. Tetraploidization means

that every gene in the genome is duplicated, in contrast to regional duplication where only some loci are duplicated. Regional duplication is thought to have produced the *IGF-II* gene from *insulin* on chromosome 11, while the *IGF-I* gene on chromosome 12 is believed to have arisen from tetraploidization [11] (Table 1.4.1).

Implications of Gene Duplication

The two tetraploidization events early in vertebrate evolution expanded the genome, creating new genomic and phenotypic diversity and enhancing evolutionary survival. Such a genetic 'safety net' is exemplified by knockout mouse studies. These are based on the premise that nature is 'thrifty', with one gene responsible for a defect. Frequently, however, knockout animals do not have the expected phenotype, teaching molecular biologists what evolutionary biologists have long

Table 1.4.1 Paralogous genes in portions of human chromosomes 11 and 12

Chromosome 11	Chromosome 12
Lactate dehydrogenase A Lactate dehydrogenase C	Lactate dehydrogenase B
Hras	*Kras*
Parathyroid hormone	Parathyroid hormone-related protein
Glutathione S-transferase 3	Glutathione S-transferase 3-like Glutathione S-transferase 12
Tyrosine hydroxylase Tryptophan hydroxylase	Phenylalanine hydroxylase
Insulin Insulin-like growth factor 2	Insulin-like growth factor 1
Progesterone receptor	Vitamin D receptor Retinoic acid receptor G

known—nature is 'extravagant', and genes can sometimes fulfil multiple roles. This is logical given the imperative to ensure survival of the species. Consequently, many diseases are polygenic. Thus, several lines of knockout mice, each with a different gene deleted, may need to be interbred to yield defects originally attributed to only one gene.

Timing of the Duplication of *PTH* and *PTHrP* Genes

The *PTHrP* gene has been cloned from various mammals (human, rat, mouse, dog) and chicken and shows such high homology that its evolutionary development can only be discerned from the sequences in lower vertebrates, including fish and sharks. It appears likely that the divergence between the *PTHrP* and *PTH* genes occurred prior to evolution of cartilaginous fish. The presence of both genes in elephant shark indicates that clues to their evolutionary relationship and possible role(s) of their corresponding proteins in calcium metabolism and other functions may best be found in lampreys, a jawless fish.

Fish as Model Vertebrates

Fish constitute the major group of vertebrates, with numbers of species estimated from 25 000–35 000. They are highly successful, with physiologies evolved to survive in water of high or low ionic strength, and sometimes both. The two major groups are the jawed bony fish and the jawed cartilaginous fish, including sharks and rays (Figure 1.4.1). Surviving jawless fish, the lampreys, and hagfishes, also have a cartilaginous skeleton. It seems likely that among bony fish modification of calcium metabolism resulted in ossification of the internal skeleton. This was essential for the future evolution of terrestrial vertebrates, providing an internal calcium store.

Originally, all fish were marine and more dependent on hypocalcaemic factors to maintain tissue calcium levels lower than the surrounding water. As fish colonized fresh water, hypercalcaemic agents would have become essential for survival, and such a hypercalcaemic agent may have developed from a factor already fulfilling a different role in marine fish such as PTH or PTHrP. Over the last decade PTHrP has been identified in tissues of lower vertebrates by immunohistochemistry and *in situ* hybridization with antisera and probes to human PTHrP [13]. Tissues were examined from bony fish, including the lungfish (a 'living fossil' believed to link fish and amphibians), cartilaginous fish, and jawless fish. PTHrP protein and messenger RNA (mRNA) localized to kidney, epidermis, vertebral elements, and muscle, a distribution resembling that reported in higher vertebrates. Conservation of PTHrP localization indicates that PTHrP's function in these tissues is essential, corroborated by successful use of antisera and probes to human PTHrP, which indicates that the *PTHrP* gene and protein are highly conserved. PTHrP was also localized to tissues unique to lower vertebrates, such as gills, saccus vasculosus, and the rectal gland of sharks, all involved in mineral ion regulation. Further examination of PTHrP in these tissues could reveal new roles it plays. No PTH has been detected in tissues of lower vertebrates using a polyclonal antiserum to human PTH (1–34) due to low homology between human and fish PTH.

PTHrP is an onco-fetal hormone in mammals. Findings in bony fish argue that PTHrP may be a classical hormone in fish, however [8]. Comparative endocrinology allows examination of the normal physiological roles of PTHrP in simpler systems. The dissection of PTHrP's roles in fish has been assisted by the isolation and cloning of zebrafish *PTH1R* and *PTH2R* genes [14].

Stanniocalcin

Calcium regulation in most marine fish is dependent upon hypocalcaemic agents such as stanniocalcin (STC), a hormone produced by the corpuscles of Stannius, an organ unique to some bony and cartilaginous fish. Fish generally have abundant access to environmental calcium, and STC prevents hypercalcaemia by targeting gill and gastrointestinal tract calcium transport [13]. STC was thought to be unique to fish with corpuscles of Stannius, but in 1995 human STC was isolated and its gene cloned [15–17]. Fish STC mRNA expression is limited, however mammalian STC mRNA is found in many tissues, including ovary, prostate, and thyroid. Human STC protein is localized to the renal cortex adjacent to the glomerula and has been detected in the circulation. The mouse Stc protein has the same length as human STC, with very high sequence similarity.

The Function of Mammalian STC

STC is localized in the renal cortical brush-border membrane of rats, and decreases calcium absorption and increases phosphate absorption in rat duodenum. STC expression has also been found in developing mouse chondrocytes, acting as a probable autocrine/paracrine factor [16]. Mammalian STC may be a regulator of calcium and phosphate homeostasis, with autocrine/paracrine roles as well as an endocrine role in cell growth and differentiation. This evolutionary progression is also seen for PTHrP, a classical hormone in lower vertebrates with predominantly autocrine/paracrine roles in mammals [17].

STC-2

A second mouse and human STC (STC-2) gene and protein have been identified [17]. *STC-2* is expressed in human tissues ranging

from spleen, peripheral blood leucocytes, and small intestine, to ovary and testes. It is also expressed in rat kidney, skeletal muscle, liver, and brain. STC-2 protein has significant similarity with fish STCs and mammalian STC-1. The difference between the two mammalian STCs is 15 histidine residues in STC-2, four of them forming a cluster near the C-terminus of the protein [17]. Clusters of histidine residues often interact with metal ions such as Co^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+}, although this has not yet been established for mammalian STC-2. A second fish STC was described in salmon corpuscles of Stannius in the same year [18]. Salmon STC-2 was less effective as an inhibitor of gill calcium transport in fish, supporting a non-calcium-related role for STC-2. Salmon STC-2 has fewer histidine residues than human, eel, or coho salmon STC-1. The increase in the number of histidine residues in STC-2 on transition from fish to mammals may reflect altered roles of STC through evolution.

Thyroid Hormones (THs)

The first clear demonstration of the function of THs was by Gudernatsch in 1912 [19], when he showed that diced horse thyroid gland prematurely turned tadpoles into 'mini-frogs'. In 1925 Allen [20] showed that removal of thyroid cells inhibited metamorphosis and, in 1926, Harington identified the main product of the thyroid gland as thyroxine (T4) [21]. The more metabolically active triiodothyronine (T3) was later identified by Hird and Trikojuus in 1948 [22] but, having been published in The Australian Journal of Science, this was not widely acknowledged. Hird visited Pitt-Rivers in London to discuss his experiments. The discovery of T3 is more commonly attributed to Gross and Pitt-Rivers in 1952 [23].

THs play a significant role in bone remodelling alongside the core systemic hormones previously discussed effecting calcium and bone homeostasis. THs are essential for normal human skeletal development, growth, and maintenance of adult bone mass [24]. THs are also more widely involved in regulation of development and metabolism, particularly of the brain. Both the timing and the quantity of TH delivered to the sites of action are crucial for normal development and metabolism. Insufficient TH during human gestation produces 'cretinism' and intellectual disability from birth, whereas reduced TH levels in adults can result in depression.

Key insights into the physiological and developmental functions of THs and their binding proteins in humans have come from studying evolution of TH distribution in vertebrates. This section will focus on insights into both TH metabolism and into forms of human amyloidosis caused by polymerization of the key TH binding protein transthyretin (TTR). We will show that for TH binding, mammalian TTRs are the exception, not the rule.

TH Distributor Proteins Ensure that THs get from the Thyroid Gland to Target Cells

THs are synthesized in the thyroid gland then secreted into the blood for distribution to all tissues by so-called thyroid hormone distributor proteins (THDPs), which are present in both cerebrospinal fluid (CSF) and blood [25]. More than 99% of TH in blood is THDP-bound. Older literature and some current textbooks state that THs are bound to THDPs due to low solubility in blood, however the solubility limit of THs at pH 7.4 is 2.3 μM, and the concentration of free TH in blood is 24 pM, or only 1/100 000 of the solubility limit [26]. THs are lipophilic, partitioning between lipid and aqueous phases at a ratio of 20 000:1 [27]. This means that THs require protein binding to counteract avid partitioning into cell membranes, to maintain a pool of circulating THs in the blood, and to ensure even tissue delivery [28]. In the bloodstream, THs can dissociate from the THDPs to enter cells, largely via membrane-bound TH transporter proteins such as MCT8, MCT10 (monocarboxylate transporters 8 and 10). THs are then subject to activation or inactivation by the family of deiodinases. In humans, the major form of TH circulating in the blood is T4 (the 'transport form'), whereas the form of the hormone with highest affinity for the nuclear receptors is T3 (the 'active form'). However, there is now a rapidly expanding literature of non-genomic actions of THs other than T3 (e.g. T4, rT3, T2). Deiodinases types 1, 2, and 3 can either active (e.g. T4 to T3) or inactivate (e.g. T4 to rT3; T3 to T2) THs within a cell. Thus, deiodinases confer a tissue-specific level of regulation of TH activity.

Within the cell, THs bind specific cytosolic proteins and are translocated into the nucleus where they bind TH nuclear receptors (TRs). T3 has the highest affinity for TRs and is the usual ligand. TRs are encoded by two genes: TRα and TRβ. Each of these genes produces at least two splice variants resulting in the four main products TRα1, TRα2, TRβ1, and TRβ2. However, TRα2 does not bind T3. Together with comodulator proteins, T3-TRs dimerize with retinoid X receptor (RXR) and bind to TH response elements (TREs) and either positively or negatively regulate expression of specific genes.

TTR is Responsible for Much of the TH Distribution in the Body and in the Brain

THs are distributed by the bloodstream. In humans, THDPs are albumin, thyroxine-binding globulin (TBG), and transthyretin (TTR). In the blood about 75% TH is bound to TBG, 15% to TTR and 10% to albumin. A small fraction is lipoprotein-bound. Albumin, TBG and TTR are synthesized by the liver. TBG is lowest in concentration but has highest affinity for T4, albumin is highest in concentration but has the lowest T4 affinity, whereas TTR has intermediate concentration and affinity for T4. T4 bound to albumin rapidly dissociates, T4 bound to TBG acts as a reservoir for T4 in the blood and TTR is responsible for the bulk of the delivery of T4 to tissues (for kinetic discussion of the free hormone hypothesis and the free hormone transport hypothesis, see [29]). This may be captured by the 'Goldilocks and the Three Bears' analogy: TBG binds THs so tightly it does not participate in biodelivery, albumin binds so weakly that it does not distribute THs effectively, but TTR has affinity for THs that is 'just right', allowing appropriate distribution and cellular delivery of THs [30].

Blood is separated from the cerebrospinal fluid (CSF) by the blood-CSF barrier. The choroid plexus, located in the lateral, third, and fourth ventricles of the brain, forms this barrier. The only THDP synthesized by the brain is TTR, which is synthesized in the choroid plexus and is involved in the transport of T4 from the blood into the CSF [27, 31, 32, 33]. Only a small amount of albumin and TBG are present in the CSF due to the leakiness of the blood-brain

barrier. Thus, TTR is responsible for the majority of TH distribution in the CSF.

Evolution of TTR Synthesis in the Body and Brain

TTR is synthesized by the livers of all classes of vertebrates at some stage during their life cycle (Figure 1.4.3) ([34]; for a review, see [29]). In some animals this is only during development (e.g. fish, amphibians, reptiles, monotremes and Australian polyprotodont marsupials) whereas in birds, diprotodont marsupial and eutherians ('placental mammals') TTR is synthesized in the liver throughout life. In general, animals that are homeothermic ('warm blooded') synthesize TTR in their livers throughout life. THs are known to be involved in the regulation of body temperature. Poikilothermic ('cold blooded') animals synthesize TTR in their livers only during specific stages of development that are regulated by THs. From comparative endocrinology, we see that the function of TTR synthesized by the liver is related to an increased demand for TH distribution: during TH-regulated development and homeothermy, which is governed largely by THs.

TTR synthesis by the choroid plexus probably began with the stem reptiles about 320 million years ago [35]. The stem reptiles are the common ancestors to the reptiles, birds and mammals (but not to amphibians and fish). Thus, TTR synthesis in the brain is a more recent event than TTR synthesis in the liver. The selection pressure for turning on the TTR gene in the choroid plexus could be the increase in brain volume, which occurred with the first traces of the cerebral cortex in the stem reptiles [36]. This increase in lipid volume could have been the selection pressure requiring a protein to better distribute TH around the brain via the CSF (see [26]). From comparative endocrinology, we see that the function of TTR synthesized by the brain is to counteract the partitioning of THs into the increased lipid pool and to ensure appropriate distribution of THs throughout the CSF.

Evolution of TTR Structure and Function

The amino acid sequences of TTRs from more than 20 vertebrate species (including fish, amphibians, reptiles, birds, marsupials, and eutherians) have been determined (Figure 1.4.4). The amino acids in the central channel of the TTR homo-tetramer that are involved in ligand binding were 100% conserved between species. A surprising finding, therefore, was that TTRs from lower vertebrates bind T3 with higher affinity than T4 [37]. Only TTRs from mammals bind T4 with higher affinity than T3. Given that the amino acids in the TH binding sites are identical in all TTRs sequenced to date, regions of the protein that changed during vertebrate evolution were sought and considered for influence of ligand binding. The region with the highest rate of evolution is the N-terminal region of the TTR subunit. This changed from longer and more hydrophobic in lower vertebrates to shorter and more hydrophilic in eutherian mammals. These structural characteristics correspond with ligand binding preferences: TTRs with longer and more hydrophobic N-termini bind T3 with higher affinity than T4, whereas TTRs with shorter and more hydrophilic N-terminal regions bind T4 with higher affinity than T3 [37]. A series of chimeric TTRs were generated, where N-terminal regions were swapped or deleted. These studies confirmed the hypothesis that the N-terminal region of the TTR subunit confers ligand preference and affinity [38, 39]. The mechanism for shortening the N-terminal region of the TTR subunit was found to be the stepwise shift in the position of the intron 1/exon 2 splice

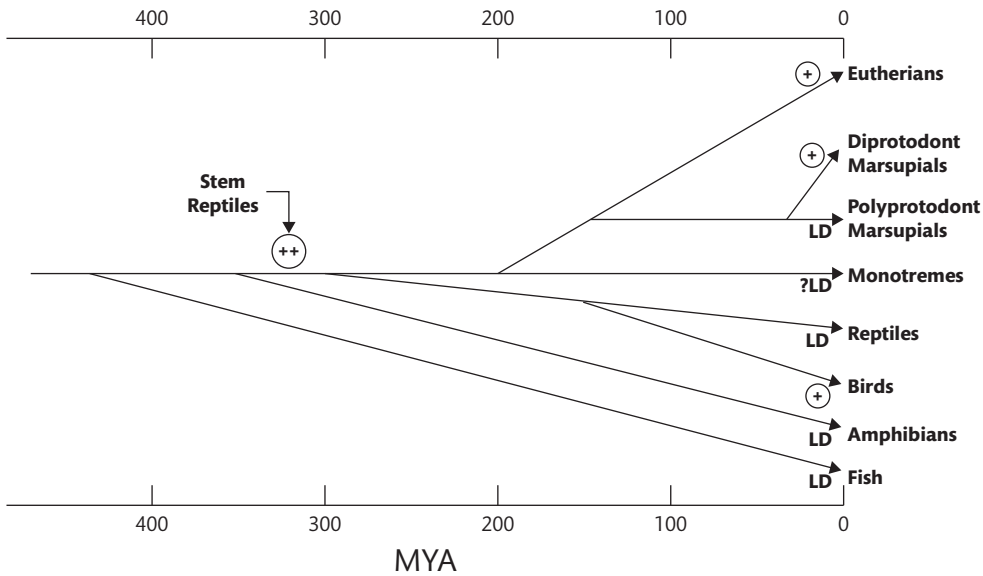

Figure 1.4.3 Evolutionary/developmental tree for TTR synthesis in the choroid plexus and liver of vertebrates. Figure 1.4.4 Human TTR mutations compared with evolutionary mutations in vertebrate TTRs. TTR amino acid sequences and those derived from cDNA sequences from 19 species aligned with human TTR. Secondary structural features for human TTR are indicated. Amino acids in other species identical to those in human TTR are indicated with asterisks. Point mutations detected in human TTRs are indicated below the human TTR sequence.

site in the 3' direction [40]. This situation is very unusual, as the TH binding site in TTR does not determine which form of TH is preferentially bound.

TTR Evolved from TTR-Like Protein, a 5-Hydroxyisourate Hydrolase

There is a very high degree of amino acid identity across all vertebrate classes, suggesting that the TTR gene evolved prior to the divergence of the vertebrates from the invertebrates [41]. Therefore, genomes of non-vertebrates were screened for open reading frames (ORFs) similar to TTR genes that could code for TTR-like proteins (TLPs). More than 100 ORFs coding for TLPs were identified, from all kingdoms [42]. It was proposed that the TTR gene evolved as a duplication of the TLP gene. Five motifs were identified as defining TLPs and three motifs were identified as defining the set of TTRs + TLPs. These motifs mapped to structurally conserved and functionally important regions of the proteins. Transcription of these ORFs was demonstrated in a bacterium, a plant, and an invertebrate animal, demonstrating their existence in nature. These TLPs had similar molecular weights and tetrameric structures to vertebrate TTRs. A subsequent study revealed the X-ray crystal structure of *Salmonella dublin* TLP to be extremely similar to that of vertebrate TTRs [43]. Thus, the 3D structure of TLP/TTR has not changed from bacteria to humans. The fact that the structure was so highly conserved throughout evolution implies that this protein serves a very important function. Even within vertebrates, the structure of TTR is extremely highly conserved, similarly to the conservation of the histones (involved in compacting DNA in eukaryotes), whose structures are among the highest conserved. This remarkable degree of conservation of structure was only revealed through comparative biochemistry (see [44]).

TLPs do not bind THs [45]). TLPs from *Salmonella*, mouse, and zebrafish are enzymes involved in the oxidation of uric acid to allantoin. TLP is a 5-hydroxyisourate hydrolase, which hydrolyses 5-hydroxyisourate (5-HIU) to 2-oxo-4-hydroxy-4-carboxy-5-ureidoimidazoline (OHCU) [43, 46, 47]. A series

of *Salmonella* TLPs with point mutations identified three conserved residues in the catalytic site that are essential for enzyme activity [43]. Comparison between the TH binding site in TTR and the equivalent region in *Salmonella* TLP revealed that the binding site was shallower and more positively charged in TLP compared to that of TTR, explaining why THs cannot be bound by TLPs [37]. TLP/TTR is a remarkable example of conservation of protein structure, but evolution of the protein's function: from a 5-HIUase to distributor of T3 to distributor of T4 (for greater detail, see [48]).

Evolution of TTR Structure Sheds Light on Human Amyloidoses: FAP and SSA

TTR can form amyloid deposits in humans, leading to two types of TTR amyloidosis: familial amyloidotic polyneuropathy (FAP) and senile systematic amyloidosis (SSA). The TTR tetramer is usually very stable. However, it can form amyloid fibrils naturally *in vivo*, and can be induced to form amyloid *in vitro* [49]. There are two types of TTR amyloid. SSA is an age-dependent disease and the TTR fibrils are formed from wild type protein. At least 65% of people over 70 years old have TTR SSA (see [50]). By contrast, FAP is a specific form of autosomal dominant hereditary polyneuropathy, which initially manifests as systemic deposition of amyloid in the peripheral nerves, but later effects many visceral organs. Many of the FAP mutations are named after their country of origin. Examples of this are being able to track the travels of the Vikings, as they left a trail of their FAP mutations in Scotland and in England; and the Portuguese explorers left a trail of their FAP mutations to Japan and back. Interestingly, there are about 200 words that are similar in Portuguese and Japanese languages.

There are at least 100 point mutations that have been documented in the 127 amino acids in the TTR subunit which result in FAP (see [51]). These mutations are evenly spread throughout the length of the TTR subunit, which is in sharp contrast to the evolutionary mutations, which are concentrated in the N-terminal regions of the subunit. TTR amyloidosis has not yet been described in a non-human species. Of the mutations in human TTR that result in amyloidosis, five are found in other species but do not result in amyloidosis: Val30Leu, Glu42Asp, Ile68Leu, Tyr69Ile and Ala81Thr (**Figure 1.4.4**) (see [29]). Of these, Leu30 is only found in sea bream TTR and Asp42 is only found in bullfrog TTR, both of which are evolutionarily quite distant from humans. However, the Ile68Leu substitution is found in seven mammalian species studied to date. Further investigation of these TTRs and comparison to the mutated human Leu68 could give valuable insight as to why Leu is tolerated in position 68 without amyloidosis formation in other mammalian species, but leads to amyloid formation in humans. This could result in understanding the molecular basis of TTR amyloid formation in humans.

All five point mutations in human TTR resulting in amyloidosis, that are the normal residue in that position in TTRs from other species, result in cardiac amyloid deposition in humans. This is highly intriguing and requires further investigation.

Implications of the Evolution of Calcium Regulation and Thyroid Hormone Distributors for Clinical Endocrinology

In summary, there has always been considerable synergy between comparative and mammalian endocrinology, with information from one field providing stimulus to the other. STC was originally identified in fish and subsequently found in mammals. Previous studies on fish stanniocalcin provided information about the potential roles of human STC-1 and the isolation of mammalian and fish STC-2 will stimulate the search for its endocrine and physiological roles in both fish and mammals. In contrast, PTHrP and PTH were originally identified in mammals and then the search for the orthologous genes in fish began. There has been considerable interest in calcium regulating factors from lower vertebrates because of the efficacy of salmon calcitonin in inhibiting bone resorption in mammals, including man. Certainly, a number of groups are interested in isolating fish PTH, or possibly PTHrP, as these fish factors or structural analogues could be potential treatments for osteoporosis in human subjects.

The identification of a second STC in both fish and mammals reflects the principle that Niall argued in 1982 [52] that nature duplicates a gene rather than creating a new gene. Through this mechanism, when a gene for a hormone is duplicated the copy is free to mutate and acquire new function(s) and receptors, leaving the first hormone carrying out its original role. This could also be the case with the duplication of PTH and PTHrP and calcitonin and calcitonin gene-related peptide. In his review, Ohno argues that for every gene present in invertebrates there could be up to four copies present in vertebrate genomes [12]. He bases his argument on the fact that there are 15 000 protein-coding genes in invertebrate genomes while there are 60 000 in vertebrate genomes as a result of two rounds of whole genome duplication. He argues that there could be up to four copies of each gene in jawed vertebrates compared to one copy of each gene in tunicates. The current evidence supports Ohno's theory. This one-to-four rule could apply to a number of other genes including the parathyroid hormone and calcitonin gene families. First it is important to establish if there are members of these gene families present in an invertebrate genome.

There are a number of other genes and hormones that have been identified in fish that have not yet been identified in mammals. One of these is somatolactin, a member of the growth hormone/prolactin family [53]. Its relationship with two of the major vertebrate hormones should stimulate the search for it in the human genome and uncover its function in both lower and higher vertebrates. This will be another project where interaction between the two fields of endocrinology will prove fruitful.

Now a number of whole genome sequencing projects, including the elephant shark, pufferfish (*Fugu rubripes)* and human are completed, and other genomes are currently being sequenced (e.g. Japanese lamprey) more information about the genes for calcium regulating factors as well as a number of other hormones are becoming accessible. When the complete sequences and genome structure are known, a shift in focus from gene to protein will be required leaving comparative endocrinology to answer the following intriguing questions: what are the roles of these factors in lower

vertebrates, compared to higher vertebrates, and how have evolutionary events modified these roles?

The evolution of the structure and function of TTR has given insights into the tissue-specific requirements of THs, both during development and during evolution. TLPs exist in all kingdoms, whereas TTRs only exist in vertebrates. The highly conserved structure of TLP was very slightly modified to allow binding of THs in the central channel. The N-terminal regions of each subunit were modified during evolution to change TTR from distributing T3 to distributing T4. This presumably resulted in an increased complexity of deiodinases at the tissue level. That certain amino acids in specific positions are tolerated in some species, but result in amyloidosis in human TTR should be exploited in order to understand the mechanism(s) of TTR amyloid formation in humans.

There are large amounts of data being generated by whole genome sequencing projects of a wide range of vertebrates and invertebrates currently being undertaken. There will be a number of exciting opportunities for collaboration between comparative and clinical endocrinology to learn more about the evolution of human endocrine conditions and possibly potential new treatments for diseases.

Hormones Across the Lifespan

James Gibney, Indraneel Banerjee, and Ken K.Y. Ho

Introduction

The endocrine system plays a central role in growth, development, metabolism, reproduction, and physical well-being throughout life. A complex developmental programme shapes distinct time-dependent changes in various components of the endocrine system during different phases of postnatal, childhood, and adult life. This permits context-dependent modulation of this multifaceted control system to subserve distinct functions according to the differing demands of different life stages. Regulation is critically dependent on feedback, which is configured distinctly in each of the reproductive, adrenal, thyroid, and growth axes from fetal to adult life.

There are three main points in the life course when pituitary function is remodelled. First, a remarkable programme of adaptation prepares the fetal endocrine system for extrauterine life no longer dependent on maternal factors, with a second shift marking the acquisition of sexual maturity at puberty. The much more gradual process of senescence in later life, which features particularly notable sexually dimorphic changes in the reproductive system (abrupt in women and gradual in men) constitutes a third phase of change.

The profiles of hormones throughout life are well characterized and provide a framework for assessing the integrity of the endocrine system in health and disease. This chapter will describe the profiles of the gonadal, adrenal, growth hormone, thyroid, and prolactin axes covering the paediatric and adult years of life. The paediatric phase spans the neonatal, childhood, and adolescent years. The endocrinology of fetal development is a major topic whose full treatment is beyond the scope of this chapter, however selected aspects are covered to provide an understanding of changes in the transition to postnatal life.

Gonadal Axis

Among the pituitary hormonal axes, the gonadal axis displays the greatest dynamic, developmental change, exhibiting distinct patterns in postnatal, childhood, and adult life that are moreover distinct in women during and at the end of reproductive life. The major measurable elements of this system are pituitary gonadotrophins and the gonadal products sex hormones and inhibin.

Development *In Utero* and Childhood

The hypothalamic–pituitary–gonadal axis (HPA) is fully intact by mid-fetal life. Its function is suppressed in the latter half of pregnancy by sex steroids produced from the fetal gonad under the influence of placental human chorionic gonadotropin (HCG) and rising maternal oestrogen levels. After placental restraint is removed at birth, gonadotrophin levels rise in early infancy, reaching a peak around 2–3 months, causing a parallel rise in sex steroid levels in early infancy (**Figures 1.5.1 and 1.5.2**). The term minipuberty is applied to this phase in early life when gonadotrophins and sex steroid levels are high, although sex hormone receptor insensitivity ensures lack of translation into secondary sexual characteristics [1]. Luteinizing hormone (LH), follicle-stimulating hormone (FSH), and sex steroid levels then decline by about six months in boys and 1–2 years in girls to prepubertal levels, entering the so-called juvenile pause, determined by neural mechanisms suppressing gonadotropin-releasing hormone (GnRH) secretion. The cause and significance of minipuberty, and the mechanisms determining the secondary inactivation of the axis, are not well understood.

The gonadal axis profile remains relatively quiescent throughout childhood, although very low amplitude pulsatile secretion of gonadotrophins does occur, with FSH levels tending to be higher than LH. Nocturnal sleep-entrained pulsatile secretion of hypothalamic GnRH activation marks the onset of puberty, driven by a hypothalamic pulse generator in which the neuropeptide kisspeptin plays a key role. During pubertal development, gonadotrophins rise, with LH levels higher than FSH, in concert with increases in the amplitude and frequency of episodic secretion extending into the

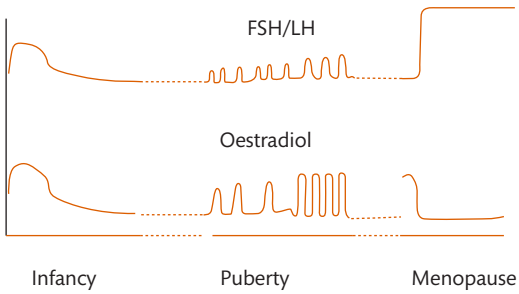

Figure 1.5.1 Schematic representation of gonadotropin (LH/FSH) and oestradiol levels in females throughout the lifespan. The figure shows concentrations in infancy through pubertal, reproductive, and menopausal phases. The LH/FSH levels depict the summated curve within a diurnal profile characterized by secretory pulses of varying amplitude and frequency. The waveform excursions during puberty represent changes during the menstrual cycle.

daytime. The progressive and sustained increase in gonadotrophin secretion leads to maturation of the gonads and production of sex steroids reaching a peak in late puberty, and occurring earlier in females than males (Figure 1.5.1).

Adulthood

Males

A gradual and progressive decrease in serum total testosterone occurs from age 20 to 80 years, with a recent study of 10 000 healthy men demonstrating a decline of 0.5% annually [2]. See Figure 1.5.2. The decline is more marked in those with chronic illness and in those who are overweight [3]. An associated increase in sex hormone-binding globulin occurs with ageing, resulting in a more marked reduction of free (bioavailable) testosterone.

The decline in testosterone results from reduced production rates and a fall in plasma clearance. Reduced testosterone production arises from changes at all levels of the HPA, including gonadotropin secretion and testicular steroidogenesis; There are also changes in negative and positive feedback interactions [4]. Testosterone displays a diurnal profile of high levels in the early morning, falling to a nadir in the late afternoon. The diurnal rhythm of testosterone production is less marked in older compared to younger men.

Mean LH and FSH levels increase with increasing age. However, the increase in LH is not proportionate to the decline in testosterone indicating alteration in the classical feedback loop. The sensitivity of pituitary LH secretion to androgen-mediated feedback inhibition is increased, and the ability of LH to stimulate testicular testosterone secretion is inhibited.

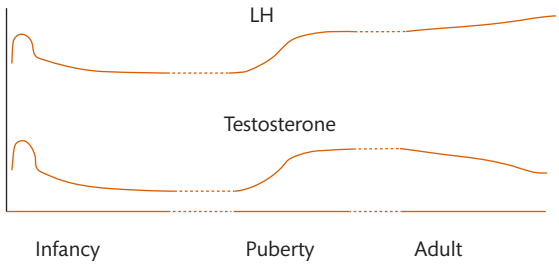

Figure 1.5.2 Schematic representation of gonadotropin LH and testosterone levels in males throughout the lifespan. The figure shows concentration in the neonatal and pubertal periods, and in adult life. The LH levels depict a summated curve within a diurnal profile characterized by secretory pulses of varying amplitude and frequency.

Changes in testicular morphology influence circulating hormone levels. Inhibin produced by Sertoli cells falls with age; in combination with increased FSH levels this indicates decline in Sertoli cell function. There is also a reduction in Leydig cell volume and number which probably contributes to reduced testosterone concentration.

As in younger subjects, interpretation of serum testosterone levels in older men is guided by timing and conditions of sampling, the validity of lower limit of the normal reference range, and whether symptoms of hypogonadism are present [5]. Current evidence that the lower level observed in later life merits supplementation to improve heath is poor.

Females

The phasic changes in gonadotrophins, oestrogen and progesterone concentrations that typify the female menstrual cycle are well covered elsewhere and will not be described here. See Figure 1.5.1.

In contrast to other hormonal axes in which there is a gradual change in hormone levels with ageing, a major change in female reproductive hormones occurs at the time of menopause. This stems from near exhaustion of the oocytes in the ovaries, which is the culmination of a gradual decrease in quantity and quality of oocytes in the ovarian cortex across reproductive life [6]. At the time of menarche, there are approximately 300 000 primordial follicles. During reproductive years, there is a gradual but accelerating decline, leaving fewer than 1000 follicles at the time of menopause [7]. The first detectable evidence of reproductive ageing is usually a lengthening of the menstrual cycle by 2 to 3 days. Subsequently insufficient availability of follicles further lengthens cycles, leading to missed periods or phases of cycle arrest. This is referred to as the menopausal transition and lasts until the final menstrual period. The average age of onset of the transition is 46 years, and the mean age of the final menstrual period is 51.

Increased FSH levels associated with decreased inhibin levels but normal LH levels accompany perimenopausal changes in menstrual cycle pattern, usually associated with slightly elevated oestradiol levels. These changes reflect decreasing ovarian reserve and are best detected on day 2 or 3 of the menstrual cycle. Serum oestradiol levels begin to decline less than a year before menopause. Ovarian production of inhibin begins to decrease after 30 years and this becomes more pronounced after age 40.

In the absence of oestrogen and inhibin from the menopause, LH and FSH levels rise sharply; LH pulse amplitude but not frequency is increased. FSH and LH levels peak a few years after menopause and slowly decline in subsequent years. Increased LH maintains significant production of androstenedione and testosterone from the ovary albeit at lower levels than in premenopausal women. Circulating oestradiol and oestrone are slightly less than average male levels postmenopausally and almost all of these steroids is derived from peripheral aromatization of androstenedione. These changes result in a marked increase in the ratio of androgen to oestrogen levels.

The function of the gonadal axes can be disrupted by many factors including stress, nutrition, body weight, and systemic illness in the absence of pathological lesions to the hypothalamus, pituitary, and gonads.

Adrenal Axis

The ontogeny of the pituitary–adrenal system features one progressive change, reflecting the diverse demands on the adrenal gland as part of electrolyte, metabolic, androgen, and cardiovascular homeostasis, and in systemic stress response.

ACTH

Development *In Utero* and Childhood

The fetal adrenal cortex is functionally active by 10 weeks [8]. It contributes significantly in the production of androgens, particularly dehydroepiandrosterone (DHEA) [9]. The fetal zone of the adrenal gland expresses high levels of sulfotransferase activity leading to a greater proportion of DHEA and DHEAS relative to cortisol and aldosterone. In turn DHEA and DHEAS are aromatized by the placental trophoblast to oestrogen, contributing significantly to the maternal pool.

The HPA axis is fully functional at birth in term infants. In babies born prematurely, adrenal function is often suboptimal, due to functional immaturity and the influence of antenatal maternal steroids [10]. Diurnal cortisol secretion within the fetal circulation is present by late gestation, controlled by maternal stimuli [11]. Following birth, cortisol secretion is unsynchronized for several months until the adrenal clock is entrained to the day–night cycle, mediated by ACTH (adrenocorticotropic hormone) secretion [12].

ACTH is secreted in a complex pattern featuring pulsatile and basal components; 12 to 30 pulses occur per day, with ACTH having a short half-life of 14–35 minutes. ACTH secretion in turn is driven by CRH rhythms; its diurnal pattern originates from the circadian pacemaker located in the suprachiasmatic nuclei of the hypothalamus. ACTH and cortisol secretion parallel one another, with a characteristic profile that peaks in the early morning, falling gradually through the day to a nadir around 12 midnight, before increasing again in the early morning.

Adulthood

Mean ACTH levels frequently sampled over 24 hours do not change with age. More subtle changes in the pattern of ACTH secretion do occur however; increasing age is associated with greater asynchrony of ACTH and cortisol secretion, and a greater proportion of brief sharp fluctuations in ACTH levels [13]. A recent intriguing finding has been the identification of a significant association between genes encoding the ACTH receptor and familial longevity [14].

Parallel age-related reductions in cortisol secretion rates and cortisol metabolic clearance result in serum cortisol levels that are unchanged or increased; clear changes in the diurnal pattern exist, however. Frequent sampling of cortisol levels over 24 hours has demonstrated an age-related phase advance of the circadian pattern with earlier nadir and peak levels (up to 3 hours), no difference in the interval between nadir and peak levels, and increased levels at the time of the nocturnal nadir, indicating reduced inhibition of nocturnal cortisol secretion. The largest study to address the effect of age on mean 24-hour cortisol levels report an increase of 20–50% between 20 and 80 years [15] although not all studies support this. Changes in the diurnal pattern of cortisol secretion reflect changes in the output of the circadian pacemaker, and potentially influence the sleep-wake cycle of older adults who tend to have earlier sleep onset, earlier morning awakening. and a more fragmented and shallow sleep.

The diurnal variation in axis function, with cortisol excursion varying across a 5–6-fold range means that caution must be exercised in assessing the integrity of the system using any isolated cortisol value, particularly if the sample time is unknown. The HPA axis plays a vital survival role by subserving the flight and fright response. The plasticity required for such immediate adaptation engenders enormous variability in ACTH-cortisol excursions in daily life.

DHEA

Childhood

Adrenal androgen production increases at around ages 5–8 years without a concomitant increase in cortisol secretion. This phenomenon is called adrenarche, and coincides with the emergence of mild androgenization including axillary and pubic hair appearance [16]. The trigger for adrenarche is poorly understood but is thought to arise from changes intrinsic to the biochemical machinery of the adrenal cortex that maximize DHEAS production. DHEAS levels later progressively rise through puberty, coinciding with appearance of androgen-driven secondary sexual characteristics. Activation of adrenal androgen secretion is usually clinically imperceptible, merging into centrally mediated puberty. DHEA and DHEAS levels peak later in adult life.

Adulthood

Serum DHEAS concentration in adult life is over 100-fold higher than the concentration of testosterone, and over 2000 times the concentration of oestrogens. DHEA and DHEAS form a pool of precursors that can be converted in various tissues to androgens and oestrogens. Most of the sex steroids in postmenopausal women are derived from DHEA and related adrenal precursors. There has been great interest in the biology of DHEAS in health because of observational studies linking higher levels to longevity and better cognition. In hypoadrenal patients, DHEA replacement improves sexual function, vitality, and quality of life [17]. The results from studies of DHEA supplementation in ageing populations with normal adrenal function have been conflicting [18, 19].

Among the adrenal hormones, the most marked age-related effects are seen for DHEA and DHEAS. Maximum levels occur at the beginning of the second decade of life before levels decrease to about 20–30% by the eighth decade, in association with selective involution of the zona reticularis of the adrenal cortex. A large Australian study which included approximately 1400 women demonstrated age-related declines in total and calculated free testosterone, DHEAS and androstenedione with no change in SHBG [20]. The decline was steepest in the early reproductive years, and flattened out in midlife, with a tendency to increase in later years. There was no effect of natural menopause on the rate of decline. Among postmenopausal women who had previously undergone oophorectomy, total and free testosterone levels but not androstenedione and DHEAS were lower than in the remainder of the cohort, indicating that the observed changes in the latter two steroids reflect reduction in adrenal production. The significance of DHEAS levels in the absence of adrenal disease is unknown. There is insufficient evidence warranting its measurement as an indicator of adrenal function.

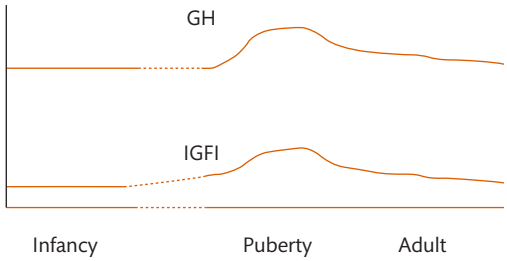

Figure 1.5.3 Schematic representation of growth hormone (GH) and IGF-I levels in males and females across the lifespan. The figure shows concentrations in the neonatal and pubertal periods, and in adult life. The GH levels depict a summated curve within a diurnal profile characterized by secretory pulses of varying amplitude and frequency.

GH Axis

Development *In Utero* and Childhood

The infantile pituitary secretes growth hormone at levels higher than in later childhood, however fetal growth is not dependent on adequacy of growth hormone secretion either from the pituitary or from the placenta. Postnatal growth is more dependent on nutrition than on growth hormone status, such that the manifestations of growth hormone deficiency are only evident after the first 2 years of life [21]. There is limited information on growth hormone (GH) secretion in infancy, but available evidence suggests that GH levels are relatively high in early infancy [22] before stabilizing during childhood until entry into puberty. There is increasing evidence that sensitivity of growth hormone-responsive tissues changes with age and plays a part in determining the magnitude of growth [23].

Spontaneous GH secretion is pulsatile with most occurring at night, triggered by onset of slow-wave sleep. Because secretion of GH is episodic, isolated basal plasma GH concentrations are a poor indicator of overall secretion. Studies employing frequent sampling over a 24-hour period have clearly demonstrated that GH secretion increases at onset of puberty, peaking by 2–3-fold at mid- to-late puberty (Figure 1.5.3). The increase in GH secretion occurs earlier in girls than in boys in parallel with entry and progression through puberty [24]. The changes in spontaneous GH secretion are attributable to changes in pulse amplitude and not frequency.

Adulthood

GH secretion starts to decline during the third decade of life and then progressively thereafter [25]. IGF-1 levels follow a similar trend to GH, increasing 2- to 3-fold at puberty in both sexes, progressively declining with advancing age to about 50% of that observed in the third decade (Figure 1.5.3). Both GH production rate and half-life decline with age, the former by 14% and the latter by 6% per decade [26]. GH secretion is reduced in obesity. Because obesity often increases with age, it is unclear the extent to which the fall in GH secretion is confounded by the age-related increase in adiposity.

The influence of age on stimulated GH secretion is less clear. Whether the GH response to insulin-induced hypoglycaemia changes with age is unresolved. The GH response to arginine, a GH secretagogue, and to GH-releasing hormone (GHRH) does not change significantly with age. In contrast, exercise-induced GH release is reduced with age and even in early middle age (mean age 42 years), the GH response to exhaustive exercise is greatly attenuated compared to younger (mean age 21 years) individuals [27].

Physical activity, sleep patterns, adiposity, and gonadal steroid status all change with age and have all been shown to regulate GH secretion. Age, body composition, and physical fitness are independent predictors of 24-hour integrated GH concentrations. GH secretion in response to arginine and clonidine in healthy adults is determined by body composition and physical fitness rather than by age while the GH response to exercise is influenced by age and physical fitness (VO_2max) but not by body fat [28]. These findings suggest that maintenance of physical fitness throughout life might attenuate the decline in GH secretion rates although notably training programmes, which improve physical fitness, do not appear to increase the GH response to exercise [27].

The age-related decline in GH secretion is mediated at the pituitary and hypothalamic or higher levels. Studies in animals have indicated that enhanced hypothalamic production of somatostatin, an inhibitor of GH secretion, is the principal mechanism for age-related hyposomatotropism, with reduced GHRH production involved to a lesser degree. Human studies using indirect approaches, however, have demonstrated an important role for reduced hypothalamic GHRH secretion in ageing. Firstly, the GH response to withdrawal of somatostatin infusion, which provides an estimate of GHRH release, is reduced in elderly compared to young women with a similar trend occurring in men. Secondly, GH pulse amplitude, a function of GHRH secretion, is reduced in elderly compared to young subjects. The suppression GH secretion by IGF-I infusion is reduced rather than enhanced in older people, implying that increased sensitivity to negative feedback by endogenous IGF-1 is not a mechanism through which this effect occurs.

In the absence of confounding factors, there is an age-dependent fall in GH and IGF-I levels that begins in the third decade well before the onset of physical frailty (Figure 1.5.3). The significance of the reduction in the activity of the GH axis is unknown; there has been enduring speculation that it may be pathological rather than adaptive biology of ageing. A beneficial effect of GH supplementation has not been established. Of interest are observations that patients with congenital isolated GH deficiency and GH receptor mutations appear to be protected from age-related diseases such as atherosclerosis, diabetes, and cancer [29, 30].

Prolactin

Prolactin is secreted by lactotrophs, the function and growth of which is stimulated by oestrogens. Prolactin secretion is under tonic inhibitory control of the hypothalamus.

Development *In Utero* and Childhood

Lactotrophs are present by 6 weeks' gestation and prolactin concentration increase gradually in the fetus throughout pregnancy. Prolactin levels in the newborn are approximately 10-fold higher than that seen in adult life in both boys and girls but gradually decrease within 3 months to a stable concentration in infancy and in childhood. The high prolactin levels are believed to be caused by the stimulatory effect of elevated maternal oestrogen levels. Prolactin levels increase slightly during puberty, to a greater extent in females

than males, and this gender difference is maintained virtually throughout adult life.

Adulthood

Prolactin is secreted in a diurnal pattern in both sexes, with episodic peaks and higher levels during the night than day. Prolactin secretion increases about 60–90 minutes after the onset of sleep coincident with non-rapid eye movement (REM) sleep and falls with the onset of REM sleep. Prolactin levels fluctuate during the menstrual cycle with higher levels at mid-cycle and lower concentrations during the luteal compared to follicular phase.

Prolactin levels decline gradually with age. In accordance with its pro-lactational function, levels rise progressively during pregnancy. Maternal prolactin levels start to rise by 6–8 weeks' gestation, increasing gradually throughout the course of pregnancy to 8–10 times higher than prepregnancy levels at term. Suckling is a potent stimulus to prolactin secretion, elevating blood levels by 3–5-fold. After termination of suckling, levels return to prenursing baseline by 1–2 hours. The suckling-evoked increase of prolactin secretion wanes with time post-partum particularly when the frequency of suckling diminishes with the introduction of formula feeds. Lactation can be maintained by regular suckling over years. On cessation, levels return to that seen before pregnancy by about 3–4 months. Prolactin has no known function in males.

Thyroid Axis

Development *In Utero* and Childhood

The fetus starts producing thyroid stimulating hormone (TSH) and thyroxine by the end of the first trimester. TSH levels remain low until 18 weeks, increasing steadily followed by rise in serum thyroxine levels through the mid and late trimesters.

TSH concentrations are higher in the fetus than in the mother throughout fetal life. At birth, TSH levels rise abruptly triggering a parallel increase in serum thyroxine levels achieving steady state values after 3–4 days of birth [31]. TSH levels fall rapidly shortly after the immediate postnatal rise, returning to baseline 48 hours after birth. The concentration of thyroxine in the neonatal period is considerably higher than in older children and adults, however, it falls gradually into the normal range of children and adults by the first month. Beyond the neonatal period, thyroid hormones levels remain stable and do not fluctuate with the onset and progress of puberty.

Newborn screening tests for the diagnosis of congenital hypothyroidism are reliant on TSH measurements in whole blood at day 5 of life, after the transient immediate postnatal surge. Because of the critical role of thyroid hormones for brain development and function, treatment of neonatal hypothyroidism aims to keep the TSH level in the normal range, including in premature babies with borderline TSH levels.

Adulthood

Interpretation of physiologic changes in thyroid hormones with ageing is complicated because rates of mild or subclinical thyroid dysfunction are high in elderly people, especially in women. Furthermore, acute and chronic non-thyroidal illness, poor nutritional status, and use of medications that influence thyroid function become more prevalent with age.

After the early neonatal period, the pituitary–thyroid axis changes minimally throughout life with TSH being the most robust indicator of thyroid status in the absence of pituitary disease. TSH is secreted constantly, exhibiting small episodic peaks and higher levels at night in both sexes while maintaining thyroid hormone levels within a tight range. With ageing, when patients with subclinical hypothyroidism or other confounding conditions are excluded from analysis, serum TSH remains within the normal range, although mean TSH levels are lower than at younger ages. Daily secretion of TSH is reduced with blunting of the nocturnal peak. It is not clear whether this reflects increased sensitivity to negative feedback or whether other mechanisms are involved.

Studies in subjects up to the 100–110 year age range report no change in total or free T4 levels, but an age-dependent reduction in Free T3 levels with levels continuing to decrease up to the eleventh decade, and age-dependent reduction in TSH [30]. Morphologic and functional changes are also seen in the ageing thyroid. There is a progressive decline in iodine uptake, while radioisotope studies have demonstrated reduced T4 distribution space, increased T4 half-life, and reduced T3 and T4 production rates. T4 degradation rates are also reduced (through reduced outer ring deiodination mediated by 5' deiodinase) with reduced generation of T3. The net effect of these physiologic changes likely explains the dissociation of T4 and T3 levels with ageing.

Conclusion

The profiles of hormones of the major pituitary axes across the lifespan differ from each other, with distinct responses seen at different stages of development and ageing, yet all are unified by a regulatory paradigm integrating peripheral feedback and converging neural cues. Fetal factors, maternal environment, and placental function shape the status and profile of each axis differently in postnatal life. When established, a central effector and peripheral feedback system provides for tight regulatory control. Developmental programming during life's transitions can bring dramatic changes of the pattern relationships between pituitary and target gland profiles within the regulated system. The hormone profiles are characterized by an orderly rhythmicity that is unique for each axis and which may not readily be discerned from single random hormone measurements. The hormone profiles of the pituitary gland provide key information on the integrity of the endocrine system across the human lifespan. An understanding of the properties and characteristics of each axis is critical for identifying disease and implementing appropriate treatment.

1.6

Pituitary Assessment Strategy

William M. Drake, Brian Keevil, and Peter J. Trainer

Introduction

The optimum methods of testing anterior and posterior pituitary function and the interpretation of the results are subjects of continuing debate. The syndromes associated with and consequences of hypo- and hyperpituitarism; and the diagnosis and treatment of diabetes insipidus are all discussed elsewhere in this book. The intention of this chapter is to describe the physiological basis and evidence in favour of the various available tests of anterior pituitary function, while at the same time acknowledging their limitations and appreciating the importance of the clinical context of testing.

The aetiology, treatment, and complications of hypopituitarism are described elsewhere (see Chapter 2.3.5) but fundamental to achieving the desired outcomes is the early diagnosis of pituitary dysfunction as, untreated, the morbidity and mortality of hypopituitarism is high, mainly as a consequence of secondary adrenal insufficiency. There are two broad groups of patients for whom pituitary function tests are required. The first group comprises all patients with symptoms suggestive of hypopituitarism. This, in turn, includes patients with target organ failure (such as hypoadrenalism, hypothyroidism, and hypogonadism) in whom low levels of cortisol, thyroxine, and sex steroid respectively are not associated with an appropriate elevation of the relevant pituitary trophic hormone; patients with cranial diabetes insipidus; patients presenting with the mechanical consequences of pituitary tumours (possibly hypersecreting, e.g. acromegaly, such as headache and visual failure; and patients in whom a pituitary mass is found incidentally during the course of radiological investigation for an unrelated symptom. In recent years, increasing recognition that immune cancer therapies (such as 'checkpoint' inhibitors) and brain injury (traumatic or vascular) may cause hypopituitarism provide important alerts to the possibility that both chronic and acute ill health may have a pituitary aetiology. The second group of patients includes those with known hypothalamic–pituitary disease or a history of radiotherapy to the head or neck who are at risk of evolving endocrine deficiency (**Box 1.6.1**). The former should be under endocrine review and be having regular pituitary function testing but the concern is that in the latter group, there may be no endocrine follow-up and the risk of hypopituitarism may not be appreciated and testing not occur. Conditions in which progressive hypothalamo–pituitary destruction may occur, such as sarcoidosis or Langerhans cell histiocytosis, require monitoring as the development of symptomatic hypopituitarism may be subtle.

The order of development of pituitary hormone deficiency is predictable with, typically, growth hormone deficiency (GHD) preceding gonadotrophin deficiency with subsequent failure of adrenocorticotrophic hormone (ACTH) and thyroid-stimulating hormone (TSH) secretion. Traumatic brain injury and lymphocytic

Box 1.6.1 At-risk patients

In such patients (e.g. those who have received pituitary radiotherapy), pituitary function tests should be performed regularly in order to detect asymptomatic hypopituitarism, although there is a paucity of data on the optimum frequency with which this should be done. Our practice is to check thereafter basal pituitary function (7 to 9 a.m.) every 2 years, with a dynamic test of ACTH reserve if the basal serum cortisol is <400 nmol/L. If patients exhibit symptoms consistent with GHD, then the dynamic test of choice will be the ITT. GHD occurs early after radiotherapy and, once it has been proven, many physicians use sequential SSTs to document the subsequent evolution of ACTH deficiency. Again, data in this regard are scarce such that accurate; robust local reference ranges are essential.

hypophysitis (including checkpoint inhibitor-induced hypophysitis) are exceptions to the rule with the order of development of deficiencies being less predictable; isolated ACTH deficiency is well recognized with the latter. In patients receiving cytotoxic and other chemotherapies, the use of dexamethasone as an antiemetic is common; and many patients carry other diagnoses (such as airways disease and skin conditions) that mandate the use of inhaled or transdermal steroid preparations. A meticulous drug history is therefore crucial prior to ascribing a low serum cortisol to ACTH deficiency. In all patients, pituitary function testing may help identify those patients whose hypopituitarism is sufficiently severe to threaten their safety, irrespective of symptoms; or exclude hormonal deficiencies as a cause of symptoms such as fatigue. For example, an asymptomatic patient with a basal serum cortisol of 120 nmol/L rising to 175 nmol/L during insulin-induced hypoglycaemia is at risk of hypoadrenalism with intercurrent illness, and requires hydrocortisone replacement therapy plus education on the implications of glucocorticoid replacement therapy. In contrast, a patient with a pituitary mass and symptoms of lethargy who has normal thyroid hormone levels, a basal serum cortisol above 400 nmol/L and normal gonadal function does not require endocrine replacement therapy. A sound knowledge of the principles of pituitary function testing is mandatory for the accurate diagnosis and optimal treatment of pituitary failure.

The anterior pituitary gland secretes six known hormones: growth hormone (GH), ACTH, luteinizing hormone (LH), follicle-stimulating hormone (FSH), TSH, and prolactin, all of which are under regulatory feedback control. Regulation of secretion of each hormone is complex with, in most cases, at least two hypothalamic peptides directly acting on the appropriate pituitary cell type to influence secretion, which in turn may be pulsatile, with underlying circadian or ultradian rhythm. In the case of ACTH, for example, this phenomenon is striking with plasma levels of its target hormone, cortisol, varying in health between undetectable (<20 nmol/L) and 700 nmol/L over 24 hours. For other pituitary hormones, such as TSH, the circadian variation is modest and there is no diurnal change in serum thyroxine concentrations. This means that a single, random blood sample is unlikely to provide sufficient diagnostic information about the function of the pituitary–adrenal axis; whereas it is rare for investigations other than basal samples to be required in the assessment of the pituitary–thyroid axis. In general, the more dynamic the physiological system in health, the more likely will be the need for a dynamic/provocative test to investigate its possible malfunction in disease. In all cases, the fundamental question being posed is: is the functioning of this 'endocrine unit' adequate for this patient's health and, if not, does it require replacement/support? It is the authors' intention to describe the physiological basis of the various tests of anterior pituitary function, to discuss the evidence in favour of their interpretation and, ultimately, to produce a rational, reliable, and safe strategy for pituitary function testing.

General Principles of Pituitary Assessment

The diagnostic evaluation of pituitary function has several complementary limbs involving laboratory and radiological investigations. First, it is necessary to demonstrate target organ hormonal insufficiency, such as low levels of thyroid hormone or gonadal steroid. Paired testing of both hormones in the pituitary–target organ feedback loop, sometimes in combination with provocative testing, will prove that target organ failure is consequent upon lack of stimulation by the relevant pituitary trophic hormone. Additional tests may occasionally be performed in order to determine whether the pituitary itself is at fault, or whether pituitary failure is secondary to understimulation by the hypothalamus. However, this distinction is seldom useful clinically and is irrelevant to the need for hormone replacement therapy. Sophisticated radiological imaging is required to establish the aetiology, together with careful neuro-ophthalmological assessment. Lastly, in cases of pituitary failure where the cause is believed to be a systemic illness (such as sarcoidosis or tuberculous hypophysitis) more specific investigations may be needed. These are discussed in the relevant sections elsewhere (see Chapter 2.3.5).

It is important to recognize that it is erroneously simplistic to think of any pituitary hormone status as being either 'adequate' or 'deficient'; the reality is there are degrees of deficiency. The biochemical criteria propagated by consensus guidelines and similar are not necessarily predicated on rigorous science but rather the notion of 'best practice'. Furthermore, the decision about intervention and replacement therapy may depend on symptoms and other variables, an obvious example being gonadotrophin deficiency in a woman over 50 years of age, which may be indicative of hypopituitarism but does not necessarily mandate the use of oestrogen replacement therapy.

Types of Laboratory Test

The literature, and in particular clinical guidelines on the diagnosis of hypopituitarism rely on biochemical criteria to define deficiency. However, application of such international consensus criteria to local practice is complicated by bias in assay performance and it is inappropriate to blindly adopt such 'cut-offs' without an awareness of the performance of local assays.

Basal Pituitary Function Tests

Basal blood tests refer to samples taken with the patient resting, unstressed and with no physiological or pharmacological manipulation of the mechanisms that control the pituitary

Box 1.6.2 Basal pituitary function tests

New patients

Basal serum investigations, at 7–9 a.m.:
- cortisol
- free T_4, TSH
- Prolactin
- LH, FSH, testosterone/oestradiol, SHBG
- Insulin-like growth factor-I
- Urine/plasma osmolality

If basal serum cortisol is <400 nmol/L and/or GHD suspected, then proceed to ITT. If any abnormality in any of the aforementioned tests, then one should proceed to pituitary imaging.

TSH, thyroid-stimulating hormone; LH, luteinizing hormone; FSH, follicle stimulating hormone; SHBG, sex-hormone-binding globulin; GHD, growth hormone deficiency; ITT, insulin tolerance test.

cell–target cell interaction (Box 1.6.2). Hence basal samples are taken between 7 and 9 a.m., when serum cortisol and testosterone levels are highest. Given that the decision to proceed to dynamic testing is based on the results of basal samples, it is logical to maximize the chances of basal investigations yielding sufficient information to avoid the need for more complex tests. Paired measurement of both limbs of a pituitary hormone–target hormone loop is required for interpretation of the target hormone level. Low levels of target hormone in association with low or normal levels of the relevant pituitary trophic hormone indicate that target gland failure is consequent upon under stimulation by the pituitary.

Provocative Tests

Provocative (stimulation) tests are employed when hypofunction of a pituitary cell type is suspected and basal investigations have not yielded sufficient information. Such tests assess the ability of a given cell type to respond acutely to a stimulus, but do not necessarily provide information about the adequacy of day-to-day hormone production by that cell type under basal conditions. Two types of provocative tests are used: those that stimulate hormone release indirectly (such as the insulin tolerance and glucagon tests) and direct stimulation tests in which pharmacological doses of synthetically manufactured peptide are injected and the target cell hormone response measured. Examples of these include hypothalamic-releasing hormone tests and the short synacthen test (see next). The virtue of indirect provocation tests is that the integrity of an entire hypothalamo–pituitary–target cell loop is tested. Hypothalamic-releasing hormone tests with thyrotropin-releasing hormone (TRH), gonadotrophin-releasing hormone, and growth hormone-releasing hormone (GHRH) are discussed briefly in the relevant sections. When introduced to clinical practice, it was thought that they would facilitate the diagnosis of hypopituitarism and forewarn of insidious pituitary failure. However, experience has shown that they have no value in diagnosing hypopituitarism and they cannot be used to predict future pituitary failure. Historically they may occasionally be of value in differentiating hypothalamic from pituitary disease, but have been supplanted by high-resolution imaging.

Assessing ACTH Reserve (the Hypothalamic–Pituitary–Adrenal Axis)

Of all the aspects of pituitary function testing, this is the most important and controversial, mainly because assessment of the adequacy of the hypothalamic–pituitary–adrenal (HPA) axis and the provision of replacement therapy (if required) has the most far-reaching consequences of all the anterior pituitary hormones. The laboratory assessment of the HPA axis is performed in two distinct clinical settings, although the aim of establishing whether cortisol production is adequate is common to both. The first clinical scenario is that of a patient with symptoms suggestive of adrenal insufficiency (such as tiredness, listlessness, and malaise), where the question being posed is: 'are the symptoms due to cortisol deficiency?' The second clinical setting is one in which the patient is known to be at risk of developing secondary adrenal insufficiency, for example patients previously treated with supraphysiological doses of corticosteroids, known to have hypothalamic–pituitary disease who may have been treated with surgery and/or radiotherapy. In these 'at-risk' people, it is necessary to assess the adequacy of the patient's response to physiological stress, even in the absence of any symptoms of adrenal insufficiency. If the test used predicts that the patient will not be able to mount an adequate stress response, then the patient requires education about the implications of ACTH deficiency and adequate steroid cover must be provided in the event of emergency, although not necessarily day-to-day therapy.

A satisfactory method for assessing the adequacy of the day-to-day cortisol production rate has not yet been identified. Isotope dilution methods are accurate but complex and not widely available, while measurement of 24-hour urinary free cortisol requires complete collection and lacks the sensitivity to detect insufficiency. The inability to adequately assess basal, unstimulated cortisol production rate mean it is of paramount importance to consider patients' symptoms and well-being when contemplating initiation of lifelong glucocorticoid replacement therapy.

Physiological Background

Although there is considerable debate about many aspects of assessing ACTH reserve, the aim of establishing whether cortisol production is adequate for the patient's health is not disputed. Measurement of the target hormone (cortisol) is common to all tests of the hypothalamic–pituitary–adrenal axis. Cortisol has a multitude of actions, including regulation of protein and carbohydrate metabolism, maintenance of vascular tone, and modulation of the immune system. Its synthesis and secretion are controlled by ACTH, whose release from the pituitary is, in turn, regulated by hypothalamic corticotrophin-releasing hormone and vasopressin. Hypothalamic function is influenced by a complex array of factors including neural stimuli (particularly from the limbic system) and humoral inputs (such as inflammatory cytokines). A change in cortisol production rate is the 'final common pathway' for all of these complex modulatory factors: hence the use of cortisol levels for the assessment of ACTH reserve. It has the added practical advantage of ease of collection, as ACTH samples require cold centrifugation and flash-freezing whereas cortisol is measured in serum.

General Aspects of Cortisol Measurements

A common pitfall in the assessment of the HPA axis is failure to document exposure to exogenous glucocorticoids, whether administered orally, transdermally, by inhaler, by parenteral or intra-articular injection. Occasionally, patients may be unknowingly exposed to exogenous glucocorticoids, for example some so-called 'skin whiteners' have been shown to contain dexamethasone [1]. Coadministration of P450 CYP3A4 inhibitors, such as itraconazole, can potentiate the glucocorticoid action of exogenous steroid. Typically, such patients are asthmatic with fungal infections and are clinically Cushingoid with undetectable serum cortisol levels which reinforces the importance of interpreting the biochemical investigations in the clinical context [2].

Only 5–10% of cortisol is free and biologically active, the remainder being bound to cortisol-binding globulin and albumin. Variations in these proteins significantly impacts on measurement of total serum cortisol. Cortisol-binding globulin is synthesized in the liver and, like sex-hormone-binding globulin (SHBG), production is increased by oral oestrogen therapy. However, while SHBG is frequently measured along with testosterone in the assessment of the pituitary–gonadal axis, cortisol-binding globulin is not routinely measured along with cortisol. Total serum cortisol levels are therefore significantly raised in pregnancy and in patients taking oral oestrogens, although serum free cortisol is essentially unchanged. Hence, oral oestrogens should be discontinued prior to assessment of the HPA axis and most authorities accept that six weeks are required for their effect on cortisol-binding globulin levels to disappear completely [3]. Transdermal oestrogen therapy does not affect circulating cortisol-binding globulin (CBG) levels [4]. Accurate assessment of the HPA axis in pregnancy is extremely difficult. Other circumstances in which cortisol-binding globulin and albumin levels may complicate assessment of cortisol status axis include conditions of protein loss, such as nephrotic syndrome and protein losing enteropathy; and failure of protein synthesis, such as hepatic cirrhosis. GH also has a subtle effect on circulating CBG, with GH replacement therapy lowering circulating cortisol levels secondary to reduced circulating CBG [5], with the reverse seen with treatment of acromegaly.

Assessment of late-night salivary cortisol secretion is widely used in the diagnosis of Cushing's syndrome but there is increasing interest in salivary cortisol in the investigation of possible cortisol deficiency. Salivary cortisol concentrations are not affected by serum CBG levels (i.e. oestrogen status) and correlate closely with serum free cortisol [6]. Oxidation of cortisol to cortisone by the enzyme 11B-HSD2 in salivary glands results in cortisone being the predominate glucocorticoid in saliva which to varying degrees cross-reacts in cortisol immunoassays, and explains the significant 'between-assay' bias [7]. Mass spectrometry measurement of salivary steroids is unaffected by cross-reactivity and has the further virtue of being able to quantify cortisol and cortisone to lower levels than immunoassays. It is believed that as mass spectrometry becomes more widely available, salivary cortisol measurement will have an increasingly important role in the investigation of cortisol deficiency, although consensus is required around cut-off criteria [8].

Liquid Chromatography Tandem Mass Spectrometry (LC-MS/MS) in Steroid Measurement

In the great majority of laboratories, cortisol is measured by immunoassay (IA), but LC-MS/MS is emerging as an alternative and superior technology as it is not blighted by the inherent limitation of IA, namely cross-reactivity of synthetic exogenous glucocorticoids such as prednisolone/prednisone, methylprednisolone and cortisol precursors, and metabolites such as 11 deoxycortisol. LC-MS/MS has the additional virtues of permitting measurement of multiple steroids at essentially the same cost as a single analyte and being able to quantify to lower limits than possible by IA.

Improvements in instrument performance have ensured that LC-MS/MS is increasingly becoming the method of choice for steroid hormone measurements, for example vitamin D, and drugs (e.g. tacrolimus and ciclosporin) due to smaller sample volumes, faster analysis times, and improved specificity compared to immunoassays. The main impediments to wider adoption of LC-MS/MS are the cost of instrumentation, greater technical complexity, speed, and turnaround of analysis. For these reasons and except for the larger specialized laboratories, the uptake of LC-MS/MS has been relatively poor in routine clinical laboratories, however once established and with high throughput MS is comparable in cost to the purchase and use of commercial IA kits.

The sample preparation process is not as simple as for IA as a clean-up/extraction is always needed before LC-MS/MS analysis to remove matrix and chemical interference. After extraction the sample needs to undergo separation on a liquid chromatography (LC) column to further remove potentially interfering substances before introduction into the mass spectrometer (**Figure 1.6.1**). The liquid eluate from the LC column is converted into either positively or negatively charged gaseous ions by the process of electrospray ionization in the mass spectrometer source. The tandem mass spectrometer instrument consists of two mass analysis quadrupoles separated by a collision cell. The strengths of this instrument lie in the ability to filter ions of a predetermined mass in the first quadrupole and then fragmentation of these ions in a compound specific way in the collision cell. Monitoring fragment ions, that have been selectively filtered in the second quadrupole, which can only have come from the parent ion, gives rise to high analytical specificity. The total process thus utilizes three different separation techniques, sample extraction, chromatography, and mass spectrometry which together confer a very high degree of specificity compared to automated immunoassay, which relies solely on the specificity of the antibody [9].

To further improve precision and accuracy, internal standards are added during the extraction process to control for ionization variability within the mass spectrometer source and the precision of the extraction procedure. The most appropriate internal standards are stable isotopes of the steroid being measured.

LC-MS/MS is particularly good at measuring urine free cortisol (UFC) with demonstrated enhanced specificity and sensitivity over IA methods [10] which results in significantly lower reference ranges. It can be debated whether the exclusion by MS of urinary cortisol metabolite measurement improves the diagnostic efficiency in Cushing's syndrome of UFC but it certainly improves the

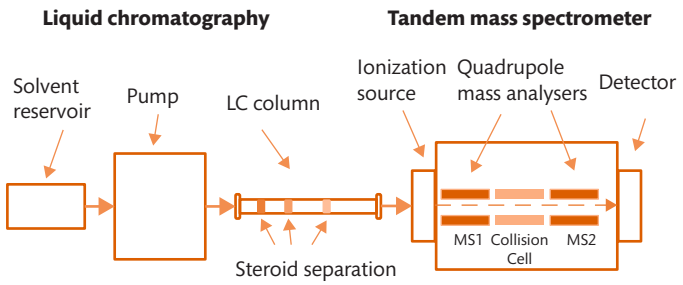

Figure 1.6.1 LC-MS/MS. Schematic of an LC-MS/MS system showing the principal components. Solvent is pumped through a liquid chromatography column to facilitate separation of the steroids of interest. The eluent from the column undergoes electrospray ionization in the mass spectrometer source, the ions generated are separated according to mass charge ratio by the first quadruple mass analyser and the specific molecular ion is selected. After fragmentation of the molecular ion in the collision cell, a specific fragment ion is selected in the second quadrupole mass analyser which is then used for quantitation.

value when used to monitor medical therapy with agents such as metyrapone [11].

Both cortisol and cortisone can be measured by LC-MS/MS in saliva with the added advantage that salivary cortisone may be a better diagnostic marker than cortisol because it agrees more closely with serum cortisol [12]. The LC-MS/MS serum methods for serum cortisol offer many advantages over IA methods when measuring samples from patients on metyrapone [11] or prednisolone therapy [13] and do not suffer some of the technical issues such as inadequate release of cortisol from CBG [14]. It also permits simultaneous measurement of cortisol and dexamethasone during a dexamethasone suppression test to ensure patient compliance.

While implementation of LC-MS/MS in the clinical laboratory has been slow, use in research laboratories has been expanding rapidly. Advances in mass spectrometer design have produced a boom in research not only in endocrinology but in other biological applications such as proteomics and metabolomics. In endocrinology, this work is being translated into the ability to measure panels of steroids adoption of which will improve diagnosis and monitoring disease [15, 16].

The ability of LC-MS/MS to perform multiplexed analysis of many steroids using similar sample extraction and instrument conditions, is often at no greater expense. Whereas, measuring steroids using IA one test at a time, adding in extra tests becomes more expensive.

Selective testing panels of steroids have been developed to assist in the management of various endocrine disorder such as congenital adrenal hyperplasia [17, 18], polycystic ovarian syndrome [19], and for the investigation of hypoadrenalism [20].

The enhanced specificity of LC-MS/MS should be contrasted with specificity problems with IA methods encountered with the move to perform 'direct' IA (without any extraction step) routinely on automated analysers. The elimination of the extraction step may streamline the assay procedure but at the expense of the potential for significant interference from other steroids.

Instrument manufacturers are bringing to market clinical mass spectrometry analysers with automation of the time-consuming sample extraction phase. These instruments currently have a limited test repertoire and are relatively expensive but offer an automated vision of the future that will undoubtedly make LC-MS/MS more attractive to a wider range of laboratories and should improve the availability of high quality tests to the clinician.

Defining an Adequate Peak Cortisol Response

The clinical spectrum of adrenal insufficiency ranges from cardiovascular collapse through to more subtle dysfunction that is apparent only during the physiological stress of sepsis, major surgery, or accidental trauma. The fundamental question is: What serum cortisol level is required under such circumstances? The defining study looked at the cortisol response to major abdominal surgery in normal and corticosteroid-treated patients. Peak intraoperative serum cortisol was closely correlated to the cortisol response to insulin-induced hypoglycaemia and that a peak serum cortisol of 580 nmol/L was associated with an adequate cortisol response during surgery [21]. Controlled iatrogenic hypoglycaemia has widely been advocated as the 'gold standard' by which to judge the ability to mount an adequate cortisol response to physiological stress.

The figure of 580 nmol/L was based on the fluorimetric method of Mattingly [22] for measurement of serum cortisol, a technique that, also detects cortisone, and with modern immunoassays a more appropriate 'cut-off' is probably in the range of 400–450 nmol/L depending on assay characteristics [23] and this has been confirmed using mass spectrometry methods [24].

Appreciation of assay performance and 'between-assay' bias is crucial to the appropriate application of cortisol measurement to the investigation and diagnosis of hypopituitarism. Bias in cortisol immunoassays arise because of the epitope-specificity of polyclonal antibodies resulting in cross-reactivity with other endogenous and exogenous steroids, matrix-differences between standards and samples, susceptibility to interference by binding proteins, and calibrator (reference-preparation) effects. In 1998, Clark *et al.* [25] documented a 26% bias between basal serum cortisol results using different assays, with highly significant differences also noted in serum cortisol levels 30 and 60 minutes after injection of synacthen. Twenty years later, little has changed with El-Farhan [24] reporting lower reference limits for six assays varying between 420 and 574 nmol/L, with differences between males and females. Evaluation of the more commonly used immunoassays against LC-MS/MS showed that much of this difference is caused by the varying ability of immunoassay kits to liberate cortisol from CBG, without which cortisol cannot bind to the antibody. This problem is exacerbated in pregnancy and those taking oral contraceptive pill in whom binding proteins are high [26]. Such findings make comparisons of cortisol responses between assays and laboratories extremely difficult and emphasize the need for centres to define/adapt appropriate reference ranges for their assay, as opposed to selecting rigid 'cut-off' values derived from studies using different methodologies.

The Testing of Cortisol Reserve

Having established a minimum serum cortisol level that is adequate for acute physiological stress, the question arises as to what is the

most appropriate stimulation test for the prediction that the patient will be able to achieve such a cortisol response when required. Several tests exist, each with its own merits and shortfalls, including measurement of basal serum cortisol, the insulin tolerance test, glucagon stimulation test, short synacthen test (standard and low dose), and the metyrapone test.

Measurements of Basal Serum Cortisol

In the interest of patient convenience and economics, it is preferable to maximize the value of basal unstimulated cortisol measurement with the goal of minimizing the number of dynamic tests undertaken. Endogenous HPA activity is maximal in the early morning and samples should be drawn between 8 and 9 a.m. or earlier if possible. In cases of suspected pituitary insufficiency, a basal morning serum cortisol of less than 100 nmol/L strongly indicates ACTH deficiency, dynamic testing is not necessary, and glucocorticoid replacement should commence immediately. In most such patients, the requirement for steroid replacement is likely to be permanent. However, in the case of ACTH deficiency prior to surgery for a pituitary tumour, recovery of ACTH reserve following surgical decompression may occur and so it is necessary to reassess the situation postoperatively.

In contrast, defining an unstimulated, basal cortisol that predicts an adequate response to stimulation is difficult. Several studies have confirmed that a close correlation exists between measurements of basal, unstressed serum cortisol to peak serum cortisol levels during insulin-induced hypoglycaemia. From these reports, it is clear that many patients can avoid a dynamic test on the basis of basal cortisol measurements, although the precise 'cut-off' that predicts an adequate response is challenging but it would be generally accepted that a baseline cortisol of 400 nmol/L or more precludes the need for dynamic testing [27–29].

Emergency Assessment of the Hypothalamic–Pituitary–Adrenal Axis

In the acutely sick patient with, for example, sepsis, trauma or checkpoint inhibitor therapy, and suspected hypoadrenalism the clinical situation dictates that a morning cortisol and/or a dynamic test of ACTH reserve are impractical and glucocorticoid support may need to be started immediately. In such a context, circadian variation of ACTH release will be absent and activity of the hypothalamic–pituitary–adrenal axis should be maximal. If adrenal insufficiency is suspected, then random serum cortisol and plasma ACTH measurements, prior to commencing glucocorticoid therapy, will suffice for an assessment of hypothalamic–pituitary–adrenal axis integrity. If, subsequently, the random cortisol level is shown to have been appropriate to the clinical situation (above 400 nmol/L) glucocorticoids may be withdrawn. If not, steroid support should continue, and dynamic testing must wait until the acute clinical situation has resolved. The plasma ACTH will indicate whether the adrenal insufficiency is primary or secondary. A serum cortisol below 200 nmol/L with a plasma ACTH above 200 pg/ml is diagnostic of primary adrenal failure.

The Insulin Tolerance Test

This test, first described in 1966 [30] seeks to simulate physiological 'stress' in a controlled, supervised environment by inducing hypoglycaemia with intravenous insulin. Hypoglycaemia is a powerful stress stimulus, which in the intact pituitary and hypothalamus induces ACTH and GH release and a rise in serum cortisol levels. It therefore assesses the integrity of the entire HPA axis and has traditionally been regarded as the 'gold standard' for this purpose. The cortisol response to hypoglycaemia has been shown to be reproducible in healthy volunteers and patients with pituitary disease [31, 32]. As discussed earlier, the assumption that the ability to respond to insulin-induced hypoglycaemia will translate into an appropriate cortisol rise in the event of acute illness or major surgery is supported by studies in which the peak cortisol levels of patients undergoing major surgery were comparable to those achieved during a preoperative insulin tolerance test [21].

Although the safety of the insulin tolerance test (ITT) has been questioned, particularly in children, the morbidity of this investigation in experienced hands within the setting of a designated metabolic investigation unit is reassuringly low, provided that the standard criteria are adhered to (ischaemic heart disease, epilepsy/unexplained blackouts, severe longstanding hypoadrenalism, glycogen storage disease are contraindications and patients should have normal thyroid function) [28]. The dose of fast-acting insulin used varies between centres. Most authorities recommend a dose of 0.1–0.15 IU/kg, with higher doses (typically 0.3 IU/kg) being required for patients with acromegaly or other conditions in which insulin resistance is a feature. Many physicians are uncomfortable with its use in older people and it requires careful supervision and monitoring of adrenergic and neuroglycopaenic symptoms.

The immediate counter-regulatory response to hypoglycaemia is characterized by catecholamine release, which, in turn, stimulates hepatic glycogenolysis and correction of hypoglycaemia. Glucocorticoids are not part of this phenomenon, although the laying down of hepatic glycogen stores does require pre-exposure to glucocorticoids. Thus, in patients with longstanding ACTH deficiency and consequent inadequate glycogen stores, recovery from hypoglycaemia may be delayed. It is therefore usual practice to administer oral glucose in the form of a sugary drink, together with a meal, at the conclusion of the test to guard against this eventuality.

A common reason to perform an ITT is to test the ability of the hypothalamic–pituitary–adrenal axis to respond to stress following the use of supraphysiological doses of corticosteroids. Such doses may lead to ACTH suppression, with secondary adrenal involution and loss of responsiveness. It is therefore essential, in this situation, to perform a short synacthen test in order to establish that the adrenals are capable of responding to ACTH, prior to an ITT. If the adrenals do not respond to ACTH, an ITT will yield no useful information.

Short Synacthen Test

This investigation was originally introduced in the 1960s [33] as a test for primary adrenal failure. It involves the injection of a pharmacological dose (250 μg) of synthetic ACTH, with measurement of the serum cortisol response, and it has been advocated as

an alternative to the ITT as a means of assessing ACTH reserve. The basis of its use, in the context of hypopituitarism, is that chronic underexposure of the adrenal glands to ACTH (either as a consequence of prolonged corticosteroid therapy or due to suspected or proven hypothalamic–pituitary disease) will result in a blunted cortisol response to exogenously administered ACTH. The test does not distinguish primary from secondary adrenal insufficiency, although clinical assessment (pigmentation) and measurement of basal plasma ACTH are usually sufficient in this regard. The major argument in favour of the short synacthen test (SST) is its simplicity, as it requires no specialist staff and takes only an hour to complete. The only reported side effect is allergy in patients with a history of atopy, although this is very rare. The SST does not assess GH reserve. It is universally accepted that the SST cannot be used for the assessment of ACTH reserve when acute hypopituitarism develops, such as following pituitary infarction (apoplexy) or the immediate postoperative assessment of the HPA axis. It takes at least 6 weeks for the adrenal zona fasciculata to involute following withdrawal of ACTH stimulation, during which time the adrenal cortex will remain responsive to supraphysiological doses of ACTH. In addition, it should be remembered, in the assessment of new patients with suspected hypothalamic–pituitary disease, that the duration of ACTH deficiency may be unknown and that, as following pituitary surgery or apoplexy, a falsely reassuring SST may result.

Two main aspects of the SST in assessing ACTH reserve have been debated: the peak serum cortisol versus increment and the level of serum cortisol that constitutes an adequate response. The increase in serum cortisol following synacthen is a poor index of adrenal responsiveness, as there is considerable overlap between normal volunteers and patients with secondary adrenal insufficiency [34]. Further, the cortisol increment is inversely correlated with the basal value and hence a smaller increment is seen in the early morning when plasma ACTH and serum cortisol levels are at their highest [35]. The peak serum cortisol response following synacthen shows no diurnal variation and is now the accepted index of adrenal responsiveness and, indirectly, endogenous ACTH exposure.

Excellent correlations exist between cortisol levels 30 min after injection of synacthen and the peak cortisol achieved during insulin-induced hypoglycaemia. This has led to the increasing use of the SST as a substitute for the ITT.

However, despite its widespread use as a method of assessing ACTH reserve, there is no study showing that a normal SST indicates that the HPA axis is capable of responding normally to major illness or stress. Critics of the use of the SST point to reports of patients with pituitary disease with symptoms and signs of adrenal failure, corrected by glucocorticoid replacement, having recently had a falsely reassuring 'normal' SST. This problem cannot be corrected by application of a more 'stringent' threshold of serum cortisol as in two such reported patients the peak serum cortisol value was more than 950 nmol/L 30 min after synacthen. However, reports exist of patients who have developed acute adrenal crisis following a reassuringly normal ITT.

The safety and simplicity of the SST have, in many units, made it the 'pragmatic default test' of ACTH and cortisol reserve with the ITT reserved for specific circumstances such as recent onset hypopituitarism or when GH and cortisol status require testing.

Low-Dose Short Synacthen Test

The use of a lower dose of ACTH (typically 1 μg) in the assessment of secondary adrenal failure has been extensively investigated over several decades. In health, the entire stored pool of pituitary ACTH is of the order of 600 μg, such that an injected bolus of 250 μg produces plasma concentrations that are unphysiological and beyond the top of the ACTH/cortisol dose–response curve. Proponents of the low-dose (LD) SST argue that chronically understimulated adrenal glands may mount a satisfactory cortisol response to the unphysiological concentration of ACTH provided by 250 μg of synacthen, but that only normal glands will respond to the small doses used in this test. Further, plasma ACTH levels following injection of 1 μg are comparable to those reached during an ITT in healthy volunteers [36]. The test is quick (a single sample only is required 30 min after injection of ACTH) and the test may be performed at any time of day. While theoretically attractive and the focus of many publications, a recent survey of 766 endocrinologists over 60 countries concluded that the 92% of centres were performing 250 μg SST, 43% low-dose, and 37% both, which by implication means very few centres relied exclusively on the LD SST. It also reported that 72% of paediatric endocrinologists used the LD SST. The attraction of a lower dose of ACTH in children is not surprising [37].

The study also reinforces one of the major concerns with the LD SST, namely the lack of a standardized, reproducible means of dilution of a 250 mcg in 1 ml vial of synthetic ACTH. The authors reported variation in dilution methods resulted in the dose of synacthen administered in a LD SST varying between 0.16 μg and 0.81 μg [37]. ACTH is prone to be adsorbed onto the plastic of syringes or saline bags and to date, there is no quality controlled 1 μg synthetic ACTH vials commercially available, so 250-fold dilution is required.

Although theoretically attractive, a compelling case has not been made that it is superior to the SST, and does not entail the additional complexity of dilution.

Glucagon Stimulation Test

The mechanism of glucagon mediated stimulation of cortisol and GH secretion is ill-understood. The subcutaneous injection of glucagon causes a transient rise in plasma glucose. During the subsequent fall in glucose levels, ACTH and GH are both released and this has led to its widespread use as a means of assessing the reserve of these two hormones. Glucagon is a less powerful or reliable stimulus to ACTH or GH release than hypoglycaemia and false negative results are common. Administration of glucagon routinely makes patients feel unwell with nausea and may cause abdominal pain and vomiting. The glucagon test has not been the subject of intense study and the interpretation of the serum cortisol response relies upon criteria established for insulin-induced hypoglycaemia. However, it remains a useful method of assessing the hypothalamic–pituitary–adrenal and GH axes, particularly when the ITT is contraindicated [38]. A 'normal' response to glucagon administration provides reassurance of adequate HPA axis function but caution must be shown before concluding a patient has inadequate cortisol reserve based on

this test and a second, confirmatory test is advisable in most patients.

Metyrapone Test

This test of adrenal reserve was first described in the 1950s [39] and its role in the assessment of ACTH reserve has therefore changed with the availability of plasma ACTH and serum cortisol assays. Metyrapone inhibits the conversion of 11-desoxycortisol to cortisol by the enzyme 11β-hydroxylase (CYP11b1). The principle of the test is that the metyrapone-induced fall in serum cortisol stimulates ACTH secretion, which in turn increases corticosteroidogenesis and in particular a rise in circulating 11-desoxycortisol. As 11-desoxycortisol has no glucocorticoid activity a rise in its level has no effect on ACTH secretion. In patients with secondary adrenal insufficiency, the metyrapone-induced fall in cortisol does not stimulate an increase in ACTH secretion and hence no rise in serum 11-desoxycortisol occurs.

A typical protocol entails oral administration of 30 mg/kg metyrapone in hospital at midnight. Simultaneous cortisol and 11-desoxycortisol levels are taken between 8 and 9 a.m. and then oral glucocorticoids are administered if the index of suspicion of ACTH deficiency is high. An 11-desoxycortisol level above 200 nmol/L (7 μg/dl) indicates normal adrenal function, irrespective of the simultaneous cortisol value. Levels less than 200 nmol/L, in the presence of a low serum cortisol level, strongly suggest secondary adrenal insufficiency [39]. A low serum cortisol level is required for the interpretation of the test as an indicator that a stimulus has been delivered to the pituitary. Anticonvulsant therapy such as phenytoin accelerates the metabolism of metyrapone and an alternative test of the hypothalamic–pituitary–adrenal axis should be used in such patients.

A major criticism of this investigation is that it is a test of the ACTH-cortisol feedback mechanism rather than of ACTH reserve. The test requires measurement of serum 11-deoxycortisol either by immunoassay or preferably by mass spectrometry, neither of which are routinely available in most centres. The test is rarely undertaken in the United Kingdom and appears to have fallen out of favour internationally, as it requires hospitalization, and specialist assays.

Conclusion

It is inevitable that the debate about the optimum method for the assessment of the hypothalamic–pituitary–adrenal axis will continue. Practical issues such as cost and staff availability will, to a large extent, affect local policy but the fundamental clinical issue of patient safety remains the same. Dynamic tests of the integrity of the hypothalamic–pituitary–adrenal axis support, rather than substitute for, clinical decisions and it is important to recognize that the use of sophisticated statistical methods for the comparison of serum cortisol levels in groups of people with or without endocrine disease can never substitute for clinical awareness in the individual patient. Even the ITT, thought for so long to be the 'gold standard' for assessing ACTH reserve cannot provide complete reassurance that an individual patient will not develop secondary adrenal insufficiency during physiological stress. Changes in methodology and variation in the assays used for cortisol measurements hinder comparisons between published experiences of hypothalamic–pituitary–adrenal testing and make it difficult to recommend a diagnostic cut-off that defines cortisol deficiency, but a cortisol level >450 nmol/L, in most circumstances, makes the diagnosis very unlikely. Endocrine physicians should always educate their patients about the possible implications of pituitary disease in terms of the stress response, particularly when it is anticipated that the functioning of the hypothalamic–pituitary–adrenal axis may change over a period of time, such as following pituitary irradiation. The ITT is the single most reliable test of the hypothalamic–pituitary–adrenal axis but should only be performed under close supervision in specialist centres. If there is any doubt about the adequacy of ACTH reserve, it is sensible to err on the side of caution with respect to the provision of emergency steroid cover; and to consider a trial of oral glucocorticoid replacement therapy in patients with symptoms suggestive of chronic adrenal insufficiency and an equivocal response to dynamic testing.

Pituitary–Thyroid Axis

Like other pituitary cell types, thyrotrophs interact with their target cells by feedback inhibition, although the marked diurnal and ultradian variations that characterize ACTH and GH release are not present. This means that investigations other than basal blood samples (free thyroxine (fT_4) and TSH) are rarely necessary for the assessment of thyroid status in the context of pituitary disease. The challenge in the diagnosis is that TSH is rarely undetectable in hypopituitarism and therefore the biochemical confirmation of deficiency relies on the context (i.e. other pituitary hormone deficiencies and falling or low circulating fT_4 levels). TSH deficiency can be the most difficult to diagnose pituitary hormone deficiency as it can insidious in onset (e.g. after radiotherapy), and free T_4 levels can fall by 50% (e.g. 20–10 pmol/L) and still be within the reference range. Secondary hypothyroidism is strongly suggested by low levels of circulating T_4 in the presence of a low or low normal TSH. TSH deficiency in the absence of gonadotrophin and GH deficiency is very unusual. Illness ('sick euthyroid' syndrome), thyroxine-binding globulin deficiency, supraphysiological doses of glucocorticoids, and drugs such as phenytoin may also produce a similar picture. The interpretation of the results is dependent on the overall clinical context. An important, practical, point is that serum free thyroxine levels vary very little through life, so the availability of previous measurements may be particularly informative if values lie close to the lower limit of the reference range but secondary hypothyroidism is clinically suspected.

A novel approach to the identification of TSH deficiency has been proposed by Jostel *et al.* [41]. The TSH Index (TSHI) is an algorithm-based approach that calculates a 'fT_4-adjusted TSH' that corrects for any physiological TSH suppression to provide a true estimation of thyrotrophic function. The TSHI, based on simple thyroid function tests (TFTs) and regardless of concomitant T_4 supplementation, correlates closely with other measures of the severity of pituitary dysfunction (i.e. GH and cortisol deficiency) in patients with a known risk of hypopituitarism. Potentially it permits the diagnosis of TSH deficiency when fT_4 and TSH values are within the quoted reference ranges. Further work is required but this approach combined with the rapid advances in machine-learning

offer the prospect of reducing delay in the initiation of thyroxine replacement therapy in patients with hypopituitarism.

TRH Testing

TRH testing is of no value in diagnosing secondary hypothyroidism or predicting imminent TSH deficiency.

Growth Hormone Axis

Recombinant GH became available in the 1985 and was approved for the treatment of GHD in adults in 1996. Tests of GH reserve in adults will be described in this chapter; the symptoms and signs and diagnosis of childhood and adult GHD and its treatment are discussed elsewhere (see Chapter 2.3.6). Due to the lack of normative data and bias in assay performance, it must be appreciated that the biochemical definition of GHD (peak GH <3 ng/ml) for the ITT and glucagon test [42] is, in part, an arbitrary cut-off but all the same important in some countries as it has been adopted by regulatory authorities to define patients' eligibility for replacement therapy. From a physiological and therapeutic stand-point, it may be more accurate to think of patients with a peak GH response of less than 3 ng/ml as having severe GHD and, based on the available data, being likely to benefit from GH replacement therapy. Patients with peak GH response of more than 3 ng/ml may still have degrees of GHD but evidence for the benefit of GH replacement therapy is less robust. In contrast to ACTH deficiency, GHD is not life-threatening and replacement therapy is not mandatory. It is only of value to test for adult GHD if GH therapy is a therapeutic option and the patient is willing to self-inject daily. In some countries, in addition to meeting the biochemical criteria for deficiency evidence of impaired quality of life is required to qualify for GH therapy, so it is clinically inappropriate to perform complex stimulation tests in patients with a normal quality of life.

Normal GH secretion is pulsatile, with four to six pulses per 24 h, mostly at night in association with stage III–IV rapid eye movement (REM) sleep, punctuated by long periods when GH levels in blood are undetectable (<0.3 ng/ml). As with the assessment of the hypothalamic–pituitary–adrenal axis, a single basal blood sample is unlikely to yield significant diagnostic information, unless the taking of the sample coincides with a GH surge. An attractive approach, therefore, might seem to be to measure 24 h spontaneous profiles, as has been employed in the diagnosis of GHD in childhood. However, this approach has proved disappointing, as there is considerable overlap in the integrated growth hormone concentration (IGHC) of normal subjects and those of hypopituitary patients and the test has little diagnostic value [43]. Other physiological methods of assessing GH secretion include sampling during sleep and exercise, both of which are associated with GH release. However, all three of these methods are prohibitively expensive and time-consuming for routine clinical use.

The symptoms, such as lethargy, of GH deficiency in adults are not specific and similarly the dynamic test of GH status described next do not have 100% specificity. It is important that testing for GHD is only undertaken in patients with a plausible cause of GHD, rather than in an indiscriminate manner in individuals with non-specific symptoms, such as fatigue or central adiposity, and no known reason for developing hypopituitarism as inevitably such an approach will result in a proportion of 'false positive' investigations and unnecessary treatment.

Most, if not all, actions of GH are mediated through the peptide hormone insulin-like growth factor-I (IGF-I). However, measurement of serum IGF-I is of limited value in the diagnosis of adult-onset GHD, as 30% of patients with unequivocal GHD may have a serum in the lower half of the age-related reference range [43]. However, in most patients with hypopituitarism GHD is the first hormone to become deficient and therefore the most recent Growth Hormone Research Society Guidelines [42] state that in the clinical context of multiple pituitary hormone deficits a very low serum IGF-I (<2 SD below the mean) is sufficient to diagnose severe GHD and that such patients do not require a dynamic test of GH reserve.

Most authorities accept that pharmacological stimulation of GH release is the most practical and reproducible method of assessing GH reserve. Hypoglycaemia is a powerful stimulus to GH secretion and, over the years, the ITT has been the most frequently employed test in this regard. It has the advantage that ACTH reserve can be assessed simultaneously and, in experience hands, is a safe investigation provided the exclusion criteria outlined earlier are adhered to. The criterion for profound GHD is met if the peak GH response to insulin-induced hypoglycaemia and glucagon tests is 3 ng/ml or less. As with cortisol measurement and for many of the same reasons, there is significant bias between different GH immunoassays which makes comparison of GH data between centres difficult and must be borne in mind when applying consensus guidelines to local practice. Similarly, the endocrine physician should be alert to the confounding effect of obesity on GH release which may lead to a false positive diagnosis of GHD [42].

Where the ITT is contraindicated, alternative provocative tests of GH reserve include the glucagon (see earlier), arginine, GH-Releasing Hormone (GHRH)+arginine.

Endocrine Society [45] and the GH Research Society guidelines [42] advocate the use of the combination of GHRH and arginine stimulation testing on the basis of evidence suggesting sensitivity and specificity comparable to that of the ITT. However, GHRH is not readily available and therefore arginine is often used on its own. Arginine is one of several amino acids (others include leucine and histidine) that stimulate GH release, with a peak occurring between 30 and 120 min after infusion. It is generally used when a second dynamic test of GH reserve is required and the ITT is contraindicated. It involves the intravenous infusion of 0.5 g/kg (maximum dose 30 g) in 100 ml normal saline over 30 minutes and sampling for 2 hours thereafter. It is frequently used as an alternative to the ITT in patients with suspected hypopituitarism following traumatic brain injury.

The GH-releasing peptides (GHRP) are a collection of synthetic peptides that act via an alternative mechanism than GHRH to be potent stimulators of GH secretion and have been studied for both the diagnosis and treatment of GHD. Studies failed to establish the therapeutic benefit of GHRPs in patients with GHD and so, while they may be of value in the diagnosis of GHD, they are no longer generally available. There is interest in the use of ghrelin mimetics as a means of testing of the GH axis but data are not yet available.

Clonidine testing is of no value in diagnosing GHD in adults.

Assessment of the Pituitary–Gonadal Axis

Assessment of the pituitary–gonadal axis differs from other aspects of pituitary function testing. First, regular menstruation in a woman implies normal gonadotroph function and measurement of serum gonadotrophins and oestradiol therefore add little to the clinical assessment. Associated ovulation is not necessarily implied by regular menstruation; measurement of luteal phase progesterone levels is required for the assessment of subfertility in a patient with pituitary disease and a regular cycle. Second, social and age-related factors may influence the need to correct any underlying gonadal deficiency in men and women. The avoidance of cardiovascular complications and loss of bone mineral density (BMD) consequent upon prolonged hypogonadism is obviously desirable, but must be set against the temporal relationship of normal physiology. For example, an 80-year-old patient with secondary hypogonadism is likely to feel differently about sex steroid replacement therapy than a patient of 30 years.

It is rare for tests other than basal measurements of gonadotrophin hormones and sex steroid levels to be required for assessment of the pituitary–gonadal axis. Both oestradiol and testosterone bind to sex-hormone-binding globulin (SHBG), such that simultaneous measurement of SHBG and gonadal steroid levels are required to assess 'free' (biologically active) levels of these hormones (see Chapter 2.3.5). Testosterone should be measured fasted between 8 and 9 a.m., as levels show considerable diurnal variation. Oestradiol is best measured in the follicular phase of the menstrual cycle (if female patients are menstruating). Ovulation is assessed by measurement of progesterone in the luteal phase (days 18–25) of the cycle.

Historically, a combination of clomiphene and gonadotrophin-releasing hormone (GnRH) tests were used in an attempt to distinguish hypothalamic from pituitary causes of secondary gonadal failure. However, such information has little clinical value in terms of therapy, and newer, more sophisticated imaging techniques are able to distinguish these two groups of causes in the majority of cases. Central hypogonadism can be isolated, occur in the context of a hypothalamo–pituitary tumour or its treatment, or be the earliest sign of incipient panhypopituitarism. Isolated gonadotrophin deficiency will either be congenital, as in Kallmann's syndrome and associated with delayed/absent pubertal development, or be acquired and secondary to systemic illness (e.g. AIDS), excessive exercise (long distance running) or psychological disturbance (anorexia nervosa). In all cases it is imperative to investigate pituitary function in detail.

Clomiphene Testing

This investigation has been used in the investigation of suspected gonadotrophin deficiency. Clomiphene citrate is a selective oestrogen receptor modulator (SERM) acting as a weak oestrogen receptor antagonist at the hypothalamus and pituitary, and as an oestrogen agonist at the liver. In healthy subjects its antagonistic action at the hypothalamus stimulates gonadotrophin-releasing hormone levels to rise, with consequent release of LH and FSH. The hepatic effect is to induce SHBG synthesis and a rise in measured total testosterone and oestradiol levels. Hence, such a rise may be misleading and does not necessarily indicate increased gonadotrophin release. Clomiphene should not be given to patients with liver disease because of its oestrogen agonist effects. The test is also contraindicated in depression, because of the risk of mood disturbance, and patients should be warned of the risk of alteration of peripheral vision. In normal women, gonadotrophin levels double by 10 days and menstruation usually accompanies a positive clomiphene test in women. However, the test is of very limited clinical value as the ability of a progesterone challenge to induce a menstrual bleed is highly predictive of the response to clomiphene. A normal response to clomiphene in a patient with amenorrhoea offers reassurance that the axis is intact and that the problem lies in the hypothalamus, but offers little indication of the aetiology. Patients with weight, exercise, and stress-induced amenorrhoea can have either a normal or absent response to clomiphene, presumably indicative of the severity of the suppression of gonadotrophin secretion.

Gonadotrophin-Releasing Hormone Testing

In an era of sophisticated imaging and an increasing array of genetic explanations of hypogonadotropic hypogonadism, GnRH testing is of very limited value in the investigation of gonadotrophin deficiency.

Prolactin

A clinical syndrome associated with prolactin deficiency is not recognized and the clinical consequences of hyperprolactinaemia are discussed elsewhere. The principle value in serum prolactin measurement is as a guide to the aetiology and severity of hypopituitarism. Prolactin physiology differs from that of other anterior pituitary hormones in that its secretion is principally under tonic inhibition by release of dopamine from the hypothalamus. Levels do not show significant diurnal variation and so tests other than basal measurements are very rarely required. Physiological stress and various medications that interfere with dopamine action, such as metoclopramide, prochlorperazine, and several antipsychotics, raise serum prolactin. TRH stimulates prolactin release but provides no additional clinically useful information compared to random serum prolactin measurements. Serum prolactin on three separate occasions minimizes the risk of falsely elevated, stress-induced hyperprolactinaemia.

Conclusion

Accurate assessment of anterior pituitary function requires a sound knowledge of its normal physiology together with careful integration of clinical and biochemical information. As discussed earlier, certain aspects of the optimum method of pituitary function testing, notably the assessment of ACTH reserve, are still disputed, with local circumstances and personal preference often dictating the final choice. Physicians are advised to acquaint

themselves with their local laboratory reference ranges and never to allow a single hormonal measurement in a single patient on a single day to substitute for clinical awareness, particularly where an evolving endocrinopathy is anticipated, such as following pituitary irradiation.

1.7

Endocrine Autoimmunity

Simon H.S. Pearce and Catherine J. Owen

Introduction

Autoimmune attack directed at endocrine target tissues is responsible for several conditions that present diverse management problems to the clinical endocrinologist, the most prevalent being the autoimmune thyroid diseases (AITDs) and type 1 diabetes mellitus (T1D). Addison's disease, premature ovarian insufficiency, hypophysitis, and hypoparathyroidism are less frequently encountered endocrine conditions that may also have an autoimmune basis. These conditions typically develop insidiously and their immunological hallmarks may be present for many years before any clinical presentation. Most of these conditions are inherited as complex genetic traits and knowledge about the immunogenetics underlying their susceptibility has advanced in recent years. In contrast, we remain largely in the dark about the molecular mechanisms through which both tissue-specific and environmental factors contribute to disease risk. At the moment most of these conditions are managed by replacing the missing hormone(s), however, immunomodulatory therapy aimed at modifying the natural history of these diseases may hold some hope for the future.

Diversity and Natural History of Endocrine Autoimmunity

With the exception of Graves' disease, autoimmune endocrine conditions present owing to clinical manifestations caused by reduced secretion of one or more hormones. Because of the multisystem influences of adrenal and thyroid hormones, the symptoms are frequently non-specific, reflecting disturbances to several bodily systems. In contrast, the features of ovarian insufficiency and insulin deficiency are relatively specific. These presentations with hormone deficiency or excess are different from those of other autoimmune diseases, such as rheumatoid arthritis or multiple sclerosis, which typically manifest with pain or reduced function at the site of autoimmune attack due directly to the associated inflammatory process. The inherent reserve capacity of hormone secretion and the regenerative capacity of many endocrine tissues means that these conditions don't present until the disease process has inflicted a critical amount of tissue damage leading to hormonal insufficiency.

Pancreatic islet cell antibodies are detectable in 70% of children who go on to develop T1D by the age of 5yrs, with about 11% of children with multiple islet cell antibodies developing overt hyperglycaemia per year [1]. Similarly, the rate of progression to overt hypothyroidism for people with positive thyroid peroxidase antibodies is around 5% per year [2]. In contrast, serum steroid 21-hydroxylase antibodies are rare in the population, but around 50% of adults found to have them will ultimately develop overt adrenal insufficiency [3]. In most conditions, these circulating autoantibodies are not believed to be a direct cause of tissue destruction/hormonal dysfunction, but are simply a marker for the autoimmune attack on the target tissue. The exception to this rule is Graves' disease, where antibodies that stimulate the thyroid-stimulating hormone (TSH) receptor directly lead to thyrocyte hypertrophy causing goitre and thyroid hormone hypersecretion [4]. For this reason, it seems likely that hyperthyroid Graves' disease becomes clinically apparent much earlier in the autoimmune process than other autoimmune diseases, because substantial tissue damage isn't necessary for its clinical presentation. This might explain its natural history to remit and relapse, whereas the majority of other autoimmune endocrinopathies seem to be monophasic, with a steady destruction of the target organ leading to hormonal insufficiency. Nevertheless, it has to be acknowledged that once patients are started on hormone replacement therapy, it is rare to re-evaluate whether there may be endocrine recovery at a later date. Thus, it remains possible that we are overtreating patients with several conditions, or treating for longer than necessary, if an unidentified proportion of patients ultimately recover function.

Epidemiology and Disease Clustering

AITDs are the commonest of the autoimmune disorders affecting around 4% of people over a lifetime with either Graves' disease or Hashimoto thyroiditis [2, 5] (Table 1.7.1). Both have a strong female proclivity (F to M 5:1) and a peak age of onset in the fifth decade of life. Autoimmune Addison's disease, while much rarer, has a similar age distribution of occurrence but the female proclivity is less strong, around 2:1. In contrast, type 1 diabetes presents in childhood, adolescence, and young adults, affects 0.5% of the population, and has no gender bias (Figure 1.7.1). Idiopathic autoimmune hypophysitis is most commonly found during the last trimester or in the year following pregnancy, however, drug-induced hypophysitis following immune checkpoint inhibitor therapy (ipilimumab) for cancer is rapidly changing the prevalence of this hitherto rare condition.

There is a strong tendency for each of these organ-specific autoimmune diseases to cluster with each other in an individual or in families. This is most marked for Addison's disease, where 50–65% of people will have a second autoimmune condition, broadly termed the autoimmune polyendocrinopathy syndrome type 2, or APS2 [6]. Autoimmune thyroid disease occurs in 70–90% of APS2 people and type 1 diabetes in 5–15%. On presentation with Addison's disease, type 1 diabetes already exists in around 10% and preventable deaths still occur in T1D patients with undiagnosed adrenal failure. Other conditions that may commonly cluster in APS2 patients in decreasing order of prevalence are pernicious anaemia, coeliac disease, vitiligo, and premature ovarian insufficiency.

Physiology of Immune Tolerance

In health, the two main arms of the adaptive immune system, T and B lymphocytes, work together via both cellular and humoral responses to protect the body against infections and tumours. Ensuring that the immune response is regulated to prevent autoimmunity is a complex process that starts early *in utero*. The immune system undergoes a process of 'education' in order to be able to exert an effective immune response while maintaining tolerance to self-antigens. This process is initially due to the development of central tolerance, however, it has recently become clear that this alone is insufficient to prevent autoimmunity and there are also important peripheral mechanisms involved.

Development of central tolerance: Immune tolerance begins *in utero* in the fetal thymus. Thymic medullary epithelial cells (mTECS) play a critical role in central tolerance—they have the ability to present antigens that are only otherwise expressed in a tissue-specific manner outside the thymus, such as glutamic acid decarboxylase (GAD) and insulin. These antigens are expressed together with costimulatory and major histocompatibility complex (MHC) molecules allowing engagement with T lymphocytes. This promiscuous gene expression in mTECs is partly controlled by the transcription factor AIRE (AutoImmune REgulator), which is responsible for the expression of the tissue-specific antigens enabling the thymus to represents the wide range of antigens that encompass the 'peripheral self' [6, 7].

The maturing T lymphocytes in the thymus (thymocytes) develop a diverse T-cell receptor (TCR) repertoire through numerous somatic recombination events. They then undergo a process of positive and negative selection by interacting with the mTECs that express high levels of MHC class I or II molecules associated with self-antigens. The nature of the T-cell interaction with MHC molecules determines its future, and if the CD4 + CD8+ thymocyte TCR is able to bind with sufficient affinity it receives survival signals (positive selection), ensuring that all mature T cells have some affinity for MHC molecules. Those thymocytes that interact with self-antigen–MHC class I develop into CD8+ cells, while those interacting with self-antigen–MHC class II complexes form CD4+ T cells. Those thymocytes whose TCRs do not bind with sufficient affinity do not receive any survival signals and become unresponsive (anergic). A negative selection process follows the positive selection, where potentially autoreactive thymocytes that bind the self-antigen–MHC complex with high affinity are either removed by apoptosis (known as clonal deletion), or differentiate into regulatory T cells [8]. Therefore, thymocytes that bind to the self-antigen–MHC complexes with low affinity will recognize antigen–MHC complexes but not become autoreactive, are allowed to develop as mature CD4+ or CD8+ T cells and leave the thymus. The CD4+ cells then develop into different T-cell subsets depending on the local cytokine environment. These include T-helper (Th) 1, Th2, and Th17 cells. In addition, some CD4+ thymocytes expressing TCRs that do bind with high affinity to self-antigen–MHC complexes express the forkhead box protein-P3 (FOXP3) and develop into T regulatory (Treg) cells [8, 9]. B cells undergo a similar process of positive and negative selection occurring in the bone marrow. Breakdown or dysregulation of this process at any of the aforementioned steps may lead to potentially autoreactive T cells escaping to the periphery, with the potential to initiate autoimmunity.

Peripheral tolerance: Although most self-reactive T cells are deleted in the thymus, some escape thymic negative selection and can be found in the periphery of most people. However, few of these go on to develop autoimmune disease, which supports the existence of peripheral tolerance which keeps these potentially 'auto reactive T cells' under control. The activation and proliferation of these cells in response to self-antigens is prevented by several different peripheral immune regulatory mechanisms, many of which are not fully understood. Some of these mechanisms are intrinsic to the T cell itself, such as activation-induced cell death, anergy [10], immunological ignorance, and phenotypic skewing. However, a key mechanism for peripheral immune tolerance is through the induction of regulatory T cells that inhibit effector T-cell proliferation.

Regulatory T cells are unique in that they develop both centrally (thymus derived) and peripherally. Central regulatory T cells form from CD4+ thymocytes that show high affinity interactions with self-peptide–MHC complexes in the thymus, and instead

Table 1.7.1 Prevalence of common endocrine autoimmune conditions

Condition	Prevalence per 100 000 population	% female
Graves hyperthyroidism	1151	88
Hashimoto's thyroiditis	791	95
Type 1 diabetes mellitus	192	48
Addison's disease	5	92

Data taken from Jacobson DL *et al.* 1997 (1)

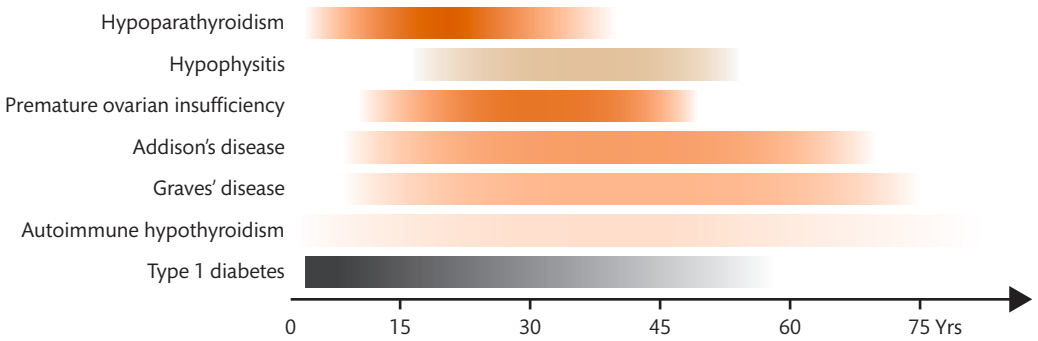

Figure 1.7.1 Age-related incidence of different autoimmune endocrinopathies.
Type 1 diabetes has the highest incidence in children and young people, and gets progressively less frequent with ageing. In contrast, autoimmune thyroid diseases and Addison's disease start to present around puberty, with a peak onset at around the age of 40 yrs. Hypoparathyroidism is almost always found in association with APS1, and commonly presents between the ages of 5 and 15 years in this context.

of undergoing apoptosis, if they express the transcription factor FOXP3+ and high levels of the IL-2 receptor alpha chain (CD25+), differentiate into the regulatory T-cell lineage [11, 12]. In addition, induced regulatory T cells, such as Tr1 cells, arise in the periphery after engagement in prolonged interactions with low affinity self-antigens (not present in the thymus) and in the gut following exposure to food antigens, bacterial flora and pathogens [13].

Regulatory T cells recognize a wide array of antigens and have a higher avidity for self-antigen/MHC complexes than other T cells, but show a limited capacity to proliferate when their TCR is engaged. Their role is to inhibit activation, proliferation, and cytokine synthesis by effector T and B cells. They exert this immunosuppressive effect through different mechanism such as the synthesis of anti-inflammatory cytokines such as interleukin (IL)-10, IL-35, and TGFβ or via cell contact. In summary, there are two functionally distinct populations of CD4+ T cells, one capable of mediating autoimmune disease and one dominantly inhibiting it, and the balance between these cell-types two maintains immune tolerance.

Breakdown of Tolerance: Autoimmunity

Endocrine autoimmunity is a consequence of the loss of immune tolerance towards tissue-specific self-antigens, and in most conditions this leads to tissue destruction and gland failure, which is mediated by cytotoxic T cells. In most conditions there is also a humoral immune response manifest as autoantibody production, although it is unclear whether this plays a direct pathogenic role or is just an epiphenomenon. The exception to this is Graves' disease, where circulating anti-TSH receptor antibodies are a prerequisite of hyperthyroidism. Nevertheless, histologically Graves' thyroid tissue shows a mixed T- and B-cell infiltrate, underlining that this isn't purely a B-cell mediated disorder. Furthermore, B-cell depletion therapy has been shown to ameliorate features of autoimmune disease in both the non-obese diabetic (NOD) mouse and in newly diagnosed type 1 diabetes patients, suggesting a significant role for B-cell at least in perpetuating the immune response [14].

Many organ-specific autoimmune diseases affect endocrine glands and it is hypothesized that this may be due to a critical role for thymic antigen presentation of low-abundance, specialist antigens such as those found in the biosynthesis, secretion, and regulation of the various hormones. This is best illustrated by the monogenic example of the autoimmune polyglandular syndrome type 1 (APS1), owing to loss of function of the AIRE gene (see next). In most other conditions, a complex interplay of multiple genetic variants interacting with environmental and endogenous factors seem to determine disease proclivity.

Genetic Factors

Monogenic Conditions

It is clear that the genetic basis of autoimmunity is complex in most autoimmune conditions, and we still do not have a clear understanding of how and why these conditions develop [9]. There are however a few monogenic forms of autoimmunity that have led to huge advances in our understanding of the development of self-tolerance and how autoimmunity develops, and further studies of these conditions are continuing to advance our knowledge. Two such monogenic endocrine polyendocrinopathies are autoimmune polyglandular syndrome type 1 (APS1) and the immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome (IPEX)—these are discussed further next.

APS1: also known as the autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy syndrome (APECED), is a rare and frequently debilitating disorder of childhood.

It is characterized by organ-specific autoimmunity affecting endocrine organs, skin, and the gastrointestinal (GI) tract. Most patients develop at least two of the three main components—chronic mucocutaneous candidiasis, autoimmune hypoparathyroidism, and autoimmune primary adrenal failure. In addition, over 40 other clinical manifestations have been associated with APS1, and many of these are autoimmune in nature [6, 15]. APS1 is inherited as an autosomal recessive condition and more than 120 different disease-causing mutations have now been identified by the defective autoimmune regulator gene, *AIRE*. It has been shown that *AIRE* encodes a nuclear transcription factor that plays a key role in the development of central immune tolerance. The highest levels of AIRE are found in mTECs where it induces the expression of tissue-specific antigens, which is an essential step in the development of central

immune tolerance. AIRE deficient mTECs show downregulation of the level of organ-specific gene transcripts compared with wild type mTECs, so in the absence of AIRE, the number of tissue-specific antigens expressed on mTECS is reduced, with consequent failure of negative selection of developing autoreactive thymocytes, which escape into the periphery [16]. AIRE deficient mTECs still express normal levels of some self-antigens such as GAD and C-reactive protein (CRP), so AIRE seems to only regulate a subset of transcripts. The full action of AIRE is still poorly understood and it may play further roles in the development of immune tolerance other than directing thymic antigen presentation. Evidence suggests AIRE may also have a role in thymocyte migration through modulating chemokine expression, helping to regulate mTEC apoptosis and differentiation [17]. In AIRE deficiency regulatory T cells express less FOXP3, so AIRE may affect peripheral immune tolerance as well by ensuring self-reactive thymocytes are directed into the regulatory T-cell lineage [18].

Most APS 1 patients are homozygous or compound heterozygous for loss of function mutations, so have no functional *AIRE* transcripts. Recently however, dominant-negative heterozygous AIRE mutations have been described [19], that are located in the AIRE PHD1 (first plant homeo-domain) zinc finger and are associated with a milder and later onset APS1 phenotype. Thus, it is now apparent that disease-causing mutations in *AIRE* are probably more common than previously appreciated and may cause a more variable autoimmune phenotype.

Immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome (IPEX): IPEX is a rare and devastating X-linked condition of male infants, affecting immune regulation and resulting in multiple autoimmune disorders. Affected males develop severe diarrhoea, failure to thrive, type 1 diabetes, and thyroiditis, usually in the first year of life. Other features include eczema, other autoimmune conditions, and immunodeficiency. IPEX is due to mutations in the *FOXP3* gene, located at Xp11, encoding a transcription factor called 'scurfin' which belongs to the forkhead/winged-helix family. Several mutations have been reported in both the coding region and regulatory regions of FOXP3 [20, 21]. FOXP3 is specifically expressed in naturally arising CD4+CD25+ regulatory T cells, and appears to convert naïve T cells to this regulatory phenotype. Thus, FOXP3 is a critical regulator of Treg development and function [11]. Severe autoimmunity in FOXP3 deficiency is thought in part to be due to the inability of CD4+CD25+ Tregs to develop and therefore there is a lack of suppression of self-reactive effector T cells that have escaped to the periphery. Although female carriers of FOXP3 mutations appear to be healthy, a small number of cases of an IPEX-like syndrome have been reported in families with affected girls in whom no mutation was found. Deleterious mutations at several autosomal loci, including the IL-2 receptor subunit *CD25, CTLA4*, and *LRBA* have been shown to cause conditions with overlapping clinical features [22, 23]. This genetic heterogeneity may explain some of the clinical variation seen in this syndrome but, as yet, no obvious genotype–phenotype relationship has been identified, and other modifying genes, such as *HLA*, as well as environmental factors may influence the outcome. Importantly, the identification of the *AIRE* and *FOXP3* genes as defective in APS1 and IPEX have led to huge leaps in our understanding of the control of thymic T-cell selection and the development of regulatory T cells and how loss of function in these critical pathways leads to the development of autoimmunity.

Complex 'Polygenic' Conditions

Apart from the special cases of APS1 and IPEX just described, each of the individual autoimmune endocrinopathies and their 'combined' APS2 syndrome are inherited as complex conditions; meaning that multiple genetic susceptibility variants interact with environmental and/or endogenous factors to lead to the disease.

The MHC on the short arm of chromosome 6 is quantitatively the dominant susceptibility locus for all of the common autoimmune endocrinopathies. Strong association of type 1 diabetes, Graves' disease, Hashimoto thyroiditis, and Addison's disease with alleles of the human leukocyte antigen (HLA) genes within the class II MHC region, which includes *HLA-DRB, -DQA*, and *-DQB* has been consistently found [24]. Furthermore, some susceptibility alleles are common to more than one condition; for instance, *HLA-DRB1*0301* (*'DR3'*) confers genetic risk of type 1 diabetes, Graves' disease, Hashimoto's thyroiditis, and Addison's disease. Carrying one susceptibility HLA allele increases the risk of type 1 diabetes three- to sixfold [25], and for Graves' disease there is a twofold increase over the background population. Fine mapping to the amino acid level of the HLA-DRB molecules has demonstrated that an arginine at position β74 is the strongest determinant of susceptibility, although residues at other positions do have lesser influences. Variation in HLA molecules likely influences the spectrum of antigens that can be presented to T lymphocytes and the avidity of the HLA–TCR interaction, which may be acting during the thymic selection of T lymphocytes.

Several variations in other immune molecules have been associated with multiple autoimmune endocrine conditions. A series of genetic polymorphisms in the cell-surface receptor cytotoxic T-lymphocyte antigen-4 (*CTLA-4*) have been associated with type 1 diabetes, Graves' disease, Hashimoto's thyroiditis, Addison's disease, coeliac disease, and other related conditions [26]. CTLA-4 is a costimulatory receptor that binds T lymphocytes to antigen-presenting cells and which acts to downregulate T-lymphocyte signalling once antigen presentation has occurred to the TCR. It now seems probable that the disease-associated variations within the *CTLA-4* gene encode receptor isoforms with higher probabilities of being shed from the T-cell surface and that these soluble CTLA-4 molecules may saturate the antigen-presenting cell partner CD86 and prevent it from binding the structurally homologous but activating T-cell molecule, CD28 [27]. An additional molecular variant that is expressed in T lymphocytes and that has been widely associated with endocrine autoimmunity is known as protein tyrosine phosphatase non-receptor-22 (*PTPN-22*). A coding variant (*R620W*) in PTPN-22 has been associated with type 1 diabetes, Graves' disease, Hashimoto's thyroiditis, Addison's disease, and several other non-endocrine autoimmune conditions [28]. Interestingly, this PTPN-22 susceptibility allele has only been found to be associated with autoimmunity in populations of white European ancestry, whereas in East Asian populations, different, non-coding variations of PTPN-22 seem to confer susceptibility. Like CTLA-4 variants, PTPN-22 alleles may act as a brake to T-lymphocyte activation, by inactivating intracellular signalling molecules downstream of the TCR, such as Lck.

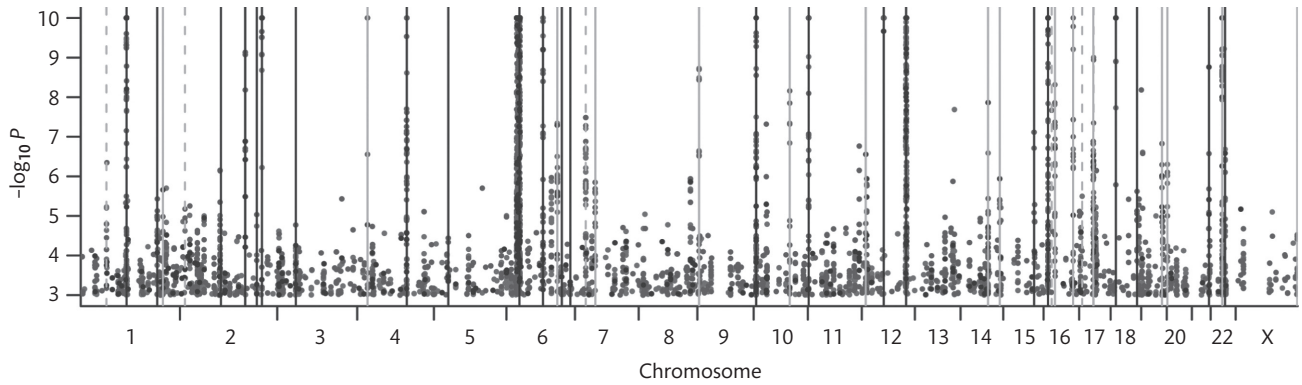

Figure 1.7.2 Manhattan plot of genetic associations for type 1 diabetes. Genomic single-nucleotide polymorphism (SNP) locations on human chromosomes 1–22, X are shown on the x-axis with the $-\log_{10}P$ value in favour of association on the y-axis. High densities of associated SNPs are found in many locations, for instance chromosome 1 (PTPN22), chromosome 6 (HLA), chromosome 12 (CD25).

Discovery-based genomic methods have now uncovered many additional genetic variants that each contribute a few per cent to the overall susceptibility to autoimmune diseases. Currently type 1 diabetes is the best studied of the conditions and genome-wide association scans have shown that allelic variants in more than 60 different genes underlie the proclivity to this disorder (Figure 1.7.2) [1, 29]. Knowledge of the diversity of the genes in which susceptibility variants have been found allows some insight into disease pathogenesis and highlights novel pathways that could be modified in attempts to ameliorate the underlying autoimmune disease process. For instance, variations in the *CD25* gene (a subunit of the interleukin 2-receptor) have been found in type 1 diabetes and AITDs, leading to current trials of low-dose IL2 therapy in recent-onset T1D [30]. Similarly, variants in B lymphocyte activating factor (BAFF) have been found in Graves' disease as well as multiple sclerosis and systemic lupus erythematosus, suggesting that specific anti-B lymphocyte therapies might be efficacious in these conditions. In addition, improved knowledge of the diverse genetic burden has begun to be used in multiallelic stratification scores to more accurately quantify disease risk in currently unaffected children who have affected family members with T1D [31]. The ultimate aim being that such stratification may be able to more precisely predict future development of T1D and that the highest risk individuals could be targeted for preventative therapies.

Antigen and Tissue-Specific Factors

As well as immune system variants, genetic studies have demonstrated that alleles of the insulin and TSH receptor genes are associated with T1D and Graves' disease, respectively [32, 33]. This establishes that variations in the target antigens, likely involving quantitative differences in expression pattern or regulation rather than qualitative alterations of the protein itself, are also important in determining the specific endocrine organ involved in autoimmunity. An important recent development is the discovery that T cells from the NOD mouse model of T1D and from T1D patients recognize hybrid insulin peptides, formed by fusion of proinsulin C-peptide and chromogranin or islet amyloid polypeptide (IAPP) fragments [34]. This finding of peptide rearrangement explains how such novel antigens can elude the thymic immune education process, and provides another layer of complexity to disease pathogenesis.

Environment and Endogenous Factors

Many different non-inherited factors have been shown to influence the risk of autoimmunity. Some are likely to be common to more than one autoimmune disorder such as stress or vitamin D insufficiency, and others may be highly specific for a certain condition such as a viral infection with a specific tissue tropism, or environmental iodine exposure which directly affects thyroid function.

Among the best characterized conditions are Graves' disease and type 1 diabetes. As mentioned earlier, dietary iodine supply is a significant factor in determining the prevalence of Graves' disease in a population. Iceland, where iodine intake is high, has more than double the rate of Graves' disease than found age-matched individuals in East Jutland, Denmark, where iodine intake was low [35]. Cigarette smoking has a clear association with thyroid-associated orbitopathy (TAO) and is also implicated in both prevalence of hyperthyroid Graves' disease and remission rate following antithyroid drug therapy. In contrast, smoking has been shown to protect against Hashimoto thyroiditis [36]. It is believed that thiocyanate compounds contained within cigarette smoke may perturb thyroid hormone production. Stress, in the form of adverse life events has been implicated in Graves' disease pathogenesis. Analysis of incidence during spells of national conflict have shown increased rates, although other, major changes that occur simultaneously could be confounding factors (e.g. dietary changes during wartime). In addition, significant life events (such as bereavement in the year before the onset of the disease) have been linked to the onset and remission rate of Graves' disease [37, 38]. In a prospective study, no correlation was found between stressful life events and thyroid peroxidase antibody (TPO Ab) status, suggesting that alterations in the cytotoxic or innate arms of the immune system might be involved [39]. Pregnancy is also a well-recognized risk factor for Graves' disease [40]. The mechanism for this presumably relates to a relative suppression of immune function during pregnancy and a

rebound of immune activity in the postpartum period. In contrast, oestrogen use protects against Graves' disease.

Several lines of evidence suggest that enteroviral infection, either maternal or in the infant, predisposes to type 1 diabetes. Enteroviral ribonucleic acid (RNA) has been identified in the blood of 10–50% of newly diagnosed T1D patients and serological evidence of enteroviral infection supports a high frequency of previous infection. Nevertheless, enteroviral infection is common in healthy controls and T1D patients have a distinct immunogenetic make up which might result in differences in viral clearance or antibody response that could be incidental to any pathogenic role for enteroviruses [41]. High birthweight, rapid early childhood growth, obesity, and other states of relative insulin resistance have been found to predispose to T1D. This gives rise to the accelerator hypothesis, which proposes that these increased insulin demands drive the autoimmune response against the pancreatic β cell [42]. Along similar lines to Graves' disease, adverse psychological stresses have been associated with T1D risk [43]. It seems possible that the metabolic consequences of this, including hypercortisolaemia and sleep disturbance could also lead to increased insulin demand ('β cell stress'), as well as direct effects on immune function. In addition, there are nutritional influences for T1D, including reductions in incidence in vitamin D supplemented children, and with diets containing more omega-3 polyunsaturated fats [43]. With the exception of vitamin D status, it remains largely unknown how these different environmental influences on T1D risk are mediated at a molecular level, and this remains an important subject for future research.β

Future Directions and Summary

Study of the rare monogenic polyendocrinopathy syndromes has unveiled fundamental insights into the mechanisms of thymic immune tolerance and peripheral T-cell regulation. In the commoner, complex conditions, several variants in both immune system and target antigen genes have been implicated. Several new treatment approaches are in development based on this understanding, including clinical trials of low-dose IL2, which may bolster Treg numbers and reduce cytotoxic T-cell responses in T1D [30]. In addition, knowledge of T-cell epitopes has led to promising studies of desensitization to target antigenic peptides [44]. Current therapies for autoimmune endocrinopathy still involve replacing the 'missing' hormone; it seems likely that specifically targeted immunomodulatory therapies may become a reality over the next few years.

Common Features of Endocrine Tumours

Anne Jouinot, Fidéline Bonnet-Serrano, and Jérôme Bertherat

Introduction

There is a broad variety of endocrine tumours, defined by their localization, differentiation, and hormonal activity. They all share in common by definition to arise from endocrine cells. For this reason, they are mostly observed in endocrine glands. This is evident for tumours primarily located in an endocrine organ, like thyroid, or pituitary tumours. However, because endocrine cells can also be present in small quantities scattered in many non-endocrine organs they can also be observed in many non-endocrine organs. For instance, pulmonary neuroendocrine tumours or paraganglioma (extra-adrenal pheochromocytoma) are well-known examples of neuroendocrine tumours arising outside an endocrine gland. In some very rare instances primary endocrine tumours can be observed in various non-endocrine organs like breast or skin. The World Health Organization (WHO) 2017 classification of endocrine tumours has listed mainly the following entities that will be the focus of this chapter: tumours of the pituitary, the thyroid, the parathyroid, the adrenal cortex, the adrenal medulla, and extra-adrenal paraganglia, the neuroendocrine pancreas, and inherited tumour syndromes [1]. Their frequency is listed in Table 1.8.1.

The endocrine symptoms caused by hormone excessive secretion can be the revealing signs of an endocrine tumour. In this case, hormonal biology guided by clinical signs leads to the diagnosis of hormone excess, and subsequently clinical and imaging investigations lead to the identification of the causative tumour. However, there is a wide range of hormone secretion dysregulation from non-secretory to subclinical and overt-secreting tumours. For this reason, the tumour can also be found incidentally on medical imaging, or due to the tumour mass and finally more rarely distant metastasis. Incidentally discovered endocrine tumour is nowadays a very frequent and classic situation for adrenal tumours, thyroid tumours, and to a lesser extent pituitary and pancreatic neuroendocrine tumours. One of the major steps in the investigations of these 'incidentalomas' is the clinical and biological investigation in search of autonomous hormone secretion. The demonstration of hormone excess is both important for diagnosis as a kind of 'tumour marker', but also for patient management. For instance, a very high prolactin level (typically above 200 ng/ml) will classify a pituitary incidentaloma as a prolactinoma. Evidence of cortisol excess will be the main parameter to decide on surgery for an incidentally discovered benign adrenal adenoma: in case of overt-cortisol excess, surgery will be indicated; in case of modest autonomy of cortisol secretion surgery will be discussed, taking into account the potential consequences and the age of the patient; finally, in case of a non-secreting adenoma with a perfectly normal suppression of cortisol after dexamethasone, there is no indication for surgery [2].

Hormone Dysregulation in Endocrine Tumours

One main characteristic of endocrine tumours is usually the partial or complete loss of the normal control of hormone secretion. For this reason, endocrine tumours can be responsible for hormone excess in keeping in most cases with their cellular origin and differentiation. The main clinical symptoms due to hormone excess and their principal biological work-up are listed in Table 1.8.1.

Various mechanisms can be responsible for this hormone excess. This can be due to the loss of the negative feedback of the peripheral hormone, as for instance adrenocorticotropic hormone (ACTH) oversecretion escaping the negative feedback of glucocorticoids in ACTH-dependant Cushing syndrome. Another level of dysregulation is the relative dedifferentiation of the tumour cells, leading to mixed secretion as, for instance, prolactin, growth hormone (GH), and thyroid-stimulating hormone (TSH) cosecretion by plurihormonal pituitary adenomas. Processing of pro-hormone can also be incomplete in endocrine tumour cells, as for example pro-insulin maturation in insulinoma. This can be explained by the level of expression of the maturing enzyme that differs from the normal

Table 1.8.1 General characteristics of endocrine tumours

	Estimated prevalence in general population	%	Hormone secretion	Main clinical presentation	Main hormonal investigations for diagnosis	Main functional imaging used in routine
Pituitary gland	0.02–0.1%					
Functional pituitary adenoma		70%				
Somatotroph		13%	GH	Acromegaly	IGF1, GH suppression test	
Lactotroph		60%	PRL	Galactorrhoea	PRL	
Thyrotroph		<1%	TSH	Hyperthyroidism	T4L, TSH	
Corticotroph		6%	ACTH	Cushing's syndrome	Midnight cortisol, free urinary cortisol, cortisol suppression test, ACTH	
Plurihormonal and double adenomas		Unknown	PRL + GH (= most frequent)	Acromegaly and/or galactorrhoea	IGF1, GH suppression test, PRL	
Non-functional pituitary adenoma		30%				
Gonadotroph		15–20%	LH, FSH, SUA	Asymptomatic	LH, FSH, SUA	
Null cell adenoma		<5%	None	Asymptomatic	No	
Silent adenomas often aggressive		<5%	None, but possible tumour immunopositivity for ACTH and/or GH and/or or TSH	Headaches, acute visual loss	No	
Pituitary carcinoma		0.1–0.2%				
Thyroid	4–5% (palpable nodules) > 50% (ultrasonographic nodules)					
Benign tumour		90–95%				
Toxic benign adenoma		15% (palpable nodules)	T4L, T3L	Thyrotoxicosis	TSH, T4L	I123 scintigraphy
Non-functional benign adenoma		85% (palpable nodules)	None	Asymptomatic	No	
Malignant tumour	**1–10 /100 000 in men 2.5–20/100 000 in women**	5–10%				
Differentiated thyroid carcinoma		95%	None	Asymptomatic	Follow-up by TG	follow-up by I123 scintigraphy (or I131 in case of concomitant treatment)
Anaplastic thyroid carcinoma	1–9/1 000 000	<2%	None	Asymptomatic/local compression	Follow-up by TG	
Medullary thyroid carcinoma	1/14 300	<5%	TCT	Asymptomatic/flush and diarrhoea	TCT	Fluoro-DOPA-PET
Parathyroid gland	0.85/1000					
Parathyroid adenoma		99%	PTH	Primary hyperparathyroidism (hypercalcaemia symptoms and complications such as nephrolithiasis and osteoporosis)	Calcaemia, PTH, 24 hours calcinuria	MIBI scintigraphy
Parathyroid carcinoma		<1%		More severe primary hyperparathyroidism with possible malignant hypercalcaemia		

Table 1.8.1 *Continued*

	Estimated prevalence in general population	%	Hormone secretion	Main clinical presentation	Main hormonal investigations for diagnosis	Main functional imaging used in routine
Adrenal cortex	5%					
Adrenal adenoma		80%				
Non-secreting		75%	None	Asymptomatic		
Aldosterone secreting (Conn adenomas)		2.50%	Aldosterone	Hypertension and hypokalaemia	Renin and aldosterone (decubitus) +/- suppression test (salt load)	
Cortisol secreting		12%	Cortisol	Cushing syndrome	Midnight cortisol, free urinary cortisol, cortisol suppression test, ACTH	Noriodocholesteror scintigraphy
Adrenocortical carcinoma	**1/1 500 000**	2–25% depending on tumour size	Adrenal steroids (glucocorticoids, androgens, mineralocorticoids) and precursors	From asymptomatic to hyperandrogenia, Cushing syndrome, hypokalaemia hypertension		FDG-PET scan
Adrenal medulla and extra-adrenal paraganglia	1–9 /1 000 000					
Pheochromocytomas	1/500 000	70% (10% malignant)	Metanephrines and Normetanephrines	Menard triad: headaches, palpitations and tachycardia, sweating	Urinary and plasmatic metanephrines and normetanephrines	MIBG scintigraphy
Paragangliomas	1/1 000 000	30% (30% malignant)			Urinary and plasmatic metanephrines and normetanephrines	Fluoro-DOPA-PET
Neuroendocrine pancreas	2–3/100 000 Malignant: 0.8/100 000					
Non-functioning		60–90%		Asymptomatic	Chromogranin A	
Functioning		10–40%			Chromogranin A	Somatostatin receptor imaging
Insulinoma		39% (<10% malignant)	Insulin	Hypoglycaemic symptoms	Insulin and C-peptide during fasting trial or concomitant with spontaneous hypoglycaemia	(somatostatin receptor scintigraphy or PET/CT with 18Ga labelled somatostatin analogues)
Glucagonoma		2% (50–80% malignant)	Glucagon	Rash, glucose intolerance, weight loss	Glucagon	
Gastrinoma		25% (60–90% malignant)	Gastrin	Pain, diarrhoea, oesophageal symptoms	Gastrin	Fluoro-DOPA-PET
VIPoma		7% (40–70% malignant)	VIP (vasoactive intestinal peptide)	Diarrhoea, hypokalaemia, dehydration	VIP	
Somatostatinoma		<1% (>70% malignant)	Somatostatin	Diabetes mellitus, cholelithiasis, diarrhoea	Somatostatin	FDG-PET scan (malignant tumours)
Serotonin-producing tumours with and without carcinoid syndrome		25% (60–88% malignant)	Serotonin	Flush, diarrhoea, abdominal pain, cardiopathy	Serotonin	
ACTH-producing tumour with Cushing syndrome		Rare (>95% malignant)	ACTH	Cushing syndrome	Midnight cortisol, free urinary cortisol, cortisol suppression test, ACTH	

cells, especially in the case of malignant tumours. A classic example of that is the processing of pro-opio-melanocortin (POMC) by aggressive lung cancer causing high secretion of this non-matured ACTH precursor by comparison with pituitary corticotroph adenoma maturing POMC almost like a normal pituitary cell [3]. Activation of cell signalling pathways controlling hormone secretion has been explained by genetic defect of main component of this pathway in some endocrine tumours. For instance, the cAMP

pathway will be activated by somatic mutations of several of its components in different types of benign oversecreting endocrine tumours (i.e. the TSH receptor in toxic thyroid adenoma, the stimulatory G protein (GNAS) in somatotroph adenomas, and the catalytic alpha of the protein kinase A (PRKACA) in cortisol-secreting adrenal adenomas). Interestingly, some germline defects activating the same cAMP pathway, like mutations of the regulatory subunit of PKA (PRKAR1A) in Carney complex, cause various endocrine tumours including GH-secreting adenomas and primary pigmented nodular adrenal hyperplasia leading to cortisol excess (ACTH-independent Cushing's syndrome) [4].

In term of biological investigations, hormone excess will be demonstrated by basal assays and/or dynamic tests depending on the type secreting tumours (see Table 1.8.1). Basal assays can be sufficient for some tumour types and often in many other tumour types in case of a severe hormone excess. These different requirements reflect mostly the physiology of the investigated hormones: a hormone with a quite stable level of secretion during the nychthemeron (e.g. thyroid hormone) will not require dynamic testing. Thyroid tumours usually require only basal assay of TSH, fT4, fT3 and, in case of medullary thyroid cancer, calcitonin. By contrast, investigations of the highly variable corticotroph axis will in most cases require multiple dynamic testing for an accurate diagnosis. It can be also the demonstration of an inadequate level of an hormone by comparison with an increased level of its target that will prove hormone excess: for instance, a still in the normal reference range of the laboratory level of parathyroid hormone (PTH) with a high calcium level will be considered as not supressed and therefore inappropriately elevated. Dynamic tests to demonstrate hormone autonomous secretion required for various tumour types are mostly suppression tests. For instance, GH oversecretion in acromegaly will be demonstrated by a non-suppressed GH level after an oral glucose load, and cortisol excess in case of Cushing syndrome by a non-suppressed cortisol level during a dexamethasone suppression test. These tests are especially needed in case of a modest autonomy of hormone secretion and for this reason are also often important to exclude oversecretion. Multiple basal hormone assays can also help to demonstrate hormone dysregulation in some endocrine tumours; for instance, repeated assays of glucose and insulin during a fasting test in insulinoma or study of the circadian rhythm of cortisol in Cushing's syndrome.

Tumours with a neuroendocrine differentiation will also present abnormal secretion of granins. Granins are a major component of secretory granules. They participate in the maturation and exocytosis of secretory vesicles releasing active neuropeptides and hormones. Among them, chromogranin A (CgA) presents an increased secretion in patients with neuroendocrine tumours of various type and location [5]. CgA is therefore used as a tumour marker in these patients, both for diagnostic and follow-up, especially in case of malignant tumours.

Membrane Receptors in Endocrine Tumours: Implications for Pathophysiology, Imaging, and Treatment

Membrane receptors belonging to the family of seven transmembrane receptors coupled to G protein (RCPG) are present in endocrine cells. Specific ligands binding these receptors play a major role in endocrine gland development, maintenance, and hormone secretion, such as TSH receptor (TSH-R) in the thyroid, or growth hormone-releasing hormone (GHRH) receptor in the pituitary somatotroph tumours. Endocrine tumours in most cases still express these receptors, except in situations of dedifferentiated tumours that are mostly observed in some rare endocrine cancers. Dysregulation of these receptors can play a role in the pathophysiology of endocrine tumours, such as activating mutations of the luteinizing hormone (LH) receptors in Leydig cells tumours or illegitimate receptors expression in bilateral primary macronodular adrenal hyperplasia (PBMAH) [6]. These receptors can also be used for imaging in part of the extension work-up. For instance, many neuroendocrine tumours express the somatostatin receptor. Scintigraphy with radio-labelled somatostatin agonist has been developed for neuroendocrine tumour imaging [7]. Somatostatin receptor scintigraphy is probably the most advanced and used peptide receptor based medical imaging in endocrine tumours. But other receptors can also be targeted for medical imaging, like GLP-1 in insulinomas.

The presence of RCPG in endocrine tumours is also the basis of various therapeutic approaches. For instance, suppressive levothyroxine treatment in differentiated thyroid cancer aims at reducing the stimulation of the TSH-R by endogenous TSH. Somatostatin analogues are used in the treatment of various type of endocrine and neuroendocrine tumours mostly to inhibit hormone secretion, but also to control tumour growth.

Outcome and Prognosis of Endocrine Tumours

The majority of endocrine tumours are benign. These benign tumours often present a very slow progression when they are simply monitored, as it can be done in many thyroid benign tumours or some incidentally discovered non-secreting adrenal adenomas. In this case, symptoms will be mostly related to hormone excess or compression of adjacent organs, the latter being usually observed in large tumours.

Malignant tumours can be observed in all the endocrine glands, but with a different frequency and aggressiveness. For instance, pituitary carcinomas or parathyroid carcinomas are very rare with a reported prevalence of only 0.1% of all pituitary tumours and less than 1% of parathyroid tumours, respectively. By contrast, malignant pheochromocytoma or paraganglioma (PPGL) or thyroid cancer account for 10–20% of all PPGL and 5–10% of all thyroid tumours, respectively. Thyroid cancers are the most frequent endocrine cancer and are estimated to represent about 2% of the total cancer incidence. It is worth to note an increase in the incidence of thyroid cancer worldwide that might be at least in part explained by the increasing use of ultrasonography leading to more frequent diagnosis [8]. This is probably the most documented example of the increased incidence of incidentally discovered endocrine tumour.

Distinguishing malignant from benign endocrine tumours may be difficult even for the pathologist. This is because endocrine cancers are often well differentiated and share common pathologic characteristics with benign endocrine tumours. Pathological expertise is therefore a key for the diagnosis of many endocrine tumours, especially for rare tumours like adrenocortical cancer. For some tumour types like PPGL, malignancy can only be firmly affirmed by the presence of distant metastasis. The malignancy of a

pituitary tumour (i.e. pituitary carcinoma), is defined by cerebrospinal and/or systemic dissemination—the central nervous system, including brain, spinal cord, and meninges, representing the most common metastatic site. In parathyroid carcinomas, reliable indicators of malignancy, including invasion of adjacent tissues or metastatic spread, are rarely observed at the time of diagnosis. Other histological features such as capsular invasion, vascular invasion, thick fibrous bands, and mitotic activity orient towards malignancy but are not specific of cancers and can also be found in parathyroid adenomas. For some cancers pathological scores have been developed to improve the diagnosis of malignancy, including the Weiss score for the adrenal cortex and the PASS (pheochromocytoma of the adrenal gland scaled score) for the adrenal medulla. However, some approaches might be more common to several endocrine tumours. For instance, the Ki-67 index reflecting cell division and mitosis is used in various endocrine tumours for the diagnosis of malignancy and/or for the prognostication of malignant tumours.

Indeed, in endocrine cancers the prognosis varies greatly from one tumour type to another (Table 1.8.2). The prognosis of differentiated thyroid cancer is generally excellent with a 10-year survival rate of 90%, while the prognosis of pituitary or metastatic adrenocortical cancer is generally poor, with a median survival not exceeding 2 years. In most endocrine cancers, tumour stage at diagnosis will impact the prognosis. However, within a single tumour type and for similar tumour stage, prognosis can vary among patients. Furthermore, one specificity of endocrine cancers is that hormone related complications may also impact survival as well as tumour burden itself. Precise prognostication of endocrine cancer is often difficult. This could be explained by some specificity of endocrine tumours but also the rarity of endocrine cancers that is a limitation to design large clinical studies to investigated prognostic markers. The hope in the near future is that molecular markers will improve diagnosis and prognostication of endocrine cancers [9].

Genetics of Familial and Sporadic Tumours

Much progress in the genetics of endocrine tumours has been made since the identification of the proto-oncogene *RET* in multiple endocrine neoplasia type 2 [10]. Endocrine tumours can be observed in many genetic diseases responsible for familial neoplasias. In this case, a germline genetic defect of a tumour suppressor gene or, more rarely, an oncogene-activating mutation is present. Some of these genes predispose to various different types of endocrine tumours, like the proto-oncogene *RET* or the tumour suppressor menin (*MEN1*). Other tumour suppressor genes are apparently responsible for a single type of endocrine tumour like pituitary adenomas in patients with *AIP* mutations or adrenocortical tumours in patients with *ARMC5* mutations. Although inherited endocrine tumours can be diagnosed at various ages, the general rule is that the younger the patient is the more likely a genetic cause could be found. For instance, pituitary adenomas are more frequently of genetic origin before the age of 20-year-old and a genetic cause of primary

Table 1.8.2 Prognosis of endocrine cancers

Tumour type	Overall survival	Factors associated with poor prognosis					
		Age	Sex	Tumour extent	Hormonal secretion	Histological features	Genetic markers
Pituitary carcinoma	50% at 2 years (metastatic tumours)			Systemic metastases	Non-functional tumours		
Differentiated thyroid carcinoma	90% at 10 years	Older age		Large tumour size Local invasion Lymph node involvement Distant metastases	High postoperative thyroglobulin level	Non-papillary subtype Vascular invasion	*BRAF* V600E mutation
Anaplastic thyroid carcinoma	20% at 1 year	Older age	Male	Large tumour size Distant metastases			
Medullary thyroid carcinoma	75% at 5 years	Older age	Male	Local invasion Lymph node involvement Distant metastases	High postoperative thyroglobulin level Calcitonin doubling time < 6 months		*RET* M918T mutation
Parathyroid carcinoma	80% at 5 years	Older age	Male	(Large tumour size) (Lymph node involvement) Distant metastases	High calcium level		
Adrenocortical carcinoma	40% at 5 years	Older age		Local invasion Lymph node involvement Distant metastases	Cortisol-secreting tumours	Ki-67 index > 20% Mitotic count > 5/50 HPF	*BUB1B-PINK1* differential expression
Malignant pheochromocytoma-paraganglioma	50% at 5 years (metastatic tumours)			Large tumour size Visceral metastases	Catecholamines excess	Paraganglioma	*SDHB* mutation
Pancreatic neuroendocrine tumours	50% at 5 years			Large tumour size Lymph node involvement Distant metastases	Non-functional tumours	Glucagonoma/VIPoma Grade 3 (Ki-67>20%) Poorly differentiated tumours Vascular invasion	

HPF, high-power field.

hyperparathyroidism is very rare after 50-year-old. Endocrine cancers occur mostly in adults, even though some paediatric cases are described, mainly as part of tumour predisposition syndrome, such as hereditary PPGL (*SDH* germline mutation), multiple endocrine neoplasia type 1 (*MEN1*) or type 2 (*RET*), or Li Fraumeni syndrome (*TP53*).

Some endocrine tumours like pheochromocytoma and paraganglioma are of genetic origin in more than 30% of the cases. Depending on the causative gene, the outcome of the tumours might differ. It is therefore important in newly diagnosed patients with an endocrine tumour to consider the possibility of a genetic cause and to identify the patients to be referred to the geneticist, not only for familial screening but also for patient management [11].

The development of genomics, allowing us in a single experiment to study at the pangenomic level of genetic and epigenetic alterations, has been very helpful to progress in the molecular genetics of sporadic as well as familial endocrine tumours and the molecular classification of endocrine tumours. The integrated genomics of various endocrine cancers has been possible. It is due to these analyses that the burden of either mutation of driver genes or chromosomal alterations are recognised as important determinants of the classification of endocrine cancers and are associated with patient outcome [12].

Management of Benign Endocrine Tumours

Treatment is required to correct or prevent tumour growth and/or hormone excess. However, some benign non-secreting endocrine tumours considered after appropriate investigations to have no significant clinical consequences and not being at risk of rapid growth will be simply monitored. This is often the case for small incidentalomas of the thyroid, pituitary, adrenal cortex, or endocrine pancreas. In all the other situations, treatment will be required. In many cases, surgery will be indicated as the treatment of choice since complete tumour removal will also treat the cause of hormone excess. Surgery will usually definitely cure a benign endocrine tumour. However, recurrence might occur in cases of tumour remnant, or genetic or environmental factors favouring the development of a second benign tumour. Furthermore, in some endocrine glands (e.g. the pituitary) complete removal might be difficult to warrant because of local invasion to the adjacent structure and recurrence might be observed, sometime years after the initial surgery. For this reason, long-term follow-up is usually needed. Some benign secreting tumours might require a specific medical treatment to control hormone excess in patients that could not be operated upon because of comorbidity, severe consequences of hormone excess, or when complete tumour removal is not possible or expected. For some tumour types, surgery might not be always the first treatment of choice when a specific medical option might offer a definitive cure. This is, for instance, the case in thyroid toxic adenoma treated with radioiodine. Antisecretory treatment will depend on the type of endocrine tumour and its secretion, and will aim at inhibiting directly hormone hypersecretion from the causative tumour or indirectly on its targets. For instance, somatostatin analogues can be used to treat ACTH-secreting tumours, but anticortisolic treatment can also be used to inhibit, at the adrenal cortex level, the cortisol production driven by ACTH excess. Medical treatment of hormone excess can also rely on drugs blocking the peripheral action of hormones at the receptor level: for instance, spironolactone to inhibit the mineralocorticoid receptor in case of primary aldosteronism, or GH antagonists to block the GH receptor in case of GH-secreting pituitary adenomas. Symptomatic treatment of the clinical consequences of hormone excess is also important, like glucose-lowering drugs in case of diabetes secondary to acromegaly or Cushing's syndrome, β-blockers in case of hyperthyroidism, or antihypertensive drugs in case of pheochromocytoma.

Management of Malignant Endocrine Tumours

In endocrine cancers, treatment will aim at controlling tumour growth and metastasis. In secreting cancers, the treatment of hormone excess will often need to be associated with the antitumour treatment. Somatostatin analogues are used in various endocrine cancers to inhibit both hormone secretion and tumour growth [13]. Some more specific drugs like mitotane, used only in adrenocortical cancer, aim at both inhibiting steroid synthesis and tumour growth. Owing to the rarity of endocrine cancers, only few randomized controlled studies have investigated medical treatments for these diseases, and surgery is still the mainstay of treatment of most endocrine malignancies (**Table 1.8.3**). In localized tumours, surgery will be indicated in the majority of endocrine cancers, aiming at complete tumour removal. This often requires experienced surgeons in a multidisciplinary setting to offer the best chance of cure, at least for the rare forms of endocrine cancers. In metastatic diseases, surgery might still have a role in some type of endocrine cancers, when the number of metastatic organs is limited as well as the tumour load, and that the tumour progression is slow. The decision usually requires a multidisciplinary discussion in expert centres to offer the best standard of care. For the same reason, progressive endocrine cancers after initial treatment might benefit from loco-regional approaches, including repeated surgeries, radiofrequency ablation, or radiotherapy. This helps to reduce the tumour burden, prevent loco-regional complications, and symptoms related to tumour mass and can also improve hormonal control for secreting tumours. This is often the case for well-differentiated pancreatic endocrine cancers or malignant PPGL with a slow progression. In case of asymptomatic, low-tumour burden, non-progressive disease, a 'wait and see' strategy could even be discussed.

Some specific radionuclide treatments are given in endocrine cancers because of the capacity of the tumour cells to uptake the administered drug in a quite specific manner (for synthesis of its specific hormone or when the cell expresses significant amount of a membrane receptor). Radioiodine (I–131) therapy is recommended in differentiated thyroid cancers after surgery in patients with high-risk of recurrence as well as in patients with metastatic disease. metaiodobenzylguanidine (MIBG) therapy can be used in malignant PPGL and somatostatin analogues radionuclide therapy is in development in pancreatic neuroendocrine tumours.

Table 1.8.3 International recommendations for antitumour treatment of endocrine cancers

Tumour type	Tumour stage	Surgery	Wait and see	External radiotherapy	Radiopharmaceuticals	Hormonal treatment (for antitumour effect)	Cytotoxic chemotherapy	Targeted therapy
Pituitary carcinoma	Localized	For all tumours		Discussed for high-risk tumours				
	Advanced	For resectable tumours		For progressive tumours despite surgery		Somatostatin analogues or dopamine agonists for functional tumours	Temozolomide	
Differentiated thyroid carcinoma	Localized	For all tumours			Radioiodine for high-risk tumours	TSH suppression		
	Advanced	For all resectable tumours	For iodine-refractory slow-progressive tumours		Radioiodine	TSH suppression		Sorafenib or lenvatinib for iodine-refractory progressive tumours
Anaplastic thyroid carcinoma	Localized	For all tumours		After surgery			Taxanes, anthracyclines, or platinum regimens discussed after surgery	
	Advanced	For resectable tumours		After surgery or for unresectable tumours			Taxanes, anthracyclines, or platinum regimens	ALK or BRAF inhibitors
Medullary thyroid carcinoma	Localized	For all tumours		Discussed for extrathyroidal extension or after incomplete resection	Peptide receptor radionuclide therapy			Vandetanib or cabozantinib
	Advanced	For slow-progressive resectable tumours	For slow-progressive unresectable disease					
Parathyroid carcinoma	Localized	For all tumours						
	Advanced	For resectable tumours						
Adrenocortical carcinoma	Localized	For resectable tumours		After incomplete resection		Mitotane for high-risk tumours		
	Advanced					Mitotane	EDP	
Malignant pheochromocytoma-paraganglioma	Localized	For all tumours		discussed after incomplete resection				
	Advanced	For resectable tumours	For asymptomatic, slow-progressive disease		MIBG		CVD temozolomide	Sunitinib
Pancreatic neuroendocrine tumours	Localized	For all ≥2 cm tumours	For some low-grade, asymptomatic, <2 cm tumours					
	Advanced	For resectable tumours	For some low-grade, asymptomatic, slow-progressive tumours		Peptide receptor radionuclide therapy	Somatostatin analogues for grade 1–2 tumours	Streptozotocin regimen or TEM-CAP for well-differentiated tumours Platinum regimen for poorly differentiated tumours	Sunitinib or everolimus for grade 1–2 tumours

EDP, etoposide-doxorubicin-platinum; CVD, cyclophosphamide-vincristine-dacarbazine; TEM-CAP, temozolomide-capecitabine.

Most endocrine cancers are not good responders to classic systemic cytotoxic chemotherapy usually administrated in many non-endocrine cancers. For this reason, systemic chemotherapy is used in a limited number of aggressive endocrine cancers. For instance, chemotherapies are given in frontline treatment of advanced anaplastic thyroid cancer with taxanes, anthracyclines, and platinum-based regimens. Systemic chemotherapy with streptozotocin is used in progressive poorly differentiated endocrine pancreatic cancers. In metastatic adrenocortical cancer, the combination of mitotane and platinum chemotherapy represents the standard frontline treatment, even though this regimen shows limited efficacy [14]. Temozolomide monotherapy gives encouraging results in pituitary cancer and malignant PPGL [15, 16].

Because of the limited efficacy of systemic chemotherapy in endocrine cancers, efforts have been developed to see whether targeted therapy might offer a good alternative. Ideally, this should be based on molecular evidence of genetic alteration in the signalling pathway targeted by the drug. A good example of this approach is the differentiated thyroid cancer in which the mitogen-activated protein (MAP) kinase pathway is commonly activated, most often due to BRAF-activating mutations. The use of BRAF and mitogen-activated protein kinase kinase (MEK) inhibitors in thyroid cancers has proved to be efficient. Interestingly, in thyroid cancer refractory to radioiodine because they do not uptake radioiodine anymore, the MAP kinase pathway inhibition allows the re-differentiation of tumour cells and restores radioiodine uptake, and therefore, response to I–131 therapy [17]. Other targeted therapies include the multitargeted kinase inhibitors sorafenib and lenvatinib, acting on angiogenesis, which is also a hallmark of differentiated thyroid cancers. Activating mutations of *RET* observed in medullary thyroid cancer also offer therapeutic perspectives. The tyrosine kinase inhibitors vandetanib or cabozantinib, which target both *RET* and vascular endothelial growth factor receptor (VEGFR) kinases, can be used in first-line systemic therapy of medullary thyroid cancer. Finally, some anaplastic thyroid cancer may respond to antiangiogenic drugs and to ALK or BRAF inhibitors[18]. The mTOR inhibitor everolimus, as well as the antiangiogenic drug sunitinib, have proven their efficacy in pancreatic endocrine cancers [19, 20]. Antiangiogenic tyrosine kinase inhibitors seem also promising in malignant PPGL, and a phase III study with sunitinib is ongoing [21].

Conclusion

The broad variety of endocrine tumours clearly illustrates very different situations in terms of tumour growth and hormone excess. They share in common the need for a specialized imaging, biological, and sometimes pathological expertise for an accurate diagnosis. Treatment will depend on the tumour type and its secretory activities, going from simple monitoring to combination of various therapies aiming at controlling both secretion and tumour growth. For tumours requiring an active treatment, the best management will often have to be discussed in a multidisciplinary specialized team.

1.9

Genetic Aspects of Endocrine Disease

Trevor Cole

Historical Introduction

The recognition of a hereditary component in plant and animal phenotypes and human disease dates back many centuries but the start of genomic medicine may best be linked to the description of DNA's double helical structure reported by Watson and Crick in 1953 [1] (**Figure 1.9.1**). It is perhaps surprising that this actually predates other discoveries, now taken for granted, such as recognition of the correct number of human chromosomes (46 not 48), reported in 1956 by Tijo and Levan [2] and 3 years later the first papers reporting numerical chromosomal abnormalities in humans, accounting for three widely recognized clinical disorders: Down, Turner, and Klinefelter syndromes [3–5].

Karyotype analysis should be considered a genomic test in that it looks at the whole genetic architecture and the potential interrelationships therein, to identify their combined influence rather than the study of a focused single gene test which scrutinizes a specific genes sequence and function (adapted from the World Health Organization (WHO)'s definition) [6]. It took a series of significant technological advances over the next three decades to bring significant progress in sequencing power and enable the delivery of more widespread genetic and genomic testing. It is important for individuals wanting to incorporate these technologies into their clinical practice understand the differences between these two types of testing, which tests they should request and the differences in the information generated (**Table 1.9.1**).

The investigation of chromosomal disorders became more sensitive during the 1970s, firstly utilizing chromosome banding technologies and then in the 1980s and 1990s utilizing fluorescent labelled probes that could detect as subtle deletions, duplications, and translocations [7] (**Figure 1.9.1**). These remain important in detecting significant copy number variants (CNVs) in endocrinology, such as the 22q11 deletion resulting in hypoparathyroidism in DiGeorge syndrome (**Figure 1.9.2**) but will likely become redundant as microarray, and then whole genome analysis, becomes the universal platform.

In 1977 Fred Sanger described a technology, now known as Sanger sequencing, which utilizes radioactive or fluorescent tagging of chain-terminating dideoxynucleotides which are incorporated into DNA during its replication [8], and with further development of polymerase chain reaction (PCR) by Kary Mullis in 1983 [9] meant sequencing individual genes became more practical. The processes were, however, slow and expensive compared to currently available technology, as only a single sequence could be read on each analysis. Despite these limitations, in 1986 Royer-Pokora reported the first successful identification of a gene by positional cloning, a process by which the chromosomal location of a disease gene is continually refined by a series of experiments until a small enough number of candidates is reached within that region to enable individual sequencing of these genes. Three papers were published in 1986 and 1987 reporting the identification of the genes for chronic granulomatous disease, Duchenne muscular dystrophy and retinoblastoma [10–12].

Over the next two decades the rate and number of genes identified by these technologies gradually increased but there was a parallel technological development occurring in the non-clinical arena which would revolutionize human genetic discovery and service delivery. Massively parallel signature sequencing (MPSS) was being developed by a series of technological advances during the 1990s which subsequently resulted in the publication of Brenner *et al.* in 2000 [13]. Although it was several years before this became commercially available, the change in the diagnostic power are readily be illustrated by gene discovery before and after the introduction of this technology which we now know as next generation sequencing (NGS). Whereas Sanger sequencing analysed just one region of genetic coding in a single experiment, NGS could analyse many thousands of sequences simultaneously. There are currently several different NGS technologies available and readers wanting to understand more about the specific platforms are referred to the paper of Reuter *et al.* [14].

In 1989 Riordan *et al.* [15] reported the cloning and sequencing of the cystic fibrosis gene utilizing a Sanger-based approach. This was the culmination of research on thousands of families, by over 100 groups worldwide, and costing many millions of pounds. In

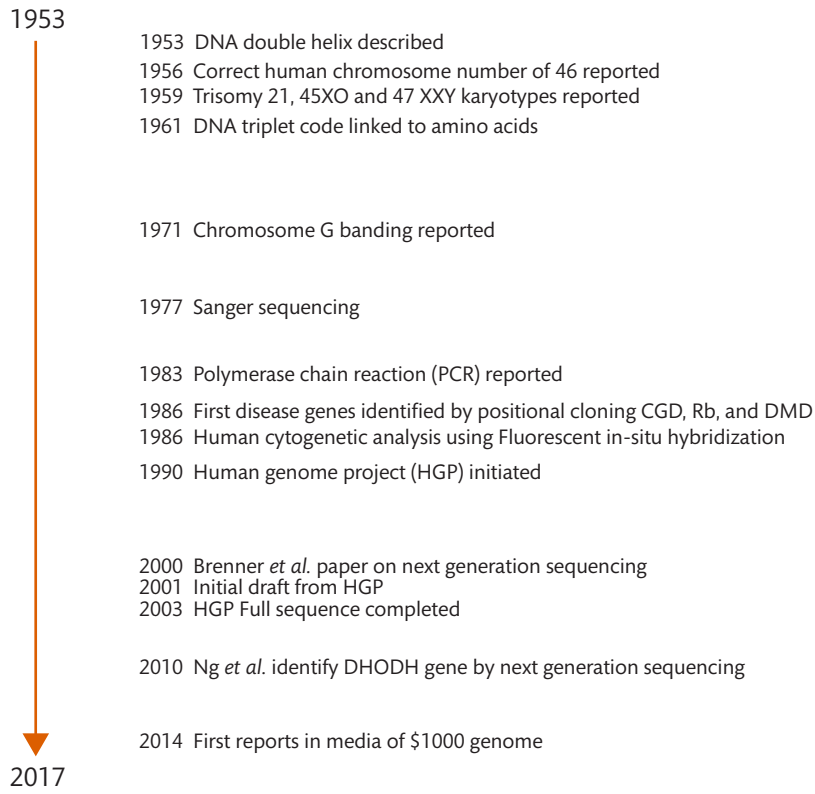

Figure 1.9.1 Timeline of genetic milestones.

2010, Ng *et al.* reported the identification of the Miller syndrome gene (DHODH), which was the work of a single collaborative group investigating four individuals in three families using NGS exome analysis, and was the first report of success using this approach [16]. The confirmed the suspected potential and many initiatives, including large scale national programmes were instigated.

In April 2011 the first patients were recruited into two national genomic projects in the United Kingdom [17] and Canada [18], which while not unique, they are illustrative of the rapid change occurring worldwide [19]. In the United Kingdom the Deciphering Developmental Disorders, was a national collaboration led by clinical geneticists and scientists from Sanger Institute in Cambridge [17] and in Canada the FORGE project (Finding of Rare Disease Genes in Canada) was led by genomic centres in Ontario, British Columbia and Quebec [18]. Within 18 months the FORGE project had discovered 41 novel genes not previously linked to human disease [18] and the DDD study has currently published over 100 papers [17]. Through projects such as these it rapidly became apparent the new challenge would not be sequencing our genome or identifying new genes but interpreting the 'avalanche' of data generated. How could this be delivered equitably, accurately and in a timely fashion across healthcare systems where it is estimated that 1 in 17 have a rare disease (a disease less frequently than 1 in 2000), of which the majority will have a genetic basis [20]?

Much of this work was underpinned by a multinational project planned to run from 1990 and 2005 to sequence the whole genome (The Human Genome Project) which published an initial draft in February 2001 and the full sequence in April 2003 [21]. This resulted in a re-evaluation of the number of human genes from the previously estimated number of over 50 000 to just over 22 000 but the function of many of these genes remains unclear. The cost of the project to sequence the initial genome of three billion base pairs was $3billion whereas now a whole human genome sequence can be generated for less than a $1000, although this does not necessarily include the larger cost of additional interpretation that is typically required (Figure 1.9.3).

The societal and political impact had also not gone unnoticed, for example, in 2009 the European Commission produced a directive to its 28 member states requiring them to develop and implement a Rare Disease Strategy for their citizens [22]. Without doubt this added impetus to numerous initiatives such as the 100 000 Genome Project which was launched in the United Kingdom in 2014 [20, 23] and a raft of clinical and laboratory initiatives across healthcare services worldwide. The challenge remains however how to deliver these aims across a whole population health system ensuring engagement of all health professionals not just those working within the specialism of clinical genetics [20, 24].

Delivery of Genetic Testing

There are significant challenges to the introduction of genetic investigation into the wider clinical setting. To date the majority of genetic testing has been organized through specialist clinical genetics services, only feasible as the number of individuals in whom testing was possible remained small. Genetic practitioners would evaluate the clinical history, assess the likelihood of an identifiable genetic cause being present based on the knowledge at that time and identify the most appropriate test. They would consent the appropriate member of the family for the initial test, typically an affected individual and not necessarily the initial consultant. The clinician would ensure individuals were aware of the medical and non-medical

Table 1.9.1 Examples of likely test selection dependent on presentation or disorder

Genetic mechanism	Disorder	Test type to order
Likely sex chromosome aneuploidy	Turner syndrome Klinefelter syndrome	Routine karyotype
Likely predictable copy number variant (CNV)	Disorder of sex development (DSD) and Wilm's tumour Hypoparathyroidism associated with DiGeorge syndrome	FISH for 11p13 deletion FISH for 22q11.2 deletion
Possible CNV—but not predictable	Developmental delay, short stature, and congenital anomalies	Microarray
Single gene disorder with known association with single gene [1]	MEN type 1 MEN2/MTC CAH due to 21 hydroxylase Deficiency Classical osteogenesis imperfecta (OI)[1] Achondroplasia short stature	Sanger sequence Menin Sanger sequence Ret oncogene Sanger sequence Cyp21A2 Sanger sequence Col1A1+ Col1A2 Sanger sequence FGFR3
Disorder that may be genetic but 'limited' heterogeneous aetiology—often less than 20 genes associated	Isolated hyperparathyroidism Isolated phaeochromocytoma DSD with undefined steroid pathway abnormality Atypical OI or bone fragility	NGS with interrogation of defined *HPT* gene panel NGS with interrogation of defined phaeochromocytoma gene panel NGS with interrogation of defined DSD gene panel NGS with interrogation of defined bone fragility gene panel
Disorder which may be genetic but extremely heterogeneous—often more than 100 genes	Syndromic short stature and developmental delay Syndromic obesity and/or overgrowth Undefined skeletal dysplaia[3]	[2]NGS with large panel of genes interrogated or alternatively Clinical exome or whole genome sequencing

[1] Some laboratories may do the sequencing on an NGS platform but only interpret specific relevant genes.
[2] Decision on whether NGS with extended panel analysis is by a clinical exome or whole genome may depend on laboratory informatics platforms.
[3] Decision on which test to select will be influenced by requesting clinicians diagnostic expertise, for example when investigating short stature due to a skeletal dysplasia the clinician might be expected to recognize and request specific test for achondroplasia rather than a skeletal dysplasia panel or clinical exome. For more complex clinical disorders, a local integrated genomic network (Figure 1.9.4) could help support and direct the most appropriate clinical test.

implications of the result to both affected family members, and those unaffected relatives who despite being asymptomatic may be at risk of developing the disorder in the future. This consent also needs to consider any relevance yet to be born individuals.

Such genetic counselling is both time-consuming and often outside the training and experience of non-genetics clinicians. The increased requirement for genetic or genomic testing, however, means that in future most diagnostic and precision management testing will have to be delivered by non-clinical geneticists. It is also pertinent that as more disorders and clinical presentations are recognized as having a monogenic aetiology or significant genetic component, the expert insight from non-clinical genetic specialists into the understanding of the natural history and management discussions, to support of clinical genetic colleagues will be equally vital if services are to be effective. The model of medical care delivery in the genomic medicine arena will therefore need to address the limited number of trained clinical and laboratory genetic specialists, necessary to deliver a service where up to 1 in 17 of the population may have a genetic disorder. Timely understanding of the genetic aetiology may have a direct impact on the optimal management, for example in some endocrine tumour or diabetic disorders. Reliance on clinical geneticists alone will delay the delivery of potential patient benefits from such expanding genomic knowledge.

Bowdin *et al.*, in their paper 'Recommendation for the integration of genomics in clinical practice' [25] provide some important and clear principles that would enable a model to be developed which is less heavily dependent on clinical genetic resources. They identify that the requesting clinician should be competent in the following broad areas: (i) obtaining an appropriate family history and genetic evaluation; (ii) ability to determine the most appropriate test; (iii) provide adequate information to obtain informed consent and iv the ability to interpret the genomic results and provide adequate post-test counselling, or identify a suitable source of such advice (Table 1.9.2).

In Tables 1.9.3 and 1.9.4 we provide some examples of the principles which may underpin the choice of test with some examples to illustrate these. The test and methodology of testing (Table 1.9.1) will be influenced not just by the evidence on detection rate and resources, but also the clinical validity and utility of the test, accessible funding, and potentially guidance within the healthcare system. Bowdin *et al.* [25] illustrate this by referring to the differences in the decision making between Canada and the United States, and even within insurance providers in the United States [25]. In other publicly funded services there may be a nationally agreed set of guidelines as documented in the United Kingdom on the UK Genetic Testing Network website [26], soon to be transferred to a national directory. Even with guidance on patient and test selection, nominating who should undertake testing, consent, and provide support mechanisms to help interpret and return results and develop patient pathways will remain a challenge. It is likely that integrated care networks or multidisciplinary team working with a 'local decision-making pathway' will improve the patient access and service delivery by identifying on-going professional education opportunities. It can also optimize data collection and provide clinical support to colleagues with hard to interpret or unexpected results (Figure 1.9.4).

Barriers and Solutions to Integrating Genomic Technologies into a Wider Healthcare Service

Evaluating the Cost

The cost is decreasingly seen as a barrier to genomic testing as the sequencing costs fall to levels at or below many other routinely ordered clinical tests. The milestone of whole genome sequencing (WGS) for under $1000 has been passed and some commercial ventures are advertising sequencing for half this figure or less which is similar to the

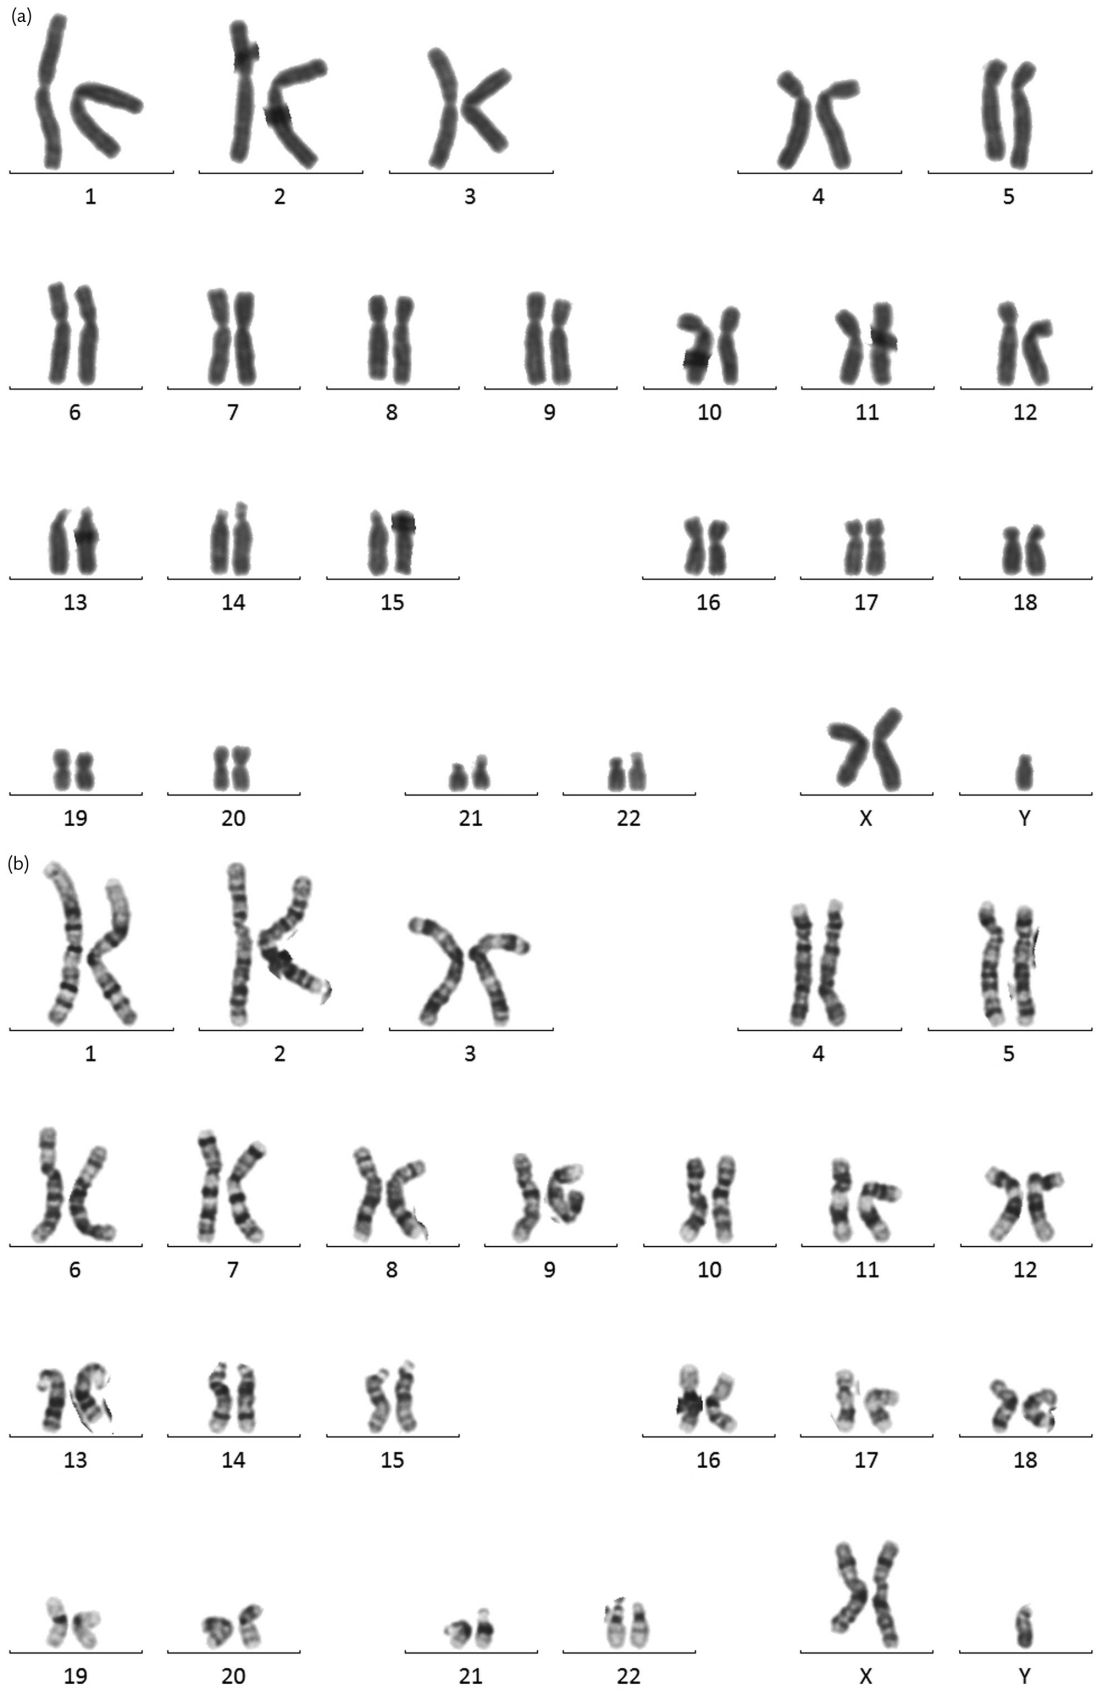

Figure 1.9.2 (a) Solid stain karyotype—47XXY Klinefelter syndrome; (b) G banded karyotyoe—47XXY; (c) Fluorescent in situ hybridization (FISH) —Di George syndrome del(22)(q11.2.q11.2). Inverted DAPI stain: the TUPLE1 probe is in red and for this hybridization, the 22q13.3 probe acting as a control in green. Table 1.9.2 Competencies recommended for clinicians ordering genomic tests as recommended by clinical genetics think tank (CGTT); Bowdin *et al.* (2016) and modified by Cole (2018)

Broad theme	Specific components
Clinical genetics evaluation	Take a family history Genetics focused history and exam Evaluate prior genetic tests
Determine which tests appropriate	Non-genomic—including metabolic Genomic—to include evaluation of specific genetic or genomic test
Pretest counselling and consent	Information on spectrum of disorder and natural history Possible test outcomes including primary and secondary coincidental findings Possible variants of unknown significance Make patient aware there may be non-medical implication such as insurance Obtain appropriately informed consent with a discussion that the information may be very relevant to other family members and ideally obtain permission to share this information in pretest consent
Post-test counselling and support	Personal ability to accurately interpret results and address patients' questions and concerns or alternatively have an identified route to provide such support with identified pathway in a network or with specialist genetic services

It is unrealistic to expect non-genetic specialist to be able to manage all these issues in all cases, but an identified mechanism to address them should be in place and the patient should be made aware that in some circumstances additional input may be required.

cost of MRI scans or endoscopies. These headline figures may not always clarify the extent of genes covered, the depth of coverage, or ability to detect CNVs, all factors which will significantly impact on the analytical validity and clinical utility of the test. Of at least equal importance when considering the cost to any health system, is the potential need for additional bioinformatic and clinical assessment and an increasing recognition that the clinical interpretation of many identified sequence variants still remains beyond our current knowledge. Therefore, a sound clinical focus on the testing that is required, at the current time remains a key component rather than relying solely on WGS as a 'scattergun' approach in all settings.

Despite these cautions the potential to personalize treatment can have a clear benefit as illustrated by a simple change of practice in the West Midlands region in the United Kingdom (population 5.5 million) (author's personal experience). In an 18-month period in 2006–2007, all apparently sporadic medullary thyroid cancer (MTC) cases were

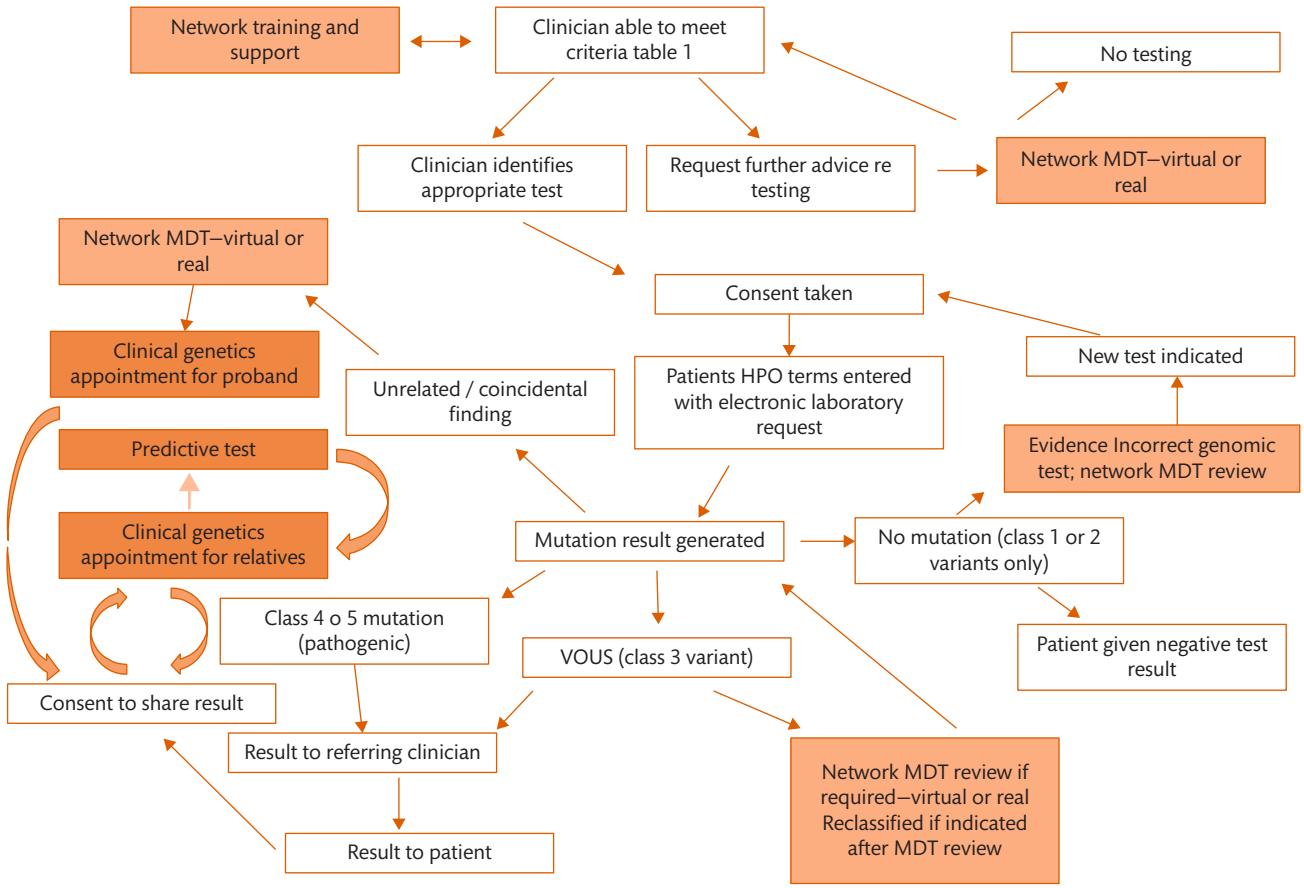

Figure 1.9.4 Example of integrated care pathway for genomic testing in mainstream healthcare. MDT active input in light orange filled boxes and from clinical genetics in dark orange filled boxes.

tested for the commonly recognized ret-oncogene mutations. This revealed pathogenic mutations in 3 of the 19 apparently sporadic MTC cases and cascade testing in the families, and uncovered 13 asymptomatic gene carriers of whom 11 underwent total thyroidectomies during this period. Pathological review identified 5 occult MTCs, 5 cases with C cell hyperplasia, and 1 normal result. Importantly, management was also modified to include parathyroid and adrenal surveillance. This illustrates the optimization of the test strategy, from confirming a previously unrecognized diagnosis (MEN2), delivering 'personalized management' and implementing effective and comprehensive cascade testing within the families (Table 1.9.3 and Box 1.9.1). While the initial cost to the health service from such systematic genetic testing is increased by subsequent consultant surveillance and surgery in asymptomatic patients, there are longer-term clinical and cost benefits, potentially many decades into the future, and typically in specialisms such as oncology and palliative care rather than clinical genetics and endocrinology where the management change was instigated and cost was incurred. All clinicians requesting genetic testing should strive to maintain the maximum clinical utility by utilizing all the potential information from informative results (Table 1.9.3 and Box 1.9.1).

Consent and Confidentiality

When requesting genetic testing, clinician instigating such testing should explain the potential outcomes and provides adequate information for the consultant, so that they, or their legal guardian in the case of children, can give informed consent. It is however important that we do not burden clinicians with a concept of 'genetic exceptionalism' such that they avoid genetic testing or refer all such cases to clinical genetics. Many blood, radiological, or pathological tests ordered by clinicians have unpredicted significances and impacts. The appropriate management of these possible outcomes, before and after results, are part of good holistic clinical care. Furthermore, a genetic diagnostic test may only be confirming a clinical diagnosis but can remove uncertainty and make possible choices for other family members. There are many instances of a diagnostic test only providing proof of the underlying condition, for example, patients presenting with an autosomal dominant (AD) family history and personal neurological diagnosis of Huntington's disease or an AD history of MTC indicative of MEN2. In these settings the genetic test does not reveal any 'unpredicted' information in the consultant, but can provide potential benefits to other family members. These tests therefore should be available to healthcare practitioners outside clinical genetics as long as they are able meet the requirements identified in Table 1.9.2, either personally or in collaboration with colleagues as part of a clinical pathway (Figure 1.9.3).

Asymptomatic family members requesting predictive testing will often have more complex issues to evaluate including the medical, psychological, and financial consequences the information may have for them and their families. In some instances, it may also have occupational or reproductive impacts and as such the counselling, consent, and testing may be better directed to clinical genetics services.

When obtaining consent for a genetic or genomic test the clinician should make the consultant aware that the result could well have an impact on other family members and where there is a clinical indication should, where possible, obtain the permission to share this information with relatives who may have the 'same genetic risk',

Table 1.9.3 Examples illustrating different impact of genetic results

Role of genetic testing	Example of disorder	Gene/Genes examined	Impact of identified mutation
Confirm diagnosis			
Example 1	Bone fractures	Col1A1 and Col1A2	Avoidance of incorrect diagnosis of non-accidental injury
Example 2	Disorder of sex development (DSD) Developmental delay (DD) Wilm's tumour (WT) and obesity	WT1 and contiguous gene deletion including BDNF	Confirm single unifying disorder
Precision management			
Example 1	Isolated Phaeochromocytoma	*SDH* and related genes, Ret-proto-oncogene, Von Hippel–Lindau (VHL), NF1	Surveillance for contralateral phaeochromocytoma and related tumour management, e.g. Thyroidectomy if Ret mutation +ve Renal surveillance if SDH or VHL mutation +ve Retinal and CNS management in VHL +ve
Example 2	Onset of diabetes in early adulthood	MODY panel of genes Including HNF1A	Trial of sulphonylurea rather than insulin
Example 3	DSD and DD	WT1 deletion	Surveillance for WT and renal function
Example 4	Isolated hypercalcaemia	CaSR	Avoidance of unnecessary investigation and inappropriate parathyroidectomy
Cascade testing and management			
Example 1	Isolated medullary thyroid cancer	Ret proto-oncogene	Cascade testing prophylactic thyroidectomy Parathyroid and adrenal surveillance
Example 2	For all scenarios above	First degree relative testing and cascade testing beyond if positive result in each tested relative	Reassure if de novo or individual tested is not a gene carrier. Implement appropriate management in proven gene carriers

Box 1.9.1 Three components to optimize clinical utility of genetic testing (somatic and germline findings)

Confirm precise diagnosis

Implement appropriate precision management (pharmacological or surgical intervention, surveillance, advice on the natural history or prognosis and genetic advice)

Implement cascade testing and management as appropriate to gene and genetic result in extended family. This includes scenarios of somatic genetic variant subsequently identified in the germline

and with anonymized databases to facilitate new interpretive knowledge. This is good practice and also provides a clear illustration of the potential impact of the possible outcomes to the consultant. These issues are often easier to discuss in the preresult setting rather than the post-test setting when the focus should be the consultant's own management. Patients may however refuse to share this information with family members. In our traditional medical model this right to confidentiality would be considered paramount but this absolute right has been questioned [26]. Non-disclosure could even result in one family member having information about a relative, of which the is relative themselves unaware. Examples might include obligatory female carriers of x-linked adrenoleukodystrophy, or a distant relative who recognizes the existence of an endocrine tumour syndrome in a second- or third-degree relative with non-penetrance in the intervening relatives, scenarios that could have profound medical implications.

Parker and Luccassen in 2018 [26] suggested that it may be inappropriate to see the information as belonging to the individual but rather belongs to the family, many of whom will share the same genetic information. The debate is illustrated by the range of published opinions, including the *British Medical Journal* (*BMJ*)'s 'head to head' in 2007 [27, 28] and nuanced differences between USA and Canadian patient surveys [29, 30]. The potential duty to inform family members, even after a patient has refused, is highlighted in the current UK high court case ABC versus St Georges Healthcare trust, in a family with Huntington's disease. This case and the broader issues are discussed by Mitchell *et al.* [31].

Thankfully such cases to date have been rare, but do illustrate that within the field of genomic medicine, some of our concepts around consent and confidentiality may be challenged. In many countries, professional guidance is currently being updated but in the meantime the clinician utilizing genomic investigations should be aware to the issues and the broader family considerations.

Our understanding of informed consent is also being challenged by what information can realistically be provided to the patient wanting to pursue WGS when offered as a diagnostic test. Coincidental findings, which are pathogenic mutations in genes unrelated to the clinical presentation, will become increasingly common on whole genome reports. The clinician cannot provide detailed information for consent on over 20 000 specific genes, especially as the function of many are not yet known and certainly many mutation specific phenotypes have yet to be identified. Future knowledge or family information may become available at a later date, such that variants that are difficult or impossible to assess at the current time may become readily interpretable. This should be included in the discussion with the patient.

Genomic investigation of broad phenotypic categories such as short stature or developmental delay, typical require the examination of hundreds or thousands of genes respectively. Within these huge panels there may be genes with unexpected consequences for the consultant, such as progressive degenerative disorders or tumour syndromes and even conditions which may be relevant to apparently unaffected parents. An example of the latter would be parents at risk of tumours due to carrying heterozygous BRCA2 mutations in a child with short stature and Fanconi's syndrome due to two pathogenic *BRCA2* mutations.

Microarrays also examine the whole genome and may identify CNVs in child with learning difficulties in an 'non-focused manner'. The coincidental finding of a 1 q deletion identified in a child with mild learning difficulties is illustrative. The deletion includes the gene *CDC73* which results in hyperparathyroid jaw tumour syndrome and is associated with a significant risk of parathyroid carcinoma (Figure 1.9.5). Without any previous history such a finding was completely unpredictable. This demonstrates the impossibility of pretesting consent covering all potential outcomes but the importance of making individuals aware of the possibility of unexpected or coincidental findings. There should be adequate post-test holistic service provision to address such scenarios. This is in lines with the principles laid out by Bowdin *et al.* [24].

Interpretation of Findings

Variants are Frequently Found but Commonly Not Significant

All humans have a unique pattern of genetic variation in both our coding and apparently non-coding DNA, for example in the paper on Ng *et al.* [16], each affected individual had over 1000 non-synonymous variants, a figure consistent with other large scale genomic sequencing projects [17]. Individuals not uncommonly have potentially pathogenic genetic changes in more than one gene which might account for the presenting phenotype [16, 17]. While it would be possible this represents a 'hybrid phenotype' or digenic inheritance (interaction of two non-allelic genes) a more likely explanation is that at least one variant is a coincidental finding. To aid accurate and consistent interpretation laboratory and clinicians need to draw on a number of tools as summarized in Table 1.9.4.

Epigenetics

Not all significant genetic variation will be detected by technologies such as microarrays, NGS, and methodologies to determine intragenic deletions or duplications. There are instances where the germline or somatic sequence remains unchanged but the gene expression is under epigenetic regulation. This typically results from modification by additions such as methyl side chains to the DNA or methyl or acetyl groups to the histones. These epigenetic changes maybe heritable or secondary to non-genetic influences and can alter many endocrine related genes [32] and are relative common mechanism in rare disorders of growth, hormone action and diabetes [33] (Table 1.9.5). Recognition of these clinical patterns may direct the clinician to alternative molecular genetic tests, such as looking at gene expression or methylation, to confirm the genetic aetiology.

Figure 1.9.5 Microarray result showing 1q deletion including CDC73. Courtesy of Graham Fews.

Coincidental Findings

The broader and less specific a genetic test the greater the potential for uncovering additional or unpredicted findings (Table 1.9.1). A single gene test for *MEN1* or *MEN2*, for example, if informative will only reveal information about those disorders. A panel test for isolated phaeochromocytoma may confirm a diagnosis of neurofibromatosis type 1, MEN2, or Von Hippel Lindau. As this later gene panel is relatively narrow, typically around 10–15 genes, these possibilities can be discussed in the consenting process. In comparison however when utilizing a gene panel for short stature or intellectual deficit, typically including between 100 and over 2000 genes, or a whole genome analysis counselling and consent cannot cover individual gene outcomes. The patient interaction should include an explanation of the possibility of either completely unexpected phenotypes, or in the case of whole genome analysis, the discovery of completely unrelated disorders. The latter are known as coincidental findings.

The clinician patient discussion should include not only the acknowledgement of such possibilities and their consequences, but also the potential strategy to deal with these. One possibility frequently proposed strategy to deal with such scenarios is an agreement not to look for additional findings or a patient request not to be informed of such coincidental findings, and informed only those findings related to the condition being investigated. Determining what might be relevant to the clinical presentation can

Calcium disorder	Pseudohypoparathyroidism 1b	GNAS abnormal maternal methylation

however be challenging. Furthermore, it leaves the managing clinician in the difficult situation of potentially having information on file, relevant to the patient's longer-term health, which has not been revealed. An added challenge to this solution is that coincidental findings may have significant medical and life-limiting implications to other family members. Failure to reveal significant genetic information to relatives has been the subject of past and present debates and legal cases worldwide [26, 27, 29–31]. This may potentially make such agreements less practical in the future.

An alternative approach is to ensure genetic testing is instigated only by clinicians able to explain these issues to the patient and working as part of a wider team with access to additional clinical and psychology support. Such additional expertise may only rarely be called upon but developing links to such a multidisciplinary team (MDT) will ensure rapid and appropriate access to clinical genetics, other medical-based specialties, and psychology services. The establishment of such MDTs or integrated care solutions will also support the discussion of hard to interpret genetic results and fulfil one of the suggested requirements from Bowdin *et al.* [25] (Table 1.9.2, Figure 1.9.3).

Conclusions

The increasing understanding of the genetic basis of much of human disease and falling cost of obtaining such information means genomics should be integrated in patient care. This will include both germline and somatic tissue testing which has the potential to make or refine a diagnosis, identify specific patient management or surveillance (personalized medicine) and alert members of the extended family to treatment or surveillance opportunities which can reduce their health own morbidity and risk of avoidable early death. The number of patients and wide spectrum of disorders where this is applicable means that delivery will be through a multitude of clinical specialities and settings. Many such services are not yet adequately developed nor are individual clinicians adequately trained or supported. The development of genomic MDT and integrated care pathways could address many of the delivery and training challenges and facilitate support and oversight by laboratory and clinical genetics with a process of gradually and iterative learning. It is vital that clinical services delivering both diagnostic and predictive genetic and genomic testing are aware of the complexity of issues highlighted earlier in this chapter and have in place solutions to address these.

Clinicians should not be swayed by unrealistic hype or blinkered to the remaining challenges and unknowns that lie in the field of genomics nor should they be deflected by fear or ignorance of the technologies available or uninformed statements that there are no proven benefits. Clinicians should be empowered to recognize the role of such testing, informed so they can select the most appropriate investigation or clinical root for such testing and apply the result to obtain the maximum clinical utility. This may be within their own clinical team or as part of a wider MDT dependent upon their knowledge and experience and the clinical scenario that is being managed. This is true in endocrinology and indeed all medical specialities.

Environmental Influences on Endocrine Disease

George Mastorakos, Markella Nezi, Djuro Macut, and Maria Papagianni

Introduction

During the last 60 years, chemical substances such as plasticizers, pesticides, detergents, paints, those found in metal food cans, flame retardants, cosmetics, and chemical waste have proliferated worldwide. Many can interfere with human and animal endocrine systems. Many natural products can also interfere with endocrine regulation (i.e. phytoestrogens). These chemicals are collectively known as endocrine disruptors (EDs). The public health risks related to EDs have raised justified concern and EDs have become the focus of major research.

Definition

According to the International Programme on Chemical Safety an ED is a chemical substance or mixture of substances that alters endocrine function(s) and consequently adversely affects health in an intact organism or its progeny [1]. It is important to distinguish permanent from transient endocrine interference by EDs. It is plausible to suggest that characterization as an ED should require a substance to change endocrine function(s) permanently, or to cause inherited changes in endocrine physiology. EDs interfere with the synthesis, secretion, transport, binding, action, and/or elimination of hormones involved in homeostasis, reproduction, development and/or behaviour [1]. Many are biologically active at extremely low doses, and their effects on humans, wildlife, and the environment have been the subject of close scrutiny internationally. EDs may cause, directly or indirectly, effects including infertility, abnormal prenatal development, precocious or delayed puberty, thyroid dysfunction, obesity, type 2 diabetes mellitus, behavioural disorders, and cancer. They can also alter nervous and immune system functions. ED Research is focused on three areas: (i) the 'time-window' of exposure to EDs, which is critical for the adverse outcome; (ii) the dose responses of EDs and their intracellular action; (iii) the ED-induced genomic or epigenetic modifications which affect offspring of exposed individuals [2]. Some EDs cross the placenta and are concentrated in the fetal circulation, while others are transferred from mother to infant through breast milk.

Historical Background

The existence of EDs has been known since the 1930s, when the oestrogenic action of some chemicals (e.g. bisphenol A; BPA) was shown in animals, and in the 1950s, dichloro-diphenyl-trichloroethane (DDT), a chemical pesticide, was reported to feminize roosters. In 'Silent Spring', an influential environmental science book of 1962, Rachel Carson presented examples of impaired development in birds, mammalian gonadal dysfunction, and human tumorigenesis. During the 1970s, the use of diethylstilboestrol (DES, a synthetic oestrogen) for prevention of abortion was common. Later, it was found that children of DES-treated women developed disorders such as vaginal carcinomas and infertility. The use of DES is now prohibited [3].

Mechanisms of Action

EDs affect concentrations and/or actions of hormones or their receptors. The most common mechanism of ED action is agonism at a hormone receptor, particularly the oestrogen receptor (ER) (e.g. BPA, DES), androgen receptor (AR) (e.g. vinclozolin) and aryl hydrocarbon receptor (AhR) (e.g. dioxins). Other EDs are competitive or non-competitive hormone receptor antagonists. Competitive antagonism usually leads to total receptor deactivation, while non-competitive antagonism causes the receptor to react more slowly or less efficiently. Typical antagonists acting at hormone receptors are the herbicides linuron and vinclozolin and their metabolites. EDs can also inhibit enzymatic hormone interconversion (e.g. aromatization of testosterone to oestrogen), induce hormone-metabolizing enzymes (e.g. cytochrome P450) or antagonize hormone binding to transport proteins, increasing bioavailability. Finally, EDs can induce receptor down-regulation or degradation [4].

Most Common Categories of EDs and Exposure Routes

The most common categories of EDs (Table 1.10.1) and their exposure routes are described next.

Polychlorinated biphenyls (PCBs): PCBs are synthetic organic chemicals formerly used as coolants and lubricants in transformers, capacitors, and other electrical equipment. Their use was banned in 1977, when their negative health effects became clear. They can still be found in old microscope or hydraulic oil, old fluorescent lighting fixtures, or electrical devices that contain old PCB capacitors. They can be inhaled when released from electrical devices heated during operation, ingested in contaminated food, or be absorbed through the skin. Infants can be exposed to PCBs through breast milk.

Phthalate esters: Phthalate esters, commonly called plasticizers, are used in plastics, rendering them more flexible and harder to break. They are found in diverse products including wall coverings, tablecloths, floor tiles, furniture upholstery, shower curtains, garden hoses, swimming pool liners, rainwear, baby pants, squeeze toys and dolls, shoes, automobile upholstery, packaging film and sheets, medical tubing, and blood storage bags. They are also added to cosmetics. There is risk of exposure by inhalation of air containing phthalate vapours or dust contaminated with phthalate particles, but minimal risk of exposure from drinking water due to low solubility in water. Phthalates can enter the body during medical procedures such as blood transfusions, kidney dialysis, intravenous fluid administration, or artificial ventilation. Elevated exposure has been documented in neonatal intensive care units [5].

Phenols-Bisphenol A: Bisphenol A is a light plastic with unique toughness, optical clarity, and high heat and electrical resistance. It has been used widely since the 1960s in eyeglass lenses, medical equipment, water bottles, CDs and DVDs, mobile phones, computers, household appliances, reusable food and drink containers, safety shields, sports equipment, industrial floorings, industrial protective coatings, can coatings, and electrical equipment. Although BPA is considered biodegradable, it can leach out of the lining in cans, potentially contaminating foods and liquids therein (3). Medical equipment may also contain BPA, and elevated BPA exposure has also been documented in neonatal intensive care units [6]. In 2011, use of BPA in baby bottles was prohibited in Europe. In France, from 2013, BPA was banned in food contacting materials for children up to 3 years old and from 2015 in all packaging, containers, and utensils in direct contact with food. However, the European Plastics Regulation (EU) authorizes use of BPA as a

Table 1.10.1 Effects of EDs on humans

Substances	Effects
***In utero* exposure**	
PCBs	Neuromuscular disorders, lower IQ, hypothalamic–pituitary–testicular axis dysregulation
Dioxins	Low birth weight, skin discoloration, bronchitis, developmental retardation
Phenols	Irregular menstrual cycles
Phytoestrogens, xenoestrogens, other substances with oestrogenic bioactivity	Ambiguous genitalia, obesity later in life, sexual differentiation problems, hormone-dependent cancers
DES	Transplacental carcinogenesis (cervicovaginal cancer in female offspring)
DDT, DDE	Low T_4 levels in infants
PCP	Altered thyroid hormone levels and thus, neurodevelopmental deficits
Nitrofen (pesticide)	Lung hypoplasia
Phthalate esters	Morphological abnormalities of male reproductive tract
Disruption in pubertal timing	
Lead	Delayed pubertal onset
PCBs, phytoestrogens, pesticides, BPA	Precocious female reproductive tract development
DDE, DDT	Earlier menarche
Disruption in reproduction	
BPA	Oocyte meiotic disturbances (i.e. aneuploidy), PCOS
Phytoestrogen genistein	Altered cyclicity, prolonged and abnormal cycles
Dioxins (TCDD)	Endometriosis
DES	Suppression of lactation
DDE, PCBs	Reduction of duration of lactation
EDs and cancer development	
Oestrogen-mimicking compounds	Breast cancer, Testicular cancer
PCBs, arsenic	Prostate cancer
Pesticides (i.e. atrazine)	Ovarian cancer
EDs and thyroid function	
BPA, PCBs, phytoestrogens	Hypo- or hyperthyroidism
EDs and obesity	
PCBs, pesticides, phthalates, BPA, metals	Weight gain
EDs and various functions	
BPA, phthalates, dioxins	Alterations in blood glucose

monomer for production of plastic with a specific migration limit of 0.6 mg/kg of food [7].

Dioxins: Dioxins are highly persistent in the environment. The most toxic is the 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin (TCDD), an unintentional by-product of many industrial processes involving chlorine, such as waste incineration, chemical and pesticide manufacturing, pulp, and paper bleaching. The major source of dioxins in the environment is waste incineration. Dioxin pollution is also encountered in paper mills where chlorine bleaching is used. People are exposed to dioxins by diet, especially meat and dairy products. Since dioxins are fat soluble, they bioaccumulate and climb the food chain. Dioxins can also cross the placenta and are present in breast milk [8].

Pesticides/Herbicides: Pesticides and herbicides such as atrazine, DDT, and trifluralin were once used widely. Atrazine is a white powder used to protect grasses and broadleaf plants from pests. It is water soluble and taken up by plants, and can be inhaled as dust or ingested through contaminated water, but is not absorbed through skin. DDT is extremely hydrophobic and strongly absorbed by soils, where its half-life ranges from 22 days to 30 years. Routes of loss and degradation include runoff, volatilization, photolysis, and aerobic or anaerobic biodegradation. In aquatic ecosystems it is quickly absorbed by organisms and soil or else evaporates, leaving little DDT in the water itself. Its breakdown products and metabolites, dichlorodiphenyldichloroethylene (DDE) and dichlorodiphenyldichloroethane (DDD), are also highly persistent and have similar properties. Trifluralin is a herbicide against grasses and some broad-leaved weeds. It is usually directly incorporated into soil, although some mixtures may be sprayed. Trifluralin may enter the aquatic environment predominantly *via* diffuse sources resulting from its recommended use (e.g. in agricultural run-offs bound mainly to soil particles). Industrial discharges, accidental spillages during transport, storage, and use are potential sources of trifluralin contamination.

Phytoestrogens: These are a diverse group of naturally occurring non-steroidal plant compounds with oestrogenic or antioestrogenic properties due to structural similarity with 17-β-oestradiol. They are important in plant defence systems, mainly against fungi. Foods with the highest phytoestrogen content are nuts and oilseeds, followed by soy products, cereals and breads, legumes, meat products, and other processed foods containing soy, vegetables, fruits, alcoholic, and non-alcoholic beverages.

Parabens: Parabens are esters of p-hydroxybenzoic acid used as preservatives in foods, drugs, and in cosmetics or deodorants; they may also be found in polyester fabrics [9]. The most commonly used in cosmetics are methylparaben, propylparaben, butylparaben, and ethylparaben. They can cross the skin and in animal studies parabens demonstrated weak oestrogenic activity. No direct link between parabens and cancer has been established despite numerous studies. According to the European Medicines Agency (EMA), methylparaben has not been associated with adverse effects on male or female reproductive organs in juvenile rats or in embryo-fetal development studies. The use of methylparaben in oral formulations up to 0.2% is not a concern for humans of any age. The EMA concluded that additional information for parabens is not necessary, however, further data are needed to evaluate potential risk of propylparaben in children below 2 years of age. The use of propylparaben-containing medicines in this age group must be justified on a case-by-case basis, by weighing the need for treatment against potential risk.

Polybrominated diphenyl ethers (PBDEs): These are used in manufacture of plastic products. Certain PBDE congeners are persistent, bioaccumulative, and toxic to both humans and the environment. The exposure of mice to low doses during intrauterine or neonatal brain growth induces irreversible changes in mental function of adults [10]. Polybrominated diphenyl ethers are not chemically bound to plastics, foam, fabrics, or other products in which they are used, making them more likely to leach out.

Effects of EDs on *In Utero* Development

Effects of *in utero* exposure to EDs are intensely studied. Exposure at critical 'time-windows' during development can cause various disorders, most of them irreversible. Several chemicals or chemical classes can cause neurodevelopmental abnormalities by interfering with neuroendocrine functions. These include PCBs, dioxins, metals, pesticides, phytoestrogens, synthetic steroids, and triazine herbicides. Any compound that mimics or antagonizes a neurotransmitter, hormone, or growth factor in the developing brain may adversely affect fetal neurodevelopment. The resulting deficit, which could include cognitive dysfunction, altered neurologic development, or sensory deficits, depends on the severity of the disturbance, for example of thyroid function, and the developmental period when exposure occurred (**Figure 1.10.1**) [11].

The classical example of endocrine disruption *in utero* producing adult disease is prenatal exposure to DES. Maternal treatment during pregnancy produces cervicovaginal cancer in daughters when in adulthood, and was the first demonstration of human transplacental carcinogenesis. Daughters of DES-exposed mothers also had functional and anatomical abnormalities of the uterus and fallopian tubes, with subfertility [12].

Exposure to DDE and its metabolites during fetal development is associated with lower cord serum T_4, emphasizing the need for further study of thyroid function, growth, and neural development in children exposed to high doses of DDT. Neuromuscular disorders have been reported in infants exposed to PCBs *in utero* and during lactation, and lower IQ in children of 4 to 11 years of age prenatally exposed. Another chemical, related to BPA and named pentachlorophenol (PCP), alters thyroid hormone concentrations in newborns and may cause neurodevelopmental defects.

In 1968 contamination of rice oil with dioxins in the Japanese city of Yusho led to low birth weight, skin discoloration, bronchitis, and developmental retardation in neonates, and hypoactivity and hypotony in infants. Intrauterine exposure to dioxins might derange thyroid function and thus newborn development [11].

Maternal exposure to environmental pollutants during pregnancy and high oestrogenic bioactivity in newborns' serum have implicated fetal exposure to EDs in ambiguous genitalia development [12]. Perinatal exposure to BPA causes irregular cycles in mice, although insufficient evidence exists to confirm this in humans [13]. Perinatal exposure to EDs with oestrogenic activity is moreover proposed to induce later life obesity [14].

Phyto- and xeno-oestrogens often inhibit steroidogenic enzymes including 3β- and 17β-hydroxyl-steroid-dehydrogenase, aromatase, sulphatases, and sulphotransferases. Both phyto- and

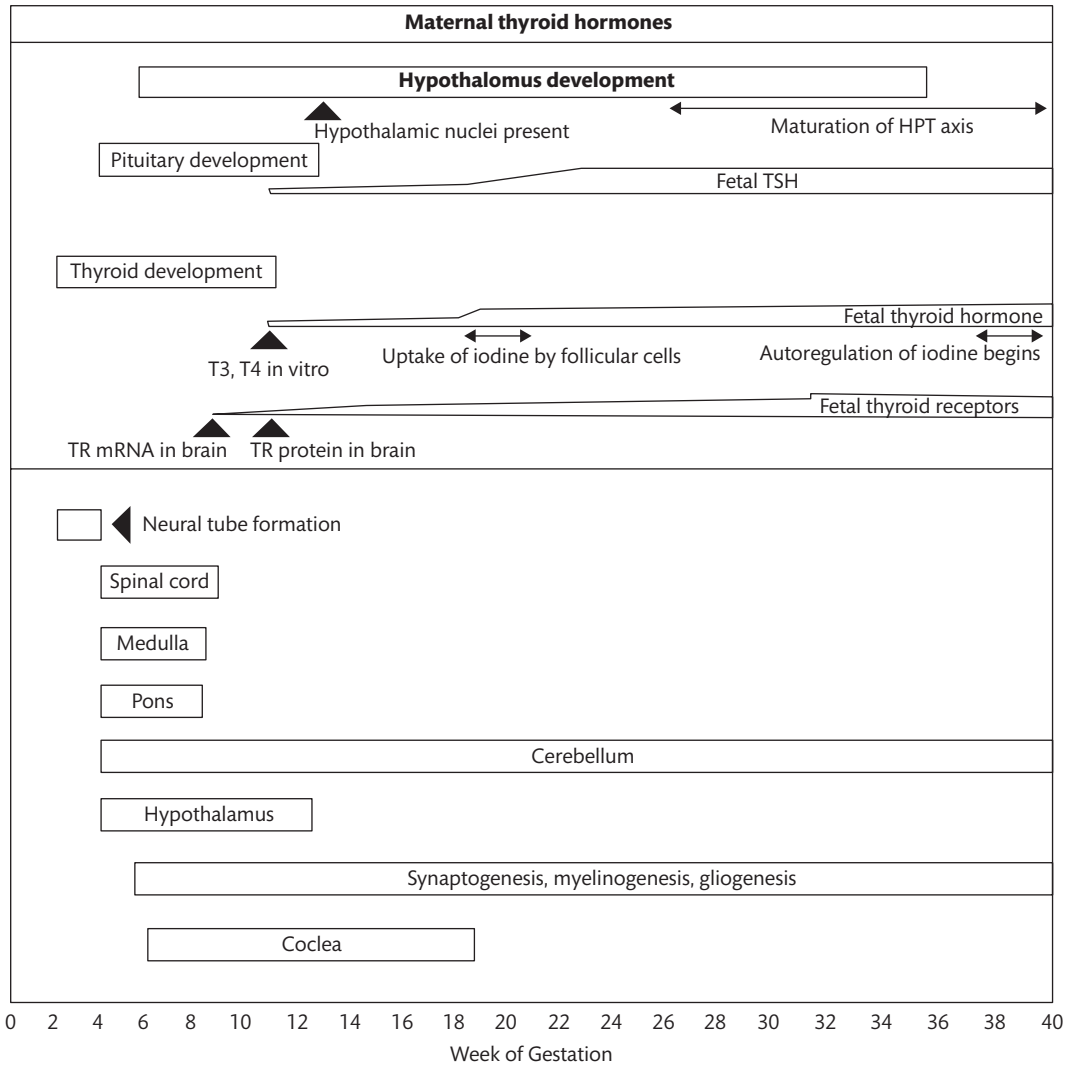

Figure 1.10.1 Fetal development of the hypothalamic–pituitary–thyroid axis during gestation with reference to development of thyroid hormone-dependent parts of the nervous system. Exposure to EDs at critical time-points may cause irreversible disorders.

xeno-oestrogens can also modulate intracellular signalling pathways, thereby inhibiting expression and activity of steroidogenic enzymes. Modulation of enzyme activity could impact sexual differentiation and development as well influencing risk of hormone-dependent cancers [15].

In utero exposure to phthalate esters is associated with morphological abnormalities of the male reproductive tract, including decreased anogenital distance, cryptorchidism, hypospadias, reduced Leydig cell numbers, and decreased testicular testosterone secretion. Testicular androgen signalling may be impaired through suppression of the hypothalamic–pituitary–testicular (HPT) axis. Exposure to DES impaired HPT signalling in rats, reducing plasma testosterone and increasing plasma follicle-stimulating hormone (FSH). The HPT axis is also disrupted in rats by PCB-169 exposure *in utero*, decreasing spermatogenesis, Leydig cell number, and plasma testosterone concentrations. Another herbicide, atrazine, with antiandrogenic and oestrogenic properties, exerts various adverse reproductive effects in rats including reduction of testicular testosterone secretion. Atrazine has low affinity for androgen and oestrogen receptors, reduces androgen synthesis, and enhances oestrogen production *via* increased intratesticular aromatization of androgens in both Leydig and Sertoli cells [16].

Numerous studies have assessed the relationship between EDs and birth weight, with inconsistent evidence of an association between reduced birth weight and exposure to insecticides, herbicides, or low-level PCBs but not DDT [17, 18]. Evidence of low birth weight related to phthalates, BPA and PBDE is similarly inconsistent [17]. Several studies have reported a relationship between exposure to PCBs, pesticides or phthalates and preterm delivery [19, 20], however further studies reported no association or even a positive association between phthalates and length of gestation [21].

Effects of EDs on Pubertal Timing

Falling age of onset of puberty and increased incidence of precocious puberty have been noted over recent decades in many countries, and cannot be wholly explained by factors such as increasing adiposity or changing living conditions. EDs are a suspected major contributing factor [22]. Recent studies have revealed an impact

of EDs on pubertal timing in both males and females, particularly for oestrogenic or antiandrogenic compounds [23]. Exposure may be gestational, lactational or juvenile, and EDs can disturb the hypothalamic–pituitary–gonadal axis through negative feedback to hypothalamus and pituitary as well as through direct gonadal effects. Lead exposure has been associated with delayed puberty, while exposure to phytoestrogens, PCBs, pesticides, or BPA was implicated in precocious female development. In male rodents, transient neonatal androgen exposure reduced testis weight and testosterone production [23].

A study of adolescent girls in Canada revealed that exposure to chemicals such as PCBs is associated with oestrogenic phenomena and may affect menarche. Lead was associated with a delayed median age at menarche, when controlling for other toxicants, age, and socioeconomic status. However different effects may occur by exposure to different doses of EDs [24]. Age at menarche is reduced in girls exposed to oestrogenic organochlorines, but discerning the exact contribution of these substances to precocious menarche is complicated by the numerous environmental variables influencing menarche. A study of women exposed to DDE through Great Lakes fish consumption found a reduction of one year in the age of menarche for each increase of 15 mg/L serum DDE, while in Chinese textile workers a 10 mg/L serum DDT increase was associated with 0.2 year reduction in menarchal age [13]. In the United States, in 1151 girls aged 6 to 8 years assessed for pubertal development, positive associations between low molecular weight urinary phthalate metabolites and breast and pubic hair development were demonstrated [25]. An inverse relationship between high molecular weight phthalates and pubic hair development was reported, but no association between BPA and pubertal development was found. A smaller study of Turkish boys demonstrated a greater concentration of high molecular weight phthalates in boys 11 to 15 years old with pubertal gynaecomastia compared to controls [26].

Effects of EDs on Female Reproduction

The impact of EDs on human fertility remains controversial. Ten years ago, because mice housed in damaged polycarbonate plastic cages were shown to exhibit a high frequency of oocytes with meiotic disturbances, oocyte-damaging effect of the oestrogenic plasticizer BPA was investigated. When BPA was added to water of mice in intact cages, similar oocyte meiotic disturbances were induced, some causing aneuploidy. Other EDs such as DES have also been implicated in meiotic disturbances.

Takeuchi *et al.* reported that plasma BPA concentrations were increased in both non-obese women with polycystic ovary syndrome (PCOS) and obese women with or without PCOS compared to non-obese women without PCOS [27]. The same authors reported an association between BPA exposure, complex endometrial hyperplasia, and endometrial cancer [28], although another study found lower BPA concentrations in patients with premalignant complex endometrial hyperplasia potential than in either control or simple endometrial hyperplasia groups. BPA may thus represent one of the many underlying causes of PCOS, perhaps acting as a modifier to worsen symptoms or contributing to the phenotype in genetically predisposed women [29]. A strong association between BPA and both plasma androgen concentrations and insulin resistance indices has been reported, implicating BPA potentially in these two major components of PCOS pathophysiology. It is also known that women with ovulatory dysfunction have higher serum BPA concentrations than normally ovulating women [27] and that both have lower BPA concentrations than men [30]. BPA binds sex hormone-binding globulin, competing with natural androgens and increasing bioactive androgen concentrations [31].

Menstrual cyclicity may be perturbed by EDs by other means also. Experimental studies of exposure of neonatal mice to physiologically relevant concentrations of the phytoestrogen genistein caused prolonged and abnormal cycles in adult animals. In humans, altered cyclicity and adult simultaneous exposure to persistent organic pollutants and pesticides have been linked. Studies examining the influence of organochlorine pesticide exposure on cyclicity and fecundity suggest that organochlorine exposure shortens menstrual cycles, while women exposed to hormonally active pesticides (non-organochlorine) have a 60–100% increased odds for long cycles, intermenstrual bleeding, and missed menstrual bleeds.

EDs acting upon the human uterus produce structural changes including in development of uterine leiomyomas, while on the other hand consumption of phytoestrogens, such as those in soy, in a Japanese study was associated to decreased hysterectomy rates, implying a potential uterine protective effect of modest phytoestrogen consumption.

Finally, there appears to be a correlation between ED exposure and lactation: Exogenous oestrogens such as DES effectively suppress lactation [12], and duration of lactation is reduced in women with elevated serum concentrations of PCBs and DDE in a dose-dependent manner [13].

Effects of EDs on Male Reproduction

Significant toxicologic data from laboratory and wild animal studies suggest that exposure to certain EDs is associated with male reproductive toxicity, manifesting as abnormalities of the reproductive tract (cryptorchidism, hypospadias), reduced semen quality, and impaired adult fertility [32]. Endocrine disruption of spermatogenesis may be accounted for by four mechanisms, including: (1) epigenetic changes to the genome; (2) apoptosis of germ cells; (3) dysregulation of androgenic signalling; and (4) disruption of Sertoli and other spermatogenesis supporting cells [16]. The effects of EDs in male reproductive anomalies are presented in **Table 1.10.2**.

The 'endocrine disruption hypothesis' suggests ED exposure during fetal, neonatal, and adult life perturbs development of male reproductive organs, altering semen quality and reproductive hormone production [33]. Many studies in rodents have supported this, demonstrating that prenatal and perinatal exposure to EDs such as BPA, phthalates, and alkylphenols causes genitourinary developmental anomalies [34], decreased epididymal [35], and increased prostate weight [35], lower sperm production [16] and, in some cases, cryptorchidism. Shorter anogenital distance and smaller testicular and penile size are also described [36]. Neonatal ED exposure can decrease sperm motility and change morphology [37], including induction of abnormalities in the acrosomal granule and nucleus in older spermatids and spermatozoa, with attendant decreased height of the seminiferous epithelium. ED exposure of pubertal rodents

Table 1.10.2 Effects of EDs on male fertility

Compound	Outcome
Dibromochloropropane	Azoospermia and oligospermia Decreased motility and morphology Elevated FSH and LH Deficit of male births
Ethylene dibromide	Decreased sperm counts
Chlordecone (kepone)	Oligospermia, decreased sperm motility
Perchloroethylene	Dose-related morphological changes
Carbaryl	Impaired semen quality
Ethylene glycol ethers	Decreased sperm counts Decreased fertility
TCDD	Reduced serum testosterone, increased LH Deficit of male births
p-Nitrophenol	Decreased sperm concentration Decreased percentage of motile sperm Increased serum LH

has been correlated with decreased epididymal spermatozoa [38], and testosterone concentrations [38], increased testicular apoptosis, and loss of seminiferous epithelium. Finally, adult ED exposed rats show decreased epididymal spermatozoa concentration, sperm count, epididymal weight and testosterone concentrations along with increased luteinizing hormone concentration [39].

In animal models, there is thus substantial evidence for adverse effects on male reproduction for several EDs, but direct evidence from human studies is required to prove that EDs cause adverse effects on the male reproductive system. Human studies are challenging, however, because of the complexity of the field, and a recent systematic review of published evidence was unable to clarify the impact of EDs on human male reproductive health [40].

Effects of EDs on Cancer Development

There is increasing concern about cancer development after ED exposure. Gestational and perinatal exposures may have long-term effects on the endocrine system that influence tumour development later in life. Not only does the synthetic oestrogen DES cause vaginal adenocarcinoma in female offspring and extensive prostatic squamous metaplasia in male offspring of exposed mothers, but elevated gestational concentrations of natural oestrogens have been associated with increased incidence of breast cancer in adulthood [41].

Many studies have investigated the effect of underarm cosmetic products (UCPs) on breast cancer. Active ingredients in most UCPs are aluminium-based compounds such as aluminium chloride and aluminium chlorohydrate. Frequent use of UCPs may lead to aluminium accumulation in breast tissue, and in an Austrian study, women who reported UCP use several times a day starting under 30 years old were reported to have increased risk of breast cancer [42]. Developmental mammary toxicants may increase mammary tumour risk if they alter circulating or intratissue hormone concentrations, receptor expression, hormone transport, or hormone metabolism to alter responses to endogenous hormones or growth factors. Many oestrogenic environmental chemicals have been measured in human breast tissue and could be associated with increased breast cancer risk, however, although animal models support this point of view, new studies are needed to clarify the role of EDs in the human breast. Investigation of the impact of multiple oestrogen-mimicking compounds, at varying doses is required. New research is also needed to clarify whether the type of ED is the key cancerogenic factor, or if the exposure time and route is rather most important in cancer development.

Studies in the last decade provided no evidence of association between PCB exposure and breast cancer. No association was found either between DDT, DDE, and breast cancer, but further studies are needed. The impact of phytoestrogens on breast cancer risk is controversial. Some studies demonstrate an association with breast cancer, while others suggest a protective effect of these compounds [43].

Initial suspicions that testicular germ cell cancer (TGCC) may be related to early life exposure to environmental oestrogens and/or antiandrogens, while logical, are currently supported by little evidence. The dramatic recent increase in TGCC incidence does indicate that environmental and lifestyle factors are likely important but no compelling evidence implicating environmental oestrogenic or otherwise hormonally active substances to this rise in Western nations has emerged. More studies are warranted, however, as the rarity of the cancer, the long lag time between the presumed fetal sensitive period and the appearance of the cancer, and the lack of a good animal model have greatly hindered understanding.

It has been suggested that the exposure to environmental chemicals such as phthalates may impair semen quality, and exposure may coincide with development of testicular cancer, cryptorchidism, and hypospadias [44]. A case–control study did not find any association between serum organochlorine concentrations and risk of TGCC, but did find that organochlorine concentrations in mothers' peripheral blood decades after their sons' birth were predictive of increased risk in their sons [45]. It is plausible that *in utero* exposure to endocrine disruptor compounds (EDCs) is the aetiological exposure window. The exact contribution of pesticide and ED exposure to development of testicular cancer has also not been fully elucidated, although genetic and environmental factors have been implicated in reduced sperm counts and cancer development. Once again, the 2–3-decade latency between fetal exposure and adult cancer appearance is a major challenge for study design, highlighting the value of large-scale epidemiological approaches [44].

Increasing evidence both from epidemiological and animal studies suggests that EDs may influence development or progression of prostate cancer. These effects appear largely linked to oestrogen signalling, either *via* interaction with ERs or influences on steroid metabolism and thus oestrogen concentrations. In human studies, exposure to PCBs or inorganic arsenic have been associated with elevated prostate cancer risk, although risk seems to be increased only by exposure during critical developmental 'time-windows' (*in utero*, neonatal, peripubertal). Thus, infants and children may be considered a population highly susceptible to increased risk of later prostate cancer due to ED exposure [46].

Ovarian cancer development may also be influenced by hormone action, and pesticides with relevant endocrine-disrupting activity remain widely used in some countries. Research to date most strongly suggests a link between atrazine and ovarian cancer risk, but other environmental and occupational exposures may also be associated and require further study [47].

Effects of EDs on Thyroid Function

The existence of many thyroid disrupting chemicals has been proven in animal and human studies. Disruption occurs at many different levels of thyroid hormone synthesis, binding, action, and metabolism. The most common EDs that affect thyroid function are BPA, pentachlorophenol, PCBs, and phytoestrogens. Most studies of EDs and thyroid physiology were performed in rodents, with only some in humans. A substantial amount of information, albeit not conclusive, has thus been gathered about HPT axis perturbation by EDs. They can target the Na/I symporter, deiodinases, transport proteins and nuclear thyroid receptor (TR) and have been implicated in hypo- or hyperthyroidism, thyroid nodule formation, and thyroid tumorigenesis. Disruption of thyroid hormones during fetal life by exposure to EDs *in utero* may also produce irreversible developmental disorders including structural and functional brain abnormalities with postnatal behavioural changes.

Isolated measurements made during pre- or postnatal period cannot accurately test the cumulative or synergistic properties of EDs during these periods. However, much of the T_4 circulating in the fetus is of maternal origin and chemicals altering maternal thyroid function seem to be associated with impaired fetal development. Thorough investigation needs to take into account maternal physiological changes during pregnancy required to meet the needs of the conceptus in terms of energy supply and waste elimination. Three different compartments—maternal, placental, and fetal—interact closely during pregnancy and they should all be approached as one entity [11]. Limited data to date do not permit firm conclusions about the effects of EDs on thyroid function, and more research will be of crucial importance [11].

Effects of EDs on Obesity Development

The role of environmental chemicals on obesity development is emerging as an area of research primarily focusing on identification of obesogens. Obesogens are defined as chemicals which influence energy balance and/or lipid homeostasis to promote adipogenesis and lipid accumulation, and experimental evidence supporting this action of numerous chemicals is growing [48]. Many mimic endogenous lipophilic hormones which exert effects via members of the nuclear receptor superfamily, and environmental oestrogenic chemicals such as BPA and nonylphenol have been shown to promote differentiation and/or proliferation of murine preadipocyte cell lines.

The hypothesis that environmental chemicals could be responsible for the obesity pandemic was first introduced by Paula Baillie-Hamilton in 2002, based in part on evidence from toxicologic studies in which low-dose chemical exposures were associated with weight gain in experimental animals [49]. More recent studies have shown that chemicals including pesticides, organophosphates, PCBs, polybrominated biphenyls, phthalates, BPA, heavy metals, and solvents might cause weight gain by interfering with weight-controlling hormones, by altering sensitivity to neurotransmitters or by altering activity of the sympathetic nervous system. However, more research is needed.

Biological effects of some EDs may be prolonged in obese individuals due to retention in adipose tissue. This can exacerbate disruptive effects of fat-soluble toxicants, such as PCBs and dioxin-type compounds.

Other Effects of EDs

Lately, it has been shown that EDs might affect other systems such as the immune system and the endocrine pancreas. For example, EDs may be involved in autoantibody production by B1 cells and could be an aetiologic factor in development of autoimmunity. Other studies suggest that concentrations of BPA, phthalates, dioxins, and persistent organic pollutants are correlated with altered blood glucose homeostasis in humans [50], and in other studies EDs have been connected with diabetes and cardiovascular diseases. Dioxins, pesticides, and BPA can also cause insulin resistance and altered β-cell function in animal models [51].

Conclusions

The impact of EDs has been a matter of concern for 60 years. However, research remains challenging due to the multiple environmental effects seen on humans, due to differences in genetic susceptibility, and due to varying routes and durations of exposure. The exact time-point of exposure is crucial. *In utero* exposure may cause irreversible outcomes. Experimental studies may furthermore not agree with human studies due to different responsiveness of laboratory animals used. More research is needed to clarify mechanisms of ED action. Ultimately a choice must be made between short-term benefits of technological advances and global quality of life rooted in respect for the environment.

Endocrinology, Sleep, and Circadian Rhythms

Georg Brabant and Henrik Oster

Introduction

Endogenous circadian rhythms enable organisms to prepare for predictable environmental changes brought about by the Earth's rotation around its axis by temporally modifying behavioural and physiological functions—including the endocrine system [1]. One of the most obvious examples of circadian behaviour is the sleep–wake cycle, closely linked to diurnal variations of locomotor activity, body temperature regulation, and water/food intake. Even subtle changes in these circadian cycles may lead to detrimental effects. Such causative relationship between these changes and adverse biological effects have been obtained not only from mutations characterized in genes responsible for the generation and the integration of circadian rhythms, but also from observational studies where circadian rhythmicity was experimentally changed. Life in modern societies tends to increasingly ignore natural time cues and these environmental insults are increasingly recognized as the underlying mechanism for many pathophysiological changes and a higher susceptibility to disease. Focusing on endocrine-related effects, this chapter will highlight our current understanding of the genetic mechanisms of circadian rhythms, their integration with the light–dark cycle, and their links to sleep-related changes.

Mechanisms Underlying Circadian Behaviour and Definitions

Definitions

Rhythmic circadian (from *circa diem* (lat.)—'about a day') behaviour is not restricted to humans, but can be detected in most animals, plants, and even in prokaryotes. Circadian rhythms synchronize biological processes to the day–night (or light–dark) cycle of the natural environment. In mammals, it was originally believed that only specialized neurons of the hypothalamic suprachiasmatic nucleus (SCN) are able to induce circadian behaviour, but recent detection of rhythmicity in most peripheral organs or cells have challenged this view. The detection of clock and clock output genes in these peripheral cells and of rhythmic behaviour when time cues from the SCN are missing suggests a general endogenous pattern. In the current model, the SCN integrates information about the external light–dark cycle and synchronizes a ubiquitous network of cellular clocks throughout the body with each other and with external time. At the cellular level, these clocks coordinate physiology through rhythmic activation of transcriptional programmes. Approximately 5–10% of genes in a given tissue show such cyclical circadian behaviour. It has been estimated that across the whole organism, 40–50% of all genes are rhythmic in at least one tissue [2].

The time interval between two peaks of an individual circadian rhythm defined as its *period* is synchronized to the 24-h cycle by external time cues, so-called *Zeitgebers*. In contrast to the SCN, which integrates time cues mainly from the light circle, peripheral cells are insensitive to light and are predominantly regulated by internal *Zeitgebers* such as hormones or autonomic signals, and the timing of

energy intake. When these time cues are missing, temporal coordination follows the endogenous sustained rhythm provided by the SCN and—under specific conditions—individual circadian rhythms may even dissociate following their own internal pace. These *free-running rhythms* have been detected in experiments with volunteers kept in long-term isolation from all *Zeitgebers*. Depending on the exact experimental conditions, free-running rhythms in humans are estimated at a period length of 24–25 h, with individual rhythms reported to show period lengths even beyond 30 h [3].

One of the most striking real-life conditions where synchronization of circadian rhythms is temporarily lost is *jetlag* due to a transmeridian flight travel. Under jetlag conditions, internal and external time do no longer match and the internal clock system transiently becomes uncoupled during the following adaptation phase. Typical jetlag symptoms involve fatigue, immune suppression, mood disorder, and gastrointestinal dysfunction. There are multiple other examples for a weakening of the coordination of circadian rhythms including (night) shift work or extreme lighting conditions during winter or summer in high-latitude regions—both of which favour the development of metabolic and mood disorders.

With the recent characterization of the molecular mechanisms' underlying circadian rhythmicity mutational changes have been described, affecting the circadian mechanism in all cells. This may result either in shorter or longer than expected underlying rhythms, alter coordination between internal and external rhythms or between different tissues, or external time cues may no longer be able to optimally synchronize circadian rhythmicity under specific conditions such as given earlier. The so-called *phase angle*, defined as interval between a reference event like the beginning of the night and the peak of a given rhythm, is altered. It can be shifted to an earlier time, i.e. become *phase advanced*, or may be prolonged and become *phase delayed*. Every individual appears to have a given phase angle of its sleep–wake rhythm relative to external time which determines its *chronotype*. Morning ('lark') or evening ('owl') types have been characterized in humans who differ by up to 4 h in their optimal cognitive function and other physiological peak and trough performances due to the setup of their molecular clock [4].

Molecular Mechanism

Seminal work in plants, flies, mice, and humans on the genetic basis of circadian behaviour led to the independent discovery of the first genes involved in circadian behaviour, from non-vertebrates to mammals. The first clock gene, *period*, was identified in a behavioural mutagenesis screen in the fruit fly *Drosophila melanogaster* by Seymor Benzer and his student Ronald Konopka in 1970 [5]. While the different components of the circadian clock system differ between species, the principle makeup appears very much conserved across most multicellular organisms, from plants to mammals. At its core, the circadian clock consists of interlocked transcriptional–translational feedback loops driving 24-h rhythms of transcriptional activity regulating cellular physiology. For their unravelling of this principle of molecular clockworks, Michael Rosbash, Jeffrey Hall, and Michael W. Young received the Nobel Prize for Physiology or Medicine 2017 (https://www.nobelprize.org/nobel_prizes/medicine/laureates/2017/).

The first mammalian clock gene was described in 1994 by Joseph S. Takahashi in mice [6]. Further molecular components of the mammalian circadian clock were unravelled in the following years building a current working model of how this clock functions at the molecular level, even though there are still many open questions remaining. In brief, two basic-loop-helix transcription factors, circadian locomotor output cycles kaput (CLOCK) and its binding partner brain and muscle ARNT-like 1 (BMAL1; also known as aryl hydrocarbon receptor nuclear translocator-like or ARNTL) drive the expression of three *Period* (*Per1–3*) and two *Cryptochrome* (*Cry1, Cry2*) genes during the day. As monomers PER and CRY proteins are highly unstable and, therefore, with a delay of several hours, PER and CRY proteins heterodimerize and translocate into the nucleus where they inhibit their own transcription following interaction with the CLOCK–BMAL1 complex. Subsequently, during the dark period, the PER-CRY repressor complex is degraded, and a new cycle of transcription is initiated. The period of one such cycle approximates 24 h. This primary feedback loop is stabilized by a second negative feedback through the nuclear hormone receptors REV-ERBα/β and RORα. REV-ERBα/β, direct targets of CLOCK-BMAL1, are strong inhibitors of *Bmal1* transcription while RORα (whose transcription is also activated by CLOCK-BMAL1) enhances *Bmal1* transcription. At least two further accessory loops have been described. This basic feedback regulation is modulated by a large number of additional factors that change the kinetics of the feedback by altering the stoichiometry of clock protein complexes. During the late afternoon and night, PER proteins are progressively phosphorylated through key kinases such as casein kinase 1δ and ε (CSNK1δ; CSNK1ε). These phosphorylation steps are crucial for the degradation of clock proteins via the proteasomal pathway. Mutants in any members of these regulators may alter the kinetic of the circadian process and result in either short or long periods. Figure 1.11.1 schematically illustrates this process. In addition, more recently the critical importance of circadian changes in histone H3 acetylation and chromatin remodelling for circadian transcription of CLOCK-BMAL1 target genes has been recognized. It supports an intimate link between the autoregulatory feedback loop and chromatin remodelling (for a recent review, see [7]).

Mechanisms of Circadian Synchronization

Role of Light and the SCN

While the current view prevails that biological clocks are present in most—if not all—cells of the body, the key importance of the hypothalamus for the integration of circadian rhythms is undisputed. Targeted ablation of hypothalamic nuclei including the SCN, the ventrolateral preoptic, and dorsomedial nucleus clearly indicates that a normal patterning of the sleep–wake cycle, locomotor behaviour, feeding, and the circadian secretion of hormones is no longer observed. Using the same molecular instrumentarium observed in many cells, the SCN appears to be the master regulator of circadian behaviour. This may be based on the extraordinarily tight coupling of rhythms between the cellular clocks in this tissue and the ability of these clocks to respond to light which has been shown for the expression of the clock genes, *Per1* and *Per2*. While SCN clock rhythms—including the rhythmic activation of *Per* genes—persists even in the absence of external light input, this photic regulation of *Per* expression is crucially involved in the alignment of internal and external rhythms termed *entrainment*. While during most of

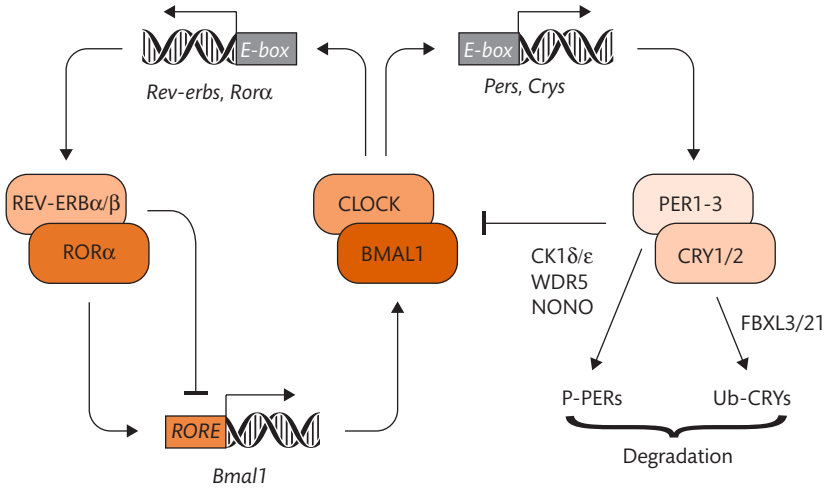

Figure 1.11.1 Current model of the mammalian circadian oscillator. The rhythm generating circuitry is based on a central molecular feedback loop with a positive (CLOCK, BMAL1) and a negative oscillator limb (PERs, CRYs) that is further stabilized via an accessory loop comprising the nuclear orphan receptors REV-ERBs and RORα. NONO, non-POU-domain-containing, octamer binding protein (an RNA-binding protein); RORE, retinoic acid-related orphan receptor response element; WDR5, WD repeat domain 5 (a histone methyltransferase-binding protein); FBXL3, F-box and leucine-rich repeat protein 3 (a ubiquitin-protein transferase) [9].

the *subjective* (i.e. internal) day the SCN clock is insensitive to light, during the first half of the subjective night light exposure elicits a strong induction of *Per1* and *Per2* transcription, while during the second part of the night only *Per2* remains light inducible. This out-of-phase activation of *Per2* mRNA and subsequent protein expression is integrated into the internal oscillator, thus resetting its phase and adjusting internal and external time. Similar responses in *Per* expression have been observed in peripheral tissues clocks, too [8]. However, here they are not part of photic entrainment but transmit internal time information provided by, for example, endocrine signals to local clocks. Both *Per* genes contain glucocorticoid (GC) response elements (*GREs*) in their promotors and, thus—as described further on in this chapter—the diurnal GC release rhythm is an important internal *Zeitgeber* of the circadian system.

The Role of Food in Circadian Entrainment

Studies in nocturnal rodents show that a shift in the availability of food has a strong effect on locomotor activity and may reset the circadian clocks of metabolic tissues such as liver, lung, adipose, and pancreas while having little effect on the SCN pacemaker which stays locked to the light–dark cycle [10]. In rats, such food-entrained rhythms persist under fasting conditions even in SCN-lesioned animals, supporting the notion that a food-entrainable oscillator (FEO) exists distinct from the well-characterized light-dependent entrainment of circadian rhythms. Ablation studies indicate that the dorsal medial hypothalamus may be involved in the food-dependent effects on circadian activity rhythms, but controversial data exist, and the current model favours a more distributed organization of the FEO. An involvement of a gut–brain communication, either via humoral or neural pathways, has been postulated as intestinal clock genes are largely independent of the light–dark cycle but respond rapidly to the timing of food intake similar to other peripheral tissues. In line with this, food-entrained circadian rhythms in physiology such as blood triglyceride levels persist even in the fasting state. The mechanisms of food-induced clock resetting are still poorly understood, but two endocrine factors, insulin and oxyntomodulin, have been implicated in aligning the liver clock and liver physiology with meal timing [11].

Sleep and Circadian Rhythms

The daily pattern of activity versus sleep is the most obvious circadian rhythm in humans. Sleep is controlled by two interacting processes: during the day, sleep propensity is low and this changes during the night (*process c*—for *circadian*). The second process increases sleep drive as a response to the duration of time spent awake. This sleep homeostat is called *process s* (for *sleep drive*). Together, process *c* and *s* control consolidated sleep profiles in humans, with most of the time spent awake during the day and asleep during the night. At the neuroanatomical level sleep–wake states are regulated by a flip-flop mechanism comprising neurons of the basal forebrain, the lateral hypothalamus, and the brainstem. Wakefulness is driven by the noradrenergic ascending arousal system of the brain stem which inhibits sleep-promoting galanergic and GABAergic neurons in the ventrolateral preoptic area (VLPO). The firing rate of these sleep promoting neurons, in turn, is high during sleep under the stimulation of adenosine inhibiting wake-promoting monoaminergic brain stem neurons. Orexins (or hypocretin) expressing neurons in the perifornical area and the lateral and posterior hypothalamus stabilize the wake state by inhibiting the VLPO and stimulating wake-inducing monoaminergic neurons [12]. Fitting to this pattern, it has been shown in animal models that orexin neurons fire during wake state. They are virtually completely inactive during rapid eye movement (REM) and non-REM sleep (NREMS). This complex interaction is highlighted by mutations of orexin receptors in animal models and humans. In both conditions, daytime sleepiness, narcolepsy, and obstructive sleep apnoea may be induced. Narcolepsy, with a prevalence of roughly 1 in 2000, is characterized by excessive daytime sleepiness but also

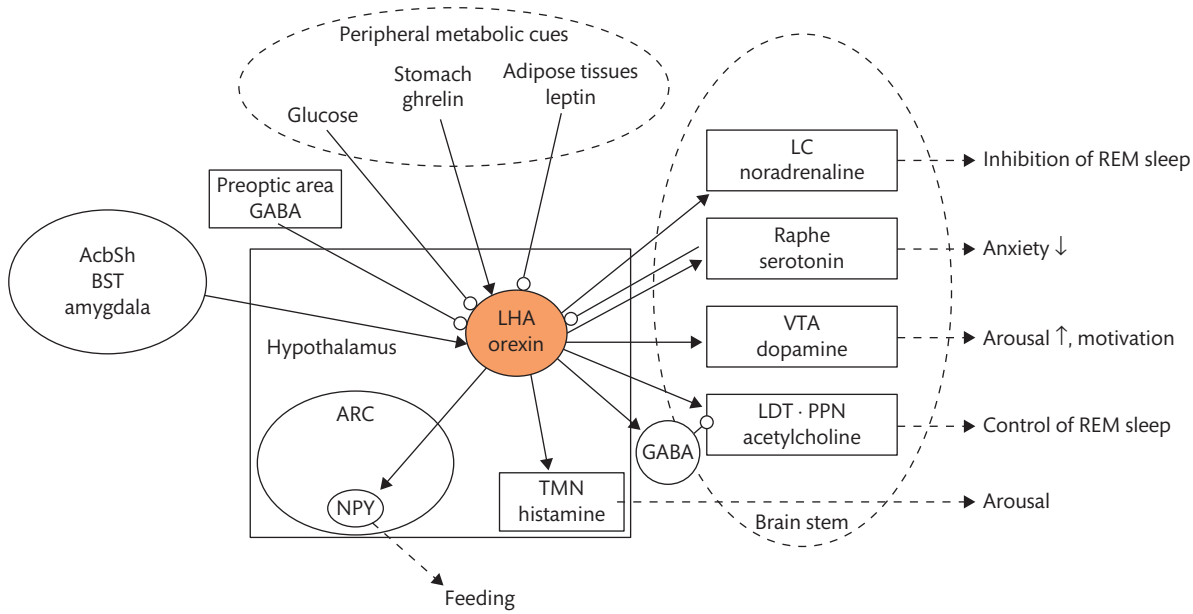

Figure 1.11.2 Orexin-centred view of sleep–wake regulation, energy homoeostasis, arousal, and locomotion [14]. ARC, arcuate nucleus; BST, bed nucleus of the stria terminalis; LC, locus coeruleus; LDT, laterodorsal tegmental nucleus; LHA, lateral hypothalamic area; PPT, pedunculopontine tegmental nucleus; TMN, tuberomammillary nucleus; VTA, ventral tegmental area.

sudden onset of weakness/atonia (*cataplexy*) fitting to orexin effects on muscle tone. Orexin promotes locomotor behaviour and energy homoeostasis. It further stimulates food intake via neuropeptide Y (NPY) but also exerts an inhibitory action on proopiomelanocortin (POMC) neurons to decrease energy expenditure.

The role of orexin highlights the intimate interplay between sleep–wakefulness, locomotion, and central as well as peripheral metabolic control into a sensitively regulated circadian system. It implies that any disturbance of the sleep–wake cycle, of energy homoeostasis, and of the interfering endocrine regulators may lead to substantial changes in other components of this highly integrated system (Figure 1.11.2).

Circadian Endocrine Rhythms and Their Relation to Sleep and Energy Homoeostasis

Multiple hormonal systems show pronounced circadian rhythmicity (see Figure 1.11.3 for examples and the link to other circadian rhythms) [13]. The physiological relevance of these rhythms is only in part elucidated so far. Multidirectional interactions between sleep, energy homoeostasis, and the endocrine system are currently best characterized, and the following section will thus focus on these interactions. As the capacity of endocrine signals to affect energy homoeostasis is reviewed in more detail in other parts of this book, the following will only review the relevance of energy shifts in relation to circadian behaviour and sleep [1].

Ghrelin and Leptin

Ghrelin and leptin are among the most important regulators of energy homoeostasis. Both hormones show a significant diurnal variation in lean subjects tied to circadian rhythms of food intake. Both in lean and obese subjects, a nightly increase of leptin has been shown with peak levels reached at around 02.00 h in the morning hours. Leptin levels decrease thereafter to reach a nadir in the hours between waking and noon. These changes have been viewed as important for the well-known regulatory effects of leptin on energy homoeostasis but also for leptin's action on other hypothalamic/pituitary hormones.

Leptin secretion is linked to another important hormone in appetite control, ghrelin. Ghrelin is released with a marked delay compared to leptin with peak ghrelin levels reached after waking in the morning. This diurnal pattern of ghrelin secretion is restricted to

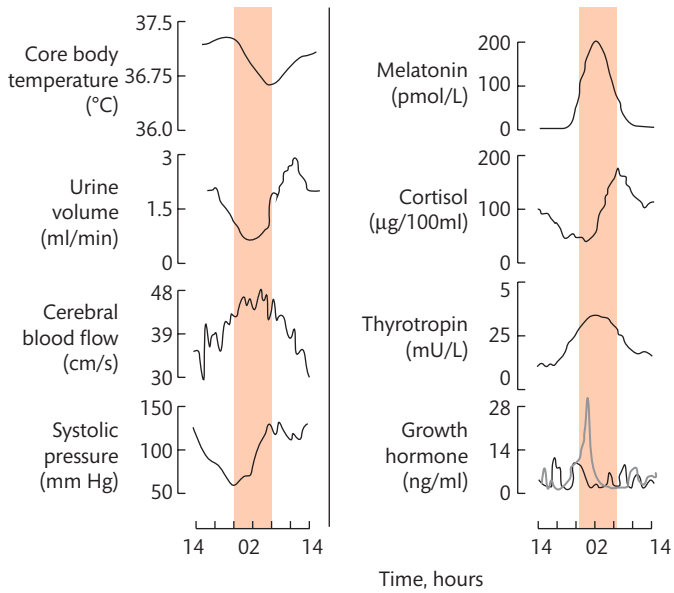

Figure 1.11.3 Examples of prominent endocrine and non-endocrine circadian rhythms [15].

lean persons only. It is interesting that the diurnal ghrelin pattern is lost in obese subjects.

Ghrelin is known to activate orexin neurons and thus plays an important role in the regulation of food searching behaviour and locomotive activity. Ghrelin also has direct effects on the machinery of circadian behaviour by inducing a phase advance and shifting *Per2* mRNA expression in dorsomedial hypothalamic neurons. On the contrary, leptin exerts an inhibitory influence on the firing of orexin neurons and counteracts feeding behaviour by activating POMC. Leptin as well acts directly on clock genes as shown in the example of mice deficient in *Per* or *Cry* in their osteoblasts. At least in this example clear phenotypic changes are found under leptin treatment, indicating that leptin acts on osteoblast proliferation via sympathetic nervous pathways and circadian gene activation.

Growth Hormone

With growth hormone-releasing hormone (GHRH) and somatostatin, ghrelin is an important regulator of growth hormone (GH). GH secretion shows a marked diurnal variation. Using high-frequency sampling techniques in several hundreds of volunteers and patients, it has been shown that GH is released in secretory pulses, and that these pulses form the basis of a circadian pattern. Modulation of frequency and amplitude of these secretory pulses shows circadian variations; a common pattern observed in many hormonal systems.

GH in humans is closely linked to sleep. Quantifying the amount of NREMS revealed that GH is robustly associated with the duration and deepness of NREMS but this relation depends on age and gender. It typically develops at about 3 months of age, reaches a peak in adolescence, and progressively decreases after 30 years of age. Despite the fact that there is a marked sex-related difference with a closer relation in males than in females, the decline in slow-wave sleep parallels the almost complete decline in nightly GH secretion above the age of 50 in both sexes.

These observational studies on a close link between GH and sleep were recently supported by investigations in mutant and transgenic animals. Growth hormone secretion in spontaneous dwarf rats (SDR) is almost completely lost due to a mutation of the *GH* gene. At variance to expectations NREMS is not reduced in these animals, but rather increased during the rest period. This suggests that growth hormone/insulin-like growth factor 1 (IGF-1) is only indirectly responsible for the reduction in spontaneous NREMS. The idea that a major part of this activity is mediated by GHRH-dependent pathways is supported by several rodent models with deletions of the GHRH receptor, such as the *lit/lit* mice or *dw/dw* rats. In both strains, GH and IGF-1 production is greatly decreased along with significantly reduced spontaneous NREMS. As no GHRH action is expected in these animals, chronic growth hormone replacement allows us to dissect GHRH action from growth hormone/IGF-1 responses. Despite successful correction of growth hormone deficiency, growth hormone replacement is unable to stimulate NREMS to normal indicating an important role of GHRH in the regulation of NREMS. This assumption fits to the detection of a circadian and sleep-related variation of GHRH in the hypothalamus. In contrast, REM sleep seems to be directly stimulated by GH secretion.

Adrenal Axis

Endogenous cortisol secretion rises sharply between 02.00 and 04.00 h at night with a peak serum concentration approximately 1 h after wakening. Under non-stressed conditions cortisol is secreted in a robust diurnal pattern overlying 90-min pulsatile patterns, both of which generally reflect the pattern of adrenocorticotropic activity (ACTH). Its high variation between nadir and peak secretions and its high reproducibility allow to use the circadian pattern as a window to evaluate changes in circadian rhythmicity in order to capture pathophysiology. Moreover, GCs have been shown to affect clock gene rhythms in target tissues, thus transmitting circadian time information across the body [16].

In Cushing's syndrome circadian cortisol variations are markedly dampened or even abolished. Whereas morning cortisol may still be within the normal range, typically midnight cortisol levels are increased. Similarly, circadian secretion is altered in normal ageing with an increased nightly secretion. This is a mild alteration whereas in depressive illnesses, as well as in chronic alcohol abuse, more pronounced shifts in circadian pattern reminiscent of Cushing's syndrome are observed. In cortisol deficiency stimulation of the entire corticotropin-releasing hormone (CRH)–ACTH–cortisol axis may be achieved by administration of the 11β-hydroxylase antagonist metyrapone, which blocks the conversion of 11-deoxycortisol to cortisol. The reduced negative feedback inhibition of cortisol on CRH and ACTH secretion can be used diagnostically in partial pituitary insufficiency. It is, however, highly dependent on circadian timing. Deoxycortisol has been shown to be maximally induced when the drug is applied at 20.00 h. This stimulation was significantly higher than after administration during the morning hours. Similarly, suppression of ACTH secretion by cortisol or synthetic analogues depends on the timing of their administration. Maximal inhibitory effects on ACTH secretion are observed just prior to the endogenous nightly rise in ACTH secretion. These effects have implications for the timing of corticosteroid treatment.

For physiological replacement therapy a slow-release preparation has recently been developed which is able to mimic the nightly cortisol increase. Application of the preparation when going to sleep will release peak cortisol levels at the physiological peak secretion time in the early morning hours. It is hoped, but still remains to be proven, that these promising preparations will improve the impaired quality of life of patients with Addison's disease. In pharmacotherapy with GCs, it is evident that the effectiveness depends on the timing. Nightly application improves the effect/dose, but side effects are higher as well. Bearing in mind interindividual variations in the sensitivity to GCs, there is no present consensus on which minimal dose is effective at which time of the day. In addition, this may vary due to disease specific factors.

Thyroid Hormone Axis

Thyrotropin (thyroid-stimulating hormone (TSH)) exhibits a marked circadian rhythm that governs a similarly phased—though far less developed—24-h rhythm of free triiodothyronine. Data on circadian thyroxine rhythms are less clear, probably due to the long half-life of several hours of the circulating hormone. There are early observations suggesting a light–dark cycle in total thyroxine but more recent data on free thyroxine do not confirm this. There are no data on the influence of light on TSH secretion but

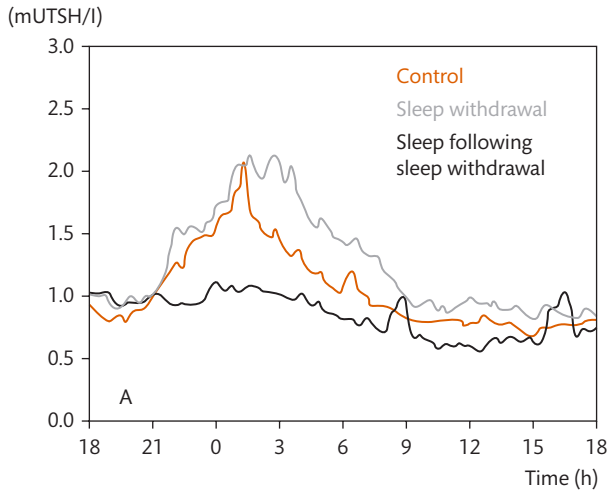

Figure 1.11.4 Effects of sleep modulation on TSH secretion in healthy volunteers. Comparing normal sleep to acute sleep withdrawal and to sleep in the night following sleep withdrawal [17].

Adapted with permission from Brabant G, Prank K, Ranft U et al. Physiological regulation of circadian and pulsatile thyrotropin secretion in normal man and woman. *J Clin Endocrinol Metab* 1990;**70**:403–9. Copyright © 1990, Oxford University Press [ref 17].

the important impact of sleep on TSH has been well investigated. Sleep withdrawal induces an acute increase and prolonged release of nocturnal TSH secretion (**Figure 1.11.4**) independent of total thyroid hormone levels. In contrast, TSH is almost completely suppressed if volunteers sleep significantly more and deeper in the night following a night of sleep withdrawal. This recovery of hormonal changes in acute total sleep deprivation is observed for other hormonal systems as well and raises the possibility that chronic sleep loss may result in long-term adverse endocrine effects via alterations in the circadian rhythmicity of hormone release. A direct link to energy homoeostasis is currently elusive. Short-term activation of the thyroid axis as in acute sleep withdrawal may, however, be linked to an activation of energy stores via the thyroid hormone system, an assumption fitting to data on fasting. Decreased energy availability following a 3-day fast almost completely suppresses circadian TSH release. Effects on the sympathetic nervous system are clearly important in this context but detailed studies are missing to date.

Melatonin

Melatonin, which is exclusively derived from the pineal gland, is secreted with a strong circadian rhythm peaking during the dark phase. Ganglionic photoreceptor cells in the retina integrate information on the light–dark cycle and signal via the retino-hypothalamic pathway to the SCN where duration, phase, and amplitude of melatonin hormone production are encoded. Nocturnal light exposure suppresses melatonin secretion, with blue light in the range 460–470 nm having the most pronounced effect (acting through retinal ganglionic melanopsin (OPN4) photoreceptors). Circulating melatonin levels show high interindividual variability which presumably is genetically determined. An age-related blunting of circadian melatonin rhythms has been suggested, but more recent data indicate that melatonin rhythms are preserved even in old age, albeit with large interindividual variations [18].

Melatonin exerts its physiological actions through G-protein-coupled specific cell membrane receptors, MT1 and MT2. The functions of the subtypes differ and are not restricted to sleep and circadian behaviour where MT1 receptor decreases neuronal firing rates and MT2 receptor regulates phase shifts. Like cortisol, melatonin is a major regulator of the circadian rhythm in peripheral tissues and of core body temperature in humans. This pattern is linked to sleep. In normal adults, the deepest level of sleep and the lowest core body temperature are reached simultaneously.

Without external light cues as in totally blind patients with a complete loss of light recognition entrainment of endogenous rhythms is lost and patients free-run with their own endogenous period (Non-24). Synchronized endogenous circadian rhythms are important for a normal quality of life. Totally blind persons lose this synchrony and exhibit cyclical sleep loss associated with daytime sleepiness and mood swings.

Exogenous melatonin affects sleep regulation largely through a phase-resetting mechanism. By its capability to readjust disturbed circadian rhythms to their correct phase position, melatonin strengthens endogenous rhythms, thus decreasing daytime sleepiness and restoring sleep quality. Circadian rhythm sleep disorders, either advanced or delayed sleep phase syndrome, have been successfully treated with melatonin [19]. A common denominator of these conditions is the loss of coordination between endogenous rhythms. Jet lag induced by a transmeridian flight across several time zones is a well-known but transient condition of such loss of entrainment as a mismatch occurs between the endogenous circadian rhythms and the new environmental light–dark cycle. Endogenous rhythms shift in the direction of the flight with a phase advance on eastbound flights but a phase delay when flying westwards. Symptoms typically include a disturbed night-time sleep, impaired daytime alertness and performance, irritability, distress, and appetite changes, along with other physical symptoms such as disorientation, fatigue, gastrointestinal disturbances, and lightheadedness. Pharmacological modification of melatonin secretion has been used to synchronize endogenous rhythms in jetlag and in shift workers. The convincing positive data in the totally blind on a coordinating role of melatonin have recently been paralleled in healthy volunteers treated with a melatonin agonist. The dose-dependent effect on sleep propensity supports an important coordinating function of melatonin on the sleep–wake cycle and on other circadian rhythms. To understand melatonin action in normal physiology, further mechanisms such as the activation of the sympathetic nerve system, which suppresses melatonin secretion from the pineal gland, may play a crucial role. Light, even dim light at night, leads to a suppression of melatonin and feedback on other rhythms. Recent data on melatonin secretion in postmenopausal women highlight this complex relation. Absolute 24-h melatonin secretion is enhanced in depressed postmenopausal women. In addition, the timing of melatonin secretion is altered, showing a delayed morning offset. This longer melatonin secretion window fits to results in seasonal affective disorders where—due to weak and noisy photic *Zeitgeber* conditions during winter—a dissociation of endogenous rhythms is observed. These patients also often show an increased melatonin secretion during the winter months. In both groups mood disturbance and sleep are improved by bright (blue-) light therapy [20].

Altered Sleep, Circadian Rhythmicity, and Metabolism

Increased melatonin secretion may further impact on the risk of insulin resistance and diabetes mellitus. Recent data from three independent groups reveal that a polymorphism of the melatonin receptor 1B, which leads to chronic overactivity of intracellular melatonin dependent signalling pathways, is an independent and strong risk factor for glucose intolerance and type-2 diabetes mellitus. The mechanism behind this is not entirely clarified but inhibition of insulin secretion from pancreatic β cells and a negative impact on incretins seem to cooperate.

Glucose tolerance, which critically depends on the ability of the pancreatic β cell to respond to a given glucose challenge, varies over the day in healthy individuals. It is much lower in the evening than in the morning. There is a further increase in plasma glucose when tested in the middle of the night, suggesting minimal glucose tolerance during sleep. Whereas reduced glucose tolerance in the evening hours is attributed to both a reduction in insulin sensitivity and a reduced insulin secretory response to glucose, the further deterioration of glucose tolerance during the night depends on sleep-related processes to maintain stable glucose levels during the extended overnight fast. During NREMS glucose utilization is lowest; it increases during REM sleep and is highest in the wake period. The underlying multifactorial causes of this circadian change in glucose tolerance are only partly unravelled. Insulin sensitivity decreases in the evening predominantly due to a decreased pancreatic insulin secretory response to glucose. Data from transgenic mice suggest that pancreatic insulin production itself is under control of the local clock gene machinery [21]. Melatonin-mediated effects may further contribute to this regulation. Glucose production and utilization fall in association with sleep during the first half of the night and increase again in the latter part. Insulin-dependent and -independent glucose disposal is reduced during sleep. In parallel, GH secretion is increased with the initiation of slow-wave sleep, cortisol is inhibited, sympathetic nerve activity is decreased, and vagal tone stimulated.

Moderate alteration of night sleep with a reduction to only 4 h/night over a period of 6 nights has been shown experimentally to profoundly affect energy metabolism. It acutely reduces insulin release predominantly via an increased sympathetic outflow and decreases peripheral insulin sensitivity on several levels. Importantly, counteractive hormone release is activated with augmented nightly GH, TSH, and cortisol secretion, and also with a higher level of cytokines and inflammatory markers. It is not surprising that testing for insulin resistance in such a state of sleeplessness revealed a metabolic state well comparable with metabolic syndrome and prediabetes. Similar data have subsequently been obtained in subjects where selective suppression of slow-wave sleep decreased the quality but not the duration of sleep.

Chronic sleep reduction as investigated in obstructive sleep apnoea is further associated with a dysregulation of the neuroendocrine control of appetite. A combined alteration of ghrelin, orexin, and leptin secretion is part of the pathomechanism leading to excessive food intake, decreased energy expenditure and, as recent data indicate, to hypertension (see Figure 1.11.5 for schematic integration of mechanisms). There is further evidence that metabolic changes in the polycystic ovary syndrome are a result of obstructive sleep apnoea. Experimental studies on partial sleep loss and their impact on energy conservation parallel epidemiological findings on the greatly increased risk of obesity and diabetes mellitus in societies. It is tempting to speculate, but remains to be proven, that sleep curtailment by modern lifestyle changes is a primary force behind the adverse metabolic effects via its impact on diurnal endocrine regulation. Mouse and human data suggest that even a short episode of mistimed and shortened sleep may profoundly affect circadian clocks in blood and peripheral tissues [22].

Conclusion

In summary, these examples clearly demonstrate a powerful circadian regulation of the endocrine and metabolic system interlinked with sleep. Evidence is accumulating that the common curtailment of normal sleep in modern society has important consequences for metabolic and endocrine functions. Data on shift workers who most frequently experience gastrointestinal disturbances support the importance of food-entrained rhythms in addition to the light–dark cycle for the timing of many endocrine rhythms and sleep-associated cycles. Constant violation of these patterns may lead to detrimental effects. The example of treatment with melatonin and melatonin agonists suggests that a better understanding of the pathophysiology of the circadian system may help to develop new means to endocrinologically modulate these cycles for the benefit of patients.

Principles of Hormone Replacement

Richard Ross

Introduction

The aim of hormone replacement is to replace the missing physiological effects of a deficient hormone. In principle this may best be achieved by replicating the physiological profile of that hormone in the bloodstream. This is easier said than done as there are many challenges to be met in order to achieve this, from defining the physiological profile of the hormone to designing and testing therapeutic formulations that can replicate that profile. This involves, accurately measuring the bioactive hormone, describing its actions, identifying biomarkers of those actions, accurately measuring those biomarkers, generating formulations of hormone or hormone mimetic drug that replace the physiological concentration and rhythm, providing a route of administration that yields bioavailability, and then demonstrating in clinical trials the short and long-term benefits of hormone replacement.

It is remarkable that in many cases providing a daily bolus of hormone is lifesaving even when it does not replicate the physiological profile, as was evident with the introduction of insulin and glucocorticoids in the last century. Thus, a daily subcutaneous injection of insulin can prevent ketoacidosis and death despite the fact that insulin in health is secreted from the pancreas into the portal circulation in a pulsatile manner under tight control of multiple nutrient sensing mechanisms, and coordinated with the secretion of glucagon. Hormone deficiencies are generally chronic diseases requiring lifelong therapy, often starting early in life. In the short term non-physiological daily administration may prevent death, but we now recognize that replacement needs to replicate physiology more faithfully to prevent poor long-term health outcomes. This is well demonstrated in type 1 diabetes mellitus, where poor glucose control over time results in large and small blood vessel disease with resultant ischaemic heart disease, neuropathy, retinopathy, and nephropathy. Thus, the emphasis in the management of diabetes mellitus in this century is on reconstituting physiology by providing basal insulin levels supplemented by mealtime boluses, or combining insulin with glucagon infusions, all with intensive glucose monitoring. Similarly, with glucocorticoid replacement in adrenal insufficiency we can prevent adrenal crises through administration of large doses of any glucocorticoid, but chronic excess glucocorticoid over time is associated with all the complications of Cushing's syndrome. This chapter explores the challenges associated with hormone replacement and through this exemplifies the principles of hormone replacement.

Physiology of Hormones

Understanding the physiological regulation and action of a hormone is essential to understanding how to provide its replacement. This is exemplified by gonadotropin-releasing hormone (GnRH), which, if given as a continuous infusion, results in downregulation of the pituitary gonadal axis. This is the opposite of what occurs in nature, where GnRH is secreted in a pulsatile manner, with the frequency and magnitude of those pulses regulating puberty and fertility (see Chapter 8.1.2). Characterizing hormone physiology is complex and requires not only an understanding of the synthesis and secretion of the hormone and its total concentration in the blood stream, but also an understanding of its binding proteins, which tissues it acts upon, what receptor(s) it acts through and its metabolism and excretion.

Some hormones are released in pulses, like GnRH, and the pulse and trough are important to the biological action, whereas parathyroid hormone is secreted at a fairly constant level. When increased in primary hyperparathyroidism parathyroid hormone causes osteoporosis, but, intriguingly, when given in pulses it has an anabolic action on bone (see Chapter 4.1). Some hormones are secreted in pulses superimposed on an underlying rhythm, exemplified by the hypothalamic–pituitary–adrenal (HPA) axis: cortisol production is controlled by the pulsatile release of adrenocorticotropic hormone (ACTH) from the pituitary, and shows an overall circadian rhythm underpinned by an ultradian rhythm. Both of these rhythms may be important in its biological actions [1].

Table 1.12.1 Current practice in hormone replacement

Hormone	Physiological profile	Replacement	Biomarkers	Future prospects
Growth hormone	3–4 hourly pulses; greatest at night	Daily s/c injection given in evening	Growth in childhood and IGF-I in adults	Long-acting formulations are in development but don't replicate physiology and therefore efficacy and safety important to demonstrate
Thyroid	T4 and T3 secretion from thyroid with circadian rhythm of T3 and peripheral conversion of T4 to T3	Thyroxine monotherapy	TSH	Development of new tissue specific biomarkers and T3 formulations that can provide the normal ratio of T4 to T3
Parathyroid	Constant secretion of parathyroid hormone (PTH) modulated by calcium level	Usually calcium and vitamin D supplementation. Subcutaneous PTH (1–84) recently licenced	Calcium level	Development of long-acting PTH supplementation as current treatment results in fluctuating calcium levels
Cortisol	Circadian cortisol rhythm with underlying ultradian rhythm	Hydrocortisone twice to thrice daily or modified release once daily	None	There is a need for tissue-specific biomarkers. There is a modified-release formulation in development that replaces the circadian overnight cortisol levels and work with s.c. pumps looking at the ultradian rhythm
Insulin	Baseline levels with postprandial surges	Short- and long-acting insulins	HbA1c	See Chapter 15.5.3
Oestrogen and progesterone	Gradually rise through puberty; varying levels during menstrual cycle	Oral and transdermal preparations; combined preparations	Menstrual cycle and dual energy X-ray absorptiometry (DEXA) scan for bone health	There is a need for biomarkers and to determine the optimal route and dose of replacement at different ages
Testosterone	Gradually rises in puberty; circadian rhythm	Parenteral or transdermal preparations	None	There is a need for biomarkers to determine optimal replacement doses and when to replace

Many hormones such as thyroid hormones and cortisol have binding proteins which influence both bioavailability and hormone measurement. Women taking oestrogens or when pregnant have a high plasma cortisol binding protein concentration and therefore have a high total cortisol level which needs to be recognized when assessing for adrenal insufficiency or measuring absorption of hydrocortisone.

Hormone receptors are variably expressed in different tissues and there may be different receptors for the same hormone in different tissues that can influence biological output of hormone exposure. As an example, there are two thyroid hormone receptors, THRα and THRβ. These are variably expressed with THRβ being more highly expressed in the hypothalamus and pituitary, mediating inhibition of thyroid-stimulating hormone (TSH), and so TSH alone may not be a suitable biomarker for thyroid action in other tissues [2]. Within cells there may be conversion of prohormones to either active or inactive forms, as seen in the deiodination of T4 to biologically active T3 or conversion of active cortisol to inactive cortisone by 11β-hydroxysteroid dehydrogenase. Finally, clearance of hormones varies between hormones in rate and site, and may feature renal clearance, hepatic metabolism, receptor-mediated tissue uptake, and/or proteolysis, all of which may influence the pharmacokinetics of a drug formulation.

Biomarkers of Hormone Replacement

A biomarker is defined as a characteristic that is objectively measured and evaluated as a surrogate indicator of a normal biological process, a pathogenic process, or a pharmacologic response to a therapeutic intervention [3]. Biomarkers are essential tools for monitoring hormone replacement and for developing new therapies for hormone replacement. Clinical endpoints, capturing how a patient feels, functions and survives, are ultimately the key objectives for hormone replacement, but these are usually not easily measurable in individual patients and are challenging to measure in clinical trials. In such trials we thus frequently depend on surrogate endpoints, or biomarkers that can accurately predict beneficial or harmful clinical outcomes.

Haemoglobin A1c (HbA1c) is an example of a validated surrogate endpoint for microvascular complication risk associated with diabetes mellitus, and has been used as the basis for approval of drugs intended to treat diabetes mellitus as well as being used in the management of individual patients. We have biomarkers for the actions of most hormones; however, few are validated as surrogate endpoints. Serum IGF-I is widely used as a biomarker in growth hormone (GH) replacement but correlates only weakly with clinical endpoints in GH treatment, although normalization of IGF-I is related to an improvement in mortality in patients with acromegaly [4]. TSH is routinely used as a biomarker of thyroid hormone replacement for the management of individual patients as well as in clinical trials. Nevertheless, in trials of T4 monotherapy at doses that normalized TSH in overt, primary hypothyroidism, not all systemic biological markers of thyroid hormone signalling were normalized, including serum cholesterol levels [2]. Identifying biomarkers that are validated endpoints is essential for management of hormone replacement both in the clinic and for developing optimized therapies and there is a need for new biomarkers in most fields of endocrinology.

Delivery of Hormonal Therapies

The route of administration for hormones depends on their intrinsic properties. Proteins such as insulin and GH have to be given

parenterally because of proteolysis in the gut. Most peptide hormones such as DDAVP (desmopressin) are also broken down in the gut, although when given at high dose sufficient hormone maybe absorbed to be biologically active. In contrast, amino acid-based hormones such thyroxine and steroid hormones such as hydrocortisone are well absorbed from the gut. The gonadal steroids testosterone and oestradiol, too, are well absorbed from the gut but undergo first pass metabolism in the liver, commonly necessitating parenteral or transdermal administration.

The route of administration will often dictate constraints in replicating physiology. Sophisticated subcutaneous pump technology performs well in diabetes, but this is generally impractical for most hormone replacement. GH is secreted in pulses approximately every 3 hours with the largest pulse occurring during deep sleep, however single daily subcutaneous GH injections given in the evening have proven effective in promoting growth in children. There are long-acting formulations of GH in development with the potential to offer weekly or less frequent dosing options. These GH formulations don't truly replicate endogenous GH profiles, but they do promote growth. Important to their development will be demonstration of a good safety profile [5]. It is also possible to modify release of drugs in the gut and in so doing to delay and/or sustain release of hormone, depending on what part of the gut the hormone is absorbed from. This approach has been used with hydrocortisone to mirror more faithfully the daily rhythm of cortisol concentration. There is now a dual-release formulation available that provides for once daily hydrocortisone replacement [6], and a delayed and sustained absorption formulation in development that replaces the overnight rise in cortisol and improved biochemical control of patients with congenital adrenal hyperplasia [7].

Summary

The last century identified most of the endocrine hormones, which can now be replaced when deficient; however, the challenge of the twenty-first century is to optimize replacement (see Table 1.12.1). The guiding principle in hormone replacement is replicating the natural levels and rhythms of hormones at different ages but this requires a good understanding of physiology. There is a need for better biomarkers of hormone actions and using these to develop new ways to deliver hormone replacement tailored to the individual. This chapter discusses current approaches to this problem.

Prevention in Endocrinology

Jonathan Valabhji and Rochan Agha-Jaffar

Introduction

At its inception in 1948, the World Health Organization defined health as 'a state of complete physical, mental, and social well-being and not merely the absence of disease and infirmity'. The widely accepted goals of healthcare systems are to promote and preserve health, to restore health when it is affected and to minimize suffering. The concept of disease prevention is embedded within these goals.

When considering disease prevention within the field of endocrinology, there has been a clear shift in focus reflecting changing epidemiology. Iodine deficiency disorders and congenital hypothyroidism were examples of conditions, which when left untreated had severe consequences and posed considerable public health challenges. However, the introduction of appropriate screening strategies and health policies has successfully increased early recognition and treatment, reducing the incidence of associated adverse outcomes. While the challenges do still exist, the epidemics of diabetes and obesity now observed have superseded both these and other preventable non-communicable diseases worldwide.

Disease prevention can take many forms ranging from public health campaigns addressing lifestyle factors to targeted interventions in at risk groups. Prevention can be classified as follows [1]:

1. **Primary prevention.** This focuses on improving health in populations' (e.g. salt iodization) programmes to prevent iodine deficiency disorders.
2. **Secondary prevention**. Here, disease development in at risk individuals is targeted (e.g. lifestyle modification in overweight individuals to prevent type 2 diabetes). The strength of this particular form of prevention is that the intervention can be matched to the needs of the individual allowing focused resource delivery.
3. **Tertiary prevention.** This aims to reduce the risk of complications associated with a disease in affected individuals (e.g. good glycaemic control to prevent microvascular complications in individuals affected by type 1 or type 2 diabetes).
4. **Quaternary prevention.** The most recent of the concepts relates to the actions taken to identify a group at risk of overmedicalization, thus protecting them from unnecessary invasive medical interventions and providing them with ethically acceptable care.

Screening

Effective secondary and tertiary prevention relies on practical screening strategies and the identification of clear modifiable factors, which when addressed, can mitigate the risk of either developing a disease or improving its associated complications.

The World Health Organization (WHO) defines screening as the 'presumptive identification of unrecognized disease or defects by means of tests, examinations, or other procedures that can be applied rapidly'. In an early series of papers on the subject, Rose and Barker stated that to ensure an effective screening programme, these three core principles should be addressed [2]:

1. Earlier treatment should improve the prognosis
2. The screening test should be valid and repeatable
3. There should be a high yield to the screening service

The WHO proposed these further recommendations for screening strategies in a clinical policy guideline [3]:

- The condition being screened for should be an important one
- Facilities for diagnosing and treating the condition should be available
- There should be an accepted treatment for those who ultimately develop the disease

- There should be a recognizable latent or early symptomatic stage
- The natural history of this condition including the progression from latent to declared disease should be adequately understood
- There should be a suitable test to screen for the condition and this test should be acceptable to the population
- The cost of case-finding (including diagnosis and treatment of patients diagnosed) should be economically balanced in relation to possible expenditure in medical care as a whole
- Case-finding should be on a continuing process and not a 'once and for all' project

When deciding on appropriate screening programmes, the sensitivity and specificity of the tests need to be considered together with the implications of false positive and false-negative results.

This chapter will explore the principle preventable diseases and their associated complications within the field of endocrinology as well as the strategies that have been employed to combat them. Two areas will be described in which public programmes of primary prevention have been implemented worldwide, the first relating to iodine deficiency disorders and the second to learning difficulties due to congenital hypothyroidism. The global epidemic of type 2 diabetes and its prevention will then be discussed, and potential prevention opportunities relating to gestational diabetes, type 1 diabetes, and osteoporosis will also be described.

Iodine Deficiency Disorders

Iodine deficiency is estimated to affect two thousand million people worldwide. Endemic goitre had been a well-recognized complication of iodine deficiency as early as the start of the twentieth century. However, it was not until much later that the links between iodine deficiency and mental as well as physical impairment were established, following which the term 'iodine deficiency disorders' was introduced (Table 1.13.1).

Dietary iodine is readily absorbed from the gastrointestinal tract, reaching the circulation in the form of iodide [4]. The latter is converted back to iodine in the thyroid gland and concentrated within the follicular cell. Iodine is an integral component of T4 and T3. A low dietary intake of iodine results in adaptive processes within the thyroid gland, which are mediated by the enhanced secretion of thyroid stimulating hormone (TSH) from the anterior pituitary gland. This in turn maintains T3 status as well as reducing the renal clearance of iodide. Despite these adaptive processes, iodine deficiency in the chronic stages results in total thyroid gland iodine depletion and hyperplasia of thyroid epithelial cells precipitating the development of goitre.

Table 1.13.1 Consequences of iodine deficiency in different age groups

Age group	Manifestations of iodine deficiency
Fetus	Spontaneous early pregnancy loss, congenital anomalies, stillbirth
Neonate	Cretinism (neurodevelopmental delay including mutism, squint, spastic diplegia), hypothyroidism, and short stature. Infant mortality
Childhood	Physical impairment, mental impairment
All age groups	Hypothyroidism, goitre, iodine-induced hyperthyroidism, increased susceptibility to nuclear radiation

In 1978, a study in the Chinese village of Jixian demonstrated that iodine supplementation in an iodine deficient population resulted in the following benefits over an eight year period: reduction in endemic goitre rates in schoolchildren (80% in 1978 versus 4.5% in 1986), reduction in incidence of cretinism (11% presupplementation versus 0% in 1986) and improvement in school performance (both school ranking and pupil failure rate) [5]. This, together with further similar studies provided evidence that mental impairment secondary to iodine deficiency could be prevented. The implications for translating this to a population level were therefore numerous particularly when considering the potential beneficial impact on socioeconomic development.

While iodine supplementation had been commonplace in countries such as the United States and Switzerland, it was not until the 1990s that a turning point in the global efforts to combat iodine deficiency was observed. This first involved concerted efforts to assess the prevalence of iodine deficiency and countries with a total goitre rate exceeding 10% were classed as iodine deficient. One hundred and ten countries fell into this remit exposing 1570 million people, equating to approximately 30% of the global population, to the risks of developing iodine deficiency disorders.

In 1990, the International Council for Control of Iodine Deficiency Disorders, UNICEF, and the World Health Organization collaborated on guidelines to address iodine deficiency, which was followed by the WHO recommending universal salt iodization (USI) programmes to combat the associated disorders. USI programmes were thought to represent the most cost-effective methodology by which to do so with the price per person per annum estimated at $0.002–0.006. The proportion of the global population consuming iodized salt increased from less than 20% in 1990 to approximately 70% in 2000. By 2004, WHO indicated that 54 countries were iodine deficient (relative to the 110 prior to the programme) indicating that the strategy was effective.

Longitudinal studies have now demonstrated that the implementation of USI programmes have improved endemic goitre rates, One example of this is the Chinese province of Hebei, where the rate has improved from 11.3% to 2.7% in school children aged 8–10 years over a 10-year period. Similar reductions in the incidence of cretinism have been observed.

However, not all regions required the implementation of USI programmes to improve iodine deficiency rate. Changes in farming practice have almost led to an accidental increase in iodine intake among the general population within certain parts of Europe and Australasia. Using the United Kingdom as an example, the endemic goitre rate was estimated at 30% in school children in the 1920s [6]. Changes to farming practice including provision of iodine-enriched feed to cattle to improve their reproductive performance led to an associated increase in the iodine content of milk. Subsequent to this, iodine deficiency rates improved across the country, which in turn was evidenced by both reductions in the endemic goitre rate (equating to approximately 11%) and increases in median urinary iodine concentrations, a surrogate marker of iodine intake. While cross-sectional surveys have suggested that iodine deficiency rates could once again be increasing in certain parts of the world, the true

prevalence, severity, and indeed long-term impact of this, has yet to be established.

Congenital Hypothyroidism

The screening programme for congenital hypothyroidism is well organized in many parts of the world and represents another important primary prevention programme within endocrinology. The condition affects approximately 1 in 3000 to 1 in 4000 neonates rendering it one of the most frequent congenital endocrine disorders. Untreated, congenital hypothyroidism results in severe intellectual disability, neurodevelopmental delay and growth impairment [7]. The majority of cases (80%) occur as a result of developmental defects within the thyroid gland itself otherwise known as thyroid agenesis or dysgenesis. In the remaining 20%, a normal or enlarged thyroid gland is found and the condition instead occurs due to disruptions in thyroid hormone biosynthesis.

The finding that normal mental development in a child with congenital hypothyroidism was contingent on both a timely diagnosis and initiation of treatment within the first three months of life prompted researchers to search for an effective screening strategy. However, screening only became viable when sensitive radioimmunoassays for TSH and T4 were introduced. The first two pilot screening studies were published in the 1970s. Subsequent to this, routine testing for congenital hypothyroidism has been introduced as part of neonatal screening programmes in many parts of the world and testing is generally undertaken between the first 48 hours and 4 days of life.

Type 2 Diabetes

The WHO has estimated that globally, 422 million adults were living with diabetes in 2014, compared to 108 million in 1980. Separate global estimates of diabetes prevalence for type 1 and type 2 do not exist. However, the majority of people with diabetes have type 2 diabetes, and policies aligned to attenuate the current trajectories of increasing incidence and prevalence of type 2 diabetes, as well as the associated complications of type 2 diabetes, are of global significance.

The aetiology of type 2 diabetes is multifactorial, with environmental and genetic risk factors, although to date only around 5% of the variability in predisposition to type 2 diabetes has been linked to specific genes. Nevertheless, family history and ethnicity are important non-modifiable risk factors, as is age. Modifiable risk factors principally involve the lifestyle risk factors relating to weight gain, poor quality nutrition, and reduced physical activity, although socioeconomic factors, with people from more deprived communities at significantly greater risk, may also be described as modifiable.

Type 2 diabetes is a disease to which all four potential prevention strategies can be applied:

1. **Primary prevention.** Type 2 diabetes is strongly associated with both overweight and obesity, the major modifiable risk factor, and reduced physical activity. Population-level interventions that address the obesogenic environment, and that encourage greater physical activity, are therefore attractive targets for interventions, interventions that have potential for wide reach across the whole population as well as carrying low unit cost. Examples include price increases applied to unhealthy food and drink choices, such as levies introduced on sugar-sweetened beverages in the United Kingdom (2018) and Mexico (2014); reformulation of products resulting in lower sugar or total calorie content; reducing promotions on unhealthy foods (e.g. buy one get one free), which have been shown to increase the amount of food and drink people buy in the United Kingdom by around 20%; limiting advertising of unhealthy foods—all forms of marketing consistently influence food preference, choice and purchasing in children and adults; promoting active transport; promoting healthy eating and physical activity in schools and in working environments; and requiring clear food labelling that indicates calorie, sugar, fat, and salt content. Although each intervention alone will carry only a small effect size, increasing the number of interventions in the national or regional portfolio of interventions will have a more significant effect. Examples of broader portfolios of interventions nationally or regionally are the UK Government's Childhood Obesity Plan (2016), the North Karelia Project in Finland, and the Amsterdam Healthy Weight Programme in the Netherlands.
2. **Secondary prevention.** It is now well established that onset of type 2 diabetes can be prevented or delayed in high-risk adults. At least five major randomized controlled trials, conducted in China [8], Finland [9], United States [10], Japan [11], and India [12] have documented 30–60% reductions in type 2 diabetes incidence in adults with impaired glucose tolerance through intensive lifestyle behavioural change programme interventions focusing on weight loss, better quality nutrition, and increased physical activity. The USA-based Diabetes Prevention Programme (DPP), the largest of the five studies, showed that an intervention targeting weight loss of around 5–7% of body weight and moderate physical activity of 150 minutes per week through a structured lifestyle change program reduced the cumulative incidence of type 2 diabetes by 58% at 2.8 years [10]. Real-world translations of these trial interventional approaches have established the effectiveness of similar group-based interventions [13], and interventions are now being established in some countries as part of routine care for those at high risk (the Healthier You: NHS DPP in England [14]; the US DPP [15]; and the Australian lifestyle intervention Programme 'Life' [16]).
3. **Tertiary prevention.** Preventing the complications of type 2 diabetes, including the microvascular complications of retinopathy, peripheral neuropathy and nephropathy, and the macrovascular complications of coronary heart disease, cerebrovascular disease, peripheral vascular disease, and renovascular disease, are of paramount importance in improving the quality of life and outcomes for people with type 2 diabetes as well as reducing the financial burden on health systems. In the United Kingdom, 80% of the direct costs associated with managing people with diabetes were associated with the management of complications [17]. Well-conducted randomized controlled trials have demonstrated the effectiveness of tighter glycaemic control in preventing the microvascular complications (UKPDS) [18], of blood pressure reduction in preventing the microvascular and macrovascular complications (UKPDS) [19], and of treatment

with statins in preventing the macrovascular complications (CARDS) [20].

4. **Quaternary prevention**. Both ageing and diabetes are recognized as important risk factors for the development of functional decline and disability. Frailty in those with type 2 diabetes, and its associated weight loss, can lead to overtreatment of glycaemic parameters and of blood pressure in those with type 2 diabetes if treatment regimes are continued without modification, resulting in hypoglycaemia and postural hypotension. Clinical recommendations that address these issues are now emerging [21].

Gestational Diabetes

Gestational diabetes is defined as 'diabetes diagnosed in the second or third trimester of pregnancy that is not clearly overt diabetes' [22]. Development of hyperglycaemia in pregnancy is associated with considerable risks to both the mother and developing baby. For the mother, these include a greater likelihood of undergoing a caesarean section, pre-eclampsia and the development of type 2 diabetes: for the baby, macrosomia, shoulder dystocia, and physiological and metabolic abnormalities such as neonatal hypoglycaemia, and obesity with insulin resistance in young adulthood. The risk factors for developing gestational diabetes mirror those for developing type 2 diabetes.

The incidence of gestational diabetes and its associated complications are increasing, reflecting the increasing prevalence of maternal overweight and obesity globally. Indeed, similar to type 2 diabetes, overweight and obesity is the major modifiable risk factor contributing to the development of hyperglycaemia in pregnancy. Preventing pathological hyperglycaemia during pregnancy has several potential benefits: reduction of associated immediate maternal and fetal adverse outcomes, potential improvements in the risk of long-term sequelae and reductions in the economic burden to healthcare systems worldwide.

Given the overlap in modifiable risk factors with type 2 diabetes, the primary prevention strategies outlined earlier, which address the obesogenic environment are also applicable to the prevention of gestational diabetes (e.g. introduction of the sugar-sweetened beverage tax in the United Kingdom). There are currently no clear proven or established secondary prevention strategies and interventions have been restricted to research settings [23]. Results from the randomized controlled trials investigating lifestyle intervention strategies in at risk cohorts have been conflicting. The reasons for this probably relate to the large degree of heterogeneity across the trials. Differences existed both in the demographics of the cohorts recruited as well as the criteria used to diagnose the condition.

Evidence relating to the tertiary prevention of complications associated with established gestational diabetes is more clearly defined. Achieving good glycaemic control mitigates the risk of many adverse maternofetal outcomes. In the first instance, dietary modification is recommended with pharmacological therapy in the form of either metformin or insulin advocated if glucose control is not achieved with the former.

The glycaemic thresholds used to diagnose gestational diabetes are the subject of debate. The Hyperglycaemia Adverse Pregnancy Outcomes study (HAPO) clearly demonstrated the linear relationship between glycaemia and fetal birth weight. On the basis of these results, the International Association of Diabetes in Pregnancy Study Group (IADPSG) and the WHO lowered the thresholds at which gestational diabetes should be diagnosed. However, there exists no evidence on treating glucose levels to the diagnostic criteria now formulated by these two organizations and concerns have been raised as to whether women who fall into lower categories of glycaemia could be overmedicalized [24].

Type 1 Diabetes

Type 1 Diabetes is a chronic autoimmune condition characterized by T-cell mediated progressive destruction of pancreatic β cells culminating in a complete deficiency of insulin. The aetiology is not completely understood. Environmental factors are thought to trigger the autoimmune process against a background of genetic susceptibility factors. The exact nature of the environmental triggers is still the subject of debate. Fetal exposure to rubella, enterovirus and maternal pre-eclampsia have been proposed as potential intrauterine factors that could contribute to later development of type 1 diabetes with early gluten exposure and infectious agents such as Coxsackie B virus thought to be possible environmental triggers in early childhood, although clear aetiological pathways have not been established.

The global incidence of type 1 diabetes has increased by 2% over the last 20 years. In the United Kingdom, this increase has been particularly pronounced and it now has one of the highest incidence rates for children under the age of 14, surpassed only by Finland, Sweden, Saudi Arabia, and Norway. Primary prevention strategies in the context of type 1 diabetes are not possible. A significant research effort is currently concentrating on potential secondary prevention strategies in at risk individuals, although at this point, identification of individuals within a latent or preclinical phase is challenging, and there are currently no translational opportunities of such research to routine clinical practice. [25]. The research includes immune modulation in the early preclinical phase, which may prevent complete β-cell destruction in individuals who are either antibody positive or who have a family history of type 1 diabetes.

Tertiary prevention is of paramount importance in type 1 diabetes. In the preinsulin era, type 1 diabetes was associated with a high mortality and was in fact almost universally fatal either acutely from complicating diabetic ketoacidosis or due to the chronic catabolic state that ensued. With the increase in life expectancy that was observed following the introduction of insulin therapy, the microvascular and macrovascular complications of the condition came to light. However, it was not until advances in insulin therapy were achieved that the efficacy of glycaemic control in preventing complications could really be assessed. The earliest trial to demonstrate this was the Diabetes Control and Complications Trial (DCCT), which was conducted in the 1980s and early 1990s. This demonstrated a clear reduction in the microvascular primary end-point of retinopathy (as well as the secondary endpoints of microalbuminuria and neuropathy) in those that had been randomized to intensive therapy compared to those in the conventional therapy arm: mean HbA1c ~7% in the intensive therapy group and ~9% in the conventional therapy group. The legacy effect of good glycaemic control has now also been established in long-term follow up studies of those originally recruited to the DCCT cohort. The first, published 20 years later, demonstrated that despite a loss in glycaemic separation, those randomized to the intensive therapy group had

a significant reduction in cardiovascular endpoints compared to those in the conventional therapy group [26]. The second described improved mortality rates with intensive therapy to the extent that they resembled those of the general adult population [27].

Similar, to type 2 diabetes, the goals of tertiary prevention in type 1 diabetes involve preventing either the onset of microvascular and macrovascular complications or their progression if established. Good glycaemic control is paramount for this with antihypertensive therapy and statin therapy also contributing significantly to reductions in microvascular and macrovascular complication risk. Screening programmes for the complications of type 1 and type 2 diabetes including retinal screening and regular foot checks, while microalbuminuria assessments are also vital in ensuring that complications are detected early and appropriate steps can therefore be taken promptly to prevent their progression.

Osteoporosis and Bone Health

Osteoporosis is defined by the WHO as a 'progressive systemic skeletal disease characterized by low bone mass and microarchitectural deterioration of bone tissue, with a consequent increase in bone fragility and susceptibility to fracture'. The clinical significance of osteoporosis relates to the fractures that arise as a result of its development. Data from the International Osteoporosis Foundation in 2017 indicated that more than 8.9 million osteoporotic fractures occurred in 1 year. In the United Kingdom alone, 536 000 fragility fractures occur each year leading to severe pain and disability on an individual basis and costing the NHS over £4.4 billion per annum [28].

During development, skeletal growth proceeds through coordinated bone deposition and resorption allowing bones to expand, otherwise known as periosteal apposition of cortical bone, and lengthen (endochondral ossification) [29]. This process begins *in utero* and continues until the third decade of life at which point peak bone density is achieved. Later development of osteoporosis has been linked to peak bone density mass and national guidelines around primary prevention; for example, those in the United Kingdom have recommended levels for physical activity, healthy lifestyle and adequate vitamin D and calcium intake in childhood and early adulthood to ensure maximum achievement in peak bone density.

In those with established osteoporosis, the following tertiary preventative measures are recommended to prevent fragility fractures (adapted from the UK Guidelines for Osteoporosis and the International Osteoporosis Guidelines):

1. Calcium (700–1200 mg daily) and vitamin D supplementation (800 units)
2. Regular weight-bearing exercise
3. Falls risk assessment if appropriate

Where appropriate, antiresorptive therapy (e.g. bisphosphonates) are recommended.

Endocrinology and Other Lifestyle Factors

In addition to considering the aforementioned lifestyle modifications (e.g. healthy diet implementation and increased physical activity), abstinence from smoking has benefits. In the first instance, smoking is important in the development of goitre. Cigarette smoke contains thiocyanate, an anion that competitively inhibits sodium iodide symporter thus preventing iodine transport and organification [30]. Within areas that are iodine deficient, thyroid goitre prevalence is closely related to smoking habits. Smoking also increases the risk of developing Graves' disease and there is more than a tenfold increase in associated Graves' orbitopathy in individuals who smoke. Cessation of smoking is therefore an important tertiary measure in preventing thyroid associated eye disease.

In addition, abstinence from smoking and smoking cessation in the context of both type 1 and type 2 diabetes has been shown to reduce the risk of macrovascular complications.

Conclusions

There is an increasing appreciation that focusing on prevention and causing health systems to be more pro-active rather than reactive, is likely to contribute to long-term sustainability of those health systems. The Global Burden of Disease Study 2013 suggested that around 40% of health services workload is potentially preventable, yet the proportion of health expenditure directed at prevention, although acknowledged to be hard to estimate reliably, was thought to be closer to 4% [31]. Prevention in endocrinology has already contributed to significant health gains globally, and is likely to continue to reap significant benefits for populations moving forward.

SECTION 2

Pituitary and Hypothalamic Diseases

2.1

Functional Anatomy of the Hypothalamus and Pituitary

John F. Morris

Introduction: The Hypothalamus and Its Many Functions

The hypothalamus forms only a very small part (0.3%) of the brain but one that is the crucial integrative centre for the control, via its autonomic and endocrine effector systems, of fluid and electrolyte balance, reproduction, thermoregulation, ingestive behaviour and energy balance, affective and emotional-response systems. To do this it has extensive, reciprocal, neural and vascular connections with all other parts of the central nervous system (CNS) and, via the autonomic and vascular systems with the rest of the body. Although this chapter must focus on the hypothalamo–pituitary relationships, it must also cover hypothalamo-autonomic relationships and the relationships between the hypothalamus, the alimentary tract, and appetite control. It also plays a major role in diurnal rhythm control.

Anatomy of the Hypothalamus and Pituitary Hypothalamus

See Figure 2.1.1. The hypothalamus is that part of the diencephalon forming the lateral and inferior walls of the third ventricle; extending from the hypothalamic sulcus (which separates it from the thalamus) to the base of the brain, and from the lamina terminalis rostrally to a plane posterior to the mammillary bodies and posterior commissure caudally. It is continuous anteriorly with the septal and orbitofrontal cortex and anterior perforated substance, anterolaterally with the optic tracts and substantia innominate, dorsolaterally with the anterior part of the subthalamus and the internal capsule, and posteriorly with the tegmentum of the midbrain. The floor of the third ventricle comprises the optic chiasm, the tuberal eminence which extends into the infundibulum/pituitary stalk, the tuber cinereum, the mammillary bodies, and the posterior perforated substance. The floor of the third ventricle is marked by a distinct infundibular recess, and by the median eminence, in the inner zone of which many peptidergic neuroendocrine fibres pass either on into the posterior pituitary or end on the fenestrated capillaries of the outer zone. Specialized ependymal cells (tanycytes) line the floor and adjacent lateral walls of the third ventricle, are sexually dimorphic, and have processes that pass through the outer zone of the median eminence to end on the fenestrated blood vessels of the outer zone.

Pituitary Gland

See Figure 2.1.1. The pituitary gland is located in the sella turcica on the dorsal aspect of the sphenoid. It is attached to the infundibulum by both the pituitary stalk (composed largely of magnocellular axons en route to the posterior pituitary) and by long portal vessels that supply the anterior pituitary. Beneath the pituitary and floor of the sella turcica is the roof of the sphenoid air sinus, a relationship exploited in the transethmoid, trans-sphenoid surgical approach to the pituitary. The bony anterior margin of the sella supports the optic chiasm; lateral to the midline on either side the internal carotid artery

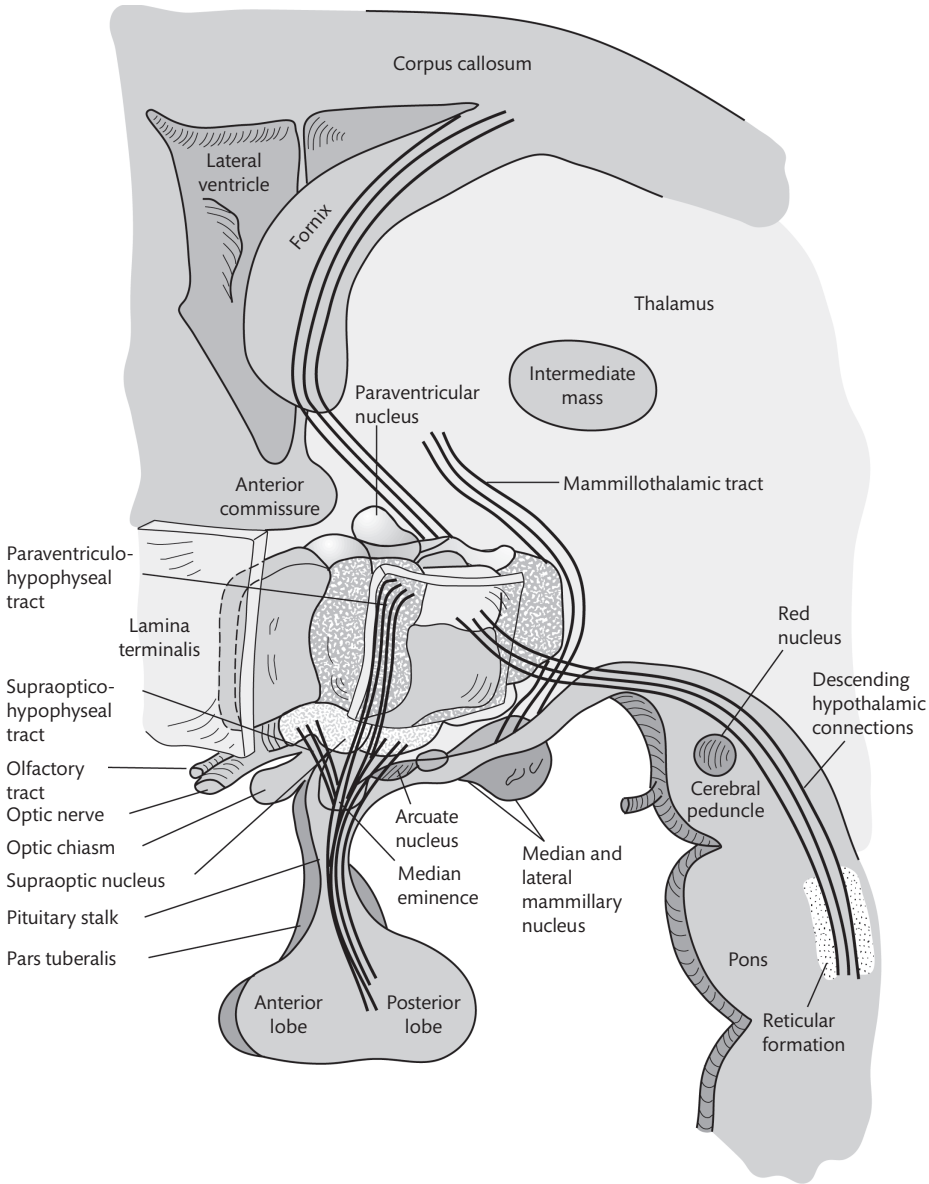

Figure 2.1.1 Hypothalamic nuclei and major tracts.

passes from the medial wall of the cavernous sinus into the subarachnoid space; lateral to the artery the anterior clinoid processes of the sphenoid give attachment to the meningeal layer of the dura forming the lateral wall of the cavernous sinus. The posterior margin of the sella is the midline dorsum sellae which ends laterally as the posterior clinoid processes to which dura forming the lateral wall of the cavernous sinus is attached. The meningeal layer of the dura continues over the pituitary as the sellar diaphragm which has a (usually) small central aperture for the pituitary stalk. The sella is lined by the periosteal layer of dura. The pituitary gland itself lacks leptomeninges which surround the stalk and below the level of the sellar diaphragm reflect on themselves forming the infradiaphragmatic pituitary cerebrospinal fluid (CSF) cistern. If this cistern is breached during transsphenoidal surgery in a person in which the diaphragmatic opening in the leptomeninges is large, persistent CSF rhinorrhoea may develop. The cavernous sinuses are situated on either side of the sella and body of the sphenoid. Each receives the superior and inferior ophthalmic veins (which communicate with the facial veins), the superficial middle cerebral vein and the sphenoparietal sinus which runs along the lesser wing of the sphenoid. The two cavernous sinuses communicate through veins anterior, posterior, and sometimes inferior to the pituitary gland. Cavernous sinus blood drains posteriorly through superior and inferior petrosal sinuses to reach the internal jugular vein and through the foramen lacerum to the pterygoid venous plexus. The oculomotor, trochlear, and maxillary and ophthalmic branches of the trigeminal pass through the lateral wall of the sinus, the internal carotid artery follows an S-shaped course in the medial wall of the sinus, with the abducent nerve on its lateral aspect. Within the cavernous sinus, the internal carotid artery gives a number of branches including fine branches which supply the sinus walls, a branch to the abducent nerve, and the posterior (but not anterior) pituitary via the inferior hypophyseal artery and pituitary capsule.

Development of the Hypothalamus and Pituitary

In the diencephalic part of the forebrain vesicle the hypothalamus develops in the floor; the thalamus develops in the roof, and eye

primordia in the lateral walls. Sonic hedgehog (Shh) secreted by the prechordal mesoderm situated below the ventral midline floor directs progenitors to hypothalamic and optic stalk fates but inhibits retinal differentiation (loss of Shh causes absent hypothalamus and cyclopia). A variety of transcription factors (including Nxk2.1, Nkx2.1, Rx, Six3) direct formation of the dorsal and ventral hypothalamus. The hypothalamus shows extensive spatial patterning with neurons becoming organized into 12–28 different nuclei. Wnt is critical in anterior-posterior patterning and BMP7 directs nuclear specification. With one exception (gonadotropin-releasing hormone (GnRH) neurons) there is little cell migration in and out of the hypothalamus after neurogenesis starts. Neurons in the lateral hypothalamic area are generated first, then neurons in the dorsomedial and ventromedial nucleus and finally those along the midline such as the arcuate nucleus. Gliogenesis occurs only after neurogenesis. GnRH neurons form from precursors which originate outside the CNS in the nasal placode and migrate in association with olfactory axon bundles. Once in the CNS, olfactory axons synapse in the olfactory bulb whereas GnRH neurons continue to migrate caudally on other axons to the hypothalamus. Mutation of a number of genes including KAL1 prevent this migration and cause Kallmann syndrome (anosmia with hypogonadotropic hypogonadism due to a failure of GnRH secretion).

The pituitary has a dual origin: the adenohypophysis (anterior lobe and intermediate zone) develops from ectoderm in the roof of the stomodeum which evaginates by week 3 of gestation to form Rathke's pouch. The dorsal portion of Rathke's pouch directly contacts the infundibulum which grows down from the floor of the developing hypothalamus to form the neurohypophysis (posterior lobe). When Rathke's pouch becomes separated from the stomodeal ectoderm by the developing sphenoid bone, remnants of the pouch form the pharyngeal pituitary. The development and differentiation of the various pituitary endocrine cell types involves the sequential and expression of several transcription factors, including PIT1 (POU1F1) and PROP 1. Corticotrophs are the earliest detectable fetal pituitary cell type, appearing by the eighth week of gestation. T-pit (Tbx19) has been identified as a critical transcription factor for both corticotroph cell differentiation and for *POMC* gene transcription (and subsequently melanotroph development in the intermediate zone). Prop-1 and Pit-1 direct the formation of somatotrophs and lactotrophs, and Pit-1 and GATA-2 that of most thyrotrophs. Finally, GATA-2 with steroidogenic factor 1 (SF1) directs the formation of gonadotrophs. Mutations in the genes encoding these transcription factors can produce pituitary hypoplasia or agenesis, and a combined deficiency of pituitary hormones (GH, PRL, TSH, FSH, LH). Mutations in the gene encoding T-pit cause congenital isolated adrenocorticotropic hormone (ACTH) deficiency. Postnatally, cell turnover in the anterior pituitary is very slow and regulated by both hypothalamic and feedback factors. The number of somatotrophs doubles during puberty and the number and size of lactotrophs changes markedly during pregnancy, lactation, and weaning. Progenitor stem cells in the anterior pituitary have been difficult to define but candidates have included the cells which line the pituitary cleft and certain types of folliculo-stellate (F-S) cells. Recently a tiny population of SOX2-expressing cells in the adult pituitary has been shown to be capable of differentiating into all the endocrine and F-S cell types. Because of the immunochemical resemblance of some F-S cells to dendritic cells a bone marrow origin has been proposed for these cells but this remains to be confirmed. Much less is known about the control of the formation of the neurohypophysis, but it has recently been shown that both Hes1 and Hes5 are required both for the evagination of the infundibulum to form the posterior pituitary, and also for the formation of pituicytes.

Blood Supply of the Hypothalamus and Pituitary

See Figure 2.1.2. The hypothalamus is supplied by small arteries which penetrate the base of the brain. These are derived from vessels forming the circle of Willis in the interpeduncular fossa. An anteromedial group from the anterior cerebral and anterior communicating arteries supply the anterior part of the hypothalamus including the optic chiasm, suprachiasmatic, and supraoptic regions and the anterior column of the fornix. A posteromedial group from the posterior communicating artery and proximal part of the posterior cerebral artery supply more posterior parts of the hypothalamus. Superior hypophyseal arteries usually arise from the internal carotid immediately after it pierces the sellar diaphragm. They form anterior and posterior branches and a plexus of vessels which surround the infundibulum. From these some branches pass toward the ependyma of the third ventricle in the median eminence where they are surrounded by a plexus of capillaries (gomitoli). In the median eminence arteries give rise to fenestrated capillaries that form an external (mantle) plexus and an internal (deep) plexus. From the external and internal plexus, long portal vessels descend along the stalk to the anterior pituitary where they branch repeatedly to form the vascular sinusoids that surround the anterior pituitary endocrine cells. Short portal vessels formed from the capillary plexus lower in the stalk also pass to the anterior pituitary. There are no capillaries among the cells of the pars intermedia. The anterior pituitary therefore has no direct arterial supply, but its fenestrated sinusoids are fed entirely by the long and short portal vessels. By contrast, the posterior pituitary and the lower part of the pituitary stalk receives a direct arterial supply from the inferior hypophyseal arteries, derived from the internal carotid artery within the cavernous sinus, and which pass directly into the posterior pituitary to form a plexus of fenestrated capillaries within that gland. A few small branches from the artery pass forward and give some supply to the periphery of the anterior pituitary. Collecting veins draining all the parts of the pituitary pass via the intercavernous and cavernous sinuses into the inferior petrosal sinus and from there into the internal jugular vein. Inferior petrosal sinus blood sampling can therefore be useful in the diagnosis of pituitary tumours.

Whereas the capillaries in most of the hypothalamus are continuous and, with the surrounding astrocytic end feet, form an effective blood–brain barrier, those in the median eminence are fenestrated, The fenestrations of the median eminence capillaries not only allow those capillaries to collect the hypophysiotropic hormones secreted by the terminals of the parvocellular neurosecretory neurons and to transfer them to the anterior pituitary, but they also provide a route whereby otherwise impermeant peptide hormones secreted by fat (e.g. leptin), the pancreas (e.g. insulin) and the gut (e.g. ghrelin) can reach neurons in the arcuate nucleus around the base of the third ventricle, where they are important signals in the homeostatic control of feeding behaviour. The median eminence is therefore one of the 'circumventricular organs' of the third ventricle (c.f. the organum vasculosum of the lamina terminalis,

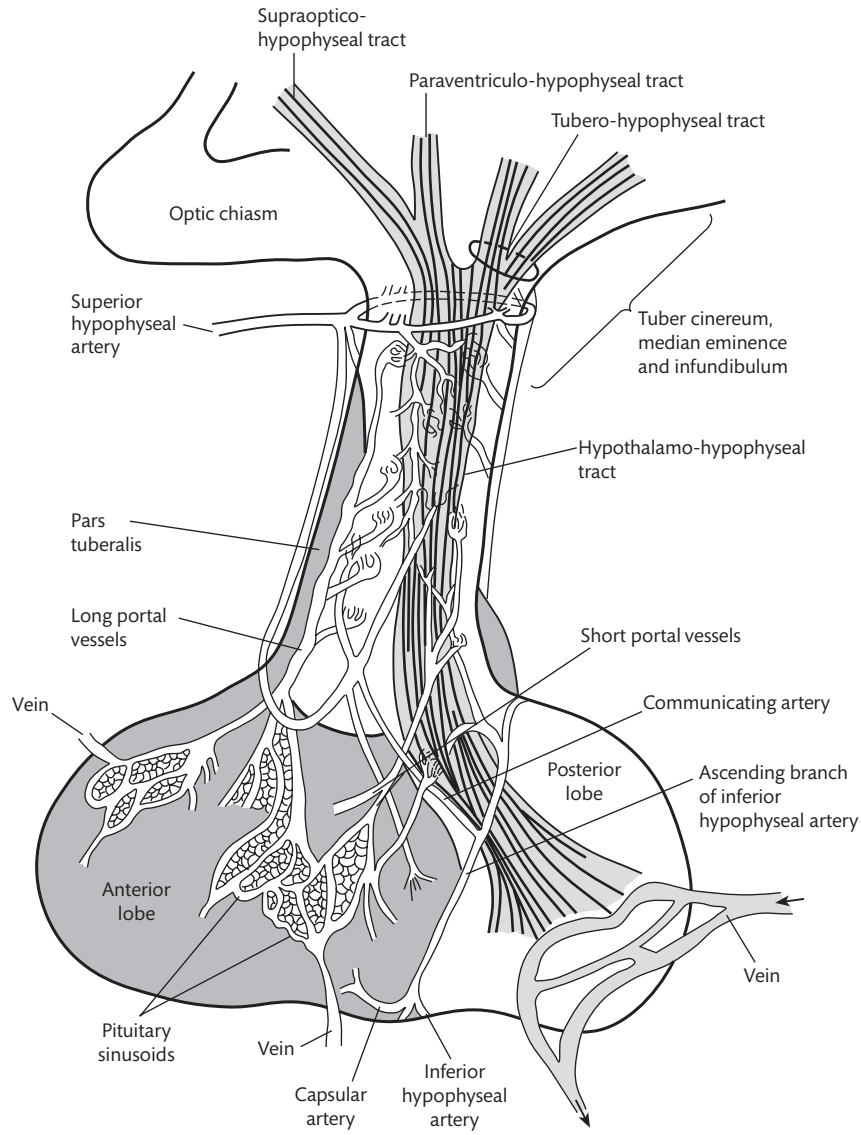

Figure 2.1.2 Vasculature of the pituitary gland.

subfornical organ, and area postrema) where the blood–brain barrier is permeable.

Cellular Structure of the Pituitary

Neurohypophysis

The neurohypophysis (posterior, or neural lobe) of the pituitary is a direct ventral extension of the infundibulum at the base of the hypothalamus. The majority of the gland is composed of the varicose axons of magnocellular neurons of the supraoptic and paraventricular nuclei which leave the nuclei and course together through the internal zone of the median eminence and pituitary stalk into the neural lobe where they branch repeatedly and form 'nerve endings' on the fenestrated capillaries. In the neural lobe the varicosities are often very large ('Herring bodies'; axonal 'swellings'). Vasopressin and oxytocin are synthesized as precursors in the magnocellular neuron cell bodies, and packaged in ~160 nm diameter dense-cored vesicles (DCV) which are transported along axonal microtubules to the neural lobe where they are released by exocytosis into the perivascular space of the capillaries. The DCV are found throughout the undilated axons, 'endings' and 'swellings' but the perivascular 'endings' are distinguished by the presence of a population of electron-lucent synaptic-like vesicles which contain glutamate the significance of which is unclear. Although the perivascular 'endings' may be the principal site of hormone release, exocytosis of DCV can occur from any part of the varicose axons. In some 'nerve swellings' there is massive lysosomal destruction of DCV, disposing of aged and effete DCV that have not been released. Intermingled among and surrounding the neurosecretory axons and also contacting the capillaries are pituicyte cells. These cells are characterized by the presence of lipid droplets and of glial acidic fibrillary protein (GFAP) an intermediate filament protein found in astrocytes. Like astrocytes, pituicytes can form gliomas ('pituicytomas'). Pituicytes express β-adrenergic and opioid receptors. When secretion of vasopressin or oxytocin is particularly active (dehydration; parturition) the extent which pituicytes enclose the neurosecretory axons is much reduced. They are also capable of

engulfing and destroying parts of the axons. Classical macrophages are located in the perivascular space of the neurohypophysis. These act to 'trim off' any neurosecretory axons that penetrate the perivascular basal lamina. The ability of neurosecretory axons to grow is also exemplified by what happens after traumatic pituitary stalk rupture. At first the distal segments of the axons die (releasing vasopressin and temporarily reducing urine output) but then, after a period of central diabetes insipidus, the increase in urine output decreases as the proximal parts of the neurosecretory axons grow and make functional contacts with capillaries in the median eminence and upper infundibulum.

Adenohypophysis

The adenohypophysis (anterior pituitary) forms about 80% of the pituitary; it comprises the large pars distalis, the very small pars intermedia, and the pars tuberalis the cells of which extend up around the infundibulum to the tuber cinereum.

The pars distalis is formed from five types of endocrine cells: corticotrophs, gonadotrophs, thyrotrophs, lactotrophs, and somatotrophs all of which synthesize and store hormone in dense-cored secretory vesicles; together with folliculo-stellate (F-S) cells—agranular, 'non-endocrine' cells, and the endothelial cells lining the vascular sinusoids. The endocrine cell types are not evenly distributed: somatotrophs and lactotrophs (acidophils) predominate laterally whereas the central zone is rich in basophil, PAS-positive corticotrophs, gonadotrophs, and thyrotrophs. Of the total, somatotrophs form about 50%, lactotrophs 20%, corticotrophs 15%, gonadotrophs 10% and thyrotrophs 5% of the endocrine cells. Somatotrophs, which secrete growth hormone (GH; 191 aa), are ovoid cells of medium size containing abundant spherical DCV of ~300 nm diameter. Somatotroph adenomas contain variable numbers of DCV, but those with few DCV tend to be more aggressive with a worse response to therapy. Lactotrophs secrete prolactin (PRL; 199aa) and exist in a number of different types, depending on the size and morphology of their DCV. Type I lactotrophs contain many large (300–900 nm) irregularly shaped DCV that are thought to represent greater storage; type II lactotrophs contain smaller (<200 nm) spherical DCV and are thought to be the more actively secreting form (though type I cells can be stimulated to exocytose their large irregular DCV). There are also intermediate forms, and some 'somatomammotrophs' produce both GH and prolactin which is not unexpected as both somatotrophs and lactotrophs are derived from a common precursor. Lactotrophs are particularly influenced by oestradiol, and in pregnancy the increased number and size of lactotrophs causes the entire pituitary to enlarge. Some lactotrophs are situated in close relationship with gonadotrophs. Increased prolactin has a marked inhibitory effect on gonadotrophs and prolactinomas are a common cause of infertility. As with somatotroph adenomas, lactotroph adenomas tend to have fewer, smaller DCV. Corticotrophs are medium sized irregular polygonal cells in which the DCV (150–250 nm) are largely situated at the cell periphery, just beneath the plasmalemma. Corticotrophs synthesize pro-opiomelanocortin (PMC) which is cleaved in corticotrophs to yield adrenocorticotrophic hormone (ACTH; 39aa), β-lipotropin, and endorphins. Most corticotroph adenomas are basophilic (many DCV) or chromophobe (few DCV) monoclonal tumours most of which secrete ACTH and cause Cushing's disease. When cortisol is excessive, corticotrophs develop Crooke's hyaline changes caused by an accumulation of microfilaments. Because the adenoma cells remain sensitive to and inhibited by cortisol, they remain small microadenomas. In contrast 'silent' adenomas or macroadenomas synthesizing high-mw POMC are aggressive and invasive.

Gonadotrophs are large basophilic cells with extensive cytoplasm; most produce both follicle-stimulating hormone (FSH; 204aa) and luteinizing hormone (LH; 204aa), though in some only one of the gonadotrophins can be detected. Their DCV tend to be scattered throughout the cytoplasm except at the time of the preovulatory gonadotrophin surge, when they are located more marginally. The DCV vary in appearance from small spherical (250 nm) vesicles with uniformly dense cores, to larger, more ovoid vesicles with a dense core and more lucent surround. The relative production of FSH and LH is determined by the frequency of GnRH pulses and the amount of inhibin. Functioning gonadotroph adenomas (mostly macroadenomas) are very rare. They can cause menstrual irregularity and ovarian hyperstimulation in premenopausal females, testicular enlargement in males, and precocious puberty in children. Most gonadotroph adenomas are 'silent' or non-functioning and the most common type of macroadenoma. They may be asymptomatic or cause neurological effects via increasing mass. Most commonly they produce FSH or the alpha subunit, but do so very inefficiently.

Thyrotrophs are the least common, the smallest and contain the smallest DCV (100–150 nm) of any pituitary endocrine cell. They produce thyrotropin (TSH; 201aa).

Folliculo-stellate cells are a heterogenous group of cells that comprise about 5% of anterior lobe cells and whose functions are only recently being revealed. They are characterized by a lack of dense-cored secretory vesicles, by the expression of S100 protein, and by their linkage together to form follicles and a network throughout the anterior pituitary coupled electrically by gap junctions and calcium waves. They produce many signalling molecules with paracrine effects on the endocrine cells including growth factors, cytokines, nitric oxide and annexin 1 (which is implicated in the early inhibitory effect of glucocorticoids on ACTH release). There is evidence that some folliculostellate (FS) cells may act as stem/progenitor cells for the anterior pituitary.

The pars tuberalis (pars infundibularis) is an upward extension of the anterior lobe along the pituitary stalk.

The pars intermedia is vestigial in human adults, but its scattered cells can produce POMC and these can intrude into the anterior margin of the neurohypophysis (basophilic invasion')

The pharyngeal pituitary is a small, but consistent embryologic remnant mass of tissue located either in the submucosa of the dorsal wall of the nasopharynx or in the sphenoid (i.e. along the line of Rathke's pouch contact with the forebrain vesicle). The cells are often chromophobe (few DCV) and inactive, but rarely form adenomas which cause Cushing's syndrome, acromegaly, hyperthyroidism, or prolactinoma.

Hypothalamic Neuroendocrine Neurons: Endocrine and Central Effects

For this volume it is particularly important to consider the neuroendocrine neurones. These form two major groups: magnocellular neurons of the supraoptic and paraventricular nuclei which project to the posterior pituitary and release oxytocin or vasopressin into the systemic circulation; and the more scattered parvocellular

neurosecretory neurons which produce the releasing- and release-inhibiting factors and project to the capillaries of the median eminence where they release their signalling molecules to control the anterior pituitary endocrine cells via the hypothalamo–pituitary portal veins. Although vasopressin and oxytocin in peripheral blood can be assayed for diagnostic purposes, the concentrations of the parvocellular releasing and release-inhibiting factors are normally too low for assay, and such measurements are useful only when investigating ectopic secretion by tumours.

Most magnocellular and parvocellular neurosecretory neurons secrete peptides. These are produced from larger precursors and packaged into DCV in the cell bodies. The DCV are transported along varicose axons of the neurosecretory neurons to their neurohaemal contacts (indeed, this defines the neurons as 'neuroendocrine'). The role of DCV in the dendrites of neurosecretory neurons was not understood until it was shown that they can be released from the dendrites and that dendritic release into the hypothalamus is controlled separately from neurohaemal axonal release and that the released peptides have important local autocrine and paracrine physiological effects. This has been demonstrated most clearly for magnocellular neurons secreting oxytocin or vasopressin, but it seems likely that it applies more generally to peptidergic neurons. Indeed, the two long processes of GnRH neurons both contain GnRH DCV and are contacted by synaptic boutons along their length, making them intermediate between axons and dendrites ('dendrons'). There is also now evidence that the oxytocinergic neurons of the posterior part of the paraventricular nucleus that project varicose axons down the spinal cord release oxytocin from non-synaptic varicosities to influence the lumbar gastrin-releasing peptide (GRP) neurons to facilitate male reproductive activity. It is clear, therefore, that peptidergic neuroendocrine neurons can have much more widespread effects in the CNS than those caused by the neurohaemal release of their products. This is consistent with the widespread distribution of receptors for the peptides, often far distant from relevant peptidergic axons. Neuroendocrine neurons are only one subset of peptidergic neurons—the extent to which these considerations apply generally to all peptidergic neurons remains to be determined.

Functional Hypothalamic Neuron Groups and Hypothalamo-Pituitary Systems

See Figure 2.1.1. The landmarks of the ventral surface of the hypothalamus are used to divide it into an anterior (preoptic and supraoptic), a middle (tuberal), and a posterior (mammillary) zone. On each side of the third ventricle is a narrow periventricular zone, a medial zone with relatively well-defined nuclei, and a lateral hypothalamic area where cell groupings are less clear. Some nuclei, such as the paraventricular nucleus, comprise a number of structurally and functionally different subnuclei. Such neuronal groupings usually reflect integrative centres from which the neurons exert efferent control.

Anterior Zone: Circadian Rhythm; Osmotic and Thermal Homeostasis; Stress Response

Preoptic region—osmotic and thermal sensing: The preoptic region comprises the periventricular grey matter around the rostral extremity of the third ventricle. One population of kisspeptin/neurokinin B neurons is located here in greater numbers in females than in males (see Figure 2.1.9). Two of the circumventricular organs where the blood–brain barrier is permeable are located the anterior region. Some organum vasculosum of the lamina terminalis (OVLT) neurons are intrinsically osmosensitive and essential for normal thirst responses (see Figure 2.1.4); others are thermo-, prostaglandin, and interleukin 1-sensitive cells involved in thermoregulation and the febrile response. The subfornical organ (SFO), located on the ventral aspect of the fornix just behind the interventricular foramen and the median preoptic nucleus are also involved in thirst and fluid regulation

Supraoptic Region

Suprachiasmatic nucleus (SCN)**—circadian control** [1]: See Figure 2.1.3. Immediately above the optic chiasm are the SCN, discrete bilateral groups of cells which form the body's principal circadian clock. Its neurons and astrocytes exhibit an autonomous timing mechanism based on transcriptional and post-translational feedback loops. It receives a direct input from light-sensitive ganglion cells of the retina which modify its intrinsic rhythmicity according to the light–dark cycle. The rhythmic output from the SCN projects dorsally into the periventricular zone and more widely, via both gamma aminobutyric acid (GABA) and neuropeptides including vasopressin and VIP, to centres in the medial hypothalamus and brainstem that control arousal, sleep, feeding, neuroendocrine behaviour, and autonomic status.

Supraoptic nucleus (SON) and **paraventricular nucleus** (PVN) [2]: Magnocellular neurons of the SON and PVN produce either vasopressin (ADH) for osmotic and volume regulation (Figure 2.1.4) or oxytocin for milk ejection and parturition (Figure 2.1.5), each with their respective neurophysin. The SON neurons lie dorsal and lateral to the optic chiasm and optic tract. Their varicose axons all project posteromedially to the inner zone of the median eminence and on into the neurohypophysis; their dendrites project ventrally to form a dendrite-rich zone on the ventral surface of the brain. PVN magnocellular neurons are located laterally in the PVN. Their axons pass laterally around the anterior columns of

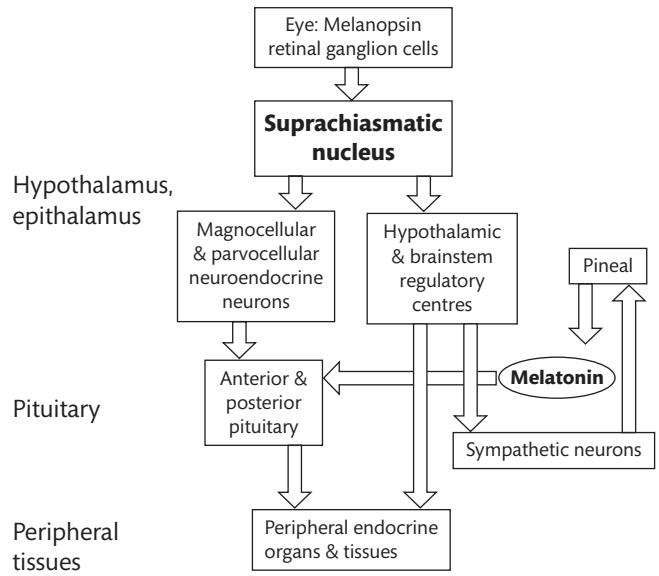

Figure 2.1.3 Control of circadian rhythms.

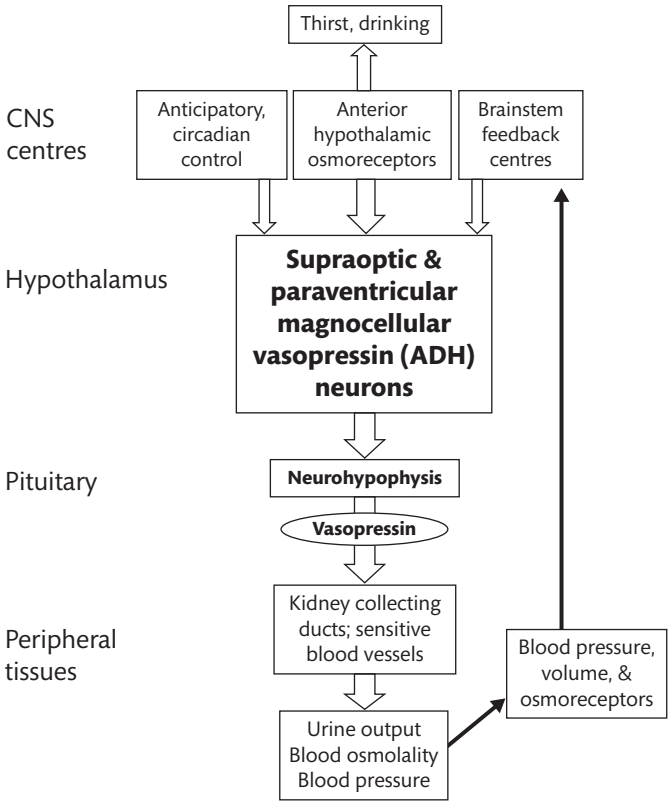

Figure 2.1.4 Osmotic and volume regulation.

fornix then ventrally to join the supraoptic axons to pass through the median eminence and into the neural lobe; their dendrites project medially and form a plexus beneath the ependyma of the third ventricle. Vasopressin neurons receive osmotic inputs from the anterior hypothalamus, volume and stress inputs from the brainstem; oxytocin neurons receive spinal inputs from the breast and uterus.

Whereas the SON is composed entirely of magnocellular neurosecretory neurons, the PVN contains many different types of neuron and forms a complex integrative centre. Parvocellular neurosecretory neurons of the PVN are located ventromedially, their axons passing ventrally to end on median eminence capillaries. They produce corticotrophin-releasing hormone (CRH; 41aa), vasopressin, or thyrotropin-releasing hormone (TRH; 3aa).

Parvocellular oxytocin neurons project to various brainstem nuclei and regions of the spinal cord. Recent evidence suggests that they involved in the modulation of feeding (Prader–Willi syndrome), cardiovascular and respiratory functions, inflammatory pain processing and, via axons ending in the sexually dimorphic nuclei of the lumbosacral cord, male sexual activity.

Hypothalamo–pituitary stress axis [3]: See Figure 2.1.6. CRH neurons are a key part of the hypothalamic–pituitary–adrenal (HPA) axis stress response system. Interestingly, limbic centres have minimal direct projections to the CRH neurons, but afferents from the hippocampus, prefrontal cortex, and amygdala mostly relay in the bed nucleus of the stria terminalis, hypothalamus, and brainstem to influence CRH neurons in the PVN. They are, however, directly responsive to glucocorticoids as are many of their inputs. Some CRH neurons also produce vasopressin when stressed and this acts synergistically with CRH to stimulate ACTH. Other parvocellular vasopressin neurons project widely in the hypothalamus and to the limbic system, the brainstem, and the spinal cord where they are involved in blood pressure and temperature regulation, including brown fat thermogenesis. Oxytocin neurons in the posterior part of the PVN project mainly to the brainstem and spinal cord where they have roles in gastric reflexes and penile erection. The PVN also act as a hypothalamic integrative centre for feeding.

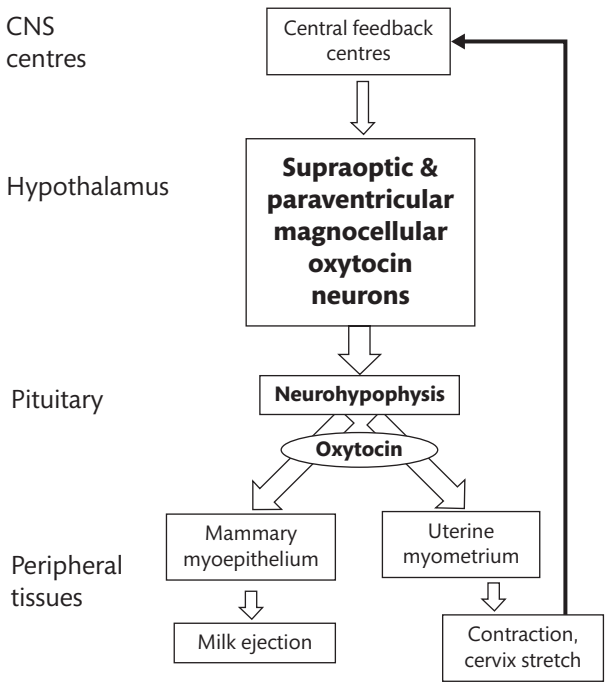

Figure 2.1.5 Oxytocin pathways and their effects.

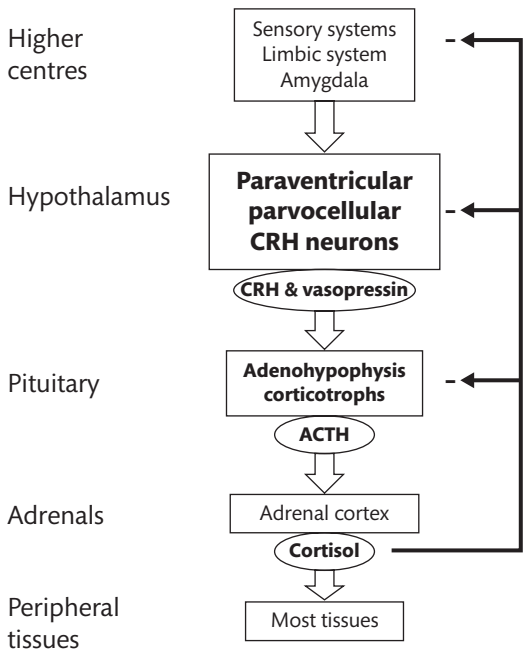

Figure 2.1.6 Endocrine and neural stress control system.

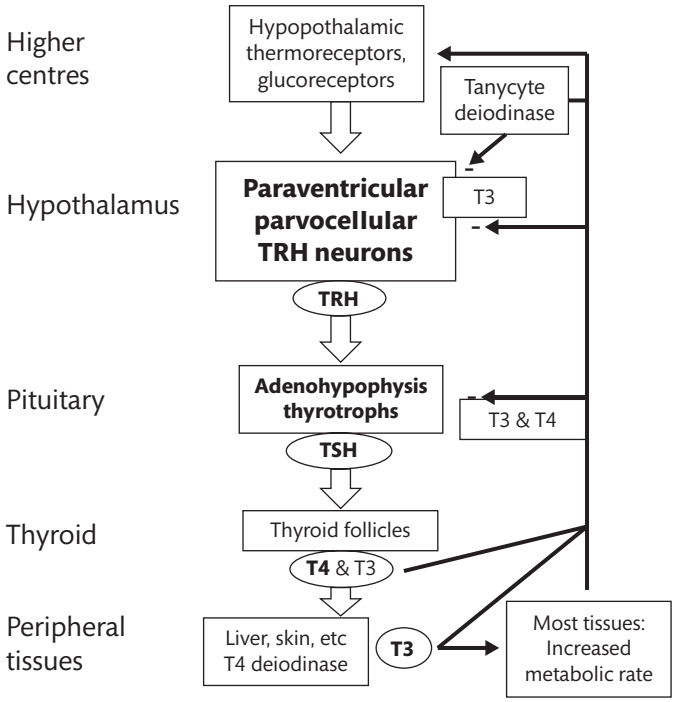

Figure 2.1.7 Hypothalamo–pituitary–thyroid system.

Hypothalamo–pituitary–thyroid axis [4]: See Figure 2.1.7. TRH-secreting neurons in the medial and periventricular parvocellular parts of the PVN act as a hypothalamic integrator of energy metabolism. They receive inputs from arcuate neurons involved in feeding control and have reciprocal connections with AHA neurons involved in thermoregulation. They express T3 receptors and hypothalamic T3 is produced by type 2 iodothyronine deiodinase in local tanycytes. Their axons project to the median eminence to control anterior pituitary TSH and thus thyroid activity and metabolism. TRH expression is reduced in fasting and by endotoxins to decrease metabolic rate.

Anterior and lateral hypothalamic areas: These areas contain less well-defined groups of neurons. The **anterior hypothalamic area** (AHA), which blends with the preoptic area and extends caudally into the middle (tuberal) zone, is the location of thermosensitive neurons that form the key body thermostat. Their thermal sensitivity is conferred by the expression of TRPM2 channels, but the neurons also receive and integrate inputs from peripheral temperature sensors and also from inflammation-derived cytokines. Fever is thought to be the result of prostaglandin E2 (PGE2) inhibition of warm-sensitive neurons hence the ability of aspirin to reduce fever. The outputs of these neurons influence the central autonomic control neurons. Warming the thermosensitive area induces heat loss via vasodilation, sweating, and behavioural adaptation; cooling triggers the opposite. It is therefore unsurprising that damage to the area (e.g. after surgery for large pituitary tumours) can cause loss of body temperature control. The neurons also activate the PVN CRH neurons in fever-induced stress. Neurons of the **lateral hypothalamic area** (LHA) are involved in a number of important functions: sleep, feeding, sex, and reward. Early lesion experiments associated the lateral hypothalamus with reduced feeding and increased sexual activity; it was therefore designated a 'feeding centre'. Studies have now shown that both wakefulness and feeding are associated with increased activity of LHA orexin neurons as well as brainstem arousal systems including the noradrenergic locus coeruleus. In contrast, LHA neurons expressing melanin-concentrating hormone (MCH) promote sleep and feeding by circuits that are still being elucidated, though both orexin and MCH neurons project to the PVN integrative centre and the LHA receives inputs from the central amygdala and from hypothalamic nutrient-sensing neurons.

Middle (tuberal zone): control of the anterior pituitary, growth, feeding and metabolism: The hypothalamus is widest in the tuberal region, and the anterior columns of fornix separate the medial group of nuclei from the LHA and medial forebrain bundle. Ventrally, the **arcuate (infundibular)** nucleus surrounds the base of the third ventricle; above it is a distinct **ventromedial** (VM) nucleus and above that a less distinct **dorsomedial** (DM) nucleus. Much recent attention has concentrated on the arcuate nucleus which has important functions in feeding (it receives peptide hormonal signals from the gastrointestinal tract and adipose tissue via the permeable capillaries in the median eminence), in reproduction (through its kisspeptin, GnRH, and dopamine neurons) and growth (though its growth hormone-releasing hormone (GHRH) and somatostatin neurons).

Feeding and metabolism control [5]: See Figure 2.1.8. Although early lesion experiments designated the ventromedial area as a 'satiety' centre, it was the discovery of leptin, and of arcuate neurons producing either neuropeptide Y (NPY) and agouti-related peptide (AgRP) which promote feeding or POMC (acting via alpha-MSH and the MC4 receptor) and CART (cocaine- and amphetamine-related transcript) which inhibit feeding, that dramatically increased understanding of homeostatic feeding control. Not only are many of the neurons of the area influenced by circulating levels of glucose, fatty acids, and some amino acids, but virtually all of the signalling molecules produced by the pancreas (insulin, amylin), the gastrointestinal tract (ghrelin, GLP-1, PYY, CCK) and adipose tissue (leptin, adiponectin, interleukins) influence arcuate neurons to signal nutritional status. Of these, ghrelin, secreted by the stomach when empty, stimulates feeding; the remainder inhibit feeding—the system has evolved to protect us against famine, not against obesity! The NPY/AgRP and POMC/CART neurons are reciprocally interconnected and connected with the LHA, the ventromedial

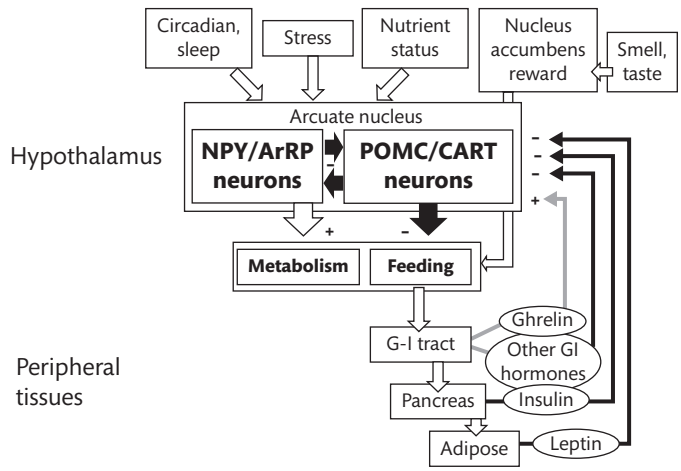

Figure 2.1.8 Feeding and metabolism control system.

hypothalamus (VMH) and dorsomedial hypothalamus (DMH), and the integrative centre in the PVN to provide a functional network that normally maintains nutritional homeostasis. However, it is also now clear that the forebrain nucleus accumbens reward centre, which responds to food taste, food novelty, energy content, and social pressures can override the hypothalamic homeostatic control of feeding—hence the current western world obesity epidemic. Mutations in leptin, the leptin receptor, POMC processing, and the MC4 receptor for alpha-MSH all produce major obesity syndromes; mutations in the other signalling systems have more minor effects because of compensation by other of the signals involved. Recently, a genome-wide scan identified the FTO (fat and obesity) gene as a major component of the polygenic control of obesity. Unsurprisingly, the FTO gene is expressed particularly in the arcuate nucleus and PVN. Hypothalamic mechanisms controlling feeding inevitably also influence the autonomic and TRH systems controlling metabolism, and the systems controlling growth and reproduction.

Gonadotrophin control [6]: See Figure 2.1.9. Reproductive function requires the pulsatile release of hypothalamic gonadotrophin-releasing hormone (GnRH; 10aa) to control FSH and LH secretion from the pituitary. During reproductive life GnRH is secreted in circhoral pulses; oestradiol speeds up the pulses in the preovulatory period whereas progesterone slows the pulses after ovulation. In primates, unlike other animals, a GnRH surge is not required to generate an LH surge; unvarying infusion of circhoral pulses of GnRH can restore fertility in Kallmann syndrome. Most GnRH neurons are located in the infundibular (arcuate) hypothalamus though scattered cells are located more anteriorly. Their essential projection is to the capillaries of the median eminence to stimulate pituitary gonadotrophs via the portal veins. Although sex hormones have feedback effects directly on pituitary gonadotrophs, the generation of a preovulatory LH surge in primate females requires a 'positive feedback' action of oestradiol in the hypothalamus. The action of progesterone to slow GnRH pulses after ovulation also occurs in the hypothalamus. However, the relevant oestradiol and progesterone receptors are located, not on GnRH neurons, but on kisspeptin (KP) neurons which are also mostly located in the arcuate nucleus. They stimulate the activity of GnRH neurons and play a vital role in the pulsatile secretion of GnRH. The failure of either GnRH or KP action causes hypothalamic hypogonadism and infertility, and constitutive activity of mutant KP receptors on GnRH neurons is a cause of precocious puberty. There appear to be at least two population of KP neurons, one of which is stimulated, and one inhibited by oestradiol; both also express dynorphin and neurokinin B. Kisspeptin neurons express leptin receptors and provide a link between low body weight, delayed puberty, and reproductive problems. Experimentally, stresses and prolactin can reduce KP expression and action suggesting a role for KP in mediating the suppression of reproductive function in hyperprolactinaemia and stress. Clinical studies in assisted reproduction suggest that administration of KP may confer less risk of ovarian hyperstimulation than hCG in assisted.

Prolactin control [7]: See Figure 2.1.10. Arcuate nucleus dopamine neurons (tubero-infundibular neurons) have long been known to project to median eminence capillaries and form the major negative control on prolactin (PRL) secretion from pituitary lactotrophs. About half also release GABA within the arcuate

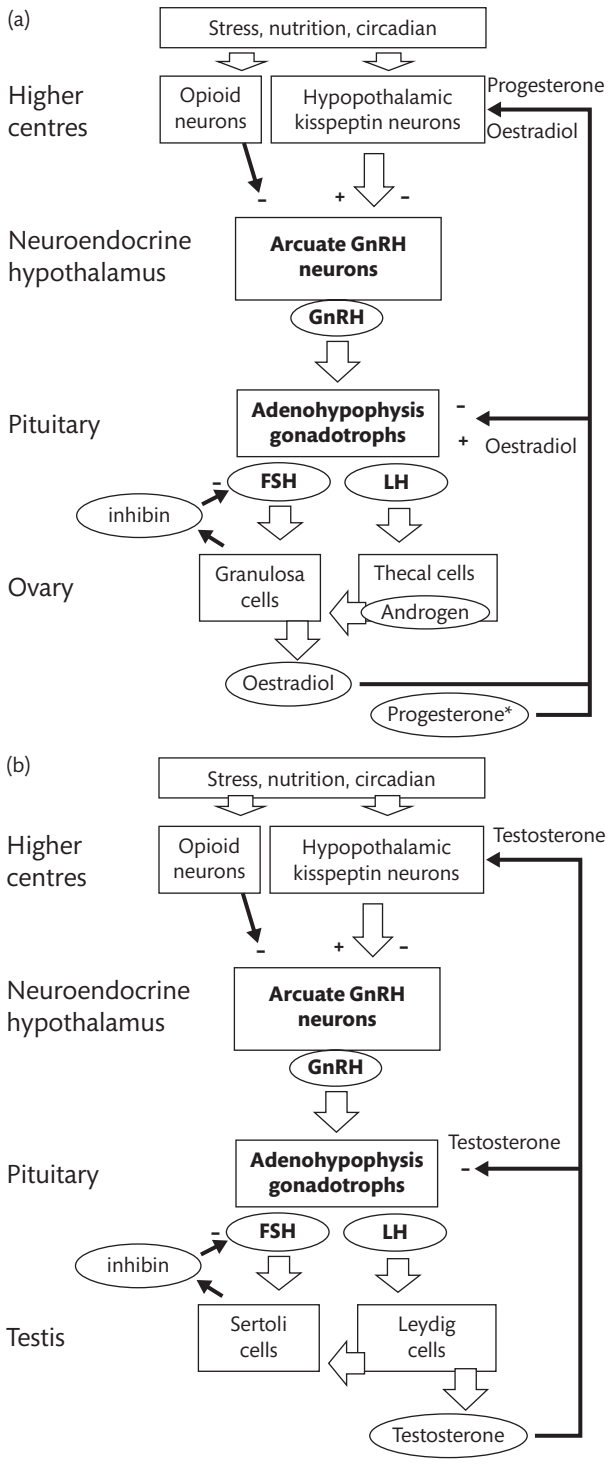

Figure 2.1.9 Reproductive control system.

nucleus and themselves express the D2 and PRL receptors creating an important a short-loop inhibitory feedback system. Humans with an inactivating mutation of the PRL receptor are hyperprolactinaemic. Exogenous administration of TRH and hypoglycaemia resulting from an insulin tolerance test both stimulates PRL secretion. Neither hypoglycaemia nor TRH are physiological regulators of systemic PRL but the TRH effect may explain the hyperprolactinaemia seen in hypothyroidism. Like GH, PRL is secreted in pulses, especially during stage 3 sleep. Circulating PRL is

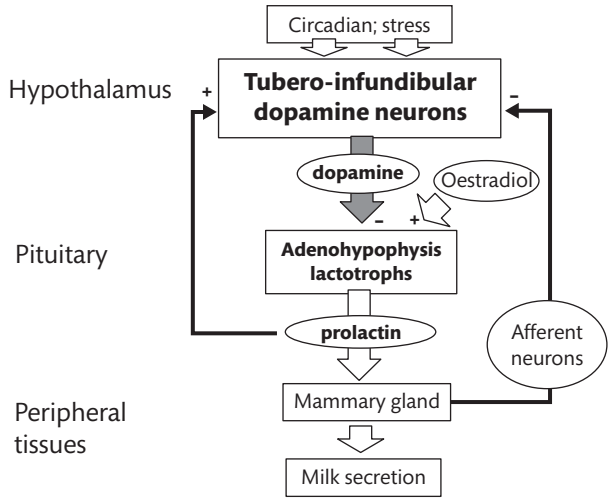

Figure 2.1.10 Growth control system.

generally maintained at low levels in men and non-pregnant women but, during pregnancy, increasing oestradiol stimulates significant lactotroph hyperplasia and prolactin secretion for mammary gland growth. During lactation, the suckling stimulus not only stimulates oxytocin secretion to cause milk ejection, but also inhibits dopamine release and thereby stimulates release of PRL to replenish mammary stores of milk. It is now clear that, like magnocellular neurons and substantia nigra dopamine neurons, arcuate dopamine neurons also release dopamine from their somata and dendrites to influence appetite, growth, and reproductive circuits in the arcuate nucleus. Hyperprolactinaemia resulting from lactotroph adenomas is well known to cause infertility in women and impotence in men through both central and systemic effects. Evidence showing widespread distribution of PRL receptors in the brain and transport of PRL into the brain via its vasculature suggest that many neural and neuroendocrine functions can be influenced by PRL.

Growth hormone control [8]: See Figure 2.1.11. The secretion of growth hormone (GH) is controlled by two hypothalamic hormones: growth hormone-releasing hormone (GHRH; 44aa) and somatostatin (14aa) and by the negative feedback of both GH and IGF-1 at the pituitary and hypothalamus. Both GHRH and somatostatin are also produced widely in splanchnic tissues (GHRH was first isolated from a pancreatic adenoma). GHRH stimulates both the synthesis and release of GH; somatostatin inhibits GH release but not GH synthesis; both are secreted in pulses. Shorter analogues of GHRH are used clinically. GH is normally released in pulses (8–12/day) with a large pulse during sleep, particularly in males; the generation of a GH pulse requires the coincidence of a GHRH pulse when somatostatin release is low. GHRH neurons are situated ventrolaterally in the arcuate nucleus; somatostatin neurones are more widespread, although the most are located in the periventricular zone of the AHA and infundibulum/arcuate nucleus. In addition to inhibiting GH release, hypothalamic somatostatin also inhibits TSH release. Like GnRH neurons, most GHRH neurons are fusiform with processes emerging from each pole; the processes of both the GHRH and somatostatin neurons form a dense network in the arcuate nucleus and contact the portal capillaries in the median eminence. Somatostatin fibres form multiple inhibitory contacts with GHRH perikarya, but GHRH fibres only rarely contact somatostatin perikarya. Feedback by GH to the hypothalamus is primarily negative feedback on somatostatin release. GH secretion is also regulated by peripheral signals such as T3, cortisol (inhibitory), androgens (stimulatory), nutrients such as glucose and fatty acids and metabolites. Hypoglycaemia and low free fatty acids (e.g. in starvation or as a result of an insulin tolerance test (ITT)) stimulate, whereas glucose infusion inhibits GHRH and thus GH release. In contrast, arginine and other amino acids stimulate GH release via hypothalamic sensors. Somatotroph adenomas cause excessive growth in children, acromegaly in adults. Although pulsatile secretion of GH stimulates growth (it increases at puberty and declines in old age) persistently raised GH causes insulin resistance. Synthetic growth hormone-releasing peptides (e.g. GHRP-6; hexarelin) which act on the ghrelin receptor can be used to stimulate GH secretion. Long-acting and selective somatostatin analogues (octreotide, lanreotide) are used to treat excessive growth and acromegaly.

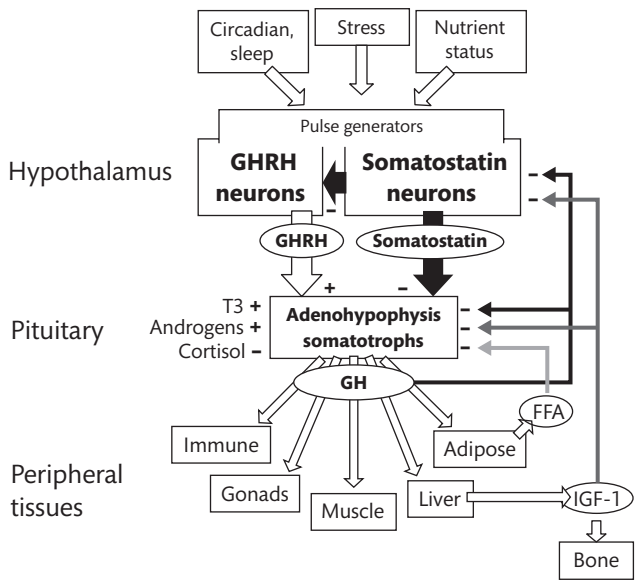

Figure 2.1.11 Prolactin control axis.

Ventromedial (VMH) Nucleus

The VMH forms a fairly well-defined group of neurons dorsal to the arcuate nuclei. Many fibres which pass between the arcuate and paraventricular nuclei pass through it, so it is not surprising that VMH lesions cause hyperphagia and hyposexuality as in Fröhlich's syndrome. Nuclear steroidogenic factor 1 plays a key role in development of the VMH and is exclusively expressed there. Like the arcuate nucleus, VMH neurons are involved in metabolic control, but VMH neurons do not produce specific peptides and its functions have been more difficult to define, though it plays a key role in controlling the sympathoadrenal response to hypoglycaemia. Experimentally, about half the VMH neurons are either stimulated or inhibited by glucose, many express the intracellular energy sensor AMP-kinase (AMPK) and many express insulin, leptin, ghrelin, and cannabinoid receptors. Other parts of the VMH express oestrogen receptor alpha and are involved in autonomic responses to aggressive or sexually attractive situations.

Dorsomedial Nucleus (DMH)

Like the VMH, the DMH is involved in the integration of many aspects of feeding, and in autonomic stress responses. It receives direct and indirect inputs from the SCN and sends projections to the sleep-promoting part of the preoptic nucleus and the orexin neurons of the LHA which promote wakefulness. It receives both neural and hormonal input from other areas important in the regulation of feeding and its activity increases at the expected time of a meal. Inputs from the amygdala signal acute stress and DMH efferents to the ventrolateral medulla and raphe nuclei mediate DMH cardiovascular effects via projections to spinal sympathetic preganglionic neurons.

Posterior Zone (Mamillary Region): Limbic and Autonomic Control

The posterior zone of the hypothalamus comprises the poorly defined posterior hypothalamic area and the well-defined mammillary bodies with various subnuclei. The posterior hypothalamus contains histaminergic neurons and orexin neurons activated in arousal. It receives inputs from diverse areas including the limbic forebrain and mid- and hind-brain areas involved in nociception. Stimulation of the posterior hypothalamus activates sympathetic responses.

Mammillary Bodies

The **mammillary bodies** are well-known as a target of hippocampal fornix fibres and an integral part of 'Papez circuit' with a role in memory. Lesions in this part of the diencephalon cause Korsakoff syndrome. The mammillary bodies comprise two main nuclei: medial and lateral. All mammillary neurons contribute axons to the mammillo-thalamic tract (MTT) that terminates in the anterior thalamus; lesions of the MTT cause anterograde amnesia and poor spatial memory. Mammillary neurons are connected with tegmental motor nuclei via the mammillo-tegmental tract.

Fibre Systems Connecting the Various Nuclei of the Hypothalamus

As would be expected of a part of the brain which integrates many different physiological functions, the various components of the hypothalamus have extensive, complex, and usually reciprocal connections with many regions of the forebrain, brainstem, and spinal cord. There are few large myelinated fibre tracts and only relatively recently have a variety of tracing techniques elucidated the more subtle connections.

Information about the light–dark cycle is passed to the hypothalamus via **retino-hypothalamic** fibres that originate from retinal ganglion cells and project to the suprachiasmatic nuclei. Olfactory inputs reach the hypothalamus from the pyriform cortex, amygdala, and orbitofrontal cortex; gustatory inputs from the brainstem and orbitofrontal cortex; both are involved in arousal and feeding behaviour. Visual and auditory inputs affect the hypothalamus after their significance has been assessed by the limbic system; nociceptive inputs influence hypothalamic function via brainstem connections and the **medial forebrain bundle** (MFB). The hypothalamus (especially the paraventricular nucleus) receives information from the viscera via ascending projections from the solitary nucleus of the medulla, which itself receives sensory input from the facial, glossopharyngeal, and vagus nerves. The MFB is actually a series of fibre bundles that run through the lateral part of the hypothalamus, interconnecting basal forebrain olfactory cortex, septum, and brainstem. The mesolimbic pathway of dopamine fibres from the ventral tegmental area to the nucleus accumbens is a component of the MFB and of the reward system. Together with mesocortical dopamine fibres it forms one of the 'fountains' that spread diffusely throughout the forebrain from the locus coeruleus (noradrenaline), raphe nuclei (serotonin), and basal nucleus of Meynert (acetylcholine). Brainstem reticular afferents from the central grey of the midbrain reach the hypothalamus via the **dorsal longitudinal fasciculus**.

The **fornix** is a large bundle that connects the hippocampal formation with the septal cortex, anterior thalamus, hypothalamus, and mamillary bodies. Most of its fibres originate from pyramidal hippocampal neurons. Commissural fibres link the two hippocampi. Anteriorly, precommissural fibres pass rostral to the anterior commissure to the septal nuclei, the preoptic and dorsal hypothalamic areas; postcommissural fibres pass caudally through the lateral part of the hypothalamus to the medial mammillary nucleus. The fornix also carries cholinergic axons from the basal nucleus to the hippocampus; degeneration of these is a feature of Alzheimer disease. The nuclei of the amygdala are connected to many parts of the hypothalamus by two distinct pathways: the **stria terminalis** (which parallels the course of the fornix) ends in the bed nucleus of the stria terminalis and medial hypothalamus; the **ventral amygdalofugal pathway** links the basolateral amygdala to the lateral hypothalamus and MFB. These convey olfactory and visceral information to the hypothalamus and are important in mediating autonomic and endocrine responses particularly to aversive stimuli ('fear reaction').

Apart from its neuroendocrine efferents, most neural efferent connections of the hypothalamus are reciprocal to its afferents. Fibre tracts link hypothalamic autonomic centres to brainstem and spinal cord preganglionic autonomic neurons; descending fibres controlling sympathetic activity pass through the lateral medulla and lateral medullary (Wallenberg) lesions cause a Horner syndrome. Neurons of the posterior part of the PVN project oxytocin fibres to the sex dimorphic nuclei of the lumbosacral cord.

The Neurohypophysis

Stephen G. Ball

Neuroanatomy, Molecular Biology, and Physiology of the Neurohypophysis

The neurohypophysis is a complex neurohumoral system with a key role in body fluid homeostasis and reproductive function. This chapter will concentrate on the physiology and pathophysiology of the two hormones made by the neurohypophysis, vasopressin (VP), and oxytocin (OT); outlining the roles of both hormones together with the molecular, cellular, and anatomical basis of their regulation and action.

The Neurohypophysis: Neuroanatomy

The neurohypophysis consists of three parts which together form a functional unit; the supraoptic and paraventricular nuclei of the hypothalamus, containing the cell bodies of the magnocellular, neurosecretory neurones that synthesize and secrete VP and OT; the supraoptico-hypophyseal tract, which includes the axons of these neurones; and the posterior pituitary, where the axons terminate on capillaries of the inferior hypophyseal artery (Figure 2.2.1).

The supraoptic nucleus (SON) is situated along the proximal part of the optic tract. It contains the cell bodies of discrete vasopressinergic and oxytocic magnocellular neurosecretory neurones which in turn, project to the posterior pituitary along the supraoptico-hypophyseal tract. In man, vasopressinergic neurones are found in the ventral SON, with oxytocic neurones situated dorsally. The paraventricular nucleus (PVN) also contains discrete vasopressinergic and oxytocic magnocellular neurones which also project to the posterior pituitary along the supraoptico-hypophyseal tract. In man, magnocellular neurones of the PVN synthesizing VP are found centrally in the nucleus, with oxytocic neurones in the periphery. The PVN contains additional, smaller parvicellular neurones projecting to the median eminence and additional extrahypothalamic areas including forebrain, brainstem, and spinal cord. A group of those projecting via the median eminence cosecrete VP and corticotrophin releasing hormone (CRH), and terminate in the hypophyseal-portal bed of the anterior pituitary. Together with other hypothalamic CRH neurones, these have a role in the regulation of adrenocorticotropin (ACTH) release.

VP magnocellular neurons in the SON and PVN coexpress the peptide apelin and the apelin receptor. Apelin is a 36 amino-acid peptide, though shorter forms (apelin-17 and apelin-13) have also been found that retain biological activity. Intracerebroventricular injection of apelin-17 inhibits the phasic firing of VP magnocellular neurons, reducing VP release. Hypertonic stress and water loading have reciprocal effects on plasma VP and apelin concentrations. Apelin receptors are also coexpressed in VP target cells in the renal collecting duct. VP and apelin are thus regulated in opposite directions and a 'yin and yang' relationship has been proposed for VP and apelin as of physiological regulators [1].

The posterior pituitary receives an arterial blood supply from the internal carotid artery via the inferior hypophyseal artery and the artery of the trabecular, which is a branch of the superior hypophyseal artery. The SON and PVN receive an arterial supply from the suprahypophyseal artery and from the anterior communicating, anterior cerebral, posterior communicating, and posterior cerebral arteries via the circle of Willis. Venous drainage of the neurohypophysis is through the dural, cavernous, and inferior petrosal sinuses.

Molecular and Cell Biology of Vasopressin and Oxytocin

Mammalian VP and OT are nonapeptides containing a closed loop, held together through a disulphide bridge between the cysteine residues at positions 1 and 6 (Figure 2.2.2). Most mammals have the amino-acid arginine at position 8. In the pig family, arginine is substituted by lysine. OT differs from VP by two amino acids. OT has isoleucine rather than phenylalanine at position 3; and leucine rather than arginine at position 8. The similarities between VP and OT probably reflects derivation from a common ancestral gene [2–4].

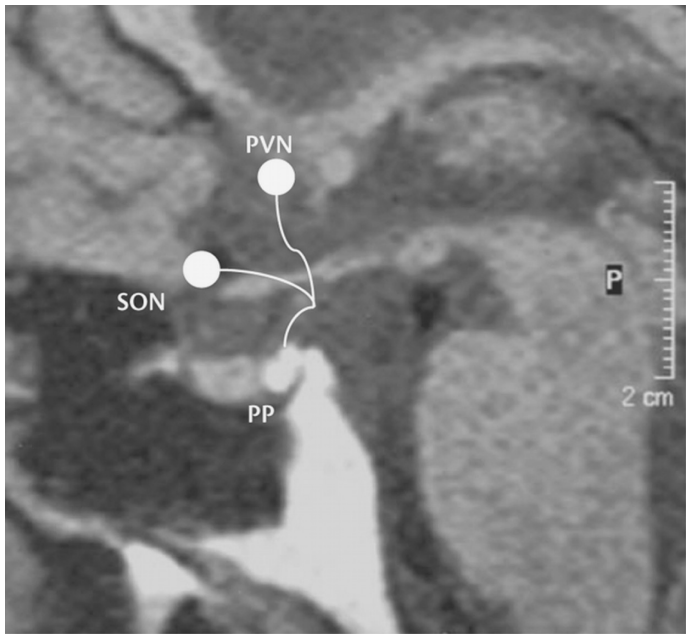

Figure 2.2.1 The neurohypophysis. MRI with overlay demonstrating relative positions of the paraventricular nucleus (PVN), supraoptic nucleus (SON) connecting to the posterior pituitary (PP) via the supraoptico-hypophyseal tract.

The Vasopressin and Oxytocin Genes

In man, the genes encoding VP and OT lie in head to head tandem array on chromosome 20p13, separated by some 12 Kb of DNA. Both are composed of three exons, encoding a polypeptide precursor with a common modular structure: an amino-terminal signal peptide; the VP or OT peptide; a hormone-specific mid-molecule peptide termed a neurophysin (NPI and NPII for OT and VP, respectively); and a carboxyl-terminal peptide known as copeptin (Figure 2.2.3). There is considerable homology between the NP sequences of both genes, positions 10–74 of the NP sequences being highly conserved at the amino acid level.

Regulatory control of *VP* gene expression is mediated through positive and negative elements in the proximal promoter. Several transcription factors bind to these elements. AP1, AP2, and CREB stimulate VP gene expression, while the glucocorticoid receptor (GR) represses expression. Cell-selective gene expression is mediated though regulatory elements in the intergenic region between the *VP* and *OT* genes, with the region –288 to –116 5' upstream of the *VP* gene promoter conferring magnocellular neuron specific expression of the *VP* gene. *VP* gene expression is also be regulated post-transcriptionally. Stability of VP mRNA is influenced by poly(A) tail length. Poly(A) tail length increases in response to water deprivation, increasing stability and enhancing translation. VP mRNA also contains a dendritic localization sequence (DLS). Interaction of the DLS with a multifunctional poly(A) binding protein (PABP) plays a further key role in ribonucleic acid (RNA) stabilization, initiation of translation, and translational silencing [2, 3].

Synthesis, Release, and Metabolism of Neurohypophyseal Hormones

Synthesis of VP and OT occur in the cell bodies of VP and OT-specific magnocellular neurosecretory neurones of the SON and PVN. Generation of both hormones entails substantial post-translational modification of a large primary precursor. Following translation, the carboxy terminal domains are glycosylated, and the precursors packaged in vesicles of the regulated secretory pathway. These migrate along their respective neuronal axons toward the nerve terminals in the posterior pituitary. Migration is microtubule dependent. During vesicle translocation, VP and OT precursors are cleaved by basic endopeptidases to produce the mature hormone and the respective NPs. These are stored as a complex in secretory granules within the nerve terminals of the posterior pituitary. An increase in the firing frequency of vasopressinergic and oxytocic neurones opens voltage-gated Ca_2^+ channels in the nerve terminals which results in fusion of the neurosecretory granules with the nerve terminal membrane and release of their contents into the circulation. The hormone and its NP are cosecreted into the systemic circulation in equimolar quantities. Apart from acting as carrier proteins for VP and OT during axonal migration, NPs appear to serve no specific biological function.

VP and OT circulate free, unbound to plasma proteins. However, VP does bind to specific receptors on platelets. VP concentrations in platelet-rich plasma are thus about fivefold higher than in platelet-depleted plasma. VP and OT have short are short half-life in the circulation: VP half-life being 5–15 minutes. VP and OT are degraded by several endothelial and circulating endo- and amino-peptidases. A specific placental cysteine aminopeptidase degrades VP and OT rapidly during pregnancy and the immediate postpartum period.

The Physiology of Vasopressin

Actions of Vasopressin

VP is the key regulator of renal water excretion and the hormone has a central role in fluid balance. However, the physiology of VP encompasses a wider context within the integrated neuro-humoral response to changes in cardiovascular status and stress [5–7].

Vasopressin Receptors

VP action is mediated by binding to specific receptors on the cell membrane of target cells. There are three VP receptor (V-R) subtypes, encoded by different genes (Table 2.2.1). All have seven

	Amino acid position 1 2 3 4 5 6 7 8 9	Distribution
Arginine vasopressin: Cys-Tyr-Phe-Glu(NH_2)-Asp(NH_2)-Cys-Pro-Arg-Gly(NH_2)		Most mammals
Lysine vasopressin	Phe Glu(NH_2) Lys	Pig family
Oxytocin	Ile Glu(NH_2) Leu	Mammals, birds

Figure 2.2.2 Amino acid sequences of vasopressin and oxytocin.

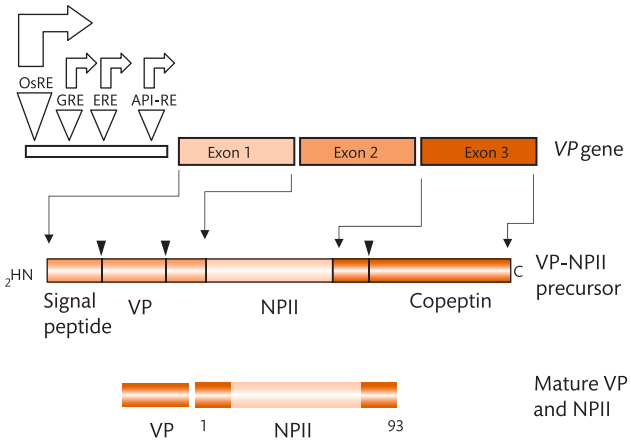

Figure 2.2.3 Functional organization of the VP gene. The VP gene consists of three exons encoding a large precursor which is cleaved to produce the mature peptide through post-translational modification. The VP 5′-promoter contains a number of response element sites that interact with transcription factors regulating VP gene expression. Os-RE, GRE, ERE, and API-RE represent the response elements for osmoregulation: the glucocorticoid receptor, the oestrogen receptor, and AP1, respectively.

transmembrane spanning domains, and all are G-protein coupled. They differ in tissue distribution, signal transduction mechanisms, and function. There is 70–80% human–rat subtype homology at the amino acid level. The human V2-R gene has been mapped to Xq28. The murine V2-R gene maps to a syntenic X-chromosome locus.

Renal Effects of VP

Although VP has multiple actions, its principle physiological effect is in the regulation of water reabsorption in the distal nephron. The hair-pin structure and electrolyte transport processes of the nephron allow the kidney to both concentrate and dilute urine in response to the prevailing circulating VP concentration. Active transport of solute out of the thick ascending loop of Henle generates an osmolar gradient in the renal interstitium which increases from renal cortex to inner medulla, a gradient through which distal parts of the nephron pass en route to the collecting system. This is the basis of the renal countercurrent osmolar exchange mechanism. The presence of selective water channel proteins (aquaporins) in the wall of the distal nephron allows reabsorption of water from the duct lumen along an osmotic gradient, and excretion of concentrated urine

A wide range of aquaporins (AQPs) has been identified. They act as passive pores for small substrates and are divided into two families: the water only channels; and the aquaglyceroporins that can conduct other small molecules such as glycerol and urea. As with other membrane channels, specific structural arrangements within the primary, secondary, and tertiary structure convey the three functional characteristics of permeation, selectivity, and gating. AQPs have a common structure consisting of two tandem repeats (each formed from three transmembrane domains), together with two highly conserved loops containing the signature motif asparagine-proline-alanine (NPA). AQP channels are formed by a tertiary complex of homo-tetramers within the cell membrane, providing four functionally independent pores with an additional central pore. Water can pass through all the four independent channels of water-permeable AQPs. The central pore may act as independent channel in some AQPs [8–10].

Seven AQPs are found in the kidney: AQP1–4 and AQP6–8. AQP1 is constitutively expressed in the proximal tubule and descending loop of Henle, where it facilitates isotonic fluid movement. Loss of function mutations of AQP1 in man lead to defective renal water conservation. AQP3 and AQP4 are both expressed in the basolateral membrane of collecting duct cells in the distal nephron, where they facilitate the movement of water from the collecting duct cells into the renal interstitium. AQP2 is expressed on the luminal surface of collecting duct cells and is the water channel responsible for VP-dependant water transport from the lumen of the nephron into the collecting duct cells. The binding of VP to V2-Rs on the interstitial surface of collecting duct cells produces increases in expression of AQP2. The increase is biphasic: one requiring new AQP2 protein synthesis and one which is independent of new protein synthesis. V2-R activation triggers an intracellular phosphorylation cascade leading activation of the nuclear transcription factor

Table 2.2.1 Vasopressin receptor subtypes

	Vasopressin receptor		
	V1a	V2	V3
Expression	• Vascular smooth muscle • Liver • Platelets • CNS	Basolateral membrane of distal nephron	Pituitary corticotroph
Amino acid structure	418 amino acids (human)	370 amino acids (human)	424 amino acids (human)
Second messenger system	Gq/11mediated phospholipase C activation: Ca^{2+}, inositol triphosphate & diacyl glycerol mobilization	Gα*s mediated adenylate cyclase activation: cAMP production and protein kinase A stimulation	As V1a
Physiological effects	• Smooth muscle contraction • Stimulation of glycogenolysis. • Enhanced platelet adhesion • Neurotransmitter and neuromodulatory function	Increased production and action of aquaporin-2	Enhanced ACTH release

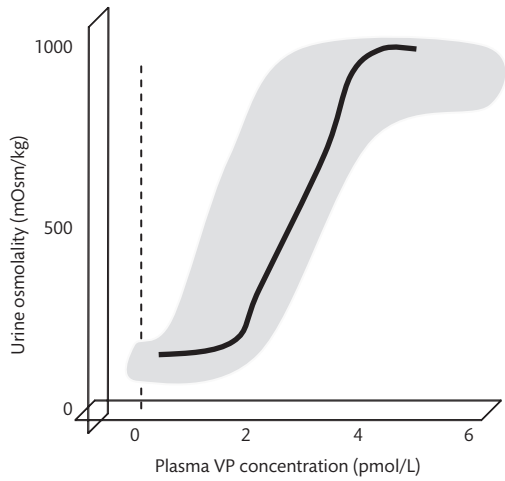

Figure 2.2.4 The relationship of plasma vasopressin concentration to urine concentrating ability. There is a sigmoid relationship between plasma vasopressin concentration and urine osmolality, with maximum urine concentration occurring at plasma vasopressin concentrations of 4–6 pmol/L. There is a range of response in the normal population depicted by the grey area, within which an individual response is demonstrated.

CREB and expression of c-Fos and stimulation of AQP2 gene expression through CRE and AP-1 response elements in the *AQP2* gene promoter. V2-R activation also stimulates an immediate increase in AQP2 activity by accelerating trafficking and assembly of presynthesized AQP2 protein into functional, homo-tetrameric water channels in luminal cell membranes [4–6].

As VP levels rise, there is a sigmoid relationship between plasma VP concentration and urine osmolality, with maximum urine concentration achieved at plasma VP concentrations of 3–4 pmol/L (Figure 2.2.4). Following persistent VP secretion, antidiuresis may diminish. Downregulation of both V2-R function and AQP2 expression may be responsible for this escape phenomenon. Maximum diuresis occurs at plasma VP concentrations of 0.5 pmol/L or less.

VP has additional effects at other sites in the nephron, which serve to augment renal concentrating ability. VP decreases medullary blood flow, stimulates active urea transport in the distal collecting duct and stimulates active sodium transport into the renal interstitium. VP also stimulates a bi-phasic up-regulation of bumetanide-sensitive sodium-potassium-chloride cotransporter (SLC12A1) expression in the thick ascending loop of Henle. VP both accelerates post-translational processing/trafficking of presynthesized SCLC12A1 and increases *SCLC12A1* gene expression [7].

Cardiovascular Effects of VP

VP is a potent pressor agent, its effects mediated via a specific membrane receptor (V1a-R). Systemic effects on arterial blood pressure are only apparent at high concentrations due to compensatory buffering haemodynamic mechanisms. Nevertheless, VP is important in maintaining blood pressure in mild volume depletion. The most striking vascular effects of VP are in the regulation of regional blood flow. The sensitivity of vascular smooth muscle to the pressor effects of VP vary according to the vascular bed; vasoconstriction of splanchnic, hepatic, and renal vessels occurring at VP concentrations close to the physiological range. Furthermore, there are differential pressor responses within a given vascular bed; selective effects on intrarenal vessels resulting in redistribution of renal blood flow from medulla to cortex. Such effects suggest that baroregulated VP release constitutes one of the key physiological mediators of the integrated haemodynamic response to volume depletion.

Effects of VP on the Pituitary

VP is an ACTH secretagogue, acting through pituitary corticotroph-specific V3-Rs. Though the effect is weak in isolation, VP and C-reactive protein (CRF) act synergistically. VP and CRF colocalize in neurohypophyseal parvicellular neurones projecting to the median eminence and the neurohypophyseal portal blood supply of the anterior pituitary. Levels of both VP and CRF in these neurones are inversely related to glucocorticoid levels, clearly suggesting a role in feedback regulation.

Behavioural Effects of VP

Vasopressinergic fibres and V-Rs are present in many areas of the brain, including the cerebral cortex and limbic system. These extensive neural networks are anatomically and functionally independent of the neurohypophysis. In rodents, these central vasopressinergic systems have key roles in mediating complex social behaviour such as mating patterns. There are similar emerging data in man. Association studies link *V1a-R* gene sequence variation with a range of behaviours. Dysregulation of central VP action may be a distal end point in conditions characterized by complex altered social and emotional behaviour [8–12].

Effects of VP on the Skeleton

Emerging data support a role for neurohypophyseal hormones in bone physiology [13]. VP inhibits osteoblast formation. This effect is opposed by OT, which has a reciprocal effect in stimulating osteoblast formation. Mice deficient in V1a-R (*Avpr1a*$^{-/-}$) have a high bone mass while both haploinsufficiency for OT and deletion of the OT receptor (*Oxr*$^{-/-}$) result in osteopaenia.

Miscellaneous Effects of VP

Several additional actions of VP are listed in Table 2.2.2.

Osmoregulation of in VP Release

In line with the hormone's key role in body fluid homeostasis, plasma osmolality is the most important determinant of VP secretion. Working in tandem, the combined osmoregulatory system for thirst and VP secretion maintain plasma osmolality within the narrow limits of 284–295 mOsml/kg. The osmoregulation of VP release and the physiological relationship between plasma osmolality

Table 2.2.2 Miscellaneous effects of VP

Action	Receptor involved
Coagulation/clotting cascade	
Factor VII release from hepatocytes	V-2r
von Willebrand factor release from vascular endothelium	V-2r
Liver metabolism	
Glycogen phosphorylase A activation	V-1ar

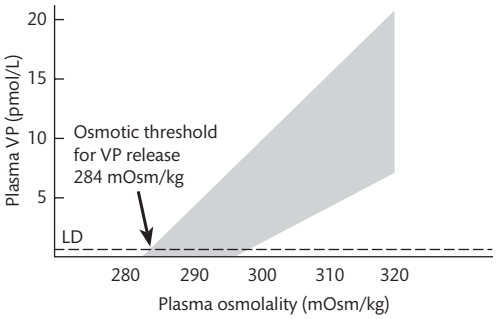

Figure 2.2.5 Relationship between plasma osmolality and plasma vasopressin (VP) concentration during progressive hypertonicity induced by infusion of 855 mmol/L saline in a group of healthy adults. LD represents the limit of detection of the assay, 0.3 pmol/L.

and plasma VP concentration is described by three characteristics; the linear relationship between plasma osmolality and plasma VP concentration; the osmotic threshold or 'set point' for VP release: and the sensitivity of the osmoregulatory mechanism.

Increases in plasma osmolality increase plasma VP concentrations in a linear manner (Figure 2.2.5). The abscissal intercept of this regression line, 284 mOsml/kg, indicates the mean 'osmotic threshold' for VP release: the mean plasma osmolality above which plasma VP starts to increase. Though there is no level of plasma osmolality below which VP release is completely suppressed, though such low levels of VP have little antidiuretic effect. The concept of a threshold of VP release thus remains a pragmatic means to characterize the physiology of osmoregulation; VP release being increased from a basal rate by activation of stimulatory osmoreceptor afferents, and decreased to minimal values by removal of this drive and the activation of synergistic inhibitory afferents. The slope of the regression line reflects the sensitivity of osmoregulated VP release. There are considerable interindividual variations in both threshold and sensitivity of VP release. Twin studies indicate a strong heritable component in this variation. However, over time, these parameters are remarkably reproducible within an individual [14].

There are several physiological situations where the tight relationship between plasma osmolality and VP concentration is lost. The act of drinking results in rapid suppression of VP release, independent of changes in osmolality. In addition, the rate of change of plasma osmolality can influence the VP response; rapid increases in plasma osmolality result in exaggerated VP release. The osmotic threshold for VP release is lowered in normal pregnancy, and a similar though smaller change occurs in the luteal phase of the menstrual cycle. Plasma VP concentrations increase with age, together with enhanced VP responses to osmotic stimulation. In contrast, thirst appreciation is blunted and fluid intake reduced. These changes, together with age-related decreases in renal handling of water loads and generation of maximal urine concentration, form the basis for the predisposition of older people to both hyper- and hyponatraemia.

Baroregulation of VP Release

As a principle determinant of fluid homeostasis, VP is a key player in maintaining haemodynamic integrity. In contrast to osmoregulated VP release, progressive reduction in blood pressure produces an exponential increase in plasma VP. Falls in arterial blood pressure of 5–10% are necessary to increase circulating VP concentrations in man. Importantly, baroregulated VP release can occur at low levels of plasma osmolality levels that would normally act to suppress VP production. This apparent 'hierarchy' of regulation is important when considering the integrated physiological response to volume depletion. It is a key pathophysiological mechanism underpinning the hyponatraemia resulting from effective circulating volume depletion.

Humoral Regulation of VP Release

Changes in circulating volume and blood pressure trigger an autonomic and endocrine cascade resulting in a coordinated physiological response. Baroregulated VP responses can be modified by other neurohumoral influences triggered as part of this coordinated response: atrial natriuretic peptide (ANP) inhibiting and norepinephrine augmenting baroregulated VP release. The renin–angiotensin system (activated in effective volume depletion) is also intricately involved in the regulation of VP production. Circulating angiotensin II stimulates VP secretion, acting centrally at forebrain centres influencing SON and PVN activation. In addition, angiotensin II stimulates VP release via a direct effect on VP magnocellular neurones, where type 2 angiotensin II receptors have been identified. In the rat, ANP inhibits both osmo- and baro-stimulated VP release centrally.

Other Regulatory Mechanisms of VP Release

Nausea and emesis are potent stimuli to VP release, independent of osmotic and haemodynamic status. Manipulation of abdominal contents is another powerful stimulus to VP release. Both contribute to the high plasma VP values and consequent impairment of water load excretion, observed after gastrointestinal surgery. VP release in response to these stimuli and others, such as neuroglycopaenia, justify its classification as a stress response hormone.

Thirst

Thirst, and the drinking response to thirst, are key components maintaining fluid homeostasis. While the two systems are discrete, it is no surprise that the physiology of VP and thirst are closely aligned.

There is a linear relationship between thirst, determined by visual analogue scale, and plasma osmolalities in the physiological range (Figure 2.2.6). The mean osmotic threshold for thirst perception is 281 mOsml/kg, similar to that for VP release. Thirst occurs when plasma osmolality rises above this threshold, the intensity varying in relation to the ambient plasma osmolality. The functional characteristics of osmoregulated thirst, just as VP release, remain consistent within an individual on repeated testing, despite wide variations between individuals [14].

As with osmoregulated VP release, there are also specific physiological situations in which the relationship between plasma osmolality and thirst breaks down. The act of drinking reduces osmo-stimulated thirst, just as it does VP release. There is a fall in the osmotic threshold for thirst in the luteal phase of the menstrual cycle. In contrast, thirst appreciation and fluid intake are blunted in older people. Thirst can be stimulated by extracellular volume depletion through volume sensitive cardiac autonomic afferents. In addition, hypovolaemia, and hypotension lead to the generation of circulating and intracerebral angiotensin II, a powerful dipsogen.

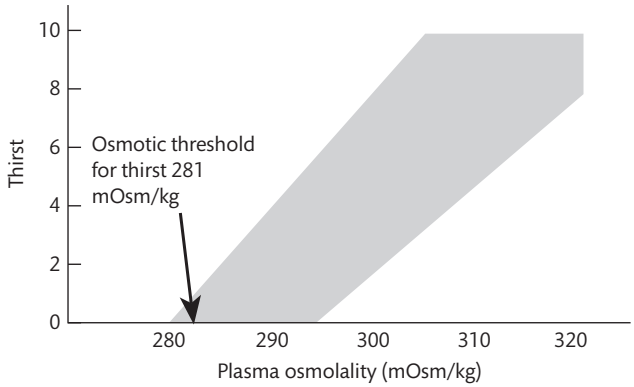

Figure 2.2.6 Relationship between thirst and plasma osmolality during progressive hypertonicity induced by infusion of 855 mmol/L saline in a group of healthy adults.

The Coordinated Regulation of VP and Thirst

The control of VP production and processes underpinning thirst perception and drinking are separate and discrete. Nevertheless, there are close functional links between the two systems: highlighted by the situations where they are activated and suppressed in parallel. It is therefore not surprising that the two systems are regulated by systems that are also closely related. The lamina terminalis within the forebrain is a key hub for integrating neural and humeral influences on VP production, thirst perception, and drinking behaviour.

The Neurobiology of Osmoregulation

The Lamina Terminalis: Anatomy, Neurophysiology, and Role in Central Osmoregulation

The lamina terminalis (LT) is a small region of the forebrain including areas just anterior and dorsal to the third ventricle. It is composed of three, interconnected nuclei: the subfornicular organ (SFO), the organum vasculosum (OVLT) and the median preoptic nucleus (MnPO). Due to local fenestrations in the blood-brain barrier, neurones within the SFO and OVLT are in direct contact with the circulation. They thus function as interoceptive sensory organs. The MnPO lies within the blood-brain barrier. While it does not have a sensory function, it is thought to have a key role in integrating the output of the LT to higher centres, including those involved in initiating drinking [15].

SFO and OVLT neurones have intrinsic osmosensitivity; neuronal firing rates increasing in line with extracellular fluid osmolality. These neurones constitute the principle central osmo-sensing mechanism regulating VP and thirst. Changes in the osmotic environment of these neurons alter their shape. This physical change alters the activity of the cell surface stretch-sensitive cationic channel TRPV1. TRPVI is the transduction mechanism linking osmolality to altered membrane potential and neurone firing frequency. Vasopressinergic neurons of the SON and PVN also express TRPV1: the basis for a direct effect of plasma osmolality on magnocellular neurone activity. Interestingly, osmoregulatory function is not lost in *Trpv*1$^{-/-}$ mice. Additional osmo-sensing pathways must therefore also be in operation [16].

Glutaminergic neurones projecting from the SFO and OVLT stimulate drinking. Glutaminergic pathways from the LT also project to the PVN and SON, providing a neuroanatomical basis for the parallel stimulation of thirst and VP release. In contrast, activation of GABAergic neurones within the LT reduces drinking, highlighting a balance of both positive and negative elements in the central neural circuitry controlling fluid balance (Figure 2.2.7).

Peripheral Osmoregulation

A related, but distinct osmo-sensory input feeds additional data on peripheral osmolar status. Sensory neurones in hepatic portal blood vessels are responsive to changes in the plasma osmolality. The transducing element in this peripheral osmosensitivity is the stretch-sensitive ion channel, TRPV4 [17].

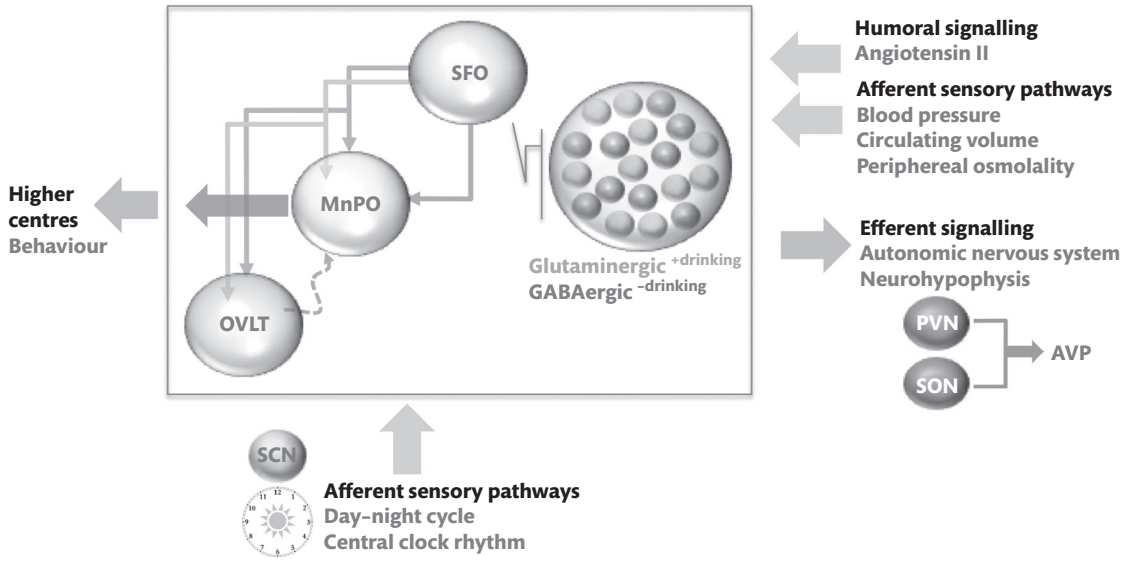

Figure 2.2.7 The role of the lamina terminalis in in the integration of thirst and AVP release. The lamina terminalis is key in the integration of sensory and humoral signals that regulate thirst and AVP release. MnPO, median preoptic nucleus; OVLT, organum vasculosum of the lamina terminalis; SCN, suprachiasmatic nucleus; SFO, subfornicular organ; SON, supraoptic nucleus; PVN, paraventricular nucleus.

Afferent Sensory Regulation of VP and Thirst

Baroregulatory influences on neurohypophyseal VP release derive from aortic arch, carotid sinus, cardiac atrial, and great vein stretch-sensitive afferents via cranial nerves IX and X. Ascending projections are via the nucleus tractus solitarius (NTS). From the NTS, further afferents project to the SON and PVN and the LT. These mechanisms act to integrate a number of afferent inputs that reflect volume status. Ascending baroregulatory pathways affect tonic inhibition of VP release, as their interruption increases plasma VP concentration.

Osmosensitivity of VP release is influenced by circadian rhythms. VP release increases during sleep, mediated by clock neurones projecting from the suprachiasmatic nucleus to the LT and neurohypophysis [18].

The act of drinking reduces thirst perception. This change occurs before any change in plasma osmolality. The effect is produced through three mechanisms: oropharyngeal sensory afferents; gastrointestinal stretch-sensitive afferents; and peripheral osmoreceptors in the hepatic portal vein. Thirst-promoting neurones in the SFO integrate sensory inputs from the oropharynx (drinking and food composition) with central osmolar status to influence thirst perception. This mechanism effectively allows anticipatory changes in water consumption that can precede changes in plasma osmolality.

Central Mechanisms Integrating Humeral Influences on VP and Thirst

Osmoregulated VP responses are modified by other components of the coordinated neurohumoral response to changes in circulating volume and blood pressure. Angiotensin II amplifies the proportional relationship between osmolality and neuronal firing in the SON. Angiotensin II triggers polymerization of intracellular actin filaments in osmosensitive neurones in the SON, altering cell shape in a manner that works in synergy with that produced by changes in extracellular osmolality. Angiotensin II thus enhances osmosensitivity. This mechanism underpins the changes in osmo-regulated VP release in hypo- and hypervolaemia: the osmotic threshold and sensitivity of VP release is lowered by hypovolaemia; while the converse is found in hypervolaemia and hypertension.

Vasopressinergic neurones within the neurohypophysis also contribute a direct 'short-loop' mechanism for the physiological coordination of VP production. Angiotensin II and relaxin excite both OT and VP magnocellular neurones. In contrast, ANP inhibits VP neuron activity. VP magnocellular neurones themselves have independent osmo-sensing properties. V-Rs are present on vasopressinergic neurons of both the PVN and SON, highlighting the potential for auto-control of VP release through direct osmoregulation and short-loop feedback.

Integrated Physiology of VP Release and Body Fluid Homeostasis

The physiological regulation of water balance is intimately linked with that of circulating volume; common systems are involved in both processes. As sodium is the major cationic osmolyte, the interrelationships of sodium and water excretion with circulating volume regulation are key to appreciating the position of VP and thirst-driven fluid intake in the physiology of fluid homeostasis.

At plasma osmolalities of 285–295 mOsml/kg, osmolar balance can be maintained by VP-dependent regulation of renal water loss. A rise in plasma osmolality within this range produces a progressive increase in plasma VP to a concentration of 3–4 pmol/L, and antidiuresis. Further increases in plasma osmolality stimulate further VP release, but this does not result in any further reduction of renal water excretion. Correction of plasma osmolality back to the range over which osmolar balance can be maintained by VP requires thirst-stimulated drinking. As the osmolar threshold for thirst is similar to that for VP release (284 mOsml/kg), the maintenance of water balance through a combination of osmoregulated VP release and thirst is clearly a seamless, coordinated process of subtle complexity.

If excessive fluid volumes are consumed, greater than those demanded by thirst, plasma VP levels are suppressed to below 0.3 pmol/L, resulting in maximum diuresis of up to 15–20 L/24 h. Ingestion of water in excess of this causes a reduction of plasma osmolality into the subnormal range, and hyponatraemia.

VP release is also regulated by other, non-osmotic stimuli. This complex regulation has a hierarchy, with significant physiological and pathophysiological sequelae. Hypovolaemia shifts the relationship of plasma osmolality with VP concentration to the left. During moderate hypovolaemia, osmoregulation is maintained around a lower osmolar set point. As the degree of hypovolaemia progresses, baroregulated VP release overrides the osmolar set point, and antidiuresis is maintained despite the potential for ensuing hyponatraemia. Coincident activation of the systemic and intracerebral renin–angiotensin systems stimulates drinking and augments VP release, in addition to independent pressor and antinatriuretic effects. The homeostatic response to hypovolaemia thus involves an integrated neurohumoral cascade, of which VP and thirst are key components.

The Physiology of Oxytocin (OT)

OT binds to specific G-protein coupled cell surface receptors (OT-Rs) on target cells to mediate a variety of effects largely concerned with reproductive function. Historically, attention has focused on the role of OT in the regulation of lactation; parturition; and reproductive behaviour. Data from animal models lacking oxytocin because of targeted disruption of the oxytocin gene have challenged this dogma, forcing a review of the physiological roles of the hormone.

Oxytocin and Lactation

In the rat, the stimulation of sensory afferents in the nipple by the act of suckling trigger a reflex cascade leading to synchronized firing bursts of oxytocic magnocellular neurones, with pulsatile OT release corresponding to this burst activity. The released OT acts on OT-Rs on smooth muscle cells lining the milk ducts of the breast, initiating milk ejection. OT is essential for completion of this milk ejection reflex in rodent. Mice lacking OT fail to transfer milk to their suckling young, and this deficit is corrected by injection of OT. In contrast, Women lacking posterior pituitary function can breast feed normally, illustrating that OT is not necessary for lactation in Humans.

Oxytocin and Parturition

OT is a powerful uterotonic agent. In many mammals there is both an increase in OT secretion during parturition, and an increase in uterine responsiveness to OT at term. These data suggest a key role for the hormone in the initiation and progression of labour.

It is believed that falling progesterone concentrations toward the end of pregnancy lead to up-regulation of uterine myometrial OT-Rs, enhanced contractility, and increased sensitivity to circulating OT. Stretching of the 'birth canal' during parturition leads to the stimulation of specific autonomic afferents, triggering increased burst firing of oxytocic magnocellular neurones and OT release. A positive feedback loop is formed, with OT both stimulating uterine contraction further and enhancing the production of local uterotonic mediators. It has been difficult to demonstrate increased circulating OT levels in women during labour, due in part to the difficulties of analysing pulsatile release coupled with the short circulating half-life of the hormone due to the action of placental cysteine aminopeptidase. In mice lacking OT, parturition is normal. Moreover, Women with absent posterior pituitary function can have a normal labour. However, the importance of OT in the birth process is highlighted by the effectiveness of OT antagonists in the management of preterm labour.

OT may have key additional offspring-facing roles in parturition. Maternal OT produces a switch in fetal central nervous system (CNS) neurotransmission with enhanced inhibitory GABAergic signalling. This increases fetal neuronal resistance to hypoxaemic damage that may occur during delivery, part of adaptive mother-fetal signalling during parturition in which OT is a major player [19].

Oxytocin and Behaviour

OT-R expression is widespread in the CNS of many species. There is clear evidence that OT has important influences on reproductive behaviour in rat; facilitating both lordosis and the development of maternal behaviour patterns. However, mice lacking OT exhibit normal sexual and maternal behaviour, indicating these effects may be species dependent. Central oxytocic transmission appears to reduce anxiety and hypothalamo-pituitary-adrenal stress responses in female rats. However, the same central oxytotic function may be required for normal adrenocorticotropin responses to stress. OT release from both dendrites and nerve terminals of hypothalamic magnocellular neurons can be regulated by other neuropeptides, highlighting the potential for magnocellular OT to integrate with central neurotransmission.

Central OT pathways have been implicated complex behaviour: social recognition, affiliation, and social bonding. This clustering has raised interest in the role of OT and OT pathways in the development of autism. A number of association studies have demonstrated linkage between autism and OT-R polymorphisms. Together, these data suggest a complex role for OT in the stress and other behavioural responses, with species and context-dependent differential effects [20, 21].

Integrated Physiology of Oxytocin

How are the proposed roles of OT in reproductive function reconciled with both human and mouse data that highlight normal function in the absence of the hormone? Clearly there are interspecies differences in OT-modulated processes that contribute important qualifications to the data. The mouse gravid uterus does not express OT-Rs, in contrast to human and rat. It is perhaps not surprising therefore, that parturition is normal in the OT null-mouse. Similarly, in contrast to rat, maternal behaviour evolves gradually in mouse, and is not acquired rapidly in the postpartum period. Mouse may therefore not be a good model for the uterine and behavioural effects of OT. Secondly, there is clearly variable redundancy in some of the physiological pathways in which OT is involved. This redundancy may vary between species. The extrapolation of OT's role in normal physiology from those responses found in its absence should thus be made with caution.

Clinical Endocrinology of the Neurohypophysis

There are no recognized clinical sequalae of OT deficiency in man. The pathophysiology of the neurohypophysis thus reflects the physiology of VP and the regulation of water excretion. Defects in VP production or action impact through disturbances in fluid and electrolyte balance. A second, related but less common group of conditions reflect primary defects in thirst. In some cases, the two may coincide, in line with the close anatomical and functional relationship of both processes.

Diabetes Insipidus

Classification

A pragmatic clinical definition of polyuria is the excretion of urine in excess of 3 l/24 h (over 40 ml/kg/24 h) in adults and over 100 ml/kg/24 h in infants). Diabetes Insipidus (DI) simply describes the excretion of large amounts of dilute urine. One of three mechanisms may be responsible.

1. Deficiency of VP: termed hypothalamic diabetes insipidus (HDI).
2. Renal resistance to VP: termed nephrogenic diabetes insipidus (NDI).
3. Inappropriate, excessive water drinking: termed dipsogenic diabetes insipidus (DDI) or primary polydipsia.

A classification of DI based on aetiology is outlined in Box 2.2.1.

Hypothalamic Diabetes Insipidus

HDI (also known as neurogenic, central, or cranial DI) is due to deficient osmoregulated VP secretion. In most cases it is a partial defect, with patients having inappropriately low plasma VP concentrations with respect to concomitant plasma osmolalities. Presentation with HDI implies destruction or loss of function of more than 80% of vasopressinergic magnocellular neurones. Though persistent polyuria can lead to dehydration, given free access to water, most patients can maintain water balance through an intact thirst mechanism. HDI is rare, with an estimated prevalence of 1:25 000 and equal gender distribution.

Aetiology

Most cases of HDI are acquired. Improvements in imaging and an appreciation of the varied presentation of inflammatory/autoimmune forms are responsible for fewer cases being designated idiopathic. Inherited/familial forms account for 5% of HDI.

Trauma, either as a result of head injury or surgery, can produce HDI through damage to the hypothalamus, pituitary stalk, or posterior pituitary. Pituitary stalk trauma may lead to a triphasic disturbance in water balance; an immediate polyuria characteristic of HDI followed within days by a more prolonged period of antidiuresis suggestive of VP excess. This second phase may last up to several weeks, and can be followed by reversion to HDI or recovery. Such

Box 2.2.1 Classification of polyuric syndromes

(A) Hypothalamic diabetes insipidus

- Primary
  - Genetic
    - DIDMOAD (Wolfram) syndrome
    - Autosomal dominant
    - Autosomal recessive
  - Developmental syndromes
    - Septo-optic dysplasia
  - Idiopathic
- Secondary/acquired
  - Trauma
    - Head injury
    - Post surgery (transcranial, transphenoidal)
- Tumour
  - Craniopharyngioma, germ cell tumour, metastases, pituitary macroadenoma
- Inflammatory
  - Granulomata
  - Sarcoidosis, histiocytosis

a 'triple response' reflects initial magnocellular axonal damage; the subsequent unregulated release of large amounts of presynthesized VP; and ultimately, either recovery or development of permanent HDI, as determined by the degree of initial neuropraxia/axonal shearing and damage. Not all phases of the response may be apparent. Recent data suggest acute HDI can occur in up to 22% of non-selected patients presenting with traumatic brain injury (TBI), persisting in some 7% of the total TBI cohort on long-term follow-up [22, 23].

Circulating antibodies to VP secreting neurons can be found in 30% of patients classified previously as having HDI with no identifiable cause, implying an autoimmune aetiology. Presence of anti-VP neurone antibodies in patients with HDI is associated with pituitary stalk thickening on magnetic resonance imaging (MRI). However, anti-VP neurone antibodies can also be found at low prevalence in patients with HDI secondary to histiocytosis X and following pituitary surgery, suggesting the specificity of the test or the auto-antibody response is low. Evidence of wider organ-specific autoimmunity common in isolated HDI [24].

Primary pituitary adenoma rarely causes HDI. Hypothalamic tumours, such as craniopharygioma and germinoma, are more common causes of HDI. Presentation with HDI can precede the radiological appearance of germinoma. Hypothalamic tumours and developmental defects such as septo-optic dysplasia (SOD) account for up to 50% of HDI in children. Hypothalamic or pituitary metastases (e.g. from primary breast or lung cancer) can present with HDI, as can primary brain malignancy and primary CNS lymphoma.

HDI can present in pregnancy. Placental vasopressinase activity can decompensate pre-existing limited antidiuretic capacity in patients with partial HDI through increased VP degradation that cannot be matched by increased hormone release. This can revert to normal after delivery, though permanent HDI may ultimately develop if the natural history of the central defect is progressive.

Wolfram Syndrome (WS)

Genetic studies have identified two subtypes of WS. WS1 is caused by loss of function mutations in the *WFSI* gene on Ch.4p16. *WFSI* encodes an 890 amino-acid glycoprotein, wolframin. Wolframin expression is restricted to the endoplasmic reticulum (ER) where it regulates ER stress and calcium homeostasis. Loss of function of wolframin triggers apoptosis and cell death. Non-inactivating mutations of *WFSI* are associated with autosomal dominant sensorineural hearing loss. WS1 may thus represent one extreme of a spectrum disorder.

WS2 is characterized by optic atrophy and diabetes mellitus. There are additional features of peptic ulcer disease and bleeding tendency which are not seen in WS1. WS2 is caused by loss of function mutations in the *CISD2* gene. *CISD2* encodes a protein expressed on both ER and the outer mitochondrial membrane. Loss of function of CISD2 disrupts calcium flux between ER and mitochondria leading to autophagy and cell death in a manner similar to that seen in several other neurodegenerative diseases [25, 26].

Autosomal Dominant Familial HDI

Autosomal dominant familial HDI is caused by mutations in the *VP* gene on chromosome 20. While it typically presents in childhood, the age of presentation varies considerably, reflecting variation in

the progressive loss of VP secretion. A variety of different missense and nonsense mutations within exons 1, 2, and 3 of the *VP* gene have been identified in affected kindreds. Mutant VP precursors accumulate in the ER of magnocellular neurones, to which they are neurotoxic. This explains the both the progressive loss of VP release in the condition, the range of presentation and its dominant inheritance pattern: the product of a single mutated allele being sufficient to trigger neural degeneration. Growth failure may be an early clinical feature [27].

The inherited HDI of the Brattleboro (BB) rat is due to a frame shift in exon 2 of the *VP* gene, resulting in a VP precursor with an altered carboxy terminus which also accumulates in the ER of vasopressinergic neurones. Interestingly, the HDI of the BB rat is inherited in a recessive manner, in contrast to the equivalent condition in man.

Investigation of Polyuric States

The strategy of investigation of DI is to confirm the polyuric state, define its basis, and to explore possible primary aetiologies. After establishing significant polyuria of greater than 3 l/24 h in adults and excluding hyperglycaemia, hypokalaemia, hypercalcaemia, and significant renal insufficiency, attention should be focused on the VP axis. Direct tests that measure plasma VP in response to osmotic stimulation would be the ideal modality to differentiate HDI from other causes of polyuria. However, access to reliable VP assays have been limited. Because of this, an indirect test using a surrogate endpoint of VP release (the ability of the kidney to produce concentrated urine during osmotic stress) has historically been used to differentiate the cause of confirmed polyuria: the water deprivation test.

Indirect Tests of the Hypothalamo-Neurohypophyseal (AVP) Axis: The Water Derivation Test

The water deprivation test assesses the capacity to concentrate urine during the osmotic stress of controlled water deprivation. The period of water deprivation can be followed by evaluation of the antidiuretic response to exogenous VP: the aim being to confirm renal sensitivity to VP or establish renal resistance. A standard protocol is outlined in **Box 2.2.2**. HDI can be distinguished by urine osmolality less than 300 mOsml/kg, accompanied by plasma osmolality greater than 290 mOsml/kg after dehydration. Urine osmolality should rise above 750 mOsml/kg after desmopressin (DDAVP), indicating normal renal responsiveness. In contrast, failure to increase urine osmolality above 300 mOsml/kg after dehydration together with failure to respond to DDAVP is diagnostic of NDI. Patients with DDI should concentrate urine appropriately during dehydration, without significant rise in plasma osmolality.

In reality however, many patients have incomplete defects and manifest mild or moderate forms of DI. Moreover, prolonged polyuria of any type can impair urine concentrating ability through dissipation of the medullary interstitial concentration gradient, resulting in a partial functional NDI. The water deprivation test can be a poor discriminator in these circumstances. The water deprivation test has been shown to support the correct diagnosis of underlying the polyuric state in some 70% of patients overall; and in only 41% of patients with underlying primary polydipsia [28].

Box 2.2.2 Protocol for water deprivation/desmopressin test

- Preparation
  - Free access to fluid given overnight prior to test
  - Avoid caffeine and smoking
  - 07.50 h weigh patient
- Dehydration phase
  - 08.00 plasma and urine osmolality, and urine volume
  - Restrict fluids up to eight hours
  - Weigh patient at two hourly intervals
  - Plasma and urine osmolality, and volume measurements two hourly
  - Stop test if weight loss exceeds 5% of starting weight, or thirst is intolerable
  - Supervise patient closely to avoid non-disclosed drinking
- Desmopressin phase
  - Inject intramuscularly 1 mcg desmopressin
  - Allow patient to eat and drink up to 1.5–2.0 times the volume of urine passed during dehydration phase
  - Collect urine for osmolality and volume at 20.00 h
- Plasma and urine osmolality, and volume measurements at 09.00 h next day

Direct Tests Used in the Differential Diagnosis of DI: The Utility of Measuring VP and Copeptin

An accurate diagnosis of HDI can be made by direct measurement of plasma VP during the controlled osmotic stress of a hypertonic 5% sodium chloride infusion. Patients with HDI have either undetectable VP levels, or values falling to the right of the normogram relating plasma VP to plasma osmolality. In NDI, plasma VP is inappropriately high for the prevailing urine and plasma osmolality, indicating VP resistance. In DDI, the relationship of plasma VP to osmolality is normal. The test is not interpretable if the patient experiences nausea, a powerful non-osmotic stimulus of VP release, during the test. Importantly, access to reliable VP assays has been limited and there are significant preanalytic obstacles in the scaling of this test to wider use. The addition of VP measurements as an adjunct to the standard water deprivation test does not add value [28, 29].

Copeptin, the c-terminal fragment of the VP-NP precursor is released in equimolar amounts to VP. In comparison to VP, the peptide is much more stable in plasma, making it an attractive alternative analyte to VP to support the differential diagnosis of polyuric states. Copeptin concentrations greater than 4.9 pmol/L during osmotic stimulation with hypertonic fluid can reliably discriminate between HDI and primary polydipsia, with a diagnostic accuracy of 96%. As with VP, the addition of copeptin to the standard water deprivation test does not improve the diagnostic accuracy of the test [30].

Additional Tests to Support the Differential Diagnosis of Polyuric States

A pragmatic alternative to VP measurements during hypertonic stress if there is diagnostic uncertainty following water deprivation is a controlled therapeutic trial of DDAVP: 10–20 mcg of intranasal DDAVP per day for 2–4 weeks, with monitoring of plasma sodium every 2–3 days. Patients with DDI exhibit progressive dilutional hyponatraemia, whereas those with NDI remain unaffected. Patients with HDI experience improvement in polyuria and polydipsia, but remain normonatraemic.

In familial autosomal dominant HDI, sequencing of the *VP* gene can help to establish the diagnosis in at-risk individuals early in the natural history of the disease and at a time when the water deprivation test can be equivocal [31].

Neuroimaging in HDI

Imaging of the hypothalamus, pituitary, and surrounding structures is essential in patients with HDI. MRI is the modality of choice. HDI is associated with the loss of the normal hyperintense signal of the posterior pituitary on T1-weighted images. Signal intensity is correlated strongly with VP content of the gland. As some hypothalamic germ cell tumours can be slow growing, imaging should be repeated after 6–18 months if the initial scan shows no demonstrable lesion. A negative scan at this stage should be taken as reassuring in the absence of a change in clinical features. Importantly, the absence of a posterior pituitary bright spot on imaging is not specific and can occur in a range of physiological situations. The finding should therefore not be taken as diagnostic of HDI.

Treatment

Patients with a urine output of less than 4 l/24 h can be managed by advising adequate fluid intake. The treatment of choice for those with more severe symptoms is the synthetic, long-acting VP analogue DDAVP; given as an intranasal spray (5–100 mcg daily), parenterally (0.1–2.0 mcg daily), or orally (100–1000 mcg daily) in divided doses. There is wide individual variation in the dose required to control symptoms. DDAVP has twice the antidiuretic potency of VP, but has minimal vasopressor activity. It is well tolerated. Dilutional hyponatraemia is the most serious potential adverse effect. This can be avoided by omitting treatment on a regular basis (perhaps weekly), to allow a short period of breakthrough polyuria and thirst [32].

Acute onset of HDI following pituitary or neurosurgery is usually transient and may not require intervention. Hypernatraemia can develop if cognition is impaired or access to water limited. Polyuria should be managed with DDAVP (parenteral administration may be required). As the situation is dynamic, a single dose of DDAVP may be sufficient to manage the patient until normal posterior pituitary function returns. Additional doses can be administered if polyuria persists or recurs. Regular DDAVP may be used if symptoms persist beyond 48 hours [33].

Nephrogenic Diabetes Insipidus

NDI is due to renal resistance to the antidiuretic effects of VP. Most forms of NDI are acquired, secondary to a range of metabolic or drug effects. The final common endpoint in many cases is downregulation of AQP2 expression. NDI secondary to lithium is common. Lithium enters collecting duct cells through the amiloride-sensitive epithelial sodium channel (ENaC) expressed on the apical cell membrane. This leads to inhibition of glycogen synthase kinase-3β (GSK3β) signalling pathways and dysregulated AQP2 expression and trafficking along the whole collecting duct. There is also dysregulated expression of ENaC in the cortical collecting duct. NDI secondary to lithium toxicity can irreversible, persisting after drug withdrawal.

Primary familial forms of NDI are rare. There are two types. A 'pure' type is characterized by water loss alone. A second, more complex type is characterized by water loss and a wider tubulopathy. X-linked recessive familial NDI is caused by inherited loss of function mutations of the V2-R. Over 70 different mutations have been described that have a negative impact on receptor expression, ligand binding, or G-protein coupling. Most mutations lead to complete loss of function. A small number lead to partial function and a milder phenotype.

Some10% of familial NDI is inherited as an autosomal recessive trait in which V2-R function is normal. In contrast to the X-linked form, autosomal recessive NDI is caused by loss of function mutations of the *AQP2* gene. Most mutations occur in the region of the gene coding for the transmembrane domain of the AQP2 protein.

A further, rare form of NDI is inherited as an autosomal dominant trait. While this form is also due to a loss of function mutation in *AQP2*, mutations and mechanisms are distinct and separate from the autosomal recessive form. The *AQP2* mutation in these kindreds involves the portion of the gene encoding the carboxyl-terminal intracellular tail of AQP2. The mutant AQP2 protein is expressed but forms non-functional, mixed tetramers with the product of the wild type AQP2 allele acting in a dominant-negative manner.

Defects in thick ascending limb and distal tubular sodium chloride transport underlie a range of inherited tubulopathies producing combinations of NDI and renal solute loss, including inherited forms of Bartter syndrome.

The mainstay of management in acquired cases of NDI is removal of the underlying cause and maintenance of hydration. While additional measures can be used for persistent symptoms, these rarely reduce urine volumes by more than 50%. High-dose DDAVP (4 mcg im. bd) can produce a response in partial NDI. There are data to support the use of amiloride in NDI caused by lithium. Additional treatment options (used alone or in combination) include hydrochlorothiazide 25 mg/24 hours; non-steroidal anti-inflammatory drugs such as ibuprofen 200 mg/24 hours; and low salt diets. The selective phosphodiesterase inhibitor Sildenafil has been shown to improve aquaresis in X-linked NDI. The proposed mechanism of action involves bypassing defective V2-R signalling through enhancement of cyclic guanosine monophosphate-mediated apical membrane trafficking [34, 35].

Dipsogenic Diabetes Insipidus

DDI is a syndrome of excess fluid intake, and consequent polyuria. Though structural abnormalities may be the cause, more commonly it is a manifestation of primary hyperdipsia, psychiatric disease, or secondary to drug effects. DDI in the absence of other identifiable illness is compulsive water drinking. It is associated with abnormalities of thirst perception, including; a low osmotic threshold for thirst; an exaggerated thirst response to osmotic challenge; and an inability to suppress thirst at low osmolalities. The structural and/or functional basis for any of these abnormalities has not been identified. The association of DDI with affective disorders is well recognized. Up to 20% of patients with long-term, persisting schizophrenia have polydipsia. Although in some cases abnormal drinking is in response to adverse effects of medication producing a dry mouth, complex abnormalities in both osmoregulated VP release and osmoregulated thirst have been described. Whether these reflect long-term effects of drug therapy or a primary defect in the central integration of thirst, is unclear.

Confirmation of the diagnosis of DDI is through direct or indirect demonstration of normal osmoregulated VP release and antidiuretic action. As with many conditions, the treatment of DDI

should address the underlying disorder. Individuals with persistent DDI are at risk of hyponatraemia if treated with DDAVP, as fluid intake is maintained despite an obligate antidiuresis. In such cases a reduced fluid intake is the only rational treatment.

Syndrome of Inappropriate Antidiuresis

Hyponatraemia (serum sodium <135 mmol/L) is a feature in some 15–20% of non-selected emergency hospital admissions. It is associated with increased morbidity and mortality across a range of conditions and data support the association of correction of hyponatraemia with improved outcome. However, the relationship of serum sodium to clinical outcomes is not straightforward and may not be a causal one. Comorbidity and underlying disease severity may be the more significant contributors to outcomes in patients with hyponatraemia [36].

VP plays a key role in many clinical situations in that include hyponatraemia. However, when VP does play a role, VP production may not be inappropriate. Hyponatraemia may reflect an appropriate physiological response to volume depletion, with baroregulated VP release persisting despite plasma osmolalities below the normal osmolar threshold for VP release. In this situation, continued physiologically appropriate VP release can lead to hyponatraemia which can be persistent. Though clinical assessment can identify the extracellular volume status of some patients, it is unreliable and has poor sensitivity and specificity [37].

Pathophysiology of the Syndrome of Inappropriate Antidiuresis

An individual with hyperosmolar plasma but a normal circulating volume and in whom in whom the plasma VP concentration is high for the prevailing osmolality, has a syndrome of inappropriate antidiuresis (SIAD) due to VP excess. A variety of conditions are associated with SIAD. To date, four patterns of abnormal VP secretion have been identified (Table 2.2.3). Absolute plasma VP concentrations may not be strikingly high; the key finding is that that they are inappropriate for the prevailing plasma osmolality. When this obligate antidiuresis is not accompanied by decreased water intake, haemodilution is inevitable.

Aetiology

Many conditions have been reported to cause SIAD (Box 2.2.3). SIAD is a non-metastatic manifestation of small cell lung cancer and other malignancies. The mechanism(s) of inappropriate VP release in many cases of SIAD are not clear. Some tumours are an ectopic source of VP, and produce a type A syndrome. However, excessive posterior pituitary VP secretion also occurs in association with malignancy. In fact, the absence of an ectopic VP source suggests a lesion in the neurohypophysis or its regulatory afferent pathways. The similarities between SIAD type B and the changes in VP regulation in response to hypovolaemia and hypotension, suggest a single lesion in the baroregulatory afferent pathways. In contrast, the normal osmoregulated VP release found in the type D syndrome suggests an increase in renal sensitivity to VP, or the action of an as yet unidentified antidiuretic factor.

SIAD is a common mechanism of drug induced hyponatraemia. It can reflect direct stimulation of VP release from the hypothalamus; indirect action on the hypothalamus via effects on higher centres; or aberrant resetting of the hypothalamic osmostat.

Box 2.2.3 Causes of SIAD

- Neoplastic disease
  - Carcinoma (bronchus, duodenum, pancreas, prostate)
  - Thymoma
  - Mesothelioma
  - Lymphoma, leukaemia
  - Ewing's sarcoma
  - Carcinoid
  - Bronchial adenoma
- Neurological disorders
  - Head injury, neurosurgery
  - Brain abscess or tumour
  - Meningitis, encephalitis
  - Guillain–Barré syndrome
  - Cerebral haemorrhage
  - Cavernous sinus thrombosis
  - Hydrocephalus
  - Cerebellar and cerebral atrophy
  - Shy–Drager syndrome
  - Peripheral neuropathy
  - Seizures
  - Subdural haematoma
  - Alcohol withdrawal
- Chest disorders
  - Pneumonia
  - Tuberculosis
  - Empyema
  - Cystic fibrosis
  - Pneumothorax
  - Aspergillosis
- Drugs
  - Chlorpropamide
  - Opiates
  - Vincristine, vinblastine, cisplatin
  - Thiazides
  - Dopamine antagonists
  - Tricyclic antidepressants
  - MAOIs
  - SSRIs
  - 3,4-MDMA agents ('Ecstasy')
  - Anticonvulsants
- Miscellaneous
  - Idiopathic
  - Psychosis
  - Porphyria
  - Abdominal surgery

Table 2.2.3 Classification of SIAD

SIAD type	Characteristics
SIAD type A	Wide fluctuations in plasma VP concentration, independent of plasma osmolality. Accounts for 35% of SIAD
SIAD type B	Osmotic threshold for VP release subnormal. Patients osmoregulate around subnormal plasma osmolar set point. Accounts for 30% of SIAD
SIAD type C	Failure to suppress VP release at low plasma osmolality, normal response to osmotic stimulation
SIAD type D	Normal osmoregulated VP release, but unable to excrete a water load. Accounts for less than 10% of SIAD

Dopamine antagonists cause SIAD through stimulation of VP release. Antidepressant medication, including selective serotonin reuptake inhibitors (SSRIs), potentiate stimulatory central adrenergic input to VP-producing neurones. Opiates also stimulate inappropriate VP release through enhancing central adrenergic drive. SIAD is commonly associated with antiseizure medication. The frequency of hyponatraemia in patients treated with carbamazepine ranges from 4.8 to 40%, though the majority of such cases are asymptomatic. Carbamazepine increases both the sensitivity of central osmoceptors, and renal sensitivity to VP.

Clinical Features, Diagnosis, and Differential Diagnosis of SIAD

The major features in the diagnosis of SIAD are highlighted in Box 2.2.4. The most frequent problem in clinical practice is distinguishing SIAD from chronic, mild hypovolaemia. In both conditions, urine osmolality tends to be higher than plasma osmolality. Plasma VP will be detectable or elevated in both. Neither is therefore diagnostic of SIAD. The diagnosis hinges on confirming excretion of urine that is not maximally dilute in the context of a dilute plasma (i.e. urine concentration greater than 100 mOsml/Kg). Renal sodium excretion should be above 30 mmol/L to make a diagnosis of SIAD. Below this value, volume depletion should be considered the more likely cause of hyponatraemia. SIAD is often associated with urine sodium concentrations of 60 mmol/L or more, as persisting SIAD is a volume expanded state. Consistent with this, there is evidence of mild sodium loss as other regulators of volume homeostasis attempt to minimize volume expansion.

The role of VP production or action in producing hyponatraemia can be confirmed indirectly by assessing excretion of a standard water load over a fixed time: the water load test (Table 2.2.4). Normal subjects excrete 78–82% of the ingested water load in the 4 h observation period. This is reduced to 30–40% in the presence of constitutive VP production or action. The test is not essential to establish a diagnosis and is not recommended as part of routine clinical practice.

Exercise-Associated Hyponatraemia

Extreme endurance exercise is a profound physiological stress. Non-osmoregulated VP release is a central feature of extreme endurance exercise, reflecting this physiological stress and determined principally by the duration of the event and the effort involved. Combined with reduced renal blood flow (another feature of extreme endurance exercise) this VP release can lead to a marked antidiuretic state. In this situation, fluid intake in excess of water loss can lead to hyponatraemia. Those athletes developing hyponatraemia during endurance exercise demonstrate weight gain over the course of the event, clearly implicating water intake in excess of water and electrolyte loss as the cause. There is a positive correlation between the odds ratio for developing hyponatraemia during extreme endurance exercise and the length of time taken to complete the event. 'Occasional' runners are therefore particularly at risk of exercise-associated hyponatraemia. They should be advised to follow their thirst and avoid rigid, time-based fluid intake. Importantly, health professionals need to be aware of the problem of exercise-associated hyponatraemia and resist resuscitation with large volumes of hypotonic fluid in the absence of appropriate indications and without biochemical monitoring [38].

Box 2.2.4 Diagnosis of SIAD

- Hyponatraemia with appropriately low plasma osmolality
- Urine osmolality that is not maximally dilute in context of on-going hyponatraemia (i.e. urine osmolality >100 mOsm/kg)
- Urine sodium concentration >30 mmol/L
- Absence of hypotension, hypovolaemia, and oedema-forming states
- Normal renal and adrenal function

Table 2.2.4 Protocol for water load test

Preparation	• Free access to fluid overnight prior to test • Avoid caffeine and smoking • 07:30 h weigh patient • Cannulate patient • Rest patient 30 minutes
Water load phase	• 08:00 plasma and urine osmolality, plasma VP • Patient to drink 20 ml/kg water over 15 minutes • Measure hourly urine output for 4 hours • Measure urine osmolality, plasma osmolality, and plasma VP hourly for 4 hours
Recovery phase	• **Plasma sodium 2 hours after test completed** • Plasma sodium and osmolality 09:00 h next day

Nephrogenic Syndrome of Inappropriate Antidiuresis

While loss of function mutations of the V2-R are the cause of X-linked nephrogenic diabetes insipidus, rare individuals express the reciprocal problem: constitutively activating mutations in the V2-R that lead to VP-independent, but V2-R mediated, antidiuresis resulting in persistent hyponatraemia. This nephrogenic syndrome of inappropriate antidiuresis (NSIAD) can have a variable phenotype. Although initially described in male infants with persistent hyponatraemia, the condition is not limited to males and may manifest in adulthood. This is consistent with in the condition being X-linked but with variable expression in heterozygous females [39, 40].

Central Salt Wasting

This acquired, primary natriuretic state is described as a combination of hyponatraemia with hypovolaemia associated with neurological or (more often) neurosurgical pathologies. The definition, true prevalence, and underlying pathophysiology remain a subject of controversy. SIAD can occur in the same group of patients in whom central salt wasting (CSW) has been reported and both are associated with urine sodium concentrations greater than 40 mmol/L. Importantly therefore, the diagnosis of CSW hinges on the natural history: the development of hyponatraemia being preceded by natriuresis and diuresis with ensuing clinical and biochemical features of hypovolaemia. In contrast to SIAD, urea and creatinine are elevated and there may be postural hypotension.

The context and opposed cause-directed management approaches to CSW and SIAD can lead to significant tension in clinical practice. CSW is a particular concern for the neurosurgical patient in whom autoregulation of cerebral blood flow is disturbed and in whom

small reductions in circulating volume can reduce cerebral perfusion. The management of CSW is volume replacement with 0.9% saline; while the cause-directed approach to SIAD would often involve restriction of fluid. A cause-independent approach to the management of the neurosurgical patient with hyponatraemia needs to balance management of hyponatraemia with the need to avoid threatening cerebral perfusion and avoidable vasospasm. A prospective, single centre study including 100 cases of hyponatraemia developing after subarachnoid haemorrhage failed to identify a case of CSW. Rather, SIAD, glucocorticoid deficiency and inappropriate fluid administration were identified as the key mechanisms of hyponatraemia [41, 42].

Treatment of Hyponatraemia Secondary to SIAD

Independent of the underlying cause, the morbidity SIAD reflects the impact of hyponatraemia on CNS function from cerebral oedema and primary neuronal dysfunction (Box 2.2.5). The relationship between serum sodium and neurological function is not simple: patients with marked biochemical disturbance may have mild symptoms if hyponatraemia develops over a prolonged period. This reflects CNS adaptation to reduced osmolality through inorganic and organic ion efflux. These adaptive CNS mechanisms can complicate the management of hyponatraemia. Over rapid correction of serum sodium following the gradual development of hyponatraemia can lead to changes in brain volume as the osmolar gradient across the blood-brain barrier alters. This change in volume can trigger CNS osmotic demyelination syndrome (ODS): a rare but serious complication of hyponatraemia and its treatment. ODS develops within 1–4 days of rapid (>10–12 mmol/L per 24 hours) correction of serum sodium. Other factors play a role in susceptibility: hepatic failure, potassium depletion, and malnutrition. Neurological manifestations include quadriplegia, ophthalmoplegia, pseudo-bulbar palsy, and coma.

In SIAD, hyponatraemia with serum sodium concentrations greater than 130 mmol/L may not require specific treatment. More significant degrees of hyponatraemia, associated with symptoms, can require intervention

Management of SIAD Associated with Severe or Moderately Severe Symptoms

Hyponatraemia associated with severe or moderately severe symptoms requires urgent management. Treatment is cause-independent and should be given priority over establishing the aetiology of hyponatraemia. The principle of treatment is to reduce immediate risk through increasing serum sodium to a level that decreases morbidity but at a rate that does not result in harm through precipitating ODS. Critically, the immediate target should not be to normalize serum sodium.

Determining hypertonic fluid prescription by calculated serum sodium deficit is associated with a significant risk of over-rapid correction. A pragmatic approach is to use small boluses of hypertonic fluid to achieve a 5 mmol/L rise in serum sodium in the first hour of treatment. The increase in serum sodium should be limited to 10 mmol/L in the first 24 hours, and no more than 8 mmol/L per 24 hours thereafter. An increase above the recommended rate should prompt review and consideration of active management with hypotonic fluid, with or without concurrent use of DDAVP to limit or reverse the trajectory in serum sodium. Once the clinical situation is stable, investigations to establish the cause of hyponatraemia are recommended to guide cause-directed therapy [43].

Management of SIAD Associated with Mild to Moderate Symptoms

Cause-directed therapy is the foundation managing SIAD in this context. In parallel, fluid restriction of 0.5–1 L/day is a reasonable parallel intervention. The increase in serum sodium should be limited to 8–10 mmol/L per 24 hours. All fluids need to be included in the restriction. As SIAD is associated with a degree of natriuresis, sodium intake should be maintained. Fluid restriction may need to be maintained for several days before sodium levels normalize and it is important that a negative fluid balance is confirmed during this period. As cause-directed therapy progresses (e.g. treatment of underlying infection or removal of drug-causing SIAD), fluid restriction can appropriately relaxed.

Drug Treatment in SIAD

If hyponatraemia persists or recurs after initial intervention, it is important that the underlying diagnosis is reviewed the intervention reconsidered. Clinical balance is key. There may be situations where withdrawal of a causal agent for SIAD (e.g. drug) is not practical or in the overall benefits of the patient. In other situations, fluid restriction may be only partly effective, be poorly tolerated, or may prove non-sustainable. Clinicians may thus have to balance the merits of incremental intervention with those of tolerating mild, persisting hyponatraemia.

V2-R antagonists (Vaptans) are a rational approach to the management of hyponatraemia due to SIAD. They are pure aquaretics, increasing renal water excretion without impacting on renal electrolyte loss. Both selective (V2-R specific) and non-selective (V2- and V1a-R antagonism) increase serum sodium in patients with normal or increased plasma volume and can increase serum sodium within 4–6 hours. There use can be associated with over-rapid correction. In the absence of robust data on cost-utility and evidence on patient-orientated outcomes other than serum sodium, the role of V-R antagonists in the management of SIAD remains to be clarified [43, 44].

Box 2.2.5 Symptoms and signs of hyponatraemia secondary to SIAD

- Headache
- Nausea
- Vomiting
- Muscle cramps
- Lethargy
- Disorientation
- Seizure
- Coma
- Brainstem herniation
- Death

Adipsic and Hypodipsic Disorders

Adipsic and hypodipsic disorders are characterized by inadequate spontaneous fluid intake due to a primary defect in osmoregulated thirst. Patients can become hypovolaemic and dehydrated. Despite this, they deny thirst and do not drink. If the defect is mild, the

Table 2.2.5 Classification of adipsic/hypodipsic syndromes

Classification	Osmoregulated thirst	Osmoregulated VP release
Type A (essential hypernatraemia)	Osmotic threshold increased Normal sensitivity	Osmotic threshold increased, normal sensitivity Normal response to non-osmotic stimuli
Type B	Normal osmotic threshold Reduced sensitivity	Normal osmotic threshold, reduced sensitivity Normal response to non-osmotic stimuli
Type C	No thirst response to osmotic stimulation	Persistent low-level VP release, no response to osmotic stimulation or inhibition Normal response to non-osmotic stimulation
Type D	No thirst response to osmotic stimulation	Normal

resultant hypernatraemia is often well tolerated. Severe disorders leading to marked electrolyte disturbances are tolerated poorly, and can lead to somnolence, seizures, coma, and renal failure. Because of the close anatomical relationship of the osmoregulatory centres for thirst and VP release, adipsic syndromes are often associated with defects in osmoregulated VP release and HDI. Understandably, this can exacerbate electrolyte and water balance problems and lead to significant and life-threatening decompensation.

Aetiology

Four distinct patterns of discorded thirst and associated VP release are recognized (Table 2.2.5; Figure 2.2.8). A range of conditions leading to or associated with adipsia/hypodipsia have been described (Box 2.2.6).

The type A syndrome can be mistaken for HDI, as patients are hyperosmolar with a dilute urine. Formal assessment of thirst confirms the diagnosis. Imaging is generally normal. While the precise nature of the problem remains unclear, normal VP responses to non-osmotic stimuli place the lesion responsible at the level of the osmoreceptor, rather than the VP magnocellular neurone. Patients effectively osmoregulate around a higher osmolar set point. They are protected from extreme hypernatraemia, as are those with the type B syndrome. In contrast, type C adipsia is associated with complete lack of osmoregulated thirst and VP release, consistent with effective loss of osmoreceptor function. Patients present with adipsic HDI. Specific precipitants include rupture and repair of anterior communicating artery (ACA) aneurysm. The OVLT receives its blood supply from perforating branches of the anterior cerebral artery and ACA. Surgery involving the anterior communicating artery can lead to damage at more distal sites, including the OVLT. Some patients with the type C syndrome have persistent, constitutive low-level VP release. The resultant obligatory antidiuresis thus also places such individuals at risk of dilutional hyponatraemia if large volumes of fluid are administered. Impaired osmoregulated thirst with normal osmoregulated VP release (type D adipsia) is very rare.

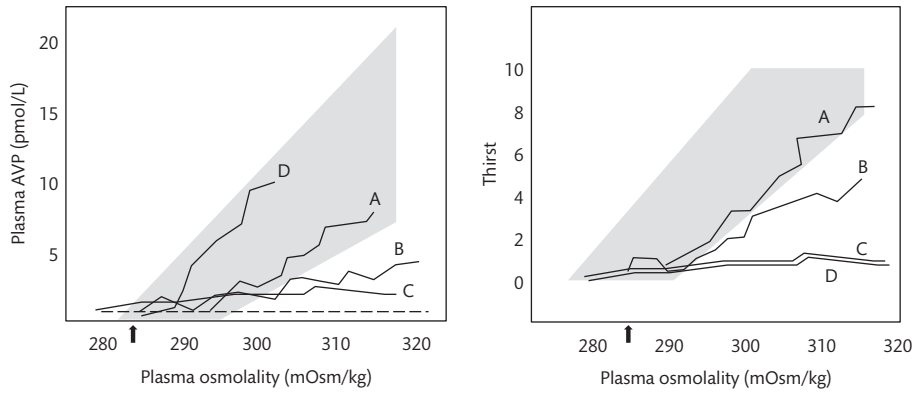

Figure 2.2.8 Patterns of plasma vasopressin and thirst responses to hypertonic stress in patients with adipsic syndromes. Normal range responses to osmolar stimulation are shown by the shaded areas. The four types of adipsic syndrome are demonstrated. Patients with the type A syndrome osmoregulate around a higher osmolar set point. Those with the type B syndrome mount vasopressin and thirst responses but with reduced sensitivity to increases in plasma osmolality. Patients with the type C syndrome have much reduced or absent vasopressin and thirst responses to osmolar stimulation while those with the type D syndrome demonstrate normal vasopressin responses to osmolar stimulation but much reduced thirst responses.

Treatment

Patients with type A and type B adipsia are protected from extreme hypernatraemia. Treatment is to recommend an obligate fluid intake of some 2 L/24 h, with appropriate adjustment for climate and season. Fluid balance may be difficult to maintain during intercurrent illness. In such circumstances, in-patient management may be required. The adipsic HDI of the type C syndrome can be difficult to manage. Structural and vascular causes of the type C syndrome may lead to associated cognitive deficits and problems with short term memory and task organization which can complicate any intervention. In addition, other problems associated with hypothalamic dysfunction may be present: such appetite and thermal balance dysregulation. The principle of management is to define an acceptable urine output (1–2 L/24 h) with regular DDAVP, and to vary the daily fluid intake depending on day to day fluctuation from a target weight at which the patient is euvolaemic and normonatraemic:

Daily fluid intake in litres = 1–2 L (i.e. the targeted urine output as dictated by the DDAVP dose set and taking into account insensible loss) + (target weight – daily weight in kg).

This formula, together with weekly checks of plasma sodium to avoid the creeping development of hyper- and hyponatraemia, can result in stable fluid balance [45, 46].

2.3

Aetiology, Pathogenesis, and Management of Disease of the Pituitary

2.3.1 Development of the Pituitary and Genetic Forms of Hypopituitarism

Louise C. Gregory and Mehul T. Dattani

Hypothalamo-Pituitary Development

Hypothalamo-pituitary (HP) development is dependent on the communication between the oral ectoderm and the overlying neural ectoderm. This occurs through a complex spatiotemporal genetic cascade of transcription factors and signalling molecules, intrinsic or extrinsic to the developing Rathke's pouch, the primordium of the anterior pituitary (AP) [1] (see **Figure 2.3.1.1**). The mature pituitary gland is situated at the base of the brain, within the sella turcica recess of the sphenoid bone, and centrally regulates growth, metabolism, reproduction, development, and homeostasis through the regulation of endocrine glands throughout the body [2]. It consists of three lobes; the anterior and intermediate lobes derived from the oral ectoderm, and the posterior lobe derived from the neural ectoderm [3, 4]. A series of tightly regulated steps resulting in cell proliferation and differentiation give rise to the five different specialized AP cell types that secrete the six AP hormones: somatotrophs [growth hormone (GH)], thyrotrophs [thyroid-stimulating hormone (TSH)], gonadotrophs [luteinizing hormone (LH) and follicle-stimulating hormone (FSH)], lactotrophs [prolactin (PRL)], and the corticotrophs [adrenocorticotropic hormone (ACTH)] [5]. Specific hypothalamic peptides travel via the hypophyseal portal system from the hypothalamus to the AP, where they bind to their specific receptors on each cell type to stimulate AP hormone production, that in turn target organs throughout the body to perform distinct roles in endocrine regulation.

Deficiencies in one or more of the six AP hormones is termed congenital hypopituitarism (CH), with GH deficiency being the most common and often seen in isolation [1]. CH severity varies widely, presenting in the early neonatal period or later in childhood, with severe cases resulting in fatality. Disordered embryogenesis can give rise to a range of midline craniofacial and brain structural abnormalities associated with CH, which may manifest as highly variable disorders, such as holoprosencephaly (HPE), septo-optic dysplasia (SOD), and Kallmann syndrome (KS), which is characterized by hypogonadotropic hypogonadism (HH) with anosmia [6].

Septo-Optic Dysplasia

SOD (n = 1/10,000 live births) is a heterogeneous variable disorder, characterized by optic nerve hypoplasia (ONH), midline neuroradiological abnormalities (such as agenesis of the corpus callosum and absence of the septum pellucidum), and pituitary hypoplasia with endocrine deficits [7, 8] with up to ~40% of SOD patients presenting with normal endocrinology. Other associated features are developmental delay, seizures, visual impairment, precocious puberty, obesity, anosmia, sensorineural hearing loss, and cardiac anomalies [9], illustrating the complexity of the disorder.

Intriguingly, SOD is associated with a younger maternal age when compared to mothers of children with isolated defects of the HP axis [10] for reasons unknown, although in some cases it may be due to excessive maternal drug and alcohol use [9, 11]. ONH occurs in 75–80% of SOD patients (unilateral [12%] or bilateral [88%]), with microphthalmia or anophthalmia occurring in rare severe cases [12]. Endocrine dysfunction may occur later [13]. The known association of midline abnormalities with hypopituitarism suggests a common developmental origin of the hypothalamus, pituitary, and midline structures within the brain [14]. Mutations in the transcriptional repressor *HESX1* were the first to be associated with the pathogenesis of rare cases of SOD, p.R160C being the first *HESX1* mutation described in association with the condition [15, 16]. Murine transgenic studies of *HESX1* revealed phenotypes that were highly reminiscent of SOD in the mice,

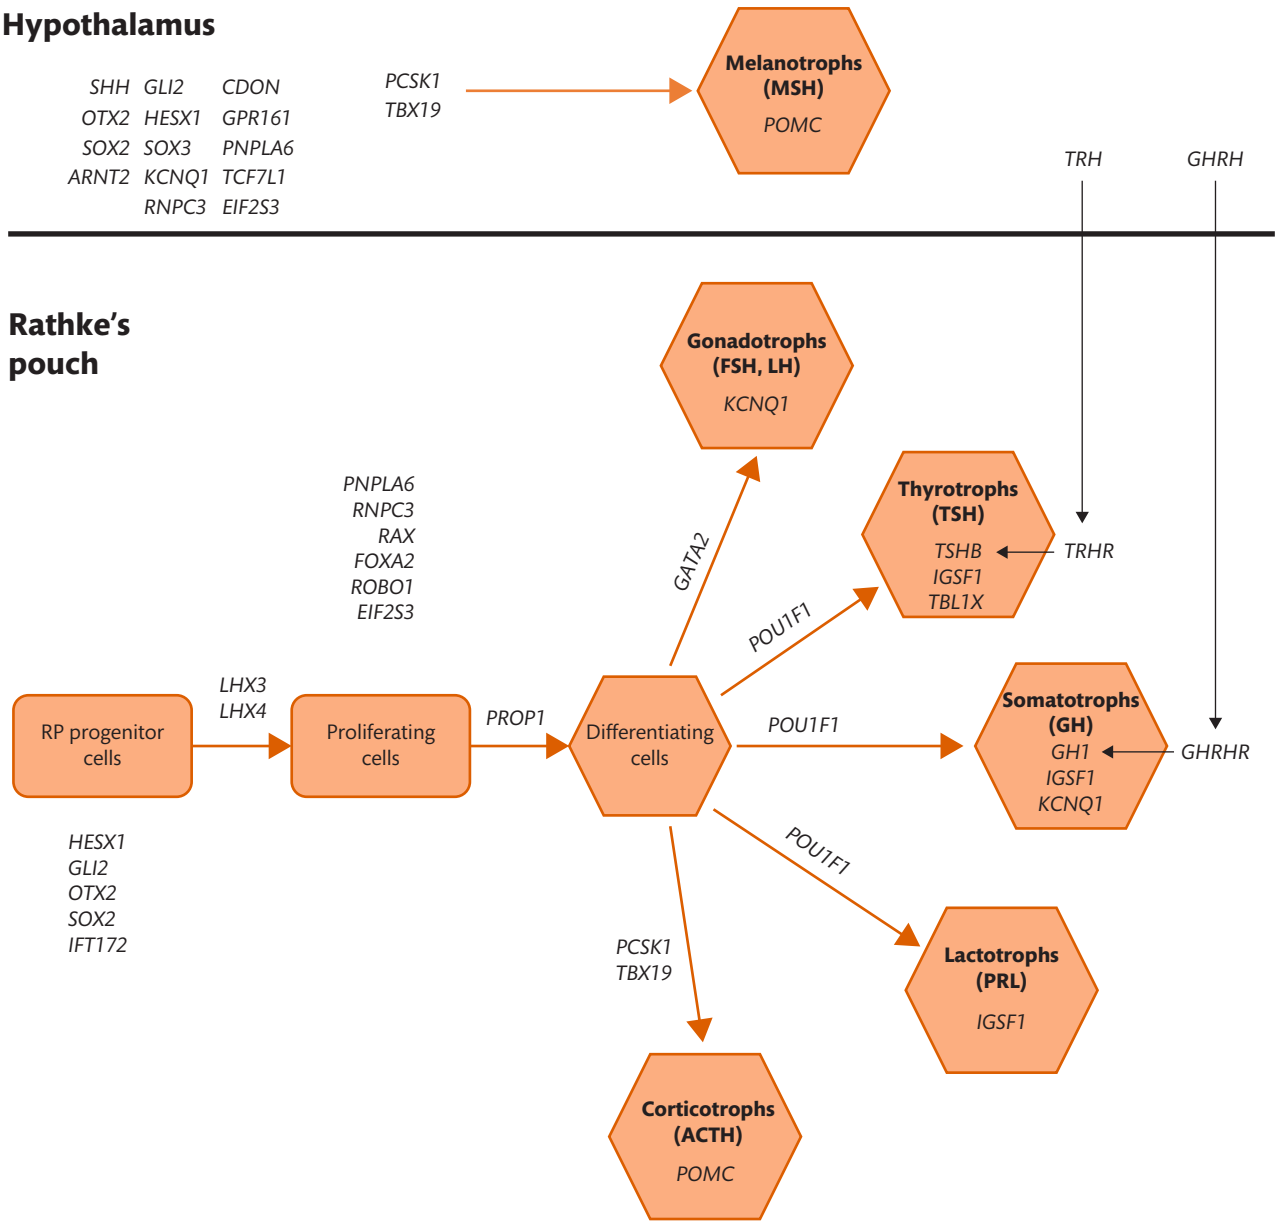

Figure 2.3.1.1 A genetic cascade of transcription factors and signalling molecules involved in hypothalamo-pituitary embryonic development.

supporting the requirement of the gene for midline and HP development, and a role for mutations in the gene in the aetiology of SOD. Subsequently, human mutations have been cloned into mouse models and studied in depth [17]. Since then, mutations in *SOX2* and *OTX2* were identified in SOD patients with severe bilateral eye defects including microphthalmia or anophthalmia, and *SOX3* mutations were identified in SOD patients with abnormalities of the hypothalamus, pituitary, infundibulum, and corpus callosum, respectively [18]. Mutations in genes implicated in KS have also been implicated in SOD. Three patients with an SOD phenotype, for example, were reported to have heterozygous mutations in *FGFR1* that altered receptor signalling, with one predicted to affect splicing. The same report described an SOD patient with an *FGF8* mutation affecting splicing and altered ligand binding [19]. Another *FGF8* mutation was identified in an SOD patient with microcephaly and neurological defects, and in a patient with semilobar HPE, diabetes insipidus, and TSH and ACTH insufficiency, respectively [6], making *FGF8* a candidate for SOD, and HPE as well as KS. Additionally, *KAL1* mutations and the *PROKR2* mutation, p.R268C, previously implicated in normosmic HH and KS, were reported in three unrelated pedigrees with SOD [20]. Heterozygous missense *TCF7L1* variants have been identified in two unrelated SOD patients [21], following studies using a conditional *Tcf7L1* murine deletion that resulted in forebrain defects and partially penetrant dwarfism [21], thus suggesting a role for *TCF7L1* in the aetiology of SOD. Table 2.3.1.1 summarizes the causative genes implicated in the aetiology of SOD and the subsequent HP-related disorders discussed in this chapter.

Table 2.3.1.1 Inheritance patterns of mutations in causative genes implicated in congenital hypopituitarism

Gene	Phenotype	Inheritance
GH1	IGHD type IA	Autosomal recessive
	IGHD type IB	Autosomal recessive
	IGHD type II	Autosomal dominant
GHRHR	IGHD type IB	Autosomal recessive Autosomal dominant (rare)
RNPC3	IGHD	Autosomal recessive
TSHB	TSHD	Autosomal recessive
TRHR	TSHD	Autosomal recessive
IGSF1	TSHD, hypoprolactinaemia, transient GHD; usually with macro-orchidism	X-linked
TBL1X	TSHD	X-linked
TBX19	IAD	Autosomal recessive
POMC	IAD; early-onset obesity and red hair pigmentation	Autosomal recessive
PCSK1	IAD, GHD, TSHD, DI	Autosomal recessive Autosomal dominant (obesity)
TCF7L1	SOD	Autosomal dominant
HESX1	IGHD	Autosomal dominant Autosomal recessive
	MPHD	
	SOD	
SOX2	HH, anophthalmia/microphthalmia	Autosomal dominant/de novo
	Hypothalamo-pituitary tumour	
SOX3	MPHD and absent infundibulum GHD	X-linked
OTX2	SOD	Autosomal dominant: haploinsufficiency or dominant negative
	MPHD	
	IGHD	
LHX3	MPHD, short neck with limited rotation	Autosomal recessive
LHX4	MPHD	Autosomal dominant Autosomal recessive
PROP1	MPHD	Autosomal recessive
POU1F1	MPHD	Autosomal dominant Autosomal recessive
PROKR2	HH/KS	Autosomal recessive Autosomal dominant
	SOD	
FGFR1	HH/KS	Autosomal dominant
	SOD	
FGF8	HH/KS	Autosomal dominant Autosomal recessive
	HPE	
	SOD	
KAL1	HH/KS	X-linked
	SOD	
	KS	
GLI2	HPE	Autosomal dominant: Haploinsufficiency
	IGHD/MPHD	
	HH	
CDON	PSIS	Autosomal dominant
GPR161	PSIS	Autosomal recessive

Table 2.3.1.1 *Continued*

Gene	Phenotype	Inheritance
ROBO1	PSIS	Autosomal dominant
ARNT2	MPHD	Autosomal recessive
PNPLA6	Oliver–McFarlane and Laurence–Moon syndrome	Autosomal recessive
KCNQ1	GHD, maternally inherited gingival fibromatosis	Autosomal dominant
IFT172	GHD, retinopathy, metaphyseal dysplasia, renal failure (ciliopathies)	Compound heterozygous

IGHD, isolated growth hormone deficiency; TSHD, thyroid-stimulating hormone deficiency; IAD, isolated adrenocorticosteroid hormone deficiency; DI, diabetes insipidus; SOD, septo-optic dysplasia; MPHD, multiple pituitary hormone deficiency; HH, hypogonadotropic hypogonadism; KS, Kallmann syndrome; HPE, holoprosencephaly; PSIS, pituitary stalk interruption syndrome.

Combined Pituitary Hormone Deficiency

Combined pituitary hormone deficiency (CPHD) is defined as the presence of at least two or more pituitary hormone deficiencies including GH, TSH, PRL, ACTH, LH, and FSH deficiencies. Mutations in the genes encoding transcription factors *PROP1, POU1F1, LHX3*, and *LHX4*, which are critical for normal pituitary development, often result in unique patterns of CPHD that reflect their differential expression during organogenesis [22]. Depending on the deficiencies in the patient, the phenotypic features may include those of hypothyroidism, delayed or absent puberty which may lead to infertility, intellectual disability, midline defects such as cleft lip or palate, and short stiff neck (specifically caused by *LHX3* mutations). The early acting transcription factors *LHX3* and *–4*, as opposed to the later acting *PROP1* and *POU1F1*, cause deficiencies of most, if not all, pituitary hormones, often referred to as panhypopituitarism or multiple pituitary hormone deficiency (MPHD). Mutated forms of all four genes affect somatotroph cell development and therefore all may give rise to severe short stature, reflecting why growth hormone deficiency (GHD) occurs with a higher prevalence. CPHD with differing endocrine deficits may also stem from mutations in *HESX1, SOX3*, and *OTX2* [18, 23, 24].

CPHD patients with mutations in genes that are implicated in KS have also been described, once again demonstrating genetic overlap with KS. For example, a CPHD patient with right microphthalmia, right renal aplasia and severe developmental delay had a hemizygous variant in *KAL1* that was predicted to be pathogenic [25]. The known *PROKR2* p.R85H mutation was identified in a CPHD patient with GH, TSH, ACTH, LH and FSH deficiencies, and a microphallus; suggesting neonatal gonadotropin-releasing hormone (GnRH) deficiency [19] and thus features of HH/KS. Furthermore, the *PROKR2* p.L173R variant initially identified in KS patients, that affects targeting to the cell surface receptor, has since been frequently identified in both CPHD and SOD patients [26]. A novel *PROKR2* variant, p.R248W, predicted to be deleterious in a CPHD patient, where a glutamine substitution at this highly conserved residue had previously been described, was identified in a patient with HH [27]. A novel loss of function mutation in *FGFR1*, p.R448W, was also recently identified in a patient with GH and TSH deficiency [28].

Furthermore, the transcription factor *GLI2*, a component of the sonic hedgehog (SHH) signalling pathway known to be implicated in HPE and other midline neurodevelopmental anomalies [29, 30], has now been implicated in CH in the absence of midline brain defects [31]. Interestingly, patients with *GLI2* mutations may have variable phenotypes ranging from isolated GHD (IGHD) to CPHD, in combination with variable polydactyly, cleft lip/palate, diabetes insipidus, dysmorphic features, and an ectopic posterior pituitary (EPP) on MRI [32–34]. This does not seem to be apparent for all components of the SHH pathway, for example mutations in the *SHH* gene itself seem to exclusively cause HPE, with no reported cases of CH to date [31].

Despite these reports implying a genetic overlap between CPHD and HH/KS, and HPE and CH cases respectively, digenic inheritance cannot be ruled out here, where another mutation may be responsible for the aetiology of at least one of the deficiencies in their CPHD. Incomplete or variable penetrance of a mutation often occurs in many of these families, especially when *GLI2* or *HESX1* mutations are present, where a heterozygous mutation with functional consequences in the child is present in the unaffected parent or a parent with a mild form of the disease, respectively [31, 35].

Isolated Growth Hormone Deficiency

Congenital IGHD has an incidence between 1/4000 and 1/10 000 live births and is the most prevalent isolated pituitary hormone deficiency. The majority of cases are sporadic with a small percentage (3–30%) of familial cases, and the aetiology of most patients is unknown [36, 37]. GH-releasing hormone (GHRH) released from the hypothalamus binds to its receptor (GHRHR) on somatotrophs resulting in the synthesis and release of GH, in the presence of the transcription factor *POU1F1* [38]. Children with IGHD manifest with moderate to severe short stature associated with a poor growth velocity and delayed skeletal maturation. Recombinant human GH (rhGH) is used to treat the condition and generally achieves a good response in patients [37].

There are four main genetic forms of IGHD. Type 1A autosomal recessive IGHD harbour complete deletions of *GH1* and these patients present with severe growth failure in the first 6 months of life with undetectable GH concentrations. These patients frequently develop anti-GH antibodies after receiving exogenous GH, which prevent the growth response expected on commencing rhGH therapy [39]. Heterogeneous homozygous *GH1* deletions (~6.7 Kb long), were the first, and remain the most common, *GH1* gene alteration in patients with IGHD type IA [40]. Since then, many other severe loss of function *GH1* mutations have subsequently been described.

Type IB GHD is associated with recessive *GH1* and *GHRHR* mutations [41], the latter also being known as Sindh dwarfism. GHD due to *GHRHR* mutations differs from the classical IGHD phenotype, as patients have limited facial dysmorphism and no microphallus, yet still manifest AP hypoplasia (APH) on MRI [42]. These patients

originate from consanguineous pedigrees in Brazil or the Indian subcontinent [43] and usually harbour loss of function *GHRHR* mutations. The first and most common *GHRHR* mutation is p.E72X, resulting in a truncated protein devoid of both the transmembrane and intracellular domains. The p.W273S, p.A176V [36, 44], and p.K329E substitutions have since been reported among many others, with the latter failing to show any cAMP response following administration of GHRH in *in vitro* studies [45]. However, there is some phenotypic variability; an unusually mild form of IGHD in two unrelated families with a novel partial loss of function homozygous *GHRHR* mutation, p.P79L, has recently been described. The patients were compound homozygous with a second variant in *GHRHR*, p.R4Q, that did not appear to compromise the cAMP pathway [46].

Type II GHD, the most common autosomal dominant form of the disease, is often caused by heterozygous *GH1* mutations that affect splicing, resulting in exon skipping [47]. The shorter 17.5kDa GH isoform, resulting from the skipping of exon 3, has been reported to exert a dominant negative effect on GH secretion, with expression levels directly related to severity of the disorder [48, 49]. Other heterozygous *GH1* missense mutations, such as p.E32A, p.R178H, and p.R183H have also been described in this form of GHD. These patients have variable height deficit (occasionally within the normal range) and severity, and may develop additional pituitary hormone deficiencies over time, including ACTH, TSH, and LH/FSH deficiencies [36]. To date, no mutations in *GHRH* have been described in association with IGHD. However, mutations in genes encoding early (*HESX1, SOX2, SOX3*, and *OTX2*) or late (*PROP1* and *POU1F1*) transcription factors implicated in murine and human pituitary development, have been reported in patients with IGHD [23, 37, 50].

Mutations in *RNPC3* have recently been associated with IGHD. The ribonucleic acid (RNA)-binding region (RNA recognition motifs [RRM]) containing 3 on chromosome 1 encodes a 65K protein component of the U12-type spliceosome. Its two RRM motifs suggest interaction with one of the small nuclear RNAs of the minor spliceosome [51]. Biallelic mutations in *RNPC3* have been described in three sisters with severe IGHD and pituitary hypoplasia, where anomalies were identified in the splicing of multiple U12-type introns in patient cells [52]. Despite the unknown direct mechanism underlying the GHD, a subset of 21 genes were found to be affected by this particular splicing. Interestingly, these genes encoded proteins with relevant functions in pituitary development, such as *SPCS2* and *SPCS3* that encode subunits of the signal peptidase complex, implicated in post-translational processing of preprohormones such as preproghrelin to proghrelin [52, 53].

An induced lethal point mutation in *rnpc3* in a zebrafish model resulted in the formation of aberrant U11- and U12-containing snRNAs that sufficiently impaired the efficiency of U12-type splicing, thus causing arrested development in the intestine, liver, and pancreas. This is the only *rnpc3* loss of function *in vivo* model reported to date. Analysis of the zebrafish transcriptome revealed that efficient mRNA processing is critical for the growth and proliferation of cells during vertebrate development [54].

GHD with Accompanying Features

Mutations in *KCNQ1* have recently been described in phenotypically variable GHD patients with mild craniofacial dysmorphic features and maternally inherited gingival fibromatosis [55]. This paternally imprinted gene, encoding the alpha subunit of the voltage-gated ion channel Kv7.1, is expressed in mouse and human somatotroph and gonadotroph cells in the postnatal pituitary, in hypothalamic GHRH neurons during murine development, and in the human hypothalamus [55]. Mutations in *KCNQ1* were previously associated with cardiac arrhythmia syndromes and other heart defects [56]. This suggests how critical ion channels act as regulators in the function of the human pituitary, thus supporting previous data implicating voltage-gated potassium channel currents in pituitary cells [57–59].

A patient with early growth retardation, APH, and an EPP on their MRI, harboured compound heterozygous mutations in the *IFT172* gene. The patient manifested retinopathy associated with metaphyseal dysplasia and hypertension with renal failure, indicative of a ciliopathy [60]. The *IFT172* gene encodes a subunit of the intraflagellar transport (IFT) subcomplex IFT-B, necessary for ciliary assembly and maintenance. Mutations in *IFT172* have previously been associated with skeletal ciliopathies with or without polydactyly, and with retinal, cerebellar, or hepatorenal malformations [61–63]. This signifies a possible role for ciliary function in pituitary development and the bridge between early-onset growth failure and ciliopathies. In further support of this theory, the *ALMS1* gene, which encodes a protein that localizes to the centrosomes and basal bodies of ciliated cells, was identified in a patient with Alström syndrome. This rare autosomal recessive disease is characterized by multiorgan dysfunction and associated with GHD [64].

Additional Isolated Hormone Deficiencies and Malformations

Congenital isolated hormone deficiencies, aside from IGHD, have been reported for all other pituitary cell lineages, such as isolated TSH deficiency (TSHD), isolated hypogonadotropic hypogonadism [IHH; LH and FSH deficiency] that may be part of KS (please see Chapter 2.4.1 'Hypothalamic Dysfunction'), isolated ACTH deficiency (IAD) and, very rarely, isolated PRL deficiency (PRLD) [65].

Defective stimulation of the thyroid gland by TSH causes inadequate thyroid hormone biosynthesis and subsequent central, or secondary, hypothyroidism in affected patients, thus TSHD. Detection of congenital hypothyroidism in neonates by T_4 and TSH screening is a highly sensitive method used to prevent intellectual disability, which may occur due to delayed diagnosis [66]. Rarely, mutations in genes that cause CPHD may present with isolated hormone deficiencies. For example, a homozygous *PROP1* frameshift was identified in a young patient with isolated central hypothyroidism [67].

Mutations in genes regulating TSH biosynthesis and secretion such as *TSHB, TRHR*, and more recently *IGSF1,* have been described in patients with isolated TSHD in rare cases [68, 69]. Patients with mutations in *TSHB*, encoding the TSHβ subunit, previously identified in hypothyroid patients, can have undetectable or highly variable TSH concentrations [70, 71]. The most frequent *TSHB* mutation is termed the homozygous 'hotspot', c.373delT (C105Vfs114X), that causes secondary hypothyroidism in several populations worldwide [71, 72].

Rare recessive biallelic inactivating *TRHR* mutations have been reported in patients with central congenital hypothyroidism (CCH), with absent TSH and prolactin responses to exogenous thyrotropin-releasing hormone (TRH) [73, 74]. The homozygous mutation, p.I131T, that decreases TRH affinity was identified in an overweight patient with CCH and normal stature [68]. Subsequently, the missense *TRHR* mutation (p.P81R) was identified in a patient with isolated CCH, and exemplified the importance of TRH receptor activation in normal TSH secretion [75].

Recently, two X-linked forms of CCH have been identified. Firstly, mutations in *IGSF1* have been described in CCH with macro-orchidism [69, 76]. *Igsf1* is expressed in murine pituitary thyrotroph, lactotroph, and somatotroph cell lineages [69], Leydig and germ cells in murine/human testes, and at low levels in Sertoli cells [77]. It has been suggested that IGSF1 stimulates transcription of TRHR thereby enhancing TSH production and function. In contrast, IGSF1 appears to inhibit the activin-Smad pathway, leading to reduced expression of *FSHB* secreted by gonadotrophs. A large hemizygous 207.873 Kb deletion on Chr. Xq26.2 incorporating *IGSF1* was identified in a patient with reduced TSH biopotency leading to hypothyroidism, macro-orchidism, and an increase in FSH secretion in neonatal minipuberty [77]. Many other *IGSF1* mutations have been reported in such patients, however it should be noted that macro-orchidism is not consistently present in every patient with *IGSF1* mutations [78], and intriguingly, heterozygous female carriers of *IGSF1* mutations may manifest a mild form of hypothyroidism [79]. The second X-linked form, identified in isolated CCH, is caused by mutations in the *TBL1X* gene, encoding a component of the thyroid hormone receptor-corepressor complex, previously associated with sensorineural hearing loss [80, 81].

In contrast to other isolated hormone abnormalities, an abnormal increase in prolactin as opposed to a decrease is more frequent in children with CH, particularly those with midline defects. Isolated PRLD, known as hypoprolactinaemia, clinically manifests only in women as puerperal alactogenesis, namely the failure of milk production during breastfeeding [82], although it remains extremely rare. Patients that have PRLD as part of CPHD are currently screened for mutations in candidate genes known to be involved in the lineage of lactotrophs, such as *POU1F1, PROP1, LHX3, LHX4, HESX1*, and *OTX2* [83]. However, the aetiology of isolated PRLD remains undetermined.

IAD is a rare, heterogeneous, and variable condition, and the diagnosis can be challenging. It can be fatal due to hypocortisolism or cholestasis if unrecognized, and is associated with neonatal hypoglycaemia, convulsions, hypercalcaemia, severe hyponatraemia, and an empty sella on MRI [84–87]. *TBX19*, formally known as *TPIT*, plays a critical role in the terminal differentiation of corticotrophs and melanotrophs; the pre-pro-opiomelanocortin (POMC) lineages. Severe loss of function *TBX19* mutations, most commonly missense in the DNA-binding Tbox domain, have been identified in ~65% of neonatal early-onset IAD cases [88, 89]. Truncated proteins formed by chromosomal deletions or aberrant splicing [90], and compound heterozygosity for the p.Arg222Lysfs*4 mutation biallelic with the known p.R286X mutation, have since been described in IAD patients. Recurrent infections may be a prominent clinical feature of adrenal insufficiency, and should alert clinicians so that diagnostic delay and subsequent life-threatening consequences can be avoided [91].

Recessive mutations in *POMC* have been reported in association with a distinct type of IAD. These patients present with early-onset obesity and red hair, often with adrenal insufficiency, hypocortisolism and hypoglycaemia [92]. Compound heterozygosity for nonsense mutations in *PCSK1*, encoding prohormone convertase (PC) 1, have previously been reported in patients with severe obesity with glucose dysregulation and gonadotrophin deficiency [93], and in isolated obesity [94], respectively. Patients with such mutations may also suffer from malabsorptive severe refractory neonatal diarrhoea, as described in an obese patient with hypoadrenalism, hypoglycaemia, and elevated circulating concentrations of prohormones [95]. Other PC1/3-deficient patients often manifest hypothyroidism and hypocortisolism diagnosed by their low blood T_4 and cortisol concentrations. They can also present with elevated TSH and ACTH, respectively [96], and in rare cases, GHD and diabetes insipidus, thus further expanding the disease manifestation in *PCSK1*-deficient patients [97]. Murine *Pcsk1* (PC1) knockouts present with growth retardation as opposed to obesity, and, together with studies using PC1-deficient human embryonic stem cells, reflect defective POMC and proinsulin processing as observed in human patient phenotypes when *PCSK1* is absent [98, 99].

Pituitary Stalk Interruption Syndrome

Pituitary stalk interruption syndrome (PSIS) is distinguished by a thin or discontinuous pituitary stalk, APH, and/or an EPP on MRI. Until recently, only genes known to cause CH, including *LHX4, OTX2, HESX1, SOX3*, and *PROKR2*, have been described to be mutated in rare cases of PSIS [23, 24, 100]. However, a novel mutation in *CDON*, another member of the SHH signalling pathway that causes HPE, has been reported in a PSIS patient. The patient presented with neonatal hypoglycaemia, cholestasis, and GH, TSH, and ACTH deficiencies, without HPE features [101]. Furthermore, two affected siblings from a consanguineous pedigree had a recessive variant in the *GPR161* gene, encoding the transmembrane orphan G protein-coupled receptor 161 suggesting a possible involvement in the aetiology of PSIS patients. Interestingly, GPR161 is predicted to interact with GLI2, GLI3, and other members of the SHH pathway [102], however functional studies on GPR161 are needed to determine its physiological role during development. These reports repeatedly demonstrate how the SHH pathway may elicit varying phenotypes when its components are mutated.

Another gene recently implicated in PSIS, is *ROBO1*; a receptor involved in Slit/Robo signalling critical for embryonic axon guidance and branching in the nervous system during development [103]. Ocular anomalies including hypermetropia with strabismus, and ptosis were present in the majority of PSIS patients harbouring these mutations [104].

Oliver–McFarlane and Laurence–Moon Syndromes

Mutations in the *PNPLA6* gene, encoding neuropathy target esterase (NTE), have recently been implicated in Oliver–McFarlane

and Laurence–Moon syndromes, two distinct neurodegenerative disorders. Aside from the characteristic phenotypic features in these patients (chorioretinopathy, spinocerebellar ataxia, spastic paraplegia, learning difficulties and trichomegaly), pituitary dysfunction in the form of variable GHD and HH, with a small AP on MRI, is usually present. Human expression studies alongside the generation of a *pnpla6*-morphant zebrafish model and analysis of patient-derived cells, signify that defective recessive *PNPLA6* alleles give rise to rare distinct pituitary-related phenotypes, when in combination with variable neurodegenerative disorders.

Variant Identification and Modern Techniques Used in Functional Analysis

The use of targeted multigene panels has become the initial preferential technique used in many laboratories to screen patients for mutations and novel variants in known and novel causative genes. If no variants are identified using this method then next generation sequencing (NGS) involving a multitude of revolutionized techniques may be used. NGS incorporates whole genome (WGS) or exome sequencing (WES), microarrays, and homozygosity mapping, with the latter technique usually employed when analysing consanguineous pedigrees. Different parameters and filters are used in the data analysis of WES to search for candidate genes and variants with different modes of inheritance. The filter settings are dependent on the phenotype and ethnic background of the patient. This has rapidly replaced the laborious and expensive Sanger sequencing approach to screening which to date has been the standard approach used in the majority of laboratories worldwide. Identification of any novel variants in highly conserved residues that are not present on control databases (e.g. gnomAD browser) may be screened in patients with similar phenotypes for further mutations in the gene of interest. Human embryonic expression, and *in vitro* functional studies investigating the significance of the novel variants may then be conducted.

WGS is the most efficient NGS technique in identifying variants when cost is not an issue. WGS interrogates all parts of the genome, potentially revealing single-nucleotide variants (SNVs), indels, structural variants (SVs), and copy number variants (CNVs) in both the ~1% part of the protein coding sequences, and the remaining ~99% of the non-coding sequence [105]. However, WGS is impractical to perform as a standard approach for every pedigree. Despite WES constituting such a low percentage of the entire genome, it still contains the majority of pathogenic mutations identified to date [106]. Therefore, WES remains the preferred choice as it costs significantly less than WGS due to it being confined to the cDNA only.

The generation of induced pluripotent stem cells (IPSC) from patient fibroblasts [107] allows the potential to differentiate cells into a multitude of relevant cell types, such as neuronal, pancreatic, adipocyte cells, and so on, dependent on the phenotype or pathway to be tested. This technique, although time-consuming, may then allow further investigation using relevant methods such as insulin secretion assays, apoptosis, and proliferation assays, using cells derived directly from the patient. This pioneering technology will limit the need for mouse models and will be more physiologically relevant than the current *in vitro* functional assays.

CRISPR-Cas9 gene editing is now routinely used to knock out a gene more efficiently and faster than previous methods using embryonic stem cells. The insertion of genetic variants such as point mutations may also be conducted using the CRISPR-Cas9 system in order to study the impact of specific variants identified in patients [108, 109]. Upon identification of any significant differences between patient and control cells following assays in patient-derived differentiated IPSC cell lines, rescue experiments may also be performed using the CRISPR-Cas9 system to correct certain variants that are under investigation. Subsequent assays may then be implemented on the rescued cells to see if the correct function or conditions have been restored.

Newer methods of interrogating patient samples and of manipulating the genome will revolutionize the practice of medicine in the future, and the aforementioned techniques mark the dawn of a new era in molecular medicine.

2.3.2 Molecular Pathogenesis of Pituitary Tumours

Shlomo Melmed

Introduction

Although clinically apparent tumours are rarely encountered, pituitary adenomas are apparent in up to 25% of unselected autopsies. The pituitary gland is composed of differentiated cell types: somatotrophs, lactotrophs, corticotrophs, thyrotrophs, and gonadotrophs. Tumours may arise from any of these differentiated cell types and their hormone secretory products depend upon the cell of origin. Functional classification of pituitary tumours is based on identification of differentiation markers by immunostaining or mRNA detection, as well as measurement of circulating tumour and target organ hormone levels. Oversecretion of adrenocorticotropic hormone (ACTH) results in cortisol excess with Cushing disease. Growth hormone (GH) overproduction leads to acromegaly with typical acral overgrowth and metabolic abnormalities. Prolactin (PRL) hypersecretion results in hypogonadism and galactorrhoea. Rarely, thyroid-stimulating hormone (TSH) hypersecretion leads

to goitre and thyrotoxicosis, and gonadotropin excess results in gonadal dysfunction [1]. Mixed tumours cosecreting GH with PRL, TSH, or ACTH may also arise from single cells. Clinically nonfunctional tumours do not efficiently secrete their gene products, and most commonly are derived from gonadotroph cells. Pituitary tumours are defined radiographically as microadenomas (<1 cm in diameter) or macroadenomas (≥1 cm in diameter).

Pituitary tumours cause morbidity by both abnormal hormone secretion as well as compression of regional structures. As a significant proportion of patients do not achieve optimal therapeutic control of mass effects and/or hormone hypersecretion despite advances in therapeutic approaches, understanding pathogenesis and pituitary tumour growth patterns in individual patients enables identification of personalized treatment targets, ultimately decreasing tumour-related morbidity and mortality [2].

Determinants of initiation and progression of pituitary adenomas are not fully understood. This chapter describes a spectrum of mechanisms implicated in pituitary tumorigenesis, including the role of pituitary plasticity, imbalances in cell cycle regulation, transcription factors, signalling pathways, and angiogenesis (Figure 2.3.2.1). Molecular events related to tumorigenesis in human pituitary adenoma subtypes are summarized in Table 2.3.2.1. The causal role for selected genetic imbalances leading to development of pituitary tumours has been recapitulated in several transgenic mouse models (Table 2.3.2.2).

Pituitary Plasticity

Although commitment of pituitary cell function is under cell-specific transcriptional control resulting in differentiated mature cell types (Figure 2.3.2.2), the pituitary gland responds to central and peripheral signals that regulate plastic pituitary cell hormone production and proliferation. Under physiological conditions, hypothalamic and peripheral hormones act in concert to regulate pituitary trophic activity. Age (puberty), and pregnancy/lactation results in increased pituitary volume, and prolonged target gland failure (e.g. hypothyroidism) and oestrogen excess are recognized causes of pituitary hyperplasia. However, there is only modest direct evidence that pituitary hyperplasia is a necessary prerequisite for pituitary tumour development. For example, hyperplastic proliferation of PRL-secreting cells during pregnancy and lactation does not increase the frequency of prolactinomas, while untreated primary hypothyroidism and exogenous oestrogen administration are very infrequently associated with adenoma development. Pituitary hyperplasia caused by ectopic tumour production of growth hormone releasing hormone (GHRH) [3] is very rarely associated with discrete adenoma formation. In general, adenohypophyseal tissue surrounding pituitary tumours is normal, supporting the notion that multiple independent cellular events such as generalized hyperplasia do not necessarily precede adenoma formation. Excess pituitary hormone secretion is usually associated with invariably benign monoclonal adenomas arising from a specific cell type supporting intrinsic pituitary defect in the process of tumour development (Box 2.3.2.1) [4].

Hypothalamic hormones, local growth factors, and circulating sex steroid hormones are likely implicated in enabling a permissive environment which potentiates cell mutation and subsequent tumour growth. Trophic pituitary stimuli may influence the intrapituitary milieu to either enhance or attenuate expansion of a monoclonal tumour cell population.

Cell Cycle Regulation

Retinoblastoma Susceptibility Gene (*RB1*)

The protein encoded by this gene (pRB) is a negative regulator of the cell cycle and behaves as a tumour suppressor. In its active, hypophosphorylated form pRB binds the E2F transcription factors, restraining cell cycle progression from the G1 to S phase.

Mice with homozygous loss of *Rb1* are non-viable, however those with heterozygous *Rb1* inactivation develop pituitary tumours with high penetrance, and less frequently thyroid medullary carcinoma, and pheochromocytoma. Interestingly, mice with deregulated intermediate lobe E2F activity develop tissue hyperplasia that does not progress to tumour formation, likely because sustained E2F activity ultimately triggers premature senescence in a pRB, p16 and p19-dependent manner [5].

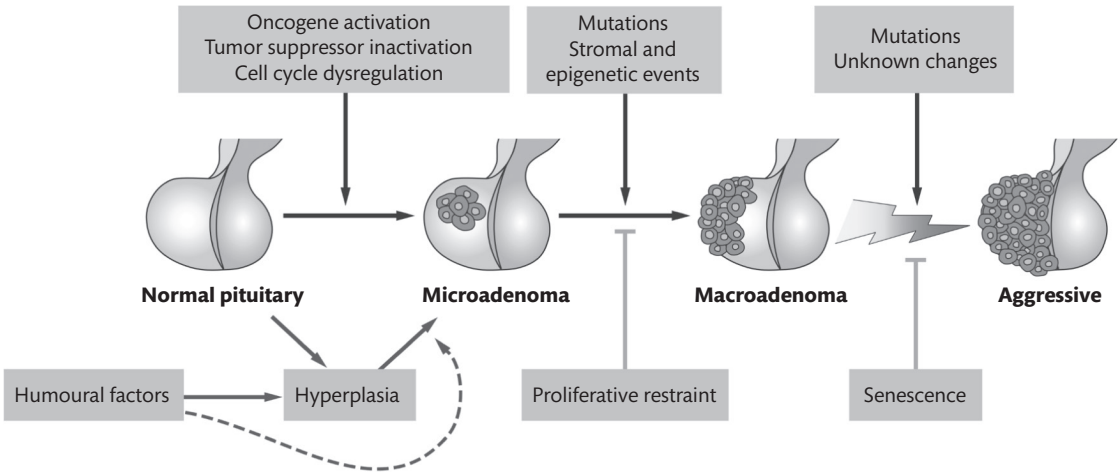

Figure 2.3.2.1 Cascade of pituitary tumorigenesis. Pituitary hyperplasia is usually reversible, as exemplified by the situation that occurs during pregnancy.

Table 2.3.2.1 Selected molecular events related to tumorigenesis in human pituitary adenoma subtypes

	Tumour type	Mechanism of activation/inactivation
Activating		
Gsp	GH adenomas	Activating mutation
CREB	GH adenomas	Increased Ser-phosphorylated CREB promoted by gsp overexpression
Cyclin B2 (*CCNB2*)	All tumour types examined	Overexpression
Cyclin D1 (*CCND1*)	Non-functioning	Overexpression
EGF/EGFR	Non-functioning	Overexpression
PTTG	All tumour types examined	Overexpression
Gal-3	Prolactinomas ACTH adenomas	Overexpression
HMGA2	Non-functioning ACTH adenomas Prolactinomas	Overexpression
FGF-4	Prolactinomas	Overexpression
USP8	Cushing	Mutation
Inactivating		
RB1	Negative pRB in ~25% GH adenomas	Promoter methylation
13q14	Aggressive tumours	13q14 loss of heterozygosity
AIP	15% of FIPA 2% sporadic GH adenomas	Inactivating mutation
MEN1	Prolactinomas in familial MEN1	Inactivating mutation
P16INK4a (*CDKN2A*)	All tumour types examined	Promoter methylation
P27Kip1 (*CDKN1B*)	All tumour types examined	Reduced expression
MEG3a	Non-functioning GH adenomas	Promoter methylation
GADD45-γ	Non-functioning GH adenomas Prolactinomas	Promoter methylation

FIPA, familial isolated pituitary adenomas.

Table 2.3.2.2 Transgenic mouse models for pituitary tumours

	Hyperplasia/Adenoma [b]
Gene overexpression [a]	
CMV.**HMGA1**	GH, PRL
CMV.**HMGA 2**	GH, PRL
Ubiquitin C.**hCG**	PRL
αGSU.**bLH**	Pit-1 lineage
GH.**galanin**	GH, PRL
PRL.**galanin**	PRL [c]
PRL.**TGFα**	PRL
αGSU.**PTTG1**	LH, GH, TSH
αGSU.**Prop1**	Non-functioning
PRL.**pdt-FGFR4**	PRL
Gene inactivation	
p27/Kip1 $^{-/-}$	ACTH, αMSH
p18/INK4c $^{-/-}$	ACTH, αMSH
Rb$^{+/-}$	ACTH, αMSH αGSU, GH, βTSH
D2R-deficient	PRL
Men1$^{+/-}$	PRL
PRL$^{-/-}$	Non-functioning

[a] Genes are listed in bold, and are preceded by the promoter that determines transcriptional control;
[b] Hormone immunoreactivity/secreting profile;
[c] Pituitary hyperplasia, with no tumour formation.

CMV, cytomegalovirus; PRL, prolactin; HMGA, high mobility group A; pdt-FGFR4, pituitary tumour-derived fibroblast growth factor receptor-4; TGFα, transforming growth factor-alpha; Men1, multiple endocrine neoplasia type 1; PTTG, pituitary transforming gene.

Reproduced with permission from Donangelo I, Melmed S. *Molecular Pathogenesis of Pituitary Tumors*. 2nd ed. Massachusetts: Blackwell Publishing; 2008.

Individuals who inherit a defective copy of *RB1* gene are at high risk for developing retinoblastoma at an early age, however, interestingly these patients do not exhibit a predisposition to development of pituitary adenomas. Aggressive human pituitary tumours and rarely encountered metastasis exhibit loss of heterozygosity of region 13q14 (*RB1* locus), however pRB usually remains expressed suggesting that a tumour suppressor gene other than *RB1* present in the same chromosomal region may be related to pituitary tumour progression. Studies based on immunodetection in tumour sections found normal expression of pRB in most non-functioning pituitary adenomas, however approximately 25% of GH-secreting adenomas exhibit loss of pRB expression, and this finding did not correlate with tumour behaviour. In some cases, decreased *RB1* expression correlated with promoter hypermethylation [6]. It is likely that *RB1* inactivation may be involved in human pituitary tumour development in a small subset of adenomas.

INK4 Family

Cell cycle is regulated by two families of cyclin-dependent kinase (CDK) inhibitors, the INK4 family and the Cip/Kip family. The INK4 family (p16INK4a, p15INK4b, and p18INK4c) inhibit G1/S progression by binding CDK4 and CDK6.

The protein p16INK4a, encoded by the *CDKN2A* gene on chromosome 9p21, maintains pRB unphosphorylated (active) by blocking CDK4. p16INK4a is not expressed due to promoter hypermethylation in most non-functioning pituitary tumours and in a smaller subset of other pituitary tumour subtypes. Loss of p16INK4a and pRB in tumours tend to be mutually exclusive, likely because functional pRB is required for cell cycle inhibition by p16INK4a and loss of both regulators of the cell cycle would not provide an additive growth advantage. Promoter hypermethylation of the *CDKN2B* gene that encodes p15INK4b was also noted in a subset of pituitary tumours. p18INK4c-deficient mice develop gigantism and widespread organomegalia, and proopiomelanocortin (POMC) intermediate lobe pituitary hyperplasia and tumours. P18INK4c is significantly underexpressed in human ACTH-secreting adenomas.

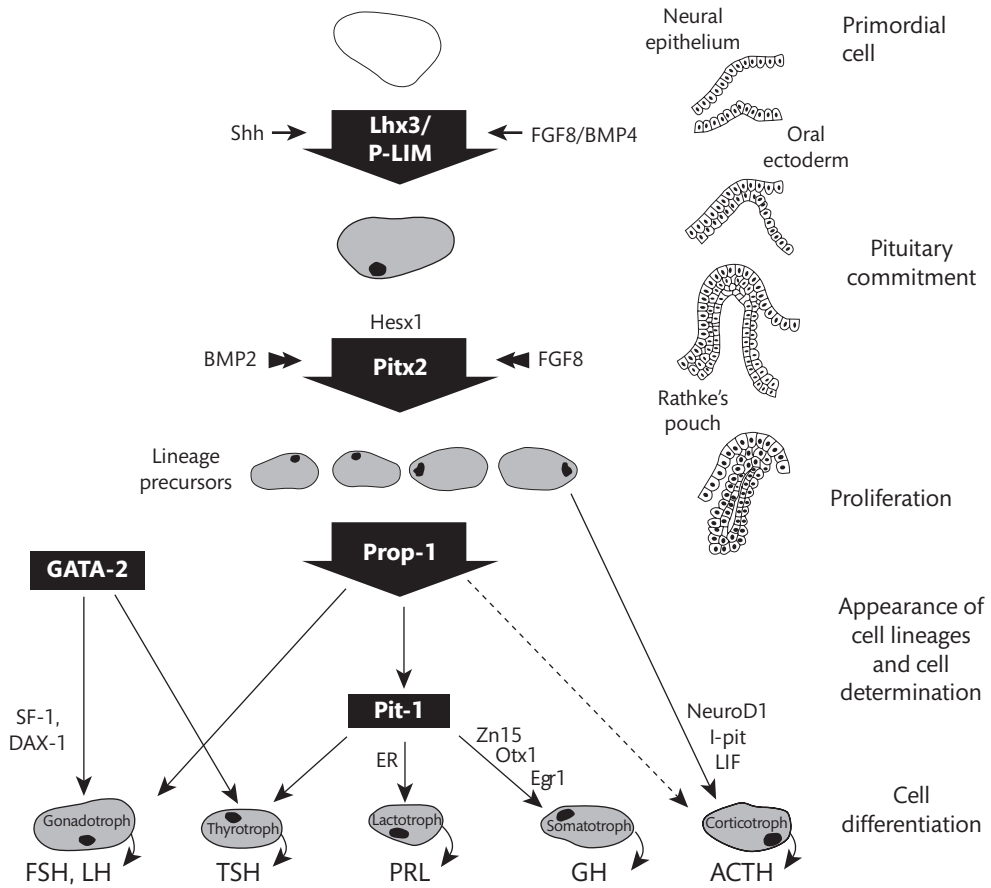

Figure 2.3.2.2 Model for development of human anterior pituitary cell lineage determination by a temporally controlled cascade of transcription factors. Trophic cells are depicted with transcription factors known to determine cell-specific human or murine gene expression.

Cip/Kip Family

Members of the Cip/Kip family (p21Cip1, p27Kip1, and p57Kip2) restrain cell cycle progression by associating with CDK1 and CDK2 complexes.

Mice with disrupted *CDKN1B* gene that encodes p27Kip1 develop overall increased body weight, multiorgan hyperplasia, female infertility, POMC intermediate lobe pituitary tumours, and hyperplasia of haematopoietic organs [7]. Intermediate lobe tumours derived from p27Kip1 null mice differ from those derived from $Rb^{+/-}$ mice in that they are more vascular, exhibit lower proliferation rates, and are oligoclonal or polyclonal (vs. monoclonal in $Rb^{+/-}$ mice).

Downregulation of p27Kip1 protein expression is common in corticotroph tumours and pituitary carcinomas, and p27Kip1 levels are lower in recurrent pituitary adenomas compared to non-recurrent adenomas. p27Kip1 mRNA expression is generally not decreased in pituitary tumours, suggesting that decreased p27Kip1 expression is likely due to post-translational factors.

P21-deficient mice develop increased risk for multiple neoplasia in late adult life, however, pituitary tumours are uncommon, and p21Cip deletion or mutation is not commonly encountered in human tumours. The role of p21Cip in oncogene-induced pituitary senescence is discussed below.

Box 2.3.2.1 Evidence for an intrinsic pituitary defect in the pathogenesis of pituitary tumours

- Pituitary adenomas are monoclonal
- Absence of pituitary hyperplasia in tissue surrounding pituitary adenomas
- Surgical resection of well-circumscribed pituitary adenomas controls >75% of patients
- Adenoma formation is rarely associated with generalized pituitary hyperplasia
- Unrestrained pituitary hormonal hypersecretion occurs independent of physiological hypothalamic feedback regulation
- Normalization of hormonal pulsatility pattern often occurs after adenoma resection

p53

p53 inhibits cell cycle progression or induces apoptosis, however, this tumour suppressor appears not to play a major role in the pathogenesis of pituitary adenomas.

Cyclins

Cyclins D and E regulate the G1 to S phase of cell cycle progression. Cyclin D1, D2, and D3 are the first wave of cyclins to be upregulated when quiescent cells (G0) enter the proliferative cell

cycle. Cyclin-CDK complexes induce phosphorylation (inactivation) of pRB, releasing E2F to prompt cell cycle transition to S phase. *CCND1* encoding cyclin D1 was studies in pituitary tumours. Allelic imbalance at the *CCND1* locus was found to be more frequent among invasive tumors, while cyclin D is more expressed in aggressive and non-functioning pituitary adenomas, than in GH-secreting adenomas [8]. However, *CCND1* allelic imbalance and cyclin D1 expression may not coexist in the same tumour, suggesting that it may not be a primary event in pituitary tumorigenesis. Similarly, cyclin A, B, and E are also more abundant in larger, highly proliferative pituitary adenomas.

Classic oncogene mutations have not been encountered in pituitary tumours [9, 10] but genomic profiling shows altered copy number variation with evidence for genomic instability [11]. Copy number variations are more prominently encountered in hormone-secreting tumours, and those also harbouring *GNAS* mutations [12].

PTTG

Overexpression of the pituitary tumour-transforming gene (*PTTG*), isolated from rat GH-secreting pituitary tumour cells, induces cellular transformation *in vitro* and tumour formation in nude mice. PTTG is a mammalian securin, a key regulator of metaphase to anaphase transition during mitosis, and overexpression causes aneuploidy by inhibiting sister chromatid separation [13]. PTTG also plays a role in pathways responsible for DNA break repair [14–16]. Because PTTG abundance correlates with pituitary gland trophic status, regulation of this gene may subserve a mechanism for affecting tumour formation (Figure 2.3.2.3). Global *Ptg* inactivation results in hypotrophic effects (i.e. pituitary, pancreatic β-cell, splenic, and testicular hypoplasia). *Ptg* inactivation in $Rb^{+/-}$ protects mice from pituitary tumour development, and combined $Rb^{+/-}$ and targeted pituitary *PTTG* overexpression further enhances pituitary hyperplasia and tumour prevalence [17].

PTTG is abundantly expressed in most pituitary tumours and PTTG tumour content is determined by RSUME-mediated sumoylation [18]. *PTTG1* mRNA was overexpressed in 54 pituitary tumours assessed by RT-PCR (23/30 of non-functioning, 13/13 GH-secreting, 9/10 prolactinoma, and 1/1 ACTH-secreting), *PTTG* expression correlates well with clinical tumour invasiveness [19].

Transgenic mice with human *PTTG* targeted to the pituitary under the α-subunit of glycoprotein hormone (αGSU) promoter exhibited gonadotroph, thyrotroph, and somatotroph focal hyperplasia and small adenomas, with elevated serum LH, testosterone, GH, and/or IGF-I levels, and prostate and seminal vesicle hypertrophy. Pituitaries derived from compound double transgenic αGSU.*PTTG1;* $Rb^{+/-}$ are enlarged as early as 2 months of age, and the incidence of anterior lobe tumours increased 3.5-fold (Figure 2.3.2.4c), suggesting that targeted *PTTG* overexpression in anterior lobe αGSU cells facilitates tumour formation [17].

Transcription Factors

The process of adenohypophyseal differentiation is a highly specific and temporally regulated series of events. Expression of transcription factors, such as PROP1, Pit-1 (POU1F1), and DAX-1 in pituitary adenomas reflects the origin of tumour cells, and possibly their level of differentiation. However, whether or not dysregulation of these transcription factors plays a causal role in the development of human pituitary tumours remains unclear.

Signalling Pathways

Guanine Nucleotide-Activating α-subunit *(GNAS)*

The McCune–Albright syndrome comprises defects in bony skeleton and skin, precocious puberty, thyrotoxicosis, acromegaly, gigantism, or Cushing syndrome. The molecular defect is a mutation in the *GNAS* gene that encodes Gsα protein, termed oncogene *gsp* which induces constitutive adenylate cyclase activation.

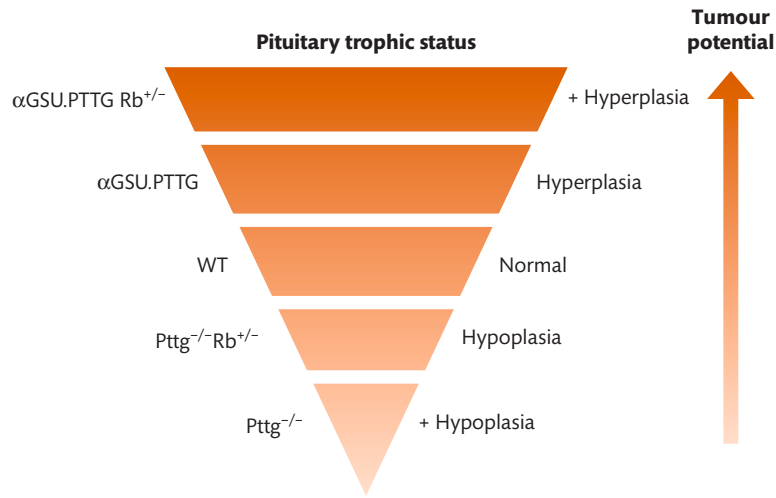

Figure 2.3.2.3 Pituitary PTTG content correlates with gland plasticity and with tumour formation potential. On the left side of the inverted triangle are listed mouse models with descending pituitary PTTG content, with or without the combination with tumorigenic $Rb^{+/-}$. Horizontal bars composing the inverted triangle represent the observed effects of the different genotypes on pituitary trophic status, which correlates with pituitary tumorigenic potential (arrow).

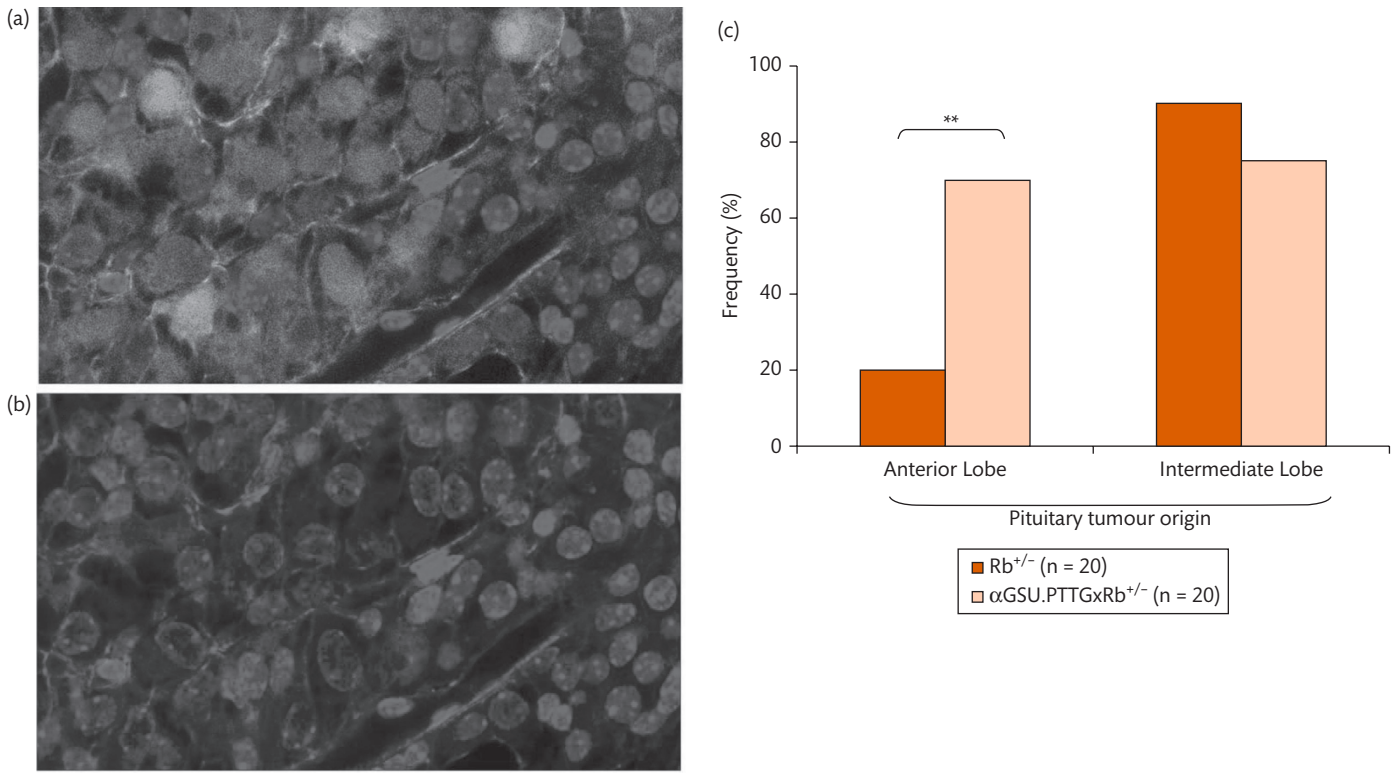

Figure 2.3.2.4 Targeted *PTTG* overexpression to anterior lobe pituitary cells results in cell hyperplasia and increased tumour formation. Panels (a) and (b) are duplicates of the same image, overview of pituitary cells expressing *αGSU.PTTG1.IRESeGFP* transgene. (a) is the untouched image, and in (b) the *green layer* (eGFP) has been hidden for better visualization of nuclear morphology. Contrast between eGFP positive (overexpressing *PTTG*) and eGFP negative (normal *PTTG* content) can be appreciated, notably presence of macronuclei and reorganization of chromatin suggestive of hyperplastic cells. Panel (c) depicts that bitransgenic *αGSU.PTTG;Rb*$^{+/-}$ mice exhibit higher prevalence of anterior lobe and similar prevalence of intermediate lobe pituitary tumours when compared with *Rb*$^{+/-}$ mice. Pathological analysis of pituitary tumours reveals that frequency of tumours arising from anterior lobe is higher in *αGSU.PTTG;Rb*$^{+/-}$ (white bars) than in *Rb*$^{+/-}$ (black bars) pituitary tumours (**, $P = 0.0036$), but frequency of tumours arising from the intermediate lobe (where there was no *PTTG* overexpression) is similar. n, Total number of pituitary tumours analysed.

In GH-secreting cells, *gsp* activates GHRH postreceptor pathways (i.e. cell proliferation and hormone secretion without necessarily requiring ligand binding to the GHRH receptor).

Although *gsp* mutations are reported in 30–40% of GH-secreting adenomas, major clinical differences between *gsp*+ and *gsp*– pituitary tumours have not been identified. *GNAS* is imprinted in normal pituitary tissue and only the maternal allele is expressed. In GH-secreting adenomas, *gsp* activating mutations mostly occur in the maternal allele. The *gsp* oncogene has been detected in <10% of non-functioning or ACTH-secreting tumours.

Activated cAMP-Response Element Binding Proteins (CREB)

The direct mechanism by which cAMP stimulates somatotroph GH-transcription may be mediated by the cAMP-responsive nuclear transcription factor (CREB), which binds as a dimer to cAMP-response elements. Transgenic mice overexpressing a phosphorylation-deficient and transcriptionally inactive mutant of CREB in the anterior pituitary exhibit dwarfism and somatotroph hypoplasia, indicating that phosphorylated CREB plays a role as a biochemical intermediate in the somatotroph proliferative response. Significantly higher amounts of Ser^{133}-phosphorylated, and hence, activated CREB was detected in a series of GH-secreting pituitary tumours compared to a group of non-functioning tumours, suggesting that constitutively activated CREB, possibly promoted by Gsα overexpression, may be another factor facilitating somatotroph transformation.

Dopamine Receptors

The dopamine 2 receptor (D2R) mediates inhibitory effects of dopamine on pituitary PRL synthesis and secretion. D2R-deficient mice exhibit hyperprolactinemia and lactotroph hyperplasia with late progression to pituitary tumours, suggesting that loss of dopamine inhibition induces murine neoplastic transformation. This finding likely cannot be extrapolated to pituitary tumour development in humans as D2R mutations have not been identified. Decreased D2R expression has been linked to dopamine agonist resistance in prolactinomas.

Somatostatin Receptors

Somatostatin receptors (SST) 1 through 5 are expressed in all pituitary tumour types [20]. Prolactinomas exhibit high SST1 expression compared to other tumour types. SST3 is frequently detected in non-functioning adenomas, while SST4 expression is relatively infrequent in pituitary tumours. In GH-secreting adenomas, SST2 and SST5 expression does not correlate with

tumour behaviour; however lower SST2 content is observed in adenomas less responsive to somatostatin analogue therapy. A germline mutation in the coding sequence of SST5 was reported in a single patient with acromegaly resistant to somatostatin analogue therapy, and no mutations have been identified in other SST subtypes. SST2 and SST5 variants do not correlate with responsiveness to somatostatin analogue therapy. The role of these receptors in the pathogenesis of pituitary adenomas remains unproven.

Somatotroph Signalling

GH production is induced by hypothalamic GHRH as well as by intracellular factors. Mice bearing a GHRH transgene develop mammosomatotroph hyperplasia that may convert to adenomas in older mice. Extrahypothalamic tumours secreting ectopic GHRH induce somatotroph hyperplasia and acromegaly that rarely progress to somatotroph adenomas [21]. The GHRH receptor (GHRHR) may be overexpressed in GH-secreting adenomas compared to normal pituitary tissue [22], but the significance of increased expression of GHRHR in the pathogenesis of GH-secreting adenomas is not clear. A related protein, GPR101 is overexpressed in a subset of short stature patients (X-linked acrogigantism) with Xq26.3 microduplication [23]. Pituitary STAT3 abundance is induced by GH and participates in a closed loop autocrine stimulation of GH leading to excess tumour hormone production. This pathway offers another target for subcellular therapy of these tumours [24].

Angiogenesis and Growth Factors

Vascularization is decreased in pituitary tumours compared to normal tissue, in marked contrast to the pattern observed in other tumour types where cancer development is linked to increased angiogenesis. In contrast to the normal pituitary which is predominantly supplied by the hypothalamic-pituitary portal vein, pituitary adenomas receive a direct systemic blood supply, and the relatively low vascular density in these tumours may occur in association with an in-growth of systemic capillaries which may dilute intrapituitary concentrations of hypothalamic factors, especially dopamine.

Microvascular density is decreased in pituitary adenoma tissue, and macroprolactinomas, invasive prolactinomas, or pituitary carcinomas have higher microvascular density compared, respectively, to microprolactinomas, non-invasive prolactinomas, or pituitary adenoma. Conversely, angiogenesis is not enhanced with tumour growth in GH-secreting adenomas, consistent with the notion that microprolactinomas may represent a pathological and clinical entity distinct from macroprolactinomas, whereas different-sized GH-secreting adenomas are components of a similar disease spectrum [25].

Vascular Endothelial Growth Factor (VEGF)

VEGF increases proliferation and migration of endothelial cells, and functions as an antiapoptotic factor promoting vessel endothelial cells survival. VEGF is detected in both the normal pituitary gland and in pituitary adenomas, and levels correlate with tumour behaviour, as VEGF is more abundant in carcinomas and macroprolactinomas. Pituitary glands derived from DR2-knockout female mice have increased VEGF expression compared with wild-type mice.

Fibroblast Growth Factors (FGFs)

FGFs participate in cell development, growth, and angiogenesis, and basic FGF (bFGF or FGF-2) is abundantly expressed in the pituitary. During the hyperplastic phase of prolactinoma development, pituitary expression of both PTTG and bFGF is increased in a time- and dose-dependent manner in oestrogen-treated rats, and bFGF synthesis is induced in NIH-3T3 cells overexpressing PTTG. In the rodent, pituitary bFGF has been localized primarily to folliculostellate cells and regulates GH, prolactin, and TSH secretion. In murine folliculostellate cells, FGF-2 induced positive autofeedback with protein kinase C mediated FGF-2 auto-induction, and stimulates cell proliferation and increased Pttg expression.

FGF-4 is encoded by heparin-binding secretory transforming (*hst*) gene and is expressed in about 30% of PRL-secreting pituitary adenomas. FGF-4 expression in prolactinomas correlates with tumour invasiveness, and GH4 cells transfected with *hst* form more aggressive tumours *in vivo* [26]. *hst* gene rearrangement have not been detected in human prolactinomas, and mechanisms by which *hst*/FGF-4 complex initiates or promotes lactotroph proliferation and prolactin secretion are unclear.

ErbB Receptors

Epidermal growth factor (EGF) has potent mitogenic activity in pituitary cells, and both EGF and epidermal growth factor receptor (EGFR) may be overexpressed in pituitary tumours, particularly in non-functioning adenomas. Examination of ErbB2 and ErbB3 expression in prolactinomas revealed positive results for both ErbB2 (7 of 8 tumours) and ErbB3 (4 of 8 tumours) especially in aggressive, recurrent tumours [27].

EGF activates EGFR and ErbB signalling in lactosomatotroph rat GH3 cells, with resulting increased PRL and GH expression. EGFR antagonist gefitinib decreases GH3 cell proliferation and PRL secretion and attenuates growth and hormone production of GH3 derived tumours in nude mice through blockage of EGFR/ERK signalling pathway [28]. Cushing disease is associated with enhanced EGFR signalling [29] and dominant *USP8* mutations lead to increased EGFR de-ubiquitination with increased ACTH production in Cushing disease [30]. These results suggest that targeted ErbB receptor inhibition could be a potential therapeutic alternative.

Familial Syndromes

Multiple Endocrine Neoplasia Type 1

Pituitary adenomas occur in a familial setting in about 5% of all cases, and over half of the cases are due to multiple endocrine neoplasia type 1 (MEN1). MEN1 is an autosomal dominant genetic disease characterized by parathyroid adenoma, pancreatic endocrine tumours, and pituitary adenomas (Table 2.3.2.3). Pituitary adenomas occur in approximately 25% of patients and these tumours may be larger and more aggressive than sporadic counterparts. Most secrete PRL, with or without secretion of excess GH, followed by those secreting GH alone, non-functional tumours, and those secreting excessive ACTH. MEN1 is caused by inactivating mutations of the tumour suppressor gene, *MEN1* [31]. *MEN1* encodes menin, a nuclear protein expressed in all organs and tissues of the body that interacts with both nuclear and cytoplasmic partners to regulate gene transcription, DNA repair, and cytoskeletal organization.

Table 2.3.2.4 Pituitary tumour genetic syndromes

	Gene	Chromosomal locus	Main clinical characteristics
Carney complex	*PRKAR1A*	17q24.2	Skin pigmentation; cardiac and cutaneous myxomas; thyroid, testis and adrenal tumours; GH-cell hyperplasia or adenoma
Familial isolated pituitary adenomas	*AIP*	11q13.2	Young familial invasive GH adenomas, often therapy resistant
Gigantism	*GPR101*	Xq26.3	X-linked gigantism due to somatotroph hyperplasia or adenoma
McCune–Albright	*GNAS*	20q13.32	Polyostotic fibrous dysplasia, café-au-lait spots, and precocious puberty with GH and/or PRL excess
MEN1	*MEN1*	11q13.1	Pancreatic, pituitary, and parathyroid gland tumours
MEN4	*CDKN1B*	12q13.1	MEN1 like, usually with GH-secreting adenomas

Hundreds of inactivating *MEN1* mutations have been identified, and it is unclear why *MEN1* mutations cause selected endocrine tumours while menin is ubiquitously expressed. Homozygous murine *Men1* deletions result in embryonic lethality while heterozygous *Men1* deletion results in pituitary tumour formation.

Rarely p27Kip1/CDKN1B functions as a tumour suppressor in patients with clinical MEN1 but without *MEN1* mutations [32]. Rare mutations in other CDK inhibitor genes, including p15INK4b/CDKN2B, p18INK4c/CDKN2C, and p21Cip1/CDKN1A, were identified in families with MEN1 phenotypes with no identifiable germline *MEN1* mutations.

Carney Complex

Carney complex is rare autosomal dominant genetic disease with myxomas of the heart, skin hyperpigmentation, and endocrine overactivity. GH-secreting adenomas are the most common pituitary tumours encountered in these patients. Up to 75% of patients have elevated levels of GH, IGF-1, or PRL, and 10% of patients exhibit clinical acromegaly. Somatotroph hyperplasia is followed by GH-secreting tumour formation associated with inactivating mutations of *PRKAR1A*, the regulatory subunit isoform 1A of protein kinase A (PKA). Inactivating *PRKAR1A* mutations result in constitutive activation of PKA catalytic subunit. Mice with a specific homozygous deletion of *PRKAR1A* develop somatotroph hyperplasia, elevated GH levels, and GH-secreting adenomas. In some patients, and in animal models, the wild-type *PRKAR1A* allele is retained in tumour tissue and it appears that decreased expression (i.e. haplo-insufficiency), rather than absence of the PKA regulatory subunit is sufficient to cause tumorigenesis.

Aryl Hydrocarbon Receptor-Interacting Protein (AIP)

Familial isolated pituitary adenoma is a syndrome defined as two or more members in a family harbouring anterior pituitary tumours without evidence of MEN1 or Carney complex. Whole-genome single-nucleotide polymorphism genotyping was performed on three Finnish families with very-low-penetrance susceptibility to pituitary adenomas. Linkage analysis provided evidence for linkage in chromosome 11q12–11q13, a region previously implicated in isolated familial somatotropinomas (IFS) [33]. No mutations or altered expression in *MEN1* were detected in this cohort. Mapping of the linked chromosomal region identified *AIP*, or aryl hydrocarbon receptor-interacting protein gene, with loss of heterozygosity detected in pituitary adenomas with *AIP* germline mutations, suggesting that AIP may behave as a tumour suppressor gene. Of 73 families with the syndrome of familial isolated pituitary adenomas, 11 (15.1%) harbour at least 10 different germline mutations in the *AIP* gene [34]. Most of these patients exhibit a young age of onset for GH oversecretion with macro-adenomas [35]. However, ~2% of patients with sporadic pituitary tumours have *AIP* mutations in germline DNA, suggesting that the majority of sporadic pituitary tumours are not associated with *AIP* mutations [36, 37].

Other Molecular Events

Growth Arrest and DNA Damage-Inducible Gene 45γ (*GADD45-γ*)

GADD45-γ identified as a candidate tumour suppressor gene for pituitary adenomas by cDNA-representational difference analysis (cDNA-RDA), is expressed in the normal pituitary gland, but absent in most non-functioning, GH-, and PRL-secreting adenomas, as well as in immortalized pituitary cell lines. *GADD45-γ* a p53-responsive gene induced by DNA damage mediates growth suppression and apoptosis. Introducing *GADD45-γ* into a rat pituitary tumour cell line decreases cell proliferation and anchorage-independent colony formation. Silencing of *GADD45-γ* in pituitary tumours likely occurs by epigenetic changes (i.e. methylation of CpG islands in the *GADD45-γ* promoter [23]).

Maternally Expressed 3 Gene (*MEG3*)

An isoform of *MEG3* contains an extra exon (*MEG3a*), and has been identified by cDNA-RDA, and is expressed in normal human pituitary, brain, and other tissues, but is diminished or absent in pituitary tumours and human cancer cell line [38]. MEG3a is undetectable in both non-functioning and GH-secreting pituitary adenomas, while introduction of *MEG3a* in cancer cells inhibits proliferation and decreases colony formation. Hence, loss of *MEG3a* in pituitary adenomas likely confers a tumour growth advantage. *MEG3* silencing in non-functioning pituitary adenomas is likely due to promoter hypermethylation.

High Mobility Group A (*HMGA*)

The HMGA family includes the related HMGA1 and HMGA2 abundantly expressed during embryogenesis, but not in normal adult tissues, including the pituitary gland. Transgenic *HMGA1* and *HMGA2* overexpression in mice causes GH-secreting adenomas and prolactinomas. Trisomy of chromosome 12, which harbours *HMGA2*, represents the most frequent cytogenetic alteration in human PRL-secreting pituitary adenomas, and *HMGA2*

overexpression was detected in a number of prolactinomas harbouring rearrangement of regions 12q14–15. *HMGA2* expression was present in 38 of 98 (39%) pituitary adenomas, and noted to be more frequent in FSH/LH cell adenomas (15/22, 68%), prolactinomas (5/15, 31%), and ACTH-secreting adenomas (12/18, 18%), however it was rarely detected in GH or mixed GH/PRL-secreting adenomas [39]. High *HMGA2* levels correlate with tumour size, invasiveness, and cell proliferation marker. *HMGA2* tumorigenic effects may be mediated by stimulation of cyclin B2 expression by HMGA2 binding to the *CCNB2* promoter [40] and by activation of the E2F pathway. There is also evidence that *HMGA2* is suppressed by microRNA *Let-7*, a putative tumour suppressor, and *HMGA2* and *Let-7* expression correlate inversely in human pituitary adenoma samples [39].

Senescence

Cellular senescence is characterized by cell growth arrest induced by diverse mechanisms including age linked telomere shortening, DNA damage, oxidative stress, chemotherapy, and oncogene activation, and has emerged as a potential new component of cancer-protective response to oncogenic events. In response to oncogene activation, protective cellular mechanisms subject the cell to apoptosis and senescence. Apoptosis of cells with oncogene removes them from the tissue population thereby completely preventing tumorigenesis. Oncogene-included senescence (OIS) is a largely irreversible process in which proliferative arrest is mediated thorough upregulation of cell cycle inhibitors including p16INK4A, p15INK4B, p21Cip1, p53, and pRB. OIS also involves participation of cytokine and chemokine pathways which may be protective for malignant transformation [41].

Cellular senescent markers are noted to be elevated in benign tumours but not in malignant carcinomas. Indeed, p21Cip1 and senescence activity were found to be elevated in human GH-secreting adenomas and in rat GH3 pituitary cells [28]. In 38 GH-secreting adenomas, 29 exhibited strong and 9 weak p21 staining. In contrast, p21 was not detected in GH-producing pituitary carcinomas, non-secreting pituitary oncocytomas, or null cell adenomas, or in aggressive breast carcinoma. Senescence-associated β-galactosidase activity (SA-β-gal), a marker of senescence, is strongly positive in GH-secreting adenomas (**Figure 2.3.2.5**). P21 and PTTG levels strongly correlated in these pituitary tumours.

Activation of the p21/p53 senescence pathway is noted to occur with both pituitary PTTG overexpression and deficiency. *Pttg*-null mice exhibit pituitary activation of senescence-like features, including

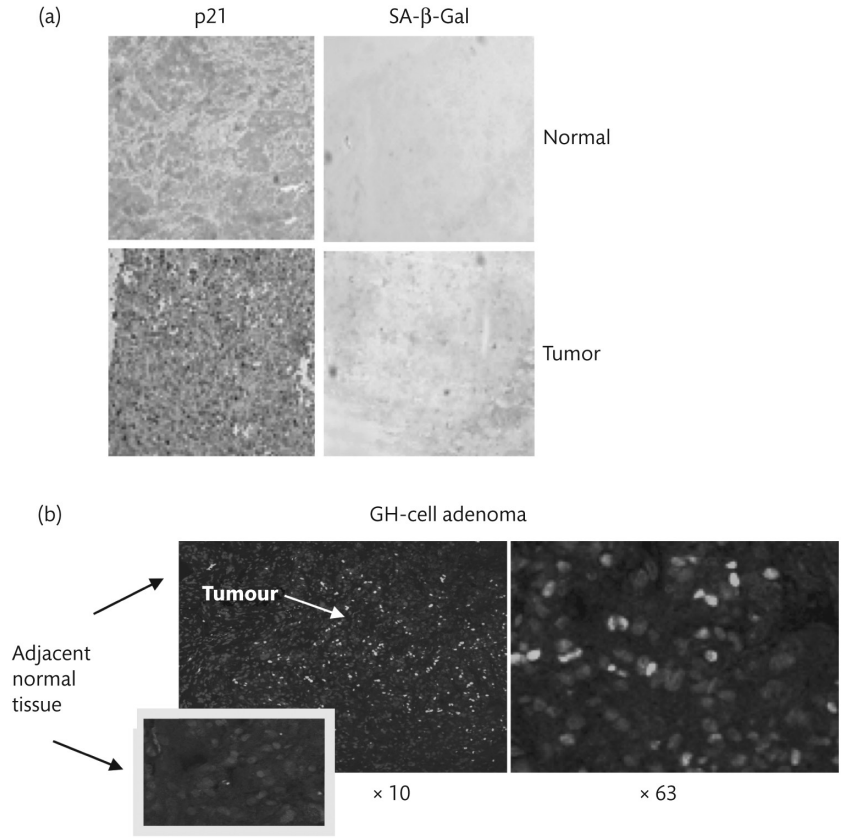

Figure 2.3.2.5 Senescence markers in human GH-producing pituitary adenomas. (a) Immunohistochemistry of the same GH-secreting human adenoma sections stained for p21 (brown) and SA-β-gal activity (blue). (b) Confocal image of double fluorescence immunohistochemistry of p21 (green) and β-galactosidase (red) proteins coexpression in human pituitary adenoma but not in normal adjacent tissue (left). High resolution (×63) image of the same slide (right). *For a colour version of this figure, please see colour plate section.*

increased SA-β-gal activity, upregulation of p21, pRB, and p19, and apoptosis blockage, which result in the pituitary hypoplasia phenotype. Telomere shortening was not noted in *pttg*-null pituitaries, indicating that activation of senescence pathway is not due to early cell ageing. Upregulation of p21 is associated with relative protection from pituitary formation in $Rb^{+/-}$ mice with *pttg* deletion ($Rb^{+/-}Pttg^{-/-}$ mice). In both *PTTG* deletion and overexpression, activation of p21/p53 senescence pathway occurs on a background of aneuploidy and DNA damage. Furthermore, autocrine IL-6 action was shown to be a determinant of pituitary senescence, with clonal tumorigenicity occurring in cells escaping senescence [42]. Taken together, these findings suggest that p21 may exert a tissue-specific tumour-suppressing function, unmasked under conditions where other pituitary genetic alterations or stresses are present. Activation of the pituitary senescence pathway may constrain pituitary tumour growth, and provides an explanation for the invariably benign nature of these tumours.

2.3.3 Histopathology of Pituitary Tumours

Luis V. Syro, Fabio Rotondo, and Kalman Kovacs

Introduction

The human pituitary gland consists of two major components: the adenohypophysis and the neurohypophysis. The adenohypophysis comprises the pars anterior, pars intermedia, and pars tuberalis [1]. The pars anterior, also known as pars glandularis or pars distalis, is the largest portion of the gland. In contrast to most mammalian species, the human gland has no anatomically distinct pars intermedia. The exclusively pro-opiomelanocortin (POMC)-producing cells of the pars intermedia are sandwiched between the anterior and posterior lobes in the majority of mammals, whereas in humans they are incorporated within the pars anterior. The pars tuberalis is a minor upward extension of the adenohypophysis attached to the exterior of the lower pituitary stalk. Histologically, the adenohypophysis consists of a central median (or mucoid) wedge flanked by two lateral wings. The hormone-producing cell types are distributed in an uneven, but specific manner. The cells are arranged within evenly sized acini surrounded by a delicate but well-defined reticulin fibre network giving the pituitary its distinct architecture. In the centre of the acini is the pituitary follicle composed of the agranular nonendocrine folliculo-stellate cells. The neurohypophysis is composed of nerve fibres from the hypothalamic nuclei that give rise to the infundibulum, the pituitary stalk, and the posterior lobe which stores and releases the hypothalamic hormones oxytocin and vasopressin.

Cell Types

The mature endocrine cell types of the anterior pituitary gland emerge from a common primordium. Cytodifferentiation occurs in response to opposing signalling gradients that emanate from distinct organizing centres [2]. To progress beyond the initial patterning, each cell type requires additional specific transcription factors in determining its cytodifferentiation and hormone production [3] (see Table 2.3.3.1). Pituitary-specific transcription factor 1 (Pit-1) determines cells that can produce growth hormone (GH), prolactin (PRL), and thyroid-stimulating hormone (TSH), while T-box transcription factor TBX19 (Tpit) determines corticotrophs. Oestrogen receptor alpha (ER-α) cooperates with Pit-1 to enhance PRL secretion, therefore, lactotrophs coexpress both Pit-1 and ER-α. Guanine-Adenine-Thymine-Adenine binding protein 2 (GATA-2) appears to be an essential contributor to thyrotroph development and is coexpressed with Pit-1 in thyrotrophs while expression of steroidogenic factor 1 (SF1), ER-α and GATA-2 categorize gonadotrophs [4]. Apart from their role in pituitary gland development, pituitary transcription factors can serve as diagnostic markers of cell lineage in pituitary tumours [5, 6] (see Table 2.3.3.2).

GH cells or **somatotrophs** make up approximately 50% of the gland, occupying mainly the lateral wings. They show strong acidophilia by histology and GH hormone immunoreactivity by

Table 2.3.3.1 Cell lineage differentiation and transcription factors

Cell lineage	Transcription factor	Adenohypophyseal cell
Acidophilic lineage	Pit-1	Somatotrophs
	Pit-1, ER-α	Lactotrophs
	Pit-1, GATA-2	Thyrotrophs
Corticotroph lineage	Tpit	Corticotrophs
Gonadotroph lineage	SF-1, ER-α, GATA-2	Gonadotrophs

Pit-1, pituitary-specific transcription factor 1; Tpit, T-box transcription factor TBX19; GATA-2, GATA binding protein 2; ER-α, oestrogen receptor alpha; SF-1, steroidogenic factor 1.

Table 2.3.3.2 Classification of pituitary adenomas

Tumour	Transcription factors	Hormones
Pit-1 Family of tumours		
Somatotroph adenomas		
Densely granulated	Pit-1	GH, α-subunit
Sparsely granulated		GH (weak)
Mammosomatotroph adenomas	Pit-1, ER-α	GH, PRL, α-subunit
Mixed GH-PRL adenomas	Pit-1, ER-α	GH, PRL, α-subunit
Plurihormonal GH-producing adenomas	Pit-1, ER-α	GH, PRL, α-subunit, ß-TSH
Lactotroph adenomas		
Densely granulated	Pit-1, ER-α	PRL
Sparsely granulated		PRL, α-subunit
Acidophil stem cell adenomas		PRL, GH
Thyrotroph adenomas	Pit-1, GATA-2	ß-TSH, α-subunit
Monomorphous plurihormonal adenomas		
Silent subtype 3	Pit-1	GH, PRL, β-TSH
Tpit Family of tumours		
Corticotroph adenomas		
Densely granulated	Tpit	ACTH
Sparsely granulated		ACTH
Crooke cell adenoma		ACTH
SF-1 Family of tumours		
Hormone-positive gonadotroph adenomas	SF-1, ER-α, GATA-2	ß-FSH, ß-LH, α-subunit
Hormone-negative gonadotroph adenomas	SF-1, ER-α, GATA-2	None
Polymorphous plurihormonal adenomas		
Plurihormonal adenomas	Multiple	Multiple
Transcription factor and hormone-negative adenoma		
Null cell adenomas	None	None

GH, growth hormone; ACTH, adrenocorticotrophic hormone; PRL, prolactin; FSH, follicle-stimulating hormone; LH, luteinizing hormone; TSH, thyroid-stimulating hormone; Pit-1, pituitary-specific transcription factor 1; Tpit, T-box transcription factor TBX19; GATA-2, GATA binding protein 2; ER-α, Oestrogen receptor alpha; SF-1, steroidogenic factor 1.

immunohistochemistry. Contingents of somatotrophs also express PRL or the α-subunit of the glycoprotein hormones. PRL cells or **lactotrophs** account for 10–30% of the pituitary gland cell population. The chromophobic or slightly acidophilic and PRL-immunoreactive lactotrophs are evenly scattered with focal accumulation in the posterolateral rim of lateral wings. The majority of adrenocorticotropic hormone (ACTH) cells or **corticotrophs** reside within the median wedge of the pituitary gland. They are basophilic, Periodic acid–Schiff (PAS) positive, and immunoreactive for ACTH as well as for other pro-opiomelanocortin (POMC)-peptides (β-endorphin, β-lipotropic hormone (LPH), corticotropin-like intermediate peptide (CLIP)). Approximately 12% of adenohypophyseal cells are immunopositive for POMC-peptides, which include a small but undetermined percentage of pars intermedia derived POMC cells as well. TSH cells or **thyrotrophs**, occupy mainly the anterior one-third of the median wedge and represent approximately 5% of adenohypophyseal cells. The slightly basophilic, angular thyrotrophs are strongly immunoreactive for β-TSH and α-subunit. **Gonadotrophs** producing follicle-stimulating hormone (FSH), and luteinizing hormone (LH) account for an estimated 15–20% of cells evenly distributed throughout the pars distalis. They are immunoreactive for β-FSH, β-LH, and their α-subunit. The hormonal function of the adenohypophyseal cell types displays considerable flexibility depending on the functional demand placed on them. Reversible transdifferentiation has been shown to occur between members of the Pit-1 group: GH cells to PRL cells during pregnancy, and GH cells to TSH cells in hypothyroidism [7]. Pituitary cell types differ not only in their function, structure, and hormone content but also in their morphological responses to functional stimulation or suppression. The **folliculo-stellate** cells, which occupy up to 10% of the anterior pituitary, have no hormonal function but both *in vitro* biochemical and morphological studies have documented that these cells are not only unexpectedly versatile but indispensable [8].

Pituitary Adenomas

Pituitary adenomas are common, accounting for approximately 15% of intracranial tumours [1]. They are monoclonal, produced by genetic and epigenetic alterations—leading to activation of proto-oncogenes or inactivation of tumour suppressor genes—that impart growth and survival advantage to a single cell. While the majority of the tumours are sporadic, some are associated with familial syndromes exhibiting different genetic background and variable phenotype; germline, somatic, and mosaic mutations have been identified [9, 10] (see Table 2.3.3.3).

Pituitary tumours may be referred to as microadenomas (less than 10 mm in diameter), or macroadenomas (greater than 10 mm in diameter). The growth pattern of these tumours may be expansive resulting in a slowly growing mass exerting increasing pressure on the surrounding healthy gland and the bony sella. In contrast, invasive adenomas spread into the surrounding normal gland, dura or other parasellar structures (sphenoid sinus, cavernous sinus) regardless of their size. Adenomas extending into the suprasellar space may compress the optic chiasm causing visual disturbances, a frequent clinical manifestation of macroadenomas.

When interpreting pituitary pathology, the clinical and radiological information must be considered as a whole [11]. At the time of surgery, gentle tissue handling is recommended with prompt and appropriate fixation of the specimen in formalin for pathological study. It is optional that a small fragment of tissue be fixed in glutaraldehyde, osmicated, and embedded for electron microscopy for cases that are difficult to diagnosis. It may also be worthwhile to obtain DNA from the patient's blood before surgery and freeze a portion of the tumour for subsequent molecular and DNA analysis [12].

A logical order of steps must be followed to study the morphology of pituitary adenomas [11, 13]. It is essential to first establish whether the tissue obtained is from a normal pituitary gland, a pituitary

Table 2.3.3.3 Clinicopathologic features of germline, somatic, and mosaic mutations in pituitary adenomas

Syndrome	Gene	Morphologic characteristics
Germline mutations		
FIPA	*AIP*	*AIP*-positive 20% Somatotroph and lactotroph, rarely other types.
	GPR101	Somatotroph adenoma or pituitary enlargement suggestive of hyperplasia
MEN1	*MEN1*	Lactotroph adenomas (60%) Non-functional adenomas (15%) Somatotroph and corticotroph less common
MEN4	*MEN4*	Somatotroph adenoma most common
Carney complex	*PRKAR1A* *PRKACA* *PRKACB*	Somatotroph adenoma or pituitary hyperplasia
Succinate dehydrogenase complex genes syndrome 3P association	*SDHA/B/C/D* *SDHAF2*	Lactotroph adenomas most common Somatotroph and non-functional adenomas Vacuolar changes in most cells
Neurofibromatosis type 1	*NF1*	Not clear yet
DICER 1 syndrome	*DICER 1*	Pituitary blastoma Neonatal or early childhood age Cushing's disease
Somatic mutations		
Somatotroph adenomas	*GNAS*	No differences between subgroups
Corticotroph adenomas	*USP8*	Small tumours with high ACTH production
Oncocytic pituitary adenomas	Complex I genes	Less aggressive tumour phenotype
All types of pituitary adenomas	*PIK3CA*	20% to 40% of various types of pituitary adenomas
Mosaic mutations		
McCune-Albright	*GNAS* (Mosaic postzygotic mutation)	Somatotroph adenomas Somatotroph and lactotroph hyperplasia
X-LAG	*GPR101* (Germline or somatic mosaicism)	Somatotroph adenoma or pituitary enlargement suggestive of hyperplasia

FIPA, familial isolated pituitary adenoma; MEN1, multiple endocrine neoplasia type 1; MEN4, multiple endocrine neoplasia type 4; 3P, paraganglioma, phaeochromocytoma and pituitary adenoma association; ACTH, adrenocorticotropic hormone; X-LAG, X-linked acrogigantism syndrome.

tumour, or a different sellar lesion. Next, immunohistochemical classification based on hormone production by the cells is accomplished and, finally, prognostic information and treatment options can be determined by analysing various biomarkers and by molecular/genetic/epigenetic investigation (See Table 2.3.3.4).

Table 2.3.3.4 Panel approach for the evaluation and diagnosis of pituitary adenomas

Stain	Stain pattern	Indication
Haematoxylin-eosin (HE)	Acidophilic, basophilic, or chromophobic	Ancillary stain which has stood the test of time For initial classification of the tumour
Periodic acid–Schiff (PAS)	Cytoplasmic	To recognize corticotrophs and Crooke cells
Reticulin, Silver stain, Collagen IV	Acinar reticular pattern	To differentiate normal pituitary gland, hyperplasia, or tumour
Chromogranin, Synaptophysin	Secretory granules	Neuroendocrine markers
TTF-1	Nuclear	Positive in posterior pituitary gland and posterior pituitary tumours
GH, PRL, ACTH, TSH, FSH, LH, α-subunit	Cytoplasmic	To identify hormone secretion
LMWK Cam 5.2	Cytoplasmic Dot patterns Ring-like pattern	Positive in somatotrophs and corticotrophs To categorize pure somatotroph adenomas as densely or sparsely granulated To identify Crooke cells
Pit-1, Tpit, SF-1, ER-α, GATA-2	Nuclear	To identify cell lineage differentiation
E-cadherin	Membrane	Absent E-cadherin expression may be correlated to tumour invasiveness
Ki67, p53	Nuclear	Proliferation markers
SSTR2, SSTR5	Membrane	Predictive biomarkers for long-acting somatostatin analogues?
AIP	Cytoplasmic	Predictive biomarker for long-acting for somatostatin analogues?
MGMT	Nuclear	To evaluate DNA repair pathway, DR Predictive biomarker for temozolomide treatment in aggressive pituitary adenomas and carcinomas
MSH2, MSH6	Nuclear	To evaluate integrity of DNA repair pathway, MMR
MPG	Nuclear	To evaluate integrity of DNA repair pathway, BER
VEGF	Cytoplasmic	To assess angiogenic growth and progression of tumour

TTF-1, thyroid transcription factor 1; GH, growth hormone; PRL, prolactin; TSH, thyroid-stimulating hormone; FSH, follicle-stimulating hormone; LH, luteinizing hormone; ACTH, adrenocorticotropic hormone; LMWK, low molecular weight keratin; SSTR2, somatostatin receptor 2; SSTR5, somatostatin receptor 5; AIP, aryl-hydrocarbon receptor-interacting protein; MGMT, O6-methylguanine DNA methyltransferase; MSH2, MutS protein homolog 2; MSH6, mutS homolog 6; DNA, deoxyribonucleic acid; DR, direct repair; MMR, mismatch repair; MPG, N-methylpurine DNA glycosylase; BER, base excision repair; VEGF, vascular endothelial growth factor.

By histology, adenomas are acidophilic, basophilic, or chromophobic. The tinctorial properties of tumours are largely unrelated to their hormonal function. After initial evaluation using the haematoxylin & eosin (H&E) stain, which allows distinction from other pathologies of the sellar region, the next step is to demonstrate the absence of reticulin fibres. This differentiates normal adenohypophysis from hyperplasia or adenoma. The normal acinar reticular pattern is enlarged but intact in cases of hyperplasia and, regardless of their size, a total dissolution of the acinar architecture is evident in every adenoma. PAS stain is used to recognize corticotrophs because of the carbohydrate moiety present in POMC which is the precursor of ACTH. Chromogranin and synaptophysin, broad-spectrum endocrine markers, are used to confirm that the lesion is of endocrine origin. Cam5.2, a low molecular weight keratin, is used to identify and confirm somatotroph and corticotroph adenomas. They are immunopositive, and the keratin pattern will help to clarify their subtype: diffuse perinuclear, paranuclear globular (dot pattern), mixed or ring-like. These characteristic patterns are specific to certain adenoma types.

The current World Health Organization (WHO) classification (2017) of pituitary adenomas recommends the use of pituitary adenohypophyseal cell lineages for their classification rather than according to their hormone production [5, 6, 14] (see Table 2.3.3.2). Accordingly, pituitary adenoma classification uses a wide range of monoclonal antibodies against pituitary hormones, and pituitary transcription factors, to differentiate the various tumour cell types. Electron microscopy, although useful, is currently only utilized in cases that are difficult to diagnose. The available immunohistochemical stains used for studying pituitary adenomas and their utility are presented in Table 2.3.3.4.

Pit-1 Family of Tumours

Somatotroph Adenomas

Somatotroph adenomas arise from Pit-1 pituitary cell lineage and express GH in excess. Approximately 15% of surgically removed pituitary adenomas represent pure GH cell adenomas [15]. Most of these tumours are associated with clinical signs of acromegaly, but silent forms have also been reported [16]. According to the density of GH-containing secretory granules in the cytoplasm of the cells, somatotroph adenomas can be densely or sparsely granulated. The clear distinction between them is crucial for proper prognosis and treatment [17].

Densely granulated somatotroph adenomas occur with the same frequency in both sexes peaking at the same time (in the sixth decade). The tumours display slow, expansive growth resulting in the typical 'ballooning of the sella' and may remain intrasellar for several years. Histologically, the densely granulated form is strongly acidophilic displaying diffuse or, less frequently, trabecular pattern. Extensive immunoreactivity for GH is usually accompanied by similarly strong positivity for α-subunit. Scattered immunopositivity for PRL and β-TSH is usually not associated with oversecretion of these hormones. Immunostaining for Cam5.2 demonstrates a diffuse perinuclear pattern.

Sparsely granulated somatotroph adenomas are diagnosed earlier, peaking in the fourth decade. The tumours tend to be macroadenomas at the time of diagnosis and are often invasive. Histology identifies chromophobic adenomas invariably displaying a diffuse pattern; GH immunoreactivity is often sparse. Nuclear pleomorphism may be evident, and adenoma cells harbour a homogeneous, spherical, juxtanuclear, practically unstained structure. This fibrous body is strongly immunopositive for Cam5.2 in a characteristic *dot* pattern and is the best histological marker for this tumour type since it is present in more than 70% of the cells. As opposed to the densely granulated type, multiple immunoreactivities for pituitary hormones are rarely noted in sparsely granulated somatotroph adenomas.

Mixed somatotroph and lactotroph adenomas, comprised of two distinct cell types, account for approximately 5% of surgically removed adenomas. The tumours are associated with acromegaly and varying degrees of hyperprolactinaemia. They tend to be aggressive and are difficult to treat. Mixed adenomas usually consist of densely granulated GH cells and sparsely granulated PRL cells. Accordingly, they are composed of acidophilic and chromophobic cells, displaying immunoreactivity for GH and PRL; α-subunit positivity is also frequent in this tumour type. Other combinations may occur, but they are rare.

The infrequent (2%) **mammosomatotroph cell adenomas** are monomorphous, consisting of one cell type displaying markers of both GH and PRL differentiation. Clinically they are associated with acromegaly and mild hyperprolactinaemia. These acidophilic tumours are immunoreactive for GH and α-subunit and, to a lesser extent, for PRL. At the ultrastructural level, the densely granulated tumour cells possess unusually large (up to 1000 nm and over) secretory granules and display lateral granule extrusions which is a PRL cell marker. The slow-growing mammosomatotroph adenomas show biological behaviour similar to densely granulated somatotroph adenomas.

Morphologic effects of treatment with long-acting somatostatin analogues are neither severe nor consistent. Remarkable shrinkage of cells and marked fibrosis are infrequent. Most common findings include the increase in size and number of secretory granules and increased lysosomal activity while significant fibrosis is less frequent. The close correlation observed between clinical response and tumour morphology in cases of prolactinomas treated with dopamine agonists does not exist in examples of somatostatin analogues therapy.

Both types of GH cell adenoma may engage in focal production of endocrine amyloid. Approximately 2–3% of morphologically typical sparsely granulated GH cell adenomas are clinically silent, the reason for which is unknown. Few cases of the sparsely granulated tumours contain variable amounts of nervous tissue (neuron-like cells and neuropil) as a likely result of neuronal differentiation within the adenoma. This variant is known as neuronal metaplasia.

Lactotroph Adenomas

Lactotroph adenomas arise from the Pit-1 pituitary cell lineage and express mainly PRL. They are classified into three histological subtypes: sparsely granulated lactotroph adenomas, densely granulated lactotroph adenomas, and acidophil stem cell adenomas.

Sparsely granulated lactotroph adenomas are the most common adenoma type accounting for 27–30% of pituitary tumours. They are associated with hyperprolactinaemia, primary or secondary amenorrhoea, galactorrhoea, and infertility in women. The less specific symptoms in men—decreased libido and impotence—usually mean a delay in diagnosis and development of macroadenomas

whereas the majority of tumours in women are small and classified as microadenoma. In both sexes, lactotroph adenomas are most frequent in the third and fourth decade of life. However, the incidence of this tumour type is significantly higher in women in their childbearing years. Lactotroph adenomas are associated with wide-ranging biological behaviours from indolent to highly aggressive, and in men usually present invasive radiological features. The PRL blood levels are roughly proportional to the tumour mass. Histologically, most lactotroph adenomas are chromophobic with a diffuse pattern. Immunostaining demonstrates strong PRL immunopositivity tracing the sacculi of the prominent Golgi apparatus (Golgi pattern). Ultrastructurally, the three salient features are masses of rough endoplasmic reticulum, prominent Golgi apparatus, and lateral extrusion of the small, sparse secretory granules—misplaced exocytosis. The latter is a specific marker of PRL differentiation.

Densely granulated lactotroph adenomas display strong and diffuse PRL immunoexpression with coexpression of Pit-1 and ER-α. They are rare and have been considered aggressive tumours.

Acidophil stem cell adenomas are rare (2%), monomorphous type tumours with morphological signs of PRL and GH differentiation. The tumours are associated chiefly with hyperprolactinaemia, but the serum PRL levels may be disproportionately low for its size. Physical stigmata of acromegaly and significant elevation of GH levels are infrequent. These tumours grow aggressively in young subjects with a tendency to invade intrasellar areas. The histological analysis demonstrates chromophobic adenomas with moderate to strong immunoreactivity for PRL. Immunopositivity for GH is weak or negative, but immunostaining for cytokeratin reveals the dot-like positivity of fibrous bodies. The striking ultrastructure is characterized by oncocytic change with the formation and increased number of giant mitochondria, sparse and small secretory granules with lateral extrusion (PRL marker), and fibrous bodies (GH marker).

Although calcification is extremely rare in other adenoma types, an estimated 10–15% of lactotroph adenomas display varying degrees of calcification. The alteration may be extreme ('pituitary stone'). Deposition of endocrine amyloid occurs infrequently.

Adequate therapeutic response with dopamine agonists is associated with striking morphological changes in adenoma cells: the nucleus becomes heterochromatic, the cytoplasm shows marked shrinkage due to loss and involution of the hormone-producing apparatus of the cell (rough endoplasmic reticulum, Golgi complex), and PRL immunoreactivity is reduced or lost. Theoretically, the morphological changes are reversible; however, portions of the neoplasm may permanently lose their responsiveness and retain their suppressed features even when treatment is discontinued. Long-term administration of dopamine agonists may also cause varying degrees of fibrosis and calcification—which presents as psammoma bodies.

Thyrotroph Adenomas

Thyrotroph adenomas express mainly TSH and also arise from Pit-1 pituitary cell lineage. They represent 1% of surgically removed adenomas and are associated either with hyperthyroidism or inappropriately elevated levels of TSH. Inexplicably, some tumours bearing immunohistochemical characteristics of thyrotroph adenomas occur in euthyroid subjects. At the time of diagnosis, these tumours are often macroadenomas with a tendency to invade. The morphology of the small group of thyrotroph adenomas exhibits surprising diversity. Histologically, the adenomas are chromophobic and negative, or mildly positive with PAS. They may be highly differentiated comprising elongated polar cells forming pseudorosettes around vessels. Alternatively, the pattern may be diffuse in some cases with considerable nuclear pleomorphism. However, another variant is markedly fibrotic. Minute calcifications may be evident as well. Immunoreactivity for TSH is variable; it is often patchy or scattered, rarely extensive. Scattered cells may exhibit immunoreactivity for GH, PRL, and α-subunit. Both Pit-1 and GATA2 are expressed. Thyrotroph adenomas possess somatostatin receptors and, in most cases, they are strongly positive for somatostatin receptor 2 (SSTR2) immunostaining.

Monomorphous Plurihormonal Adenomas

Plurihormonal adenomas produce more than one hormone. They can be monomorphous or plurimorphous, consisting of two or more different cell lineages. They include **plurihormonal Pit-1 positive adenomas** previously called silent subtype 3 adenomas. They have a frequency of approximately less than 1% and are clinically significant owing to their aggressive behaviour. This tumour type is equally frequent in both sexes, but it has a strikingly different age-related distribution. In men, they may occur at any age from the second to the seventh decade while in women it occurs between the second and fourth decade, peaking in the late twenties, but rarely occurring after 40 years of age. Plurihormonal Pit-1 positive adenomas can mimic lactotroph adenomas in women and are associated with low-grade hyperprolactinaemia. Some cases may present with acromegaly. Histologically, they are often acidophilic and may show mild PAS positivity. The large adenoma cells form a diffuse, or lobular pattern. Immunohistochemistry may demonstrate scattered, minor positivity for various adenohypophyseal hormones, but the majority of tumour cells are immunonegative for all known pituitary hormones, showing extensive nuclear expression of Pit-1.

Molecular Pathology of the Pit-1 Family of Tumours

Approximately 40–60% of sporadic somatotroph adenomas present somatic mutations in the gene encoding the α subunit of the stimulatory G-protein (*GNAS)*. These mutations are commonly found in densely granulated somatotroph adenomas. The somatic activating mutations, known as *gsp mutations*, prevent hydrolysis of guanosine-5'-triphosphate (GTP), leading to a constitutive activation of the cAMP pathway, which in somatotrophs increases GH secretion and cell proliferation [9, 18, 19]. A hallmark of somatotroph adenomas is the genetic and epigenetic alterations in the *GNAS* gene with the ensuing dysregulation of the cAMP pathway. Somatotroph adenomas with *gsp mutations* tend to have higher serum GH and IGF-I, but there are no differences between sparsely and densely granulated subtypes [20]. Epigenetic alterations that are common to both somatotroph and lactotroph adenomas include *CASP8, CDKN2A, DAPK1, MGMT, RB1*, and *TP73* [12].

AIP-mutation positive patients present with somatotroph and lactotroph adenomas in 85% of the cases [21]. In MEN 1, lactotroph adenomas are the most frequent, followed by clinically non-functioning adenomas, somatotroph and corticotroph adenomas [10]. In thyrotroph adenomas, inactivating mutations of *MEN1* gene have been reported.

Tpit Family of Tumours

Corticotroph Adenomas

Corticotroph adenomas arise from Tpit pituitary cell lineage and express ACTH and other POMC-derived peptides. They are classified into three subtypes: densely granulated corticotroph adenomas, sparsely granulated corticotroph adenomas, and Crooke cell adenomas. Corticotroph adenomas may also be clinically silent.

Densely granulated corticotroph adenomas account for 10–12% of surgically removed adenomas and are responsible for Cushing's disease. These tumours exhibit a marked female preponderance. The age-related occurrence of corticotroph adenomas is similar in both sexes peaking in the fourth decade. Most corticotroph lesions are small microadenomas causing florid Cushing's disease [22]. The tumours, often measuring only a few millimetres in diameter, may be too small to be conclusively detected by imaging or to be identified at surgery. Therefore, serial sectioning of the biopsied tissue fragments is often needed, which may not always result in the demonstration of the tumour. Histologically, corticotroph adenomas are basophilic and PAS-positive with a sinusoidal or diffuse pattern. Immunoreactivity can be demonstrated not only for ACTH, but for β-endorphin, β-LPH, and CLIP as well. Perinuclear bundles of cytokeratin filaments, characteristic for the human corticotrophs are demonstrated with Cam5.2 as cytoplasmic, perinuclear pattern.

In a minority of cases, pituitary-dependent Cushing's disease is brought about by larger tumours. These neoplasms are often associated with a milder form of hypercortisolism, but the tumours grow aggressively, often invade, and are frequently macroadenomas at the time of diagnosis. Histologically they exhibit variable, often weak PAS positivity and immunoreactivity for ACTH. A few cases of aggressive macroadenomas also display immunoreactivity for LH and α-subunit. Morphological features of corticotroph adenomas in cases of Nelson's syndrome are similar to those of densely granulated corticotroph adenomas in Cushing's disease with few or no cytokeratin filaments.

Sparsely granulated corticotroph adenomas are composed of faintly basophilic or chromophobic cells. They are PAS-positive with patchy immunopositivity for ACTH.

Crooke hyalinization (i.e. excessive accumulation of cytokeratin filaments) is the ubiquitous response of the normal human ACTH cells to the long-lasting elevation of circulating glucocorticoid levels. Accumulation of these cytokeratin filaments causes a glassy hyaline appearance to the cytoplasm and displacement of PAS and ACTH-positive granules to the cell periphery. These 'Crooke cells' can be identified using Cam5.2 immunostaining, which displays a strong ring-like pattern around the nucleus. In cases of Cushing's disease with persistent hypercortisolism after surgery, no evidence of a corticotroph adenoma at pathology, and only pituitary gland obtained, analysis for the presence of Crooke cells is pertinent. Presence of Crooke cells confirms the previous hypercortisolism and will dictate the next step of treatment [22]. Accordingly, Crooke hyalinization would be noted in (1) non-tumorous corticotrophs adjacent to corticotroph adenomas; (2) in ectopic ACTH/corticotrophin-releasing hormone (CRH) syndrome; (3) in patients with glucocorticoid secreting adrenocortical tumours; (4) and subjects taking glucocorticoids (factitious Cushing syndrome). In cases of pseudo-Cushing, Crooke cells will not be present in the pituitary tissue.

Crooke cell adenomas are a rare type of pituitary tumours. They produce ACTH causing Cushing's disease or may be endocrinologically silent. Crooke hyalinization is not expected to develop in corticotroph tumours yet, a minority of such adenomas contain a variable percentage of adenoma cells displaying this alteration, identical to the Crooke cells seen in the adenohypophysis of patients with glucocorticoid excess. If this change affects more than 50% of the cells, tumours are diagnosed as Crooke cell adenomas [23]. The reason for which Crooke cell adenomas produce ACTH while simultaneously displaying Crooke hyaline changes in response to increased glucocorticoid excess is not well understood. These tumours are usually invasive, may exhibit aggressive clinical behaviour, and often recur with a low success of cure after reoperation and radiotherapy. Due to their rarity, they present considerable difficulties in assessing prognosis, treatment, and clinical management [23].

Silent corticotroph adenomas are unassociated with functional activity and present as clinically non-functional tumours. There are two subtypes of silent corticotroph adenomas. **Silent corticotroph adenomas subtype 1**—densely granulated—show less female preponderance and different age-related occurrence than corticotroph adenomas associated with Cushing's disease. The tumours display a high propensity for haemorrhage and may present with pituitary apoplexy. Morphologically the adenomas have the same basophilia, PAS positivity, ACTH and β-endorphin immunoreactivity and ultrastructural features as corticotroph tumours associated with Cushing's disease. **Silent corticotroph adenomas subtype 2**—sparsely granulated—have a frequency of 1.5–2.0% and show marked male preponderance. The tumours appear as non-functioning masses and are usually diagnosed at the macroadenoma stage. Histology reveals chromophobic tumours comprised of small cells, which exhibit only modest PAS positivity and scattered immunoreactivity for ACTH and β-endorphins. No cytokeratin filaments are present with Cam5.2. They can present with aggressive clinical behaviour [5]. These two adenoma types are possibly derived from cells of the pars intermedia.

Molecular Pathology of the Tpit Family of Tumours

In approximately 40–60% of corticotroph adenomas, somatic mutations in Ubiquitin Specific Peptidase 8 gene (*USP8*)—resulting in increased EGFR expression and increased mRNA levels of POMC—have been demonstrated [24, 25]. Corticotroph adenomas with mutated *USP8* are commonly found in females, present as small tumours with high ACTH production, and are associated with better prognosis [24]. *USP8* mutations have not been confirmed in silent corticotroph tumours. Epigenetic mutations in *TP53* are linked to corticotroph adenomas.

MicroRNA (miRNA) studies revealed a large number of miRNAs that are upregulated and downregulated. Among those, it was shown that miR-26a plays a crucial role in cell cycle control of corticotroph adenomas [12].

Pituitary blastoma, in *DICER1* syndrome, is a rare developmental early childhood invasive neoplasm arising within the fetal adenohypophysis causing infantile-onset Cushing disease. It consists of a combination of Rathke-type epithelial rosettes, small

primitive appearing cells, and secretory cells expressing ACTH. Genetic analysis has revealed a germline *DICER1* mutation which is often accompanied by a somatic mutation affecting the RNase IIIb domain of *DICER1* in the cases studied [26].

SF-1 Family of Tumours

Gonadotroph Adenomas

Gonadotroph adenomas arise from SF-1 pituitary cell lineage and produce β-FSH, β-LH, and α-subunit. They can also express ER-α and GATA2. Their incidence in the surgical material is about 10%; they occur with similar frequency in both sexes. Most gonadotroph adenomas appear as slow-growing, expansive macroadenomas causing local symptoms. A discrepancy between clinical parameters and morphological signs of gonadotroph differentiation is common; tumours displaying FSH/LH immunoreactivity and signs of a high degree of functional differentiation, may be unassociated with elevated serum FSH or LH levels. Some clinically non-functioning pituitary adenomas are gonadotroph adenomas due to their lack of any endocrine activity. The morphology of gonadotroph adenomas is variable. Histology may reveal either polar cells forming pseudorosettes around vessels or a diffuse pattern. Oncocytic change, an excessive increase of number and volume density of mitochondria, is frequent. Immunoreactivity for FSH or LH is variable, often patchy; α-subunit, which is a useful clinical indicator, is not a reliable morphological marker.

Molecular Pathology of the SF-1 Family of Tumours

Molecular studies involving tumours from the SF-1 lineage found that they have a lower number of germline and somatic mutations compared to other pituitary adenomas. Silencing of *MEG3* located on chromosome 14q32 which has an antiproliferative role in adenomas was also found to have an important role in the development of gonadotroph adenomas. To date, in MEN-1, no gonadotroph adenomas have been reported. Both non-functioning adenomas and gonadotroph adenomas have shown to have loss of p16 protein (tumour suppressor encoded by *CDKN2A* gene) and hypermethylation of *CDKN2A*.

Polymorphous Plurihormonal Adenomas

Plurihormonal Adenomas

Polymorphous plurihormonal adenomas are rare tumours, often with unique ultrastructure. The most common combinations are GH-TSH-PRL or PRL-TSH, but other combinations of different cellular lineages can also occur.

Transcription Factor and Hormone-Negative Adenomas

Null Cell Adenomas

Null cell adenomas are composed of adenohypophyseal cells that do not display evidence of cell lineage differentiation by pituitary transcription factors or pituitary hormones. These hormonally inactive adenomas account for approximately 25% of surgically removed tumours. They are twice as common in males, and peak in the sixth decade in both sexes. Most of the tumours are slowly growing, expansive macroadenomas causing local symptoms and varying degrees of hypopituitarism. Low-grade hyperprolactinaemia may occur ('stalk section effect'). Histologically they are chromophobic with a predominantly diffuse staining pattern. Pseudorosette formation, characteristic of glycoprotein hormone-producing tumours, may also occur. Null cell adenomas are immunonegative for adenohypophyseal hormones and transcription factors. Oncocytic change can occur, and in this case, they are referred to as pituitary oncocytomas.

Oncocytomas characteristically have a diffuse staining pattern by histology. The adenoma cells are larger than null cells and may display acidophilia due to non-specific binding of acidic stains by mitochondria. The pattern of immunoreactivity is similar to null cell or gonadotroph adenomas. By electron microscopy, the sole ultrastructural marker is the extensive accumulation of mitochondria, whereas the other organelles are poorly developed.

Molecular Pathology of Null Cell Adenomas and Oncocytomas

Promoter methylation has been reported in many genes (*LGAL3*, *PLAG1*, and long non-coding RNA *MEG3* and *WIF1*) that function as tumour suppressors with antiproliferative activity. Recent studies reported that the *ENC1* gene, which has an essential role in tumour invasion, may have an important role in null cell adenomas and oncocytomas. Patients with MEN1 have an increased risk of developing null cell adenomas. Approximately 60% of oncocytic pituitary adenomas show somatic mutations in mitochondrial DNA genes, coding for various respiratory complex I components. These mutations contribute not only to the development of oncocytic change, but also to a less aggressive tumour phenotype [27].

Pituitary Carcinomas

Pituitary carcinomas can be diagnosed only when a pituitary neoplasm gives rise to distant, craniospinal, or less frequently, extracranial metastasis. Such tumours are extremely rare and have been associated with poor prognosis. They usually present as invasive macroadenomas and grossly they appear similar to other pituitary adenomas. To date, no criteria have been found to quickly and easily distinguish between an invasive adenoma and one that has the potential to become a carcinoma. Most pituitary carcinomas produce either PRL or ACTH. Other types, including those unassociated with signs of hormone overproduction, are exceptionally rare. Pituitary carcinomas are not accompanied by specific histological features; enhanced mitotic activity, nuclear and cellular pleomorphism do not necessarily indicate malignancy, and vice versa. Neoplasms with bland features may give rise to metastasis. Application of the cell proliferation marker, Ki-67 is more useful; carcinomas display nuclear labelling consistently higher than adenomas [28]. Immunoreactivities of pituitary carcinomas follow the pattern of their non-malignant phenotype, although the degree of immunopositivity may be variably reduced. The p53 expression has been used as a marker for tumour behaviour and high p53 expression is associated with malignancy in both the primary lesion and metastases. Studies have not been able to conclusively confirm the reliability of p53 pertaining to pituitary carcinomas since studies have shown that p53 expression may be negligible or absent in both lesions [29].

Molecular Pathology of Pituitary Carcinomas

Although several studies have reported molecular and genetic defects in both pituitary carcinoma metastases and primary lesions, to date, there is no definitive data on the molecular or genetic profiles of pituitary carcinomas.

Aggressive Pituitary Adenomas

Clinically aggressive pituitary adenomas comprise a broad, and not yet clear, group of tumour types which are diagnosed later, do not respond well to therapy, and are generally associated with a poor prognostic outcome. Aggressive tumours can be either microadenomas or macroadenomas, have the potential to invade into surrounding structures, and are characterized by a higher rate of recurrence compared to their benign adenoma counterparts [30]. A specific histopathological description of the multiple pituitary adenomas may assist in recognizing characteristics suggestive of aggressiveness. According to WHO classification of pituitary adenomas (2017), sparsely granulated somatotroph adenomas, lactotroph adenomas in men, silent corticotroph adenomas, Crooke cell adenomas, and plurihormonal Pit-1 positive adenomas are considered as high risk (of recurrence) adenomas [6]. Apart from the histologic and morphologic methods utilized to classify the tumour types, no single feature can provide a reliable assessment to predict aggressive behaviour. To date, the most reliable and accepted immunohistochemical analysis to evaluate aggressive behaviour in pituitary adenomas is the assessment of the Ki-67 nuclear labelling. If the Ki-67 nuclear labelling index is more than 10%, the tumour may be classified as aggressive, although there is no agreement on this [3]. Another histologic marker used to correlate tumour behaviour is the p53 expression. Studies have shown that tumour behaviour is associated with p53 expression since it is absent in non-invasive pituitary adenomas but large, invasive pituitary adenomas demonstrate strong, diffuse nuclear immunopositivity for p53, although, as with Ki-67, studies have not conclusively confirmed the reliability of p53 as a marker for aggressive behaviour [30]. A clinicopathological classification, which considers proliferation markers, invasion, and size, has been proposed [31], and, recognizing the variable behaviour of pituitary tumours in patients, a recent suggestion to replace the term pituitary adenoma to pituitary neuroendocrine tumour (PitNET) has also been made [32].

Immunohistochemical study of MGMT expression may be used as a prognostic marker for aggressive pituitary adenomas. Studies have shown that progression and recurrence of pituitary adenomas are often associated with loss of MGMT expression [4, 33, 34] and that low MGMT expression may be both a predictive marker for temozolomide response, and a prognostic marker of tumour recurrence and poor prognosis in pituitary adenomas.

Adenomas

Non-Functioning Pituitary Macroadenomas

Non-functioning pituitary macroadenomas are by far the most common macroadenomas. They are also named non-secreting pituitary adenomas and, more recently, pituitary neuroendocrine tumours (PitNET). They are divided into eight subtypes, based on the immunohistochemical expression of anterior pituitary hormones and pituitary transcription factors [1].

They are revealed by symptoms of mass effect, such as headache and visual field defects, less frequently by anterior pituitary insufficiency. On the contrary, the presence of diabetes insipidus allows in nearly all cases to reject the diagnosis of pituitary adenoma. Non-functioning pituitary macroadenomas are also discovered by chance in more than 30% of the cases.

The role of MRI is essential:

- to make the proper diagnosis and eliminate other sellar masses
- to evaluate the optic chiasm and optic nerve compression
- to localize the normal pituitary gland
- to search for signs of aggressivity, such as cavernous sinus invasion
- to look for remnants or recurrence after surgery.

Pituitary macroadenomas are centred by an enlarged sella turcica and frequently present with lobular contours. Tumoural extension is usually directed upwards to the suprasellar cistern, with compression and /or thinning of the optic chiasm and amputation of the inferior recesses of the third ventricle. Hyperintensity of the whole optic chiasm or a rail-like pattern on coronal T2-weighted images is a criterion of severity of nerve fibre lesion/damage and must prompt rapid surgical decompression. It has been demonstrated that an angle less than 114 degrees measured between the optic nerve and the floor of the anterior fossa is a sign of poor prognosis despite surgery (Figure 2.3.4.1).

Giant non-functioning adenomas can extend to the frontal or temporal lobes. Blockade of the foramens of Monro can be responsible for hydrocephalus. Extension can also be directed inferiorly within the sphenoid sinus or laterally in the cavernous sinus, most of the times unilaterally.

Non-functioning pituitary macroadenomas usually present with a moderate hypointense signal in T1 and a hyperintense signal on T2-W images. In large pituitary adenomas, T1 as well as T2 signal is usually heterogeneous, with areas of T1 hyperintensity and/or T2 hyper- or hypointensity revealing haemorrhagic or necrotic phenomena. A fluid-fluid level indicates an old haemorrhage. In contrast, meningiomas most of the time display a homogeneous signal on T1 as well as on T2-W images. Post-gadolinium enhancement of the solid part of the tumour is variable but usually moderate. A characteristic microcystic pattern is observed on T2-W images in 50% of silent corticotropic adenomas. The normal residual anterior pituitary gland is visualized on T2 coronal images and after gadolinium infusion. It is compressed and pushed laterally on one side, against the cavernous sinus and superiorly, but almost never inferiorly. The opposite is true for meningiomas, craniopharyngiomas, and Rathke cleft cysts, where the normal gland is pushed down and can be seen inferiorly, below the tumour (Figure 2.3.4.2). The posterior pituitary bright spot is flattened and remains visible on axial T1 sequences; nevertheless, as soon as the tumour height reaches 20 mm, pituitary

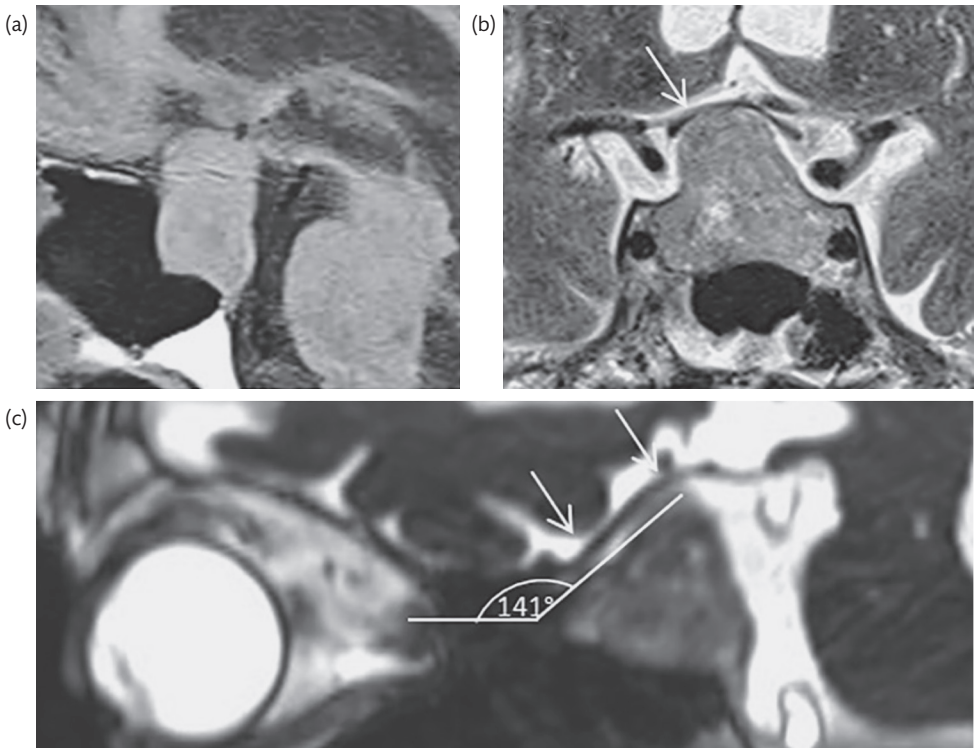

Figure 2.3.4.1 Non-functioning pituitary macroadenoma on sagittal T1 (a) and coronal T2 (b) W images. A sagittal oblique contrast enhanced FIESTA (c) demonstrates the angle between optic nerve and anterior cranial fossa.

stalk compression leads to an ectopic vasopressin storage at the infundibular level.

Sequential coronal MRI exams obtained rigorously with the same projection, for instance in our practice perpendicularly to the subcallosal line, are mandatory to detect recurrence as early as possible (Figure 2.3.4.3).

Cavernous Sinus Invasion

Invasion of the cavernous sinus is usually obvious: enlargement of the laterosellar space, bulging of its lateral wall, blurring of the intracavernous veins with encasement but without narrowing of the intracavernous internal carotid artery make the diagnosis clear. Subtle invasion occurs initially at the posterior part of the cavernous sinus and is better identified on axial views. Integrity of the medial dural wall, more frequently visible on coronal or axial T2-W images at 3.0 T, excludes cavernous sinus invasion (Figure 2.3.4.4). In non-functioning pituitary adenomas, the cavernous sinus invasion, which represents a sign of aggressiveness, is usually unmodified by the surgeon/usually persists after surgery and is a potential source of tumoural regrowth years after surgery [2].

Apoplexy

Apoplexy is a severe complication of pituitary adenomas resulting from an ischaemia or a brutal haemorrhagic event. Apoplexy is symptomatic, unlike subacute haemorrhage from which it has to be differentiated. Most pituitary apoplexies complicate pituitary middle-sized macroadenomas but rarely giant adenomas, as if haemorrhagic infarction preferentially occurs when the responsible

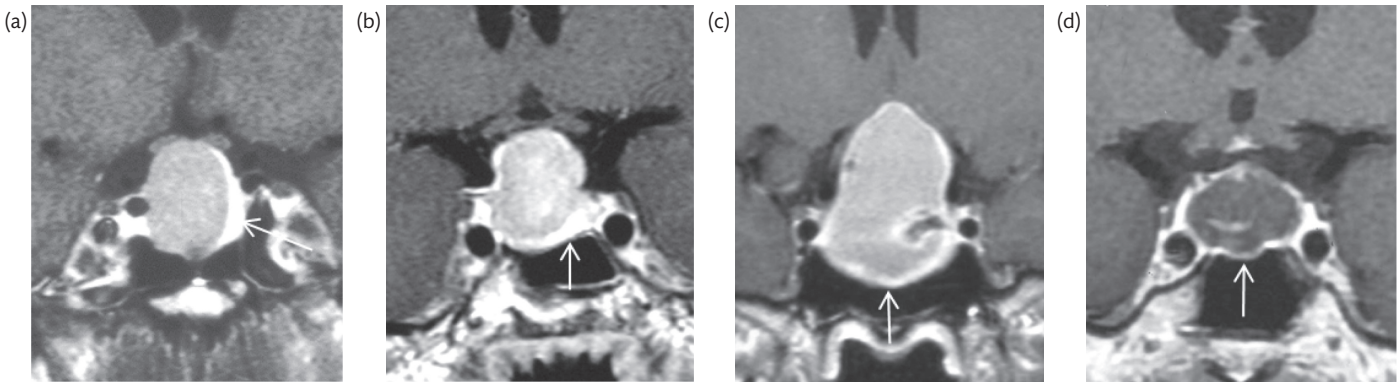

Figure 2.3.4.2 Coronal enhanced T1-W images demonstrating the normal anterior pituitary gland (arrows) in pituitary adenoma (a), sellar meningioma (b), craniopharyngioma (c), and Rathke cleft cyst (d).

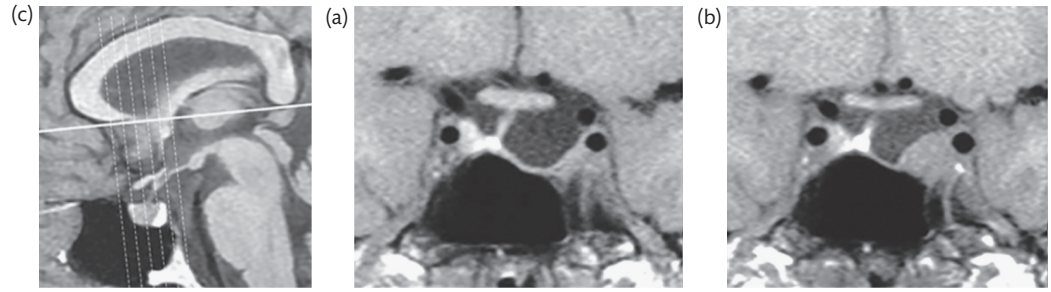

Figure 2.3.4.3 Sequential coronal T1-W images (a, b) are easily compared when obtained perpendicularly to the subcallosal line drawn on (c), sagittal T1-W image.

pituitary adenoma is still contained by the sellar diaphragm. Not infrequently, apoplexy reveals the pituitary adenoma. Apoplexy of an adenoma remnant can also occur years after surgery [3]. Diagnosis may be difficult in the early stage, the classical predominant hyperintensity on T1 being frequently absent; the T2 sequence is more sensitive by demonstrating heterogeneous low signal intensity. Diffusion-weighted images can show an increased signal intensity if compared with the normal brain and a low apparent diffusion coefficient. Thickening of the sphenoid sinus mucosa is present from the early stage (Figure 2.3.4.5). After gadolinium injection, peripheral enhancement is noticed with no or minimal enhancement of the central part of the sellar content.

Sequential MRI will demonstrate the gradual increase in the T1 hyperintense signal, from the periphery towards the centre of the mass. If surgery is not indicated, as is usually the case, MRI will show shrinkage of the sellar content in several weeks or months.

The Postoperative Sella

In the immediate postoperative period, some neurosurgeons request for an MRI to eliminate a possible complication. But blood products and packing material can obscure the sellar content and possible residual tumour in the first weeks after surgery. Postoperative MRI is then usually not obtained before 3 months after surgery. At this time, blood and most of the packing material, if any, are resorbed at the exception of fat grafts which can persist many years after surgery. Coronal high-resolution 2 mm thick T2-W sequence is the most informative, whereas contrast enhanced MRI can frequently be spared. Remodelling of the normal pituitary gland occurs 6 months after surgery at the latest; it appears as a homogeneous triangular or oval small mass in contact with the sellar floor and the medial wall of the cavernous sinus, most of the times isointense to the brain cortex on T2-weighted sequences. The T2 signal of the tumoural remnant, if any, is quite always more or less hyperintense if compared with that of the residual normal pituitary tissue and of course the same as preoperatively. In subsequent years, MRIs rigorously performed with the same parameters and the same inclination will be able to demonstrate stability or an early slight increase in volume of the remnant and no change of the normal pituitary tissue (Figure 2.3.4.6) [4, 5].

Prolactin-Secreting Pituitary Adenomas

In women with amenorrhea and galactorrhoea and a prolactin level above 35 ng/ml, the chances to find a prolactinoma on MRI are very high. These adenomas display a T1 hypointense signal and a more or less hyperintense signal on T2 (Figure 2.3.4.7). When the clinical presentation is clear and the diagnosis confirmed by T1/T2 MRI sequences, the protocol can be simplified and gadolinium injection avoided. Most are microprolactinomas and there is a good correlation between prolactin level and adenoma size. For instance, a prolactin level of 60–90 ng/ml usually corresponds to an adenoma of

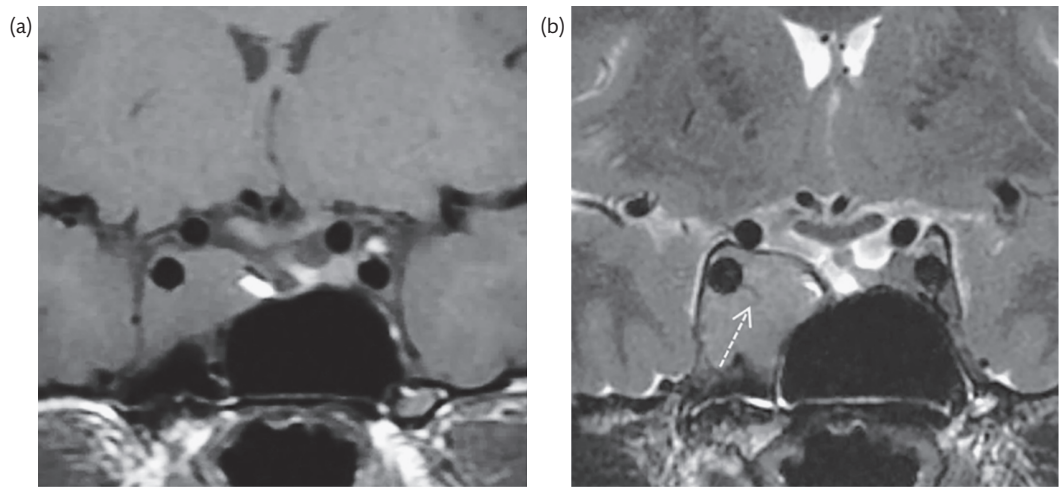

Figure 2.3.4.4 Non-functioning pituitary adenoma years after surgery with intrasellar and intracavernous tumoural remnant. T1- (a) and T2-W images (b). Flap of the medial wall of cavernous sinus (arrow).

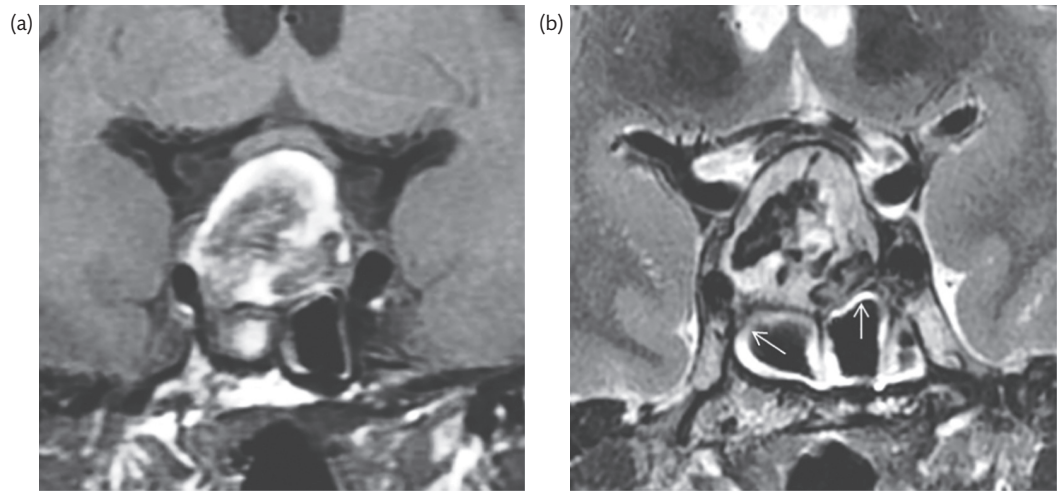

Figure 2.3.4.5 Pituitary apoplexy on coronal T1 (a) and T2 (b) W images. Thickened sphenoid sinus mucosa (arrows).

7–10 mm in diameter. Nevertheless, some adenomas do not obey this rule. A frank T2 hyperintensity reflecting degenerative changes or a T1 hyperintensity indicating a partial haemorrhagic transformation is less secreting and correlate with a lower prolactin level. Such a haemorrhage is usually asymptomatic and frequently seen at diagnosis as well as after cabergoline treatment. Prolactin levels above 150–200 ng/ml correspond to pituitary macroadenomas with suprasellar extension and/or cavernous sinus invasion.

After cabergoline treatment, shrinkage of the adenoma occurs quickly, as soon as a few days or weeks and the hyperintense T2 signal increases. If pregnancy is obtained and cabergoline withdrawn, the size of the adenoma roughly doubles when compared with its size before treatment. This has to be kept in mind for the management of prolactinomas during pregnancy. As a general rule, pregnancy has no adverse effect for microprolactinomas. Nevertheless, a close supervision has to be discussed in haemorrhagic adenomas, in prolactinomas with unusually T2 hypointense signal or T2 microcystic pattern or in women with a small sella [6].

In men, most prolactinomas are macroadenomas and even giant adenomas. In contrast with the usual T2 hyperintensity of prolactinomas, some harbour T2-hypointense areas corresponding to calcifications or amyloid deposits. Prolactin levels are very high, and can reach thousands of ng/ml. Cavernous sinus invasion is very frequent. Extension to the entire sphenoid sinus can simulate an ear/nose/throat (ENT) cancer (Figure 2.3.4.8). Cabergoline is usually efficient with a rapid tumour shrinkage but can lead to a cerebrospinal fluid (CSF) fistula in case of erosion of the sphenoid sinus walls. Initiation of treatment with low-dose dopamine agonists does not always allow to avoid this complication [7].

Growth Hormone-Secreting Pituitary Adenomas

Growth hormone (GH)-secreting pituitary adenomas or somatotropinomas represent the third most frequent type of pituitary adenomas following prolactinomas and non-functioning tumours. Their prevalence ranges from 8 to 16% of all types of adenomas with an incidence of 3–4 cases/million inhabitants/year.

Most of the times, somatotropinomas are revealed during the imaging studies that follow the diagnosis of acromegaly. Rarely, they can be an incidental finding on an imaging examination performed for a different reason in a patient that was not known to suffer from acromegaly.

Studies performed on large series of patients with acromegaly have shown that somatotropinomas are macroadenomas in over two-thirds of cases at diagnosis. The largest diameter of most GH-secreting adenomas is between 1 and 2 cm. Giant tumours are rare. There seems to be an inverse relationship between adenoma size

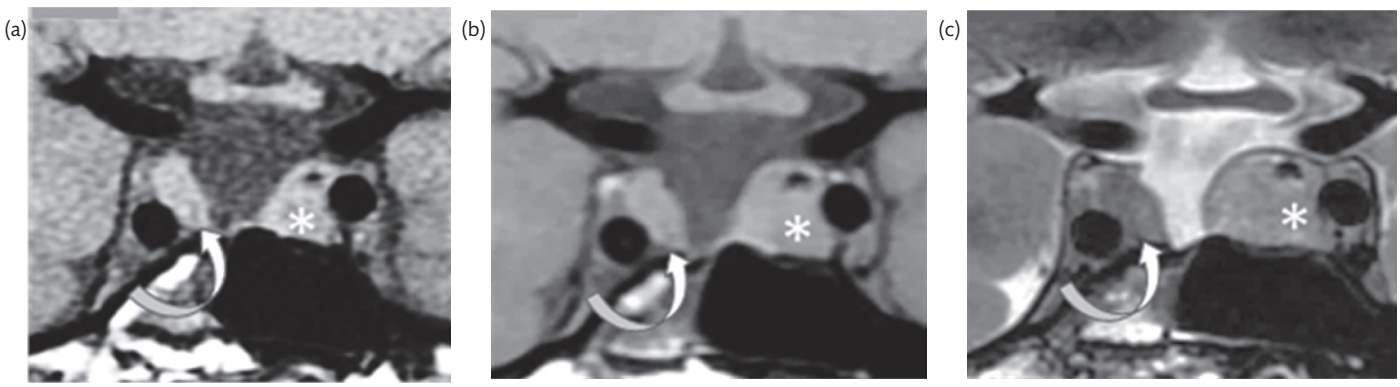

Figure 2.3.4.6 Pituitary adenoma remnant. Sequential T1-W images (a, b) show an enlargement of the remnant (asterisk). In c, coronal T2-W image, the normal pituitary gland (curved arrow) is unchanged and less intense than that of the tumoural remnant.

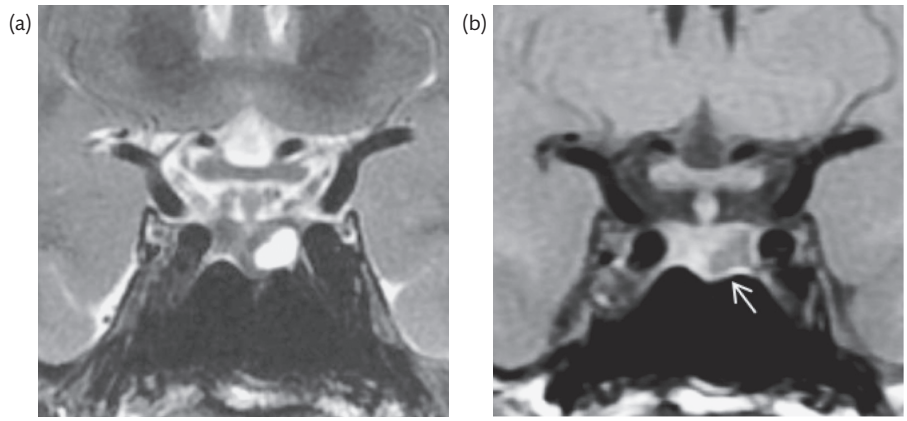

Figure 2.3.4.7 Microprolactinoma hyperintense on T2 (a) and hypointense on T1-W images (b).

and patient age at diagnosis, with younger patients often developing larger tumours. Among these younger patients, tumours develop more frequently in a genetic context and, when appearing before the closure of the growth plates, will lead to gigantism. The biochemical anomalies (GH and IGF1 increases) seem to also be related to tumour size with bigger tumours being responsible for higher levels of GH and IGF1. This is valid for adenomas measuring up to 20 mm of largest diameter. Beyond this threshold, correlations between secretory levels and tumour size are no longer found.

A particularity of the natural evolution of GH-secreting adenomas is their tendency to extend towards the sphenoid sinus. The reasons behind this propensity towards infrasellar development are not yet clear and may involve local effects of the somatotropinoma or the consequences of GH secretion on connective tissue. Suprasellar extension with optic chiasm compression is rarer than infrasellar extension, which explains why visual field defects are not very common at the diagnosis of acromegaly.

Unlike other types of pituitary adenomas, GH-secreting ones exhibit a T2-hypointense signal in around 50% of cases, whereas prolactinomas and non-functioning adenomas are more rarely T2-hypointense. Although different definitions of T2-weighted signal intensity have been employed in the existing literature, we believe

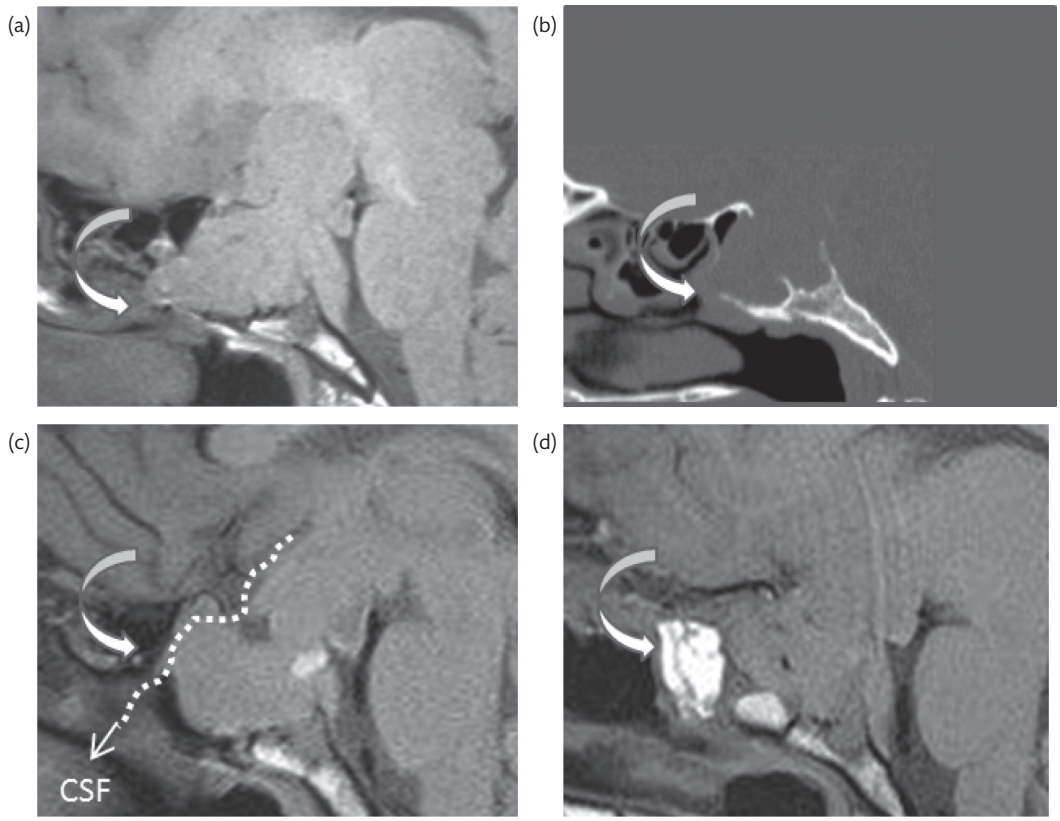

Figure 2.3.4.8 Macroprolactinoma invading sphenoid sinus in a male. Prolactin level is 10 000 ng/ml. (a) Sagittal T1-W image. Huge tumoural process extending upwards, downwards, and posteriorly. The inferior surface of the sphenoid bone is eroded as demonstrated on (b), sagittal CT (curved arrow). In (c), after low dose cabergoline, limited tumoural shrinkage leading to a CSF fistula. (d) Fat graft interposition to cure the fistula.

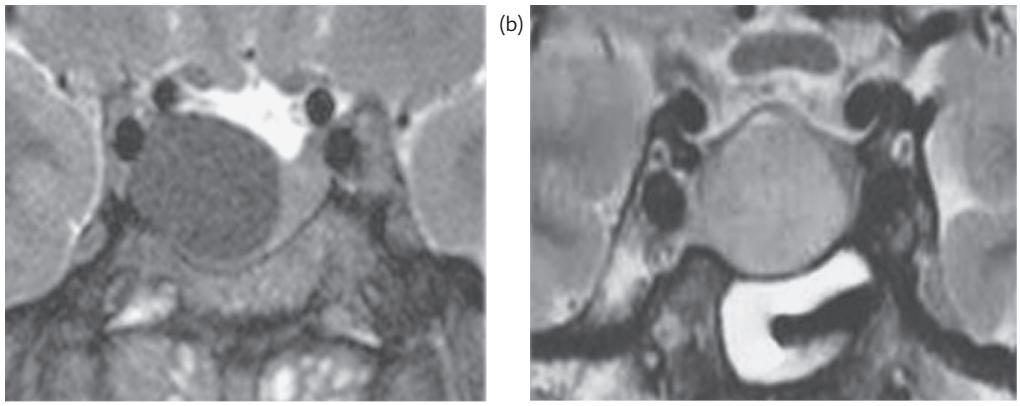

Figure 2.3.4.9 Growth hormone-secreting adenomas on T2-W images: T2 hypointense (a) and T2 hyperintense (b).

that the most accurate one is comparison with normal pituitary tissue and, only when the latter is not visible, with the grey matter of the temporal lobe. T2-hypointense somatotropinomas present different characteristics compared to T2-hyper and isointense ones. T2-hypointense adenomas seem to be smaller, less invasive tumours, with higher secretory levels (Figure 2.3.4.9). These T2-hypointense GH-secreting adenomas respond better to somatostatin analogue treatment. This is true both for primary treatment in terms of decreases of GH and IGF1 and of tumour reduction and for adjunctive therapy following surgical failure with hormonal control being achieved more frequently in patients with T2-hypointense tumours.

Current research is focusing on the relationships between T2-W signal intensity in somatotropinomas and histologic parameters. These might explain on one hand the different T2-W signal intensity of somatotropinomas and, on the other, the differences in adenoma behaviour, whether spontaneous or in response to somatostatin analogue treatment. Although not confirmed on large studies, it is believed that the densely granulated pattern of somatotropinomas correspond to T2-hypointensity, whereas T2-hyperintense adenomas are mostly sparsely granulated. Iron, fibrous tissue, or amyloid content do not seem to influence T2-W signal intensity. One study found that T2-hypointensity is correlated to expression of the somatostatin receptor type 5 (SSTR5), whereas no difference seems to exist with regards to SSTR2. Further detailed studies on larger series are required in order to clarify the matter [8].

Corticotropic Pituitary Adenomas

Corticotropic pituitary adenomas are responsible for adrenocorticotropic hormone (ACTH)-dependent hypercorticism. Their detection is of major importance for the treatment of Cushing's disease and represents a difficult challenge for radiologists. Less of half of corticotropic pituitary adenomas are macroadenomas. Most are microadenomas and a large number are picoadenomas (i.e. less than 3–4 mm in diameter). Moreover, a significant number escape MRI detection even at 3.0 T. In these cases, inferior petrosal sinus blood sampling for plasma ACTH measurements has an important role. 11C methionine PET-computed tomography (CT) combined with 3D MRI is also very promising but for now is not able to detect the tiniest pituitary adenomas. Macrocorticotropic adenomas do not differ from other adenomas. They are hypointense on T1 and more or less hyperintense on T2-weighted sequences. Micro and picoadenomas can be located centrally or laterally in the sella, more readily posteriorly and in contact with the posterior lobe. They are suspected through the presence of a small or even millimetric T2 hyperintense area and confirmed by a localized enhancement defect on 3D MRI. Cavernous sinus invasion can be present even in microadenomas. Optimized MRI sequences are here mandatory, but increase the risk of false positive findings. Dynamic MRI has been proposed to distinguish ACTH-producing adenomas from non-functioning pituitary adenomas, the time-intensity curve of enhancement featuring a rapidly enhancing and slow washout pattern in the first ones. However, dynamic imaging can lead to false positive images, particularly if a laterally positioned posterior lobe is not recognized (Figure 2.3.4.10). Delayed washout of corticotropic adenomas could also be demonstrated on a late postcontrast FLAIR sequence. Administration of corticotropin-releasing hormone (CRH) during 3T MRI has also been proposed to improve the detection of corticotropic adenomas. These data have to be confirmed in larger series of patients [9].

Silent corticotroph pituitary adenomas are clinically and biologically silent, but harbour ACTH-secreting cells at pathology. Because they are endocrinologically silent, silent corticotroph adenomas are either diagnosed when large or incidentally and behave like non-functioning macroadenomas [10]. A cystic or microcystic pattern on T2-W images is present in more than 50% of silent corticotroph adenomas (Figure 2.3.4.11).

Rathke Cleft Cysts

Rathke cleft cysts (RCC) are intra and/or suprasellar lesions believed to derive from remnants of the Rathke pouch. If 'microRCCs' are considered, they represent the most frequent lesions of the sellar region revealed on MRI and have to be evoked first when an incidentaloma is revealed. Characteristic imaging patterns make their diagnosis easy, provided that MRI sequences are carefully selected.

RCC's can be classified by location, content, and related symptoms.

RCC's Originate Intra–Or Suprasellarly

Intrasellar RCCs are by far the most frequent, diagnosed by their location, just in front and in close contact with the posterior lobe. Most are hyperintense on T1 and can be mistaken for the

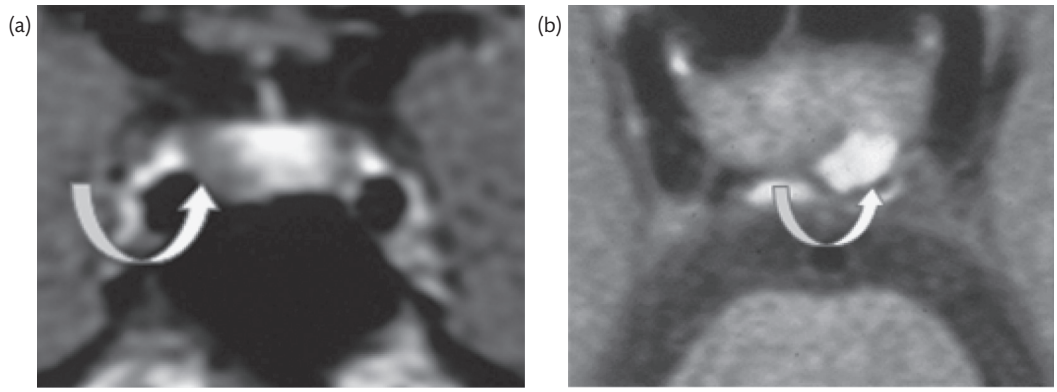

Figure 2.3.4.10 False positive diagnosis of a pituitary microadenoma on early phase of dynamic imaging: the pseudo right defect in enhancement (curved arrow in a, coronal T1-W image) is related to a lateral normal position of the T1 hyperintense posterior lobe visible on (b) axial T1-W image.

posterior lobe or even for a fatty dorsum sellae: axial T1 sequence with fat saturation solves the problem. They are strictly midline and symmetrical with a curved regular anterior border, except when coexisting with a pituitary adenoma (Figure 2.3.4.12). Most intrasellar RCCs are asymptomatic, but can expand into the chiasmatic cistern.

Suprasellar RCCs are said to originate from the pars tuberalis. They are seen on the upper surface of the pituitary gland or embedded in the pituitary as an egg in an eggcup, on the midline (Figure 2.3.4.13a) very rarely off midline. They can also involve the pituitary stalk and simulate a tumour (Figure 2.3.4.13b). These pituitary stalk RCCs never prevent the normal vasopressin storage within the posterior lobe. Suprasellar RCCs can be hypo- or hyperintense on T1 but usually less hyperintense than when intrasellarly located and more or less hyperintense on T2-weighted sequences. Cyst signal is related to its proteic content and can vary with mucus secretion from its wall and dehydration. Cyst volume can also vary with time; it can increase, decrease, or even disappear spontaneously. In about 70% of the cases, a T2 hypointense hyperproteinic nodule is able to make the diagnosis of RCC indisputable; this nodule can be tiny or involve the whole RCC (Figure 2.3.4.14). After gadolinium infusion, the thin monocellular cyst wall does not enhance in asymptomatic cysts [11].

Figure 2.3.4.11 Silent corticotropic adenoma. Microcystic pattern on coronal T2-W MRI.

We Used to Differentiate Symptomatic from Complicated RCCs

Symptomatic RCCs are responsible for mass effects due to their size, mainly visual field defects if the optic chiasm is threatened, headache, rarely anterior pituitary deficits [12]. Mild hyperprolactinemia due to stalk compression can be encountered. **Complicated RCCs** can present with haemorrhage, infection or rupture and are mainly responsible for anterior and/or posterior pituitary deficits, sometimes after one or several short episodes of severe headache, probably related to a reactional hypophysitis. These pituitary deficits usually occur in a short period of time. In these cases of complicated RCCs, the cyst wall is thickened and appears enhanced with gadolinium infusion. The distinction between wall enhancement and normal pituitary tissue encircling the cyst has to be made; dynamic imaging could help to this purpose (Figure 2.3.4.15).

The characteristic pattern of RCCs presented here render the differential diagnosis with pituitary adenomas usually simple. Moreover, mass effect, such as enlargement of the sella is less frequent in RCCs than in pituitary adenomas. Finally, the position of the normal pituitary gland is important to consider: unlike what is observed in pituitary adenomas, the normal gland in RCCs can be typically seen between the cyst and the sellar floor (Figure 2.3.4.2d).

Perisellar Tumours

Craniopharyngioma

Craniopharyngioma is an epithelial tumour, classified World Health Organization grade 1. They represent approximately 5% of all intracranial tumours. Craniopharyngiomas are derived from remnants of the Rathke's pouch and can occur anywhere along the course of the craniopharyngeal duct, from the nasopharynx to the third ventricle. They are characterized by a bimodal age distribution, with a main peak in children (5–14 years) and a second peak in adults (fifth–seventh

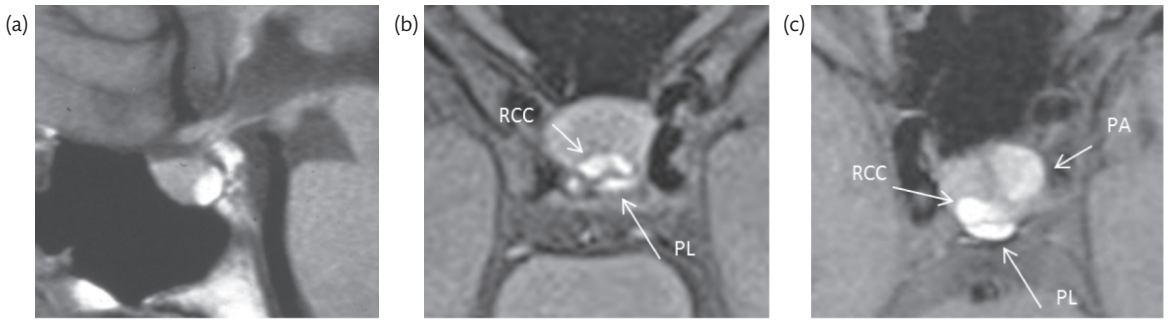

Figure 2.3.4.12 Micro Rathke cleft cyst on sagittal T1 (a) and axial T1 Fatsat (b) W images. Coexisting haemorrhagic pituitary adenoma on axial T1-W image on (c).

decade). There are two histologic subtypes: the adamantinomatous type, the most common form, typically seen in children and adolescents, and the papillary type, seen almost exclusively in adults, usually in the third ventricle. They most commonly involve the suprasellar and sellar area, where they are either anterior to, or posterior to the optic chiasm. In fewer cases, their location is purely suprasellar or entirely intrasellar. This explains the variability of the clinical symptoms. Headache, visual field defects, decreased visual acuity, and hormone disturbances are the common clinical symptoms in the suprasellar location. The most common endocrine dysfunctions encountered in children are growth retardation, delayed or precocious puberty. Global hypopituitarism, hyperprolactinemia, and diabetes insipidus are the other endocrine disorders that can be encountered. Rare locations include the third ventricle and the infrasellar region (sphenoid bone, ethmoid bone, and nasopharynx) [13].

Adamantinomatous craniopharyngiomas typically present with three components: solid, cystic, and calcified portions which occupy the suprasellar cistern (Figure 2.3.4.16). The cystic component is single or multiple, usually hyperintense on T1, T2, and FLAIR weighted images reflecting high protein concentration, cholesterol, or methaemoglobin contents. Less commonly, a CSF-like signal pattern can be seen in huge craniopharyngiomas with a thick wall enhancement. The solid component has variable signal intensities and shows contrast enhancement. Calcifications are common, they are better seen on computerized tomography. The sella is often enlarged and may be eroded.

Papillary craniopharyngiomas usually appear as predominantly solid or mixed solid and cystic spherical tumours in the suprasellar region. They are characterized by a more upward growth towards the third ventricle. The solid parts classically show isointense signal intensity on T1- and T2-weighted images, hypointense signal on diffusion-weighted images reflecting the low-grade character and a homogeneous or reticular enhancement. They less frequently contain calcifications. Surgical removal is easier in this subtype than in the adamantinomatous type.

Although histologically benign, craniopharyngiomas are aggressive neoplasms and recurrences are common because complete surgical resection is difficult. Treatment usually consists of surgical resection with or without adjuvant radiation therapy.

Optochiasmatic and Hypothalamic Glioma

Chiasmatic and hypothalamic gliomas are childhood tumours, 75% occurring in the first decade of life, with a similar gender distribution. In children, low-grade astrocytoma is the most frequent type of lesion, and 10–70% of these patients have neurofibromatosis type 1 (NF1). Visual loss with optic atrophy and growth delay are the most common signs. Intracranial hypertension syndrome with hydrocephalus is seen in large tumours. Optic glioma associated with NF1 is frequently asymptomatic. Optic and hypothalamic gliomas appear as rounded or lobulated solid suprasellar masses hyperintense on T2-W images, hypointense on T1-W images with a variable, often heterogeneous enhancement. A posterior extension along the optic tracts is usual (Figure 2.3.4.17). Suprasellar

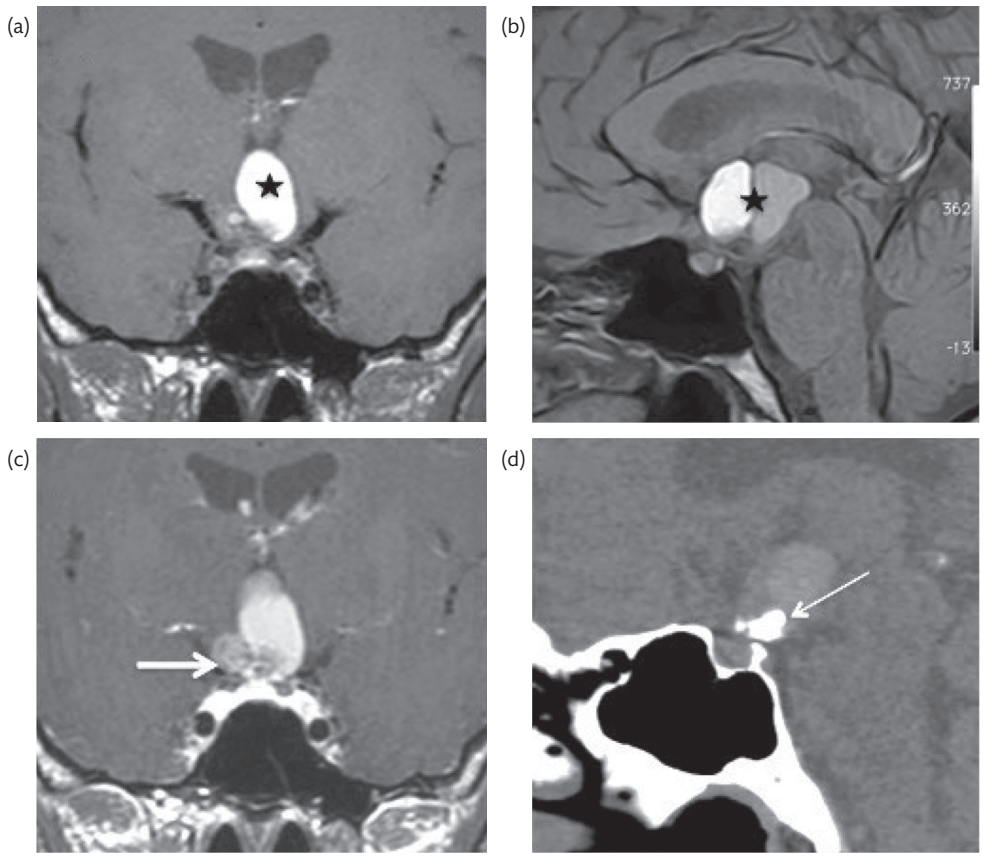

Figure 2.3.4.16 Suprasellar adamantinomatous craniopharyngioma on coronal (a) and sagittal (b) T1-W images, coronal T1-W image after contrast (c) and coronal CT-scan (d). Suprasellar multiloculated mixed mass with varying mainly bright signal intensities (asterisk) and solid calcified component heterogeneously enhanced (arrow). Posterior tumoural extension along the left optic tract (curved arrow).

extension compressing the third ventricle may be responsible for hydrocephalus [14].

Suprasellar Germinoma

Germinoma is the most common germ cell tumour of the suprasellar region. It can be a primitive or a metastatic lesion from a pineal germinoma. It is most commonly seen in adolescents and young adults with no gender preference. Clinical symptoms include diabetes insipidus, precocious puberty, or growth failure and visual loss. Tumour markers such as alpha-fetoprotein and human chorionic gonadotropin can be found in the serum and/or CSF. The most precocious radiological sign is the infundibular thickening with the absence of the posterior lobe bright spot on T1-W images. As it grows, the lesion appears as a well-delineated round or lobulated lesion markedly enhanced. Intraventricular extension and infiltration of the basal ganglia and the corpus callosum can occur. Leptomeningeal spread with drop metastases along the spinal cord are reported, so before treatment, a complete examination of the brain and spinal canal is required (Figure 2.3.4.18). Early diagnosis may reduce the risk of dissemination and the morbidity of treatment [15].

Meningioma

Meningiomas are the most common intracranial tumours in adults, with 20% occurring at the skull base and arising from the arachnoidal cells of the meninges. The common sites of origin are the planum sphenoidale, the tuberculum sellae, the clinoid processes, the sellar diaphragm, and the cavernous sinus.

Pre- and suprasellar meningiomas can be revealed by anosmia, frontal syndrome, and visual disturbances when the optic chiasm or optic nerves are compressed. Meningioma appears iso to hyperintense on T2-W images and is hypo- to isointense on T1-W image with a marked homogeneous enhancement after gadolinium. Hyperostosis is commonly associated. Upward convexity of the jugum sphenoidale in the area near the insertion of the meningioma, termed blistering, can be seen (Figure 2.3.4.19). Posterior extension can completely cover the sellar diaphragm, making the identification of the site of tumour insertion difficult. Diagnosis of meningiomas of the sellar diaphragm can be tricky. They should be differentiated from the underlying normal pituitary gland (Figure 2.3.4.2b) [16].

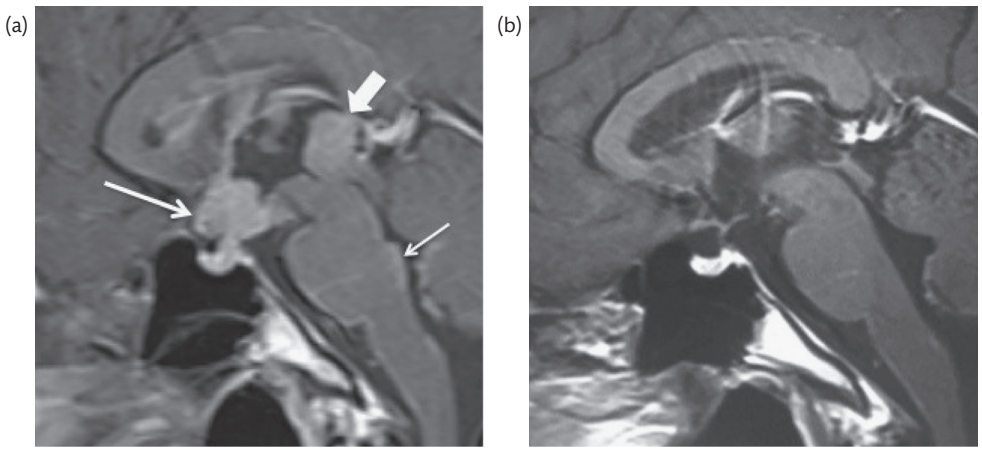

Figure 2.3.4.18 Suprasellar and pineal germinoma. Sagittal T1-W images after gadolinium before (a) and after treatment (b). Suprasellar tumour strongly enhanced involving the optic chiasm (arrow). Contrast enhanced pineal mass (thick arrow). Metastatic leptomeningeal linear and micronodular enhancement (short arrow). After treatment, complete radiological remission.

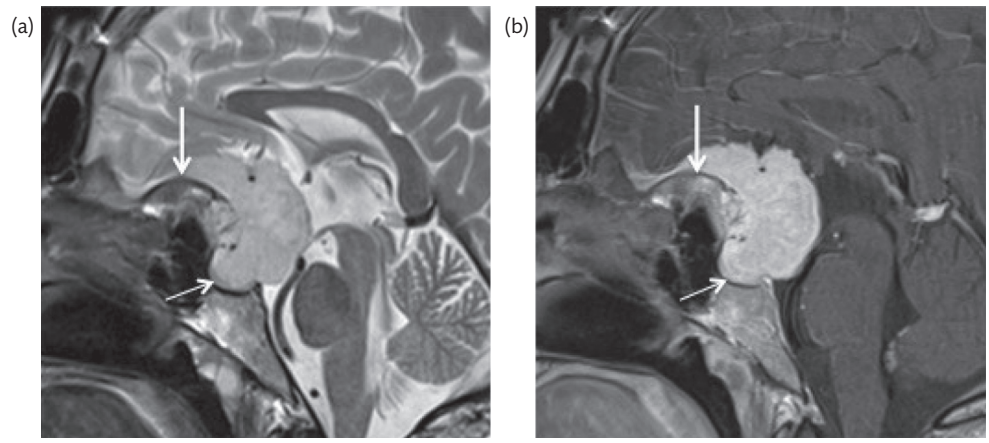

Figure 2.3.4.19 Presellar meningioma with posterior extension in the suprasellar cistern. Sagittal T2 (a) and T1 after contrast (b) W images. The tumour is hyperintense to the grey matter on T2 with strongly and homogeneously enhancement (asterix). Blistering of the jugum sphenoidale (arrow). The pituitary gland is pushed inferiorly (thin arrow).

Cavernous sinus meningiomas are revealed by oculomotor deficit, ptosis, diplopia, anisocoria, or complete ophthalmoplegia. Compression of the internal carotid artery can be responsible for ischaemic events. Some of them arise from the lateral dural wall, while others are developed exclusively inside the cavernous sinus. These frequently extend into the sella turcica, pushing the pituitary gland towards the opposite side (Figure 2.3.4.20).

Metastasis

Pituitary metastases are rare. They are found particularly in breast and lung cancer patients. The pituitary gland can be reached via hematogenous spread, via the skull base, or by meningeal spread. The posterior lobe is the most frequently involved, probably because of its direct arterial blood supply by the inferior hypophyseal arteries. Diabetes insipidus is the most frequent symptom. Oculomotor nerves palsies are seen if the cavernous sinus is involved. On MRI, loss of hyperintensity in the posterior pituitary is constant. We can also see a non-specific isolated thickening of the infundibulum, a large intra- and suprasellar dumbbell-shaped tumour with or without invasion of the cavernous sinus. Erosion or destruction of the dorsum sellae is better appreciated on CT. Rapid growth of the lesion on sequential MRIs suggests a malignant disease [17].

Lymphoma

Primary central nervous system lymphoma (PCNSL) is rarely limited to the sellar region. Sellar and suprasellar locations represent a diagnostic challenge. The most common presentation is hypopituitarism, followed by headache, diplopia, diabetes insipidus, hyperprolactinemia, and fever. Prognosis is generally poor and the disease is rapidly progressing.

The common MRI finding is a T2 hypointense mass lesion resulting from the dense cellularity and high nucleus-to-cytoplasm ratio of lymphoma. Contrast enhancement is typically intense and homogeneous in immunocompetent patients, but inhomogeneous or ring-like in immunocompromised patients. Diffusion, perfusion, and MR spectroscopy may help differentiate central nervous system (CNS) lymphomas from other brain lesions. Peritumoral oedema is generally less pronounced than in metastases. Confirmation of diagnosis is most frequently obtained after surgery [18, 19].

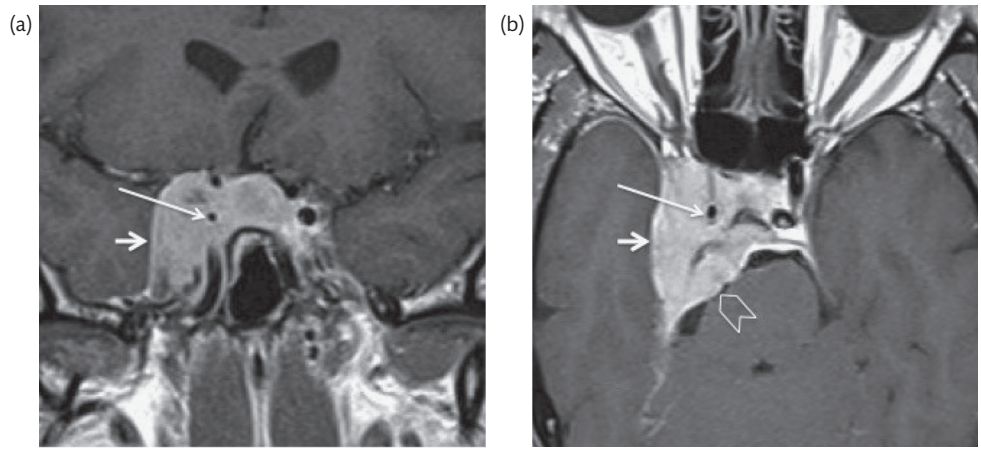

Figure 2.3.4.20 Meningioma of right cavernous sinus with intrasellar extension. Coronal (a) and axial (b) T1-W images. Bulging of the lateral wall of the right cavernous sinus (short arrow) and convexity of the upper pole of the sellar content; meningioma and normal pituitary gland are not differentiated. Severe reduction of the right intracavernous internal carotid artery (arrow). Posterior extension in the prepontine cistern (arrowhead).

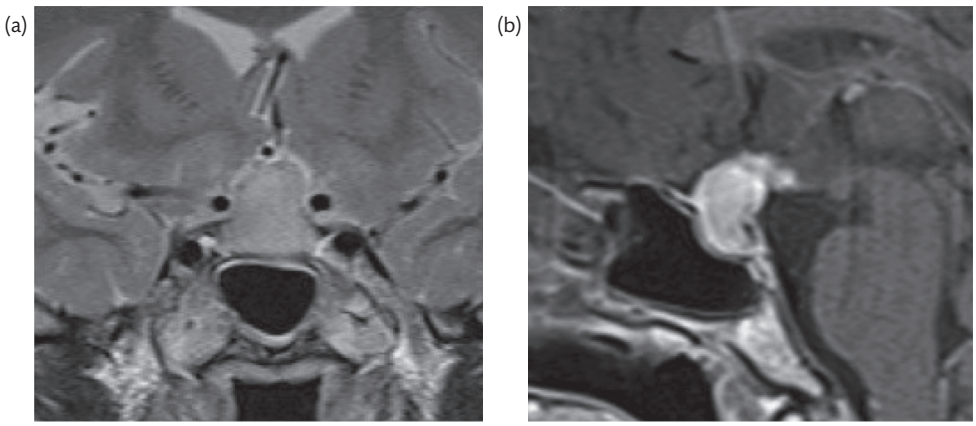

Figure 2.3.4.21 Pituicytoma. Coronal T2-W image (a) and coronal T1-W image after gadolinium (b). Hyperintense intrasellar mass with suprasellar expansion and strong homogeneous enhancement.

Primary Neurohypophyseal Glial Tumours

The pituitary stalk and the posterior pituitary gland, which are composed of specialized glial cells called pituicytes, can host neoplastic glial processes. We distinguish astrocytomas, tanycytomas, and granular cell tumours. Astrocytomas (pituicytomas and pilocytic astrocytomas) and tanycytomas are specific to the neurohypophysis, whereas granular cell tumours (GCT) can also be encountered elsewhere in the central nervous system.

Pituicytomas, formerly called infundibulomas, are considered grade I glial neoplasms by the 2007 World Health Organization (WHO) classification. They are seen in adults with a mean age of 50 years old without gender predilection. The main clinical signs are visual impairment, headache, hypopituitarism, and fatigue. Paradoxically, diabetes insipidus is an uncommon symptom in pituicytomas. On MRI scans, the normal bright spot on T1 of the posthypophysis is typically absent. The pituicytoma appears as a solid, well-circumscribed mass with a size ranging between 5 and 30 mm. It can be suprasellar, intra- and suprasellar, or rarely purely intrasellar, occasionally with cavernous invasion. This tumour is hyperintense on T2-W images, iso- or hypointense to grey matter on T1-W images, with typically an intense and homogeneous enhancement. Sellar enlargement is uncommon. The final diagnosis is made by immunohistochemistry and electron microscopy (Figure 2.3.4.21). A total surgical resection is curative with no recurrence or need for adjuvant therapy. **Pituitary pilocytic astrocytomas** are indistinguishable from pituicytomas on imaging. The differential diagnosis is made on anatomopathology.

Tanycytomas are hypothalamic–suprasellar tumours, clinically aggressive, with high recurrence rates. They are characterized by their large size, their encasement of the circle of Willis with possible infarction. They appear hyperintense on T2-W images, hypointense on T1-W images with cystic and solid components. The latter is intensely enhanced. Prognosis in children is worse than in adults.

GCTs, previously called granular cell myoblastomas or choristomas, are rare and benign tumours, considered WHO grade I glial neoplasms. They are usually diagnosed in the fifth decade and are twice as common in females than in males. In most cases, GCTs are asymptomatic. When symptomatic, the signs consist of visual disturbances, hypopituitarism, hyperprolactinemia, and headache. The appearance of GCT on MRI is non-specific, with an enhancing suprasellar or supra and intrasellar mass, which is isointense to grey matter on both T2- and T1-W sequences. Homogeneous or heterogeneous but intense enhancement is possible and reflects its high vascularity. Absence of the normal pituitary bright spot may be a clue for the neurohypophyseal origin, but this finding is not specific. Treatment for symptomatic GCT is surgical; postoperative radiation is controversial.

Germ cell tumours are discussed earlier [20].

Spindle Cell Oncocytomas

Spindle cell oncocytomas arise from the adenohypophysis. Visual disturbances, headache, and panhypopituitarism are the most common symptoms. Diabetes insipidus has never been reported. On MRI, they appear as intra- and suprasellar masses. It is difficult to distinguish them from pituitary adenomas or lymphocytic hypophysitis based on imaging features alone [20].

Perisellar Pseudotumours

Hamartomas of the Tuber Cinereum

Hamartomas of the tuber cinereum are not true tumoural lesions, but rather congenital malformations formed by the accumulation of normal neurons and glia in an unusual location, the tuber cinereum, located between the optic chiasm and the mammillary bodies. They are usually revealed by a very early precocious puberty, gelastic seizures; less frequently, the only clinical manifestation is a developmental delay in relation with isolated GH deficit or panhypopituitarism. There is no correlation between the clinical symptoms and the size of the hamartoma. On MR studies, the hypothalamic hamartoma appears as a round suprasellar mass, sessile or pedunculated. The size is variable, from a few millimetres to 5 cm in diameter. The signal is similar to that of grey matter on all sequences without enhancement after gadolinium injection (Figure 2.3.4.22). However, T2 hyperintense foci are occasionally seen in large hamartomas [21].

Aneurysms

Cerebral aneurysms are focal outpouchings of the wall of the cerebral arteries. They mainly develop close to the circle of Willis around the

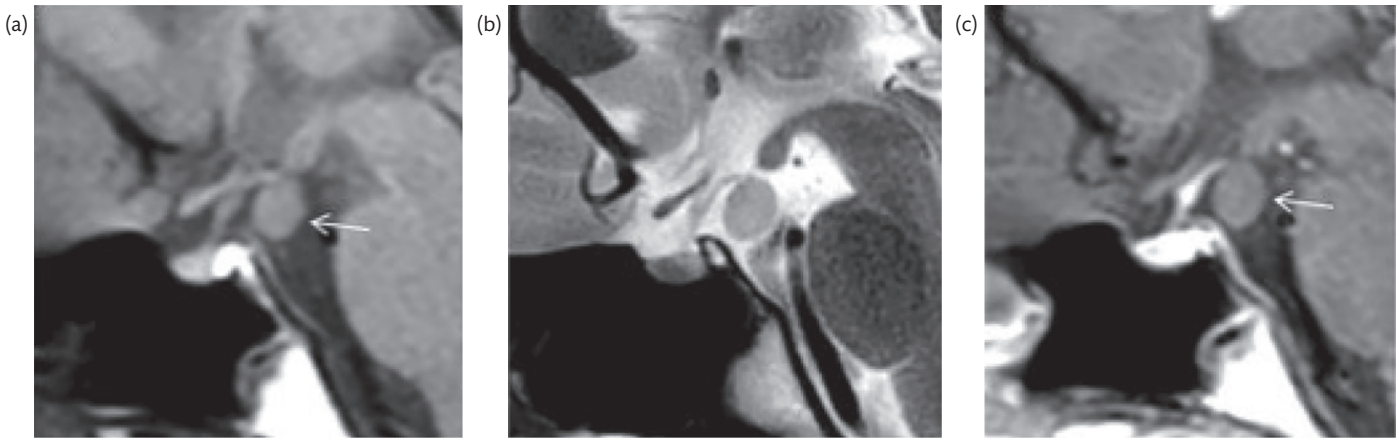

Figure 2.3.4.22 Precocious puberty in a 3-year-old male. Sagittal T1 (a), T2 (b) and T1 after gadolinium (c) W images. Large hamartoma of the tuber cinereum (arrow), between the optic chiasm and the mammillary bodies. No enhancement is noted.

sellar region and can be intra, supra, or laterosellar. They can exert mass effect on the pituitary gland, the stalk, or the cranial nerves or may be discovered incidentally. On MRI, they appear as well-delineated, round, hypointense lesions on all spin-echo sequences (Figure 2.3.4.23). They may enhance on gradient-echo sequences. Aneurysms may also be partially thrombosed, appearing heterogeneous on both T1- and T2-W images. An aneurysm may coexist with a pituitary adenoma incidentally or in a context of acromegaly in which the risk to develop an intracranial aneurysm is increased. When an aneurysm is suspected, it should be confirmed by magnetic resonance angiography before any biopsy or surgery [11].

Secondary Hypophysitis

Secondary hypophysitis can be due to systemic diseases (e.g. sarcoidosis, Langerhans' cell histiocytosis, Wegener granulomatosis) and systemic inflammatory processes and systemic infections (e.g. tuberculosis, syphilis). It can also be associated with a local process such as Rathke's cleft cyst rupture or with an autoimmune process in ipilimumab-induced hypophysitis.

Hypophysitis and Main Systemic Diseases

Systemic diseases affect multiple organs and sometimes associate sellar region involvement. They are numerous and encompass various autoimmune diseases, connective tissue diseases, granulomatosis, and vasculitis. They can be located within the anterior pituitary lobe and/or in the stalk or in the infundibulum or in the parasellar meninges, cavernous sinus, skull base, or neighbouring brain. The diagnosis is easy when the systemic disease is already known. Otherwise, the radiologist has to evoke the diagnosis on particular patterns suggestive of each disease. Here, granulomatous hypophysitis such as sarcoidosis, histiocytosis, or Wegener granulomatosis are detailed.

Sarcoidosis is a multisystemic granulomatosis, characterized by the presence of epithelioid granulomas, without caseous necrosis. Intracranial sarcoidosis lesions develop on the meninges, the brain, and the cranial nerves, with a predilection for the optic chiasm and hypothalamus-pituitary regions. Diabetes insipidus is the most frequent clinical symptom, followed by hyperprolactinemia and hypogonadism. On MRI, lesions of neurosarcoidosis are often multiple and diffused, affecting the

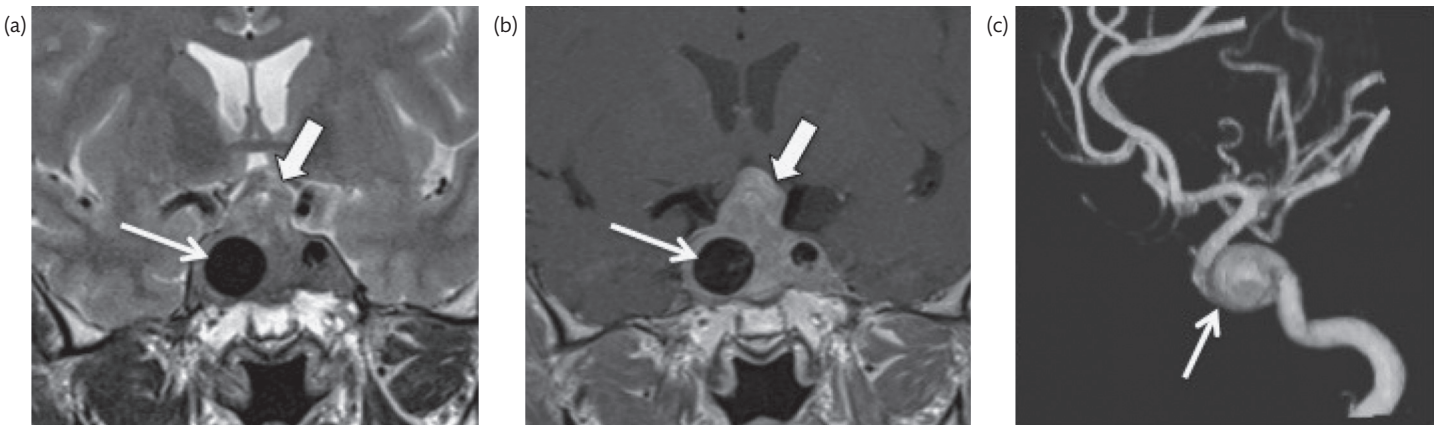

Figure 2.3.4.23 Right intracavernous internal carotid artery aneurysm with intra and suprasellar macroadenoma. Coronal T2 (a) and T1 spin-echo after gadolinium (b) W images. 3D volume rendering reformatted MRA(c). The aneurysm appears as a well-demarcated lesion within the right cavernous sinus and demonstrates marked hypointensity on T2 and T1 spin-echo after gadolinium W images (arrow). MRA confirms the flow in this aneurysm (arrow). Associated intra and suprasellar macroadenoma (thick arrow).

meninges, the brain, and the cranial nerves at variable degrees. In the sellar region they can involve the hypothalamus, the infundibulum, the stalk, the adenohypophysis, the cavernous sinus, and the optic chiasm. The micronodular or linear gadolinium uptake along the surface of the brain, with a predilection for the suprasellar area and the base of the brain is highly suggestive (Figure 2.3.4.24). Intracerebral and spinal lesions are also frequently observed. All these lesions are presumed to regress partially or fully under treatment with corticosteroids or other immunosuppressive therapy [22].

Langerhans' cell histiocytosis. Different types of histiocytosis are associated with tissue accumulation of histiocytes: Langerhans cell histiocytosis (LCH) and non-Langerhans histiocytosis. LCH mainly develops in children aged 1–5 years. It is a multiorgan disease that mostly affects the cranial region, liver, spleen, lymph nodes, and bone. It also touches the endocrine system, principally the hypothalamic-pituitary axis, with a predilection for the pituitary stalk, causing anterior or both anterior and posterior hypopituitarism: diabetes insipidus, hyperprolactinemia, hypopituitarism, and hypogonadotropic hypogonadism. The MRI can reveal the absence of the posterior pituitary bright spot with or without an associated suprasellar abnormality: stalk enlargement (Figure 2.3.4.25a), infundibular thickening (Figure 2.3.4.25b), small nodule, or large hypothalamic mass. As in sarcoidosis, such lesions exhibit T2 hypointensity, T1 isointensity, and a marked enhancement after gadolinium. A peripheral dark rim surrounding the adenohypophysis may be observed on T2-W images. This sign, described in lymphocytic hypophysitis, may be consistent with fibrosis. Specific additional lesions may help to evoke the diagnosis: supratentorial intra-axial masses and cerebellar hemisphere hyperintensity in all histiocytosis, infiltrative lesion in the pons and lytic lesions of the vault in LCH and intraorbital enhancing mass lesions and osteosclerosis of the walls of the sinus in Erdheim–Chester disease. Radiation therapy, chemotherapy, or a combination of both are usually proposed to patients with histiocytosis [23].

Wegener granulomatosis is a granulomatosis with polyangiitis (GPA) associating necrotizing small vessel vasculitis and giant cell necrotizing extravascular granulomas. It is known to involve the respiratory tract, the kidneys, and the ENT area. Pituitary involvement is usually a late manifestation causing diabetes insipidus and gonadotropin deficiency. MRI will reveal pituitary enlargement mimicking an adenoma, stalk thickening or loss of the posterior lobe pituitary bright spot [24].

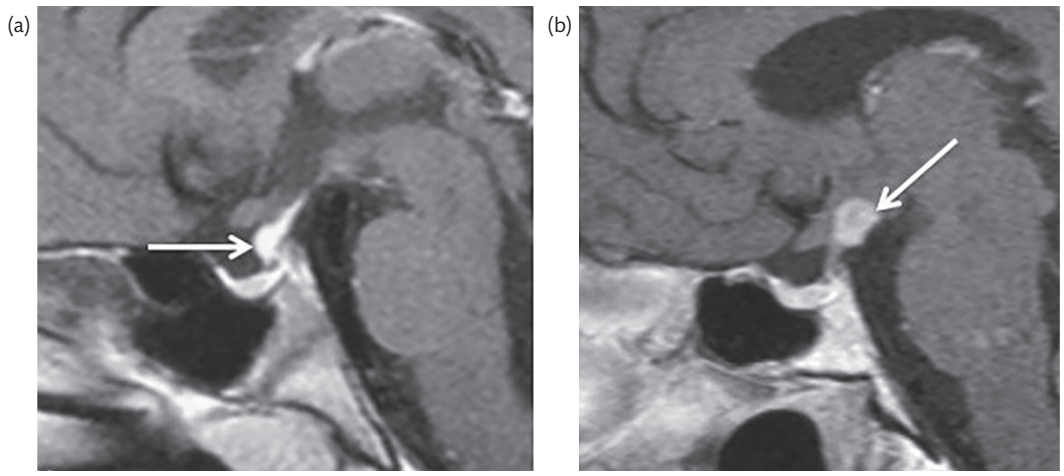

Figure 2.3.4.25 Histiocytosis in two different patients with diabetes insipidus. Sagittal T1-W images after gadolinium. Stalk enlargement (a), infundibular thickening mass lesion (b) which enhance homogeneously after gadolinium.

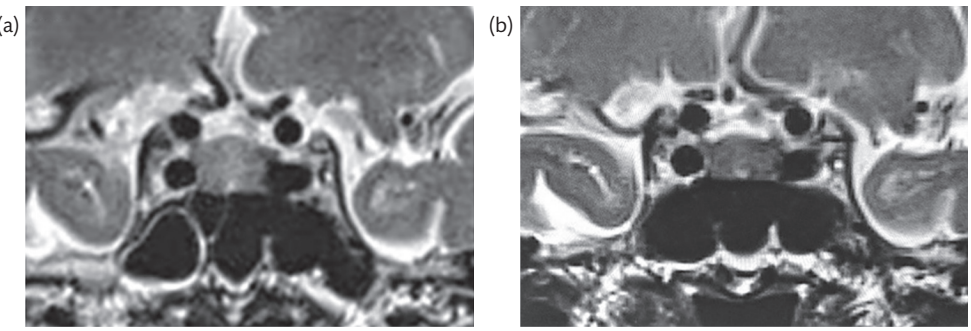

Figure 2.3.4.26 Immunotherapy induced hypophysitis in the acute phase (a) and one month after replacement therapy (b) on T2-W images. Enlargement and T2 hyperintense signal of the pituitary gland resolve quickly.

Ipilimumab-Induced Hypophysitis

Ipilimumab-induced secondary hypophysitis [25] is a newly described entity induced by administration of ipilimumab which is a human monoclonal antibody blocking cytotoxic T-lymphocyte antigen 4 (CTLA-4). This treatment is efficient in certain types of cancer, but with some side effects including enterocolitis, hepatitis, uveitis, dermatitis, arthritis, and different endocrinopathies such as hypophysitis that can lead to panhypopituitarism. MRI findings are not specific, characterized by a diffuse enlargement of the pituitary gland with homogeneous or less commonly heterogeneous enhancement. Follow-up imaging shows resolution after drug cessation, steroid therapy, and hormone replacement (Figure 2.3.4.26). Endocrinologists, neurooncologists, and neuroradiologists should be aware of the potential side effects of ipilimumab to induce immune-mediated hypophysitis [25].

Primary Hypophysitis

Primary hypophysitis comprises five histologic forms: lymphocytic, granulomatous, xanthomatous, necrotizing, and IgG4 plasmacytic. The two main types are lymphocytic and granulomatous hypophysitis. IgG4-related hypophysitis is a newer variant [26].

The role of MRI in primary hypophysitis is to eliminate the main alternative diagnosis of a pituitary mass, which is adenoma. Diffuse and symmetric enlargement of the pituitary gland is seen in **adenohypophysitis,** with frequent superior extension. This tumoural syndrome contrasts with a normal-sized pituitary fossa. Moreover, the pseudocapsule formed by the compressed normal pituitary gland is not seen after gadolinium administration. Signal intensity on T2- and T1-weighted images before and after contrast administration is usually homogeneous and intense but can be moderate and heterogeneous (Figure 2.3.4.27). A non-specific perisellar dural enhancement can be seen. Another more specific but later sign has been described in lymphocytic hypophysitis, appearing 2 to 20 months after the initial MR exam. It consists of a dark rim around of the gland and in the cavernous sinuses on T2-weighted images, due to fibrosis (Figure 2.3.4.28). Anterior pituitary atrophy with an empty sella is the common final outcome of adenohypophysitis. Thickened pituitary stalk and loss of the posterior pituitary bright spot on the precontrast images are seen in **infundibuloneurohypophysitis**. At a later stage, pituitary stalk thickening usually resolves and atrophy takes place, with slow decrease in size of the anterior lobe. However, recurrence of the stalk thickening can be seen. Loss of the posterior lobe bright spot is usually permanent. In cases of **panhypophysitis**, signs of both entities will be seen. Exploration of the brain and spinal cord is recommended, as it could show other signs that will help guide diagnostic orientation. Primary hypophysitis management

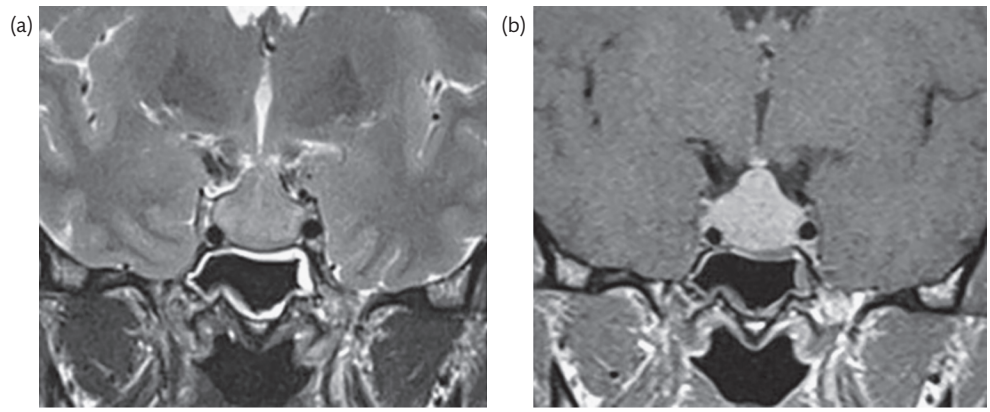

Figure 2.3.4.27 Primary adenohypophysitis. Coronal T2 (a) and T1 after gadolinium (b) W images. Diffuse and symmetric enlargement of pituitary gland in a normal-sized pituitary fossa with suprasellar extension and optic chiasm compression. The mass is slightly hyperintense on T2 with a homogeneous and moderate enhancement. No normal pituitary gland is seen.

Figure 2.3.4.28 Lymphocytic adenohypophysitis 6 months after acute episode. Coronal T2-W image. Hypointense encircling the pituitary gland.

should be done under clinical, biological, and neuroradiological supervision. The main differential diagnoses are pituitary adenoma and non-adenomatous pituitary masses such as germinomas, choristomas, and pituitary metastases and pituitary hyperplasia secondary to hypothyroidism.

Distinguishing primary hypophysitis from secondary hypophysitis is a diagnosis of exclusion. Investigations will have to rule out the numerous aetiologies cited earlier.

Pituitary Hyperplasia, Pregnancy, and Primary Hypothyroidism

The normal pituitary gland enlarges gradually during pregnancy because of oestrogen-stimulated hyperplasia and hypertrophy of prolactin cells. Its height increases linearly by 0.08–0.1 mm/week (i.e. by 3–4 mm at term) and can reach 10 mm during the last trimester and 12 mm in the immediate postpartum period, and approach the optic chiasm. At the same time, T1 signal intensity of the pituitary gland increases, particularly during the last trimester; this is clear when comparing the T1 signal of the anterior pituitary with that of the temporal white matter.

Pituitary enlargement in primary hypothyroidism in adults and children is rare, and can result from both acquired and congenital hypothyroidism. On imaging studies, pituitary hyperplasia is characterized by a spherical enlargement of the gland with suprasellar extension. The T2 signal can be slightly hyperintense; enhancement is homogeneous after gadolinium injection. Shrinkage of the mass occurs very quickly, as soon as a few weeks after thyroxine hormone replacement therapy [27].

Sheehan Syndrome

Sheehan syndrome corresponds to pituitary necrosis following severe postpartum haemorrhage and hypovolemia [28]. It may manifest itself very early after delivery, with headache and hypopituitarism responsible for lack of milk production immediately or some weeks later. More frequently, Sheehan syndrome is diagnosed years later. In the following days after the ischaemic infarct, MRI typically shows an enlarged, non-haemorrhagic pituitary gland, hypointense on T1-W images, heterogeneous with hyperintense foci on T2-W images and a peripheral enhanced rim. Afterwards, the pituitary gland becomes atrophic, making the passage of CSF within the sella possible, which leads to the so-called empty sella.

2.3.5 Hypopituitarism

Replacement of Adrenal, Thyroid, and Gonadal Axes

Miles J. Levy, Ragini Bhake, and Narendra Reddy

Adrenal Replacement in ACTH Deficiency

Choice and Timing of Glucocorticoid Replacement

Hydrocortisone, the generic pharmaceutical name for cortisol, is the standard form of glucocorticoid replacement for ACTH deficiency, and directly replaces the missing active hormone. Cortisone acetate was previously widely used, but is metabolized to cortisol to achieve its glucocorticoid activity, so that its onset of action is slower than hydrocortisone (a slight disadvantage) and biological half-life slightly longer (potentially a slight advantage).

The normal pattern of diurnal cortisol secretion is difficult to mimic precisely with oral therapy and there is no universal agreement regarding the appropriate dose, timing, and monitoring of hydrocortisone replacement, although the need for close attention has been highlighted. Cortisol diurnal rhythm in normal individuals is regulated by the suprachiasmatic nucleus in hypothalamus (the body clock). Cortisol rises between 03.00 hrs and 04.00 hrs, peaks within an hour of waking, falls over the day with a quiet period from 19.00 hrs, and nadirs at 00.00 hrs [1]. In addition to this diurnal variation, variable peaks of cortisol secretion (ultradian rhythm) may occur due to other factors such as in response to stress, meal, and exercise. There is currently no ideal glucocorticoid regime available to mimic this rhythm. The best approximation to this pattern is with hydrocortisone in three divided doses per day: 10 mg of hydrocortisone on awakening, 5 mg at lunch and 5 mg in the early evening [2]. This is widely believed to achieve 'physiological' plasma cortisol levels compared to a traditional twice daily regime, which usually results in very low cortisol levels in late afternoon before the evening dose.

Patients with ACTH deficiency may still experience symptoms of hypoadrenalism on hydrocortisone leading to development of two compounds namely, Duocort® or Plenadren® [3] and Chronocort® [4], purported to mimic normal circadian rhythm more closely. Plenadren® is a dual-release once daily hydrocortisone formulation (available in 20 mg and 5 mg tablets), currently available for prescription in the United Kingdom and rest of Europe. It has an immediate release coating with an extended release core obviating the need for midday dosing when taken first thing in the morning. It has been shown to reduce cardiovascular risk factors (weight, HbA1c, and blood pressure) and fatigue [5]. Its prime advantage, due to 20% lower bioavailability than conventional hydrocortisone, may include reduction in cardiovascular risk factors, although dose adjustment may be required. The main limitation however is same as that for hydrocortisone as it too can only be taken after waking. Chronocort®, on the other hand, with its pH-sensitive enteric coated modified-release multiparticulate hydrocortisone capsule formulation, is reported to have an edge in this regard, it provides an overnight cortisol rise and peak around awakening. It is taken twice daily, 20 mg at 23.00 hrs and 10 mg 07.00 hrs. The potential clinical advantage of this compound may be alleviation of early morning fatigue experienced by some of these patients.

Another potentially useful route of hydrocortisone administration, currently under evaluation, is continuous subcutaneous hydrocortisone infusion (CSHI) via a programmable pump [6]. This has been used with variable success, and needs more evidence and safety data prior to routine clinical use.

Some groups have advocated the use of low-dose prednisolone (3–4 mg daily) instead of hydrocortisone in patients with hypoadrenalism. Prednisolone has a longer half-life, given as a once daily preparation, and may have a comparable cardiovascular risk profile to hydrocortisone and provide better patient satisfaction [7]. The lack of widely available prednisolone assays for monitoring purposes along with reported adverse cardiovascular and bone health outcomes [8], has led to some concerns about the use of prednisolone, although this may simply be due to higher doses of prednisolone being used in these studies. Currently, it may be reasonable to use prednisolone 3–5 mg/day in patients who have difficulty in adhering to multiple-dose regimen, non-availability of hydrocortisone, or in patients who have a poor quality of life despite optimization of their hydrocortisone regime [9]. Dexamethasone should be avoided as a replacement glucocorticoid due to the high incidence of adverse glucocorticoid effects.

Assessment of Hydrocortisone Replacement

Conventionally, glucocorticoid replacement with hydrocortisone is monitored using plasma cortisol measurements at multiple times throughout the day—a hydrocortisone day curve (HCDC). Studies using frequent sampling for plasma cortisol have identified wide interindividual variations in plasma cortisol levels obtained after the same dose of hydrocortisone and highlighted the need for individual adjustment of hydrocortisone dose, but such frequent sampling is rarely possible or necessary in routine practice.

One such conventional practice is to monitor hydrocortisone replacement with a simple HCDC involving collection of a 24 h urine for free cortisol (UFC) on the day prior to the test, and three plasma cortisols during a day-case attendance [2]. However, this strategy is now not recommended as the practice was based on underpowered short term-studies; given lack of objective evidence, guidelines currently advocate basing hydrocortisone dose adjustments on clinical criteria alone [9, 10].

The criteria for deciding optimum hydrocortisone regimes are inevitably a compromise between theory, practicality, and patient convenience. A thorough history of patients' daily habits should be accounted for dose adjustments, including sleep timings, shift-working nature, dips in energy, daytime somnolence, and general well-being. Clinical markers of over-replacement are weight gain, insomnia, and peripheral oedema. Markers of insufficient replacement include nausea, lethargy, postural dizziness, weight loss, and lack of appetite.

Even thrice daily regimes fail to accurately mimic the normal physiological circadian rhythm of cortisol and attention has been focused on the differences in circulating cortisol levels overnight in patients on hydrocortisone replacement (where levels are low or undetectable throughout the night) compared to normal individuals (where levels rise substantially during the last hours of sleep). These differences would be hard to avoid using standard preparations of hydrocortisone, since few patients would be prepared to wake to take a tablet during the night, but certainly represent an unphysiological feature of current replacement regimes, may contribute to an overnight deficiency of a variety of metabolic fuels and is potentially an area where the newer delayed preparations described earlier, particularly Chronocort®, may have a role. For now, in practical terms, patients should be advised to take hydrocortisone as soon as possible after wakening to avoid prolonged activity with low circulating cortisol levels, and those who habitually wake in the early hours some time before rising might benefit from taking their hydrocortisone dose at that time. Patients with ACTH deficiency should not require mineralocorticoid replacement, since the renin-angiotensin-aldosterone axis is not disrupted by pituitary disease.

Replacement During Intercurrent Illness

During intercurrent illness, glucocorticoid replacement is mandatory, and doses need to be increased for all but the most minor illness in order to mimic the normal increase in ACTH and cortisol secretion, which occurs during stress and illness. Appropriate patient education on this aspect of replacement is a vital part of management of hypoadrenalism. Patients must be advised to double their normal oral dose of hydrocortisone during common pyrexial illnesses, and understand the need for parenteral glucocorticoid replacement if illness, operation, vomiting, or diarrhoea prevents the effective administration or absorption of oral glucocorticoid. Patients should seek medical advice if symptoms worsen in spite of increased oral hydrocortisone, should keep an 'emergency' ampoule of hydrocortisone at home, and if possible they or their family should be taught to give the injection if medical help is unavailable. Some patients also find a symptomatic need for increased glucocorticoid replacement during psychological stress, but this is much more difficult to define or regulate. During severe intercurrent illness or major surgery, immediate parenteral injection of hydrocortisone 100 mg (50 mg/m^2 for children) should be administered, followed by parenteral hydrocortisone 200 mg/day in divided doses every 6 hourly [9]. This regime is noted to provide consistent, high levels of circulating cortisol comparable with those found in normal individuals during such stress in cases of primary adrenal insufficiency. Some studies indicate lower hydrocortisone dose requirements (25–75 mg/24 hrs) in the first 24 hours after non-pituitary surgery, in secondary adrenal insufficiency. However, the former regime is recommended based on common practice, as it is the safer approach. Intravenous boluses of hydrocortisone produce wide swings in cortisol levels and are therefore less desirable, but stable, high plasma cortisol levels can be achieved by an intravenous infusion of hydrocortisone 5 mg/hr (preceded by a 25 mg intravenous bolus), although this is only appropriate in circumstances where an intravenous infusion can be reliably maintained and monitored.

Patient support groups have developed clear formatted guidance on replacement for intercurrent illness and during surgery and other procedures, which are readily available on the internet and useful for providing advice to patients and surgical colleagues [11].

In summary, following should be made mandatory for care providers in all healthcare settings dealing with steroid dependent patients:

1. Verbal and written patient education information should be provided about drug compliance, risk of hypoadrenal crisis, steroid sick-day rules, and emergency hydrocortisone injection technique at each clinical encounter.
2. Patients should be encouraged to carry an emergency card, wear a medical alert bracelet, or pendant, and carry a rescue-pack of hydrocortisone at all times.

3. Patients should be issued an emergency intramuscular hydrocortisone kit designed for self-injection; enquired if there is a need for reissue in case of expired ampoules; patient confidence and satisfaction with their injection technique should be ascertained at each consultation.

Adverse Effects of Hydrocortisone Replacement

It is challenging to balance adverse effects of chronic supraphysiological glucocorticoid exposure, which are serious and well known, against those of deficiency. In theory perfect physiological replacement should lead to no adverse effects, since circulating cortisol levels would be no different from normal subjects, but close attention to replacement doses is essential in order to achieve this.

Gross Cushingoid side effects and symptoms of severe hypoadrenalism are usually clinically obvious and most endocrinologists can avoid such extremes of inappropriate replacement. Minor degrees of over- or under-replacement may be clinically undetectable, resulting in morbidity (poor quality of life, cardiovascular risks, osteoporosis) or even mortality. Several studies support this view: glucose tolerance and insulin secretion alter with hydrocortisone replacement, and blood pressure rises with replacement therapy. The European Adrenal Insufficiency Registry data suggest that the type of glucocorticoid, dose, and regimen are very variable. One in eight patients are noted to be on hydrocortisone ≥30 mg/day, a cut-off level that increases the risk of endothelial dysfunction, higher arterial stiffness, poor quality of life, and dose-related high cardiovascular and metabolic consequences [12].

Therefore, if minor over-replacement caused slight worsening cardiovascular risk factors such as glucose intolerance, central obesity, or blood pressure, then this might be undetectable in an individual yet have a significant influence on overall cardiovascular morbidity. Studies of cortisol production rates using stable nucleotides show daily secretion of 5–7 mg/m^2, equivalent of 9–11 mg/day of hydrocortisone [13]. Unlike Addison's disease, where severe cortisol deficiency is noted, hypopituitary individuals often have some residual cortisol secretion. Hydrocortisone 10 mg am/5 mg pm regimen showed improved quality of life, beneficial cardiovascular profile secondary to weight loss (average 7 kg weight loss when reduced from higher doses), reduced arterial stiffness, and a more physiological nocturnal blood pressure dip. In summary, it appears the lower the hydrocortisone dose the better in terms of metabolic and cardiovascular risk. It may be appropriate to use doses of hydrocortisone as low as 10 mg/day in patients with partial adrenal insufficiency while monitoring for hypothalamic–pituitary–adrenal (HPA) axis recovery.

It is well recognized that bone health is adversely affected with overexposure of glucocorticoids. Increased incidence of vertebral fractures was noted in hypopituitarism individuals on hydrocortisone 30 mg/day dose, despite correction of gonadotrophin deficiency. Reduction of hydrocortisone to 15 mg/day showed increased bone formation and better bone remodelling ability [14].

In summary, there is a need to avoid even subclinical glucocorticoid over-replacement and aim for the lowest total dose of hydrocortisone replacement compatible with good health. Conversely avoidance of very low cortisol levels before the next dose seems advisable to minimize the risk of hypoadrenalism if intercurrent illness or stress occurs at that time.

Thyroid Replacement in TSH Deficiency

Choice of Replacement Therapy

The synthetic version of endogenous human thyroid hormone, levothyroxine is the routine replacement used for treatment of thyroid-stimulating hormone (TSH) deficiency. Its long plasma half-life (6–10 days) ensures stable levels of thyroid hormones on once daily administration, and conversion to T_3 *in vivo* results in appropriate blood levels of both T_4 and T_3. Liothyronine (T_3; triiodothyronine) can be used, but has no advantage in most circumstances, and may raise safety concerns due to elevated free T_3 levels indicating supraphysiological T_3 exposure. Combined T_4 and T_3 replacement and the use of 'natural' thyroid extracts has been advocated in print and on the internet by a variety groups, but clinical trial evidence is limited and where available suggests no benefit [15].

Commencing Levothyroxine Replacement

The starting dose and regime of levothyroxine replacement depends on the clinical circumstances. Prior to commencing levothyroxine, it is essential to know the status of the ACTH-adrenal axis since starting levothyroxine without glucocorticoid replacement in a patient with severe ACTH deficiency may precipitate a hypoadrenal crisis. If ACTH deficiency is present, hydrocortisone must be started before levothyroxine. Thereafter, many patients with TSH deficiency have serum free T_4 levels only slightly below the reference range, and in patients with such mild deficiency and no evidence of cardiovascular disease replacement can be simply commenced with a near-full replacement dose of levothyroxine 100 μg once daily. This dosage is comparable to the study that increased the dose from 1 mcg/kg/day to 1.6 mcg/kg/day, which led to weight loss, alleviation of hypothyroid symptoms, reduced body mass index (BMI), low density lipoprotein (LDL) cholesterol and serum creatine kinase levels. In patients with more profound reductions of serum free T_4, a lower starting dose of 50 μg daily, increased after a few weeks to 100 μg may be better tolerated. In elderly patients, or any patient with known cardiovascular disease—particularly ischaemic heart disease, more caution is required: in most cases a starting dose of 25 mcg will be well tolerated, increased slowly in 25 mcg increments over several weeks until the target dose is achieved.

Monitoring Levothyroxine Replacement

Defining the optimal replacement dose of levothyroxine in TSH deficiency is problematic, and little scientific evidence is available to guide the clinician. Unlike primary hypothyroidism, where serum TSH is a sensitive marker of under- or over-replacement, there is no biochemical marker to indicate precise physiological levels of replacement for an individual patient—indeed serum TSH may be low, normal, or even slightly elevated in untreated TSH deficiency. Therefore, instead of relying on 'reflex TSH strategy', adjustment is based on the clinical response and on measurement of circulating thyroid hormone levels, which are

limited by the very wide reference ranges in the normal population [16]. Serum free T_4 appears the most appropriate marker with which to adjust the levothyroxine dose and the conventional recommendation is to maintain free T_4 in the middle or upper part of the reference range for normal individuals, although this is certainly not 'evidence-based' and begs the question of the criteria used to define TSH deficiency since it implies that patients with pituitary disease (and indeed 50% of the normal population!) with a free T_4 in the lower half of the normal range might benefit from levothyroxine replacement therapy. Some workers have advocated using a levothyroxine dose based on body weight (1.6 μg/kg) but in doing so increased free T_4 levels close to the upper limit of the reference range.

On comparison of free T4 levels of secondary hypothyroid patients to that of patients with primary thyroid disease in our centre, it was found that TSH deficiency was substantially underdiagnosed and under-treated [17]. The twentieth to eightieth centile range for controls on levothyroxine was a free T_4 level of 14–19 pmol/L (normal range 9–26 pmol/L) in our laboratory (in general, middle third of the range) and we propose to use this as target range for replacement levels in TSH deficiency in future.

Ultimately, such controversies regarding appropriate levothyroxine replacement dosage and monitoring can only be answered by a controlled trial. In the meantime, a serum free T_4 anywhere in the middle centiles of the normal range when the patient is asymptomatic is accepted, with an option to move the free T_4 into the upper part of the reference range if the patient experiences symptoms suggestive of hypothyroidism.

Adverse Effects of Levothyroxine Replacement

Although thyrotoxicosis of the primary gland is a well-documented risk factor for osteoporosis, bone density remains normal even in patients on deliberate supraphysiological replacement with levothyroxine. However, thyrotoxicosis is also a risk factor for cardiovascular disease and, although there is no direct evidence of such adverse effects of levothyroxine replacement, the association of suppressed TSH levels and risk of atrial fibrillation in older patients in population-based studies indicates the need for caution to avoid unnecessary over-replacement.

Gonadal Steroid and Gonadotrophin Replacement in Gonadotrophin Deficiency

In the context of hypogonadism, consideration has to be given to both sex-hormone replacement and fertility potential, while accounting for individual's choice of route of administration, timing, social, and cultural beliefs. The beneficial evidence noted for sex-hormone replacement therapy in primary hypogonadism is extended to secondary hypogonadism, as there is a lack of direct evidence in the latter group. Unlike adrenal and thyroid replacement, replacement of gonadotrophin deficiency offers an extensive choice of gonadal steroid therapy for both sexes, and the choice of gonadotrophin or gonadotrophin-releasing hormone (GnRH) therapy if and when fertility is desired. In most cases, the choice between different treatment modalities is largely a matter of patient and physician preference rather than being 'evidence-based'.

Female: Choice of Replacement Regime

All female patients of premenopausal age with gonadotrophin deficiency require oestrogen replacement to maintain bone mass, to avoid vasomotor symptoms of oestrogen deficiency (hot flushes and night sweats), and to improve vaginal atrophy, urinary frequency and dysuria [18]. Cyclical progestogen is also essential in patients with an intact uterus to avoid endometrial hyperplasia and neoplasia; oestrogen alone suffices in women who have had a previous hysterectomy.

Oral

The choice of oral replacement is extensive, including all forms of oral oestrogen marketed for postmenopausal oestrogen deficiency and all combined oestrogen-progesterone contraceptive pills, with little or no objective evidence to choose between regimes. In younger women the low dose (20–35 mcg ethinyloestradiol) oestrogen-progesterone pill is often preferred since there are extensive data on its safety in long-term use in women of this age, particularly in context of hypogonadism. It may also be preferred due to its lower cost, and acceptability as in some cases taking the 'pill' may feel more 'normal' psychologically than taking hormone replacement therapy (HRT). 17-β-oestradiol containing preparations can potentially be monitored by blood oestrogen measurements, but this is unreliable with most preparations, therefore not recommended. Most preparations and regimes provide adequate levels of oestrogen to avoid effects of deficiency, and in an individual patient a regular menstrual withdrawal bleed is considered an adequate bioassay of oestrogen effect. When future pregnancy is planned it may be appropriate to monitor uterine size and endometrial thickness by ultrasound to ensure that the uterus is adequately oestrogenized.

Transdermal

A variety of transdermal oestradiol delivery systems are available—some of which also deliver transdermal progestogen. Gel preparations are available but have not been widely used.

Such regimen have the advantage of achieving near normal physiological levels of natural 17-β-oestradiol with administration of lower doses as they bypass the first pass metabolism and directly enter the blood stream. Disadvantages include skin reactions, unsatisfactory skin adherence in some patients, unacceptability due to visibility, and of increased cost of some preparations. This form of oestrogen replacement has advantages as first line in patients with complex pituitary disease since it avoids the effects of oral oestrogen on other hormone binding proteins and has less interaction with growth hormone replacement. Transdermal oestrogen may also be particularly appropriate in patients where direct hepatic effects need to be avoided (e.g. in rare patients who develop hepatic adenomas on oral oestrogen, or in young patients with known thrombophilia or previous thromboembolic disease). However, studies comparing the effects of oral combined oestrogen-progestin contraceptive pill and transdermal HRT in the context of central hypogonadism are lacking.

Risk-Benefit Analysis

In recent years large studies of gonadal hormone replacement in postmenopausal women have suggested that, although HRT

certainly reduces the risk of osteoporosis and probably bowel cancer, the increased risk of thromboembolism and cardiovascular disease at postmenopausal age means that the overall effect on health may be trending towards negative [18]. These conclusions do not however apply to younger women with oestrogen deficiency, including those with gonadotrophin deficiency, since the risk of osteoporosis is greater and the risk of cardiovascular events lower due to younger age. Indeed, it is now noted as previously hoped that oestrogen replacement reduces the risk of premature vascular disease and mortality [19]. Resolution of local and systemic symptoms of oestrogen deficiency provides additional drivers for routine oestrogen replacement in all gonadotrophin deficient women of premenopausal age. Balanced against these positive effects is a slight increase in risk of venous thromboembolism compared to the deficient state (which nevertheless remains a very low absolute risk), and mixed evidence on a possible slight increase in risk of breast cancer. In addition, some women will suffer from unwelcome cyclical changes similar to those that may be experienced in the normal cycle.

In the younger women the balance of risks seems overwhelmingly in favour of routine oestrogen replacement. In women of postmenopausal age, the choice of whether or not to take oestrogen replacement is ultimately no different to that in women without pituitary disease.

Male

Hypogonadism treatment in men has two goals: elevating testosterone levels to physiological levels, and induction of spermatogenesis. Androgen replacement therapy is usually aimed at improving libido, sexual function, energy levels, sense of well-being, muscle mass, reduce fat mass, reversal of anaemia and osteoporosis secondary to testosterone deficiency [20]. It is also used for inducing and maintaining secondary sexual characteristics. Caution needs to be exercised if planning for fertility within 6 to 12 months as exogenous testosterone suppresses spermatogenesis, which though reversible may lead to prolonged recovery of the hypothalamic-pituitary-testes axis for men aiming for non-assisted fertility success.

Choice of Replacement Regime

Intramuscular (IM) Depot Testosterone

Depot Testosterone ester preparations were the traditional form of androgen replacement, typically given as testosterone enanthate, 250 mg IM every 3 weeks (range 2–4 weeks) or mixed testosterone esters (Sustanon) IM every 3 weeks. These regimes are the cheapest preparations but do not mimic normal physiology, resulting in high or high normal levels of plasma testosterone in the days immediately following injection falling to low normal or subnormal levels before the next dose. Most patients will notice some changes in mood, libido, muscle strength or general 'drive' consistent with these hormonal fluctuations, which some find troublesome. The need for IM injections also usually necessitates regular visits to the surgery, which may be inconvenient, although occasionally patients may self-administer. Newer forms of testosterone replacement that have become available in recent years have become the preferred methods of replacement in many countries.

A depot preparation of testosterone undecanoate 1000 mg administered deep IM every 3 months (Nebido®) is a popular alternative, which gives more stable and physiological testosterone levels, achieved more rapidly if the second injection is given after 6 weeks. Timing of doses can be adjusted by measuring trough levels of testosterone prior to injection.

Oral

Testosterone undecanoate, a 17α-hydroxyl ester, is also active orally since its highly polar side chain and oily vehicle allow direct absorption into the lymphatic system bypassing hepatic metabolism. Its half-life is relatively short, and multiple daily doses are necessary—typically 40 mg, 2–3 times daily—but oral therapy is preferred by some patients. This preparation is not currently approved for use in the United States given weak efficacy, drug interactions, and gynaecomastia, nevertheless is available in some countries.

Other oral formulations of testosterone are either ineffective or have an unacceptable incidence of hepatic side effects and are no longer used.

Implant

Testosterone pellets (Testopel) can be implanted subcutaneously by trocar and provide stable testosterone levels, typically using testosterone 600 mg every 6 months. The need for repeated surgical procedures means that long-acting depots now largely supersede this form of replacement.

Transdermal

Transdermal gel preparations (typically 50 mg in 5 ml of 1% gel) have become increasingly popular in recent years [21]. They are available in a variety of formulations including sachet, tube, and pump dispenser—all of which have advantages and disadvantages in terms of convenience and ability to adjust doses. In each case the patient applies the gel to shoulders, arms, or abdomen after bathing or showering, typically first thing in the morning. Contact of gel, or gel treated areas, with females or children needs to be avoided. This form of treatment is convenient for many patients but can be problematic for individuals who need to wash or shower frequently.

Transdermal patch (Androderm) preparations are discontinued in United Kingdom; still available in some countries, but their use has been largely overtaken by gel preparations. The patch may cause troublesome skin reactions in 5–10% of patients.

All forms of transdermal therapy achieve physiological peak levels of testosterone and can even mimic the normal testosterone circadian rhythm and hence preferred by some endocrinologists.

Monitoring Androgen Replacement

Testosterone levels can be measured in blood on all forms of replacement and is generally aimed at mid-normal range as that of healthy male population. With conventional intramuscular depot, the majority advocate measuring levels one week after injection (which should be in the upper part of the reference range for normal individuals) and just prior to injection (which will usually be low normal); frankly subnormal levels prior to injection may indicate the need for more frequent injection, while very high peak levels may necessitate a reduction in dose. On the 3-monthly depot,

a preinjection nadir level is most informative, and should be at the lower end of mid-normal reference range. Testosterone levels 2–8 hours post-transdermal preparations' application should be in the mid-reference range. Random testosterone measurements are often low or low normal on oral testosterone undecanoate, but the short half-life makes these measurements less reliable, and dihydrotestosterone levels may be preferentially raised.

Sexual Function

Severe androgen deficiency causes a reduction in libido and erectile potency, which are normally restored by appropriate replacement therapy. In patients who have been hypogonadal for many years counselling of the patient and their partner will be necessary before starting therapy. However, a proportion of men presenting with sexual dysfunction will also be found to have testosterone levels in the borderline low range, without elevation of gonadotrophins, but with no other evidence of pituitary disease; improvement in libido and particularly potency is far less certain with replacement in these patients. Testosterone trials have shown that androgen replacement in 'age-related' hypogonadism may improve sexual function, bone density and anaemia but does not improve vitality or cognition [22].

Adverse Effects of Androgen Replacement Therapy

Randomized and open-label trials indicate that replacement dose testosterone in young men has a low frequency of side effects, but common drug-related side effects are acne, oily skin, and breast tenderness. Excess androgen replacement may cause polycythaemia, and this can also occur in elderly men, in chronic obstructive airways disease and in sleep apnoea with high normal replacement doses, so that haemoglobin levels need to be monitored in such patients. The possibility of long-term adverse effects on the prostate remains controversial. Hypogonadal men have lower prostate volume and prostate-specific antigen levels than the normal population, and induction of hypogonadism in patients with established prostate cancer induces temporary disease remission and reduction in prostate volume—thus raising the possibility that testosterone replacement might increase the incidence of prostate cancer and prostatic hypertrophy. While it seems likely that replacement will raise the incidence of these conditions to those of the normal population there is currently no evidence to suggest an absolute increased risk of either condition with appropriate replacement. In spite of this, and the current lack of evidence that screening for prostate cancer is beneficial in the normal population, some form of prostate monitoring is usually recommended in older men on testosterone replacement. One such strategy is to monitor serum prostate-specific antigen (PSA), with further necessity of urological evaluation only if PSA levels rise above normal, but some recommend repeated rectal examination and/or prostate imaging. Some clinicians advocate testosterone treatment in fully resected gland-confined cancer, rendered 'cured' with or without adjuvant therapy with normal PSA level for 2 years post-treatment. Lack of long-term outcome data to suggest that this strategy is safe is a limitation to make a general recommendation. Hence this warrants close liaison with Urologist and discussion with patient regarding benefits and risks prior to treatment commencement. The link between testosterone and cardiovascular events is controversial. Previous evidence to suggest that low testosterone itself may be associated with the metabolic syndrome and increased cardiovascular risk and that testosterone replacement may therefore be beneficial to cardiovascular health remains to be proven conclusively as to whether the low testosterone is an association or cause to effect relationship exists. Although number of metanalyses have examined the causal relationship between exogenous testosterone and MACE (major adverse cardiovascular events) and deaths in RCTs [23], given variety of limitations including heterogeneity, lack of CV events adjudication, different dosing and formulations, and so on, there are insufficient data to establish this causal link. Nevertheless, the Food and Drugs Administration (FDA) in United States following a citizen petition has mandated pharmaceutical companies to label their products with a warning about potential increased risks of CV events associated with androgen replacement whereas Medicines and Healthcare products Regulatory Agency (MHRA) and European Medicines Agency (EMA) have maintained that the evidence is inconclusive to mandate such warning.

Puberty Induction

Where gonadotrophin deficiency develops before puberty, special care is required to induce pubertal developmental at an appropriate speed in both sexes. Simply commencing full adult replacement doses will result in inappropriately rapid pubertal development with insufficient time for usual psychological adaptation, in less satisfactory secondary sexual development and in possible attenuation of the pubertal growth spurt and final height.

Gonadal steroid replacement is commenced in low doses in both sexes. In females, low doses of oral oestrogen (e.g. ethinyloestradiol 10 mcg daily, or even lower doses where available) or transdermal oestradiol (e.g. 25 mcg or less, twice weekly) is commenced at very low dose, and gradually increased to full adult replacement dosage over 2.5 years with eventual addition of cyclical progestogen [24]. Males may commence with testosterone enanthate 50–100 mg IM every 3–4 weeks for many months before increasing towards adult replacement dosage; similar low-dose regimes can be devised using transdermal testosterone or oral testosterone undecanoate but have not been widely accepted. Other factors sometimes require attention: girls with prepubertal panhypopituitarism may fail to develop pubic hair, and use of topical testosterone creams has been described if normal hair growth is desired; boys may need reassurance that pubertal gynaecomastia is common, and that normal adult facial and body hair develop slowly over many years once testosterone levels have reached the normal adult range.

Growth

Normal individuals show a pubertal growth spurt associated with gonadal steroids, particularly in males, yet gonadal steroids are also responsible for epiphyseal fusion and the cessation of linear growth. Appropriate adjustment of replacement doses of gonadal steroid and growth hormone are therefore essential in patients with hypopituitarism during induction of puberty. Overall, studies indicate that although early puberty (spontaneous or induced) reduces final height, deliberately delaying puberty induction to allow increased time for growth probably does not increase final height significantly, and may be associated with obvious adverse psychological consequences.

Fertility Induction

Gonadal steroid replacement does not induce fertility, but ovulation and spermatogenesis can be stimulated by therapy with gonadotrophin injections (initially human menopausal, now increasingly recombinant) or by pulsatile GnRH administered subcutaneously by infusion pump.

Female

The use of gonadotrophin therapy and pulsatile GnRH are both highly successful, resulting in fertility rates approximating normal levels with repeated cycles of treatment in expert hands [25]. GnRH therapy is mostly used where the gonadotrophin deficiency is considered primarily 'hypothalamic', but may also be successful in patients considered to have primary pituitary disease. As always, such therapy should only be undertaken with close biochemical and ultrasound monitoring of the ovarian response, and in centres with extensive experience of ovarian stimulation techniques, and precise description of treatment regimes is beyond the scope of this book.

Male

Gonadotrophin and GnRH therapy can both induce spermatogenesis, but induction of adequate spermatogenesis takes a minimum of 3 months and may require 1–2 years. luteinizing hormone (LH) therapy is usually used first in the form of human chorionic gonadotropin (hCG) typically 1000–2000 IU, 2–3 times/week which should result in adequate testosterone levels and may sometimes be sufficient to allow spermatogenesis, but follicle-stimulating hormone (FSH) activity is usually required for adequate fertility. A wide variety of regimes have been recommended with successful fertility in a majority of patients, which may occur at surprisingly low total sperm counts. Coexistent primary testicular defects (e.g. related to cryptorchidism) may cause failure of therapy. The need to wear an infusion pump or attend for regular intramuscular injections over many months may be a disadvantage, but self-administration of low doses of gonadotrophins subcutaneously may also be successful in both induction of fertility and increase in testicular size [26]. When pregnancy is achieved spermatogenesis may occasionally be maintained by testosterone replacement alone although usually continued or repeated gonadotrophin therapy is required. Sperm may also be frozen after successful treatment for use in future attempts at fertility.

Hypopituitary Crisis

Acute Hypopituitarism Crisis or Pituitary Apoplexy

An acute hypopituitary crisis or pituitary apoplexy, derived from the Greek word *apoplēxia* meaning 'striking away', is a potentially life-threatening condition due to acute ischaemic infarction or haemorrhage of the pituitary gland characterized by sudden onset headache, vomiting, visual impairment, ophthalmoplegia, and altered consciousness. Apoplexy is often the first presentation of a pre-existing pituitary tumour resulting in acute hypopituitarism causing haemodynamic instability, mainly due to ACTH deficiency. Prompt corticosteroid replacement along with intravenous fluids is vital to treat haemodynamic instability, followed by hormonal, radiological and visual status evaluation [27] as demonstrated in Figure 2.3.5.1.

Surgery versus conservative management for treatment of apoplexy remains controversial. A pituitary apoplexy scoring system using neuro-ophthalmic criteria to assess apoplexy severity to guide the management may be useful [28]. The majority of patients do well with conservative management, but need close monitoring of neurological and visual status, and surgical decompression is to be considered if neuro-ophthalmic signs persist or worsen.

Chronic Hypopituitarism Crisis or Pituitary Coma

Chronic hypopituitarism or pituitary coma is a rare, but life-threatening presentation of severe, long-standing, untreated hypopituitarism, usually precipitated by stress including infection, trauma, surgery, or infarction. Treatment is firstly full replacement with parenteral hydrocortisone, as described previously in this chapter, followed by correction of other factors which may precipitate or worsen coma including hypothermia, salt and water depletion due to hypoadrenalism and/or diabetes insipidus (DI), hyponatraemia due to excessive desmopressin or hypothalamic dysfunction and gradual replacement of hypothyroidism. Radiation-induced hypopituitarism may cause a hypopituitarism crisis if patients are suboptimally managed, as the time of onset of new pituitary deficiencies varies. In the majority of cases, this takes few years to develop, therefore requiring patient education of the symptoms to look out for, together with life-long monitoring and prompt treatment of deficiencies to avoid hypoadrenal crisis and/or death.

Interactions with Other Therapies

Steroid Replacement

Adrenal insufficiency can mask the presence of partial DI as glucocorticoid deficiency impairs free renal water clearance. Therefore, patients should be warned to look out for symptoms of polyuria and polydipsia when they are started on steroids. Typical examples are dexamethasone commencement following cranial radiotherapy for a variety of brain tumours, and hydrocortisone commencement for ACTH deficiency from pituitary radiotherapy or hypophysitis.

Drugs that induce hepatic CYP450 isoenzyme activity (e.g. many anticonvulsants, rifampicin, and so on) may modestly reduce prednisolone concentrations, requiring cautious dose increments in such circumstances. This effect is usually clinically insignificant in case of hydrocortisone, except in case of oxcarbazepine, which accelerates cortisol elimination via cytochrome CYP450 3A4 induction. Nevertheless, it is good practice to be vigilant for symptoms of under-replacement when such drugs are used.

Growth hormone (GH) suppresses the conversion of cortisone to cortisol, and concomitant GH replacement therapy has been shown to reduce cortisol levels in patients on a stable dose of hydrocortisone. This effect appears to be mediated by a reduction in levels of corticosteroid-binding globulin (CBG) and so it is important to look out for symptoms of hypoadrenalism after GH initiation, particularly in cases of partial ACTH deficiency.

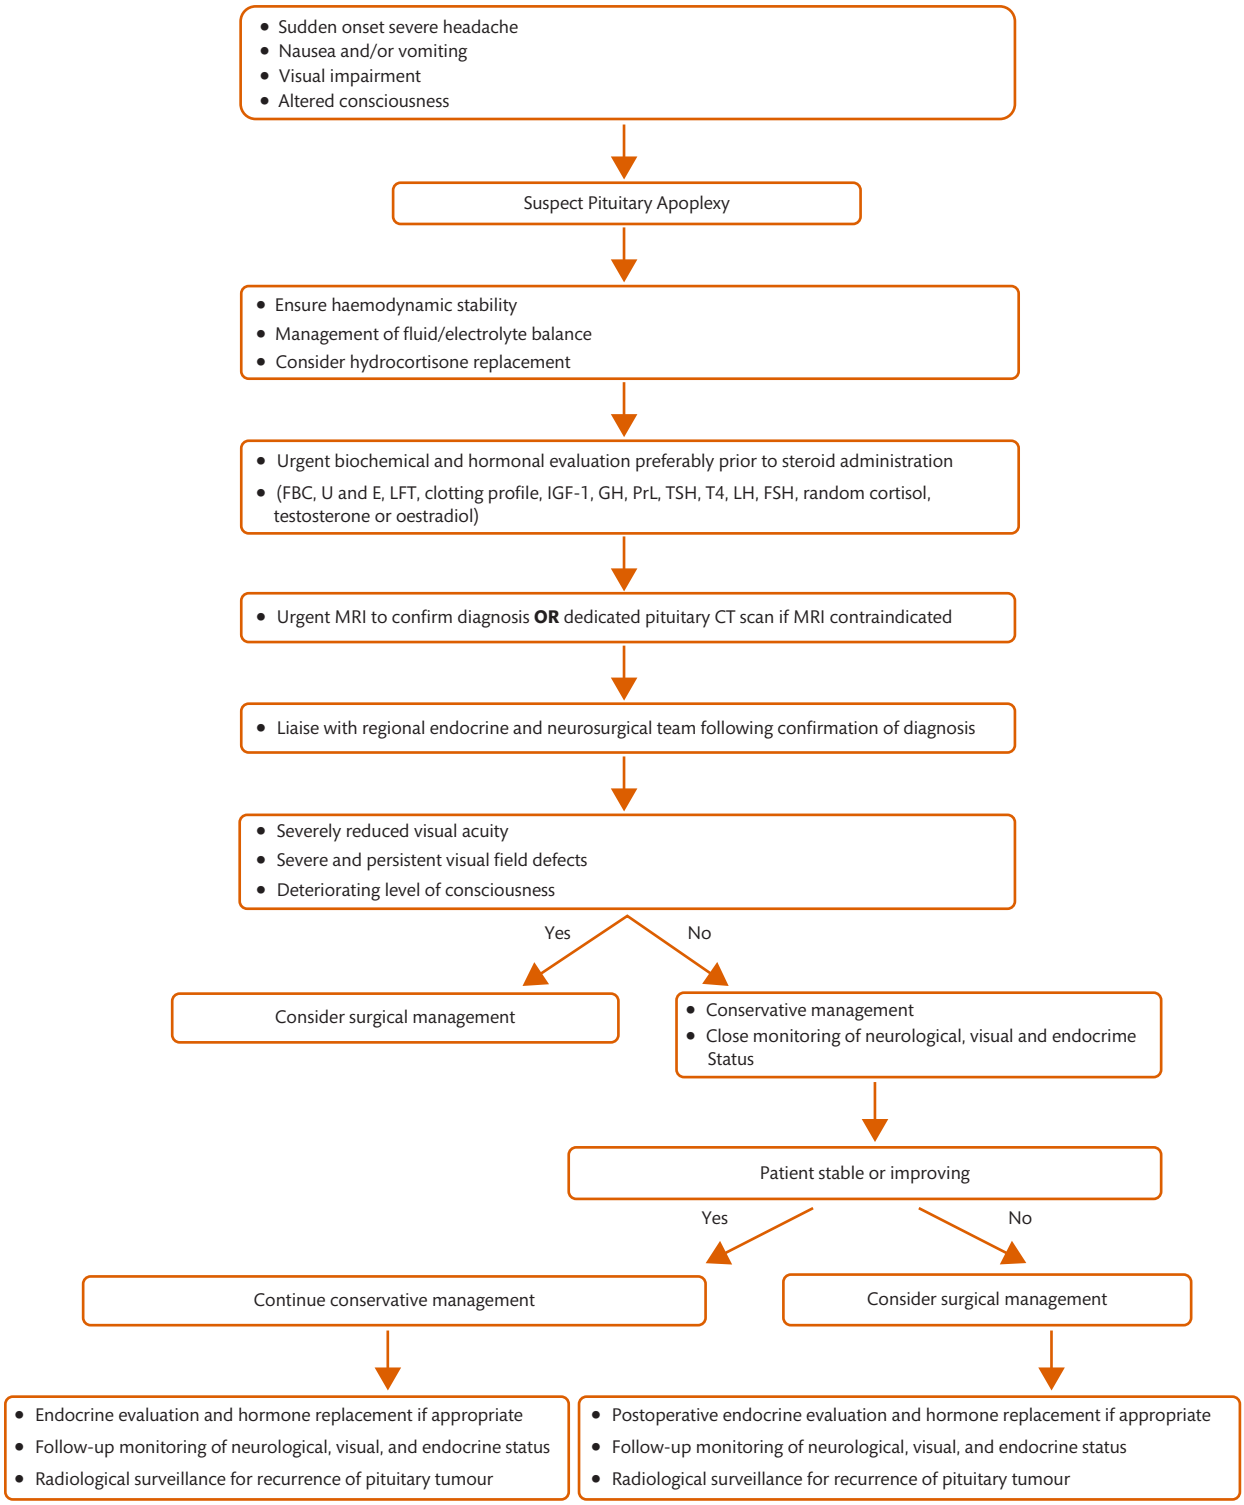

Figure 2.3.5.1 Algorithm for the management of pituitary apoplexy.

Thyroid hormone accelerates endogenous cortisol clearance and could unmask adrenal insufficiency, hence HPA axis should be assessed prior to commencement of levothyroxine to avert a hypoadrenal crisis [16].

Thyroxine Replacement

The simultaneous use of proton pump inhibitors or antacids, calcium carbonate, and ferrous sulphate may reduce absorption of levothyroxine and result in altered dose requirements. It is therefore advised to take levothyroxine on an empty stomach without any interference from food, beverages, or any other drugs for at least 30 minutes.

Administering GH in GH deficient individuals can reduce free T_4 levels thereby unmasking central hypothyroidism. Therefore, the hypothalamic–pituitary–thyroid axis should be tested prior to GH initiation. Central hypothyroidism should be fully treated prior to diagnosing GH deficiency.

Sex Steroid Replacement

Oral oestrogen increases CBG and in turn elevates total, but not free cortisol level but vigilance towards HPA axis re-assessment or hydrocortisone dose evaluation would be appropriate. This effect does not seem to apply to the transdermal route of oestrogen replacement. Similarly, oral oestrogen raises plasma total T_4 level by increasing thyroid-binding globulin. This does not influence active levels of thyroid hormone or change the necessary dose of replacement, but does make biochemical monitoring of thyroid reserve and/or replacement dose more difficult. It is therefore usually best to fully assess both thyroid and adrenal axes and/or optimize replacement levels before starting or during oral oestrogen therapy, or to use transdermal oestradiol as an alternative.

Oral oestrogen also causes a slight reduction in IGF-1 and rise in GH levels, which may require dose adjustment to concomitant GH replacement therapy in order to maintain IGF1 in the target range.

Special Circumstances

Management of Hypopituitarism in Pregnancy

Natural pregnancy in the context of hypopituitarism is rare because secondary hypogonadism resulting in infertility is quite common. Assisted Conception is often necessary, and with appropriate monitoring, women with hypopituitarism usually have an uneventful pregnancy.

Hydrocortisone is degraded by placental11-β-hydroxy steroid dehydrogenase 2, and hence does not cross the placenta, making it the preferred glucocorticoid of choice in pregnancy. Dexamethasone should not be used, as the placenta does not inactivate it. HPA axis is activated in pregnancy with a resulting twofold increase in total cortisol and eightfold increase in aldosterone [29]. Given that total cortisol levels are falsely 'normal' due to raised CBG, there is a danger of masking of frank adrenal insufficiency in the first trimester when clinical features may be mistaken for hyperemesis or that of normal pregnancy. A cortisol of <100 nmol/L with classical symptoms should raise suspicion of adrenal insufficiency. The ideal hydrocortisone replacement dose in pregnancy is not well defined and dose adjustment is largely based on clinical symptoms, but often the dose is increased as pregnancy progresses and may require an increase by 20–40% towards end of third trimester [29]. Parenteral hydrocortisone of 50 mg or 100 mg during second stage of labour, 100 mg at induction of anaesthesia, and subsequent 8-hourly 100 mg dosing for caesarean section is recommended [9].

Secondary hypothyroidism may not require levothyroxine dose escalation as done routinely for primary hypothyroidism in pregnancy. This is due to human chorionic gonadotrophin activating the inert thyroid gland, due to common α-subunit similar to TSH, to produce thyroid hormones, particularly in first trimester. It is advisable to dose adjust based on thyroid hormone levels which should be taken at 4 to 6 weekly intervals. Some clinicians advocate measurement of total T_4 as many free T_4 assays are found to be less precise in pregnancy, and local assay protocols should be evaluated to choose the preferred monitoring test. TSH is unreliable in secondary hypothyroidism, and is not helpful in this context.

Pregnancy may unmask mild DI as vasopressinase enzyme produced by the placenta can inactivate endogenous vasopressin (antidiuretic hormone, ADH). Hence there may be a need to increase DDAVP (i.e. desmopressin) particularly towards the end of pregnancy, and DDAVP is generally safe in pregnancy and for the baby even during lactation periods. The majority of guidelines advocate discontinuation of GH treatment due to lack of safety or efficacy data, but an observational study showed no harm with normal pregnancy outcomes on continuing GH in about 100 pregnancies [30].

Cancer Immunotherapy-Induced Hypopituitarism

A novel class of cancer immunotherapy with monoclonal antibodies targeting both T cell and tumour cells has been found effective in wide range of cancers. They enhance antitumour immunity by blocking negative regulators (checkpoints) on the T cell, and are therefore called immune checkpoint inhibitors (CPIs). The main checkpoints targeted are cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4) (ipilimumab and tremelimumab), programmed cell death-1 receptor (PD-1) (nivolumab and pembrolizumab) and its ligand PD-L1 (avelumab), resulting in improved survival rates in variety of cancers such as melanoma, non-small cell lung cancer, renal cancer, bladder cancer, non-Hodgkin's lymphoma among others [31]. Introduced since 2011, this class of immunotherapy has resulted in increasingly recognized autoimmune toxicities of various systems, including that of endocrine system. These side effects are called immune related adverse events (IRAEs) and the main endocrinopathies described are thyroiditis (15%), hypophysitis (9%), adrenalitis (1%) and type 1 diabetes mellitus (<1%) [32]. Typically, the onset of endocrine IRAEs following initiation of CPIs is between 6 to 12 weeks but the range can be from 3 weeks to as late as 3 years. Endocrine IRAEs have a slight male preponderance; often do not resolve on CPI cessation, particularly hypoadrenalism. The clinical features of CPI-induced hypopituitarism are similar to hypophysitis, although interestingly DI does not seem to be a feature. Identification and

treatment of individual endocrinopathies including hypopituitarism secondary to CPIs is the same as any other aetiology that causes isolated or combined endocrine pathologies [32], and is outlined in Figure 2.3.5.2.

Some clinicians believe CPIs should be discontinued if hypophysitis occurs, but current clinical practice is to continue with CPIs with the aim of malignancy regression. If there is evidence that vision has been affected by an enlarged inflamed pituitary gland, a pituitary MRI scan should be performed, and steroid immunosuppression started. Intravenous methylprednisolone is the usual steroid of choice and at the same time any hormonal deficits should be replaced. The mechanism by which CPIs induce endocrinopathy warrants further research as these new molecular targets and pathways may shed light on these old endocrine diseases, resulting in a better understanding of the pathophysiology of hypopituitarism.

Traumatic Brain Injury

Hypopituitarism following traumatic brain injury (TBI) has received increasing attention in the past few years. Evidence suggests that this is a significant cause of reversible morbidity in patients who may remain symptomatic for many years after the injury [33]. One or all of the pituitary axes can be deficient following TBI, and a high index of clinical suspicion is required in order to trigger appropriate testing and endocrine replacement. A summary of identification, treatment and monitoring of hypopituitary patients resulting from any aetiology including that of TBI is depicted in Table 2.3.5.1. It is good practice for endocrinologists to liaise with the specialist looking after patients with TBI in order to design simple endocrine screening protocols in this group of patients.

Patient Education and Participation

Pituitary disease is best managed in specialized centres possessing dedicated pituitary multidisciplinary team equipped with robust patient pathways and protocols. It has become almost necessary to mandate this, quite appropriately, given complexity of hypopituitarism, growing pituitary tumours, risk of pituitary apoplexy, desire for fertility, multiple comorbidities, polypharmacy, poor quality of life, and so on. Optimal management is only possible when the patient is fully aware of the nature and consequences of the disorder and can participate actively in the adjustment of replacement therapy. Patient education is therefore an essential part of management, and patients should also be encouraged to obtain further information and support from groups such as the *Pituitary Foundation* (UK) (https://www.pituitary.org.uk) or *Pituitary Network Association* (USA) (https://www.pituitary.org).

Table 2.3.5.1 Management of hypopituitarism

Pituitary axis deficiency	Clinical features	Diagnosis	Treatment	Monitoring
GH	Fatigue Reduced exercise capacity Decreased lean body mass/increased fat mass Muscle weakness Osteoporosis Hypertension Hyperlipidaemia Insulin resistance Impaired cardiac function Premature atherosclerosis Impaired sleep quality Depression	• Low IGF-1 • >11 score on AGHDA (Assessment of GH deficiency in adults) symptom questionnaire • Inadequate GH response upon dynamic pituitary testing: (a) Insulin tolerance test or Glucagon stimulation test (expected > 3–5 mcg/L depending upon BMI); (b) GHRH + Arginine test (expected > 4 mcg/L; obesity may blunt GH response)	Recombinant human GH	• IGF-1 in upper third of normal range of normal healthy population • AGHDA symptom questionnaire
LH/FSH Male	Fatigue Reduced exercise capacity Low libido Erectile dysfunction Hot flushes Infertility Pallor Loss of body hair Muscle weakness Osteoporosis Impaired sleep quality Depression	• Low testosterone • Low or inappropriately normal LH • Low or inappropriately normal FSH • Low sperm counts, morphology, and function	• Androgen replacement therapy • HCG, gonadotrophin	Fasting 08.00–09.00 serum Testosterone, PSA, Haemoglobin & haematocrit, Lipids, sperm analysis in context of infertility treatment
LH/FSH Female	Fatigue Reduced exercise capacity Low libido Hot flushes Infertility Vaginal dryness Pallor Loss of body hair Muscle weakness Osteoporosis Oligo/amenorrhoea Impaired sleep quality Depression	• Low oestradiol • Low or inappropriately normal LH • Low or inappropriately normal FSH	Oestrogen replacement until age of 50 years Cyclical progesterone combined with oestrogen if uterus intact Stimulation of ovaries with gonadotrophin, GnRH, assisted conception techniques for infertility treatment	Serum oestradiol level generally not useful
TSH	Fatigue Weight gain Cold intolerance Dry skin Pallor Loss of body hair Muscle weakness Reduced exercise capacity Dyspnoea constipation Oligo/amenorrhoea Infertility Hypertension Bradycardia Hyperlipidaemia Insulin resistance Impaired cardiac function Premature atherosclerosis Cognitive decline Osteoporosis impaired sleep quality Depression	Free T_4	Levothyroxine	Free T_4 in mid-range of normal healthy population

Table 2.3.5.1 *Continued*

Pituitary axis deficiency	Clinical features	Diagnosis	Treatment	Monitoring
ACTH	Fatigue Weight loss Reduced exercise capacity Cognitive decline Dry skin Pallor Loss of body hair Orthostatic hypotension Hypoglycaemia Impaired cardiac function Dyspnoea Anorexia Nausea/vomiting Diarrhoea/loose stools Osteoporosis Oligo/amenorrhoea	• Inadequate cortisol response (<500 nmol/L) on insulin tolerance test • 250 mcg corticotropin stimulation test 30 or 60 min cortisol response of <500 or 550 nmol/L depending upon the assay	Hydrocortisone Prednisolone	• Clinical features of excess: weight gain, insomnia, and peripheral oedema • Clinical features of insufficient replacement: nausea, lethargy, postural dizziness, weight loss, and lack of appetite
ADH	Polydipsia Polyuria/nocturia Clinical evidence of dehydration	• High serum osmolality • Low urine osmolality • Hypernatraemia • Hyperuricaemia	Desmopressin (DDAVP) nasal spray/oral/sublingual	Serum osmolality Urine osmolality Serum urea & electrolytes

2.3.6 Adult Growth Hormone Deficiency

Jens O.L. Jørgensen

Introduction

A growth-promoting activity of anterior pituitary extracts was discovered a century ago, and growth hormone (GH) was isolated in 1944 and tested in human subjects ten years after [1]. The protein anabolic and lipid catabolic effects of GH were documented in both children and adults, and it was hypothesized that GH replacement therapy in adults with hypopituitarism could be beneficial [2, 3]. Growth hormone for clinical use originally derived from human cadaveric pituitaries and the limited supply was restricted to treat hypopituitary children with severe growth retardation. The introduction of biosynthetic human GH enabled other indications such as GH replacement in adult patients with GH deficiency (GHDA).

The first placebo-controlled trial included young adult patients with childhood-onset GHDA in whom prior GH treatment discontinued several years before [4]. A significant increase in muscle mass and reduction in fat mass were recorded together with improved aerobic exercise capacity. The study also revealed a marked increase in the circulating and urinary levels of bone remodelling biomarkers [5, 6], increased extrathyroidal conversion of T4 to T3 [7], and increased sweating [8]. The second placebo-controlled trial comprised adult patients with adult-onset GHD due to a pituitary tumour and its treatment [9]. Lean body mass increased significantly after 6 months GH replacement together with a significant reduction in fat mass. This was associated with an increase in energy expenditure and exercise capacity. These pivotal findings were confirmed by numerous groups and led to the approval of GHDA as an indication for GH replacement.

Pathophysiology

It is important to emphasize that GHDA as a disease entity only exists within a clinical context of overt pituitary pathology. The reasons for this are several. First, GH secretion in the general population declines gradually as a function of age and adiposity, and the symptoms and signs of GHDA are unspecific. Second, even though diagnostic biochemical criteria exist, they are not sufficiently specific to exclude the diagnosis in elderly individuals with simple obesity. Third, a clinical benefit of GH replacement has only been documented in patients with a clinical history of pituitary disease [10].

One appropriate clinical context is a history of childhood-onset GHDA, which accounts for approximately 30% of GHDA. The cardinal symptom of GH deficiency (GHD) in childhood is longitudinal growth retardation and the underlying cause in this group is frequently idiopathic.

The second clinical context is adult-onset GHDA caused by a pituitary mass lesion or its treatment, of which pituitary adenomas constitute 70% (**Box 2.3.6.1**).

Box 2.3.6.1 Aetiology of GHDA

Cause

Adult-onset disease (70%):
Pituitary adenoma (40%)
Craniopharyngioma (8%)
Non-pituitary intracranial tumours (7%)
Other causes[a] (15%)

Childhood-onset disease (30%):
Idiopathic (15%)
Craniopharyngioma (7%)
Non-pituitary intracranial tumours (5%)
Congenital (3%)

[a] Including pituitary apoplexy, empty sella, Sheehan's syndrome, granulomatous disease, hypophysitis, irradiation, brain trauma.

GH is typically the first pituitary hormone to become deficient in response tumour pressure, pituitary surgery, cranial irradiation, or any other trauma [11]. Traumatic brain injury (TBI), which is a very frequent occurrence, may cause hypopituitarism, but the prevalence of permanent GHD after TBI is only 1% [12]. The annual incidence and the prevalence of adult-onset GHDA are approximately 15/million and 300/million, respectively [13].

Clinical Features

The syndrome of GHDA is used as a term to describe the clinical features and the effects of GH replacement [14]. The syndrome overlaps with the metabolic syndrome as regards visceral obesity, hyperlipidaemia, and atherosclerosis (Box 2.3.6.2). Moreover, premature cardiovascular morbidity and mortality are prevalent in GH-untreated hypopituitary adults [15, 16]. Untreated GHDA is accompanied by reduced total body water and extracellular fluid volume [17], which is reversed by GH replacement [18, 19]. Impaired thermoregulation in response to the ambient outside temperature [20] and during strenuous exercise [21, 22] are also present and partly attributed to reduced sweating capacity [8].

Insulin resistance, which is a hallmark of the metabolic syndrome, is not part of the GHDA syndrome, rather the opposite. GH antagonizes the effects of insulin on glucose metabolism in both the liver and skeletal muscle, which is causally linked to the lipolytic effects of GH [23]. Indeed, increased insulin sensitivity and reactive hypoglycaemia is characteristic of children with GHD, whereas the opposite is true for active acromegaly. The insulin-antagonistic effect of GH is rapidly reversible and in normal physiology, it operates in the fasting state, where insulin activity is low [24, 25].

Box 2.3.6.2 The clinical features of GHDA

Fatigue and impaired quality of life

Abnormal body composition:
- Increased fat mass, particularly central and visceral fat deposition
- Decreased lean body mass
- Decreased total body water

Reduced bone mineral density

Abnormal lipid profile and increased cardiovascular risk profile:
- Increased levels of total and low-density lipoprotein (LDL) cholesterol and reduced high-density lipoprotein (HDL) cholesterol
- Increased carotid intima media thickness
- Increased C-reactive protein levels

Impaired cardiac function:
- Reduced left ventricular wall mass
- Left ventricular systolic function

Decreased sweating

Reduced muscle strength and aerobic exercise capacity

Diagnosis of Adult GHD

In the absence of specific clinical indicators to discriminate GHDA from the normal population, the diagnosis is based on the results of biochemical testing within an appropriate clinical context [10]. For childhood-onset GHD, retesting in adulthood is necessary in patients with isolated idiopathic GHD, since spontaneous normalization of GH status is recorded in almost 70% [26]. Retesting is not required for those with an identified genetic cause and those with more than three pituitary hormone deficits.

Since GH is secreted in a pulsatile fashion, a single random GH measurement is only informative if a high value is incidentally encountered. Therefore, a stimulation test is necessary to perform. The insulin tolerance test (ITT) is the 'gold standard' but is contraindicated in patients with ischaemic heart disease or seizures [10]. Alternative tests include the glucagon stimulation test, GH releasing hormone (GHRH) with arginine, and GHRH with growth hormone-releasing peptide 6. The diagnostic threshold for the ITT and the GST is less than 3 μg/L. The response to GHRH + arginine is reduced in obesity, wherefore threshold levels stratified by body mass index (BMI) are recommended (Box 2.3.6.3).

The anabolic effects of GH are mainly mediated by insulin-like growth factor I (IGF-I), which is present in the circulation and not subject to diurnal fluctuations. In the absence of severe concomitant illness, a low serum IGF-I level is a strong predictor of GHD, but a normal serum IGF-I level does not rule out the diagnosis. Thus,

Box 2.3.6.3 Diagnosis of GHDA

Who to test
- **Only patients with a history of hypothalamic-pituitary disease:**
  - Adult-onset evidence of structural lesions and trauma
  - Adolescent and adult patients with childhood-onset idiopathic GHD

How to test
- **A single stimulation test is sufficient:**
  - Insulin tolerance test (ITT) is gold standard (cut-off: <3 μg/L)
  - Glucagon stimulation test if ITT is contraindicated (cut-off: 3 μg/L)
  - GHRH and arginine stimulation test if ITT is contraindicated (cut-off: <11 μg/L in normal weight patients; reduced cut-off in obese patients)
- **Patients with three or more pituitary deficits and a subnormal IGF-I level do not need a test**

Outcomes	No. of trials	Treatment		Weighted mean (SD) change (GH-placebo)
		GH	Placebo	
Lean B mass	19	473	474	2.82 kg (2.68)
Fat mass	13	352	345	−3.05 kg (3.29)
BMI	8	134	134	−0.12 kg/m^2 (1.40)
TG	11	202	203	0.07 mmol/L (0.36)
HDL Chol.	13	267	261	0.06 mmol/L (0.09)
LDL Chol.	13	255	248	−0.53 mmol/L (0.29)
Total Chol.	15	310	306	−0.34 mmol/L (0.31)
DBP	10	200	201	−1.80 mm Hg (3.77)
SBP	9	190	191	2.06 mm Hg (5.34)
Insulin	11	192	194	8.66 pmol/L (6.98)
Glucose	13	254	257	0.22 mmol/L (0.14)

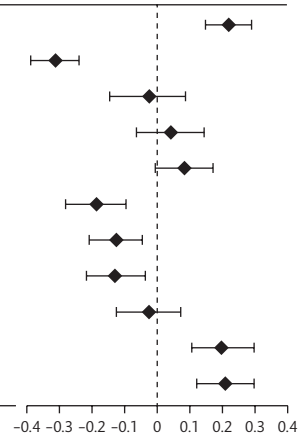

Figure 2.3.6.1 Results of meta-analysis of GH effects on cardiovascular risk factors *from Maison et al. (28).* Abbreviations: Lean B mass, Lean body mass; TG, triglycerides; Chol, cholesterol; DBP, diastolic blood pressure; SBP, systolic blood pressure; ns, non-significant.

in patients at high à priori risk of GHD, a subnormal serum IGF-I value may substitute for a GH stimulation test [27].

Effects of GH Replacement

Several meta-analyses of placebo-controlled trials of GH replacement in GHDA have been published on outcomes such as cardiovascular risk factors [28], muscle strength and exercise capacity [29, 30], bone mineral density [31, 32], body composition [33], and cardiac function [34] (Figure 2.3.6.1).

The studies confirm and substantiate beneficial effects of GH replacement on body composition, bone mineral density, cardiac function, and exercise capacity, as well as side effects attributable to fluid retention and insulin resistance [28, 33].

GHDA patients are highly sensitive to GH in terms of serum IGF-I generation and side effects [35], and male patients are more responsive to GH as compared to females [36, 37].

It remains an open question whether GH replacement therapy improves patient-reported outcomes such as quality of life (QoL) or cognitive function in the adult patient, since neither original studies nor meta-analyses provide unambiguous answers [33, 38–40]. Most QoL studies have utilized generic or disease-specific questionnaires, which mainly record and depend on the respondents' remembrance and it is possible that improvements in remembered QoL wane with time. It is interesting that the most compelling beneficial effects of adult GH replacement on QoL was recorded in a placebo-controlled crossover study, in which the spouse of the patient was asked to score the patient [41]. The National Institute for Health and Care Excellence (NICE) in the United Kingdom requires impaired pretreatment QoL in order to initiate adult GH replacement [42].

Transition from Childhood to Adulthood

Normal puberty marks the transition from childhood to adulthood and is dominated by the pubertal growth spurt and the development of secondary sexual characteristics and reproductive capacity. Muscle and bone mass increase markedly during the transition and depend in part on a marked physiological increase in GH secretion and action resulting in grossly elevated IGF-I levels [43] (Figure 2.3.6.2).

Serum IGF-I levels remain elevated 2–5 years after puberty suggesting additional physiological actions of GH on muscle and bone mass accrual.

Previously, GH replacement in childhood patients terminated when a target height was reached, but the availability of biosynthetic GH enabled continuation during the entire transition phase.

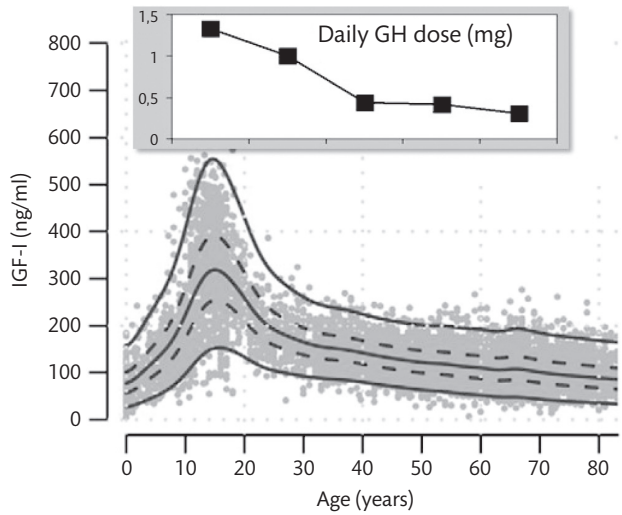

Figure 2.3.6.2 Serum IGF-I levels (2.5%, 50%, and 97.5% percentiles) as a function of age. The insert shows the corresponding daily GH dosage targeted to achieve a serum IGF-I level within the upper normal range.

A placebo-controlled study comparing continuation vs. discontinuation of GH in transition patients revealed that GH discontinuation result in decreased IGF-I levels and increased body fat, which reversed by resumption of GH therapy [44, 45]. Therefore, childhood-onset GH replacement should continue during the transition period and into adulthood, but it is important to retest GH status in the absence of either a genetic cause or additional pituitary deficiencies.

The Senescence

The decline in endogenous GH and IGF-I production with age [46] runs in parallel with senescent changes in body composition and physical performance (Figure 2.3.6.2). Interestingly, in mid-life adults, abdominal adiposity is the strongest and negative determinant of endogenous GH secretion [47]. These associations have led to speculations about a causal link between reduced GH production and the physical frailties of ageing, which has been coined 'somatopause'. This concept is dubious and a meta-analysis of GH treatment studies in elderly subjects without overt pituitary disease record only limited positive effects and a high prevalence of GH-related side effects [48].

Despite the age-associated decline GH secretion, GHDA patients aged 60–80 years have reduced GH and IGF-I levels compared to age-matched controls [49] and seem to respond to respond to GH replacement in the same manner as younger patients [50–52].

GH Dosing and Side Effects

The goal of GH replacement in GHDA is to correct the abnormalities associated with adult GHD with a minimum of side effects [27]. The daily starting dose of GH in young men and women are 0.2 and 0.3 mg, respectively, and in older patients 0.1 mg (Figure 2.3.6.2).

Serum IGF-I is a useful biomarker of GH replacement and the aim is to achieve a level within the upper half of the age-related normal range. GH is administered as subcutaneous self-injections in the evening. Quantification of body composition and bone mineral density by dual X-ray absorptiometry (DXA) should be considered on an individual basis, and body composition can also be assessed using anthropometric measures such waist to hip ratio or skinfold thickness, and bioelectrical impedance. Regular measurements of cardiovascular risk factors such as plasma lipids are also recommended, since they may be abnormal at baseline and modified favourably by GH replacement. Growth hormone replacement is considered life-long, but a trial of withdrawal can be considered if a patient perceives no benefit. In the United Kingdom, NICE advises that GH replacement should be discontinued in patients who fail to demonstrate improvement in QoL the first 9 months of therapy [42]. This recommendation, however, is pragmatic rather than based on evidence from placebo-controlled trails.

Oral oestrogen treatment suppresses hepatic IGF-I production and the GH dose requirement may change accordingly. GH replacement may modify the dose of levothyroxine or unmask incipient central hypothyroidism by increasing the peripheral conversion of T4 to T3 [7]. Finally, GH reduces the enzymatic conversion of cortisone to cortisol, wherefore GH replacement occasionally necessitates a dose increase of glucocorticoid replacement in a patient with concomitant adrenocortical insufficiency.

Reversible fluid retention is a frequent but reversible and dose-dependent side effect of GH replacement in GHDA. The mechanism involves sodium retention. Of note, this increase in hydration accounts for a part of the GH-induced changes in body composition [53]. The direct insulin-antagonistic effects of GH do not compromise glucose tolerance during physiological conditions, since endogenous GH levels are suppressed by food intake. Daily subcutaneous GH injections in the evening, however, is unable to fully imitate the endogenous GH pattern [54], wherefore GH replacement therapy may result in moderate elevations in fasting levels pf glucose and insulin [25] despite favourable changes in body composition [28].

Absolute contraindications for adult GH replacement therapy include active malignancy and proliferative retinopathy.

Although early pregnancy is not a contraindication, GH replacement is discontinued after the first trimester, where placental GH production sets in [27].

GH Replacement and Mortality

Increased mortality in hypopituitary patients due to cardiovascular disease is well established and has been attributed to unsubstituted GHDA [16, 55]. However, numerous underlying mechanisms may be equally—or more—likely, e.g. the underlying disease, treatment complications, and suboptimal substitution of additional pituitary deficiencies. It is also noteworthy, that mortality and cancer incidence are increased in acromegaly [56, 57], and epidemiological human studies suggest a U-shaped association between serum IGF-I levels and all-cause mortality in the general population [58]. Controlled studies of GH replacement therapy with mortality as an endpoint do not exist, but observational studies in GHDA suggest that mortality is reduced in GH replaced patients as compared to GH-untreated patients [55, 59–61].

Conclusion

Metabolic effects of GH were documented in hypopituitary adult patients more than half a century ago, and GH replacement in GHDA has been routinely used for 15 years. The change in body composition with reduced fat mass and increased lean body mass is the most robust effect, together with improved aerobic exercise capacity and cardiac function. Bone turnover is acutely stimulated and there is evidence to suggest increased bone mineral density (BMD) after prolonged GH replacement therapy. Whether this reduces the risk of osteoporotic fractures is uncertain, but observational studies suggest a reduced fracture risk [62]. The impact on QoL is less certain, since the results from placebo-controlled trials are ambiguous, and the results from open and observational studies are likely biased. Cancer risk is not increased with GH treatment, and mortality [63], if anything, is reduced [59, 60]. Side effects in terms of fluid retention and impaired insulin sensitivity are recognized, but are dose-dependent, rapidly reversible, and probably of limited concern. Nevertheless, caution is mandated to avoid overtreatment, not least of the elder patient.

2.3.7 Surgery of Pituitary Tumours

David L. Penn, Caroline S. Repetti, and Edward R. Laws Jr

Introduction

Among the numerous different pathologies, pituitary tumours represent the second most common primary brain tumour found in human beings, with an incidence of 10–15% [1, 2]. More interestingly, there exists an extremely wide variety of tumour types deriving from this small organ located in the anterior portion of the skull base, near the centre of the brain (Table 2.3.7.1). These neoplasms were recently re-classified in the 2017 World Health Organization Classification of Tumours of the Endocrine Organs [3]. By far the most prevalent type are the pituitary adenomas, a neuroendocrine tumour, which occurs with an incidence ranging from 14.4–22.5% [1, 4]. Pituitary adenomas fall into two general categories, functional tumours that present from hypersecretion of different hormone products and non-functioning tumours that present with symptoms caused by mass effect exerted on surrounding structures. Similar to non-functioning pituitary adenomas, there are a category of non-adenomatous tumours and cysts from and within the pituitary gland that present with symptoms of mass effect. Among the more common of these include craniopharyngiomas and Rathke's cleft cysts [2, 5–8]. Lastly, there are a number of relatively less common pituitary lesions that can present with various forms of hypopituitarism, such as adrenal insufficiency or diabetes insipidus, from destruction of the normal gland, or again from mass effect as the tumour grows and compresses the normal surrounding anatomy.

Table 2.3.7.1 Tumours of the sellar region

Tumours of the sellar region	
Neuroendocrine tumours	• Pituitary adenoma – Null cell adenoma – Gonadotroph adenoma – Somatotroph adenoma – Corticotroph adenoma – Lactotroph adenoma – Thyrotroph adenoma • Pituitary carcinoma
Non-neuroendocrine tumours	• Pituicytoma • Granular cell tumour • Spindle cell oncocytoma • Gangliocytoma • Astrocytoma (posterior pituitary)
Tumours of non-pituitary origin	• Craniopharyngioma – Adamantinomatous – Papillary • Meningioma • Chordoma • Langerhans cell histiocytosis • Metastatic tumour • Germinoma • Schwannoma
Cystic lesions	• Rathke's cleft cyst • Arachnoid cyst • Epidermal/dermoid cyst
Inflammatory lesions	• Lymphocytic hypophysitis • Granulomatous hypophysitis • Xanthomatous hypophysitis • Sarcoidosis
Vascular lesions	• Cavernous angioma • Aneurysm • Pituitary tumour apoplexy

Although a few pituitary tumours are managed primarily with medical or radiation therapy, for a majority of them, surgical resection still represents the first-line treatment [9–11]. The primary role of surgical management is for maximal safe resection and decompression of mass effect on the surrounding neurovascular structures, most importantly, the optic nerves and chiasm that course superiorly to the tumours that arise within the sella and extend into the suprasellar space. A secondary role for surgical resection is the removal of a hyperfunctioning pituitary adenoma. With the exception of prolactinomas, surgical resection remains the primary treatment modality for functioning tumours, such as suspected growth hormone (GH) and adrenocorticotrophic hormone (ACTH) adenomas [9, 11, 12]. These subtypes of tumours do not always present with symptoms of mass effect secondary to excessive growth, but will present secondary to the downstream effects of hypersecretion of their respective hormones: acromegaly and Cushing's disease, respectively. In these cases, to offer patients the best chance of remission from these syndromes caused by hormonal excess, it is imperative to attempt to remove the entirety of the tumour, balancing the risks of gross total removal with possible complications of an aggressive operation. Lastly, surgery of pituitary tumours plays a role in diagnosis of some of the less common tumour entities that have equivocal clinical and radiographic presentations. In this setting, biopsy and histopathological analysis can help guide clinicians to proceed with the most appropriate medical management or radiotherapies to achieve optimal patient outcomes.

Multiple different surgical approaches exist for operating upon pituitary tumours, often chosen based on individual surgeon preference, that include transcranial and endonasal approaches. The most common procedure for surgery of the pituitary gland is by far the endonasal transsphenoidal approach, using either the operative microscope or endoscope for visualization. Although some of the subtleties of these two techniques differ, both provide entry to the sella and the pituitary gland through the sphenoid sinus, minimizing retraction of normal brain and providing direct access to the pathology.

This chapter will discuss the indications, goals, and outcomes of surgical intervention for tumours of the pituitary gland, with particular focus on the most common tumour types. The role of multiple different surgical approaches in the treatment of pituitary tumours will be reviewed to provide both medical and surgical providers with an overview of how these different techniques play a role in delivering safe and efficacious treatment to patients affected with these lesions.

Clinical Presentation and Surgical Indications

Pituitary tumours can manifest in multiple ways, ranging from symptoms caused by mass effect on the surrounding, normal neurovascular structures and pituitary gland, as well as the plethora of symptoms and comorbidities from hormonal hypersecretion. For the majority of pituitary tumours, symptomatic lesions warrant surgical resection as first-line treatment, with the exception of prolactinomas, which are often successfully managed medically with dopamine agonists [9–12]. Given that the vast majority of pituitary tumours are benign, asymptomatic lesions, especially the pituitary adenomas and Rathke's cleft cysts, many can be managed

conservatively with interval neuroimaging studies [13]. Some more aggressive lesions, such as craniopharyngiomas, should undergo attempted gross total resection, even if they are asymptomatic; however, because of the relatively low incidence of these lesions, clinical guidelines have not been delineated and are a subject of continuing debate [14–17]. Lastly, any pituitary lesion where the diagnosis is unclear and may be amenable to medical management or chemo/radiotherapy may require surgical biopsy for definitive diagnosis.

Mass Effect

As lesions gradually grow in size, they can exert effects on the normal surrounding structures in the sellar and suprasellar space. Initially, as the tumour grows it can begin to stretch the surrounding dural layers, in particular, the diaphragma sellae, which can result in intractable headaches [18]. The pathophysiological mechanism for headaches is based on the fact that the dura has nociceptive fibres within its layers transmitting pain through the sensory distribution of the trigeminal nerve. Although pituitary patients can present with almost any type of headache, headaches caused by lesions arising from the sella are often referable to the frontal region or behind the eyes, and sometimes to the occipital region. Work up of any type of headache, including migrainous or tension-type headaches, can uncover a sellar lesion, but often these headache types are not believed to be related to these lesions. Headache can be a chief complaint of 16.0–62.1% of patients found to have non-functional adenomas [19–21].

Pituitary tumours can often cause neurological deficit as they exert pressure on the surrounding cranial nerves. In particular, the optic nerves that travel superiorly to the sella are at risk. Compression of the optic nerves classically can result in a bitemporal hemianopsia; however, based on the growth patterns of pituitary tumours and their relation to the optic nerves and chiasm many different types of visual field and optic nerve deficits can be detected. Bitemporal hemianopsia is the result of mid-chiasmal compression and classically progresses from the superior temporal fields into the inferior temporal fields as the chiasm becomes thinned and more compressed. Compression of the anterior chiasm can cause junctional scotoma and pressure on the posterior chiasm or optic tracts can cause an asymmetric homonymous hemianopsia. Of patients with non-functioning adenomas, up to 60% present with visual deficits [19–21]. In addition to visual field defects, patients can experience decreased visual acuity and loss of red-green distinction when the optic nerves are compressed. Pituitary tumours invading the cavernous sinus can compress cranial nerves III through VI which run within this venous structure resulting in complete or partial ophthalmoplegia or loss of facial sensation, or facial pain. Very large tumours can exert mass effect on the brain stem posteriorly or obstruct cerebrospinal fluid (CSF) flow causing obstructive hydrocephalus.

Compression of the normal pituitary gland by enlarging tumours can result in signs of hypopituitarism and is found in 30–40% of patients with non-functioning adenomas [19–21]. In general, gonadotroph dysfunction is the first manifestation of hypopituitarism causing decreased sexual function or libido in men or amenorrhoea in women. As more damage is done to the pituitary gland, thyrotrophic, somatotropic, and corticotropic function can be lost. It is very uncommon for pituitary adenomas to cause symptomatic compression of the posterior pituitary gland, resulting in diabetes insipidus (DI). Patients presenting with DI are more likely to have lesions originating from the remnant Rathke's pouch, such as craniopharyngiomas or Rathke's cleft cysts, or invasive pituitary tumours that cause destruction of the gland. Of patients found to have craniopharyngiomas, 17–27% can present with DI, which is less prevalent with Rathke's cleft cysts [16, 22, 23]. In contrast, one presentation of mass effect on the normal pituitary gland is hyperprolactinemia which is caused by interruption of inhibitory input from the hypothalamus through distortion or compression of the infundibulum as it travels from the hypothalamus to the anterior pituitary gland. Hyperprolactinemia often results in galactorrhoea and amenorrhoea in women.

Hypersecretion

There exist a number of subtypes of pituitary adenomas that produce hormone products causing elevated systemic levels of the hormone, most commonly somatotroph, corticotroph, and lactotroph adenomas, less commonly thyrotrophs and gonadotrophs. Somatotroph adenomas cause excess growth hormone levels and acromegaly. Symptoms of acromegaly include coarsening of facial features, increased hand or foot size, joint pains, skin tags, snoring, diabetes mellitus, hypertension, and cardiomegaly. Patients with corticotroph adenomas, or Cushing's disease, experience elevated levels of ACTH and cortisol causing central obesity, moon facies, thinning of the skin and easy bruising, joint pains, violaceous striae, increased susceptibility to infections, amenorrhoea in women, hypertension, osteopaenia, and diabetes mellitus, which can greatly affect quality of life and lead to medical morbidity and premature mortality [24, 25]. Lastly, lactotroph adenomas present with hyperprolactinemia, which, as previously mentioned, can induce galactorrhoea and breast tenderness in both men and women, amenorrhoea in women, and signs of hypogonadism in men. Although hyperprolactinemia can be a result of both a hypersecreting tumour and a tumour-causing stalk effect, serum prolactin levels in prolactinomas are generally considered to be much higher, with the existing literature claiming levels greater than 150 to 250 as pathognomonic [26–28] of tumour rather than stalk effect. In contrast to non-functioning tumours, hypersecretory tumours commonly present smaller in size and with fewer symptoms of mass effect. The symptoms caused by the clinical syndromes they produce are often detected and diagnosed before they grow to such a size.

Incidentalomas

With continually increasing utilization of imaging modalities for a multitude of symptoms, as well as improved resolution of these techniques, the incidence of incidentally discovered pituitary tumours is increasing [13]. Tumours that are small in size, do not show signs of imminent compression of the optic chiasm, and are determined to not be attributable to the patient's presenting symptoms can be managed conservatively, following them for clinical changes and interval neuroimaging studies to ensure that the lesion is not enlarging.

Pituitary Tumour Apoplexy

Pituitary tumours, in particular pituitary adenomas, as they grow can outstrip or compress their blood supply, causing the tumour itself to become necrotic and swell in size or to haemorrhage from defective tumour blood vessels. The occurrence of this phenomenon can result in a syndrome of acute onset, with severe headache, visual

loss, nausea/vomiting, and altered mental status, known as pituitary apoplexy [29, 30].

Although uncommon, this presentation represents a clinical emergency, requiring hormone replacement, especially of the adrenal axis, and when presenting with neurological deficit, such as visual loss or ophthalmoplegia, should be managed with emergent surgical decompression and resection of the tumour [31, 32].

Clinical Evaluation and Preoperative Planning

All patients with pituitary lesions should undergo a full endocrine laboratory panel to check for signs of hypopituitarism or for the presence of a potential functional pituitary adenoma. Serum prolactin levels should be performed with dilution to ensure that falsely low levels are not the result of the 'Hook Effect', a phenomenon caused by flooding of the detection assay with extraordinarily high prolactin levels. Patients with signs and symptoms of hypopituitarism should be managed appropriately with hormone replacement. A particular situation is when hypothyroidism or adrenal insufficiency is noted. Rapid thyroid repletion without regard to the cortisol status may increase metabolic stress and precipitate adrenal insufficiency which must be optimized preoperatively.

When feasible, non-urgent patients with clinical vision loss should undergo a full neuro-ophthalmologic evaluation to establish a preoperative baseline. Evaluation should include pupillary responsiveness, range of extraocular muscle movement, Humphrey automated perimetric assessment, and optical coherence tomography to assess thinning of the retinal nerve fibre layer.

As part of both the diagnostic and preoperative evaluation, all patients with suspected pituitary tumours should undergo high-resolution imaging. Although computed tomography (CT) can be helpful in the initial detection of pituitary tumours, and can be helpful in appreciating calcifications within the tumour to help determine whether the lesion may represent a craniopharyngioma, pituitary focused magnetic resonance imaging (MRI) is the ideal study (Figure 2.3.7.1). MRI of the brain with and without gadolinium and with high-resolution sequences through the sella provides the best anatomic delineation of the lesion and the surrounding normal structures, particularly the carotid arteries adjacent to the sella. This allows for improved surgical planning in order to determine the best surgical approach to safely remove the lesion in its entirety, as well as allowing surgeons to recognize obstacles such as a narrow intercarotid artery distance or the relationship between the tumour and the optic apparatus that could make surgery more challenging. Additionally, high-resolution sequences can be used with many computerized neuronavigation systems which allow surgeons to localize instruments and maintain orientation to vital structures in real time throughout the operation.

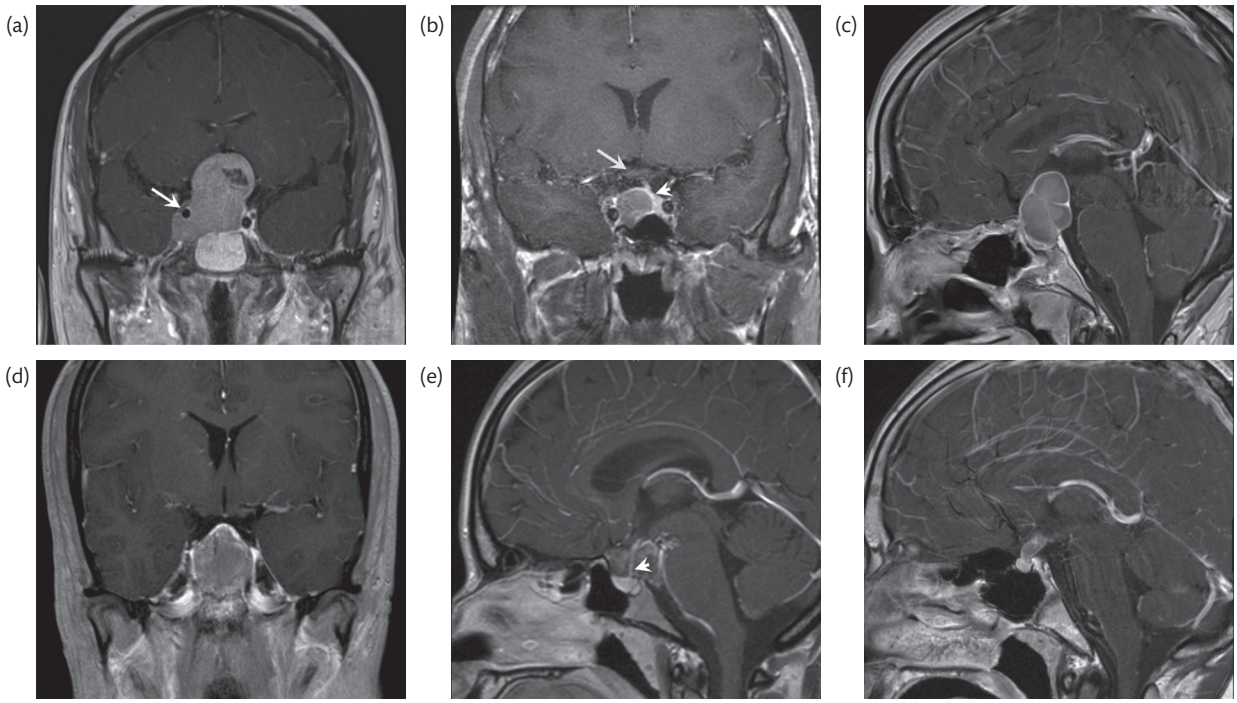

Figure 2.3.7.1 Contrast enhanced MRI Brain demonstrating a number of different pituitary tumours. (a) Shows a large homogenously enhancing gonadotroph adenoma with a hypointense cystic component representing prior haemorrhage. The lesion encases the carotid artery on the right (white arrow) and displaces the optic chiasm superiorly (which is not visible radiographically secondary to severe thinning). (b) Illustrates a somatotroph adenoma growing from the pituitary gland, displacing the normal gland to the left (white arrowhead). There is no compression of the optic chiasm (White arrow). (c) Reveals a large septated hypointense Rathke's cleft cyst causing compression of the optic apparatus and bitemporal hemianopsia. (d) Demonstrates a heterogeneously enhancing craniopharyngioma. The normal pituitary gland is not visible because it has been engulfed by the tumour. (e) Exhibits a heterogeneously enhancing, dermoid cyst in the suprasellar space, surrounding the infundibulum (white arrowhead). (f) Displays a hypointense lesion, expanding the pituitary stalk, with small punctate points of enhancement, consistent with suprasellar germinoma.

Surgical Approaches

There are two major groups of surgical approaches for lesions of the pituitary gland: transcranial and endonasal. Although the endonasal transsphenoidal approach is by far the most popular, there still exist indications and a role for transcranial surgery of the pituitary gland.

Transcranial Surgery

Transcranial surgery for the pituitary gland involves a scalp incision and creation of a craniotomy to access the pituitary gland in the sella. These approaches take advantage of fissures between the lobes of the brain and the subarachnoid spaces to avoid transgression through normal brain parenchyma. A number of common approaches used for transcranial surgery of the pituitary gland include the pterional craniotomy and its transsylvian approach, the cranio-orbitozygomatic approach accessing the pituitary gland via the subfrontal or transsylvian route, and bifrontal craniotomy via the subfrontal route [33, 34], and the so-called supraorbital subfrontal approach through an eyebrow incision. Transcranial surgery for tumours of the pituitary gland is most useful in lesions with extensive suprasellar extension. Examples include giant pituitary adenomas, craniopharyngiomas with invasion posteriosuperiorly within the third ventricle and/or hypothalamus, biopsy for tumours or lesions of the pituitary stalk, and recurrent Rathke's cleft cysts requiring resection of the cyst wall. The advantages of craniotomy for pituitary tumours include increased exposure and control of the major arteries of the circle of Willis and improved visualization for dissecting tumour planes away from major neurovascular structures that are more poorly visualized from an endonasal approach. The unique disadvantages of these approaches include increased risk to normal brain from retraction, and the need for a visible incision on the scalp; however, the overall risk of major neurovascular injury or mortality is approximately the same as with the endonasal approach.

Endonasal Transsphenoidal

This surgical approach involves exposing and entering the sphenoid sinus, and subsequently the sella through the nasal cavities (Figure 2.3.7.2). Enlargement of the opening in the sphenoid sinus allows access laterally to tumours that have invaded the cavernous sinuses, superiorly for tumours that extend to the tuberculum sellae, and inferiorly to the clivus for tumours invading the clival bone or with extension to the pons. This approach allows for removal of very large lesions given that they tend to arise from within the sella. As they grow, they tend to extend superiorly, displacing normal anatomy. In particular, pituitary adenomas, as well as Rathke's cleft cysts, have a very soft and sometimes liquid consistency that allows relatively easy removal from the smaller cranial opening created by transsphenoidal surgery. The tumour can then be separated from the normal surrounding gland using a number of blunt curettes, minimizing damage to the surrounding normal gland. Further advances in the transsphenoidal technique have allowed for effective resection of the more solid and adherent tumours; however, preoperative imaging should be carefully studied for appropriate selection of these cases to ensure that the tumour can be removed without significant risk to the surrounding neurovascular structures, such as the cranial nerves and carotid arteries. For instance, retrochiasmatic craniopharyngiomas with suprasellar extension, tumours arising superiorly to the chiasm from the infundibulum, and giant pituitary adenomas with growth into the temporal lobe, should be considered for a transcranial approach to avoid crossing these vital structures with instruments, placing the patient at risk for a major complication.

The endonasal transsphenoidal operation can be performed with the operating microscope or endoscope (2D or 3D) for visualization. Both techniques place the surgeon at the face of the sella, operating through the nasal cavities; however, there exist subtleties in the steps of the procedure and the visualization offered between the two. Performing the procedure with the operating microscope involves placement of a nasal speculum along the perichondral surface of the septal mucosa. The speculum is placed within the sphenoid sinus at the face of the sella, and opened to enter the sinus and provide appropriate exposure. With the speculum in place, the microscope offers a lighted but necessarily narrowed corridor to the sellar opening. Technically, there are a few disadvantages with this approach, such as a smaller field of vision, limited illumination, and collision of instruments with the microscope in place. When using the endoscopic approach, the endoscope is placed through the nasal cavity and the posterior bony septum is removed posterior to anterior. The sphenoid sinus is opened and then subsequently the sellar floor is removed. Disadvantages with the 2D endoscopic approach include decreased three-dimensional perspective when operating while looking at a two-dimensional monitor; however, this disadvantage is mitigated by the use of three-dimensional endoscopes [35]. Advantages to the endoscope include improved illumination with the light source at the tip of the camera and panoramic visualization with the image coming directly from the operative field. Furthermore, advances in technique using the endoscope have allowed for the development of extended endoscopic approaches with more access to the anterior and middle skull base, allowing for the removal of larger and more extensive and invasive tumours than previously.

Both approaches are safe and effective for the resection of appropriately selected pituitary tumours. The use of the operative microscope or the endoscope has become largely one of surgeon preference, recognizing that there is a lack of Level I evidence to prove the superiority of one technique over another. Studies comparing the two techniques in patients with pituitary adenomas have shown no statistically significant differences in outcomes, including extent of resection, endocrinologic function, visual improvements, and postoperative CSF leak rates [35–38]. Similar results were found comparing techniques in patients with secretory tumours, such as ACTH adenomas, as well as similar remission and recurrence rates [39].

Postoperative Care

Patients undergoing surgery for pituitary tumours have a number of unique considerations relating to the immediate postoperative period. At our institution, patients undergoing transsphenoidal surgery are transferred to the postoperative anaesthesia unit and then our neurosurgical floor, while patients undergoing transcranial surgery are monitored in the intensive care unit. Neurological status,

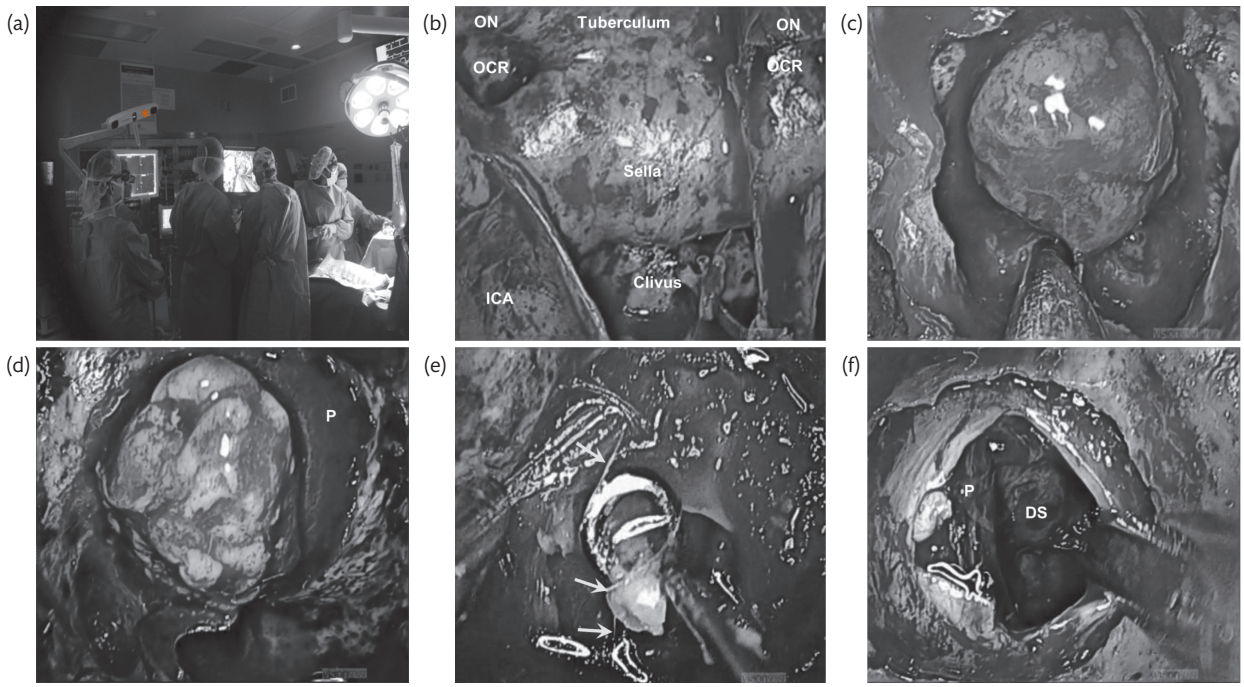

Figure 2.3.7.2 Intraoperative photographs. (a) Demonstrates the operative team at our institution and the set-up of the operating room. With an assistant holding the endoscope through a binostral approach, the primary surgeon can use bimanual technique to perform the operation. The monitor for the endoscope is positioned directly in front of the surgeons with the neuro-navigation system (orange asterix) to the left and the instrument table and nursing team to the right. (b) Exhibits the face of the sella and relevant anatomy. ON, optic nerve; OCR, opticocarotid recess; ICA, internal carotid artery. (c) Shows the removal of a gonadotroph macroadenoma. Intracranial pressure aids in tumour removal pushing the tumour out of the sella and down from the suprasellar space. (d) Illustrates resection of a right-sided, somatotroph adenoma. Note the classic, white appearance of the tissue and the normal pituitary gland (P) on the right. (e) Shows resection of a suprasellar dermoid cyst using blunt curettage. The classic fatty, white appearance of the contents is shown, as well as a number of hairs growing within the tumour (white arrows). (f) Shows the resection cavity once the tumour has been removed. Prolapse of the diaphragma sellae (DS) is a good sign that the nerves superiorly have been decompressed. Normal pituitary gland (P) can be observed on the right.

in particular visual fields and acuity, is monitored closely for signs of changes.

One of the primary concerns following pituitary surgery is the development of either DI or the syndrome of inappropriate antidiuretic hormone secretion (SIADH). During the initial postoperative period, strict fluid intake and output measurements are recorded, and patients undergo regular serum sodium evaluations and urinalysis for determination of specific gravity. Mild DI is managed conservatively with oral fluid replacement, as this is often temporary and self-limited. Patients with more severe DI or DI that is significantly interrupting sleep are treated with oral or IV desmopressin that is titrated to the patient's symptoms. Signs of SIADH, as indicated by progressive decreases in or less than normal serum sodium values are managed with strict fluid restriction. In severe cases, hypertonic 3% saline may also be administered. Patients are at highest risk for SIADH between postoperative days 2 and 10 [40]. Because our patients are normally hospitalized for two to three days, we prophylactically discharge patients on a 1 L per day fluid restriction, which has brought our hospital readmission rate for hyponatraemia to zero [41].

Patients with preoperative laboratory evidence of adrenal insufficiency receive steroid replacement at the time of surgery with hydrocortisone. Hydrocortisone is then tapered to physiological levels over the next few days. The total duration of hydrocortisone replacement is determined based on the clinical and biochemical severity of adrenal insufficiency and need for replacement. Conversely, patients not requiring steroid replacement are monitored daily with fasting morning cortisol levels to ensure that hypopituitarism does not develop as a complication of the operation.

After discharge from the hospital, patients return to the office, one week after their procedure, for a serum sodium check, as well as potentially other short-term laboratory studies that may affect clinical management, such as fasting morning cortisol. At 6 weeks postoperatively, patients return for follow-up with a full endocrine panel and at three months for a postoperative MRI of the brain, to assess the extent of tumour resection and to establish a baseline for annual routine imaging going forward.

Outcomes

Overall, the surgical management of pituitary adenomas is successful in relieving symptoms of mass effect, such as headache and visual loss, as well as achieving control of symptoms from functional tumours, with acceptable morbidity and mortality. In patients with non-functioning adenomas, relief of symptoms caused by mass effect are reported as high as 90% [19, 20, 42–46]. Restoration of normal pituitary gland function has been reported as high as 48% [31, 47, 48]. Furthermore, one study demonstrated superiority of the transsphenoidal approach in improving and preserving pituitary function [49]. Although surgical intervention provides excellent results for symptoms of mass effect, functional adenomas can be

more complex, since relief of symptoms and achievement of lasting remission may require removal of every single hyperfunctioning cell, which can be extremely difficult for aggressive and invasive tumours. Despite the challenge, surgery is still effective for Cushing's disease, with initial remission rates reported as high as 95% in selected cases, and acromegaly, with remission rates as high as 70% [50–55]. Recurrence rates can be affected by multiple factors, including extent of resection, mitotic index, invasiveness, tumour type, and the number of prior procedures; however, for pituitary adenomas, the rate of recurrence is generally accepted to be approximately 10% at 10 years, with ACTH adenomas being among the more challenging, with long-term recurrence rates approximating as high as 30% [20, 56–60].

Outcomes for other common tumour types, such as craniopharyngiomas, are more complex. Similar to pituitary adenomas, surgery is effective for relief of symptoms caused by mass effect. Rates of visual improvement have been reported to be as high as 69.2% [61, 62]. Because of the tumours' intimate association with the pituitary gland, infundibulum, and hypothalamus, the rates of pituitary gland preservation are lower, as evidenced by the rates of DI being reported as high as 93% [14, 23, 61, 63]. In some cases, in order to achieve definitive resection of the tumour, the infundibulum must be sharply divided which can result in panhypopituitarism. Dissection of the tumour from the hypothalamus can also result in hormonal dysfunction and subsequent obesity, especially in paediatric patients [61, 62, 64]. In addition, the extent of resection greatly influences recurrence rates. Following subtotal resection, ultimate progression rates can be as high as 90% [61, 65].

Complications

Although complications exist in transcranial and endonasal approaches for pituitary surgery, the notable complications in transcranial surgery are neurovascular injury to surrounding structures, which is common to many neurosurgical procedures. Severe complications associated with endonasal transsphenoidal surgery include injury to the major vasculature, most commonly the internal carotid arteries that lie laterally to the pituitary tumour. When performing extended approaches for larger pituitary tumours, other vessels can be damaged including the basilar artery or any of the vessels comprising the circle of Willis; however, this is much less common. In addition, damage can occur to the cranial nerves that course adjacent to the sella, primarily the optic nerves that lie superiorly. Visual loss occurs secondary to a number of mechanisms, including direct injury from dissection of the tumour, haemorrhage, overpacking of closure material, or devascularization of the nerves from the minute vessels originating from the superior hypophyseal artery. In addition to visual loss, ophthalmoplegia or facial numbness can occur when dissecting tumours from the cavernous sinus. Other complications that can occur include infection/meningitis, epistaxis, and chronic sinusitis. One large series of 506 patients undergoing transsphenoidal surgery for non-functioning adenomas revealed an overall complication rate of 9.1%, with the most common complication being CSF leak and severe complications such as visual loss or vascular injury being less than 1–2% [66].

In addition to neurovascular injury, the normal pituitary gland can be damaged when attempting to remove pituitary tumours. Temporary or permanent dysfunction of the anterior and/or posterior pituitary gland may occur resulting in hypopituitarism, such as isolated adrenal insufficiency or DI, or even panhypopituitarism. Rates of hypopituitarism after endonasal transsphenoidal surgery vary, and can be heavily influenced by the pathology present. For instance, invasive or inflammatory pathologies, such as metastatic tumours, lymphocytic hypophysitis, or germinomas, cause inherent damage to the gland, and therefore, removal of these lesions can result in greater levels of hypopituitarism, further influenced by the extent of removal.

One complication more uniquely associated with all types of endonasal surgery is persistent postoperative CSF leak. As tumours from the pituitary gland enlarge, they can stretch the diaphragma sellae, causing this normally thickened, protective layer to become thinned and fragile, or invasive tumour pathologies can erode the membrane or produce holes in it. When the tumour is removed, CSF leak can occur either from damage to the diaphragma sellae from surgical manipulation or removal of the tumour that was previously plugging a defect that can now leave a communication. CSF leak needs to be managed at the time of surgery to decrease the risk of complications such as meningitis, pneumocephalus, or intracranial haemorrhage. There are a number of techniques for sellar closure in the event of a leak to prevent persistent fistulization, such as autologous abdominal fat or fascia lata, biologic glues, synthetic and xenograft dural substitutes, free nasal mucosal flaps, and vascularized nasoseptal flaps [67–69]. Although a number of factors can affect the rate of persistent postoperative CSF leak, the incidence of complications can be as high as 17% for pituitary adenomas and 33% for large lesions that create larger dural defects and high-flow spinal fluid leakage [70–72].

Conclusions

Although there are a multitude of different tumours that can arise from the pituitary gland and the surrounding structures related to the sella, surgery is generally considered the first-line treatment for a vast majority of these pathologies. Growing lesions can result in headaches, visual loss, and hypopituitarism, and hyperfunctioning adenomas can cause symptoms and comorbidities from excess circulating hormones. Although there are a number of ways to surgically approach these lesions, the transsphenoidal approach is the most popular, and use of the endoscope is rapidly becoming the standard method for treating these tumours. Symptomatic relief via this approach is largely successful, with acceptable morbidity and low rates of serious complications from neurovascular injury. The most prevalent complication is persistent CSF leak; however, advancing techniques have greatly diminished its occurrence. Significant and continued surgical experience improves outcomes and decreases complication.

2.3.8 Pituitary Radiotherapy

Naomi Fersht and Francesca Soldà

Introduction

Pituitary adenomas are the most common pituitary disorder in the adult population [1].

Their progressive growth within and outside the sellar region is responsible for the onset of characteristic mass-related symptoms (cranial nerve dysfunction and optic pathway compression), while a hypersecretory endocrine state is the common modality of disease presentation in functioning lesions.

The optimal management of pituitary adenomas involves a multidisciplinary collaboration between neurosurgeons, endocrine specialists and clinical (radiation) oncologists, and often requires a combination of treatments.

The main goal of all treatments is to provide long-term tumour control and/or to normalize the hormonal hypersecretion. While surgery has been historically considered the first approach in all symptomatic pituitary tumours, radiotherapy maintains an important and long-established role in the management of secreting and non-functioning adenomas, with a considerable number of patients receiving external beam irradiation in course of their disease.

In patients with non-functioning tumours, radiotherapy is withheld until evidence of further tumour progression after surgery, unless significant concerns are raised by new symptoms (visual impairment), or by specific histological features (atypical features, silent corticotroph adenoma). Often a second surgery is considered before radiotherapy. In progressive, non-functioning adenomas radiotherapy achieves tumour control in over 90% of patients at 10 years, and in 85–92% at 20 years [2–7].

For functioning tumours, radiotherapy is indicated when rapidly progressive or recurrent lesions are detected or in those patients failing to achieve hormonal normalization after other treatments (previous surgeries and medical therapy). Hormone levels decline slowly, normalizing in the great majority of patients over months or years after radiotherapy, depending on pretreatment hormone values [8, 9].

Modern radiotherapy techniques allow the delivery of an effective dose of radiation to the treatment target while minimizing the dose delivered to surrounding normal tissues thus potentially decreasing the long-term risk of normal tissue damage.

Radiotherapy for Pituitary Adenomas: Treatment Plan and Fractionation

Regardless of the technology used to deliver it, pituitary radiotherapy aims to:

- Accurately identify the treatment target within the sella and the adjacent structures;
- Calculate the dose to deliver to the treatment target by using a computerized treatment planning system;
- Accurately deliver the predefined dose of radiation in one or multiple fractions (radiosurgery or fractionated radiotherapy);
- Minimize the dose received by the surrounding uninvolved brain hence reducing the risk of normal tissue injury.

In general, the treatment target or GTV (gross tumour volume) is identified on high resolution imaging (thin cuts MRI sequences without contrast) accurately fused with computed tomography (CT) imaging acquired for planning purposes. During the planning scan the patient head is immobilized in a closely fitting relocatable frame (generally used in fractionated radiotherapy) or with the use of more invasively fixed frames (mainly employed in single fractionated treatments).

The GTV is manually contoured in three planes to generate a 3D volume encompassing the macroscopically visible lesion. An isotropic margin is added to account for areas of uncertainty in volume delineation, the trans-sphenoidal surgical route, and any set-up variation relative to the single radiotherapy centre. The generated volume is defined as the planning target volume (PTV). A careful delineation of all the organs surrounding the PTV and at potential risk of irradiation (OARs, organs at risk) is mandatory. The entire optic pathway, the brainstem, and the hypothalamic structures are routinely outlined. All OARs are expanded to create a planning risk volume (PRV) which margin, as for the PTV, should reflect the accuracy of daily local set-up (**Figure 2.3.8.1**).

The treatment dose is calculated with a sophisticated computerized planning system that defines the best arrangement of the radiotherapy beams to deliver the dose homogenously to the PTV while minimizing the dose received by non-target structures.

In conventional radiotherapy, this is achieved by dividing the total dose over multiple sessions (fractionated radiotherapy). Fractionated pituitary irradiation is given to total dose of 45 to 50.4 Gy at 1.8 Gy per fraction, once a day, five days per week. Fractionation is used for lesions larger than the ones treated with single fraction radiotherapy—often referred as radiosurgery—or for tumours abutting or compressing the optic apparatus.

Radiotherapy Techniques

3D Conformal Fractionated Radiotherapy

Conventional radiotherapy for pituitary adenoma is delivered with photons using a linear accelerator (LINAC), the most common machine used to deliver external beam radiotherapy.

Figure 2.3.8.1 Target delineation of a pituitary adenoma. Gross tumour volume/planning target volume (GTV/PTV) and organs at risk are outlined. GTV (brown)/ PTV (red); left optic nerve (pink); right optic nerve (light orange); brainstem (orange). *For a colour version of this figure, please see colour plate section.*

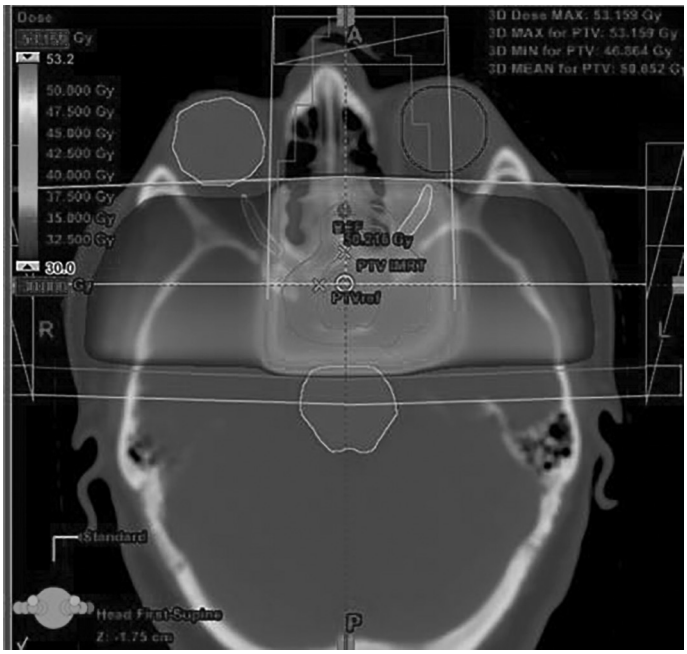

Figure 2.3.8.2 Example of beam arrangement and dose distribution in a conventional three fields CRT plan (an anterior oblique and two lateral opposed beams).

Three-dimensional (3D) conformal fractionated radiotherapy (CRT) is used to treat functioning and non-functioning adenomas of small or large volumes.

To achieve reproducible head position and aid treatment precision, a custom-made closely fitting thermoplastic mask is applied and moulded directly to the patient's face in the treatment planning process. The repositioning accuracy of the mask during treatment is around 3–5 mm [10], and can be improved to 2–3 mm, by using tighter fitting masks [11].

Imaging for treatment planning is performed with the patient lying in supine position with the head in the immobilization device. Planning CT and pre- and postoperative MRI scans are coregistered on the planning system for 3D target delineation (GTV) with an isotropic margin of 5–10 mm added to account for uncertainties in planning or treatment delivery.

In 3D-CRT, three fixed fields of radiation are commonly used to irradiate the PTV: an anterior oblique field directed to the pituitary area through the forehead and two lateral opposed beams coming from the temporal regions (Figure 2.3.8.2). If a different beam arrangement is adopted, the planning system defines the optimal number and orientation of each field to achieve a conformal dose distribution within PTV, limiting the dose to the adjacent normal OARs. Each beam of radiation is shaped to conform to the profile of the PTV with a multileaf collimator (MLC): an array of computer-controlled parallel leaves moving in and out to create an adjustable aperture through which the beam is delivered. The use of a dynamic MLC (with the leaves moving during the gantry rotation) also allows to alter the intensity of the radiation during its path (intensity-modulated radiotherapy, IMRT) resulting in a more homogeneous dose distribution within targets of any shape. A technique of arcing IMRT (described as volumetric modulated arc therapy (VMAT) or RapidArc) offers a fast way of delivering complex IMRT treatments and is increasingly in use as an alternative to conventional fixed field 3D-CRT. Arc techniques are used to minimize the dose bilaterally to the temporal lobes with the aim of reducing the impact of treatment on patients' cognitive function.

Stereotactic Radiotherapy

The stereotactic techniques represent an evolution of 3D-CRT where the combination of more robust patient immobilization and on-treatment imaging (image guidance) guarantee accurate treatment delivery.

Originally, the term 'stereotactic' referred to the use of a system of external 3D coordinates, generally a neurosurgically fixed head frame, adopted to determine the location of a lesion within the brain. While in some contexts the stereotactic localization has been superseded by the integration of modern imaging within the radiotherapy planning system, the term 'stereotactic' is still widely in use.

With more precise target localization and accurate dose delivery compared with 3D-CRT, stereotactic radiotherapy (SRT) results in a reduction of the volume of normal brain tissue irradiated to high doses of radiation.

SRT can be delivered in daily fractions over few days (3–5 fractions, **hypofractionated radiotherapy—hSRT**), or over few weeks (up to 25–28 fractions in pituitary adenoma, conventionally **fractionated stereotactic radiotherapy—fSRT**), or in a single fraction (**radiosurgery—RS**).

In deciding between these methods, several considerations must be taken into account. Large adenomas (3 cm or more in maximum diameter) or adenomas close to radiation-sensitive structures (such as the optic chiasm) are more safely treated with fractionated radiation (3D-CRT, fSRT, or less commonly hSRT). At the standard total doses of 45–50.4 Gy delivered in fractions of less than 2 Gy, the

risk of radio-induced damage to the optic pathway is around 1%. As the risk of optic neuropathy is dose-dependent, a single large dose of radiation delivered with RS results in an unacceptable toxicity if the adenoma abuts or displaces the surrounding critical structures (optic apparatus) [12, 13].

Fractionated Stereotactic Radiotherapy (fSRT)

fSRT is delivered on LINACs with patients immobilized in relocatable frames with a reported relocation accuracy of 1–2 mm [14, 15], or in precisely fitting thermoplastic mask systems with an accuracy of 2–3 mm [11].

A smaller PTV margin is used in fSRT (generally 3–5 mm) as a result of the more precise patient immobilization devices adopted and the concomitant use of frequent imaging during the course of radiation (image guidance). On-treatment imaging (orthogonal X-rays or cone beam CT scans) enables instant, real-time correction for patient positioning deviations with respect to the planning scans, thus improving the precision of the daily treatment.

fSRT is delivered using multiple static beams of radiation (usually 4–6), each beam conforming to the shape of the PTV using an MLC (mini MLCs with a 5 mm width or micro MLCs with 3 mm width). As for 3D-CRT, the use of MLC allows to modulate the beam intensity during its delivery (IMRT). VMAT or RapidArc is also possible on dedicated LINACs (Figure 2.3.8.3).

Adapted LINACs mounted on a robotic arm capable of movements in six degrees of freedom (Cyberknife) can be used to treat pituitary adenomas either in a single fraction or by hypofractionating the total dose of radiation in three to five fractions.

Single Fraction Stereotactic Radiotherapy (Radiosurgery–RS)

Single fraction radiotherapy, usually referred as radiosurgery (RS), is a high precision localized technique of irradiation used as a non-invasive alternative to surgical excision (hence the misleading term of 'radiosurgery') in patient with both malignant and benign brain conditions.

RS for pituitary adenomas was first delivered on the Gamma Knife unit (GK), a multiheaded cobalt device in which multiple cobalt-60 sources (192 in the current version) are arranged in a hemispherical distribution. The generated multiple beams of radiation converge with high precision at a single point (isocentre) to achieve a circumscribed dose distribution within the PTV. For more complex shaped adenomas, a multiple isocentre arrangement is often chosen resulting in a combination of several spherical dose volumes encompassing the treatment target.

In the planning phase of the procedure, an MRI-compatible frame is neurosurgically attached to the skull of the patient in four points, under local anaesthesia. A system of fiducial markers coupled to the frame during the planning imaging allows a frame-based coordinate system, where any point within the brain is located with submillimetric precision. The number and the position of the isocentres are calculated by the planning system to shape the prescription dose to the lesion profile (marginal dose). Due to the invasive nature of the frame, the treatment planning and delivery procedures necessitate been carrying out and completing within a single day.

RS for pituitary adenomas is given to doses of 12–35 Gy to the tumour margin with maximum doses to the optic pathway and the cranial nerves in the cavernous sinus limited to 8–10 Gy and 16–18 Gy, respectively (Figure 2.3.8.4).

LINACs initially modified with external mechanical supports to deliver RS have been replaced by LINACs with a high level of precision not requiring adaptation for RS. Non-invasive relocatable frames coupled to image-guided techniques can be used in alternative to fixed frames. In this so called 'frameless RS', the high single dose of radiation is delivered with single or multiple arcs of radiation (VMAT) or multiple fixed fields. With Cyberknife (CK) LINACs, the freedom in movements of the robotic arm allows the delivery of a wide range of single non-coplanar beams intersecting one other to create a uniform dose distribution in the target.

Proton Beam Radiotherapy (PBT)

Proton devices are increasingly used to treat brain tumours and the renewed interest in proton beam radiotherapy (PBT) is associated to the physic properties of these heavy particles. Unlike photons, protons are able to deliver most of their energy when they hit the target. The very low entry dose and minimal exit dose beyond the target boundaries allow to deliver the prescribed treatment also to

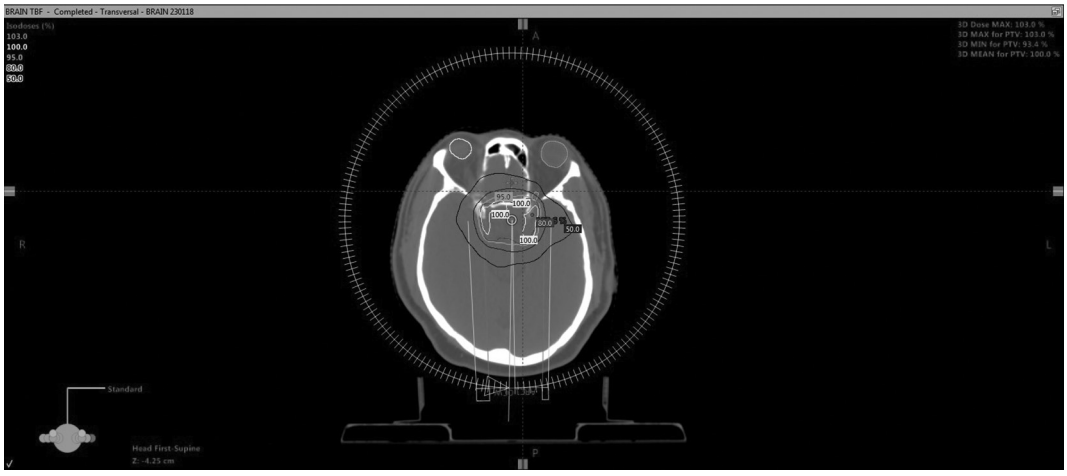

Figure 2.3.8.3 Example of isodose distribution in a VMAT plan. (in red the PTV) *For a colour version of this figure, please see colour plate section.*

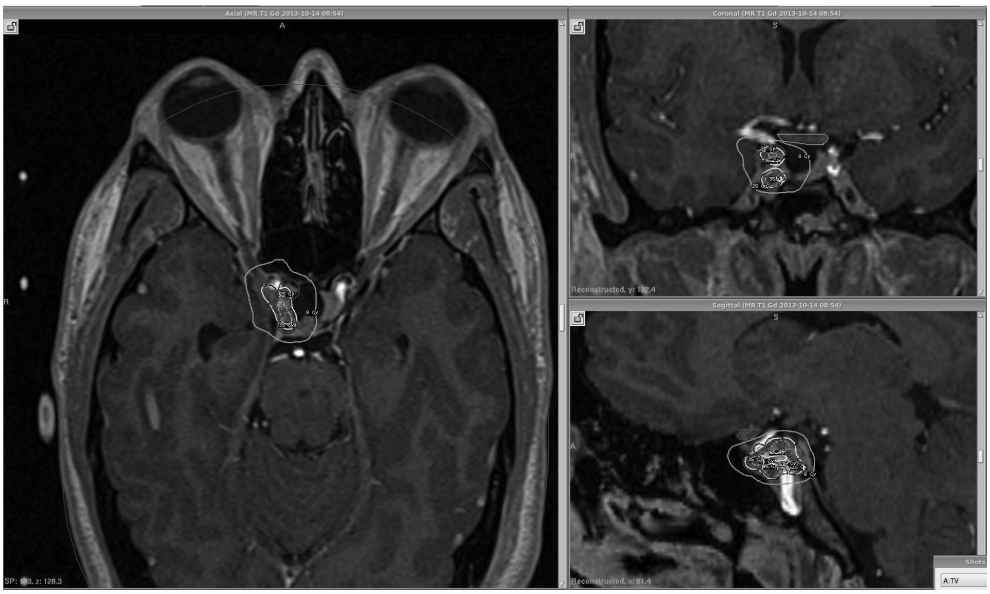

Figure 2.3.8.4 Example of Gamma Knife plan for a residual secreting pituitary adenoma within the right cavernous sinus (marginal dose 25 Gy—yellow). White line shows the 8 Gy isodose distribution with respect to the optic pathway. *For a colour version of this figure, please see colour plate section.*

large, irregular volumes with optimal sparing of the surrounding healthy tissues [16].

Protons are produced by large particle accelerators (cyclotrons or synchrotrons) where the atom is stripped of its electron to produce heavy positive charged particles. The steps involved in PBT are similar to photon-based treatments with relocatable frames commonly used for patient immobilization.

Current indications for the use of protons within the UK Specialised Commissioning Team include the treatment of pituitary adenomas up to the age of 24 years old based on theoretical reduction in the possible late side effects of brain radiation, such as second malignancy, neurocognitive deficits and cerebrovascular disease (Figure 2.3.8.5) [17].

Toxicity of Radiotherapy

Hypopituitarism is the most common consequence of radiation treatments for pituitary adenomas, after both fractionated and single dose radiation therapy. It is more frequent in patients with previous insults to the pituitary gland (post-surgery, from the tumour itself) and its clinical manifestations can gradually develop over several years from treatment (the increased risk of hormonal deficiency is as high as 80% by 10–15 years).

Permanent cranial nerve injuries secondary to radiotherapy are far less common than hormonal failure in pituitary adenomas treated with fractionated irradiation, where the risk of neurotoxicity increases markedly only at doses >60 Gy at ≥1.8 Gy/fraction. In single fraction RS, the risk of radiation-induced optic neuropathy is estimated at 1.7%, 1.8%, 0%, and 6.9% for a Dmax of <8, 8–10, 10–12, and >12 Gy, to the optic apparatus, respectively, so the frequency of complications should be low if an appropriate patient selection for RS is adopted [12].

Patients with pituitary adenoma treated with radiotherapy also seem to have a significantly increased risk of cerebrovascular complications (CVAs) compared to the general population [18], although these data are not confirmed in all studies [19, 20].

Radiation is recognized to be a contributing factor in the development of second brain tumours and an increased risk of developing a radiation-induced malignancy in pituitary adenomas treated with fractionated radiotherapy has been reported [21, 22]. The relative risk of radiation-induced tumours after RS has not been precisely determined and the relatively short follow-up of most published series does not allow for meaningful comparison to fractionated radiotherapy.

Clinical Outcome of Pituitary Radiotherapy

Despite several differences in treatments-related parameters between LINAC, GK, and CK radiotherapy in pituitary adenomas, the published data on the clinical efficacy of the various techniques is based on the results of retrospective case studies reporting on a single technique and non-randomized comparative studies.

The major limitation of these types of studies is the difficulty in understanding the real efficacy of an intervention due to the lack of control over factors that influence the outcome being measured, making the presumed superiority of one technique against other still a matter of debate.

The clinical efficacy of radiotherapy for pituitary adenomas should be measured in terms of overall survival, actuarial tumour control (progression-free survival, PFS), and quality of life. The most frequently reported endpoints of radiation treatment for non-functioning pituitary adenomas are local tumour control and long-term morbidity.

Hormone normalization following treatment should be described in relationship to pretreatment hormone levels and defined as the time to reach 50% of pretreatment values.

Furthermore, although the total dose delivered with fractionated meanings of irradiation is largely consistent within different

Figure 2.3.8.5 Example of two-beam (lateral opposed) and three-beam (superior-oblique and two laterally opposed) arrangement in a recurrent pituitary adenoma treated with fractionated PBT (50.4 Gy/28#).

publications (45–50.4 Gy), the range of dose prescriptions between secretory and non-functioning adenomas treated with RS tends to be different (from 12 to 30 Gy). The rationale behind this practice is based on the observation that a more rapid hormone normalization was reported in single studies using higher doses to treat secreting tumours. In absence of a strong radiobiological model and of prospective randomized studies in support, the relationship between dose delivered and endocrine remission warrants further investigation.

Outcome of 3D-CRT

The long-term outcomes from case series published in the literature for 3D-CRT in pituitary adenomas are shown in Table 2.3.8.1. The actuarial PFS varies from 87% to 98% at 10 years [3, 23–25] with the majority of the studies providing consistent long-term follow-up data and the largest study also reporting figures on PFS at 20 years [2]. In secreting tumours, normalization of the pretreatment values is achieved at variable times from irradiation. Stabilization of growth hormone (GH) hypersecretion mainly depends on pre-RT levels, with GH/IGF-1 normalization in up to 70% of patients 10–15 years after RT. A reduction to 50% of pretreatment levels is detected after 2 years from treatment [26, 27]. Biochemical remission with normalization of cortisol secretion has been reported in 73%, 78%, and 84% of patients at 3, 5, and 10 years, respectively. Urinary free cortisol (UFC) is reduced to 50% of the pretreatment levels after an interval of 6–12 months, and plasma cortisol after around 12 months [28]. Large recurrent prolactinomas are reported to be less sensitive to radiotherapy but data are scarce because of its limited use. The reported 10-year tumour and hormone control rates are 90% and 50%, respectively [29–31].

Data about toxicity of 3D-CRT show low rates of complications after treatment. The most common long-term complication is hypopituitarism, occurring in 30–80% of patients at 10 years from radiotherapy. The incidence of symptomatic radio-induced optic neuropathy following 3D-CRT is 1–3%, but long-standing compression of the visual pathway in large tumours might contribute to these figures.

Cerebrovascular mortality has been found increased in patients with pituitary adenomas treated with radiotherapy compared with the general population [18, 32]. The metabolic and cardiovascular effects of hormone imbalance and the consequences of surgery might play a significant role in the long-term occurrence of these conditions.

There is a slight but significant 2–2.7% increased risk of secondary brain tumours after conventional radiotherapy for pituitary adenoma reported in various studies [21, 33, 34].

Outcome of Fractionated Stereotactic Radiotherapy (fSRT)

The outcome of 1166 functioning and non-functioning pituitary adenomas treated with fSRT is reported in Table 2.3.8.2.

The length of follow-up after fSRT is shorter than reported for cohorts of patients treated with 3D-CRT.

At a corrected median follow-up of 58 months (range 9–152 months), tumour control was achieved in 96% of patients with the largest study reporting a PFS of 99% at 5 years [35]. Few studies reported the same data at 10 years with similar results as per 3D-CRT.

Only limited data are available on the efficacy of fSRT in secreting tumours. Normalization of GH levels was reported in 21 (84%) and 6 (33%) acromegalic patients after a median follow-up of 26 months and 39 months, respectively [24, 36]. Data on biochemical remission in ACTH-secreting lesions are limited but it is unlikely to be different from those obtained with CRT using the same dose fractionation.

The insufficient number of patients with prolactinoma who fail previous medical or surgical treatment does not allow definitive conclusion on the efficacy of fSRT in achieving hormone normalization.

The incidence of complications after fSRT is in line with the same figures reported for CRT although a 20% mean rate of hypopituitarism might still reflect the short duration of follow-up for this group of patients.

Outcome of Single Fraction Stereotactic Radiotherapy (Radiosurgery–RS)

The results of GK SRS in non-functioning pituitary adenomas have been summarized in Table 2.3.8.3.

Table 2.3.8.1 Summary of results of published series on 3D-CRT for pituitary adenomas

NFA, non-functioning adenoma; SA, secreting adenoma; NA, not assessed, ACTH-Cushing, GH-acromegaly, * hormone concentration normalization, ** no time specified.
Updated with permission from Soldà F, Fersht N. Radiotherapy for Pituitary Tumours. [Updated 2017 Dec 5]. In: De Groot LJ, Chrousos G, Dungan K, *et al.*, editors. Endotext [Internet]. South Dartmouth (MA): MDText.com, Inc.; 2000. Available from: https://www.ncbi.nlm.nih.gov/books/NBK278955/ Copyright © 2017, MDText.com, Inc.

The actuarial 5-year control rate (PFS) following GK is 95%, with limited data at 10 years. The reported treatment doses vary from 12 to 20 Gy (mean dose) [37, 38]. Although outcome results are in line with the corresponding figures for 3D-CRT and fSRT, smaller tumours are generally considered for treatment with GK.

Hormonal response following GK RS for GH-secreting tumours is shown in Table 2.3.8.4.

Data published up to 2016 on 34 available studies showed that 41% of patients achieved normalization of serum GH, after a median follow-up of 46 months. A large study on 136 patients reported higher actuarial remission rates (normal age and gender-matched serum IGF-1 level and, in some patients, a GH level less than 1 ng/ml after oral glucose tolerance test (OGTT)) at 2, 4, 6, and 8 years after RS of 31.7, 64.5, 73.4, and 82.6%, respectively. The strongest prognostic factor for endocrine remission was a lower pre-RS IGF-1 [39].

The reported rate of hypopituitarism at 5 years varies from 8% to 33% in the studies with longer follow-up data.

The outcome of GK RS in patients with Cushing's disease is reported in Table 2.3.8.5.

Biochemical remission (defined as normalization of plasma cortisol and 24-hour UFC level) was achieved in 52% of patients at a corrected median follow-up of 50 months after RS.

In a recent international multi-institutional study on 278 patients (mean follow-up 5.3 years), the reported rate of new hypopituitarism was 25% [40]. The same study also reported a recurrence rate up to 20% after initial disease remission, suggesting the importance of a continuous follow-up even in patients with early hormonal normalization.

Small prolactinomas in patients resistant or intolerant to dopamine agonist can be considered for RS.

In 24 studies reporting on 692 patients, 33% of them had normalization of serum prolactin concentrations at a corrected median follow-up of 43 months (median range 6–60 months), following RS (Table 2.3.8.6). There are insufficient data to assess the rate of decline of prolactin following GK RS in comparison to data following 3D-CRT or fSRT.

The most commonly reported complication following GK RS is hypopituitarism, with a crude incidence ranging from 0% to 66%, thus largely comparable to fSRT and 3D-CRT. The incidence of cranial nerve deficits after RS is generally low (in the range of 0–6%), although higher rates of complications are occasionally reported in selected studies suggesting a potential inappropriate selection of patients for treatment (large tumours/tumours close to the optic apparatus) [41, 42].

* Case series includes secreting adenomas.

The risk of RS-associated secondary brain tumours has not been precisely determined and longer follow-up data are required.

Outcome of LINAC-Based Single Fraction Radiotherapy (Radiosurgery–RS)

A limited number of studies reported the results of LINAC-based RS for both functioning and non-functioning pituitary adenomas (Table 2.3.8.7), with results in terms of tumour control and hormone normalization broadly in the range of those achieved with GK RS.

Similar considerations are valid for series on robotic RS (CK) (Table 2.3.8.8). The main limitation of both groups of data is the duration of the follow-up provided that does not allow drawing definitive conclusions on the superiority of these techniques over fractionated approaches.

Outcome of Proton Therapy

The use of PBT, both fractionated and single fraction, has been described to treat functioning and non-functioning lesions [53–57]. A recent study on 47 patients treated with fractionated PBT reported a high rate of post-treatment complications including a case of temporal lobe necrosis, 3 patients with new significant visual deficits, and 11 patients with new hypopituitarism. Early data on tumour control rate are not dissimilar from those reported with 3DCRT and stereotactic treatments (87% at 6 months) [56].

The largest study on stereotactic PBT reported on the biochemical response of a population of secreting adenomas (74 ACHT, 50 GH, 9 PRL, 8 Nelson, 3 TSH). At a median follow-up of 52 months, 42% of patients did not achieve endocrine control with acromegalic patients having the longer time to biochemical response (49% at 5 years). The risk of developing hypopituitarism was 62% at 5 years. Four patients (3%) experienced post-treatment temporal lobe seizures, with associated temporal lobe changes on imaging (1 month to 9 years from proton treatment) [57].

Pituitary Re-irradiation

Re-irradiation of recurrent/progressive adenomas unsuitable for surgical resection should take into careful consideration the position of the adenoma with respect to the optic pathway or other

Table 2.3.8.3 Summary of results of published series on RS for non-functioning pituitary adenomas

cranial nerves, the previous dose of treatment received and the time from primary irradiation.

The effects of a previous irradiation might take several years to develop (especially in secreting tumours) and a further dose of radiation might be associated with an unacceptable increase in treatment-related complications. Few retrospective studies on small groups of selected patients treated with highly conformal fractionated radiotherapy or RS have been reported [58–60]. A recent study evaluating the outcome and toxicity of re-irradiation in 15 secreting and non-secreting adenomas reported an early occurrence of radiation-induced neuropathy (13% at 14 months) and a high rate of temporal lobe necrosis (13%) [61]. Conversely, no visual sequelae or further loss of anterior pituitary function at a median follow-up of 33 months were described in another study reporting on 21 patients retreated with LINAC-based RS [62].

Based on the paucity of available data, a judicious selection of patients for pituitary re-irradiation must be considered. The use of 'stereotactic' techniques and fractionation could theoretically reduce the incidence of late sequelae.

Conclusions

Both fractionated and single fraction treatments achieve excellent rates of tumour control with figures as high as 90% at 5 and 10 years also reducing hormone hypersecretion in approximately 50% of patients at 10 years. Normalization of excessive secretion is generally variable and might require a long interval after treatment.

Careful selection of patients for RS must be considered in view of the potential risks of radiation-induced toxicity following a high single dose of radiation on the surrounding sensitive structures, with small tumours away from the optic chiasm usually preferred for RS.

Despite the large number of reports on the outcome of the different available techniques of irradiation, there are no prospective comparative studies supporting the clinical efficacy relative to other treatment and mature follow-up data are needed to fully evaluate the rate of long-term side effects of stereotactic meanings of treatments in comparison with conventional fractionated radiotherapy.

2.3.9 Prolactinomas and Hyperprolactinaemia (Including Macroprolactinaemia)

Nicholas A. Tritos and Anne Klibanski

Introduction

Prolactin is a single chain (23 kDa) polypeptide hormone, which is secreted by anterior pituitary lactotroph cells [1]. Prolactin secretion is predominantly under tonic inhibition by hypothalamic dopamine working through the D2 receptor [2]. In addition, a variety of factors, including thyrotropin-releasing hormone (TRH), vasoactive intestinal peptide (VIP), serotonin, and other neuropeptides and neurotransmitters influence prolactin secretion to lesser degrees. Prolactin secretion is also affected by oestrogen. Prolactin exerts its actions by binding to dimerized forms of its cognate receptor, a member of the cytokine receptor superfamily [3]. Prolactin has a central role in reproduction and lactation.

Extrapituitary sources of prolactin have been described, including the decidua and other sites [4]. Prolactin synthesis in the decidua may promote maternal tolerance to fetus *in utero*. A host of metabolic functions and paracrine effects have been proposed for extrapituitary prolactin on the basis of animal studies [5]. However, the function of prolactin synthesized outside the pituitary remains obscure in humans.

Hyperprolactinemia can be a consequence of increased prolactin secretion and/or decreased prolactin clearance. There are numerous causes of hyperprolactinemia as discussed in a separate section [6]. Prolactin-secreting pituitary adenomas (prolactinomas) are the most frequent functioning pituitary tumours.

Hyperprolactinemia may cause central hypogonadism, infertility, and bone loss (in hypogonadal patients). Galactorrhoea may occur (especially in women) and gynaecomastia may develop in men. However, prolactin excess can also be asymptomatic. Large pituitary tumours associated with hyperprolactinemia may additionally cause mass effect, including headache, vision loss, and anterior hypopituitarism.

The diagnosis of hyperprolactinemia is made by measuring serum prolactin in specimens optimally obtained in the fasting state while minimizing physiologic stress [7]. The hook effect, heterophilic antibodies, exogenous biotin, and macroprolactinaemia may confound the interpretation of the results of prolactin immunoassays, as will be detailed in a separate section. Pituitary imaging is generally advised in patients with hyperprolactinemia in the absence of a clear-cut, alternative explanation (such as pregnancy).

Medical management of hyperprolactinemia with dopamine agonists, including bromocriptine and cabergoline, is generally first-line therapy for this condition [6, 7]. However, asymptomatic patients with hyperprolactinemia who do not have macroadenomas can often be carefully monitored without therapy, as will be subsequently discussed.

The management of women with hyperprolactinemia and prolactinomas during preconception and pregnancy raises special concerns regarding the effects of prolactin excess during preconception, the impact of pregnancy on prolactinomas and the safety of medical therapy [8, 9].

Pituitary surgery and radiation therapy generally represent second- and third-line therapies, respectively, in patients with hyperprolactinemia and prolactinomas, as will be detailed in separate sections [7].

Causes and Epidemiology of Hyperprolactinemia

Hyperprolactinemia is fairly common in the general population, wherein its prevalence is estimated to be approximately 0.4% [6, 10]. There is a large number of causes of hyperprolactinemia, which can be grouped into physiologic states, medication-related, systemic illnesses, and pituitary lesions (please see **Box 2.3.9.1**). In addition, hyperprolactinemia can be idiopathic.

There are diverse physiologic stimuli of prolactin secretion, including food consumption, sleep, exercise, nipple stimulation and coitus [6]. Serum prolactin levels rise transiently after meals or during slow wave sleep. Exercise leads to an acute, albeit transient, increase in prolactin levels, which is not sustained long-term in individuals who exercise frequently. Nevertheless, it is prudent to obtain blood specimens intended for prolactin assay after an overnight fast while minimizing exercise, stress, or other factors that might trigger prolactin secretion. Pregnancy and lactation represent major physiologic causes of hyperprolactinemia [9]. Stimulated by oestrogen of placental origin, pituitary lactotrophs undergo substantial hyperplasia during pregnancy. As a consequence, serum prolactin levels rise progressively during gestation and may reach or exceed 200–300 ng/ml (8700–13 000 pmol/L). Prolactin secretion has a central role in inducing differentiation of the breast epithelium, thus preparing the mammary gland for lactation after delivery. Prolactin levels remain elevated for several months after delivery in women who are nursing. There are also secretory prolactin spikes that occur in response to each suckling episode.

Box 2.3.9.1 Causes of hyperprolactinemia

Physiologic
- Pregnancy
- Lactation
- Food consumption
- Sleep
- Exercise
- Coitus
- Nipple stimulation
- Other physiologic stress (seizure, hypoglycaemia, etc.)

Medications
- Phenothiazines
- Haloperidol
- Risperidone, paliperidone
- Tricyclic antidepressants
- Fluoxetine
- Monoamine oxidase inhibitors
- Metoclopramide, domperidone
- Alpha methyldopa
- Verapamil
- Opioids
- Cocaine

Systemic conditions
- End-stage renal disease
- Cirrhosis
- Primary hypothyroidism
- Primary adrenal insufficiency
- Polycystic ovary syndrome
- Ectopic secretion (rarely)
- Genetic (prolactin receptor mutation)
- Spinal cord injury
- Chest wall lesions (burns, zoster, etc.)

Pituitary lesions
- Prolactin-secreting adenomas
- Cosecreting tumours (acromegaly; rarely Cushing's disease or thyrotropinoma)
- Non-functioning pituitary adenomas
- Cystic sellar lesions
- Meningiomas
- Sarcoidosis
- Hypophysitis
- Idiopathic

Many medications can cause hyperprolactinemia, including antipsychotic agents (both typical and atypical), tricyclic antidepressants, fluoxetine, monoamine oxidase inhibitors, metoclopramide, domperidone, opioids, cocaine, alpha methyldopa, and verapamil [11]. Among antipsychotic drugs, older agents (such as chlorpromazine and haloperidol) and some of the atypical antipsychotic drugs (such as risperidone and paliperidone) may raise serum prolactin levels substantially, sometimes exceeding 100 ng/ml (4300 pmol/L) as a result of dopamine receptor inhibition. In contrast, other atypical agents, including aripiprazole and ziprasidone, are less likely to cause hyperprolactinemia, in part because of their weaker inhibition of dopamine receptors and their partial agonist effects. Although some patients can be switched to aripiprazole as an antipsychotic medication, add-on aripiprazole therapy may suppress hyperprolactinemia due to other neuroleptic agents as a consequence of its partial dopamine agonist effect [12–14]. Aripiprazole has also been used to treat patient with known prolactinomas who require antipsychotic therapy in whom dopamine agonists such as cabergoline or bromocriptine may be contraindicated.

Several systemic illnesses and conditions, including primary hypothyroidism, (rarely) primary adrenal insufficiency, chronic renal failure, cirrhosis, polycystic ovary syndrome, spinal cord injuries, chest wall lesions (such as zoster or burns) have been associated with hyperprolactinemia [6]. In addition, ectopic prolactin secretion has been reported in a very small number of patients with a variety of tumours (ovarian teratoma, gonadoblastoma, bronchogenic carcinoma, and others). Germline, heterozygous inactivating mutation of the prolactin receptor gene were reported in 3 sisters with hyperprolactinemia who had no evidence of a sellar mass; 2 of these patients had oligomenorrhea and 1 had infertility [15].

A large number of sellar masses can cause hyperprolactinemia, either as a consequence of prolactin secretion by tumorous lactotrophs (prolactinomas) or as a result of disinhibition of prolactin secretion by normal lactotrophs, induced by interference with dopamine outflow from the hypothalamus to the pituitary ('stalk effect') [6]. Examples of the latter include clinically non-functioning pituitary adenomas, cystic sellar lesions (Rathke's cleft cysts, craniopharyngiomas, and others), meningiomas, hypophysitis, sarcoidosis, and Langerhans cell histiocytosis. Stalk transection and radiation therapy to the sella are also associated with hyperprolactinemia, likely as a consequence of hypothalamic dysfunction.

Prolactinomas are the most common type of secretory (functioning) pituitary adenomas. Earlier studies suggested that the

incidence and prevalence of prolactinomas is about 10 cases per million per year and 100 cases per million in the general population, respectively [16]. In contrast, several recent reports have found that the incidence and prevalence of clinically detected prolactin-secreting tumours is about five times higher than previously reported (please see Table 2.3.9.1) [17–21]. Such differences may be partly explained based on improved detection rates in the recent past. Autopsy studies have found that clinically unsuspected pituitary adenomas are present in approximately 11% of subjects autopsied, almost all of them (>99%) microadenomas [22]. Of note, about 40% of adenomas detected at autopsy stained for prolactin on immunohistochemistry; whether these tumours were truly asymptomatic during life is unclear [23].

Most prolactinomas are sporadic. However, the multiple endocrine neoplasia 1 (MEN 1) syndrome, caused by germline inactivating mutations of *MENIN* (a tumour suppressor gene) accounts for a minority of cases [24, 25]. The coexistence of a pituitary adenoma and primary hyperparathyroidism (a constellation that defines an index case for MEN 1) was reported in 14% of patients with prolactinomas who were screened for hypercalcaemia and did not have a positive family history for the syndrome. In addition, a small minority of patients with prolactinomas may have a familial predisposition as a consequence of germline inactivating mutations in the *aryl hydrocarbon receptor interacting protein (AIP)* gene [26, 27]. This is an autosomal dominant trait with incomplete penetrance. Patients with *AIP* mutations have an increased risk of developing somatotropinomas, prolactinomas, or cosecreting tumours. Moreover, these patients generally present at a younger age and are more likely to harbour locally aggressive macroadenomas than patients with sporadic disease.

Microprolactinomas (<10 mm in greatest diameter) predominate at the time of clinical diagnosis. Macroadenomas (≥10 mm in greatest diameter) represent a larger proportion of prolactinomas in men than in women, as well as in children/adolescents than in adults.

Microprolactinomas have a relatively low growth potential. In earlier studies, tumour growth was found in 9 out of 139 women (6.5%) followed up to 8 years [28–31]. Macroprolactinomas have a higher growth potential than microadenomas and can be locally aggressive. Rarely, these tumours may evolve into carcinomas, defined by the development of metastases within the skull or at distant sites (liver, lymph nodes, bone) [32]. A minority of prolactin-secreting pituitary adenomas may cosecrete growth hormone or occasionally thyrotropin (TSH), corticotropin (ACTH), or follicle-stimulating hormone (FSH).

Idiopathic hyperprolactinemia is characterized by the absence of a demonstrable cause despite thorough diagnostic evaluation. These patients likely represent a diverse group. It is indeed possible that some patients have very small prolactinomas that are below the resolution of magnetic resonance imaging (MRI). Other patients may have dysregulated prolactin secretion. Idiopathic hyperprolactinemia has been reported to resolve in about one-third of patients without treatment. Pituitary microadenomas may occasionally develop during follow-up of patients with idiopathic hyperprolactinemia (reported in 23 out of 199 patients who were followed for 2–6 years) [28, 33].

Clinical Features of Hyperprolactinaemia and Prolactinomas

In patients with prolactinomas, the magnitude of prolactin elevation is generally proportionate to tumour size [6, 7]. This is an important concept because modest degrees of prolactin excess in patients with large sellar masses demonstrated on MRI scan may not represent prolactinomas, or in some cases a diagnosis other than a pituitary adenoma. Patients with hyperprolactinemia can be either asymptomatic or demonstrate clinical manifestations of prolactin excess (please see Table 2.3.9.2). Hyperprolactinemia often leads to central hypogonadism in patients of both genders, primarily caused by suppression of hypothalamic gonadotropin-releasing hormone (GnRH) pulsations [34].

In women, hyperprolactinemia is often associated with galactorrhoea, irregular menstrual cycles (oligomenorrhea or secondary amenorrhea) and infertility [6, 7]. Bone loss may occur as a consequence of long-standing hypogonadism. In contrast, hyperprolactinaemic women with regular menses are unlikely to develop osteoporosis because of an elevated prolactin level unless prior amenorrhea had occurred [35, 36]. Women may develop hyperandrogenism (hirsutism, acne) as a consequence of stimulation of adrenal androgen secretion by prolactin excess. In men, hyperprolactinemia may lead to low libido, erectile dysfunction, and infertility [6, 7]. Gynaecomastia may develop in some men; however, galactorrhoea is quite uncommon in men. Anaemia and bone loss may occur in men with long-standing hypogonadism. Children and adolescents of both genders may present with delayed puberty, including primary amenorrhea in girls [37].

Patients with large sellar masses (including macroprolactinomas) may develop anterior hypopituitarism and require thorough evaluation of anterior pituitary function. However, diabetes insipidus

Table 2.3.9.1 Epidemiology of prolactinomas based on the findings of several recent studies*

Table 2.3.9.2 Clinical manifestations of hyperprolactinemia and prolactinomas

System or area	Women	Men	Children/adolescents
Pituitary gonadal axis	Secondary amenorrhea or oligomenorrhea, infertility	Erectile dysfunction, low libido, infertility	Delayed puberty, primary amenorrhea (in girls)
Breast	Galactorrhoea	Gynaecomastia, galactorrhoea (very uncommon)	Galactorrhoea (more common in girls); gynaecomastia (in boys)
Adrenals	Androgenic manifestations (hirsutism, acne)		
Skeleton	Osteoporosis	Osteoporosis	Delayed growth
Sella	Headache, visual field defects, ophthalmoplegia (rare), anterior hypopituitarism	Headache, visual field defects, ophthalmoplegia (rare), anterior hypopituitarism	Headache, visual field defects, anterior hypopituitarism

is distinctly rare in patients with pituitary adenomas who did not undergo pituitary surgery [38].

Additional evidence of mass effect may occur in patients with macroadenomas [6]. Headache may occur as a result of pressure exerted on the dura. Patients with pituitary apoplexy typically present with severe headache of acute onset as a result of haemorrhage within a pituitary adenoma. Patients whose tumours extend into the suprasellar cistern may experience visual field deficits as a consequence of compression of the optic apparatus. Central scotomas may occur as a result of prechiasmatic optic nerve compression, whereas impingement on the optic chiasm may result in bitemporal vision loss; compression of one of the optic tracts may lead to homonymous hemianopsia.

Pituitary tumours may also extend laterally into the cavernous sinuses where they may impinge upon cranial nerves III, IV, V1, V2, VI [6]. However, the vast majority of patients with cavernous sinus involvement have no clinical evidence of cranial nerve dysfunction, with the exception of patients with pituitary apoplexy or occasional patients with aggressive pituitary adenomas, who may experience ophthalmoplegia, facial pain or numbness. Very infrequently, large pituitary tumours compressing the temporal lobes may cause complex partial seizures. Giant prolactinomas that extend into the third ventricle may lead to obstructive hydrocephalus [39, 40]. Tumours that extend inferiorly may erode the sphenoid and extend into the sphenoid sinus [39, 40]. These patients may rarely experience rhinorrhoea as a result of cerebrospinal fluid (CSF) leak, precipitated by dopamine agonist therapy that causes shrinkage of a macroprolactinoma and unmasks rents in the dura and bone, and require surgical intervention to correct the leak.

A minority of patients have manifestations of associated conditions, including patients with the MEN 1 syndrome, who often have primary hyperparathyroidism (90%) or entero-pancreatic neuroendocrine tumours (30–40%). These conditions are discussed in separate chapters. To identify the possibility of MEN 1 syndrome in the absence of a pertinent family history, it is prudent to measure serum calcium levels in all patients presumed to have prolactinomas.

Diagnostic Evaluation

The diagnosis of hyperprolactinemia is made by documenting elevated serum prolactin levels using a prolactin immunoassay. Pituitary imaging is generally advisable in these patients in the absence of an obvious explanation for hyperprolactinemia (such as pregnancy), as will be detailed next.

Laboratory Testing

Prolactin secretion is pulsatile; about 14 peaks in prolactin secretion occur every 24 hours [41]. The pulse amplitude increases during slow wave sleep. In patients with suspected hyperprolactinemia, blood specimens are obtained by venipuncture while avoiding physiologic stimuli of prolactin secretion (such as recent food consumption or exercise). Borderline prolactin elevations should be confirmed by repeat testing.

Prolactin is measured in serum specimens using two-site immunoassays, which feature a capture antibody that collects the antigen (prolactin) onto a solid surface (such as microbeads or coated tubes), and a reporter antibody that binds to the antigen (prolactin) at a different site and subsequently yields a detection signal by means of a luminescent or radiolabelled tag [42, 43].

Several caveats need to be considered in the interpretation of the results of prolactin immunoassays, including the hook effect, artefacts related to the presence of heterophilic antibodies, the presence of macroprolactin or exogenous biotin (please see Box 2.3.9.2) [44]. Immunoassay artefacts should be considered when serum prolactin levels do not decrease in a linear manner upon serial serum dilutions or in situations wherein there appears to be a discrepancy between the clinical picture and serum prolactin levels.

The hook effect is an immunoassay artefact that may lead to substantial underreporting of true prolactin values in specimens containing very high concentrations of the analyte (prolactin, in this case) [45]. This can rarely occur in patients with larger macroadenomas, wherein it is a consequence of the presence of vast stoichiometric excess of prolactin over the concentration of the two antibodies (capture and reporter) used in the immunoassay. In these rare cases, the concentration of the two antibody

Box 2.3.9.2 Caveats and artefacts that may confound the interpretation of prolactin levels

Hook effect
Heterophilic antibodies
Macroprolactin
Exogenous biotin

molecules is insufficient to allow formation of the heterotrimeric complex (consisting of capture antibody—prolactin—reporter antibody) that is required for prolactin detection. This artefact appears to be uncommon but is clinically significant, since patients with presumed prolactinomas are typically offered medical therapy as a first line intervention, whereas patients with minimally elevated prolactin levels (as a result of stalk effect) are referred for surgery. The hook effect can be circumvented by diluting the serum specimen (1:10 or 1:100), which helps restore an optimal stoichiometric relationship between prolactin and the two antibodies *in vitro*. Thus, it is advisable to request that the laboratory run serum prolactin specimens in dilution, particularly in patients with large tumours.

Heterophilic antibodies, such as human antimouse antibodies, can be present in human serum and falsely raise the results of prolactin immunoassays [46]. In these cases, the heterophilic antibody forms a bridge between capture and reporter antibodies in the absence of prolactin, generating a false detection signal. To avoid this artefact, immunoassays often include 'blocking' animal serum or heterophilic antibody blocking tubes.

Macroprolactin denotes the presence of prolactin aggregates in the serum, consisting of several prolactin monomers, either alone or together with immunoglobulin (IgG) [47–49]. In healthy individuals, macroprolactin accounts for less than 10% of prolactin in the serum, the rest being monomeric prolactin. Macroprolactin species can be detected and resolved by gel filtration. Since this is a labour-intensive process, it is used in research but very rarely in routine clinical laboratories. In daily practice, polyethylene glycol (PEG) is added to precipitate macroprolactin in serum specimens after centrifugation. Prolactin is then reassayed in the supernatant; the difference between prolactin concentration in the original serum specimen minus that in the supernatant can then be taken to quantify the presence of macroprolactin in the original specimen. Of note, hyperprolactinemia can be entirely attributed to the presence of macroprolactin only if the prolactin level is normal in the supernatant after PEG-induced macroprolactin precipitation.

Macroprolactin appears to have decreased biologic activity in some bioassays [47]. Women with macroprolactinaemia who were treated with dopamine agonist therapy did not show clear-cut improvement in menstrual patterns [48, 50]. As a corollary, the presence of macroprolactinaemia should be suspected in patients with hyperprolactinemia who have no evident symptoms that are typically associated with prolactin excess. Macroprolactinaemia has been reported in patients with either pituitary tumours or idiopathic hyperprolactinemia [51]. Therefore, pituitary imaging should be considered in patients with macroprolactinaemia. Overall, the clinical utility of macroprolactin assays is very limited in symptomatic patients with hyperprolactinemia.

Biotin ingestion in large doses can introduce artefacts, if the two-site immunoassay employs the biotin streptavidin reaction, wherein the capture antibody is biotinylated and collects prolactin onto streptavidin-coated microbeads [52, 53]. The presence of exogenous biotin in excess can interfere with this assay step, thus leading to substantial underreporting of prolactin levels. To avoid this artefact, patients can be cautioned to avoid consuming biotin for several days before submitting blood specimens for testing.

Once hyperprolactinemia is established, additional testing is required in order to clarify the underlying aetiology and assess other aspects of the patient's pituitary function [6]. It is advisable to consider the possibility of pregnancy in hyperprolactinaemic women of reproductive age and obtain a pregnancy test. In addition, laboratory evaluation of kidney and thyroid function is advised to exclude renal dysfunction and primary hypothyroidism, respectively, as underlying causes of hyperprolactinemia. Laboratory testing for hypogonadism is generally advised in hyperprolactinaemic patients (with the obvious exception of pregnancy or women who maintain menses despite elevated prolactin levels). The possibility of growth hormone cosecretion should be considered in hyperprolactinaemic patients with a sellar mass and serum IGF-1 levels be measured. In addition, all patients with macroadenomas require evaluation for hypopituitarism.

Imaging

Pituitary imaging is recommended in hyperprolactinaemic patients in order to detect an underlying sellar mass unless another compelling aetiology (such as pregnancy or severe primary hypothyroidism) is identified [54]. High resolution pituitary imaging should be obtained using a dedicated imaging protocol, preferably using MRI. Computed tomography (CT) is usually being advised as an alternative in patients who have contraindications to MRI, although the resolution of CT is more limited.

Patients taking medications that may raise serum prolactin levels cannot be always presumed to have medication-induced hyperprolactinemia. In most of these patients, baseline prolactin levels (obtained before the initiation of the medication in question) are not available. However, if the potentially offending medication can be safely discontinued, then prolactin levels should be rechecked 4 days later [6]. If hyperprolactinemia resolves on follow-up testing, then the medication can be reasonably presumed to be the culprit. However, it is often inadvisable to discontinue medications suspected to induce hyperprolactinemia (such as antipsychotics) and coordination with the prescribing physician is essential. Pituitary imaging is advised in these patients to exclude an underlying sellar lesion.

A thorough review of imaging data can be very helpful in narrowing down the differential diagnosis in hyperprolactinaemic patients, besides yielding important information on lesion size and its relationship to surrounding structures (please see **Figure 2.3.9.1** and **Figure 2.3.9.2**) [6, 7].

In patients with prolactinomas, there is a good correlation between tumour size and the magnitude of prolactin elevation. Patients with macroprolactinomas generally have serum prolactin levels that exceed 200 ng/ml (8700 pmol/L). Prolactin levels may not be proportionate to tumour size in patients with cystic prolactinomas, or poorly functioning prolactinomas wherein only a minority of cells secrete prolactin. The former can be diagnosed based on MRI scan characteristics. In contrast, patients with non-functioning lesions that cause stalk effect generally raise prolactin levels rather modestly (usually below 150 ng/ml [6500 pmol/L]). As a corollary, patients with macroadenomas and mildly elevated prolactin levels are likely to have a non-functioning lesion provided that the hook effect is excluded.

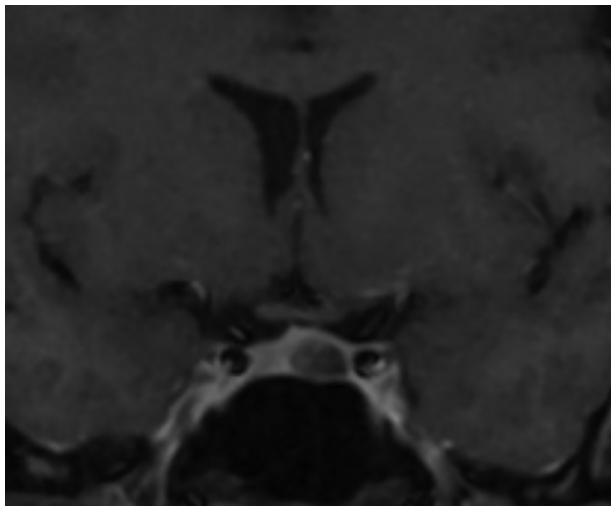

Figure 2.3.9.1 Coronal T1–weighted MRI image of the sella of a 34-year-old woman with a microadenoma, measuring 5 mm in greatest diameter (image obtained after gadolinium administration). She presented with secondary amenorrhoea. Her serum prolactin level was 82 ng/ml (3560 pmol/L) [normal, up to 20 ng/ml (870 pmol/L)]. Additional tests showed evidence of central hypogonadism. She was treated with bromocriptine, leading to restoration of menses and prolactin normalization. Tumour size decreased substantially on follow-up imaging.

Follow-up pituitary imaging is helpful in assessing tumour response to medical therapy and establishing the underlying aetiology [6, 7]. Prolactinomas generally decrease in size in response to dopamine agonist therapy, whereas non-functioning sellar masses are unlikely to shrink and may even grow after the institution of dopamine agonist therapy.

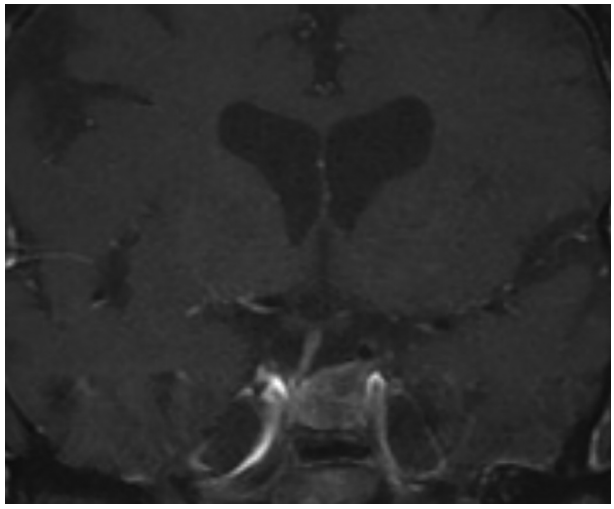

Figure 2.3.9.2 Coronal T1–weighted, gadolinium–enhanced MRI image of the sella of a 52-year-old man with a macroprolactinoma, measuring 2 cm in greatest diameter. He presented with new onset headache, low libido, and erectile dysfunction. His serum prolactin level was 302 ng/ml (13 130 pmol/L) [normal, up to 15 ng/ml (650 pmol/L)]. Evidence of central hypogonadism was present. He was treated with cabergoline, leading to symptomatic improvement, prolactin normalization, resolution of hypogonadism, and decrease in tumour size on follow-up imaging.

Management

The goals of therapy include control of hyperprolactinemia and amelioration of related symptoms, including resolution of hypogonadism. In addition, tumour control, relief of mass effect and restoration of pituitary function are important goals in patients with macroprolactinomas [6, 7].

Dopamine agonist therapy is generally first line therapy in patients who require treatment [6, 7]. Pituitary surgery and radiation therapy are second- and third-line interventions in selected patients, as will be discussed next.

Asymptomatic patients with microadenomas or no evident sellar mass, who are eugonadal and are not actively pursuing pregnancy can be followed expectantly without therapy [6, 7]. These patients require periodic follow-up, monitoring of prolactin levels, and periodic pituitary imaging to detect any evidence of progression (such as the development of symptoms or tumour growth) that would require the institution of medical therapy.

Medical Therapy

Medical therapy with dopamine agonists, including bromocriptine, cabergoline, or quinagolide (the latter being available in some countries outside the United States), represents the cornerstone of management in hyperprolactinaemic patients. As shown in Box 2.3.9.3, indications for dopamine agonist therapy in patients with hyperprolactinemia/prolactinoma include the presence of central hypogonadism, current interest in fertility, bothersome galactorrhoea, gynaecomastia, androgenic manifestations in women (hirsutism, acne), and tumour control in patients with presumed macroprolactinomas (with or without mass effect) [6, 7]. Of note, hyperprolactinaemic patients with stable microadenomas whose only symptoms are related to central hypogonadism and are not pursuing pregnancy can also be treated with sex steroid replacement and forego dopamine agonist therapy [6, 7].

Bromocriptine and cabergoline are both ergot alkaloid derivatives, whereas quinagolide is a non-ergot dopamine agonist [6, 7]. Pergolide was previously used off-label in hyperprolactinaemia, but was withdrawn from the United States and other countries because of the increased risk of cardiac valvulopathy associated with its use in high doses among patients with Parkinson's disease.

Bromocriptine is the first dopamine agonist introduced to treat hyperprolactinemia and prolactinomas [6, 7]. Bromocriptine therapy leads to prolactin normalization in about 75% of patients; most treated women resume menstruating regularly [1].

Box 2.3.9.3 Possible indications for dopamine agonist therapy in patients with hyperprolactinemia/prolactinomas

Central hypogonadism
Infertility
Galactorrhoea (if bothersome)
Gynaecomastia
Hirsutism, acne
Large tumour size (macroprolactinoma)
Mass effect (headache, visual field defects, etc.)

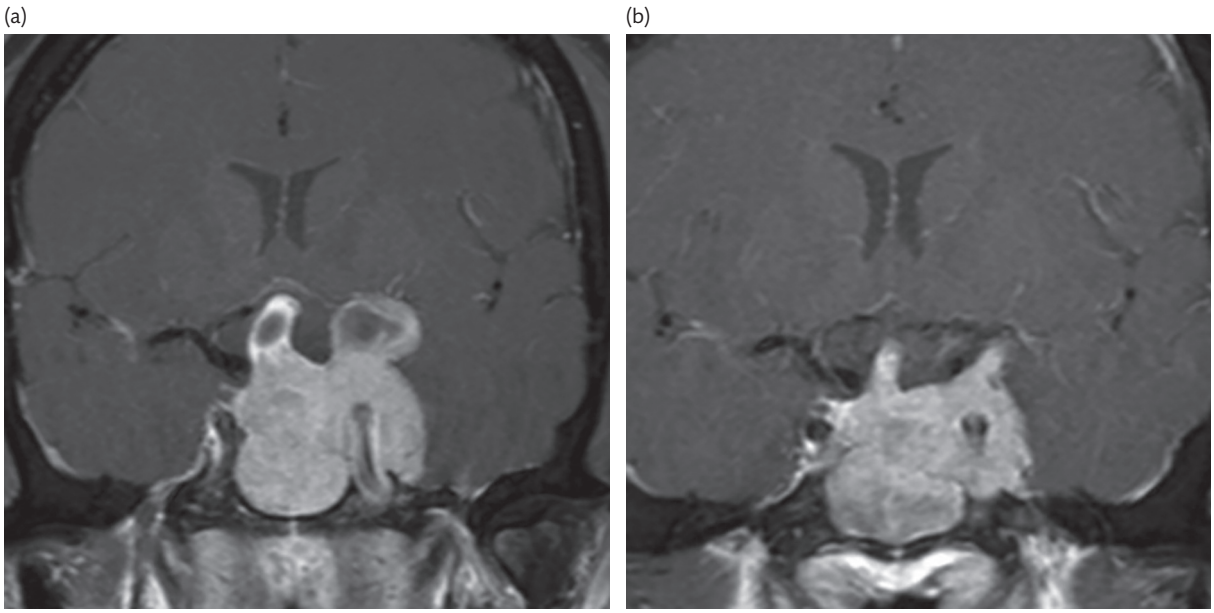

Figure 2.3.9.3 Coronal T1—weighted, gadolinium—enhanced MRI images of the sella of a 38-year-old man with a macroprolactinoma, measuring 3.5 cm in greatest diameter at presentation. Images were obtained before (a) and 3 weeks after (b) the institution of cabergoline therapy. He had presented with frequent headache of new onset, erectile dysfunction and bitemporal visual field deficits. At presentation, his serum prolactin level was 9487 ng/ml (412 475 pmol/L) [normal, up to 15 ng/ml (650 pmol/L)]. Evidence of central hypogonadism was present. He was treated with cabergoline, leading to resolution of visual field defects, improvement in prolactin levels, and decrease in tumour size on follow-up imaging. Testosterone replacement was ultimately advised since hypogonadism persisted despite prolactin normalization.

Cabergoline therapy is a selective D2 receptor agonist and is more effective than bromocriptine in inducing prolactin normalization and restoring eugonadism. In a randomized clinical trial of 459 women (most of whom harboured microadenomas), cabergoline administration normalized prolactin levels in 83% and restored eugonadism in 72% of cases, whereas bromocriptine normalized prolactin levels in in 59% and restored gonadal function in 52% of cases [55]. Cabergoline was also shown to have a more favourable side-effect profile than bromocriptine (as will be detailed subsequently).

Dopamine agonists also exert antiproliferative effects on prolactin-secreting tumours and cause involution of cellular organelles, accounting for their effects on tumour size (1). Bromocriptine therapy leads to a decrease in size of 76% of treated prolactinomas. Cabergoline has been reported to decrease tumour size in 96% of cases among naïve patients. In addition, cabergoline administration induces a decrease in tumour size in the majority of patients whose tumours are resistant to bromocriptine [56]. The extent of tumour shrinkage exceeds 50% in most patients treated with cabergoline over a variable time course (typically ranging from a few weeks to many months). An example of tumour response to cabergoline therapy in a patient with a macroprolactinoma is shown in Figure 2.3.9.3. Dopamine agonist therapy can ultimately lead to disappearance of visible tumour in some cases over a period of several years. Of note, improvement in mass effect can be very rapid in patients with macroprolactinomas treated with dopamine agonists, who often experience an improvement in visual field deficits within 1–3 days from treatment initiation [1]. In addition to gonadal dysfunction, other anterior pituitary hormone deficits may also resolve in treated patients as mass effect is relieved.

Bromocriptine has a relatively short half-life. Treatment is usually started at a dose of 0.625–1.25 mg daily and is advanced every 3–4 days to 2.5 mg daily. It is usually advisable to take the medication at bedtime with a small snack to minimize intolerance. The drug is titrated every 4 weeks towards normal prolactin levels, provided that it remains well-tolerated. Bromocriptine is generally given in divided doses (2–3 times daily) if a total dose over 2.5 mg daily is required.

Cabergoline has a longer half-life, owing to its slow release from binding sites and enterohepatic cycling [1]. Cabergoline is usually commenced at 0.25–0.5 mg weekly and is usually titrated every 4–6 weeks towards achieving normal prolactin levels, provided that the medication remains well-tolerated. It is sometimes advisable to advance cabergoline dose more quickly, including patients with giant macroprolactinomas. The majority of patients receiving cabergoline therapy require no more than 3.5 mg per week. However, resistance to all dopamine agonists is present in approximately 10% of patients, who may then need additional treatments (surgery, radiation therapy, or in the case of aggressive prolactinomas, temozolomide) [1, 57].

Dopamine agonists are generally well-tolerated. However, careful patient monitoring is advised to detect possible adverse effects (please see Box 2.3.9.4). Common adverse effects include nausea, dizziness, orthostasis [6, 7]. These adverse effects appear to be less frequent or severe with gradual dose titration (especially in the case of bromocriptine) and often improve over a period of several weeks. Some women may tolerate dopamine agonists better after intravaginal, rather than oral, administration although this is typically limited to short-term use only in patients seeking fertility. Less frequent adverse effects include nasal congestion, headache, constipation, nightmares, vivid dreams, digital vasospasm (akin to Raynaud's disease). As stated earlier, cabergoline is generally better tolerated than bromocriptine and can often be used to successfully treat patients who are unable to take bromocriptine because of intolerance [56].

Box 2.3.9.4 Adverse effects associated with dopamine agonist therapy

Common
Nausea
Dizziness, orthostasis

Less common
Headache
Nasal congestion
Constipation
Digital vasospasm
Vivid dreams, nightmares

Infrequent
Anxiety, depression, psychosis
Impulsivity–related manifestations

Rare
Fibrotic reactions
Cardiac valvulopathy*

* Reported in patients with Parkinson's disease on high doses of cabergoline or pergolide.

Tumour fibrosis has been reported in patients exposed to bromocriptine [58]. Very rarely, mediastinal and retroperitoneal fibrosis have been reported. In addition, patients with Parkinson's disease on very high cabergoline or pergolide doses (but not bromocriptine) were found to have a higher risk of cardiac valvulopathy [59, 60]. Such fibrotic reactions are thought to be a consequence of serotonin (5HT2B) receptor activation. Available data suggest that the risk of cardiac valvulopathy is related to the cumulative cabergoline dose. In contrast to the worrisome findings in patients with Parkinson's disease, patients with hyperprolactinemia who are generally treated with lower cabergoline doses (up to 2.0 mg weekly) have not been shown to be at risk for this complication [61]. Nevertheless, it is prudent to inform patients of this theoretical risk, particularly in patients who are taking high doses of dopamine agonists. Echocardiographic monitoring can be considered in such patients.

Rare adverse effects include the development of impulsivity (such as gambling, compulsive shopping, hypersexuality, and others) or psychosis, which can be serious but resolve after the offending drug is discontinued [62, 63]. Dopamine agonists should be avoided in patients with psychosis. However, some antipsychotics, such as aripiprazole, have both dopamine antagonist as well as partial dopamine agonist properties, and could be used in this setting in collaboration with the patient's psychiatrist. Patients with depression or anxiety can often be treated with dopamine agonists as long as the patient's psychiatrist has been consulted.

Patients who have shown good responses to dopamine agonist therapy can often be gradually downtitrated, as tumours may become more sensitive to the drug's effects as they get smaller. In some cases, the dopamine agonist can be withdrawn entirely after 2–3 years of therapy [64–66]. Good candidates for medication withdrawal are those who have maintained normal prolactin levels and have little or no visible remaining tumour on pituitary imaging. In one study of patients with normoprolactinaemia on cabergoline therapy, the risk of recurrence of hyperprolactinemia was higher in patients with visible tumour on MRI than those who had no residual tumour; in addition, patients with macroadenomas were at higher risk of recurrence of hyperprolactinemia than those with microadenomas [65]. If dopamine agonist therapy is withdrawn, patient education and careful monitoring are needed to detect possible recurrence.

Pituitary Surgery

Pituitary surgery is generally performed via the transsphenoidal approach [67]. Among patients with prolactinomas, pituitary surgery is generally second-line therapy (please see Box 2.3.9.5). Indications for pituitary surgery include lack of response to dopamine agonist therapy, including patients with persistent mass effect or tumour growth on medical therapy [67]. Cystic prolactinomas that are not responsive to dopamine agonists may be amenable to surgical resection [68]. Patients with resistance to medical therapy or intolerance to dopamine agonists and patients in whom these medications are contraindicated (including patients with psychosis) are also considered for surgery. In addition, patients with pituitary apoplexy (occurring either de novo or in response to dopamine agonist therapy) and those with CSF leak occurring in response to medical therapy are surgical candidates [67]. Patient preference should also be considered, as some patients with microprolactinomas may wish to avoid long-term medical therapy [69]. The role of surgery in the preconception setting is discussed in a separate section.

Surgical outcomes depend on tumour size and location [67]. In addition, surgical expertise is critical in order to achieve optimal outcomes. Published data typically represent the outcomes of experienced pituitary surgeons with a high procedural volume [70]. Surgery is very effective in relieving mass effect, particularly visual field deficits, by decompressing the optic apparatus. In aggregated case series, normoprolactinaemia was achieved in 75% of 2137 patients with microprolactinomas but only 34% out of 2226 patients with macroprolactinomas who were evaluated early postoperatively [1]. On long-term postoperative follow-up, normoprolactinaemia was reported in 60% of patients with microprolactinomas and 25% of patients with macroprolactinomas as a consequence of recurrence of hyperprolactinemia, particularly in patients with macroadenomas.

Pituitary function may improve in about 35% of patients with anterior hypopituitarism, whereas new anterior pituitary function

Box 2.3.9.5 Indications for pituitary surgery in patients with prolactinomas

Persistent mass effect (including visual field defects) despite dopamine agonist therapy
Tumour growth despite dopamine agonist therapy
Resistance to dopamine agonist therapy
Intolerance to dopamine agonist therapy
Contraindications to dopamine agonist therapy (including psychosis)
Pituitary apoplexy
Cerebrospinal fluid leak (rhinorrhoea)
Women with macroprolactinomas seeking fertility
Patients' preference (e.g. those with microprolactinomas who wish to avoid medical therapy)

Table 2.3.9.3 Safety of dopamine agonist therapy in the preconception setting*

	General population (%)	Patients who received bromocriptine [n (%)]	Patients who received cabergoline [n (%)]
Pregnancies		6239	789
Miscarriages	10–15%	620 (9.9%)	60 (7.6%)
Terminations	20%	75 (1.2%)	59 (7.5%)
Preterm deliveries**	12.7%	519 (12.5%)	67 (11.6%)
Congenital malformations***	3.0%	93 (1.8%)	21 (3.2%)

* Data were extracted from reference 8.
** Data were available on 4139 women who received bromocriptine and 547 women who received cabergoline before pregnancy.
*** Data were available on 5123 women who received bromocriptine and 664 women who received cabergoline before pregnancy.

deficits may occur in up to 20% of cases postoperatively [67]. Diabetes insipidus (DI) is often transient; permanent DI is uncommon in patients operated upon by experienced neurosurgeons. Other complications include cerebrospinal fluid rhinorrhoea, epistaxis, tumour haemorrhage, stroke, and meningitis [67]. Lower perioperative morbidity and mortality rates are achieved by expert neurosurgeons [71].

Radiation Therapy

Radiation therapy is reserved for patients with macroprolactinomas who cannot achieve adequate tumour control with dopamine agonist therapy and surgery [72]. Radiation therapy can be administered either as conventional radiation therapy or via a stereotactic approach (including Gamma Knife™, Cyber Knife ™, or proton beam radiation therapy). Stereotactic radiation therapy can be given in a single session ('radiosurgery') in patients whose tumours are distant from the optic apparatus. Radiation therapy is very effective for tumour control. However, control of hyperprolactinemia is slowly achieved over several years. All patients who have received radiation therapy are at lifelong risk of anterior hypopituitarism and require long-term follow-up [73]. Uncommonly, vision loss, ophthalmoplegia, stroke, temporal lobe necrosis, or secondary tumour formation may occur; whether stereotactic radiation therapy is safer than conventional radiation therapy has not been established.

Chemotherapy

Temozolomide is an alkylating agent that is absorbed orally and has been used off-label as therapy for locally aggressive pituitary adenomas or carcinomas (including prolactin-secreting tumours) [74–76]. It is generally used in patients whose tumours do not adequately respond to dopamine agonists, surgery, and radiation therapy. Using either tumour size or prolactin levels as treatment endpoints, temozolomide appears to benefit up to 73% of patients with locally aggressive adenomas. In some studies, tumour expression of O6-methylguanine-DNA methyltransferase (MGMT), a DNA repair enzyme, has been reported to show a negative association with response rates to temozolomide therapy [74–76]. Escape from the beneficial effects of temozolomide often occurs over time.

Hyperprolactinaemia and Pregnancy

Hyperprolactinemia and prolactinomas raise several concerns in women who are planning to conceive or are pregnant. Important considerations include subfertility in hyperprolactinemia, the safety of dopamine agonist therapy in the preconception setting and the effect of pregnancy on prolactinomas.

Hyperprolactinemia often impairs fertility in patients of both genders as a consequence of central hypogonadism [8, 9]. In addition to anovulation, the length of the luteal phase of the menstrual cycle is shortened, which can decrease the likelihood of implantation after oocyte fertilization. Dopamine agonist therapy which results in a normal prolactin level improves fertility in patients of both genders [77].

The safety of any medical therapy is of prime importance in the preconception setting as well as during pregnancy. Compiled, retrospectively collected data on many thousands of pregnancies have shown that bromocriptine therapy administered during the preconception period does not raise the risk of adverse maternal or fetal outcomes during a subsequent pregnancy (please see Table 2.3.9.3) [8, 9, 78]. Data on the safety of cabergoline are also reassuring. However, the published experience is substantially larger for

Table 2.3.9.4 Risk of prolactinoma growth during pregnancy*

Tumour size before gestation	Number of patients	Pituitary surgery and/or radiation therapy before gestation	Patients with symptomatic tumour growth during pregnancy [n (%)]
Macroprolactinoma	214	No	49 (22.9%)
Macroprolactinoma	148	Yes	7 (4.8%)
Microprolactinoma	658	No	18 (2.7%)

*Data were extracted from reference 8.

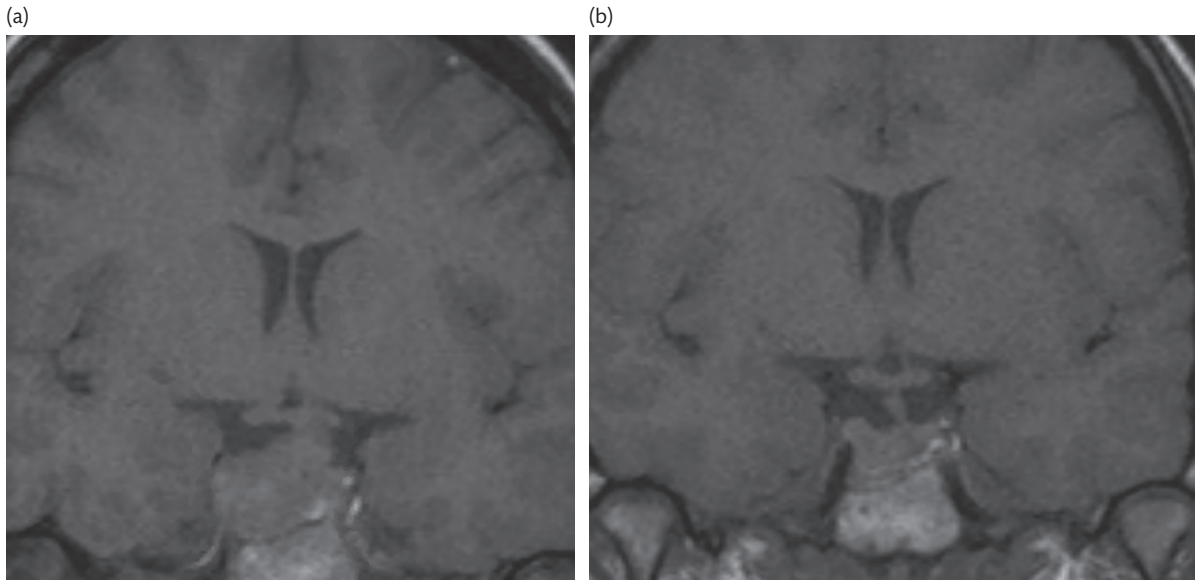

Figure 2.3.9.4 Coronal T1–weighted MRI images of the sella of a 23-year-old woman with a macroprolactinoma, measuring 2 cm in greatest diameter, which caused temporal visual field defects during the third trimester of pregnancy (a). Institution of bromocriptine therapy during pregnancy led to resolution of visual field defects as a result of tumour shrinkage (b).

bromocriptine than cabergoline [8, 9, 79]. As a corollary, bromocriptine is the agent of choice in the preconception setting or during gestation.

During pregnancy, oestrogen is copiously secreted by the placenta and may potentially promote prolactinoma growth. In aggregate, retrospective data suggest that the risk of microprolactinoma growth during pregnancy is low (please see Table 2.3.9.4) [8, 9, 80]. In contrast, the risk of tumour growth during gestation is higher in women with macroprolactinomas [8, 9]. A case of a patient with a macroprolactinoma that enlarged during pregnancy is shown in Figure 2.3.9.4. The risk of tumour growth during gestation is mitigated in women whose macroprolactinomas were resected before conception.

Hyperprolactinaemic women who are planning to conceive are offered bromocriptine therapy; cabergoline can be used in patients who are intolerant to bromocriptine. Pituitary surgery is considered in women with macroprolactinomas whose tumours do not substantially shrink in response to medical therapy in order to mitigate their risk of tumour growth during a subsequent pregnancy.

In patients with microprolactinomas, it is advisable to discontinue dopamine agonist therapy when pregnancy is established. During pregnancy, these patients can be followed clinically. Monitoring serum prolactin levels is of no diagnostic value during gestation. In the unlikely event that mass effect develops (including visual field deficits), limited views of the sella are obtained via non-contrast MRI and dopamine agonist therapy (preferably bromocriptine) is reinstituted. Limited data from case series suggest that bromocriptine and cabergoline are often effective in relieving mass effect during pregnancy and are not associated with increased risk [8, 9].

Medical management is individualized in patients with macroprolactinomas, who are at higher risk for tumour growth during gestation. In most cases, dopamine agonist therapy is discontinued when pregnancy is established. In some cases, including tumours close to the optic apparatus, dopamine agonists are continued during gestation to minimize the risk of tumour growth during that period. All pregnant patients with macroadenomas require careful follow-up, including frequent visual field-testing during gestation. If evidence of mass effect develops, then dopamine agonist (preferably bromocriptine) therapy is reinstituted and can be effective in relieving mass effect [8, 9, 81]. Alternatively, pituitary surgery can be performed to restore vision in patients who are unresponsive to dopamine agonist therapy. However, any surgical procedure performed during gestation is associated with a risk of miscarriage [8, 9].

Asymptomatic women with prolactinomas should be encouraged to nurse. Dopamine agonists are avoided in asymptomatic women who are nursing, since they suppress milk production and, in cases of partial suppression of lactogenesis, may expose the infant to dopamine agonists which are present in breast milk. There is no evidence that nursing is associated with an increased risk of tumour growth postpartum [8, 9].

2.3.10 Acromegaly

John A.H. Wass, Peter J. Trainer, and Márta Korbonits

Definition

Acromegaly almost always is the result of an anterior pituitary tumour and is a consequence of growth hormone (GH) and insulin-like growth factor-I (IGF-1) excess. It is characterized by enlargement of the hands and feet (Greek: *akron*, extremities; *megas*, great). Gigantism is the juvenile (prior to epiphyseal fusion) counterpart of acromegaly and results in excessive linear growth.

History

Giants are the material of legend and fairy tale. The earliest plausible description of a giant is Goliath (alleged to have been 290 cm tall), whose death, while fighting David, has been speculated, to have been a result of the disadvantage caused by a temporal field defect as a result of his pituitary tumour. The skeleton of Irish giant Charles Byrne (234 cm) is exhibited in the Royal College of Surgeons of England and has twice provided insight into our understanding of the pathophysiology of acromegalic gigantism. Harvey Cushing in 1910 had the skull opened to confirm an enlarged pituitary fossa, and more recently, a tooth was extracted to allow isolation of DNA which resulted in a genetic explanation for Byrne's disease as well as for the folklore of the Irish Giants [1]. The tallest man recorded was Robert Wadlow (272 cm), an American who died in 1940 at the age of 22 years, most likely suffered from X-linked acrogigantism (see next). Comprehensive historical and illustrated descriptions of acromegaly and gigantism are available [2].

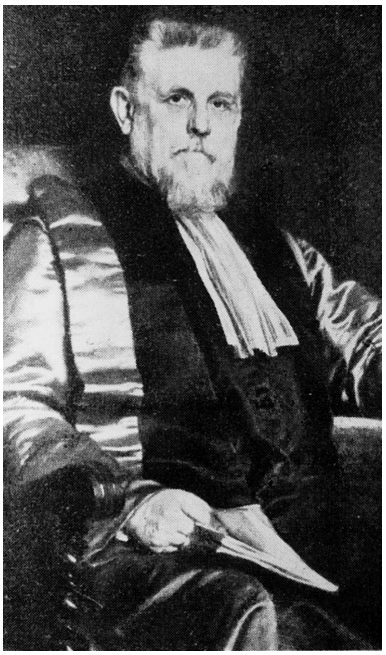

Figure 2.3.10.1 Pierre Marie, the describer of acromegaly.

Although there had been excellent previous descriptions, for example, the first description by a Dutch physician Johannes Wier in 1567 of a giant female patient, it was Pierre Marie (1886) who gave the name to the condition (Figure 2.3.10.1). He did not, at the time, appreciate that the pituitary was the cause of the problem. The recognition of the link between an enlarged pituitary and acromegaly is attributed to Minkowski (1887). Familial acromegaly was depicted by the illustrator John Kay of the Irish giant Charles Byrne with his twin giant cousins, the Knipe twins at the end of the 18th century [1]. Its clinical description was a century later [3]. The first gene identified causing acromegaly was *GNAS*, both as a change in the pituitary only [4] or as an embryonic mutation as part of McCune–Albright syndrome [5]. The first MEN1 syndrome patient had gigantism [6] with the gene responsible identified in 1997 [7]. Most young-onset acromegaly families have *AIP* (aryl hydrocarbon receptor interacting protein gene) mutations [8], while the tallest giants have *GPR101* duplication as a germline [9] or mosaic [10] condition. The first attempt at surgical treatment was by Caton and Paul in Liverpool (1893) who attempted to relieve the headache by surgical removal of part of the skull vault. Transsphenoidal operation on a patient with acromegaly was first reported von Eiselsberg in Vienna 1908. Harvey Cushing was convinced that acromegaly was a form of hyperpituitarism and operated on numerous cases via the transsphenoidal route. Béclère (1909) was the first to use pituitary radiation therapy. The modern era of management was marked by the development of radioimmunoassays for GH in the 1960s which provided the ability to measure disease activity. Landmarks in the medical management of acromegaly are represented by the introduction of dopamine agonists in 1972 [11], somatostatin analogues in 1985 [12], and the GH receptor antagonist pegvisomant in 2000 [13].

Epidemiology

The prevalence ranges from 28 to 137 per million with an incidence between 2 and 11 cases per million [14]. Acromegaly occurs in all races with an approximately equal sex incidence. The average age at diagnosis is 44 years, but patients with acromegaly can present at any age. The mean time between development of symptoms to diagnosis is 5 years according to the latest data. Young patients typically have larger, more aggressive tumours and grossly elevated serum GH levels (see next) while a more subtle phenotype with smaller and less aggressive tumours is typically encountered in older patients.

Aetiology

Over 99% of patients with acromegaly have a GH-secreting adenoma, which, in up to a third of cases, may cosecrete prolactin. Very rarely GH and thyroid-stimulating hormone (TSH) are cosecreted, causing acromegaly and thyrotoxicosis with detectable TSH (**Box 2.3.10.1**).

Less than 1% of patients with acromegaly have a GH-releasing hormone (GHRH)-secreting tumour, as a result of a neuroendocrine tumour of either the pancreas (often associated with MEN1 syndrome) or the lung, with extremely rare cases from a phaeochromocytoma. Ectopic GHRH results in a global enlargement of the pituitary as a consequence of somatotroph hyperplasia and presents a diagnostic challenge. Hypothalamic GHRH-producing tumours have been also described, such as a gangliocytoma. Pituitary carcinomas represent 0.1% of pituitary tumours, with GH-secreting carcinomas being the third most common subtype, after prolactinomas and corticotrophinomas [15]. Most often the metastases are found in the cerebrospinal axis, but they have been described outside the central nervous system.

Acromegaly can occur as part of a genetic condition either as part of a syndromic disease (MEN1, MEN4, Carney complex, pituitary adenoma associated with paragangliomas or McCune–Albright syndrome) or as an isolated condition (familial isolated pituitary adenoma, FIPA), as discussed next.

Pathology

Somatotroph cells in the normal pituitary are usually located in the lateral region of the pituitary, and at least in rodents this pool of somatotrophs expands significantly in puberty, possibly explaining the characteristic cavernous sinus invasion of these adenomas. Somatotroph adenomas can either be densely granulated with strong GH staining and diffuse distribution of cytokeratin or sparsely granulated with characteristic dot-like cytokeratin staining [16]. The sparsely granulated somatotroph adenomas occur more often in young patients, have a greater tendency to tumour invasiveness and respond poorly to somatostatin analogue therapy. Expression of somatostatin receptors can be assessed by immunohistochemistry, with subtype 2 and 5 being the most prominent, and their correlation with response to first- and second-generation somatostatin analogues has been studied [17]. Somatotroph hyperplasia can be seen in 25% of patients with X-linked acrogigantism, in 70% of patients with Carney complex, in patients with McCune–Albright syndrome, if the pituitary area is affected, with or without adenoma development and in patients with GHRH-secreting tumours. Silent somatotroph tumours (clinically non-functioning pituitary adenomas with GH staining on histology) have been observed in 7–8% of somatotroph adenomas [18].

Box 2.3.10.1 Lesions associated with excessive secretion of GH and IGF-1

- Pituitary
  - Growth hormone-secreting adenoma
  - Growth hormone and prolactin mixed adenoma
  - Growth hormone and TSH mixed adenoma
  - Plurihormonal adenoma
  - Growth hormone-secreting carcinoma
  - Somatotroph hyperplasia
- GHRH-producing neuroendocrine tumour (pancreas and lung)
- GHRH-producing hypothalamic lesions such as gangliocytoma
- GH-secreting ectopic tumours (only three cases described)

Molecular Endocrinology of GH-Secreting Pituitary Adenomas

The molecular pathogenesis of sporadic GH-secreting pituitary tumours is best considered by discussing changes which activate factors leading to increased tumour formation (e.g. oncogenes) or alterations which inactivate cell proliferation controlling genes (e.g. tumour suppressor genes). The GHRH—GHRH receptor—stimulatory G-protein α-subunit—cAMP—protein kinase A—CREB—Pit-1 pathway is key for somatotroph cell function. Activating genetic alterations include the stimulatory guanine nucleotide-binding protein (G-protein) α-subunit gene (*GNAS*), the orphan G-protein associated 7 transmembrane receptor GPR101, cyclin D (*CCDN1*), fibroblast growth factor receptor 4 (*FGFR4*), and pituitary tumour transforming gene (*PTTG*).

The stimulatory G protein ($G_s\alpha$) is involved in the activation of adenylate cyclase which mediates the regulatory actions of GHRH to stimulate GH synthesis and secretion. Missense mutations of *GNAS* at codons 201 and 227 (termed 'gsp' mutations) result in inhibition of the intrinsic GTPase activity of the α-subunit of the G protein, while its adenyl cyclase activating capacity is intact resulting in high intracellular levels of cyclic adenosine monophosphate (AMP). The downstream signalling pathway includes increased protein kinase A and cyclic AMP-response element binding protein (CREB) activity, increased binding, and activation of the *POU1F1* promoter resulting in activate GH synthesis and release. This results in autonomous GH secretion (**Figure 2.3.10.2**). Somatic *GNAS* mutations have been demonstrated in 40% of human GH-secreting pituitary adenomas and are the most commonly described genetic defect. If the gsp mutation occurs in embryonic stage and is found in a mosaic form in various organs contributing to activation of various G_s-coupled receptors, the patient develops McCune–Albright syndrome (see next). Patients with *GPR101* mutation develop infant onset somatotroph or somatomammotroph hyperplasia or tumours. The role of GPR101 is unclear in the somatotroph adenoma tumorigenesis. This cAMP-coupled receptor is normally expressed in the hypothalamus and could be upstream of GHRH. Embryonic overstimulation of GHRH and therefore GH/PRL-secreting cells may lead to tumorigenesis, a phenomenon

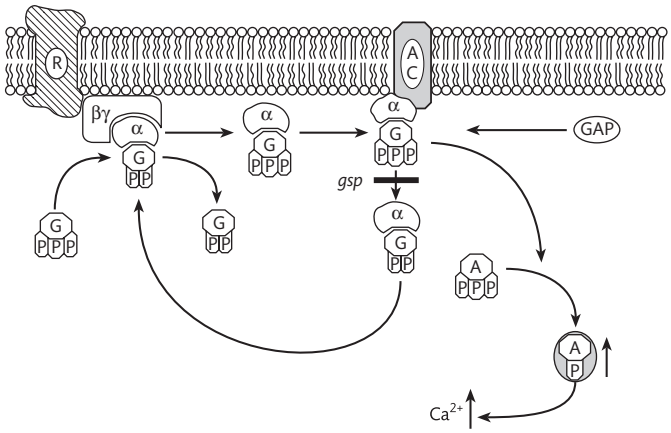

Figure 2.3.10.2 The G-protein abnormality seen in the pituitary of 40% of Caucasian patients with acromegaly.

observed in animal models. Increased *PTTG1* mRNA expression has been demonstrated in somatotroph adenomas and correlates with tumour size. FGFR4 and cyclin D overexpression have been described in pituitary tumours; however, this is not specific for somatotroph adenomas.

Tumour suppressor genes that may be involved in pituitary tumour pathogenesis include the retinoblastoma gene, cyclin-dependant kinase inhibitors, such as p27 (*CDKN1B*) and p16 (*CDKN2A*) as well as growth arrest and DNA damage-inducible protein (*GADD45γ*) and maternal imprinting gene 3 (*MEG3*). Some of these proteins are lost in pituitary tumours due to epigenetic mechanisms such as hypermethylation. p27 expression is reduced in all types of pituitary adenomas including somatotrophs. GADD45γ is a pro-apoptotic factor which is lost in GH-secreting adenomas. *MEG3* is an imprinted gene encoding a non-coding RNA that suppresses tumour cell growth; it is lost in non-functioning pituitary adenomas but not in somatotroph tumours. Germline *AIP* mutations have been described in patients with sporadic or familial isolated pituitary adenomas and *in vitro* studies confirm that loss of function of this protein is in the pathogenesis of these adenomas. AIP may play a role in the somatostatin induced inhibitory pathway regulating the tumor suppressor gene *ZAC1* or the inhibitory G protein $G_i\alpha 2$ [19].

Genetic Alterations Associated with Acromegaly

McCune–Albright Syndrome

This syndrome is characterized by polyostotic fibrous dysplasia, hyperpigmented cutaneous patches, and endocrinological abnormalities including precocious puberty, thyrotoxicosis, acromegaly or gigantism, and Cushing's syndrome. The extent of the mosaic activating mutations determine the severity of the disease in the various organs where $G_s\alpha$ plays an important role. The pituitary and the surrounding tissues are affected in 20–30% of the cases. A third of patients present in childhood and may develop gigantism, especially if there is hypogonadism due to excess prolactin, although the combination of early puberty and GH excess may result in a normal final height. The pituitary shows hyperplasia in just under half of the cases with micro or macroadenomas in the rest [20]. These patients present a challenge for treatment as the surrounding fibrous dysplasia in the bones renders difficult surgical access. Combination treatment with dopamine, somatostatin agonists, and GH-receptor antagonist can provide biochemical control.

Multiple Endocrine Neoplasia Type 1 and Type 4

MEN1 and MEN4 are an autosomal dominant disorders which are described elsewhere (see Section 4, 'Parathyroid, Calcium and Bone Metabolism Disorders') (see pg. 632). Following prolactinomas and clinically non-functioning adenomas, acromegaly is third commonest pituitary tumour type to occur in MEN1 syndrome, although plurihormonal adenomas are also characteristic of MEN1. In patients with MEN1-related GH excess, especially in childhood, GHRH-secreting pancreas neuroendocrine tumours should be considered. MEN4 has been described in a few patients with an MEN1-like phenotype and germline mutations in cell cycle inhibitor genes, such as p27 (*CDKN1B*), p15 (*CDKN2B*), p18 (*CDKN2C*), and p21 (*CDKN1A*). The most common tumour type is somatotroph adenomas, including a case with childhood-onset disease.

Carney Complex

This is an autosomal dominant condition caused by a loss-of-function mutation in the protein kinase A regulatory subunit gene (*PRKAR1A*) in over 70% of the cases, with others mapping to 2p16. A single patient with duplication of the activating subunit of protein kinase A (*PRKACB*) has also been described. It is characterized by spotty cutaneous pigmentation, cardiac and other myxomas, and endocrine overactivity, particularly Cushing's syndrome due to nodular adrenal cortical hyperplasia. Abnormal GH dynamics can be detected in two third of cases and with 10% of the patients developing true adenomas [21].

Familial Isolated Pituitary Adenomas

Patients with FIPA usually have no other endocrine abnormality. The genetic background and the clinical characteristics are heterogeneous.

X-linked Acrogigantism (XLAG)

Patients with germline or mosaic duplication in the *GPR101* gene, which is located on the X chromosome, develop infant onset acromegaly diagnosed <5 years of age with symptoms starting < 2 years [9]. Patients have pituitary hyperplasia or adenoma, secreting usually both GH and prolactin. The majority of the patients are females with a *de novo* germline mutations, while males are either have mosaic mutation or inherited the mutation from their mother. Unless treated, these patients develop extreme tall stature. As the whole gland is involved, treatment is challenging with either total hypophysectomy, combination medical treatment or radiotherapy.

Aryl Hydrocarbon Receptor Interacting Protein

Loss-of-function heterozygous germline mutations in the *AIP* gene cause young-onset acromegaly with incomplete (20–30%) penetrance [22]. Most patient have acromegaly manifesting in the second decade, with prolactinomas occurring in 10% of the cases and other pituitary tumour types rarely. Patients with *AIP*

mutations usually have early-onset, with 50% reporting onset of symptoms in the second decade [23]. The invariably sparsely granulated adenomas may show invasive growth and respond poorly to somatostatin analogue therapy. Genetic cascade screening can identify carrier family members leading to earlier diagnosis and better chance of a cure.

FIPA Families Currently Without a Known Mutation

The majority (89%) of the FIPA families do not harbour known disease-causing mutations. Patients in these families have an age of onset similar to sporadic pituitary adenoma patients and the associated tumour types are wider than in AIP or XLAG cases. About half of the families are homogenous (i.e. all affected family members have the same pituitary adenoma type) with the other half presenting with heterogeneous type of adenomas, acromegaly and prolactinoma being the most common tumour types [23]. While penetrance is 100% in XLAG and 20–30% in AIP kindreds, it is somewhat lower in AIP-negative FIPA families.

Symptoms of Acromegaly

Gross, long-standing acromegaly is easily recognized, the challenge is recognizing the more subtle phenotype and shortening the interval between the onset of disease and diagnosis. The most noticeable feature is usually a change in facial appearance. Vague symptoms such as fatigue may predominate, while increased sweating and sebaceous activity with acne can be problems. There is enlargement of the supraorbital ridges, prognathism, and macroglossia (see Figures 2.3.10.3 and 4); interdental separation occurs. This, together with the obvious changes in the hands and feet, often makes the diagnosis easy (see Box 2.3.10.2). Headache is a typical symptom, more commonly than other types of pituitary

Figure 2.3.10.4 Macroglossia in a patient with acromegaly. The patient had to have surgical tongue reduction.

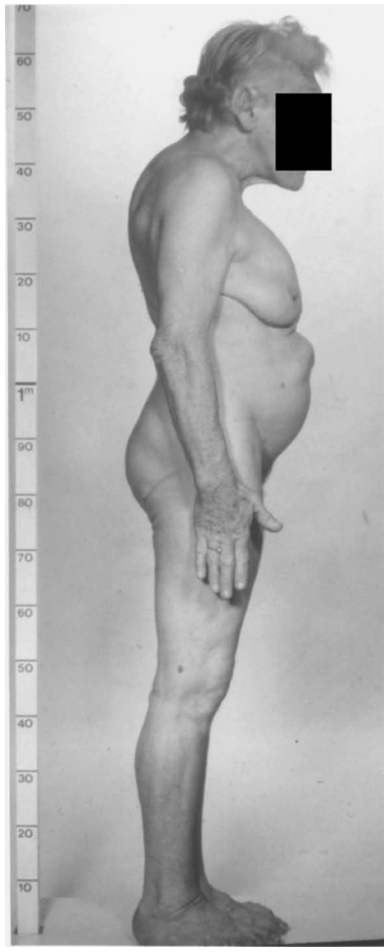

Figure 2.3.10.3 Kyphosis in a patient with acromegaly.

Box 2.3.10.2 Clinical features of acromegaly

Acral enlargement
- Increased hand-, shoe-, and ring size
- Prominent nasolabial fold
- Frontal bossing
- Prominent supraorbital ridge

Skin
- Increased sweating
- Oiliness and increased sebaceous activity
- Hirsutism
- Hyperpigmentation
- Thickened skin (detected on the dorsum of the hand)
- Skin tags
- Furrowing of the skin on the forehead or back of the head (cutis verticis gyrate)

Cardiovascular
- Hypertension
- Congestive heart failure
- Ventricular hypertrophy
- Cardiomyopathy [25]

Respiratory
- Sleep apnoea, snoring
- Enlarged sinuses
- Deep voice

Musculoskeletal
- Arthropathy, knee, hip, lumbar spine [26]
- Kyphosis (Figure 2.3.10.3)
- Prognathism
- Dental malocclusion

Box 2.3.10.2 *Continued*

- Muscle weakness
- Increased height

Alimentary

- Macroglossia (Figure 2.3.10.4)
- Visceromegaly (liver, spleen, kidney, bowels, salivary glands)
- Colonic polyps, constipation

Neurological

- Headache
- Sudden severe headache often with ptosis (pituitary apoplexy)
- Carpal tunnel syndrome (Figure 2.3.10.5)
- Paraesthesia

Reproductive

- Amenorrhoea
- Galactorrhoea
- Impotence
- Prostatic hypertrophy

Metabolic alterations

- Increased insulin resistance, diabetes mellitus
- Hypercalciuria, hypercalcaemia [27]

Endocrine system

- Cosecretion of prolactin or TSH
- Galactorrhoea
- Hypopituitarism
- Multinodular goitre

Psychological effects

- Anxiety due to distorted body image
- Tiredness, fatigue, apathy, depression

Local tumour effects

- Headache
- Visual field defects (bitemporal hemianopsia)
- Cranial nerve palsy

adenoma. Patients may present to rheumatologists, orthopaedic surgeons (joint pain and abnormalities), dentists (separation of the teeth, jaw pain), neurologists (carpal tunnel syndrome), gynaecologists (menstrual disturbance), ophthalmologists (visual problems), cardiologists (high blood pressure, heart disease) or to physicians treating the patient's sleep apnoea, hypertension, or diabetes mellitus [24]. Often the symptoms are present and progress insidiously over several years. It can be useful to review serial old photographs to show the presence and progress of subtle facial appearances.

Symptoms of an enlarged pituitary fossa are the same as with non-functioning tumours and are discussed elsewhere and include visual field defects, headache, and pituitary apoplexy (more often in younger patients).

The Phenotypic Changes of Acromegaly

Skin on the back of the hand is thickened and excessive sweating occurs in 80% with patients looking older than their years.

In the cardiovascular system, hypertension is present in 50% due to a direct effect of GH on sodium absorption, and there is also increased left ventricular muscle mass. Ischaemic heart disease is also present, possibly exacerbated by insulin resistance and is a major cause of morbidity and mortality. Myocardial hypertrophy with fibrosis leading to ventricular dilatation and biventricular failure are features of an acromegalic cardiomyopathy.

Respiratory symptoms are also common and account for part of the increased mortality of the condition. Sleep apnoea may result from significant airway obstruction caused by prognathism, macroglossia, and hypertrophied nasal structures and narcolepsy may be a presenting symptom in patients with acromegaly. Difficulty in tracheal intubation can be a problem in patients with acromegaly undergoing anaesthesia.

In the alimentary tract macroglossia, constipation and visceromegaly are common. A high prevalence of colonic polyps in acromegaly is reported and these may progress to colonic carcinoma. GH and/or IGF-1 may possess direct mitogenic effects on colonic epithelial cells.

Metabolic Consequences of Acromegaly

Increased insulin resistance occurs because of direct anti-insulin effects of GH and can result in diabetes mellitus and carbohydrate tolerance, which is reversible with successful treatment of the GH hypersecretion. Hypercalciuria occurs in 80% of patients because of GH being facultative in the synthesis of 1,25-dihydroxyvitamin D increases calcium absorption from the gut and reabsorption in the kidney. Hyperphosphataemia may occur due to the direct effect of GH/IGF-1 on renal phosphate reabsorption. If hypercalcaemia is detected, hyperparathyroidism and MEN1 syndrome (3%) needs to be investigated. Multinodular goitre occurs with increased frequency in acromegaly. IGF-1 is a major determinant of thyroid cell growth. Thyroid dysfunction (hyperthyroidism) occurs in acromegaly and is most commonly due to a multinodular goitre, but TSH secretion from a mixed pituitary tumour should be considered if the TSH is inappropriately normal/elevated in association with thyrotoxicosis. See Figure 2.3.10.5.

Cardiovascular and Respiratory Risk

This increased risk relates to hypertension and diabetes. There is no characteristic lipid disturbance in acromegaly. Before 1966, 50% of patients with acromegaly died before the age of 50, cardiovascular

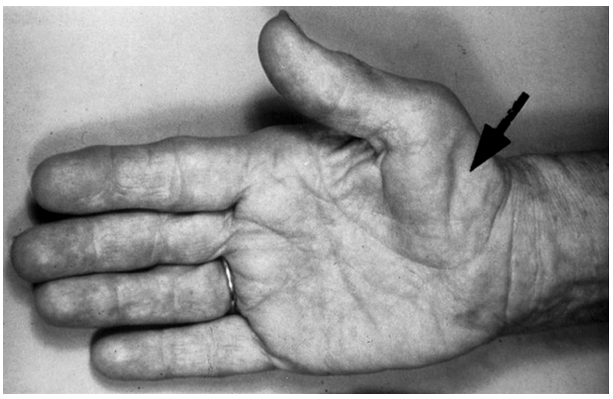

Figure 2.3.10.5 Carpal tunnel syndrome in acromegaly. Thenar wasting is clearly seen (arrow).

disease being the commonest cause of death. Cardiovascular disorders accounted for about 25% of deaths, followed by respiratory (20%) and cerebrovascular disease (15%). More recent data suggest a twofold risk of cardiovascular disease and no increased respiratory mortality [17].

Malignancy in Acromegaly

Whether acromegaly increases the risk of malignant disease is a controversial issue. The large German registry found no increased risk [28], while a Danish study found slightly increased risk [29]. A recent meta-analyses highlighted the contradictory findings of the various studies and acknowledged that some may have had positive bias but equally recognized that as patients with acromegaly live longer, the effect of GH/IGF-1 excess on cancer risk may become more apparent [29–31].

Mortality

Untreated acromegaly is associated with decreased life expectancy. This was first documented in the 1950s and was attributed to increased cardiovascular and respiratory mortality. Overall mortality of untreated disease is approximately double of the normal rate, while mortality in patients who are well controlled is not significantly different from that of the general population [32]. More recently the possibility of increased mortality due to malignant disease has been raised [31].

Biochemical Confirmation of Acromegaly

The greatest challenge in the diagnosis of acromegaly is for the disease to be considered; biochemical confirmation is rarely a challenge and relies upon a combination of an elevated, age-controlled IGF-1 level and failure of GH to suppress to <0.4 μg/L during an oral glucose tolerance test (OGTT) [33]. In patients with acromegaly, there may even be a paradoxical rise in GH in response to OGTT, and this have been attributed to increased expression of the receptor for gastrointestinal inhibitory hormone (GIPR) [34]. False positives do occur (**Boxes 2.3.10.3 and 4**), but few conditions apart from adolescence and pregnancy are likely to cause diagnostic confusion. In tall adolescents, possibly as a consequence of large GH pulses, GH levels may not adequately suppress during an OGTT, and during puberty IGF-I levels may overlap with those encountered in acromegaly. Careful examination for phenotypic changes and a pituitary scan should clarify the situation.

Box 2.3.10.3 Conditions associated with a failure of suppression after a glucose load

- Adolescence
- Diabetes mellitus
- Liver failure
- Renal failure
- Malnutrition
- Laron dwarfism
- Anorexia nervosa

Box 2.3.10.4 Investigation of acromegaly

Establish diagnosis
- 75 g OGTT
- IGF-1

Metabolic consequences of high GH
- OGTT (for glucose)
- HbA1c
- 24-h urine calcium

Pituitary function

- Sleep apnoea
- Hypertension
- Spine X-ray

fT4, free thyroxine; LH/FSH, luteinizing hormone/follicle-stimulating hormone; OGTT, oral glucose tolerance test; TSH, thyroid-stimulating hormone.

Initial Investigations

Imaging

MRI of the pituitary is essential and will demonstrate a macroadenoma (>1 cm) in approximately 60–70% of patients. Visual fields should be objectively documented if there is any suggestion of visual pathway compression. Plasma GHRH should be measured if an ectopic source of acromegaly is suspected, or if occasionally, pituitary histology reveals hyperplasia. A thyroid ultrasound should be done if there are thyroid nodules.

Other Associations

Essential hypertension is common, often associated with an increase in intravascular volume and low renin and increased aldosterone secretion [27]. Phaeochromocytoma is not normally associated with acromegaly, except in exceptional cases (genetic condition causing paraganglioma/phaeochromocytoma and pituitary adenoma, or ectopic GHRH secretion from a phaeochromocytoma [35]); however, it is important to exclude a phaeochromocytoma in a hypertensive patient with acromegaly, particularly prior to surgery.

Treatment

Ideal Treatment

The ideal treatment will render GH secretion normal, completely ablate the pituitary tumour mass, while preserving normal pituitary

function and reverse the acral and other systemic complications, while ensuring there is no biochemical or tumour recurrence [36, 37]. The reality is that some phenotypic changes, such as osteoarthritis of the weight-bearing joints or hypopituitarism may be irreversible, and all treatments have limitations and the potential for complications. The greatest improvement in outcomes would come from earlier diagnosis. Deaths due to mass effects of the pituitary tumour are rare in acromegaly, with mortality and morbidity being largely a consequence of the metabolic complications of long-term elevation of circulating GH and IGF-1 levels and hypopituitarism. Several studies have suggested that lowering IGF-1 levels into age-related reference ranges is associated with restoration of normal life expectancy [31, 32, 37].

Modes of Treatment

Transsphenoidal surgery, undertaken by a pituitary specialist surgeon, is the treatment of choice. In patients not cured by surgery, medical treatment can be effective at achieving biochemical disease control. Modern radiotherapy is extremely effective at controlling tumour growth and will with time control GH secretion (Box 2.3.10.5) A multidisciplinary team, consisting of, at a minimum, a pituitary endocrinologist, specialist pituitary surgeon, radiotherapy oncologist, neuroradiologist, and histopathologist should be involved in all major therapeutic decisions, while clinical geneticist, nurse practitioner, pituitary pathologist also contribute to patient care.

Defining the Biochemical Goals of Treatment

An expert consensus conference defined biochemical diagnosis and successful treatment as a nadir GH during an OGTT of <0.4 μg/L and an IGF-1 within a vigorously established, age-related reference range [37]. The adoption of a GH nadir value of <0.4 μg/L reflects an era of ultrasensitive GH assay which for the first time permits routine quantification of GH as low as 0.05 μg/L, which is lower than the nadir values encountered after a glucose load in healthy subjects [38]. Historical cut-off criteria, such as 1 μg/L, were not underpinned by an evidence base [39], were known to be associated with significant numbers of patients with discrepant GH and IGF-1 results and in particular resulted in reports of patients with unequivocal acromegaly with elevated IGF-1 values but nadir GH values <1 μg/L [40, 41].

The pulsatile nature of GH secretion, even in acromegaly [42], means that it is unwise to rely on a single random measure of GH. The nadir GH during an OGTT and the mean of five GH samples taken over the course of a single day have both been widely used. Both means of assessment are closely correlated to serum IGF-1 levels, but recent consensus criteria have predominately relied upon the OGTT. IGF-1 is the preferred measure of disease activity as it has dual advantages over GH: (i) convenience of a single, randomly-timed sample and (ii) it is a measure of GH action rather than tumour secretion that better correlates to biological end-points such as glucose tolerance [43]. That said, it needs to be recognized that saturation of IGF-1 generation occurs at GH levels of approximately 20 μg/L [44]. This implies that for example partial surgical resection of an adenoma may lower circulating GH levels from 100 to 50 μg/L, but that change may have little impact on circulating IGF-1. The relationship between mean GH levels and IGF-1 is also modulated by oestrogen therapy, prior radiotherapy, age, and liver disease, therefore when possible both GH and IGF-1 status should be assessed.

A major challenge in applying international consensus criteria to local practice is bias in assay performance which is an issue with both GH & IGF-1. Endocrinologists need to be aware of the characteristics of the assays used in their laboratories.

Box 2.3.10.5 Modes of treatment of acromegaly

Surgery
- Transsphenoidal
- Transfrontal

Medical therapy
- Dopamine agonists
- Somatostatin analogues
  - First generation (octreotide or lanreotide)
  - Second generation (pasireotide)
- Growth hormone receptor antagonist

Stereotactic radiotherapy
- Multifractional
- Radiosurgery (single fraction), e.g. Gamma Knife®
- Proton beam therapy

Transsphenoidal Surgery

Factors Affecting Outcome

Pretreatment GH levels have been shown to affect outcome such that high levels are associated with a less successful surgical outcome [45]. The presence of micro- or macroadenoma and extent of cavernous sinus invasion has a key role affecting success of surgery [46, 47]. As opposed to tumour size and GH levels, the determinant of outcome that an endocrinologist can influence is the choice of surgeon. The outcome of surgery is very dependent on the skill and experience of the surgeon with significant differences being reported both in terms of disease control and complications is crucial to outcome [48]. The outcome is less good when large numbers of surgeons doing a small number of operations, and several centres have reported considerably improved outcomes following transition to having one or two surgeons to do all pituitary surgery. Complications are also less common with experienced surgeons [47].

Postoperative Assessment

The impact of surgery on GH status can be assessed 3 days postoperatively, but it can take three months for IGF-1 to reaches its nadir. The first routine postoperative scan should be undertaken at 6 months. The available figures in the best surgical hands show that between 70% and 90% of microadenomas and between 45% and 66% of macroadenomas can reach GH and IGF-1 levels in the safe range with surgery [47].

Complications

New hypopituitarism develops in between 12% and 18% of patients undergoing transsphenoidal surgery for acromegaly and implies

	SSTR1	SSTR2	SSTR3	SSTR4	SSTR5
Somatostatin	0.9	0.2	0.6	1.5	0.3
Octreotide	280.0	0.4	7.1	>1000	6.3
Lanreotide	2129	0.7	98	1826	5.2
Pasireotide	9.3	1.0	1.5	>1000	0.2

Figure 2.3.10.6 Left panel: receptor-binding profile of somatostatin analogues IC50 (nM) [52, 53]. Right panel: the structure of somatostatin-14 and the three somatostatin analogues currently used for the therapy of acromegaly.

the need for lifelong pituitary hormone replacement therapy. Occasionally pituitary function may recover [49]. Other complications include transient or permanent diabetes insipidus, cerebrospinal fluid leaks, haemorrhage, and meningitis. Recurrence of acromegaly occasionally occurs (5.5% at 3 years).

Transcranial Surgery

Developments in transsphenoidal techniques, particular the endoscope, mean that transcranial surgery is rarely indicated. A transcranial approach may be required when there is a very large suprasellar extension or a tumour extending out laterally which is unreachable transsphenoidally. In these cases, the reduction of GH to desired levels is virtually never obtained.

In patients with larger extrasellar tumours, surgical debulking of the tumour should take place which will lower GH and IGF-1 levels and improve the efficacy of medical treatment [50].

Medical Therapy

For the great majority of patients first line therapy is surgery, and medical therapy is reserved for patients with persisting disease activity after surgery.

Somatostatin Analogues

For more than 25 years first generation somatostatin analogues octreotide and lanreotide have been the mainstay of medical therapy for acromegaly. Both are synthetic octapeptide analogues of somatostatin but with longer duration of action than the native peptide with activity only on the type 2 somatostatin receptor (SSTR2) (Figure 2.3.10.6). Comparison of octreotide long-acting release (LAR) and lanreotide Autogel show similar numbers of patients obtaining disease control [51]. Recognition that GH secretion is regulated by both SSTR2 and 5 resulted in the development of second-generation pasireotide, that has high affinity for SSTRs 1, 2, 3 and, particularly, 5, for patients unresponsive to lanreotide and octreotide.

The significant proportion of patients respond to somatostatin analogue therapy to a greater or lesser extent, although controversy persists on the proportion that normalize IGF-1 and/or GH levels. The lack of clarity in part reflects the evermore stringent definition of disease control. As discussed earlier, the goal in terms of GH, in response to a glucose load, has been lowered from 1 to 0.4 μg/L, while better validated, age-related IGF-1 reference ranges have resulted in significantly lowering of the target range for IGF-1. In 1998, Newman *et al.*

reported control of IGF-1 at 3 years in 73% of patients with octreotide as primary therapy [54]; however, the target range for IGF-1 of 0.4 – 2.2×10^3 U/L in women and 0.4 – 1.9×10^3 U/L in men is unrecognizable by modern standards and not age-adjusted. Using strict criteria (GH <2.5 μg/L and normalized age-related IGF-1) in unselected patients, full control is only achieved in 25% [55]. A meta-analysis found that approximately 40% of patients achieve IGF-1 normalization with octreotide or lanreotide [56]. A prospective, randomized, double-blind, multicentre, 12-month study in a total of 358 patients reported control of IGF-1 in approximately 23% of patients treated with octreotide and 38% of patients on pasireotide [57]. Patients on somatostatin analogue therapy can be followed by IGF-1 and probably mean GH levels rather than the response to OGTT [58]. There are several oral somatostatin analogues under development. They are unlikely to result in improved disease control but will offer patients an alternative to the existing parenteral preparations.

Acromegaly related headache can improve in response to somatostatin analogue therapy. Short-acting octreotide injections can relieve headache in some patients resistant to other treatment modalities [59].

Effect on Carbohydrate Tolerance

The impact of octreotide and lanreotide can be variable and unpredictable in individual patients [60]. The balance between the benefit of lower GH levels against the impact of suppression of insulin secretions means octreotide and lanreotide therapy can result in either improved or deterioration of glucose tolerance. In contrast, pasireotide results in hyperglycaemia or diabetes mellitus in 70% of patients [61].

Side Effects

Diarrhoea and abdominal pain occur in 30% of patients to a mild or moderate degree initially but in the vast majority these usually settle. The most important chronic side effect is gallstones, which complicates long-term therapy with octreotide and the somatostatin analogues. The rate varies widely between 14% and 60% and probably depends on the length of treatment. They develop because octreotide decreases gallbladder contractility by suppressing cholecystokinin release. Bile also becomes abnormal, possibly in relation to prolonged intestinal transit and altered bacterial flora. The abrupt withdrawal of octreotide may be associated with the development of acute pancreatitis or gallstone colic [62]. Otherwise, gallstones developing on somatostatin analogues very rarely cause symptoms [63]. Antibody formation occurs but rarely and is very infrequently significant in terms of altering GH levels. Patients with acromegaly related headache using short-acting octreotide have been found to develop dependency to octreotide [59].

Place of Treatment

Most frequently somatostatin analogues are used postoperatively following 'non-curative' surgery. There has been interest in the use of somatostatin analogues either as an alternative to surgery (primary medical therapy) or for a limited time preoperatively with the desire to reduce morbidity and possibly, by shrinking the tumour, to improve the surgical cure rate. The proponents of primary medical therapy have pointed to the poor results of surgery undertaken by inexperienced surgeons and associated morbidity and subsequent need for long-term postoperative somatostatin analogue therapy and argued that there is little to be gained if surgery is not curative. However, with the recognition, as discussed earlier, that only a modest proportion of patients achieve biochemical control with somatostatin analogue therapy and open-ended, lifelong somatostatin analogue therapy is extremely expensive, a more appropriate solution is to ensure access to surgeons with documented excellent outcomes. Furthermore, there is evidence that the fall in GH levels from debulking, non-curative increases the prospect of subsequent somatostatin analogue therapy achieving disease control [50, 64, 65]. Primary therapy should be confined to patients not fit for surgery.

Presurgical somatostatin can result in significant reduction in tumour size of at least 20% in 75% of the patients. Although a meta-analysis suggest preoperative somatostatin analogue therapy for macroadenomas increases the chance of biochemical control of acromegaly 3 months after surgery [66], with long-term follow-up there is no significant benefit [67, 68]. The apparent explanation is that at three months the effect of the prior somatostatin analogue therapy has not fully washed-out. Presurgical somatostatin analogue therapy can be indicated in patients to reduce peri-operative morbidity and reduce soft tissue changes that can make intubation difficult. To date no study, however, has shown clear results in these regards.

Dopamine Agonists

Pharmacology

Bromocriptine, cabergoline, and quinagolide are selective agonist at the D_2 dopamine receptors. Their administration results in the paradoxical fall of GH levels in patients with acromegaly [69, 70], while in normal subjects they stimulate GH levels. Bromocriptine is the only dopamine agonist licensed for the treatment of acromegaly but cabergoline is the most potent and best tolerated and probably the most widely used in these circumstances.

Effects on Growth Hormone

It is not possible to predict the response to bromocriptine or cabergoline. Overall between 10% and 20% of patients have GH levels that are safe on treatment with bromocriptine (usually 20–40 mg daily) or cabergoline (1–3 mg weekly). The best responses are obtained with patients who before treatment have only marginal elevation of GH & IGF1 [70]. Carbohydrate tolerance improves because of the lowering of GH levels and prolactin levels are suppressed to below normal.

Side Effects

Acute postural hypotension, nausea, and vomiting. Usually these settle with time. Very rarely, particularly on high doses, psychosis and digital vasospasm may also develop. Impulse control disorders are a well-recognized but rare complication and can manifest as pathological gambling, shopping, eating, and hypersexuality. Patients should be warned of the risk. Cardiac fibrosis has been described with the high doses of cabergoline used for Parkinson's disease and it is recommended that all patients treated with high-dose

ergot-derived dopamine agonists (e.g. cabergoline) have an echocardiogram. Although patients with acromegaly and prolactinoma are routinely given much lower doses, recent recommendations suggest pretreatment baseline echocardiography, with a repeat at 5 years if cabergoline dose ≤ 2 mg/week, or yearly if dose is > 2 mg/week [71].

Place of Treatment

Dopamine agonists are less expensive than somatostatin analogues and orally administered. When medical treatment is indicated it should theoretically be the case that dopamine agonists are tried first. In practice, because the response rate is low this does not happen. However, it should be noted that occasionally patients who are not responsive to a somatostatin analogue may respond to a dopamine agonist.

Growth Hormone Receptor Antagonist (Pegvisomant)

Pegvisomant is a pegylated recombinant growth hormone analogue that inhibits GH action by binding the GH receptor without inducing signal transduction and IGF-1 induction [72]. As it does not lower circulating GH, serum IGF-1 is the principal biochemical means of monitoring effectiveness of treatment. With appropriate dose titration, serum IGF-1 level can be controlled in over 90% of patients [13]. The maximum licensed dose is 30 mg per day, although doses up 60 mg per day have been used. Although marketed as a daily injection, the long half-life of pegvisomant means that it is effective when administered once or twice weekly, although the volume of injection can be a challenge at higher doses [73].

Due to its mode of action the ability of pegvisomant to lower IGF-1 is independent of any tumour characteristics and is effective in patients resistant to somatostatin analogues and dopamine agonists. Pegvisomant may also be used in combination with somatostatin analogues and dopamine agonists [74, 75].

The drug is generally well tolerated, although liver function disturbance, specifically elevation of transaminase shortly after initiation of treatment, has been reported. Lipohypertrophy may occur at the site of injection.

When first introduced there was concern that pegvisomant therapy would be associated with pituitary tumour expansion but close follow-up of patients on long-term therapy has provided reassurance, although annual MRI is recommended.

Place of Treatment

Pegvisomant is indicated for patients with persistent disease despite expert surgery and optimal somatostatin analogue treatments, with the choice being whether to add it to ongoing somatostatin analogue treatment or substitute pegvisomant in its place. The decision depends on individual patient circumstances (e.g. good tumour shrinkage with a somatostatin analogue would be a reason for combination treatment while deteriorating glucose tolerance argues for monotherapy) [37].

Radiotherapy

Indications

There are two indications for radiotherapy in patients with acromegaly: either to control tumour growth, and/or to lower GH secretion with the goal of achieving biochemical disease control.

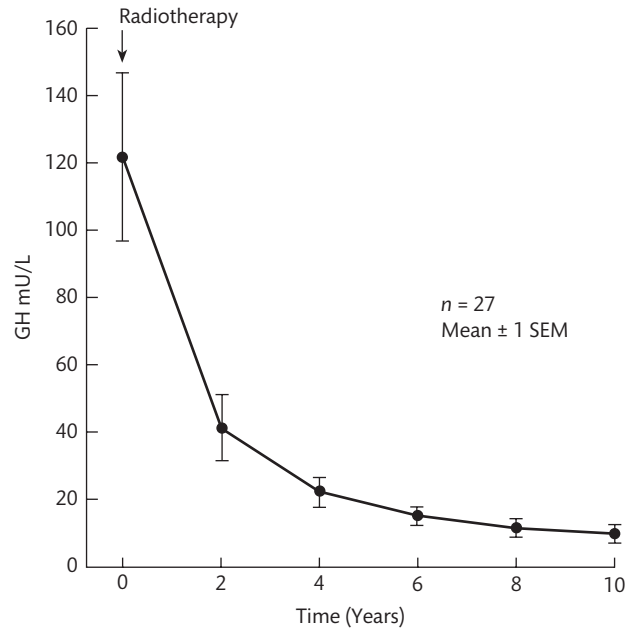

Figure 2.3.10.7 The exponential fall in GH levels after radiotherapy in patients with acromegaly studied over 10 years.

Modern radiotherapy is an effective, safe, and appropriate third-line treatment in patients with persisting hormonal excess or an expanding tumour after surgery and optimized medical therapy. The frequently cited papers describing the complications of pituitary radiotherapy largely pertain to conventional radiotherapy delivered many years ago using what is now obsolete technology. The latency of complications is long and therefore it is difficult to make definitive statements, but the combination of MRI and conformal radiotherapy allows size, shape and exact location of the tumour to be defined and beam shaping to the precise tumour contours which greatly reduces normal tissue doses. All modern radiotherapy is stereotactic and can be delivered in multiple small doses (fractionated stereotactic radiotherapy) or in a single session (stereotactic radiosurgery).

Radiotherapy is extremely effective at controlling tumour growth in 91–100% of patients [76]. ln general terms, radiotherapy can be expected to reduce GH levels by 50% in two years and by further 25% by 5 years [77]. See Figure 2.3.10.7.

Side Effects

As discussed elsewhere (see Chapter 2.3.8), external beam radiotherapy is well tolerated. Hypopituitarism is common and after exclusion of patients with preirradiation hormone deficiency; post-radiotherapy, gonadal, adrenal, and thyroid deficiency occur in 50, 35, and 35%, respectively, at 10 years. Pituitary function deterioration develops gradually so that it is necessary for regular (usually annual) assessment. Visual loss and radiation-induced late malignancy are discussed elsewhere and there is no specific increased risk associated with acromegaly. The effect of external

pituitary radiotherapy on memory and mental function requires further study.

Acromegaly and Pregnancy

Fertility is impaired in patients with acromegaly, but pregnancy is generally safe in terms of hormonal and tumoural stability, although there is an increased risk of gestational diabetes and hypertension. The hormonal changes of acromegaly, and their assessment, during pregnancy are complex [78, 79]. The elevated oestrogen levels of pregnancy antagonize GH action, while placental GH secretion, GH-V, has similar biological characteristics as 22 kD GH but is variably detected by routine GH assays. Typically IGF-1 remains satisfactory for the duration of pregnancy. The lack of normative data for GH and IGF-1 during pregnancy makes biochemical assessment challenging and in most cases is not necessary. Visual fields should be monitored in case of tumour enlargement.

Somatostatin analogue exposure may increase the chance of low birth weight, so it is recommended that drug treatment is ceased during pregnancy and for 2 months prior to a planned pregnancy. An exception to this could be the development of severe headache during pregnancy. There are limited data of on the safety of pegvisomant, available data did not reveal any apparent drug-related complications, but pegvisomant and it should be stopped in any patient trying to conceive or on confirmation of pregnancy [80].

Treatment Paradigms

Optimal outcomes require the input of a multidisciplinary team coordinated by a pituitary endocrinologist and including a specialist pituitary surgeon, neuroradiation oncologist, neuro-radiologist, and access to adequately validated GH and IGF-1 assays.

Patients with microadenomas should be 'cured' by transsphenoidal surgery. The outcome in macroadenomas is dependent on the size and invasiveness of the tumour but, in general terms, should be 'curative' in around 55%. Surgery is usually performed for macroadenoma even if surgical cure is unlikely, because debulking surgery improves the outcome of treatment with somatostatin analogues [50]. As approximately 60–70% patients have a macroadenoma, a significant number of patients require further therapy with somatostatin analogue or dopamine agonist therapy. Somatostatin analogue therapy offers the better prospect of achieving biochemical disease control, but occasionally, in non-somatostatin analogue responsive patients, dopamine agonists may be effective. In patients with persisting active disease the choice lies between pasireotide and pegvisomant, with the latter being used either as an alternative to octreotide or lanreotide or in combination. Comorbidities should be longitudinally monitored (e.g. blood pressure, carbohydrate tolerance, arthritis, and sleep apnoea).

It is important to consider radiotherapy in patients in whom there is evidence of tumour expansion or if medical therapy is ineffective. Radiotherapy will take several years to adequately control GH and IGF-1 levels but does offer the prospect of patients eventually being able to discontinue high-cost medical therapy.

Differential Diagnosis of Acromegaly Phenotype

Acromegaly is a characteristic disease and once the possibility of its diagnosis has been suggested, it is relatively easy to make a firm clinical and biochemical diagnosis. There are a few conditions, however, when clinical or biochemical features resembling acromegaly are present but there is another underlying diagnosis, these conditions can be summarized as pseudoacromegaly [81]. Acromegaloidism (insulin-mediated pseudoacromegaly) refers to the development of acromegaly-like features (e.g. jaw, hand, and feet enlargement) together with acanthosis nigricans caused by very severe insulin resistance. GH and IGF-1 values are normal. Pachydermoperiostosis (OMIM 1671002), is a familial condition associated with acromegaloid facial features and enlarged hands and feet with characteristic clubbing of the fingers and toes. Cantu syndrome also shares some facial features with acromegaly. The differential diagnosis of tall stature (constitutional or due to another disease) and gigantism can also sometimes cause problems, especially as the biochemical diagnosis of true abnormal GH excess is challenging in teenagers. Biochemical alterations of elevated GH with normal or low IGF-1 can be seen in some conditions, but clinically these do not represent differential diagnostic problems (e.g. kidney disease).

A unique, recently identified condition due to *IGFS1* mutation in some patients, despite the lack of pituitary adenoma, can present with elevated GH and IGF-1, some acromegalic features and somewhat taller stature (therefore not fulfilling the pseudoacromegaly criteria) [82]. There is no explanation currently for the abnormal GH axis in this condition.

2.3.11 Clinically Non-Functioning Pituitary Tumours and Gonadotropinomas

Nienke Biermasz and Wouter R. van Furth

Introduction

Non-functioning pituitary tumours (NFPAs) are pituitary adenomas without clinically overt hormone secretion. The vast majority of NFPAs (80%) arises from gonadotroph cells and are monoclonal expansions. They show positive staining for glycoprotein hormones, usually luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Only 20% of adenomas have no evidence of any hormone staining and this subgroup may be called 'null-cell tumour'.

In this chapter the term 'clinically non-functioning pituitary adenomas' is used to describe pituitary tumours, which in most instances produce no, or low quantities of hormones causing no clinically recognizable symptomatology. In the very few instances, in which such tumours produce intact gonadotropins that activate testicular or ovarian activity, the term 'gonadotropinomas' is used.

Box 2.3.11.1 Presenting features of clinically non-functioning pituitary adenomas

Compression of the optic chiasm (bitemporal hemianopsia, decreased visual acuity, nerve palsy—rare)
Hypopituitarism (e.g. fatigue, hypogonadism, Addisonian crisis)
Galactorrhoea
Chronic headache
Liquorrhoea (rare)
Acute headache with neurological symptoms (rare, in case of apoplexia)
Incidental finding

Clinical Presentation

The clinical presentation is highly variable, from completely asymptomatic to severe symptoms (see Box 2.3.11.1). Due to the lack of hypersecretion of hormones and due to a slow growth pattern, non-functioning pituitary adenomas classically present due to mass effects and compression of surrounding tissues. Patients typically report that in hindsight, symptoms developed gradually in the years prior to diagnosis and a delay in diagnosis is usually at least 1–2 years.

Hypopituitarism, of the anterior lobe, due to compression may give rise to a variety of symptoms (e.g. fatigue, amenorrhea, infertility, hypogonadism). The classical order in which deficiencies occur is thought to be GH, LH, FSH, thyroid-stimulating hormone (TSH), and ultimately adrenocorticotropic hormone (ACTH). However, in individual cases, all axes need to be tested.

Galactorrhoea by hyperprolactinemia can result from mass effects of the NFPA with compression of the pituitary stalk and the loss of inhibition of the dopaminergic tone. Prolactin values due to stalk compression are typically only slightly elevated (2–5 times ULN), in contrast to clearly elevated levels in case of (macro)prolactinoma.

Suprasellar extension may lead to compression of the optic chiasm and optic nerves resulting in the classical bitemporal hemianopsia and ultimately decreased visual acuity or blindness.

Headache can be a symptom of pressure, typically midline frontally, however, there is an extensive differential diagnosis. Acute onset, severe headache can be a presenting symptom of apoplexia, an ischaemic or haemorrhagic event, in a pre-existing pituitary adenoma.

Lateral, parasellar extension in the cavernous sinus, may result in dysfunction of the third, fourth and sixth cranial nerve resulting in ophthalmoplegia (diplopia and ptosis), which is rare outside apoplexia or aggressively growing tumours. Trigeminal neuralgia is exceedingly rare.

Inferior extension may result from invasive growth and destruction of the sellar floor and growth into the sphenoid sinus. An exceptional complication is liquorrhoea.

Pituitary incidentalomas are pituitary lesions without clinical features of pituitary disease, discovered on imaging done for unrelated reasons. With the advancing radiological techniques and scan indications, they are increasingly found. Incidentalomas can be microadenoma, macroadenoma, or invasive macroadenoma. They also need diagnostic work-up to exclude hormone overproduction and to assess indications for treatment.

Non-functioning adenoma may be 'giant' (>4 cm) and sporadically tumours of exceptional size may give rise to neurological symptomatology (e.g. temporal lobe epilepsy), obstruction hydrocephalus and, for example, hypothalamic dysfunction.

Epidemiology

Non-functioning pituitary adenoma account for 14–54% of pituitary adenoma depending on the population studied. The prevalence is 7–41.3/100 000 and standardized incidence rate 0.65–2.34/100 000. The peak occurrence is in middle age and elderly (40–80 years) [1]. It is the second most prevalent pituitary tumour after prolactinoma. However, when macroadenomas are considered there is a preponderance of NFPA over prolactinoma.

Pituitary incidentalomas are quite prevalent, in unselected populations they are reported to be 10–38% for microadenoma and 0.16–0.3% for macroadenoma on MRI scanning and 11% in autopsy series. So, the vast majority of incidentalomas is small, not hormone producing, and will not require treatment, however, needs follow-up and therefore burden for patients and healthcare system.

A small subset of NFPAs are a manifestation of a hereditary syndrome (MEN1, familial isolated pituitary adenoma, SDH). The majority of pituitary adenoma of hereditary syndromes are functioning lesions. Systematic screening with pituitary scans of genetic carriers will reveal more non-functioning microadenomas. The presence of a hereditary syndrome should be considered in younger patients and those with a positive family history. Non-functioning pituitary tumours in children are extremely rare.

The growth pattern of NFPA is highly variable and considered non-linear. Generally, it can be stated that the majority of macroadenomas will show gradual growth in years, resulting in treatment indication to prevent symptoms by compression of optic chiasm over time. In contrast, only a small minority of microadenomas will show clinically relevant growth.

Pathogenesis and Aetiology

In the late 1970s and early 1980s, much work has been done on defining the pathological properties of pituitary tumours. The work of Asa and Kovacs is specially known for the accurate description of the microscopic findings of non-functioning pituitary adenomas [2]. These tumours are morphologically classified into two groups, those which have hormone immunoreactivity and ultrastructural features of known adenohypophyseal cell types but are clinically silent, and those composed of cells that do not resemble non-tumorous adenohypophyseal cell types (null-cell adenomas). It is now known that non-functioning adenomas represent a heterogeneous group with staining by immunocytochemistry in the majority of cases. The pathogenesis is complex and include genetic and epigenetic events, hormonal stimulation, growth factor overproduction, pituitary stem cells derangements, microRNA deregulation promoting cell growth and proliferation [3].

Gene mutations involved are MEN1 gene, the tumour suppressor gene CDKN1B (MEN4) and the oncogene AIP.

Diagnostic Evaluation

Most sellar masses will be pituitary adenomas. However, many other neoplastic, inflammatory, infectious, and vascular lesions, may affect the sellar region and mimic pituitary tumours. These lesions must be considered in a differential diagnosis of non-functioning pituitary adenomas. The diagnosis of such lesions involves a multidisciplinary approach, and detailed endocrinological, ophthalmological, neuroimaging, neurological, and finally histological studies may be required.

Radiological Investigations

MRI dedicated to the pituitary region with T1- and T2-weighted images and gadolinium contrast series is the gold standard for evaluation and differential diagnosis of sellar and suprasellar masses. A pituitary adenoma usually appears hypo- or isointense compared to pituitary tissue on T1. Acute haemorrhage will appear hyperintensive. Cystic lesions can be identified.

The size and extension of the adenoma are evaluated with the Hardy-Wilson classification (microadenoma (I), macroadenoma (II), invasive adenoma into sellar floor (III/IV)) and suprasellar (A, B, C) and parasellar (D, E) extension. The Knosp classification [4] evaluates the cavernous sinus invasion in relation to the carotid artery, which is related to the chance of success of surgical resection, particularly relevant for hormone producing tumours. The relation of the tumour with and the severity of displacement of the optic chiasm are described. An important feature of pituitary macroadenoma is an enlarged sella. Radiological differential diagnosis of other sellar masses are for example craniopharyngioma, meningioma, cysts, hypophysitis, germ cell tumour, aneurysm.

Neuro-Ophthalmological Investigations

In particular, in NFPA in the vicinity of the optic chiasm or optic nerves, careful ophthalmological investigation is warranted [5]. Visual symptoms include visual field defects, loss of central vision, and motility problems. Evaluation of visual fields by automated static perimetry, visual acuity, and assessment by an ophthalmologist is the cornerstone of evaluation. Usually abnormalities in these assessments precede clinical symptoms. Other assessments include functional (visual evoked potential (VEP)) and anatomic (disc appearance and optical coherence tomography (OCT)). The findings of these modalities will be concordant in many cases, however, there may be disparities due to the innate differences in tests. Large-scale data on prediction of visual recovery after chiasm decompression by NFPA resection of the newer tests (e.g. OCT), are not yet available. Postoperatively, tests are repeated to document recovery up to stabilization with 3 to 6 monthly intervals and thereafter less frequently.

Endocrine Diagnosis

The endocrine work-up of NFPA is directed to the exclusion of hormone oversecretion, including a high dose hook effect to exclude prolactinoma, on the one hand, and detection of hypopituitarism on the other hand.

Initial assessment includes: IGF-I, cortisol, prolactin, FSH/LH, oestradiol or testosterone, Ft4 and TSH. In emergency clinical practice, basal evaluation of adrenal and thyroid function may suffice as preoperative evaluation, and evaluation of growth hormone deficiency and dynamic corticotrope function is postponed to the postoperative situation [1].

Histopathological Classification

The World Health Organization (WHO) classification of pituitary adenomas was revised in 2017 and a new name of PitNETs (pituitary neuroendocrine tumours) was proposed [6].

Non-functioning pituitary tumours represent a heterogeneous group, and they are being considered as a variant of functioning tumours with the exception of the null-cell adenomas without any hormone staining.

Based on the expression of anterior pituitary hormones and pituitary-specific transcription factors, gonadotroph tumours dominate within the group of clinically non-functioning tumours, followed by corticotroph type; however, also other less common types of the non-functioning tumours can be identified on the basis of staining.

Assessment of mitotic account, proliferative Ki-67 index, and tumour invasiveness is important to identify potentially aggressive tumours. Application of pituitary-specific transcription factors (Pit-1, T-Pit, SF1) plays an important role in recognition of less differentiated tumour types, some of which may demonstrate aggressive behaviour.

Predictive markers may be included in the classification (somatostatin receptors, dopamine receptors, low MGMT expression), particularly when pharmacological therapy is under consideration. There are three categories: typical adenoma (most frequent), high risk pituitary adenoma, pituitary carcinoma (exceptional) There are eight subtypes based on the immunohistochemical expression and pituitary-specific transcription factors.

First Management

The aims of treatment will differ depending on the clinical situation, individual patient's characteristics, preferences, and symptomatology on the one hand, and tumour size and extension, compression of critical structures, and growth rate on the other hand.

Aims for treatment may be symptom reduction: visual field deficits, headache; prevention of symptoms in case of tumour growth approaching the visual system, or future pregnancy wish; and/or diagnostic, to obtain histopathological diagnosis.

Therapeutic modalities for non-functioning pituitary adenoma include observation (wait and scan), surgery, radiotherapy, and medical therapy (see Figure 2.3.11.1).

Observation

It is good to bear in mind the natural course of growth of NFPA. Microadenomas (<10 mm) rarely grow (10%) and convert to a macroadenoma. Macroadenomas, in contrast, tend to grow and the tumour volume of macroadenomas increases gradually in approximately 25–50% of patients [7, 8]. Radiological surveillance could be performed annually for 3 years and thereafter with longer intervals (2–5 years). Those larger adenomas (>2 cm) and those abutting the chiasm should be followed more closely and also with visual field tests. In case of growth or visual field defects surgery should be considered.

Surgery

Indications for surgical resection are: mass effect resulting in compression and functional deterioration of the optic nerves, chiasm, or other neurological structures, (growing) tumours with anatomic relation threatening the optic chiasm, pituitary apoplexia resulting in the aforementioned deficits or extreme headache [9–12]. Relative indications include pituitary insufficiency and headache potentially caused by the mass effect. In recent years, several guidelines on surgical management have been published. Urgent indications are severe and progressive visual symptoms and apoplexia with intractable headache and compressive symptoms. Major goals of surgery are preserving pituitary function.

Pituitary surgery is primarily performed by the transnasal transsphenoidal approach (Figure 2.3.11.2) with endoscopic or

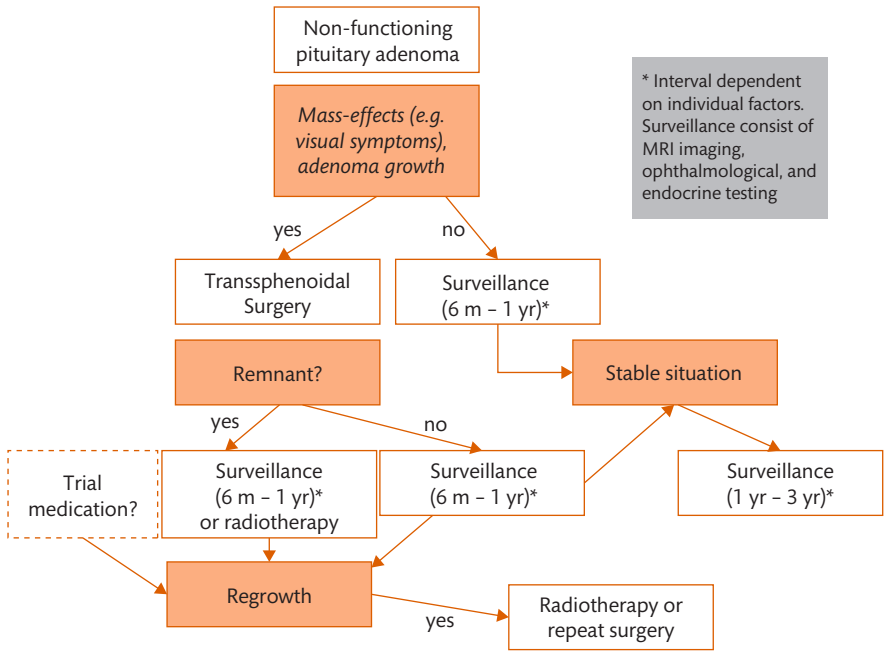

Figure 2.3.11.1 Treatment and surveillance algorithm for non-functioning pituitary adenoma.

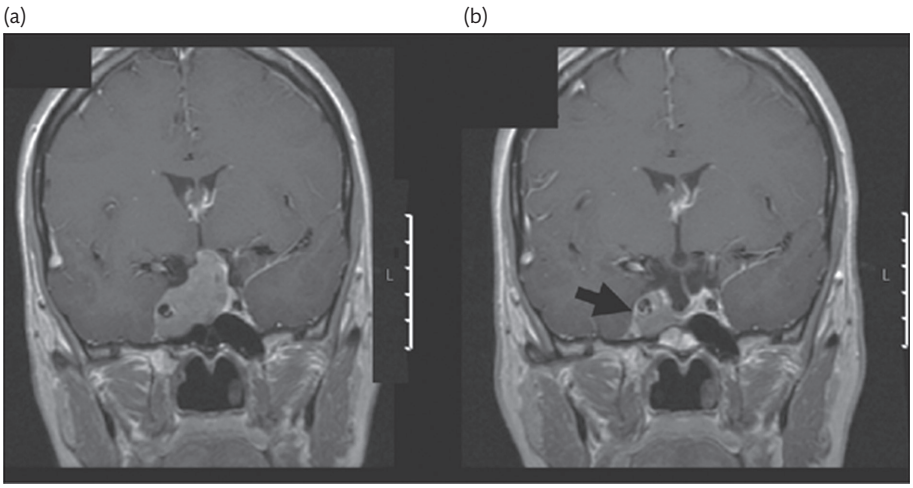

Figure 2.3.11.2 A 48-year-old woman with suspicion of a clinically non-functioning pituitary macroadenoma with compression of the optic chiasm leading to impaired visual acuity and bitemporal visual field defects. Postoperatively, visual function recovered while anterior pituitary function remained intact. (a) Baseline MR image. (b) Following transsphenoidal subtotal resection. Note the tumour remnant encasing the right carotid artery (arrow). However, significant tumour reduction has been achieved with complete decompression of the optic chiasm.

microscopic visualization. Advantages of endoscopic surgery are a wider and closer view of the surgical area, also of the supra- and parasellar regions, with less nasal trauma, and usual no need for postoperative nasal packing. During the intervention, the sphenoid sinus is entered and subsequently the sellar bone is opened. Also tumours with large suprasellar and parasellar compartments can successfully be resected via the transsphenoidal route. Tumours usually have a soft consistency and blunt curettes are used for removal of those parts. Leakage of cerebral spinal fluid during surgery needs to be anticipated. This is depending on the tumour size and invasion; however, it may occur in any surgery. There are multiple techniques available to treat leaks, including abdominal fat, fascia lata implants, and nasal septal flaps.

A transcranial approach via the pterional or subfrontal route is needed in exceptional cases with a dominant extrasellar tumour compartment and a small sella turcica, a large eccentric tumour extension into the middle, anterior, or posterior cranial fossa, or a coexisting aneurysm of the carotid artery. Combination of transcranial and trans-sphenoidal approach may be indicated for giant adenomas (>4 cm diameter).

The trans-sphenoidal surgery is usually very well tolerated, with some nasal morbidity in the early postoperative phase. The perioperative period is best done by a multidisciplinary team, involving both endocrinologist and neurosurgeon. Main complication to monitor is disturbance of fluid balance by evaluation of urine output and gravity, plasma sodium concentrations, and patient thirst experience because of transient diabetes insipidus or postoperative hyponatraemia that may occur up to 10 days. Adrenal function and other pituitary function require careful monitoring. Depending on tumour size and preoperative situation the chance for new onset hypopituitarism is considered to be about 1–5%. Length of hospital stay is about 2–5 days. Severe complications like intratumoral bleeding or meningitis are very rare and depend mainly on tumour size. Surgical mortality is less than 1% in experienced hands.

After trans-sphenoidal resection, improvement of visual function is achieved in 60–90% of patients. The rapidity of visual recovery depends in part on the duration of optic nerve compression. Recovery of visual function can already be observed in the first days postoperatively and can continue up to a year after surgery. In patients with pre-existing (partial) hypopituitarism, pituitary function is not likely to restore after resection of the adenoma, although in some patients improvement can be demonstrated, and figures vary between 2% and 50%. Headache may improve in 80–100% of cases operated. Still, performing an operation for headache alone is controversial since headache may be unrelated to pituitary adenoma. Gross total resection of tumour can be achieved in 50–70% of patients, depending on tumour size and extension. Regrowth op tumour remnant is described in up to 20% patients, for which repeat surgery can be considered or alternatively radiotherapy.

Radiotherapy

Complete removal of a macroadenoma cannot be achieved in all patients and up to 40–60% of patients will have a small or a clear remnant post-surgery. Since the goal of surgery is often to decompress vital structures, while preserving the pituitary gland, surgical strategy is to avoid risks associated with resection of the most distal parasellar tumour parts. In addition, some patients (up to 10–50%) particular those with a remnant in situ will face regrowth of tumour in time and will require additional therapy.

External beam radiotherapy has been used for pituitary adenoma for 50 years [13]. There is no doubt that excellent tumour volume control can be established with irradiation in NFPA. However, toxicity of radiotherapy is not negligible and therefore the indications to irradiate these benign, usually slow growing remnants, need to be carefully weighed against the negative effects.

So, the optimal treatment strategy of patients with a residual tumour after trans-sphenoidal surgery (example shown in Figure 2.3.11.2b) is still a matter of debate. Based on observational studies on the natural course of macroadenoma remnants it is clear that tumour remnant growth or recurrence may occur in long-term follow-up, usually at a slow growth rate and that there are only some predictive factors such as parasellar invasion before surgery and (the degree of) suprasellar extension of the postoperative remnant adenoma, but that we are unable to predict reliably for clinical practice. Unfortunately,

no morphological tumour features or molecular markers of cell proliferation are available that predict tumour growth.

Postoperative external radiotherapy is applied in non-functioning pituitary adenoma to achieve long-term tumour control by induction of tumour shrinkage or stabilization. In patients who receive conventional radiotherapy, progression free survival at 10 years is more than 90%, significantly higher compared to patients who were observed alone. Overall, no randomized trials have been performed that compare radiotherapy with a wait and see policy. It is important to note that radiotherapy cannot control tumour growth in each patient. Studies vary with respect to follow-up duration, number of invasive tumours, and other aspects, but regrowth of residual adenomas in patients treated with radiotherapy has been observed, so radiological surveillance remains to be done also after radiotherapy. Adjuvant radiotherapy has beneficial effects on tumour regrowth but this should be balanced against the complications of radiotherapy (i.e. radiation damage to the optic nerves with visual impairment, development of (partial) hypopituitarism in up to 50–75% of patients, increased risk of cerebrovascular events, and an increased risk on secondary brain tumours).

Therefore, the treatment strategy in patients with a residual adenoma after trans-sphenoidal surgery should be individualized and factors such as age, comorbidity, remnant tumour size, tumour distance to the optic chiasm, and status of pituitary function should be involved in the decision on adjuvant radiotherapy. Patients not treated with radiotherapy should carefully be observed with MRI and ophthalmological evaluation. If regrowth occurs, radiotherapy is still effective, but repeat surgery can also be considered. Some centres generally favour a strategy to irradiate remnants, while others wait for progression before radiotherapy is considered. The former has the advantage that radiological surveillance will need to be less stringent and critical but that side effects needs to be taken into account. The latter requires critical evaluation of future scans in a multidisciplinary team with expert neuroradiological expertise setting to decide on the scan intervals and the best moment to intervene in case of significant remnant growth. There is no clear advantage of any of the policies with respect to tumour growth control. Reasonable candidates for the observational approach are patients that present with 'not too big' tumours at presentation, small residual lesions, and no signs of aggressive growth. In patients with larger remnants, who had bigger tumours at presentations, or have suspected faster growth rate, it is probably wise to consider earlier radiotherapy.

There are various radiation techniques and innovations in the field, such as better imaging, better software for planning of dose delivery, probably have an improved balance between efficacy and safety because the surrounding tissues get less radiation. 3D conformal radiotherapy has evolved to stereotactic radiotherapy. Fractionated stereotactic radiotherapy is delivered in many small fractions for 20–25 days. Stereotactic radiosurgery with a Cobalt-60 gamma knife or a cyberknife or LINAC (linear accelerator), delivers the full dose in a single session. However, long-term results of new techniques need to be awaited to draw conclusions on long-term safety. Proton beam radiation of pituitary adenomas have been done in some centres, showing similar outcomes compared to photon radiotherapy.

Radiosurgery is suitable for small adenomas with sufficient distance to the optic nerves and optic chiasm, which are radiosensitive tissues. Fractionated stereotactic radiotherapy can be applied in larger tumours and tumours with a closer proximity to the optic chiasm. With both forms of stereotactic radiotherapy tumour control can be achieved in more than 90%. No data are available yet that compare recurrence rates and long-term safety and complications of conventional radiotherapy and stereotactic radiotherapy. There are no comparative studies between stereotactic fractionated radiotherapy and radiosurgery.

Medical Treatment

In other pituitary adenoma, particular in somatotropinoma and prolactinoma, there is a clear role for medical treatment for both tumour volume control, if needed, and control of hormone oversecretion. The role of medical treatment in NFPA is not established [14]. Potentially available drugs are dopamine agonists, somatostatin analogues, and temozolomide. When used in NFPA, it is off-label use.

The treatment goal of medical treatment could be tumour growth stabilization, or shrinkage, in the presence of few side effects and with acceptable costs, since long-term treatment is anticipated. Research in this field is difficult because of the variable and slow growth pattern of tumours and remnants requiring long-term studies to draw conclusions. Nevertheless, there is a clinical need for medical strategies to control NFPA, because of the limitations of surgery (resection of difficult parts of tumour in cavernous sinus and risk of complications) and radiotherapy (late toxicity particular induction of hypopituitarism and limited dose application once the tumour is in the vicinity of the optic nerves). Several different drugs (combinations) have been investigated. In the presence of a new classification for pituitary adenomas, in which the majority of NFPA will harbour some hormone staining, and receptors for medical treatment (dopamine receptors and somatostatin analogue receptor subtypes can be assessed, rationale molecular based medical treatment could be anticipated); however, at present no large-scale supporting data are available.

Based on the available literature, mainly uncontrolled studies, dopamine agonists have the best available evidence that they have a positive effect on tumour stabilization and are generally well tolerated. Some advocate a role for dopamine agonists (DAs) in patients with a postoperative remnant, others consider Das in selected cases with observed growth, there is no consensus.

Dopamine Agonists

In physiology, dopamine exerts tonic inhibition on prolactin-producing cells via the D2-receptor. Many pituitary adenomas, also NFPA express D2 receptors. Both tumour volume and hormone oversecretion of prolactinomas is very responsive to DA. It is reasonable to think that also other tumours expressing D2-receptors could respond as well to DA. There are several Das; bromocriptine and quinagolide, and the more potent specific D2 receptor agonist cabergoline.

The largest study to date included 79 patients [15], treated with a target dose of 2 mg/week and two-thirds of patients were treated. Tumour control was achieved in 87% (DA) vs. 47% (control), and DA decreased the need for additional treatment to 13% (DA) vs. 42% (control). Less favourable results were obtained in younger and male patients and those with a large preoperative tumour. D2R expression was not associated with responsiveness and so, there are no predictors of responsiveness to DA.

If DA is indicated, a 2 mg/wk cabergoline dose is most often used, aiming at stabilization of tumour size and so avoiding additional treatments (e.g. repeat surgery and radiotherapy). Logically, careful radiological surveillance is still needed, at an interval of 6 months for 2 years or so and thereafter yearly. A higher dose is not reasonable based on the limited data available. In patients who experience side effects, orthostatic hypotension, or psychiatric side effects, alternative treatment options are preferable especially because of the lack of firm evidence.

Somatostatin Analogues

Somatostatin analogues have antiproliferative and antisecretory effects through binding to one or more of the five subtypes of the somatostatin receptor. Lanreotide and octreotide are preparations that preferentially bind to the SSTR2. Main indication is acromegaly, but also TSH adenomas can be treated with somatostatin analogues. Not all tumours express SSTR2 and a substantial number of patients will be partially or fully resistant to these drugs. Pasireotide is a next generation somatostatin analogue that binds somatostatin receptor (SSTR) more universally, and especially the binding to the SSTR5. It has been shown to be effective in acromegaly and in Cushing, albeit with the drawback of a high incidence of diabetes mellitus.

Somatostatin receptors are expressed in non-functioning pituitary adenoma, with a predominance of the somatostatin receptor subtype 3 (sst_3), followed by sst_2 and sst_5. Although *in vitro* there was a significant antiproliferative and antisecretory effect of somatostatin in NFPA, clinical treatment has not shown to be efficient. Small and short-term studies showed a 12% tumour size reduction, 5% growth, and an 83% stable tumour mass, which is inconclusive in view of a study duration of 6 months on average. Preselection of patients for example based on positive octreotide receptor scintigraphy could be a strategy to select patients with better response rate; however, larger scale, long-term, and well-designed studies are needed to justify this form of (expensive) treatment for this indication. There are no clinical studies on pasireotide treatment and the safety profile is not attractive in a long-term treatment setting as for NFPA.

Gonadotropin-Releasing Hormone Agonists and Antagonists

The release of gonadotrophins by normal anterior pituitary cells is regulated by pulsatile secretion of gonadotropin-releasing hormone by the hypothalamus. The chronic administration of gonadotropin-releasing hormone to normal individuals produces an initial rise in gonadotropin levels, followed by gonadotroph desensitization, leading to efficient suppression of gonadotrophin release. Several case reports describe the occurrence of pituitary apoplexy after the administration of gonadotropin-releasing hormone as a test agent or as an agonist for the treatment of prostate cancer. Long-term treatment with gonadotropin-releasing hormone analogues had no effect on tumour size or visual fields in patients with non-functioning pituitary adenoma. This treatment modality is currently not anymore under clinical investigation.

Temozolomide

Temozolomide has been proposed as a treatment option for pituitary carcinomas and aggressive pituitary adenomas. The clinical experience is rather limited, but this is the modality of choice in exceptional pituitary adenomas with aggressive behaviour. Overall response rate is 22–50%. Non-functioning pituitary tumours tend to respond less than prolactinomas and corticotroph tumours [16], with partial complete response in 22% (6/27 patients), stable disease in 48% (13/27), and progression in 30% (8/27) according to a recent review of literature. In a recent survey of the European Society of Endocrinology, 47 patients with clinical non-functioning tumours were reported: 2% had complete regression, 15% had partial regression, 49% had stable disease, and 34% progression [17].

Management of Remnants/Regrowth

Radical removal of NFPA cannot be accomplished in all patients, for example because of growth into the cavernous sinus. There is a delicate balance between trying to be as radical as possible versus sparing normal pituitary gland and complication avoidance in general. In clinical practice, the postoperative situation is usually evaluated 3 to 6 months post-surgery. Postoperative remnants are identified, although small remnants may be difficult to distinguish from postoperative changes. This initial postoperative MRI scan is used as a reference scan. All patients need radiological surveillance, since there is a chance for regrowth in the years after surgery, especially in non-irradiated patients. In some centres, postoperative radiotherapy is applied on remnants, which is effective in preventing regrowth. However, it has side effects (e.g. common hypopituitarism) and rarely cerebrovascular disease, secondary brain tumour development, neurocognitive dysfunction, and so on.

In an off-label setting for medical treatment, primarily Das are considered as preventive medication for recurrence; however, these strategies are expert-based and not evidence-based.

The postoperative gross total resection rate is about 50%, so 50% of patients will have some remnant. Regrowth is observed in 10–50% of patients in long-term follow-up. Predictive factors of regrowth are presence of a remnant, young age, initial tumour size, especially invasive growth pattern. Tumour growth-free survival is twice as low in patients without versus with a remnant. Residual tumour doubling time has been investigated to be 3.4 years, confirming the need for long-term monitoring. It is important that new scans are not only compared with the previous scan but always also with the initial postoperative, reference scan. Tumour volume doubles times is a measure of growth velocity, the time it takes for a tumour to double in volume [18]. Pituitary tumours may show either an exponential growth, or linear or logistic growth. Exponential growth is usually more rapidly.

Pathological subtype is also a potential predictive factor to consider. Silent corticotrophtumours are considered to be more aggressive. With respect to the pathological classification the Ki-67 index is most used, with a cut-off of 3% revealing unusually high proliferation index and 10% being suspicious for malignant behaviour. Studies on gene expression have not been able to identify a set of prognostic markers for NFPA. The oestrogen receptor alpha is of potential interest because the suggestion that males with low expression had higher reintervention rates. In summary, for clinical practice these developments have not yet proven their benefit. So, patients operated for NFPA, especially those with remnants require long-term radiological surveillance [19].

Clinical Outcome of Patients

In general patients with a pituitary condition have significant morbidity, increased mortality, and decreased quality of life [20, 21]. Although this may be more pronounced in patients with functioning adenoma, also NFPA will have long-term consequences of their disease. From literature it is thought that intervention is able to improve quality of life scores, but that impairments persist despite optimal treatment including hormone replacement strategies. We assume hypopituitarism as important factor determining clinical outcome, in particular adrenal insufficiency. However, also visual impairments, headache, and psychosocial factors may be of relevance. To ensure optimal outcome a multidisciplinary team is required to address patient's issues not only at the medical level but also addressing psychosocioeconomical issues.

Gonadotropinomas

Hyperstimulation by excessive FSH secretion of gonadotropinomas has been described in only a few patients. An example of this is the observation of high serum FSH concentrations, but with normal luteinizing hormone and testosterone and large testes in four men with pituitary macroadenomas. After pituitary surgery there were decreases in serum gonadotropin and testosterone levels, which were accompanied by decreases in testicular volume. In females, a similar example was the description of a woman whose gonadotroph adenoma caused supranormal serum concentrations of FSH, which resulted in the development of multiple ovarian cysts, persistent elevation of her serum oestradiol concentration, and endometrial hyperplasia.

Future Perspective and Research Agenda

The variation in clinical course and presentation of non-functioning pituitary adenoma is tremendous (e.g. the new WHO classification in which only a small subset of clinically non-functioning pituitary adenomas are null-cell adenomas, and most have variable immune staining). The association with subtle clinical hormone secretion, clinical course, and presentation needs further research. A change in policy to be more restrictive in postoperative radiotherapy poses challenges to the multidisciplinary team, since careful surveillance of non-irradiated remnants is key in the high-quality care of this patient group.

New drug options are interesting but require long-term follow-up to evaluate added value; and although ideally randomized trials are needed, the variable and slow growth pattern will need large and long-term studies. In this respect, future registries for example on aggressive tumours may help to answer their questions.

2.3.12 Thyrotropinomas

Mark Gurnell, Olympia Koulouri, and Waiel Bashari

Introduction

Thyrotropin (TSH)-secreting pituitary adenomas (also known as thyrotropinomas or TSHomas) have traditionally been considered rare tumours, sometimes referred to as the 'one in a million pituitary adenoma', and accounting for approximately 1% of all pituitary tumours in historical surgical and pathological series [1]. However, just as the overall prevalence of clinically relevant pituitary adenomas has been shown to be higher than previously suspected (between 1:1000 and 1:1500 of the general population), findings from a national Swedish registry covering the interval 1990 to 2010 indicate (i) an incidence rate of 0.15 and (ii) a prevalence rate of 2.8 clinically overt thyrotropinomas per million population [2]; interestingly, the detection rate increased fivefold during the 20 year study interval (1991–2011). Consistent with this, following the first case report in 1960, fewer than 300 cases had been described by the mid-1990s; however, in the last two decades TSH-secreting pituitary adenomas have been recognized and reported with increasing frequency. Several factors are likely to account for this, including: (i) availability in routine clinical laboratories of ultrasensitive and highly specific TSH assays; (ii) increasing use of combined measurement of free thyroid hormone and TSH levels to screen for suspected thyroid dysfunction; (iii) improvements in (together with more widespread use of) pituitary magnetic resonance (MR) imaging and (iv) increased awareness of the condition. In parallel, a change in the proportion of microadenomas versus macroadenomas has emerged. Early case series reported macroadenomas in more than 80% of patients with TSH-secreting tumours, with up two-thirds manifesting extrasellar extension. However, recent studies indicate that micro-TSHomas are being increasingly diagnosed [2, 3] and, with the advent of more sensitive cross-sectional and alternative (e.g. positron emission tomography (PET)) techniques for detecting small functioning tumours [4], it seems likely that the balance will be even further redressed. The majority of patients are diagnosed in middle age (with both genders equally affected), but case series involving both paediatric and elderly (>80 years) subjects have been described [5].

Increased awareness among clinicians, coupled with improved diagnostics, has the potential to reduce the delay between the onset of hyperthyroidism and definitive treatment, thus mitigating the risk of complications such as atrial fibrillation, osteoporosis, and compression of the optic chiasm. At the same time, it increases the likelihood that a surgically-resectable adenoma will be identified. Equally as important however, is the need to reliably distinguish central hyperthyroidism due to a thyrotropinoma from the much more common causes of primary hyperthyroidism (e.g. Graves' disease, toxic nodular goitre, toxic adenoma) in order to avoid inappropriate thyroid ablation, and from the numerous other conditions that can masquerade as hyperthyroxinaemia with non-suppressed TSH [6].

Central hyperthyroidism caused by a TSH-secreting pituitary adenoma is sometimes referred to as neoplastic inappropriate secretion of TSH. This differentiates it from non-neoplastic inappropriate TSH secretion, as is seen in the syndrome of resistance to thyroid hormone (RTH) caused by mutations in *THRB* (encoding the β isoform of the thyroid hormone receptor). However, the term central hyperthyroidism is generally preferred as it more clearly identifies the site of the primary abnormality (autonomous pituitary TSH secretion in the case of a thyrotropinoma).

The utility of long-acting somatostatin analogues (SSA), both in the diagnostic algorithm and as an adjunct to surgery, is gaining prominence with several groups reporting examples of complete normalization of thyroid function and significant tumour shrinkage (even resolution) following SS therapy. Indeed, most patients can be managed through a combination of transsphenoidal surgery and medical therapy, with radiotherapy increasingly reserved for the small proportion of tumours that display aggressive behaviour and/or resistance to SSA treatment.

Aetiopathogenesis and Pathology

Normal thyrotrophs represent less than 5% of all anterior pituitary cells [7], which may explain why thyrotropinomas are so rare. In normal physiology, the set-point of the hypothalamic-pituitary-thyroid axis is maintained within a tight range, and reflects a balance between positive (e.g. hypothalamic thyrotropin-releasing hormone [TRH]) and negative (e.g. somatostatin [SA]; triiodothyronine [T3]) regulation (**Figure 2.3.12.1**). The critical role of thyroid hormone in constraining thyrotroph expansion/growth is emphasized by the development of thyrotroph hyperplasia in patients who are chronically under-replaced or non-compliant with thyroxine replacement therapy.

The aetiopathogenesis of thyrotropinomas remains poorly understood. While the majority arise within the sella, a small number of cases of TSH-secreting adenomas located within the nasopharynx have been reported [8]. Although they have been observed in the context of multiple endocrine neoplasia type I [9] and familial isolated pituitary adenoma (due to mutation in the aryl hydrocarbon receptor-interacting protein (AIP)) [10], such cases are rare and the majority appear to arise sporadically. Data from analyses of

all pituitary tumour subtypes (including a small number of TSH-secreting adenomas) point to clonal expansion from a single transformed cell [11]. Evidence for aberrant transcriptional regulation of thyrotrophs (with consequent TSH hypersecretion and unrestrained growth) has been sought but, to date, most studies have proved largely uninformative (including those examining proto-oncogenes (e.g. Gsp, ras) and tumour-suppressor genes (e.g. Rb or p53)). The pituitary-specific transcription factor Pit-1 is overexpressed in some TSH-secreting pituitary adenomas, and might play a role in cell proliferation as well as promoting hormone cosecretion in this subgroup of adenomas.

The hallmark of TSH-secreting pituitary adenomas is constitutive and autonomous secretion of TSH with failure of negative regulation by thyroid hormone. A somatic mutation of *THRB* (encoding TRβ), as well as aberrant expression of a TRβ4 isoform, have been proposed as potential mechanisms for the impaired regulation of TSH by triiodothyronine (T3) [12, 13]. Thyrotropin-releasing hormone (TRH) receptors are present on most tumour cells. However, the attenuated/absent response of TSH and α-subunit to exogenous TRH administration in the majority of patients with TSH-secreting pituitary adenomas suggests that the TRH receptor signalling pathway is impaired/non-functional in these tumours. Most thyrotropinomas express somatostatin receptor (SSTR) subtypes 1, 2, 3, and 5, with SSTR2 the predominant isoform. Native somatostatin negatively regulates TSH secretion and has been implicated in cell cycle arrest. Depot somatostatin analogue therapy rapidly normalizes thyroid function in most patients with thyrotropinomas and can promote tumour shrinkage [14], suggesting that the primary molecular defect is unlikely to involve this pathway, although somatostatin analogue (SSA) resistant tumours are recognized.

Using an alternative approach, a recent study of whole-exome sequencing of a small number of thyrotropinomas similarly failed to identify a single common driver, suggesting that discrete primary events may underlie tumorigenesis in different patients [15].

Normal thyrotrophs share a common lineage with somatotrophs and lactotrophs, and are dependent on expression of Pit-1. It is not surprising then that cosecretion of growth hormone (GH) and/or prolactin (PRL) is observed in a significant proportion of cases (up to 30%) (Figure 2.3.12.2). Intriguingly, not all patients with biochemical evidence of abnormal GH secretion manifest overt acromegaly. In addition, a subgroup of tumours demonstrates positive immunohistochemical staining for GH and/or PRL, but do not exhibit clinical or biochemical acromegaly or hyperprolactinaemia. Similarly, so-called silent thyrotropinomas (clinically non-functioning pituitary adenomas, but with abundant positive TSH staining on immunohistochemistry) are well recognized [16]. TSH-secreting macroadenomas are often accompanied by unbalanced hypersecretion of α-subunit, and double-immunostaining studies have suggested the existence of two different types of cells: one secreting α-subunit alone and another cosecreting α-subunit and β-TSH [17].

TSH-secreting pituitary adenomas are almost always benign, with only a handful of malignant tumours (with metastases to brain, lung, liver, and/or bone) reported to date [18, 19]. A subgroup of thyrotropinomas are more fibrotic than other pituitary tumours, which has been linked to local secretion of basic fibroblast growth factor by the adenoma cells [20]. In this context, both microscopic and macroscopic calcification may be seen and can confound the interpretation of MR imaging, and make surgical resection more challenging (Figure 2.3.12.2).

Finally, not all TSH-secreting pituitary adenomas are associated with overt elevation of serum TSH levels—indeed it has been estimated that between 30% and 40% of cases have a TSH level which repeatedly falls within the reference range, but it is inappropriately normal for the ambient raised thyroid hormone levels. This may be explained, at least in part, by an increased bioactivity of neoplasm derived TSH [1].

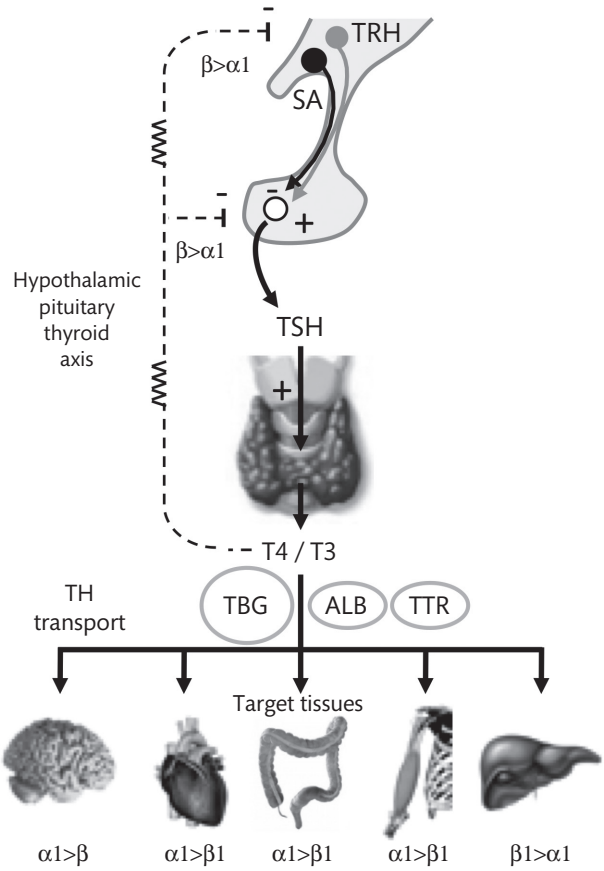

Figure 2.3.12.1 Schematic representation of the hypothalamic-pituitary-thyroid axis and major target organs. Key: α, thyroid hormone receptor α; β, thyroid hormone receptor β; ALB, albumin; SA, somatostatin; T3, triiodothyronine; T4, thyroxine; TBG, thyroxine-binding globulin; TR, thyroid receptor; TRH, thyrotropin-releasing hormone; TSH, thyrotropin; TTR, transthyretin.

Clinical Presentation

Clinical manifestations of central hyperthyroidism secondary to a TSH-secreting pituitary adenoma resemble those seen in primary hyperthyroidism (including palpitations/arrhythmias, tremor, heat intolerance, weight loss, sleep disturbance, etc.) but without disease-specific (e.g. Graves' ophthalmopathy or dermopathy) manifestations. Symptoms and signs may be progressive (although some patients report little change over intervals as long as a decade). However, in a surprisingly large number of patients the clinical features are milder, with some individuals appearing relatively asymptomatic (Koulouri, Bashari, and Gurnell, unpublished observation).

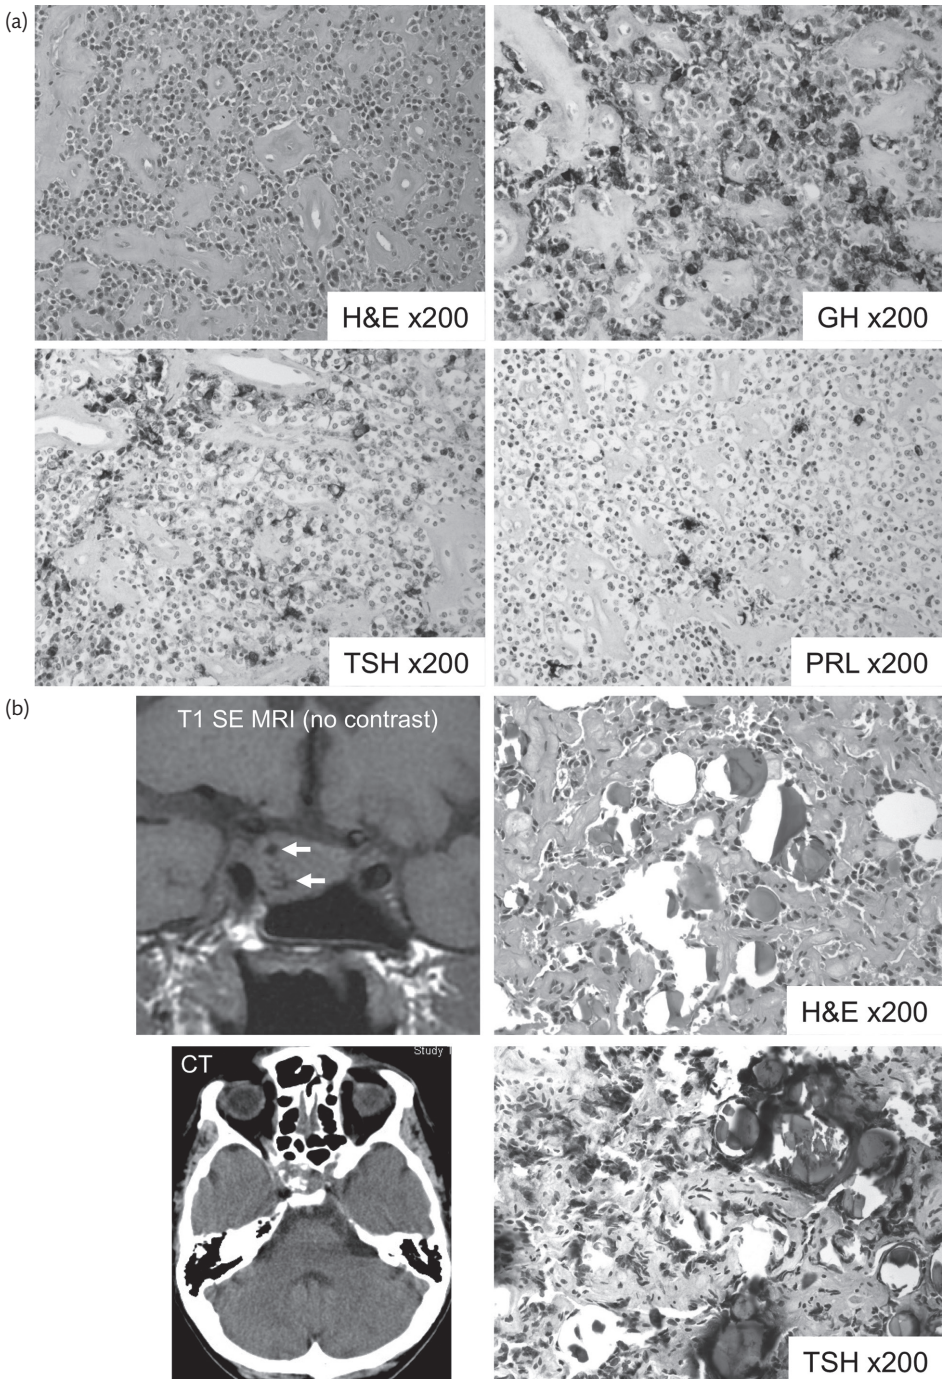

Figure 2.3.12.2 Spectrum of histological appearances in thyrotropinomas. (a) pituitary adenoma demonstrating positive immunohistochemical staining for growth hormone (GH), TSH and (to a lesser extent) prolactin (PRL). (b) thyrotropinoma with significant fibrosis and calcification—note the hypodense areas within the right side of the sella (arrows) on MRI (which may be mistaken for vascular structures, but which are confirmed as foci of calcification on CT). *For a colour version of this figure, please see colour plate section.*

Histology images provided courtesy of Dr Kieren Allinson, Department of Neuropathology, Addenbrooke's Hospital, Cambridge.

Importantly however, following successful treatment many of these patients report an improvement in their well-being, coinciding with resolution of previously unrecognized clinical symptoms. Estimates of the mean latency between onset of hyperthyroidism and establishment of the diagnosis are typically around 4–5 years.

Goitre and/or thyroid nodules may be present and are likely due to sustained TSH stimulation of thyroid follicular cells over many years. The co-occurrence of differentiated thyroid carcinoma has been described in a small number of cases [21]. Autoimmune thyroid dysfunction may also coexist and give rise to diagnostic uncertainty [22, 23].

In older case series, compressive symptoms (such as visual field defects (80%) and headaches (20%)), prevailed over those due to hyperthyroidism. However, this is no longer the case, as many patients present at an earlier stage and the proportion of microadenomas is increasing. Unilateral exophthalmos due to

Box 2.3.12.1 Causes of hyperthyroxinaemia with non-suppressed TSH

1 Raised thyroid hormone-binding capacity (leading to increased total T4 and total T3, but typically normal free hormone levels, e.g. due to oral oestrogen therapy)
2 Assay interference
  a) Falsely elevated free thyroid hormones
    i Heterophilic antibodies
    ii Anti-iodothyronine antibodies
    iii Familial dysalbuminaemic hyperthyroxinaemia (FDH)*
  b) Falsely non-suppressed TSH
    i Heterophilic or human antianimal antibodies
    ii Macro-TSH
3 Thyroxine replacement therapy (including poor compliance)
4 Medications (e.g. amiodarone, heparin)
5 Non-thyroidal illness (NTI) (including acute psychiatric disorders; neonatal period)
6 TSH-secreting pituitary adenoma
7 Resistance to thyroid hormone (RTH)
8 Disorders of thyroid hormone transport or metabolism

Key: *FDH is also associated with a true increase in total thyroid hormone levels as the mutant albumin exhibits increased binding capacity; at the same time artefactual elevation in free T4 (and in some instances free T3) may be observed on some laboratory platforms.

orbital invasion by the pituitary tumour is very rare, but must be distinguished from asymmetric exophthalmos of Graves' disease. In mixed secreting tumours, clinical findings are dependent on the nature of the hormone cosecreted (e.g. acromegaly features, amenorrhoea, and/or galactorrhoea). In macroadenomas, concomitant hypopituitarism (e.g. hypogonadism, hypoadrenalism) may be present. TSH-secreting pituitary adenomas have been reported in pregnant women, in patients with multiple endocrine neoplasia type I, and in atypical McCune–Albright syndrome [9, 24, 25].

Differential Diagnosis

Since the advent of ultrasensitive TSH assays, the classical biochemical signature of TSH-secreting pituitary adenomas is readily recognized: elevated or detectable (i.e. non-suppressed) TSH in the face of biochemical hyperthyroidism (with increased free thyroxine (fT_4) and triiodothyronine (fT_3)). However, this laboratory picture is not exclusive to thyrotropinomas and it is important to consider other possible causes before proceeding to further investigation (Box 2.3.12.1).

Elevated total thyroid hormone (TT4, TT3) levels, with inappropriately normal or elevated TSH, may be observed when thyroid hormone-binding capacity is increased, e.g. during pregnancy when thyroxine-binding globulin (TBG) levels are raised, or in individuals with familial dysalbuminaemic hyperthyroxinaemia (FDH), where point mutations in the *ALB* gene increase albumin's affinity for thyroid hormone [26]. FDH may also perturb commonly used fT_4 (± fT_3) assays to yield falsely elevated levels. Close liaison with the laboratory is therefore required to exclude these and other conditions (e.g. heterophilic antibodies or anti-iodothyronine antibodies) which are capable of producing false positive TSH or fT_4 (± fT_3) assay readouts. In addition, careful consideration must be given to other conditions and medications (e.g. heparin, amiodarone) that may yield a blood profile suggestive of central hyperthyroidism [27].

Investigation of Hyperthyroxinaemia with Non-Suppressed TSH

Step 1—Clinical Assessment

Even when a patient appears to have been extensively investigated, it is always important to revisit the clinical history and examination findings to: (i) identify potential confounding factors (intercurrent illness; amiodarone, heparin); (ii) determine the thyroid status of the patient; and (iii) check for other clues that might point to a TSH-secreting adenoma (e.g. coexistent acromegaly or hyperprolactinaemia; local compressive features), or indeed suggest the possibility of assay artefact (e.g. dysthyroid eye signs in a patient with primary thyroid dysfunction and an unreliable TSH readout).

Step 2—Exclusion of Laboratory Assay Interference

Close liaison with the Clinical Biochemistry laboratory is critical to avoid further inappropriate investigation in cases where either hyperthyroxinaemia or a non-suppressed TSH is due to assay interference. Confirmation that free thyroid hormone levels (free T4 and T3) are genuinely raised may require referral to a reference laboratory with the ability to perform a two-step assay or equilibrium dialysis to detect conditions such as FDH or anti-iodothyronine antibodies. TSH dilution studies, polyethylene glycol (PEG) precipitation or even gel filtration chromatography may be required to exclude interference in the TSH assay [6].

Step 3—Distinguishing a TSH-Secreting Pituitary Adenoma from *THRB* RTH

Once genuine hyperthyroxinaemia with non-suppressed TSH has been confirmed, the key challenge is to distinguish a TSH-secreting pituitary adenoma from rare genetic disorders of thyroid hormone transport, metabolism, and action (in particular RTHβ due to mutations in *THRB*). The degree of clinical thyrotoxicosis and the magnitude of elevation of thyroid hormone and TSH levels show considerable overlap when comparing cohorts of patients with thyrotropinomas and *THRB* RTH. Accordingly, other investigations are required to reliably distinguish between the two conditions.

Family History/Genetic Screening

Although a small number of individuals with thyrotropinomas have been found to harbour mutations in genes associated with familial pituitary disease (MEN type 1 and familial isolated pituitary adenoma), most TSH-secreting adenomas are sporadic. In contrast, *THRB* RTH is an autosomal dominant disorder and affected family members can be readily identified by performing thyroid function testing, thus guiding subsequent genetic screening. However, between 10% and 15% of patients with RTHβ do not have a demonstrable mutation in *THRB* (see Chapter 3.4.5, 'Syndromes of Resistance to Thyroid Hormone').

Alpha Subunit (ASU) and ASU:TSH Molar Ratio

Classically, an increased plasma ASU level and increased ASU:TSH molar ratio were considered important diagnostic markers for thyrotropinoma. The ASU:TSH molar ratio has been recommended to help avoid misinterpretation due to raised gonadotrophin levels (e.g. in postmenopausal women), reflecting the shared common alpha subunit with luteinizing hormone (LH) and follicle-stimulating hormone (FSH). However, in this context, the population reference range for ASU:TSH molar ratio is so wide [28] as to render it of limited value for the detection of all but the most obvious macroadenoma. As a general rule, a raised ASU (and/or ASU:TSH molar ratio) may help to support suspicions of a thyrotropinoma, but a normal result certainly does not exclude the possibility.

Sex Hormone-Binding Globulin (SHBG)

Hepatic production of SHBG is directly regulated by thyroid hormone operating via the TRβ1 isoform of the receptor. In RTHβ the liver is therefore resistant and SHBG levels remain within the age- and gender-related reference range. In contrast, in the presence of a TSH-secreting tumour, raised thyroid hormone levels cause hepatic thyrotoxicosis with raised SHBG. Unfortunately, however, normal SHBG levels may sometimes be seen, especially when there is cosecretion of GH by a thyrotropinoma. Similarly, other factors (e.g. concomitant oral oestrogen therapy) may cause an elevated SHBG in RTH.

Dynamic Testing

The use of dynamic testing can be particularly helpful in discriminating between *THRB* RTH and a TSH-secreting pituitary adenoma:

(a) TRH test (200 mcg i.v.):
- Thyrotropinoma: attenuated or absent response of TSH following exogenous TRH stimulation
- *THRB RTH:* preserved or exaggerated response

(b) Depot somatostatin analogue (Lanreotide Autogel® 90–120 mg or Sandostatin LAR® 20–30 mg) every 4 weeks for three injections):
- Thyrotropinoma: rapid and sustained normalization of free T3, free T4, and TSH levels in more than 90% of patients
- *THRB RTH:* a transient reduction in free thyroid hormone levels may be observed, but returns to baseline by the conclusion of the test

(c) Liothyronine (L-T3) suppression test (various protocols exist, including progressive dose escalation or fixed dosing over a 10-day period):
- Thyrotropinoma: absent or only slight reduction of TSH
- *THRB RTH:* TSH suppression is marked (although not always complete)

However, in practice the L-T3 suppression test is often reserved for those cases in whom results remain equivocal despite extensive investigation, or for detecting low level residual or recurrent disease following pituitary surgery. It is important to note that patients with known or suspected cardiac disease (arrhythmias, ischaemia or heart failure) and those with a history of psychiatric disease should not be exposed to high doses of thyroid hormone as is required for the L-T3 suppression test.

Table 2.3.12.1 summarizes the typical findings in TSH-secreting pituitary adenoma and *THRB* RTH across the various tests.

Step 4—Pituitary Imaging

Once the diagnosis of a TSH-secreting pituitary adenoma has been confirmed, then attention turns to tumour localization to help guide management. It is important however, to bear in mind that the presence of a pituitary microadenoma in a patient with inappropriate secretion of TSH, although strongly suggestive, is

Table 2.3.12.1 Distinguishing between TSH-secreting pituitary adenoma and TRβ resistance to thyroid hormone (*THRB* RTH)

	TSH-secreting adenomas	Resistance to thyroid hormone (*THRB*)
Family history	Usually absent	Possible
Genetic analysis	Usually negative	Positive in 85–90% of cases
Increased free thyroid hormones	Yes	Yes
Normal or high TSH	Yes	Yes
Circadian TSH secretion	Absent	Preserved
SHBG	Increased (but may be normal if cosecretion of GH)	Normal
α-subunit level	Increased/normal	Normal
α-subunit/TSH molar ratio	Increased/normal	Normal
Response to TRH stimulation test	Absent/attenuated	Preserved/exaggerated
Response to L-T3 suppression test	Absent/markedly attenuated	Present, although may not be complete
Response to depot SSA trial	Rapid and sustained suppression of TSH in majority of cases resulting in restoration of euthyroidism	No effect
GH and or prolactin cosecretion	+	–
MRI	Adenoma (although some microadenomas may not be visualized on standard clinical MR sequences)	Normal (but incidentalomas in 10–15%)

Key: GH, growth hormone; L-T3, Lio-thyronine; MRI, magnetic resonance imaging; SHBG, sex hormone-binding globulin; SSA, somatostatin analogue; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

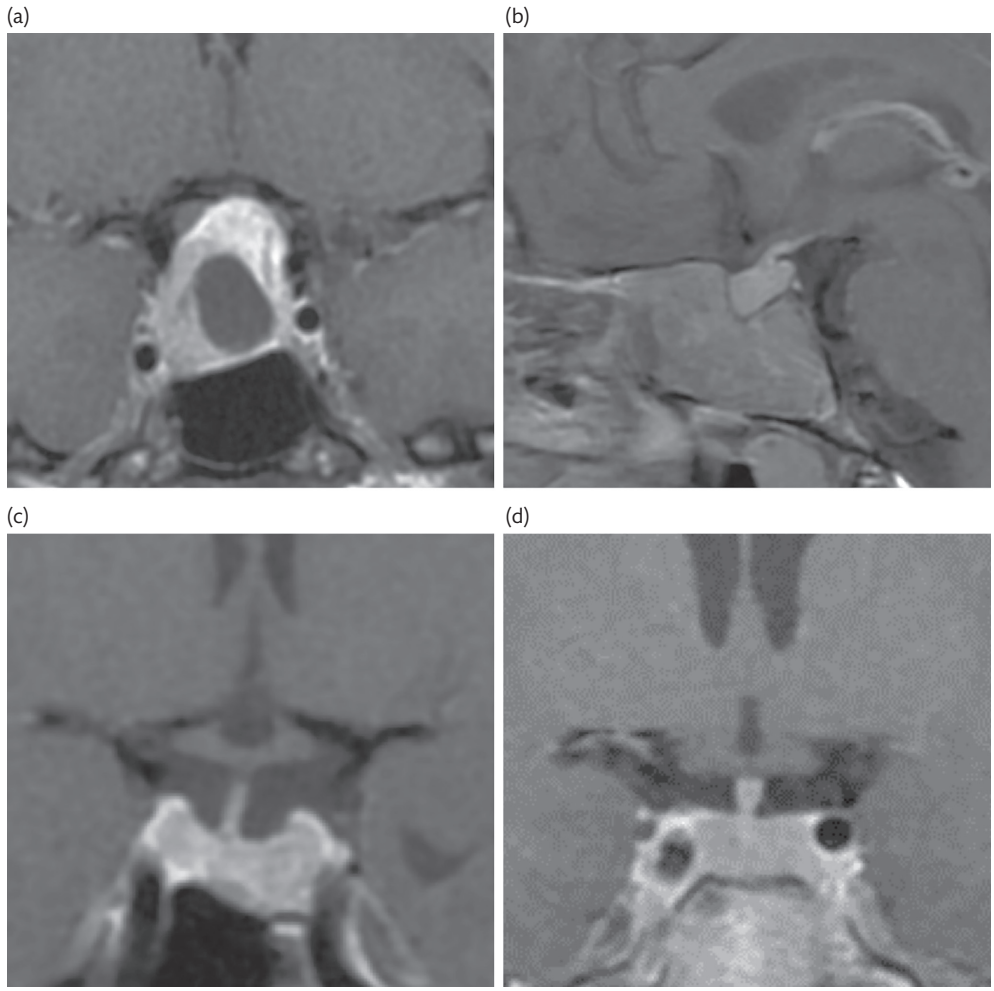

Figure 2.3.12.3 Spectrum of TSH-secreting pituitary adenomas. (a) Macroadenoma with predominant suprasellar extension compressing the optic chiasm. (b) Macroadenoma filling the sphenoid sinus—note how the adenoma appears discrete from the normal pituitary gland in the sella, raising the possibility of an extrasellar ectopic origin. (c) Left-sided microadenoma. (d) No visualized adenoma.

not diagnostic of a TSH-secreting pituitary tumour given that pituitary incidentalomas are found on MRI in ~10–15% of the general population. In contrast, incidental macroadenomas are much less commonly encountered. In patients with TSH-secreting pituitary adenomas there is no correlation between serum TSH levels and tumour size. In older case series, patients commonly presented with macroadenomas with suprasellar and sphenoidal extension, whereas in more recent series microadenomas feature much more frequently. Indeed, it is now clear that thyrotropinomas exhibit a spectrum ranging from large invasive (even giant) tumours through to microadenomas that cannot be readily visualized using conventional MR sequences (analogous to some Cushing's microadenomas) (Figure 2.3.12.3). For the latter, various approaches have been tried to aid localization of the tumour (including inferior petrosal sinus sampling with TRH stimulation and octreotide scintigraphy). However, the most promising approach appears to be functional imaging with ^{11}C-methionine PET-CT coregistered with volumetric MRI, which may aid precise localization of the tumour (Figure 2.3.12.4), especially when performed pre-and post-somatostatin analogue therapy [4].

Management

In patients with TSH-secreting pituitary adenomas, the goal of therapy is to restore euthyroidism and, in patients with large tumours, to eliminate any symptoms of mass effect. Early diagnosis and correct treatment of these rare tumours helps prevent complications (such as visual failure and hypopituitarism), and may also improve surgical cure rates.

The success of treatment depends on the criteria used. It has been suggested that an early test of cure might be an undetectable TSH concentration seven days after surgery (when the normal thyrotrophs remain suppressed as a consequence of prolonged exposure to raised circulating thyroid hormone levels) [29]. However, many patients are now treated with somatostatin analogues prior to surgery, often with rapid normalization of hyperthyroidism, which may therefore allow recovery of normal thyrotroph function prior to theatre. Normalization of dynamic tests (e.g. TRH test, T3 suppression test) might therefore represent a better (later) test of cure. In any case, long-term follow-up is necessary to detect relapse and recurrence.

Transsphenoidal surgery remains the treatment of choice in many patients with TSH-secreting pituitary adenomas. Historically, pituitary surgery alone has been reported to result in normalization

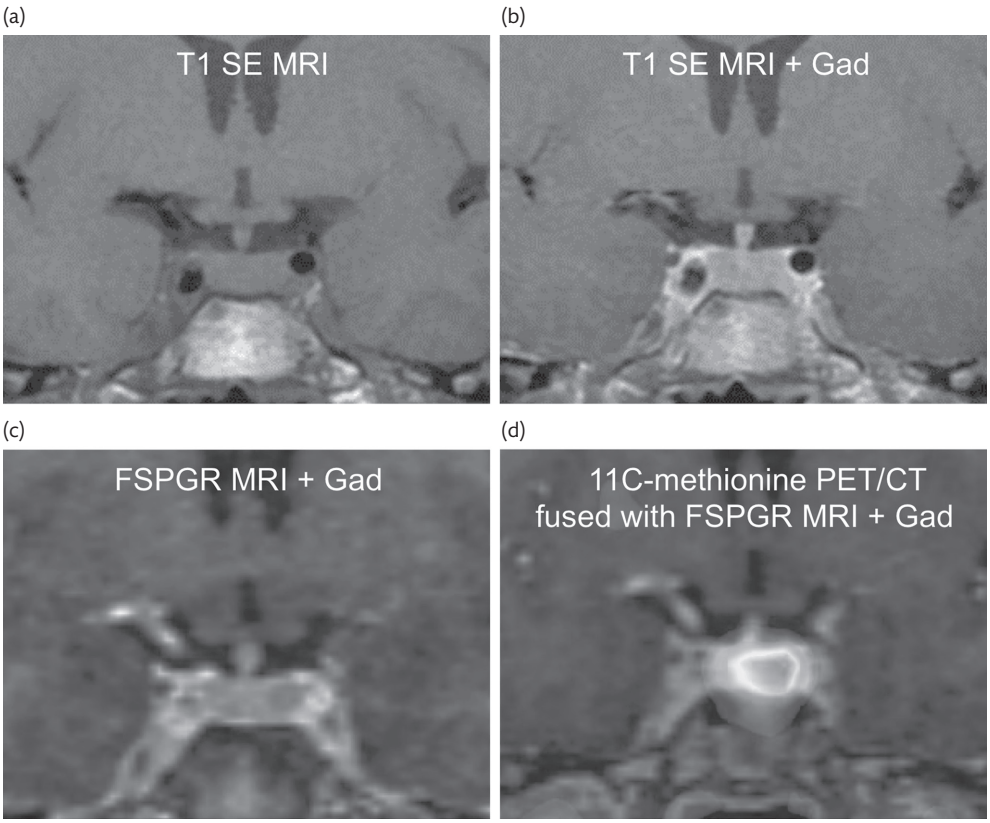

Figure 2.3.12.4 Confirmation of the site of a microadenoma using volumetric MRI and functional imaging with 11C-methionine PET. (a, b) Standard clinical spin echo (SE) MR sequences pre- and post-gadolinium (Gad) fail to identify a thyrotropinoma. (c) Volumetric (fast spoiled gradient recalled acquisition (FSPGR)) MR sequences (1 mm slices) identify a possible left-sided microadenoma adjacent to the cavernous sinus. (d) ^{11}C-Methionine PET/CT coregistered with FSPGR MRI demonstrates avid tracer uptake at the site of the suspected lesion. Transsphenoidal surgery and histological analysis confirmed a left-sided TSH-secreting microadenoma. *For a colour version of this figure, please see colour plate section.*

of thyroid hormone secretion and resolution of the pituitary mass in approximately 50% of patients, achieve normalization of thyroid parameters despite incomplete tissue removal in approximately 25% of patients, and is unsuccessful in nearly 30% of cases. However, an increase in the surgical cure rate has been reported in more recent series, probably reflecting improved surgical techniques and earlier diagnosis [29].

Medical treatment is an alternative option to pituitary surgery in patients with TSH-secreting pituitary tumours. Dopamine agonists are an effective treatment in true mixed TSH/prolactin-secreting pituitary adenomas, whereas success is limited when bromocriptine is used in patients with pure TSH-secreting pituitary adenomas [30]. In contrast, depot somatostatin analogues (octreotide LAR or Lanreotide Autogel®) suppress TSH secretion in more than 90% of TSH-secreting pituitary adenomas, and normalize thyroid hormone levels in approximately 75–90% of patients. However, significant shrinkage of the adenoma is only observed in approximately 50% of cases, and total resolution of a macroadenoma with maintenance of long-term cure in response to somatostatin analogue therapy has been reported in only a single case [31]. As a general rule, the effects of somatostatin analogues are reversible, with the need for long-term administration, with possible tachyphylaxis requiring increasing doses of the drug to maintain good control of the disease in up to 10% of cases, and with true resistance in a small number of patients [32]. The second generation somatostatin receptor ligand pasireotide may offer an alternative for treatment resistant cases, although experience to date is limited to a single patient in whom it was not clear whether there was true resistance to first line SSA therapy [33]. Somatostatin analogues remain expensive and may be associated with side effects such as cholelithiasis and carbohydrate intolerance. Accordingly, although some patients and their clinicians might elect to pursue long-term primary SSA therapy, for many patients these remain an important bridge to surgery (allowing anaesthesia to proceed safely) and as adjunctive therapy when surgery is unable to achieve full remission, or while awaiting the beneficial effects of radiotherapy.

It is appropriate to briefly mention conventional antithyroid drug (ATD) therapy, which may be used for a short duration in preparation for surgery. However, concerns remain that longer term use may predispose to tumour expansion (Nelson's-like phenomenon) [1], and for that reason permanent thyroid ablation is also generally best-avoided, although may occasionally be indicated in those with recalcitrant arrhythmias or cardiac failure.

Conventional radiotherapy and stereotactic radiosurgery have also been employed in the management of TSH-secreting pituitary tumours, especially when surgery and/or medical therapy has proved unsuccessful [34]. However, the number of reported cases, especially using modern radiotherapy techniques, remains relatively small. As with other pituitary tumour subtypes, and allowing for the long time period necessary for the full effect to be realized, and potential late side effects (e.g. hypopituitarism, second tumour, possible increased cerebrovascular disease), radiotherapy is generally reserved for the small number of cases in whom combination

surgery and medical therapy is unable to achieve satisfactory biochemical and/or tumour control.

Conclusions

TSH-secreting pituitary adenomas are a rare cause of hyperthyroidism. The main prognostic factors of these adenomas are size and invasiveness of the tumours, duration of symptoms, and intensity of hyperthyroidism. Early recognition of central hyperthyroidism, and localization of the causative lesion should now be readily achieved in most cases, reflecting the availability of ultrasensitive TSH assays and improvements in pituitary imaging. Reflecting this, the spectrum of disease and approach to the treatment of these rare pituitary tumours has changed significantly during the past decade. Patients typically present with mild or moderate symptoms and signs of hyperthyroidism, hormonal evaluation shows increased free thyroid hormone concentrations with detectable serum TSH levels, and MRI increasingly identifies patients with micro- rather than macroadenomas. Trans-sphenoidal surgery remains the treatment of choice, although depot somatostatin analogue therapy is now established as a key component in the management pathway: either pre- and, in selected cases, post-surgery, or sometimes as long-term primary medical therapy.

2.3.13 Pituitary Carcinoma

Ann McCormack

Definition and Epidemiology

Pituitary carcinomas (PC) are tumours originating from cells of the adenohypophysis with evident craniospinal or systemic metastatic disease [1]. They are rare, accounting for 0.12–0.2% of all pituitary tumours with an incidence of 4 per 1 000 000 person years [2–4]. However, the incidence is likely underestimated as frequently metastatic deposits are only detected at autopsy [5–7]. Most commonly PC presents in the fourth to sixth decades of life, with a mean age at diagnosis of 44 [7–9]. Paediatric cases are very rare but have been described [10, 11]. There is a slight male predominance [2, 8]. More than 80% of PC are clinically functioning, the majority corticotroph and lactotroph tumours, less commonly somatotroph and thyrotroph PC [8]. Notably, 20% of PC evolve from initially clinically silent to functional tumours. Silent hormone expressing PC are more frequently encountered among the clinically non-functioning PC with true gonadotroph and null cell PC comprising a small subset [8]. PC has been described in the setting of familial cancer syndromes, including patients with germline mutations in *MEN1, SDHB*, and DNA mismatch repair genes (Lynch syndrome) [12–15]. However, there is no evidence that PC are more common in patients with familial predisposition to pituitary tumours.

Clinical Presentation and Diagnosis

Pituitary tumours destined to become PC almost always begin as macroadenomas. However, size at presentation does not correlate with potential for malignant behaviour as giant lactotroph tumours can be highly sensitive to dopamine agonist treatment [16]. Commonly there is a history of relatively indolent behaviour with emergence of aggressive disease years later preceding the identification of metastases. There is considerable variability in the latency to development of metastatic disease from months to more than 20 years from diagnosis with a mean of 7 years [9]. Clinically aggressive tumour behaviour may be evident at presentation with fulminant progression [17].

Mass effect symptoms, such as visual impairment, headache, and cranial nerve palsies, tend to dominate the clinical presentation of PC. Unusual neurological signs, such as ataxia or motor weakness, should raise concern about the possibility of PC. Diabetes insipidus (DI) is rarely encountered in PC, and in general the presence of DI should alert to an alternative diagnosis, such as metastasis to the sellar arising from a non-pituitary primary [18].

Systemic metastases occur most commonly (47%), are more frequent among lactotroph compared with corticotroph tumours and most often involve the liver, lung, and bone, with rare sites of metastatic disease including the orbit, heart, pancreas, kidney, ovary, myometrium, and pelvic lymph nodes [9]. Systemic dissemination occurs through haematogenous spread via the cavernous sinuses and/or jugular veins [3]. Metastases to cervical lymph nodes are also seen and thought to result from invasion of lymphatics of the skull base and soft tissues [3]. Craniospinal metastases also occur frequently (40%), spread occurring through cerebrospinal fluid dissemination. Both craniospinal and systemic metastases are seen in 15% of patients [9].

The primary diagnostic modality is structural imaging with magnetic resonance imaging (MRI) or computed tomography (CT) with attention to site-specific symptoms such as neck or back pain that may indicate a site of metastatic disease. Functional imaging modalities may be useful in detecting otherwise occult metastases. Ga68 Dotatate and F18 FDG-PET/CT may identify different sites of metastatic disease when used concurrently, with potential therapeutic and prognostic implications [19, 20]. According to 2017 WHO criteria, the following need to be met in order to diagnose a PC: (1) the primary lesion must be a histologically proven adenohypophyseal tumour; (2) an alternative primary lesion must be excluded; (3) discontinuous spread must be present in the craniospinal axis; and (4) the pathological features of metastases should be similar to those of the primary pituitary tumour [21].

Thus, while imaging may suggest PC, a surgical biopsy may be required to confirm the diagnosis. However, fine needle aspiration biopsy of metastases within cervical lymph nodes, liver and lung have been successfully performed [22, 23].

Only a minority of aggressive pituitary tumours (APT) ultimately manifest metastases. However, recognition of an APT is vital to identify tumours with malignant potential. Furthermore, the morbidity and mortality of APT are increased even in patients without metastases [24]. An APT demonstrates invasion and displays an unusually rapid growth rate, or continued growth despite multimodal treatment (surgery, radiotherapy, standard medical therapy) [24]. Serial MRI imaging is required to determine tumour growth rates, with accurate reporting of tumour dimensions and ideally tumour volume measurements. In a large study of 153 pituitary tumours (functioning and non-functioning), the mean tumour volume doubling time (TVDT) was 1147 +/– 870 (SD) days (range 60–3478). Tumours with a more rapid growth rate (below 1 SD TVDT) had a TVDT under 1 year [25]. Younger patients with non-functioning pituitary adenomas (NFPA) and females with functioning tumours have been found to have faster growth rates [25, 26]. The rapid growth of a corticotroph pituitary tumour following bilateral adrenalectomy (Nelson's syndrome) is also cause for concern and has been found in 67% of corticotroph PC [18]. Metastatic disease should be suspected when there are discordant biochemical and radiological findings, for example rising prolactin (PRL), adrenocorticotropin hormone (ACTH) or growth hormone (GH) levels in the setting of low volume sella-based disease [24].

Functioning PC typically exhibit very high hormone levels, however there is significant overlap with levels found in pituitary adenomas (PA). One hallmark that may indicate malignant transformation of a PA is the emergence of resistance to medical treatment. This is particularly seen with prolactinomas, where resistance to dopamine agonist (DA) therapy may be a feature present early in the disease course but can also be acquired during treatment [27]. Transformation of a PA from silent to functioning may also herald malignant progression, well described for silent corticotroph adenomas but also reported in silent somatotroph tumours and in one case of an initially hormone-immunonegative tumour that subsequently transformed into a thyroid stimulating hormone (TSH) and PRL-secreting PC with brain metastases [28–31]. Conversely, tumour de-differentiation is thought to account for cases where reduced hormone secretion has been observed [18, 32].

Pathological Evaluation

There are no histopathological, immunohistochemical, or ultrastructural features to reliably differentiate PC from PA. Microscopically, PC usually appear as well-differentiated neuroendocrine tumours akin to benign PA. While histological features of hypercellularity, nuclear pleomorphism, necrosis, haemorrhage, or invasion may be present in PC, they are also common in PA. Neuronal metaplasia has been reported in PC but is rare. Metastatic deposits often have more atypical cytological features compared to the primary pituitary tumour [21]. Mitoses are more frequently seen in PC compared with PA, although there are cases of PC without significant mitoses [7]. In one study, mitoses were present in 3.9% of non-invasive PA, 21.4% of invasive PA and 66% of PC, while in the large European Society of Endocrinology (ESE) survey cohort of APT a raised mitotic count (>2 mitoses/10 high powered field (HPF)) was found in 90% of PC compared with 63% of APT [8, 33].

The neuroendocrine origin of PC can be confirmed on immunohistochemical analysis with expression of markers such as chromogranin A and synaptophysin. Pituitary hormone expression does not differentiate PC from PA but is important to determine tumour subtype. Tumour subclassification, utilizing immunohistochemical analysis of transcription factors and low-molecular-weight cytokeratin, can assist in identifying a tumour with an increased potential for more aggressive behaviour (Table 2.3.13.1) [34]. Clinically non-functioning but immunohistochemically classified Pit-1 positive plurihormonal adenomas (previously termed silent subtype 3 PA) are particularly recognized for their inherently aggressive behaviour. Cytokeratin staining identifies the fibrous bodies of a sparsely granulated somatotroph adenoma and also hyaline changes of Crooke's cell adenomas [34]. Ultrastructural evaluation is no longer necessary in the routine classification of pituitary tumours [21].

Measurement of Ki67, using the MIB-1 antibody, provides an assessment of the number of cells in the S-phase of the cell cycle, and is an important marker of the rate of cellular proliferation [7]. Metastatic deposits frequently exhibit higher Ki67 indices than the primary pituitary tumour [21]. Higher Ki67 indices have been correlated with invasive adenomas, risk of recurrence and malignant behaviour [8, 33, 35, 36]. The mean Ki67 in one series was 1.37% for non-invasive PA compared with 4.66% for invasive adenomas and 11.91% for PC [37]. Similarly, in the ESE survey cohort 46% of APT

Table 2.3.13.1 Pituitary tumour subtypes with potential for aggressive behaviour

Tumour subtype	Hormone	Cytokeratin	Transcription factor
Sparsely granulated somatotroph adenoma	GH +/- PRL	Dot-like (fibrous bodies)	Pit-1
Lactotroph macroadenoma in men	PRL +/– GH (acidophilic stem cell adenoma)	+/– fibrous bodies (acidophilic stem cell adenoma)	Pit-1 ER-α (sparsely or densely granulated)
Crooke cell adenoma	ACTH	Ring-like pattern	Tpit
Silent corticotroph adenoma	ACTH	Diffuse pattern	Tpit
Plurihormonal Pit-1-positive adenoma	GH, PRL, TSHβ +/– α-subunit	N/A	Pit-1

Modified with permission from Osamura RY, Lopes MBS, Grossman A, Kontogeorgos G, Trouillas J. *Pituitary Adenomas*. In: Lloyd RV KG, Rosai J, editor. WHO classification of tumours of endocrine organs, 4th edn. Lyon: IARC Press; 2017.

and PC were found to have a Ki67 ≥ 10% [38]. A threshold Ki67 ≥ 3% has commonly been used as a marker associated with an increased risk of tumour recurrence while a Ki67 ≥ 10% is considered by some authors to indicate a malignant pituitary tumour [21, 24]. However, there is substantial variability in Ki67 reported among PC from 0% to 34% [7, 8]. This may result from tumour heterogeneity as well as differences in interpretation of Ki67 labelling [9].

Used in isolation, the Ki67 measurement has limited prognostic potential [39, 40]. Increased expression of p53 has been reported in 100% of a cohort of PC compared with 7.1% of PA, while in other studies p53 expression has progressively increased during the progression from adenoma to carcinoma [7, 9]. It has also been found to be absent in PC and considerable debate exists over its reliability [7, 9, 24, 41]. The combination of Ki67 >3% and extensive p53 immunoreactivity has been associated with an increased recurrence rate of PA in some studies, but not in others [42, 43]. In the 2004 WHO classification of pituitary tumours, an 'atypical pituitary adenoma' was defined by the presence of Ki67 >3%, p53 overexpression, and increased mitotic rate, however this category was abandoned in the 2017 WHO classification given the lack of clinical validation as a prognostic tool [1, 21]. Nevertheless, measurement of Ki67, along with p53 immunostaining and evaluation of mitotic count, remain recommended in the assessment of an APT [24]. The utility of these proliferative markers may be most useful in determining risk of recurrence for invasive PA. This formed the basis for a clinicopathological grading classification system in which invasive and proliferative PA demonstrated a 12-fold increased risk of tumour progression compared with non-invasive, non-proliferative PA [44].

Pathogenesis and Genetics

The exact pathogenesis of PC is uncertain, but progression from PA to PC is thought to arise from an accumulation of molecular alterations or development of a subclone of tumour cells with critical genetic and epigenetic change(s) that form metastatic deposits [9, 21]. The multistep genetic progression from benign to malignant pituitary tumours has been illustrated in rat studies utilizing SMtTW lineages derived from spontaneous PRL tumours [45]. The most frequent somatic genetic event affecting PA are chromosomal alterations affecting whole chromosome arms [46]. In PC, there are an increased number of chromosomal aberrations, particularly gains, with an average of 8.3 imbalances per tumour [47]. Chromosomal gains in 1q, 3p, 5, 8, 14q, and 19p have been reported in PC, and loss of chromosome 11 may be important in malignant transformation [48]. Pituitary tumour transforming gene (*Pttg*), is a securin protein critical in the spindle checkpoint machinery and error-free mitosis. *Pttg* overexpression results in genetic instability by causing DNA breaks and is a key oncogene driving pituitary tumour development and progression [49]. Increased *Pttg* expression correlates with higher levels of Ki67 and is associated with more aggressive pituitary tumour behaviour [50]. In a rat model of malignant prolactinoma, markedly elevated nuclear *Pttg* levels was postulated to be important in the development of an aggressive tumour phenotype [48]. *Pttg* has been identified as a key gene involved in tumour metastasis within solid malignancies [51].

Unlike many solid cancers, PA are not characterized by recurrent focal genetic driver mutations. Activation of classic oncogene genes, such as *Ras*, and mutations in tumour suppressor genes, such as *p53*, are not found in PA but have been described in PC [52–54]. In fact, *p53* and *p21* upregulation are key features of senescence, an essential mechanism controlling cellular proliferation in benign PA [49]. Reduced expression of important cell cycle inhibitors, such as *p21* and *p27(Kip1)*, appear to be critical in pituitary tumour progression, with undetectable levels seen in PC [55, 56]. Similarly, reduced expression of other proteins, such as retinoblastoma (*Rb*) gene and *nm23*, also involved in regulation of cell cycle progression have been described in PC [7]. Consequent upregulation of cell cycle proteins, such as cyclin D1, and increased cellular proliferation are central events in the malignant transformation of pituitary tumours [48]. Increased cyclin D1 levels have also been proposed to play a role in stimulating cell migration, angiogenesis, transcription factor activation, chromosomal instability, and miRNA expression [57]. Concurrent with increased cellular proliferation, rates of apoptosis are higher among PC compared with PA which have been correlated with decreased expression of the antiapoptotic protein Bcl-2 [58]. However, increased telomerase activity, responsible for cellular immortality, has been described in association with PC development [59].

Proteins involved in DNA repair have also been implicated in pituitary tumour progression. DNA topoisomerase IIα (Topo IIα) plays an important role in DNA replication and mitosis. It is linked with cell cycle activity and rates of cellular proliferation [60]. High expression of Topo IIα has been found in PC, although its correlation with other measures of cellular proliferation in PA, such as Ki67, has been reported in some but not all studies [60, 61]. Low expression of a DNA repair protein, 06-methylguanine-DNA methyltransferase (MGMT) has been reported more frequently in aggressive PA and PC [62, 63]. In a microarray study, low MGMT-expressing pituitary tumours were found to have upregulation of gene sets involved in DNA repair and transcription [64]. A reduction in expression of mismatch repair genes, a family of proteins that correct DNA replication errors, have been implicated in pituitary tumour proliferation and reduced apoptosis [65]. In particular, loss of MSH6 immunoexpression has been described in cases of PC [66, 67].

Activation of epidermal growth factor receptor (EGFR) signalling is an important feature in APT, with both epidermal growth factor (EGF) and EGFR highly expressed in PC [68]. Furthermore, *HER-2/neu* (a member of the EGF receptor family) is commonly amplified in PC [7]. Increased EGFR signalling results in upregulated expression of matrix metalloproteinase 9 (MMP-9), which is critically involved in the degradation of the extracellular matrix and tumour cell migration and is upregulated in PCs and recurrent invasive PAs [69]. MMP-9 also plays a role in stimulating angiogenesis, another attribute of tumours with malignant potential. Vascular endothelial growth factor (VEGF), a potent angiogenic factor involved in endothelial cell proliferation, vascular permeability, and cell mobility, is stimulated by MMP-9 [57, 70]. VEGF expression, and other contributors to tumour angiogenesis including cyclooxygenase-2 (Cox-2) and hypoxia-inducible factor 1-alpha (HIF-1α) have also found to be higher among PC compared with PA [71–73]. Tumour angiogenesis is commonly assessed by studying microvascular density, and while found to be higher in PC compared to PA, substantial overlap exists, so in isolation it may not be a useful prognostic marker [7, 74, 75]. Furthermore, measures of cell proliferation,

such as Ki67, are not positively correlated with markers of angiogenesis, suggesting these two processes are not aligned in malignant transformation [76].

MicroRNA are also thought to play a role in malignant transformation of pituitary tumours. In one study, increased miR-20a, miR-106b, and miR-17-5p were found in metastatic deposits of a PC and six atypical PA and predicted to reduce PTEN and TIMP2 expression thereby promoting metastasis [77]. Utilizing an integrative genomic approach, down-regulation of miR-183 was found in a small cohort of aggressive PA and demonstrated to target KIAA0101 resulting in cell cycle activation [78]. The overexpression of miR-122 and miR-493 have also been found to be upregulated in ACTH-PC [79]. In fact, one of the predicted targets of miR-493 is *LGALS3* mRNA, which regulates the expression of galectin-3 (Gal-3), a β-galactoside-binding protein widely implicated in cancer biology with roles in tumour proliferation, adhesion, angiogenesis, apoptosis and metastasis [80, 81]. Gal-3 is thought to have an important role in pituitary tumour progression and has been found to be increased in ACTH and PRL-PC compared with PA [82, 83].

Management

The management of PC is challenging requiring a multimodal approach overseen by an expert multidisciplinary team. Surgery, radiotherapy, and systemic therapies all have a role in the management of PC. Treatment decisions should consider factors such as disease burden (single metastatic deposits or widely disseminated disease), tumour location, prior therapies, and patient comorbidities.

Surgical Treatment

In patients with PC, surgical resection is rarely curative but substantial tumour debulking can be achieved with significant relief of compressive symptoms [9]. In the case of isolated metastatic disease, complete surgical excision may result in long-term disease-free progression particularly when combined with adjuvant radiotherapy [84, 85]. This has been reported not only for craniospinal disease but also for bone and liver metastatic deposits [85–87]. In addition, repeated surgical resections of recurrent metastases may prolong survival [88]. While advances in endoscopic skull base techniques may assist in wider control of sellar-based disease, frequently transcranial approaches are still required to manage other intracranial disease.

Radiation Therapy

Radiation therapy is most often used in a palliative approach as there is no evidence that radiotherapy improves survival in PC [9]. However, radiotherapy may arrest or slow tumour growth in PC and is often used in an adjuvant setting following surgical excision or debulking of metastatic sites of disease. Chemotherapy with adjuvant radiotherapy is increasingly considered in PC [8]. Not infrequently patients with PC have already had at least one radiotherapy treatment over the course of their disease and further doses may be limited due to the risk of brain necrosis [9]. There has been more experience with use of fractionated external beam radiotherapy (EBRT) in PC but stereotactic radiosurgery (SRS) has also been reported with effect, most commonly with Gamma Knife (GK) [84, 87–90]. The choice of radiation technique and modality (linear accelerator, GK) is often based on safety considerations, such as proximity to optic chiasm, volume of disease and local centre availability [24, 91].

Medical Therapy

Standard medical therapies should be used in conjunction with other treatment in PC at maximally tolerated doses [24]. Lactotroph PC typically display complete resistance to DA, although there are case reports of reduction in prolactin levels and less commonly tumour size [18, 92–94]. High dose DA should be trialled (3.5–11 mg per week) although side effects including nausea and postural hypotension may limit the dose [9, 24]. Cabergoline is more effective compared with bromocriptine, and there is limited experience with quinagolide although it does not appear to be superior in PC [18, 24]. DA resistance may result from decreased dopamine D2 receptor expression, although other mechanisms may also exist [24]. Use of DA has been associated with a reduction in GH and IGF-1 levels and symptomatic improvement in rare cases of somatotroph PC but with no effect on overall disease progression, however use in corticotroph and thyrotroph PC is ineffective [5, 32, 95, 96]. Treatment with tamoxifen has unsuccessful in lactotroph PC [18].

A lack of response to first-generation somatostatin analogue (SSA) therapy (octreotide, lanreotide) is typical in PC, although temporary benefit in a thyrotroph PC case has been described [18, 32]. Resistance to octreotide may correlate in some cases with reduced somatostatin receptor (sst) 2 expression [97]. Sparsely granulated somatotroph PA, typically more aggressive than their densely granulated counterparts, and corticotroph PA more frequently express sst5 and may exhibit better response to second-generation SSA (pasireotide) with broader sst action, particularly against sst5 [24, 98]. In patients with acromegaly not responding to octreotide, a switch to pasireotide, can result in biochemical improvement [99]. However, there is no data about its use in malignant somatroph tumours. In limited cases of corticotroph PC pasireotide has not been effective [24].

In addition to attempts to control tumour growth in PC, medical therapy may be required to reduce hormonal hypersecretion. This is particularly important in patients with corticotroph carcinomas in whom unrestrained hypercortisolism is frequently a direct cause of death [9]. Adrenal-directed inhibitors of glucocorticoid synthesis, such as ketoconazole and metyrapone, are frequently used in this setting.

Chemotherapy

When disease burden is unable to be controlled with surgery and/or radiotherapy, chemotherapy should be considered. Almost always this requires systemic therapy although hepatic chemoembolization afforded temporary local control of liver metastases in a corticotroph PC [100]. Aggressive treatment of patients with PC with chemotherapy has been associated with improved survival [18]. Historically, many different chemotherapy regimens have been used with variable responses, most often limited to partial and transitory disease control [9]. Commonly employed agents have included lomustine (CCNU) in combination with 5-FU or dual cisplatin (or carboplatin) and etoposide [24].

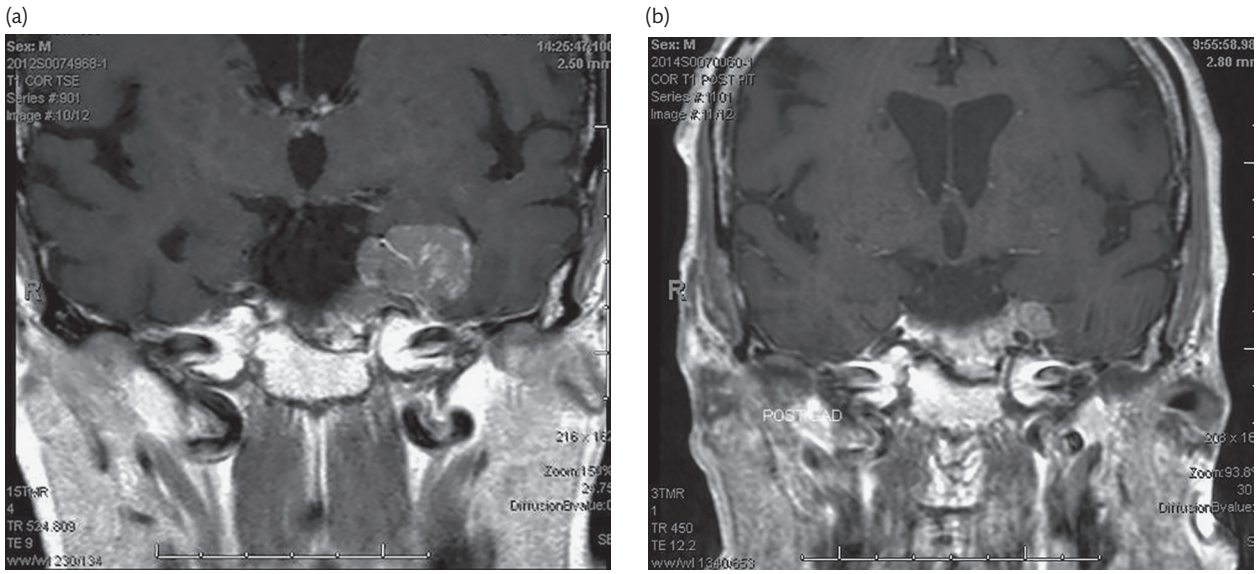

Figure 2.3.13.1 Sustained response to temozolomide.

However, the last decade has seen a major advance in the chemotherapeutic option for PC with the demonstration of response to temozolomide (TMZ) in a significant proportion of cases (Figure 2.3.13.1) [8, 101–103]. TMZ is an oral second-generation imidotetrazine alkylating agent which forms toxic methyl adducts with DNA bases and resulting ineffective DNA repair leads to DNA-strand breaks, cell cycle arrest and apoptosis [104]. In the largest published cohort of PC, comprising 40 patients, 43% of patients demonstrated a complete or partial response to temozolomide, with an additional 18% exhibiting stable disease [8]. Functioning tumours are more likely to respond than non-functioning tumours (Table 2.3.13.2) [8]. TMZ is now recommended as first-line chemotherapy for patients with PC [24]. It is delivered as outpatient oral chemotherapy, most commonly as monotherapy however some centres have proposed using TMZ following capecitabine pretreatment (CAPTEM) although evidence is lacking regarding superior efficacy with this or other combination regimes [24, 105]. The most common TMZ dosing regimen employed is 150–200 mg/m² for 5 consecutive days every 28 days. TMZ in combination with adjuvant radiotherapy may be more effective when maximal radiotherapy doses have not been reached [8, 24]. Response to TMZ therapy, most often concurrent biochemical and radiological improvement, is seen within 3–6 months. The appropriate duration of therapy has not been determined, but it is reasonable to continue for 6 months with longer duration considered in patients receiving clinical benefit. Generally well-tolerated, common side effects include fatigue, nausea/vomiting, and myelosuppression [24]. Sustained responses to TMZ therapy are frequent following treatment discontinuation, although subsequent tumour regrowth occurs in the majority of patients with a median time to progression of 12 months [8]. Low tumour MGMT expression may predict a positive response to TMZ, however cases with low MGMT expression and lack of response have been described [24]. Loss of expression of MSH6 has been reported in such a case [67]. Conversely, high MGMT expression is frequently associated with a poor response to TMZ, but in the absence of other effective chemotherapeutic options a trial of TMZ in such cases is still currently advocated [24].

Second-line therapy for patients progressing during or following cessation of TMZ, remains a challenge. Second courses of TMZ in patients who initially respond is unsuccessful in the majority of cases [24]. Drugs that inhibit the action of EGF/EGFR (e.g.

Table 2.3.13.2 Response to temozolomide based on subtype

Functional subtype	Pathological subtype	Complete response	Partial response	Stable disease	Progressive disease
Functioning (n = 33)	Corticotroph (n = 18)	2	7	1	8
	Lactotroph (n = 14)	1	6	4	3
	Gonadotroph (n = 1)	0	0	1	0
Non-functioning (n = 7)	Corticotroph (n = 1)	0	0	0	1
	Lactotroph (n = 1)	0	0	0	1
	Somatotroph (n = 2)	1	0	0	1
	Immunonegative (n = 3)	0	0	1	2

lapatinib, erlotinib) and VEGF/VEGFR (sunitinib, bevacizumab) pathways have encouraging *in vitro* results and reports of response in a few patients with APT [8, 106–108]. Promising preclinical studies in PA using inhibitors of the PI3K/Akt/mTOR pathway, such as everolimus, have translated into only occasional modest benefit when trialled in patients with APT [8, 109–112]. Finally, immunotherapy may prove useful in management of PC with a recent report of significant tumour shrinkage in a patient with an ACTH-secreting PC [113].

Peptide Receptor Radionuclide Therapy (PRRT)

There is good theoretical rationale in the use of PRRT to treat PC given sst expression and uptake of 68Ga-DOTATATE within pituitary tumours [20]. 111Indium-DPTA-octreotide, 177Lutetium-DOTATATE, 90Yttrium-DOTATOC, and 177Lutetium-DOTATOC have all been reported in a limited collective experience with PRRT for APT, with tumour regression seen in only a couple of patients thus far [24].

Prognosis

Prior to the TMZ era, the mean survival of patients with PC was less than 4 years, although there were cases of long-term survivors [7, 88, 90, 114, 115]. Patients with corticotroph PC and those with systemic compared with central nervous system (CNS) metastases have poorer survival [7]. In patients treated with TMZ, 3–4-year overall survival is reported between 50% and 60% [103, 116]. There is a clear survival benefit in patients who respond to TMZ therapy with a median survival of 44 months among responders compared with 16 months in non-responders [116]. The highest mortality is seen among patients progressing during TMZ therapy [8].

Conclusion

PC are rare and the diagnosis requires the documented presence of metastatic disease remote from the pituitary. Typically, PC arise many years following the diagnosis of PA. During the course of malignant transformation aggressive behaviour is exhibited which is important for clinicians to recognize because of the associated substantial morbidity and mortality. Unusually rapid tumour growth, hormonal hypersecretion in a previously silent PA, resistance to standard medical therapy and markers of increased proliferation such as elevated Ki67 should raise concern for a tumour with malignant potential. Management of PC requires multimodal therapy, including surgery, radiotherapy, and chemotherapy. Prognosis is poor although improved in patients responding to TMZ. Identification of other effective therapeutic options in PC remains an important area for future research and requires collaboration among physicians caring for these rare cancers. The use of tyrosine kinase inhibitors, antiangiogenic agents, immunotherapy, and PRRT may hold promise in the management of PC. An improved understanding of tumour genetics and biomarkers of response may prove essential in patient selection to effective therapy modalities.

2.3.14 Pituitary Incidentalomas

Niki Karavitaki, Shu Teng Chai, and Shahzada Ahmed

Definition

A pituitary incidentaloma is defined strictly as a 'totally asymptomatic non-functional tumour, clinically and biochemically silent, which was discovered incidentally in a patient who is asymptomatic' or, less strictly, a pituitary mass discovered in the course of evaluation for an unrelated problem [1–3]. Based on the second definition, the term incidentaloma may not be appropriate to many of these lesions, as an incidentally detected macroadenoma may still be clinically relevant.

Box 2.3.14.1 Differential diagnosis of pituitary incidentalomas

Pituitary adenomas (functioning, non-functioning)
Germ cell tumours (germinoma, dermoid, teratoma)
Gliomas
Craniopharyngioma
Rathke's cleft cyst
Meningioma
Chordoma
Primary lymphoma
Pituitary carcinoma
Metastasis
Pituitary hyperplasia
Arachnoid cyst
Inflammatory lesions (e.g. sarcoidosis, hypophysitis, histiocytosis X)
Infectious lesions (e.g. abscess, tuberculosis)
Haemorrhage
Aneurysm
Cavernous angioma
Cavernous sinus thrombosis

Frequency of Detection

Autopsy Studies

The mean frequency of adenoma detection in the largest collection of autopsy case series, which examined 18 902 pituitaries, was 10.7% (ranging from 1.5% to 31%). All but seven of these lesions had a diameter smaller than 10 mm, indicating that almost all of the pituitary adenomas found in autopsy series are microadenomas. There was also no age or gender preponderance [4]. A detailed analysis of immunohistochemical staining of 334 pituitary adenomas in 316 pituitaries out of 3048 autopsy cases revealed 39.5% immunopositivity for prolactin, followed by 13.8% for ACTH, 6.6% for gonadotropins, 2.1% for growth hormone (GH), and 0.6% for thyroid-stimulating hormone (TSH) and α-subunit, respectively. Negative immunostaining was reported in 22.5%, while plurihormonal adenomas accounted for 2.7% [5].

Imaging Studies

The detection of incidental pituitary lesions on imaging depends on the modality used, the administration of contrast agents and

Table 2.3.14.1 Natural history of pituitary incidentalomas

Series	Number of subjects	Size of lesion	Follow-up duration	Outcome
Reincke *et al.*, 1990 [16]	14	≥1 cm, n = 7 <1 cm, n = 7	Median 22 months	Increase (all with intact visual acuity): • 14% of those with mass <1 cm • 29% of those with mass >1 cm Regression: • 14% of those with mass <1 cm • 0% of those with mass >1 cm
Donovan & Corenblum, 1995 [17]	31	>1 cm, n = 16 <1 cm, n = 15	<1 cm mean 6.7 years >1 cm mean 6.1 years	Increase: • 25% of those with mass >1 cm (one developed visual deterioration and was treated surgically) • 0% of those with mass <1 cm
Nishizawa *et al.*, 1998 [18]	28	>1 cm, n = 28	Mean 5.6 years	Increase: • 7%
Feldkamp *et al.*, 1999 [19]	50	>1 cm, n = 19 <1 cm, n = 31	Mean 2.7 years	Increase (none developed visual field defect): • 3% of those with mass <1 cm • 26% of those with mass >1 cm Decrease: • 3% of those with mass <1 cm • 5% of those with mass >1 cm
Sanno *et al.*, 2003 [20]	242	–	Mean 26.9 months	Increase: • 12.4% (among them, 67% had initial size >1 cm and none had shown visual disturbance) Decrease: • 12% No change: • 74.4%
Day *et al.*, 2005 [21]	46	>1 cm, n = 29 <1 cm, n = 17	Mean 3.2 years	Among those not treated surgically or medically at the outset, significant tumour growth was seen in: • 9% of those with mass <1 cm • 14% of those with mass >1 cm
Arita *et al.*, 2006 [22]	42	<1 cm, n = 5 ≥1 cm, n = 37	61.9 months	Lesion's height surpassing 110% of its initial measured height (48% had visual deterioration, diplopia, or hypopituitarism): • 40% of those with mass <1 cm • 51% of those with mass >1 cm Apoplexy developed in 9.5% of total group

Table 2.3.14.2 Natural history of non-operated presumed non-functioning pituitary adenomas

Series	Number of subjects	Size of lesion	Follow-up duration	Outcomes
Dekkers *et al.*, 2007 (23)	28	All macroadenomas	85 months	Increase: 50% (out of which 64% had worsening visual field defect) Decrease: 29% Stable: 21%
Karavitaki *et al.*, 2007 [24]	40	Macroadenoma n = 24 Microadenoma n = 16	Mean 42 months	Increase: • 50% of macroadenomas (67% of them had visual field defects) • 12.5% of microadenomas 48-month probability of enlargement: • 44% for macroadenomas • 19% for microadenomas Stable: • 33.3% of macroadenomas • 81.3% of microadenomas Decrease: • 16.7% of macroadenomas • 6.3% of microadenomas
Lenders *et al.*, 2016 [25]	50	Macroadenoma n = 23 Microadenoma n = 27	Mean 36 months	≥20% increase in volume: • 39% of macroadenomas • 7% of microadenomas

the slice thickness used [6]. Pituitary incidentalomas have been reported with increasing frequency paralleling the advances in imaging techniques and the wider use of brain scans. The prevalence of pituitary incidentalomas found by CT ranges from 3.7% to 20% and of those found by MRI is 10% [7]. Similar to autopsy series, radiological studies on subjects undergoing imaging for reasons not related to a pituitary problem have found frequency of macroadenomas between 0.16% and 0.20% [2].

Differential Diagnosis

The most common aetiology of pituitary incidentalomas is pituitary adenomas, the majority (>75%) of which are non-functioning [8]. Apart from adenomas, the differential diagnosis of pituitary incidentaloma is extensive (Box 2.3.14.1).

Diagnostic Evaluation

A cost-effective approach is required to exclude potentially harmful conditions, as well as to decrease patient anxiety.

Imaging techniques are helpful in the diagnostic evaluation of an incidentally found pituitary mass. MRI has been proven to be more sensitive than CT for the detection of pituitary adenomas [9]. CT is superior in detecting calcifications and is, therefore, helpful for the diagnosis of craniopharyngiomas and meningiomas [10]. There are no studies providing correlation between MRI and pathological features of pituitary masses. Nevertheless, specific MRI features of a number of sellar masses (including meningiomas, metastatic disease, craniopharyngiomas, Rathke's cleft cysts, arachnoid cysts, hypophysitis, abscess) may be useful in the differentiation from an adenoma [11–13].

Given that the most common lesion in the sellar area is a pituitary adenoma, assessment for hormonal hypersecretion is recommended. This includes clinical evaluation for relevant manifestations combined with biochemical screening for hormonal excess:

a) Prolactin (2–3 measurements) for prolactinomas.
b) Insulin-like growth factor-I, which in cases of suspected acromegaly could be combined with an oral glucose tolerance test.
c) 24-hour urine free cortisol and overnight dexamethasone suppression test for Cushing's disease.
d) TSH, free T4, and free T3 for TSH-secreting tumour.
e) FSH, LH, alpha subunit, oestradiol, or testosterone for functioning gonadotroph adenomas.

Smaller incidentalomas (5 mm or less in diameter) do not generally compromise the pituitary function and routine screening may not be necessary; however, evaluation for hypopituitarism is recommended for patients with larger lesions [3]. Assessment for the presence of diabetes insipidus is suggested particularly when there is suspicion of craniopharyngiomas [14] and pituitary metastases [15].

All patients who have a pituitary lesion abutting or compressing the optic nerves or chiasm on MRI, should undergo a formal visual field (VF) examination [3].

Natural History

The studies on the natural history of pituitary incidentalomas are limited. The shortcomings of currently available literature include patient heterogeneity, relatively small patient series, and lack of prolonged follow-up. Their results including masses of various pathologies are summarized in Table 2.3.14.1. Overall, the published data suggest that lesions smaller than 1 cm follow a benign course. In contrast, masses greater than 1 cm are associated with higher risk of enlargement often leading to pressure effects and requiring neurosurgical intervention. These data are in accord with the reported outcomes of non-operated presumed non-functioning pituitary adenomas (Table 2.3.14.2 and Figure 2.3.14.1). Indeed, a systematic review and meta-analysis of 11 cohort studies of significant heterogeneity showed that non-functioning pituitary adenomas and incidentalomas which were bigger than 1 cm and solid had a greater event rate of tumour

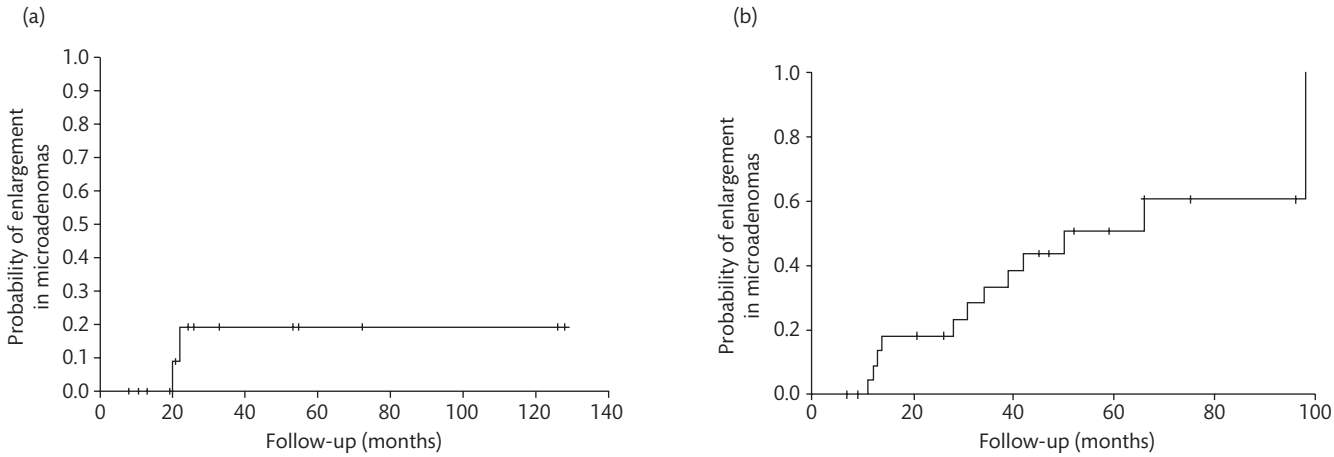

Figure 2.3.14.1 Natural history of (a) microadenoma versus (b) macroadenoma.
From Karavitaki N, Collison K, Halliday J, et al. What is the natural history of nonoperated nonfunctioning pituitary adenomas? *Endocrinol (Oxf)*. 2007; 67:938–943. Reproduced with permission from John Wiley and Sons.

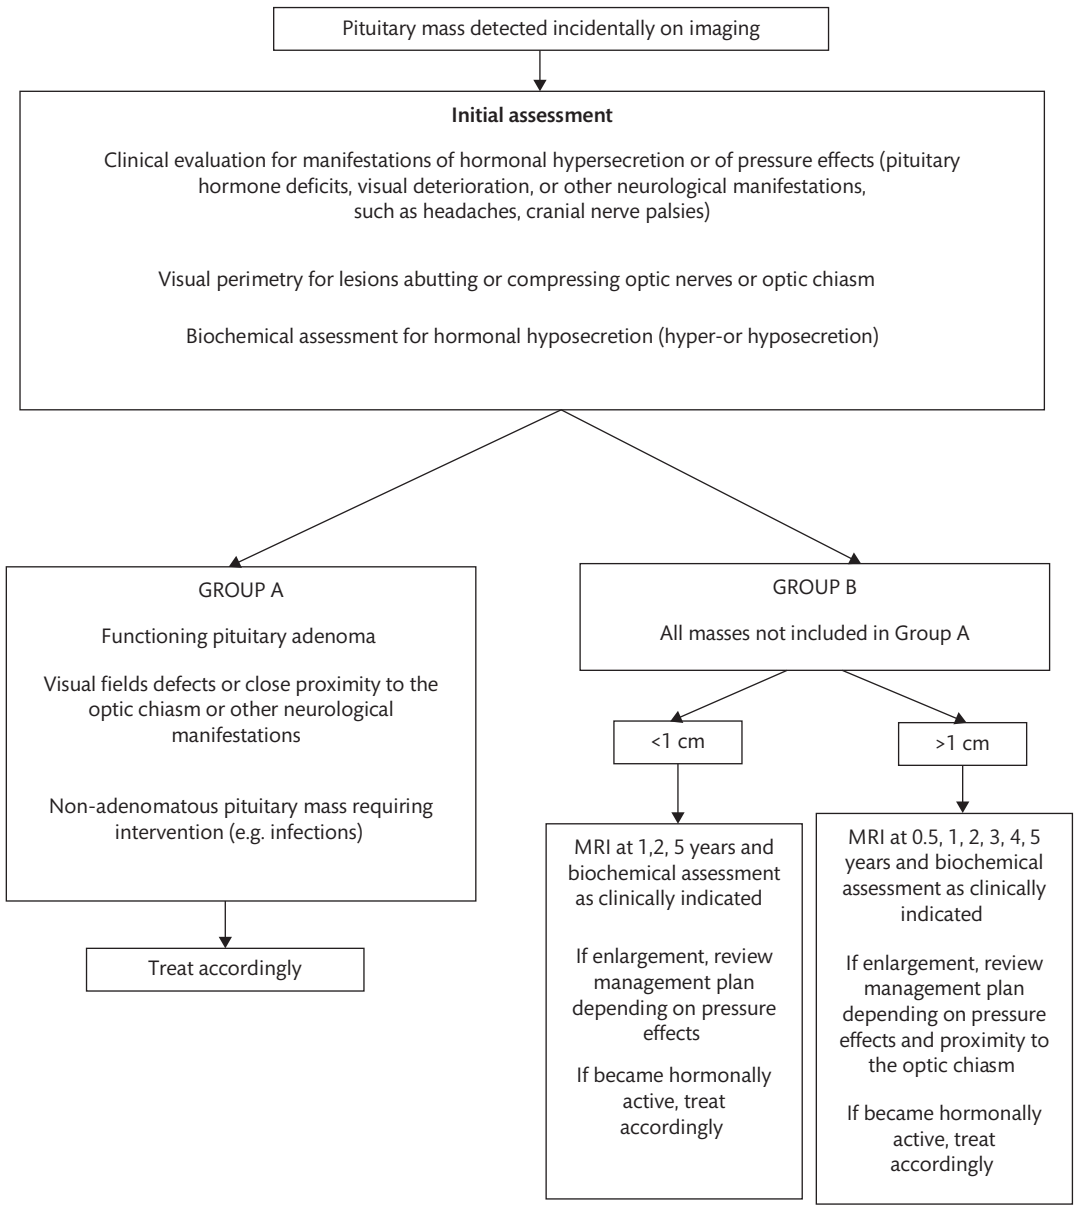

Figure 2.3.14.2 Algorithm for the evaluation and management of pituitary incidentalomas.

growth compared to smaller and cystic lesions, albeit the quality of evidence was deemed low [26].

It is noteworthy that majority of the reported studies have a follow-up period of less than 5 years, a duration which is deemed short considering the natural history of pituitary tumours. Hence, more studies with longer observation periods are needed to clarify the behaviour and outcomes of pituitary incidentalomas.

Despite the rare occurrence of pituitary apoplexy, its risk should always be taken into consideration, particularly in patients exposed to predisposing factors (e.g. anticoagulation).

The potential of incidentally found adenomas to become hormonally active at a later stage has not been fully elucidated and reliable data on the chance of developing relevant endocrinopathy is lacking.

Management

The Endocrine Society Clinical Practice Guideline recommends surgery by an experienced pituitary surgeon for patients with a pituitary incidentaloma who present with VF deficit or other visual abnormalities due to the lesion, lesion abutting, or compressing optic nerves or chiasm on MRI, pituitary apoplexy or hypersecreting tumours other than prolactinomas [3]. In cases not meeting the aforementioned criteria, conservative management with regular follow-up is recommended [3]. As the long-term natural history of incidentally detected pituitary masses is still unclear, the current consensus is largely based on expert opinion [3, 12].

Our proposed algorithm for the initial evaluation and management of these lesions is shown in **Figure 2.3.14.2**. Since the optimum duration of imaging surveillance is unknown, decisions on monitoring of a mass not showing enlargement 5 years after its detection should be individualized. Finally, cost remains an important factor in determining the optimum follow-up strategy of pituitary incidentaloma. Randall *et al.* reported the total cost of endocrine tests, imaging, and physician fees incurred during a year of follow-up of pituitary incidentaloma to be USD 6215.28 for males and USD 6061.78 for females. This was expected to account for a conservative estimate of nearly USD 7 million on the United States healthcare system in year 2005 [27]. It is important to note that this estimate does not include expenditure involved during further follow-ups. Hence, the cost-effectiveness of the suggested or other approaches remains to be elucidated.

2.4

Aetiology, Pathogenesis, and Management of Diseases of the Hypothalamus

2.4.1 Hypothalamic Dysfunction (Hypothalamic Syndromes)

Hoong-Wei Gan, Manuela Cerbone, and Mehul T. Dattani

Background

The hypothalamus consists of a dense congregation of nuclei lying superior to the pituitary gland and sella turcica, inferior to the thalamus, and surrounding the third ventricle, extending from the optic chiasm anteriorly to the mammillary bodies posteriorly. Despite its small dimensions (approximately the size of an almond in an adult), it has numerous axonal projections to the cerebral cortex, brainstem, reticular formation, limbic system and autonomic nervous system, and is responsible for regulating a wide variety of functions, including appetite, metabolism, thirst, circadian rhythms, arousal, memory, and behaviour. The ill definition of some of these nuclei, and the limited resolution of current neuroradiological techniques, means that the circuitry of these various hypothalamic pathways is incompletely understood. Hypothalamic gene expression studies result in downstream effects on multiple neuronal subtypes, and, in some instances, lethality, making it additionally difficult to decipher the role of these various genes in the early development of this region [1, 2]. The hypothalamus is the 'master regulator' of the neuroendocrine system, and damage to or maldevelopment of this area can have widespread consequences on a variety of homeostatic mechanisms.

Development of the Hypothalamus

Like pituitary development, much of our current understanding of hypothalamic development in humans is based on mouse and rat models, although they are less well-characterized than that of the pituitary (see Chapter 2.3.1) [1, 2]. Additionally, despite several rodent models with hypothalamic gene mutations already described in the literature, only two of these genes have thus far been demonstrated to be associated with human hypothalamic disease [3, 4].

The primordium of the hypothalamus and infundibulum originates from the ventral diencephalon, and is located posterior to the anterior pituitary placode which appears as a localized ectodermal thickening in the anterior neural ridge of the developing embryo at mouse embryonic day E7.5 [5, 6]. Sonic hedgehog (*Shh*) signalling has been shown to be crucial for the early development of the hypothalamus [7], and is subsequently downregulated with the concomitant upregulation of bone morphogenetic proteins (BMPs) [8], *Fgf8*, and *Fgf10* [1]. The hypothalamic primordium itself becomes evident in the rostral part of the neural plate at E9.5, and neurogenesis commences at E10, concomitant with the expression of the hypothalamic patterning genes *Sim1, Arnt2, Otp, Nkx2.1*, and *Nr5a1* which peak at E12–14 [9]. Neurogenesis is complete by E16, but development is only completed in the postnatal period [9].

Sim1 is expressed in the paraventricular (PVN), supraoptic (SON) and anterior periventricular nuclei (PeVN) from E10.5 and continues postnatally. Homozygous mutants demonstrate significant anterior hypothalamic hypoplasia and early postnatal death [10]. SIM1 heterodimerizes with ARNT2, and homozygous *Arnt2* knockout mice therefore demonstrate a very similar phenotype [11, 12]. Both *Sim1* and *Arnt2* mutants additionally exhibit absent *Brn2* expression, which encodes a transcription factor required for differentiation of corticotrophin-releasing hormone (CRH), arginine vasopressin (AVP), and oxytocin (OXT)-producing neurons [1, 2, 11].

The role of other early hypothalamic developmental genes is beginning to be elucidated through other mouse models. *Otp* null

mice demonstrate absence of somatostatin, AVP, OXT, CRH, and thyrotropin-releasing hormone (TRH), and a failure of *Brn2* expression [13, 14]. *Nkx2.1* null mice demonstrate agenesis of Rathke's pouch and the ventromedial (VMN) and arcuate (ARC) nuclei, as well as lung and thyroid defects [15]. *Nr5a1* null mice demonstrate failure of migration of VMN precursors and disorganization of the dorsomedial VMN, alongside the well-described defects in pituitary gonadotroph development, and agenesis of adrenal and gonadal tissue [2, 16, 17]. Double knockout $Hmx2^{-/-}/Hmx3^{-/-}$ mice demonstrate severe growth hormone-releasing hormone (GHRH) deficiency in the ARC and postnatal dwarfism [18]. *Sox3*, a member of the Sry-related high mobility group (HMG) box group of transcription factors, has been well-described in association with X-linked congenital hypopituitarism, but is more highly expressed in the developing hypothalamus than the anterior pituitary [2]. Changes in *SOX3* dosage in humans have been described to be associated with not just anterior pituitary hypoplasia, but also ectopic posterior pituitary and an absent infundibulum, indicating its role in hypothalamic development [19].

The close association between the developing Rathke's pouch (the prospective anterior pituitary) and the ventral diencephalon (the prospective infundibulum and posterior pituitary) is crucial to the development of both the hypothalamus and pituitary gland [1, 20]. As the Rathke's pouch invaginates from the oral ectoderm, the infundibulum evaginates from the ventral diencephalon at E10.5 to come into contact with it; this apposition is maintained thereafter throughout development [1, 2]. Terminal axonal projections from the prospective supraoptic and paraventricular hypothalamic nuclei travel with the infundibulum to the developing posterior pituitary, where they ultimately secrete AVP and OXT directly into the peripheral circulation [20]. Gonadotrophin-releasing hormone (GnRH) neurons migrate from the olfactory placode to the developing hypothalamus, with GnRH being expressed in the hypothalamus from E10.5 [1, 2, 21, 22]. This is followed by dopamine at E10.5 [23], GHRH at E11 [21, 24], TRH at E13 [25, 26], CRH at E13.5 [24, 27], and somatostatin at E17 [28].

Structure of the Mature Human Hypothalamus

The mature adult hypothalamus is a highly neuron-dense area measuring about 0.7 cm^3 on either side of the third ventricle [29]. It is subdivided into the preoptic, anterior, tuberal and mammillary regions rostrocaudally, and into the periventricular, medial, and lateral regions mediolaterally [2, 29]. The various nuclei can be structurally classified by their location within the mediolateral divisions of the hypothalamus (Table 2.4.1.1).

The hypothalamus is intimately connected to the pituitary gland via two routes, both of which are carried by the pituitary stalk (infundibulum). The first of these, the hypothalamo-hypophyseal portal vascular system, arising from the superior hypophyseal arteries and draining into the vein of Galen, is responsible for transporting hypothalamic stimulatory and inhibitory releasing hormones secreted by parvocellular neurons to the anterior pituitary where they regulate secretion of pituitary hormones into the peripheral circulation. Other parvocellular neurons project to other areas of the brain to regulate appetite, metabolism, thirst, circadian rhythms, arousal, memory, and behaviour. The second pathway consists of direct axonal projections from magnocellular neurons arising from the hypothalamic PVN and SON to the posterior pituitary gland, where the neurohypophyseal hormones arginine-vasopressin (AVP) and oxytocin (OXT) are secreted directly into the peripheral circulation.

Table 2.4.1.1 Hypothalamic nuclei subdivided by their mediolateral, rostrocaudal then supero-inferior positions within the hypothalamus and their roles in controlling various bodily functions

Division	Nucleus	Role
Periventricular	Suprachiasmatic nucleus (SCN)	Control of circadian rhythms
	Paraventricular nucleus (PVN)	Release of TRH, CRH, oxytocin, and AVP
	Periventricular nucleus (PeVN)	Release of somatostatin
	Arcuate nucleus (ARC)	Release of GHRH and dopamine, control of appetite
Medial	Medial preoptic nucleus (MPN)	Release of GnRH, thermoregulation
	Anterior hypothalamic nucleus (AHN)	Thermoregulation
	Supraoptic nucleus (SON)	Release of AVP and oxytocin
	Dorsomedial nucleus (DMN)	Control of the autonomic system
	Ventromedial nucleus (VMN)	Control of appetite and satiety
	Mamillary nucleus	Memory
Lateral	Preoptic area (POA)	Control of thirst
	Lateral hypothalamic area (LHA)	Control of feeding and arousal via release of orexin
	Tuberomammillary nucleus (TMN)	Control of arousal

Clinical Presentations and Management of Hypothalamic Dysfunction

See Box 2.4.1.1.

Central Diabetes Insipidus (CDI)

CDI is the archetypal form of hypothalamo-pituitary endocrine dysfunction arising distinctly from the hypothalamus, as a result

Box 2.4.1.1 Clinical features of the hypothalamic syndrome

Endocrine features
- Hypopituitarism (especially central diabetes insipidus, central precocious puberty, hypogonadotropic hypogonadism)
- Hypothalamic obesity
- Diencephalic syndrome/hypothalamic anorexia

'Non-endocrine' features
- Temperature dysregulation
- Sleep dysregulation
- Behavioural difficulties
- Memory dysfunction
- Autonomic dysfunction

of congenital or acquired AVP neuronal deficiency, dysfunction, or damage. The resulting lack of ability to concentrate one's urine results in polyuria and polydipsia, which can often lead to patients drinking several times their total circulating volume. In most cases, where thirst is intact and patients have unrestricted access to fluid, plasma sodium concentration and osmolality are normal. True CDI must be differentiated from other causes of polyuria and polydipsia, such as diabetes mellitus, hypercalcaemia, renal disease, and primary polydipsia. The latter diagnosis may be difficult to differentiate from partial CDI (where some residual but insufficient AVP secretion is retained), and water deprivation tests may not sufficiently dehydrate the baseline hypoosmolar state present in these patients to confirm normal urine concentrating ability. Concurrent measurement of plasma copeptin, the C-terminal cleavage product of AVP secretion, may help with the diagnosis, with concentrations of ≥4.9 pmol/L after water deprivation having a 94% sensitivity and 96% specificity in determining the diagnosis [30]. In patients with multiple pituitary hormone deficiencies, coexistent central adrenal insufficiency may mask CDI, as cortisol has a permissive effect on free water clearance by suppressing AVP secretion.

Management is by AVP supplementation in the form of desmopressin (1-deamino-8-D-arginine vasopressin, DDAVP), which can be administered parenterally, enterally, or intranasally. Patients must be allowed free access to water, and careful fluid management is required whenever this is restricted (e.g. preoperatively). Given the distinct hypothalamic locations of AVP neurons (PVN and SON) and the thirst centre (POA), the concurrent presence of hypothalamic adipsia is rare, and where present, requires that a mandatory fluid intake requirement be set. Care is particularly required when CDI and adrenocorticotrophic hormone (ACTH) deficiency coexist; the management of an adrenal crisis with coexisting CDI needs very careful handling of glucocorticoid and DDAVP replacement with frequent measurement of electrolytes and other biochemical parameters.

Hypogonadotropic Hypogonadism and Central Precocious Puberty

Unlike other hypothalamic neurons, GnRH-secreting neurons arise from outside the hypothalamus in the olfactory placode and migrate along the olfactory nerve, crossing the cribriform plate to the olfactory bulbs to settle in their final position in the medial preoptic nucleus (MPN) at around the sixth week of gestation [31]. Congenital disruption of this process results in hypogonadotropic hypogonadism, although the timing of presentation can vary from neonatal (micropenis, cryptorchidism) to adulthood (subfertility). Some causes of hypothalamo-pituitary endocrine deficits such as septo-optic dysplasia and suprasellar tumours can also cause (in addition to or in isolation) central precocious puberty (testicular volume >4 ml in boys at <9 years of age, breast Tanner stage B2 in girls at <8 years of age), for reasons that are poorly understood [32, 33]. It is worth noting that a history of central precocious puberty in this situation does not preclude the future possibility of hypogonadotropic hypogonadism [33]. Treatment for the former is by GnRH analogue injections, while the latter is managed with gonadal steroid replacement. The use of recombinant β-hCG and/or gonadotrophins, particularly in children, is still untested in high quality trials and cannot therefore be currently recommended.

Hypothalamic Obesity

Hypothalamic obesity (HyOb) is a syndrome of intractable weight gain observed frequently after any hypothalamic damage [34] (septo-optic dysplasia, 50%; craniopharyngioma, 77%, low-grade glioma, 50%) [33, 35]. Despite having been described over 100 years ago, management remains complex and as yet there is no effective treatment [36]. Current understanding of the hypothalamic-gut-adipose tissue circuitry governing the regulation of appetite and metabolism remains incomplete, although with the advent of molecular genetic techniques and the discovery of leptin in the *ob*/*ob* (obese) mouse in 1994 [37] the identification of other peptides involved in this complex network rapidly followed.

Metabolic homeostasis is governed by the balance between anorexigens (appetite-suppressing peptides) and orexigens (appetite-inducing peptides) which signal to the ARC and VMN via afferent pathways [34, 38]. In the fed state, the peripheral anorexigenic signals leptin (from adipose tissue) and insulin (from pancreatic β cells) signal to these nuclei, alongside the central anorexigen brain-derived neurotrophic factor (BDNF) to increase the processing of pro-opiomelanocortin (POMC) to α-melanocyte stimulating hormone (αMSH) and the synthesis of cocaine- and amphetamine-regulated transcript (CART). αMSH binds to melanocortin-3 (MC3R) and melanocortin-4 (MC4R) receptors in the ARC, VMN, PVN and lateral hypothalamic area (LHA) and is modulated by CART. Concurrently, glucagon-like peptide-1 (GLP-1) and peptide YY (PYY) are secreted by the gastrointestinal tract and bind to receptors in the PVN and on orexigenic neurons to increase the output of the efferent anorexigenic pathway while suppressing orexigenic output, respectively. Efferent neurons from the PVN and LHA then signal to the locus coeruleus and nucleus tractus solitarius via signalling peptides OXT and nesfatin-1 to increase sympathetic nervous system output and limit meal size (via the potentiation of the effect of cholecystokinin) [39–41]. This then leads to increased energy expenditure, including increased lipolysis and glucose metabolism, thereby closing the feedback loop.

Conversely, in the fasted state, the key peripheral orexigen ghrelin is secreted by the stomach and bind to receptors in the ARC and VMN [34, 38]. This leads to increased secretion of the central orexigens neuropeptide Y (NPY) and agouti-related peptide (AgRP), which in turn inhibit the POMC/CART pathway. This reduces MC3R and MC4R occupancy in the PVN and LHA, which project efferent neurons to the dorsal motor nucleus of the vagus nerve to increase anabolic processes, including lipogenesis, peristalsis, nutrient absorption, and insulin secretion, once again counterbalancing the effects of starvation.

The complexity and redundancy of the various circuits in this network means that the development of targeted treatments for HyOb has proven difficult. Patients with HyOb have classically been described to be hyperphagic, but food intake diary studies in these patients have suggested that the number of calories consumed is no different to that of BMI-matched controls [42]. In children with HyOb, parents' perceptions of the degree of hyperphagia are also not significantly different from BMI-matched controls (unpublished data). In Prader–Willi syndrome, the archetypal genetic HyOb disorder, weight gain usually precedes hyperphagia by months to years [43]. Taken together, these data suggest that HyOb is not primarily driven by an increase in appetite and caloric intake, and instead is

a disorder of energy expenditure. Indeed, the basal metabolic rate and degree of physical activity is reduced in HyOb [42, 44] but the mechanisms behind this are incompletely understood, with one study showing reduced urinary catecholamine secretion [45], while another showed no significant differences [46].

Thus far, treatments which have been used for HyOb have included pancreatic vagotomy [47], dextroamphetamine [48], supraphysiological doses of triiodothyronine [49], octreotide [50], sibutramine [51], caffeine and ephedrine [52], diazoxide and metformin [53], and liraglutide [54]. None of these studies have demonstrated long-term sustainability of weight loss or even weight maintenance in a large cohort of individuals with HyOb. In some cases (sibutramine and triiodothyronine), treatment can be associated with unwanted side effects. Bariatric surgery has been shown to be capable of inducing significant amount of weight loss, potentially by concurrently resetting the hypothalamic-gut axis, but such intervention should not be taken lightly in patients with multiple comorbidities particularly from hypopituitarism [55].

Syndromes of Emaciation

The Diencephalic Syndrome

Hypothalamic dysfunction can conversely present with syndromes of emaciation, the most well-described of which is the diencephalic syndrome [56]. This rare syndrome is typically seen in infants younger than 2 years of age as a presenting feature of a hypothalamic tumour, having been described most commonly in hypothalamic low-grade gliomas (<10%) [33, 57], but also high-grade gliomas [58], craniopharyngiomas [59], germinomas [60], teratomas [61], ependymomas [62], epidermoid cysts [63], and even in tumours away from the suprasellar region such as brainstem gliomas [64]. The original description of diencephalic syndrome defined four 'major' criteria: profound emaciation, preserved (or accelerated) linear growth, hyperactivity, and euphoria, and three 'minor' criteria: pallor without anaemia, hypoglycaemia, and hypertension [56]. Other features include nystagmus, papilloedema, optic atrophy, vomiting, ataxia, sweatiness, and tremulousness. Endocrine biochemical findings include high random plasma growth hormone (GH) concentrations with low-normal IGF-1 concentrations, the former not being suppressed by an oral glucose tolerance test, increased ghrelin, and reduced insulin and leptin [65–67]. The resting energy expenditure is increased [68]. Without treatment, the outcome is universally fatal, but with modern chemotherapy and molecular therapy techniques, weight is often regained, with a rapid disappearance of presenting clinical features [69]. Patients may eventually land up having HyOb [68].

Hypothalamic Anorexia

It is worth noting that anorexia is frequently reported in patients with hypothalamic space-occupying lesions, and due to the vagueness of the symptom, this may result in a delay in diagnosis by several years [70]. Central nervous system tumours outside the suprasellar region can also present with anorexia, alluding to our incomplete understanding of the neuroendocrine circuitry which governs appetite and the role of inflammatory cytokines (e.g. tumour necrosis factor-α (TNFα), interleukin-1 (IL-1), interleukin-6 (IL-6) and interferon-γ (IFNγ)) on these circuits [71–73]. Differentiating hypothalamic anorexia from anorexia nervosa may be difficult, particularly in the adolescent female patient presenting additionally with primary or secondary amenorrhoea which may be the result of organic hypogonadotropic hypogonadism [74]. Anorexia due to hypothalamic lesions usually resolves with treatment, while true anorexia nervosa should fulfil International Classification of Diseases criteria for diagnosis [75]. A full auxological, pubertal, and endocrine biochemical and radiological assessment should be performed to exclude neuroendocrine disease, particularly in male patients.

'Non-endocrine' Clinical Presentations of Hypothalamic Dysfunction

'Non-endocrine' clinical manifestations of hypothalamic dysfunction include temperature and sleep dysregulation, behavioural, memory and learning difficulties, and autonomic dysfunction. The exact prevalence and severity of these disorders as a consequence of hypothalamic dysfunction in the paediatric population is unknown, due to the fact that these clinical conditions are difficult to diagnose and grade in childhood. Accurate clinical diagnostic tools (e.g. neuroimaging techniques and biomarkers) are lacking and young children are mostly unable to accurately self-report these symptoms. The management of the 'non-endocrine' clinical manifestations of hypothalamic dysfunction is difficult and requires multidisciplinary approach. At present, aetiological treatments are lacking for these disorders and the management strategy mainly consists of supportive care and symptomatic management in specialized centres. A detailed description of these disorders and their management is outside the scope of this chapter. The following sections contain a summary of the role of the hypothalamus in temperature, sleep, behaviour, memory, and autonomic regulation and explains the pathophysiological basis of these disorders.

Temperature Dysregulation

Thermoregulation is an example of integrative functioning of the human hypothalamus requiring a combination of autonomic and behavioural responses as well as endocrine functions. The MPN of the hypothalamus is the key structure for integrating thermal inputs from the skin and from thermo-sensitive neurons within the brain, such as neurons in the preoptic regions. The spinal cord contains warm and cold-sensing neurons projecting to the para-brachial nucleus of the pons, the relay station for transferring visceral sensory information from the spinal and cranial nerves to the hypothalamus and from the latter to the autonomic reflex and motor cell groups. Experimental studies in rabbits have shown reversible temperature dysregulation after acute hypothalamic compression and decompression [76]. Clinical observations on patients after operations on suprasellar tumours showed similar results, with the degree of temperature dysregulation correlating with the degree of hypothalamic compression [76]. In patients with cerebral trauma and intracranial haemorrhage, temperature studies showed significant differences between surviving and non-surviving patients, and diencephalic syndrome seemed relevant to clinical deterioration [76]. Hypothalamic dysfunction can be associated both with hyper- and hypothermia, with the first finding being more commonly documented in children [77].

Sleep Dysregulation

Sleep is one of the most highly conserved physiological processes in mammals, but its actual function is as yet incompletely understood. Circadian rhythm of sleep-wakefulness is controlled

by the master clock located in the SCN. Several hypothalamic circuits for sleep and wakefulness have been discovered over the last 30 years. In particular, neurons in the posterior part of the hypothalamus have been shown to promote wakefulness, with different cellular types being extensively connected to the cerebral cortex by direct excitatory projections. Additionally, arousal-promoting neurons in the brainstem all pass through the lateral hypothalamus and project directly to the cerebral cortex. Conversely, sleep-promoting neurons have been identified in the ventrolateral POA and MPN.

Sleep homeostasis is regulated by a number of neurochemicals, with the hypothalamic neuropeptides hypocretin (HCRT, or orexin) A and B playing a crucial role [78]. HCRT neurons are found exclusively in the posterior lateral hypothalamus. Their signalling is strongly associated with wakefulness and it has been suggested that HCRT neuronal degeneration may cause narcolepsy [78, 79]. In addition to HCRT, melanin concentrating hormone (MCH)-producing neurons in the LHA are also implicated in the regulation of sleep/wakefulness. In contrast to HCRT, MCH neurons are active during sleep but become silent during wakefulness [79].

Sleep disorders have been associated with damage in the hypothalamo-pituitary area in children with brain tumours, regardless of the treatment received, with the primary determinant being the area of the brain that was damaged [80]. Sleep disruption is associated with substantial adverse short- and long-term health consequences, and has been shown to increase the risk of obesity and metabolic dysfunction [81, 82]. Hence, in children and adolescents with hypothalamic dysfunction, sleep disruption is likely to greatly impact on their health-related quality of life and to contribute to their increased mortality.

Behavioural Difficulties

The hypothalamic control of behaviour is complex. Specific hypothalamic centres and circuits regulate sexual behaviour, aggressiveness, and feeding behaviour [83]. Sexually dimorphic neurons in the ventromedial hypothalamus are known to govern mating in both sexes and aggression in males [84]. LHA HCRT neurons play a role in reward-seeking and addiction [85]. OXT is considered a 'social neuropeptide', as it is involved in bonding, attachment, and other complex social behaviours that are essential for effective social interactions. The concentration of plasma OXT is abnormal in autistic spectrum disorders (ASD) and this abnormality is linked to dysregulation of OXT signalling pathways [86]. Studies have also suggested that polymorphisms of the OXT receptor contribute to oxytocinergic dysfunction in ASD [87]. Functional and anatomical differences in the hypothalamus of ASD patients have been postulated to reflect abnormal oxytocinergic modulatory mechanisms [88, 89].

Memory Dysfunction

The hypothalamus is part of the limbic system and, together with the hippocampus, the amygdala, and several other brain areas nearby, is responsible for the formation of memories. Cellular activation of hypothalamic *Hcrt* neurons facilitates short-term spatial memory in mice [90]. Discrete populations of neurons within the hypothalamus (as well as the amygdala and the lateral septum) are specifically activated by auditory fear conditioning and may be directly involved in fear learning and memory [91]. Social memory deficits are associated with reduced OXT levels in the hypothalamus of mice [92].

Memory and learning difficulties are described in patients with hypothalamo-pituitary lesions from various aetiologies. Memory deficits and difficulties in the retrieval of learned information have been documented in children after surgical treatment of craniopharyngioma [93]. Similarly, individuals with a history of treated craniopharyngioma self-reported a high prevalence of problems in everyday memory and cognition [94]. Finally, patients with hypothalamic hamartoma also display deficits in a broad range of cognitive functions, including visual and verbal learning and memory [95].

Autonomic Dysfunction

The hypothalamus controls the autonomic nervous system via a set of neurons that, from the PVN, LHA, and ARC, directly innervate both the parasympathetic and sympathetic preganglionic neurons and various cell groups in the brainstem. The PVN has emerged as one of the most important autonomic control centres in the brain and it has been proposed as a potential target for integrative treatment of autonomic dysfunction [96]. Disrupted hypothalamic functional connectivity has been documented in patients with Parkinson's disease and autonomic dysfunction [97]. Autonomic dysregulation is one the clinical features of a syndrome associated with hypothalamic dysfunction, so called ROHHAD (rapid-onset obesity, hypothalamic dysfunction, hypoventilation, autonomic dysregulation). In a case series of 15 patients with ROHHAD syndrome, symptoms of autonomic dysregulation were consistently identified in all patients, with ophthalmologic manifestations being the most frequent (86%), followed by gastrointestinal dysmotility (66%) [98].

Congenital Causes of Hypothalamic Dysfunction

Monogenic 'Non-Syndromic' Hypothalamic Obesity Syndromes

The advent of the molecular genetic era has led to the discovery of several monogenic obesity syndromes involving mutations in genes encoding the various peptides participating in the hypothalamic-gut-adipose tissue circuitry regulating appetite and metabolism, as well as their receptors. The first of these to be discovered, congenital leptin deficiency, confirmed the equivalent phenotype of the *ob/ob* (obese) mouse in humans [99] with subcutaneous recombinant leptin replacement therapy being curative [100]. Since then, other monogenic causes of obesity in humans have been described (Table 2.4.1.2), all of which are characterized by marked hyperphagia. Although these forms of obesity have often been described as 'non-syndromic', additional phenotypic features are often observed.

Syndromic Forms of Hypothalamic Obesity

Syndromic obesity is defined as the presence of obesity along with characteristic additional pleiotropic clinical features such as developmental delay, dysmorphism, and other congenital abnormalities.

Table 2.4.1.2 Monogenic non-syndromic causes of hypothalamic obesity. αMSH, α-melanocyte stimulating hormone; ACTH, adrenocorticotrophic hormone; GH, growth hormone

Gene	Inheritance	Primary mechanism	Other clinical features
SIM1 [101, 102]	Dominant/heterozygous *de novo*	Disrupted hypothalamic development	Hypogonadotropic hypogonadism, facial dysmorphisms, behavioural difficulties, 'Prader–Willi syndrome'-like phenotype
Leptin (*LEP*) [99]	Recessive	Leptin (anorexigen) deficiency	Hypogonadotropic hypogonadism
Leptin receptor (*LEPR*) [103]	Recessive	Leptin resistance	GH deficiency, central hypothyroidism, hypogonadotropic hypogonadism
Pro-opiomelanocortin (*POMC*) [104, 105]	Recessive	POMC (αMSH (anorexigen) precursor) deficiency	ACTH deficiency, red hair, pale skin (GH deficiency, central hypothyroidism, hypogonadotropic hypogonadism)
Prohormone convertase 1 (*PCSK1*) [106, 107]	Recessive	Failure of cleavage of POMC to αMSH and ACTH (and other prohormones)	GH/ACTH deficiency, hypogonadotropic hypogonadism, impaired glucose tolerance/diabetes mellitus, diabetes insipidus, postprandial hypoglycaemia, malabsorptive diarrhoea
Melanocortin 4 receptor (*MC4R*) [108, 109]	Dominant/recessive	αMSH resistance	
Melanocortin 3 receptor (*MC3R*) [110]	Dominant (heterozygous *de novo*)	αMSH resistance	
Cocaine-amphetamine-regulated transcript (*CARTPT*) [111]	Dominant	CART (anorexigen) deficiency	
Brain-derived neurotrophic factor (*BDNF*) [112]	Dominant (heterozygous *de novo*)	BDNF (anorexigen) deficiency	Only described as part of 11p13–14 contiguous gene deletion WAGRO syndrome (Wilms' tumour, aniridia, genitourinary abnormalities, cognitive disability, obesity)
Tyrosine receptor kinase B (*NTRK2*) [113]	Dominant (heterozygous *de novo*)	BDNF resistance	Developmental delay
SH2B adaptor protein 1 (*SH2B1*) [114]	Dominant (heterozygous *de novo*)	Disruption of insulin/leptin (anorexigen) signalling	As part of 16p11.2 contiguous gene deletion syndrome, associated with developmental delay

A recent systematic review by Kaur *et al.* (2017) [115] identified 79 unique obesity syndromes in the published literature, of which only 19 had been fully genetically elucidated. In the vast majority of these, the biological mechanisms linking the specific mutation with obesity remain unknown. In some, contiguous gene deletions result in disruption of the hypothalamic-gut appetite-regulating circuit due to disruption of anorexigenic signalling (Table 2.4.1.2) [112, 114]. Two syndromes where hypothalamic dysfunction is known to play a major role in obesity are Prader–Willi syndrome and rapid-onset obesity, hypothalamic dysfunction, hypoventilation, autonomic dysregulation, and neural crest tumour (ROHHADNET) syndrome.

Prader–Willi Syndrome

Prader–Willi Syndrome is a contiguous gene deletion syndrome involving the paternal copies of several imprinted genes within the 15q11–13 region (*SNRPN, NDN, MAGEL2, MKRN3, SNORD116*), with a birth incidence of 1 in 30 000 [116, 117]. The deletion can either arise directly (75%), via maternal uniparental disomy (25%), or through an imprinting defect (<1%). Phenotypically, infants are born with profound hypotonia and diminished swallowing and sucking reflexes, resulting in the need for nutritional support in the first year of life. Dysmorphic features gradually become more apparent—a narrow bifrontal diameter, almond-shaped, upslanted eyes, strabismus, hypopigmentation, and full cheeks. Hypothalamic dysfunction manifests as GH deficiency, hypogonadotropic hypogonadism, central hypoadrenalism, early onset weight gain (from a median age of 2 years), and marked hyperphagia (from a median age of 4.5 years), the latter leading to parents often needing to lock fridges and cupboards at night to prevent nocturnal foraging [43, 118, 119]. Intellectual impairment and self-mutilation in the form of skin picking manifests later in adolescence and adulthood [120]. Management includes treatment with GH, not just to improve linear growth but also to improve body composition and hypotonia [121].

ROHHADNET

ROHHADNET syndrome was first described by Ize-Ludlow *et al.* (2007) [98]. The genetic cause of this extremely rare disorder remains unknown despite extensive study, and diagnosis remains clinical, with obesity and hypoventilation being the core features. Apart from early-onset obesity, all forms of hypopituitarism (particularly CDI or the syndrome of inappropriate antidiuretic hormone secretion (SIADH)) have been observed. Hypoventilation is both central and peripheral in aetiology and often requires respiratory support. Autonomic dysfunction manifests as ophthalmological symptoms, temperature dysregulation, gastrointestinal dysmotility, and hypoalgesia. A proportion of patients will have tumours of neural crest origin such as ganglioneuroblastoma and ganglioneuroma [122, 123]. Mortality is high, and usually from cardiorespiratory failure, with no cases reported beyond the age of 18 years.

Septo-Optic Dysplasia (SOD)

SOD is a rare disorder of development of the forebrain, eye and pituitary gland occurring in about 1 in every 10 000 births [124]. Its aetiology is multifactorial, and although single gene mutations in a variety of hypothalamo-pituitary transcription factors have been identified (e.g. *HESX1, FGF8, TCF7L1, PROKR2*) [125–129] in the majority of cases no single causative factor can be found. The

diagnosis is made in the presence of at least two components of the triad of optic nerve hypoplasia, midline forebrain defects (e.g. agenesis of the corpus callosum, absent septum pellucidum), and hypopituitarism [130]. Although the latter is not always present, abnormal pituitary imaging (e.g. anterior pituitary hypoplasia, ectopic posterior pituitary, absent infundibulum) is a risk factor [131] and endocrinopathies may evolve over time necessitating long-term follow-up [130]. GH deficiency is the commonest endocrinopathy observed, followed by thyroid-stimulating hormone (TSH) and ACTH deficiencies. Gonadotrophin secretion may remain intact, or patients may conversely present with central precocious puberty suggesting a degree of hypothalamic dysfunction.

Holoprosencephaly

Holoprosencephaly arises due to a developmental defect in the separation of the forebrain resulting in a spectrum of abnormalities from failure of division of the cerebral hemispheres to agenesis of the corpus callosum. It has an incidence of 1 in 10 000 to 20 000 in the general population [132, 133] and is associated with a wide variety of genetic mutations (e.g. *SHH, PTCH1, GLI2, FGF8*) and cytogenetic abnormalities [132, 134]. It can be associated with a variety of midline facial defects including cyclopia, anophthalmia, midfacial hypoplasia, hypotelorism, cleft lip and/or palate, and a single central incisor. Hypothalamic dysfunction most commonly manifests as CDI, but anterior hypothalamo-pituitary hormone deficiencies have also been reported [127, 132].

Kallmann Syndrome and Congenital Hypogonadotropic Hypogonadism

See Table 2.4.1.3. Given their developmental origins, defects in GnRH neuron formation or migration can therefore be expected to also affect the function of olfactory neurons, leading to the combination of congenital hypogonadotropic hypogonadism and anosmia, otherwise known as Kallmann syndrome. Numerous genes have been implicated in this condition, including *ANOS1* (previously *KAL1*, causing the X-linked form), *FGFR1, FGF8, PROK2,*

Table 2.4.1.3 Genes associated with Kallmann syndrome and hypogonadotropic hypogonadism

Gene	Inheritance	Clinical features
ANOS1 (previously *KAL1*)	X-linked recessive	Kallmann syndrome, unilateral renal agenesis, synkinesis
FGFR1	Autosomal dominant, variable penetrance	Kallmann syndrome, normosmic hypogonadotropic hypogonadism, cleft lip/palate, abnormalities of corpus callosum, limb/digital abnormalities, dental anomalies
FGF8	Autosomal dominant/recessive	Kallmann syndrome, normosmic hypogonadotropic hypogonadism, cleft lip/palate, camptodactyly, holoprosencephaly
FGF17	Haploinsufficiency, possibly digenic	Kallmann syndrome, normosmic hypogonadotropic hypogonadism
IL17RD	Haploinsufficiency, possibly digenic	Kallmann syndrome, hearing loss
DUSP6	Haploinsufficiency, possibly digenic	Kallmann syndrome
PROK2	Autosomal dominant/recessive	Kallmann syndrome, obesity, normosmic hypogonadotropic hypogonadism
PROKR2	Autosomal dominant/recessive	Kallmann syndrome, normosmic hypogonadotropic hypogonadism
CHD7	Autosomal dominant	Kallmann syndrome, normosmic hypogonadotropic hypogonadism, hearing loss, CHARGE association (coloboma, heart defects, atresia choanae, retardation of growth, genitourinary abnormalities, ear abnormalities)
HS6ST1	Autosomal dominant/recessive	Kallmann syndrome, normosmic hypogonadotropic hypogonadism
WDR11	Autosomal dominant	Kallmann syndrome
SEMA3A	Autosomal dominant	Kallmann syndrome
SEMA3E	Autosomal dominant	Kallmann syndrome
SOX10	Autosomal dominant	Kallmann syndrome, Waardenburg syndrome (deafness, skin/hair/iris hypopigmentation), hearing loss, learning difficulties
FEZF1	Autosomal recessive	Kallmann syndrome
SPRY4	Haploinsufficiency, possibly digenic	Kallmann syndrome
FLRT3	Haploinsufficiency, possibly digenic	Kallmann syndrome
NELF	Haploinsufficiency, possibly digenic	Kallmann syndrome
CCDC141	Biallelic	Kallmann syndrome
GNRH1	Autosomal recessive	Normosmic hypogonadotropic hypogonadism
GNRHR	Autosomal recessive	Normosmic hypogonadotropic hypogonadism
KISS1	Autosomal recessive	Normosmic hypogonadotropic hypogonadism
KISS1R (previously *GPR54*)	Autosomal recessive	Normosmic hypogonadotropic hypogonadism
LEP	Autosomal recessive	Normosmic hypogonadotropic hypogonadism, obesity
LEPR	Autosomal recessive	Normosmic hypogonadotropic hypogonadism, obesity
TAC3	Autosomal recessive	Normosmic hypogonadotropic hypogonadism
TAC3R	Autosomal recessive	Normosmic hypogonadotropic hypogonadism

PROKR2, CHD7, HS6ST1, WDR11, SEMA3A, SOX10, and *FEZF1* [135, 136]. A proportion of patients with these mutations will have isolated hypogonadotropic hypogonadism without anosmia, although this is more usually associated with a different subset of mutations defining gonadotroph development and function, including *GNRH1, GNRHR, KISS1, KISS1R, LEP*, and *LEPR* [136].

Patients may present in the neonatal period with micropenis and cryptorchidism in males, and delayed or arrested puberty and subfertility in adolescence and adulthood. Other features associated with specific mutations may also be present, including synkinesis and renal agenesis (*ANOS1*), coloboma, heart defects, choanal atresia, retardation of growth, genitourinary defects and ear abnormalities (the CHARGE association, *CHD7*) or marked obesity (*LEP, LEPR, PROK2*). A number of other syndromes associated with hypothalamic dysfunction may also be associated with hypogonadotropic hypogonadism. These include Prader–Willi syndrome, Warburg Micro syndrome, and 4H syndrome. Treatment involves sex steroid supplementation (not just for puberty but also bone mineralization) and induction of fertility (with pulsatile GnRH or hCG and FSH) [136].

Congenital Central Diabetes Insipidus (CDI)

Congenital CDI is rare, and is usually found in combination with other hypothalamo-pituitary hormone deficits such as SOD or holoprosencephaly. Isolated congenital CDI is usually due to mutations in the AVP preprohormone gene, *AVP-NPII*, and is inherited in an autosomal dominant manner [137]. Interestingly, although the genetic mutation is present from birth, CDI usually presents after the neonatal period, suggesting that it results in progressive degeneration of AVP neurons via a dominant negative effect [138]. In the Wolfram (DIDMOAD) syndrome, mutations in *WFS1* result not just in CDI but also diabetes mellitus, optic atrophy, sensorineural deafness, and progressive neurodegeneration [139].

Other Genetic Causes of Hypothalamic Dysfunction

ARNT2

ARNT2 mutations were first described in a highly consanguineous family with six children with postnatal microcephaly, frontotemporal lobe hypoplasia, hypopituitarism, central diabetes insipidus, seizures, global developmental delay, severe visual impairment, and congenital renal tract abnormalities including hydronephrosis, vesicoureteric reflux and neurogenic bladder [3]. Homozygosity mapping and whole exome sequencing revealed a homozygous frameshift mutation in *ARNT2* (c.1373_1374dupTC), a gene encoding a basic helix-loop-helix transcription factor which is expressed in the developing hypothalamus, pituitary, thalamus, retina, lung, stomach, and renal tubules in the human embryo. Patients with the mutation exhibited markedly reduced *ARNT2* mRNA and ARNT2 protein, confirming the mutation as functionally deleterious, and extending the spectrum of *ARNT2* mutation-related phenotypes from that of the *Arnt2* knockout mouse to include renal tract and visual anomalies.

Acquired Causes of Hypothalamic Dysfunction

Acquired causes of hypothalamic dysfunction are covered extensively in Chapters 2.4.2–2.4.4. The manifestations of hypothalamic dysfunction are similar to that of congenital causes, although the resolution of current neuroimaging techniques precludes our ability to predict the risk of developing clinically apparent disease based on the degree or location of structural damage to the region. Certain acquired causes of hypothalamic dysfunction tend to present with particular endocrinopathies, for reasons which are not completely understood. For instance, germinomas, Langerhans cell histiocytosis, granulomatous diseases, and lymphocytic hypophysitis all have a predilection for the infundibulum and therefore present with CDI. Similarly, hypothalamic hamartomas often present with central precocious puberty. Over time, however, multiple pituitary hormone deficiencies often ensue, with the concurrent risk of the hypothalamic syndrome in many of these patients. Given the lack of optimal treatments for many of the 'non-endocrine' aspects of the hypothalamic syndrome, there is increasing recognition of the need to avoid hypothalamic damage in the first instance in the treatment of these acquired causes as far as possible, such as by limiting the extent of neurosurgical resection of hypothalamic tumours.

Conclusion

Hypothalamic dysfunction is rare in childhood, but it is associated with significant morbidity and mortality. Given the variety of neuroendocrine functions displayed by the hypothalamus, it is not surprising that hypothalamic dysfunction can present with a wide range of clinical manifestations including endocrine disorders, temperature, and sleep dysregulation, behavioural and learning difficulties, memory deficits, and autonomic dysfunction. The diagnosis of hypothalamic dysfunction is challenged by the lack of accurate diagnostic tools for this condition. Targeted treatment for hypothalamic obesity and the 'non-endocrine' clinical manifestations of hypothalamic dysfunction has proven difficult and supportive care and symptomatic management are the only strategies currently available for these patients.

2.4.2 Craniopharyngiomas

Niki Karavitaki

Epidemiology

Craniopharyngiomas are rare tumours with a reported incidence of 0.13 cases per 100 000 person-years. They account for 2–5% of all the primary intracranial neoplasms and 5.6–15% of the intracranial tumours in childhood populations, in which they are the commonest lesion involving the hypothalamo-pituitary region. They may be detected at any age, even in the pre- and neonatal periods and almost half of the total cases have been described in adults. They show a bimodal age distribution with peak incidence rates in children of 5–14 and adults of 50–74 years old [1].

Pathology and Pathogenesis

Craniopharyngiomas are epithelial tumours arising along the path of the craniopharyngeal duct (the canal connecting the stomodeal ectoderm with the evaginated Rathke's pouch). Based on the World Health Organization (WHO) classification, they are grade I tumours. Rare cases of malignant transformation (possibly triggered by previous irradiation) have been described. Two main pathological subtypes have been reported: the adamantinomatous and the papillary, but transitional or mixed forms have also been described [1, 2].

The adamantinomatous type is the most common subtype and may occur at all ages. Macroscopically they have cystic and/or solid components, necrotic debris, fibrous tissue, and calcification. The cysts may be multiloculated and contain liquid ranging from 'machinery oil' to

shimmering cholesterol-laden fluid consisting of desquamated squamous epithelial cells, rich in membrane lipids and cytoskeleton keratin. They tend to have sharp and irregular margins, often merging into a peripheral zone of dense reactive gliosis, with abundant Rosenthal fibre formation (consisting of irregular masses of granular deposits within astrocytic processes) in the surrounding brain tissue and the vascular structures. The epithelium of the adamantinomatous type is composed of three layers of cells: a distinct palisaded basal layer of small cells with darkly staining nuclei and little cytoplasm (somewhat resembling the basal cells of the epidermis of the skin), an intermediate layer of variable thickness composed of loose aggregates of stellate cells (termed stellate reticulum), whose processes traverse empty intercellular spaces and a top layer facing into the cyst lumen with abruptly enlarged, flattened and keratinized to flat plate-like squamous cells (Figure 2.4.2.1). The flat squames are desquamated singly or in distinctive stacked clusters and form nodules of 'wet' keratin, which are often heavily calcified and appear grossly as white flecks. The keratinous debris may elicit an inflammatory and foreign body giant cell reaction. The presence of the typical adamantinomatous epithelium or of the 'wet' keratin alone are diagnostic, whereas features only suggestive of the diagnosis in small or non-representative specimens include fibrohistiocytic reaction, necrotic debris, calcification, and cholesterol clefts [1].

The papillary variety has been almost exclusively described in adult populations (accounts for 14–50% of the adult cases and for up to 2% of the paediatric ones). Calcification is rare and the cyst content is usually viscous and yellow. It is generally well circumscribed and infiltration of adjacent brain tissue by neoplastic epithelium is less frequent than in the adamantinomatous type. It consists of mature squamous epithelium forming pseudopapillae and of an anastomosing fibrovascular stroma without the presence of peripheral palisading of cells or stellate reticulin (Figure 2.4.2.2). The differential diagnosis between a papillary craniopharyngioma and a Rathke's cleft cyst may be difficult, particularly in small biopsy specimens, as the epithelial lining of the Rathke's cysts may undergo squamous differentiation; however, the lack of a solid component and the presence of extensive ciliation and/or mucin production are suggestive of Rathke's [1, 2].

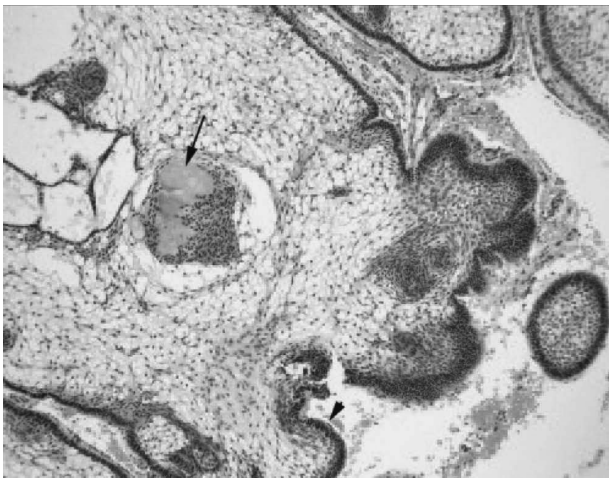

Figure 2.4.2.1 Adamantinomatous craniopharyngioma. The epithelium consists of a palisaded basal layer of cells (arrowhead), an intermediate stellate reticulum, and a layer of flattened, keratinized squamous cells. Nodules of 'wet' keratin (arrow) are also shown.

Although the pathogenesis of craniopharyngiomas has not been fully elucidated, our understanding on this field has increased significantly in the recent years. B-catenin gene mutations have been identified in the adamantinomatous subtype affecting exon 3 which encodes the degradation targeting box of β-catenin; the mutant form is resistant to degradation leading to accumulation of nuclear β-catenin protein (a transcriptional activator of the Wnt signalling pathway). Furthermore, strong β-catenin expression has been shown in the adamantinomatous subtype indicating re-activation of the Wnt signalling pathway and subsequent de-regulation of several downstream pathways [3–5]. A number of studies using whole exome sequencing, next-generation panel sequencing, pyrosequencing and Sanger sequencing have shown the presence of activating mutations in *BRAF* (V600E) in the papillary subtype; the prevalence varies according to the sequencing method between 81% and 100% [4]. It has also been suggested that the two pathological subtypes have different epigenomic and transcriptomic signatures and that the cell clusters in the adamantinomatous subtype may have a functional role in the promotion of tumour invasion [4].

Location/Imaging

Most of the craniopharyngiomas are located in the sellar/parasellar region. The majority (94–95%) has a suprasellar component (purely suprasellar 20–41%/both supra- and intrasellar 53–75%), whereas the purely intrasellar ones represent the least common variety (5–6%. Other rare locations include the nasopharynx, the paranasal area, the sphenoid bone, the ethmoid sinus, the intrachiasmatic area, the temporal lobe, the pineal gland, the posterior cranial fossa, the cerebellopontine angle, the midportion of the midbrain or completely within the third ventricle [1, 6].

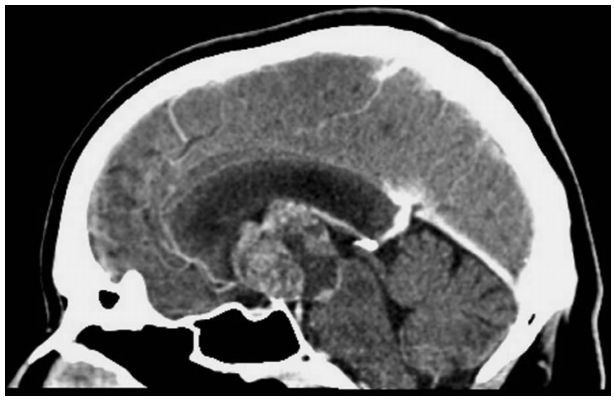

Figure 2.4.2.3 CT head: craniopharyngioma in the suprasellar area associated with mass effect on the third ventricle and hypothalamus. The lesion shows a multicystic appearance with calcifications and a marked inhomogeneous enhancement.

Imaging tools for the diagnosis of craniopharyngiomas include plain skull X-rays, CT, MRI, and occasionally, cerebral angiography. Plain skull X-rays, although seldom used nowadays, may show calcification and abnormal sella [1]. CT is helpful for the evaluation of the bony anatomy, the identification of calcifications, and the discrimination of the solid and the cystic components; they are usually of mixed attenuation, the cyst fluid has low density and the contrast medium enhances any solid portion, as well as the cyst capsule [1] (Figure 2.4.2.3). The MRI is particularly useful for the topographic and structural analysis of the tumour. The appearance of the craniopharyngioma depends on the proportion of the solid and cystic components, the content of the cyst(s) (cholesterol, keratin, haemorrhage) and the amount of calcification present. A solid lesion appears as iso- or hypointense relative to the brain on precontrast T_1-weighted images, shows enhancement following gadolinium administration and is usually of mixed hypo- or hyperintensity on T_2-weighted sequences. Large amounts of calcification may be visualized as areas of low signal on both T_1- and T_2-weighted images. A cystic element is usually hypointense on T_1- and hyperintense on T_2-weighted sequences. On T_1-weighted images a thin peripheral contrast-enhancing rim of the cyst is demonstrated. Protein, cholesterol, and methaemoglobin may cause high signal on T_1-weighted images, while very concentrated protein and various blood products may be associated with low T_2-weighted signal [1] (Figure 2.4.2.4).

The size of craniopharyngiomas has been reported as being larger than 4 cm in 14–20% of the cases, 2–4 cm in 58–76%, and smaller than 2 cm in 4–28%. Their consistency is purely or predominantly cystic in 46–64%, purely or predominantly solid in 18–39%, and mixed in 8–36%. Calcification has been demonstrated in 45–57% and is probably more common in children (78–100%). The calcification patterns vary from solid lumps to popcorn-like foci or less commonly, to an eggshell pattern lining the cyst wall. Hydrocephalus has been reported in 20–38% and is probably more frequent in childhood diagnosed disease (41–54%). There is no agreement on the radiological features discriminating the two histological subtypes. The differential diagnosis includes a number of sellar or parasellar lesions, including Rathke's cleft cyst, dermoid cyst, epidermoid cyst, pituitary adenoma, germinoma, hamartoma, suprasellar aneurysm, arachnoid cyst, suprasellar abscess, glioma, meningioma, sarcoidosis, tuberculosis, and Langerhans cell histiocytosis. Differentiation

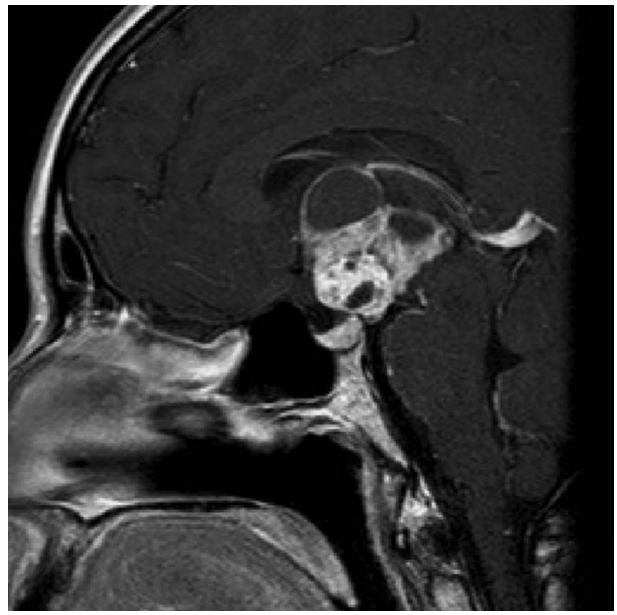

Figure 2.4.2.4 MRI of pituitary: large suprasellar craniopharyngioma with complex internal signal. There is cyst formation and enhancement after contrast.

from a Rathke's cleft cyst (typically small, round, purely cystic lesion lacking calcification), or from a pituitary adenoma (in the rare case of a homogenously enhancing solid craniopharyngioma) may be particularly difficult [1, 6–9].

Presenting Manifestations

Patients with craniopharyngioma may present with a variety of clinical manifestations attributed to pressure effects on vital structures of the brain (visual pathways, brain parenchyma, ventricular system, major blood vessels, and hypothalamo-pituitary system). Their severity depends on the location, the size, and the growth potential of the tumour. The duration of the symptoms until diagnosis ranges between 1 week to 372 months [1]. The presenting clinical manifestations (neurological, visual, hypothalamo-pituitary) and the pituitary function in a large series of cases are shown in Tables 2.4.2.1 and 2.4.2.2. Headaches, nausea/vomiting, visual disturbances, growth failure (in children) and hypogonadism (in adults) are the most frequently reported.

Treatment

Surgical Removal Combined or Not with External Beam Irradiation

Surgery combined or not with adjuvant external beam irradiation is currently one of the most widely used first therapeutic modalities for these tumours. Craniopharyngiomas remain challenging tumours, even in the era of modern neurosurgery. This is mainly attributed to their sharp, irregular margins and to their tendency to adhere to vital neurovascular structures making surgical manipulations potentially hazardous to vital brain areas. The attempted extent of excision has been a subject of significant debate and depends

Table 2.4.2.1 Presenting clinical features in children and adults with craniopharyngioma

	Children	Adults	Total
Headaches	78%	56%	64%
Menstrual disorders (adult women, n = 37)		57%	
Visual field defects	46%	60%	55%
Decreased visual acuity	39%	40%	39%

on the size (achieved in 0% of lesions >4 cm) and location (particularly difficult for retrochiasmatic or within the third ventricle) of the tumour, the presence of hydrocephalus, of more than 10% calcification and of brain invasion, as well as on the experience, the individual judgement during the operation and the general treatment policy (aggressive or not) adopted by each neurosurgeon [1, 8, 9]. Reasons for incomplete removal, as reported in 56 patients who underwent primary surgery, include firm adherence to hypothalamus (26.8%), obstructed view (21.4%), major calcifications (14.3%), adherence to perforating vessels (10.7%), adherence to major vessels (7.1%), severe bradycardia during dissection (5.4%), advanced age of the patient (3.6%), high blood loss because of co-existent aneurysm (1.8%), very thin capsule (1.8%) and impression of complete removal (7.1%) [8]. The perioperative morbidity ranges between 1.7% and 5.4% for primary operations [1, 6, 7, 10]. The irradiation of cystic craniopharyngiomas carries the risk of enlargement, which may later regress or necessitate further intervention [6, 11].

Recurrent tumours may arise even from small islets of craniopharyngioma cells in the gliotic brain adjacent to the tumour, which can remain even after gross total resection. The mean interval for their diagnosis after various primary treatment approaches ranges between 1 and 4.3 years and relapses as late as 36 years after initial therapy have been reported. Remote recurrences after apparent successful removal have been described with possible mechanisms including transplantation during the surgical procedures and dissemination by meningeal seeding or cerebrospinal fluid (CSF) spreading [1, 6].

Series with radiological confirmation of the extent of resection show that the recurrence rates following gross total removal range between 0% and 62% at 10 years follow-up. These are significantly lower than those reported after partial or subtotal resection (25–100% at 10 years follow-up). In cases of limited surgery, adjuvant radiotherapy improves significantly the local control rates (recurrence rates 10–63% at 10 years follow-up). Series with statistical comparisons of the recurrences achieved by gross total removal or combination of surgery and radiotherapy have not provided consistent results. Finally, radiotherapy alone, which however, can be offered to selected tumours, provides 10 years recurrence rates ranging between 0% and 23% [1, 6–16] (Table 2.4.2.3). Particularly focusing on series using proton therapy (aiming to reduce late toxicity) postoperatively, 5 years local control rates range between 85% and 100% [17].

In cases of predominantly cystic tumours, fluid aspiration provides relief of the obstructive manifestations and facilitates the removal of the solid tumour portion; the latter should not be delayed for more than a few weeks, as there is significant risk of cyst refilling (reported in up to 81% of the cases at a median period of 10 months) [6, 8]. The interpretation of the data on the effectiveness of each therapeutic modality has to be done with caution, since the published studies are retrospective, non-randomized, and often specialty biased. Although not widely accepted, it has been suggested that the tumour control correlates with the irradiation dose and doses below ≤5400 cGy are associated with poorer outcome. The growth rate of craniopharyngiomas varies considerably and reliable clinical, radiological, and pathological criteria predicting their behaviour are lacking. Thus, apart from significant impact of the treatment modality, attempts to identify other prognostic factors (age

Table 2.4.2.3 Recurrence rates at 10 years follow-up after treatment of craniopharyngioma by surgery and/or radiotherapy

Primary treatment	Range of 10-year recurrence rate
Gross total removal	0–62%
Partial/subtotal removal	25–100%
Partial/subtotal removal + Radiotherapy	10–63%
Radiotherapy	0–23%

group at diagnosis, sex, imaging features, pathological subtypes, immunoreactivity of the tumour proliferation marker MIB-1) have not provided consistent data [1].

The management of recurrent tumours remains difficult, as scarring/adhesions from previous surgeries or irradiation decrease the chance of successful excision. In such cases, total removal is achieved in a significantly lower rate when compared with primary surgery (0–25%) and is associated with increased perioperative morbidity and mortality (10.5–24%), suggesting that for many recurrent lesions palliative surgery is the most realistic target. The beneficial effect of radiotherapy (preceded or not by second surgery) in recurrent lesions has been clearly shown [1, 6, 15, 16].

Other Treatment Options

Intracavitary irradiation (brachytherapy) is a minimally invasive approach involving stereotactically guided instillation of β-emitting isotopes into cystic craniopharyngiomas and delivering higher radiation dose to the cyst lining than the one offered by external beam radiotherapy. It causes destruction of the secretory epithelial lining leading to elimination of the fluid production and cyst shrinkage. A number of beta- and gamma-emitting isotopes (mainly ^{32}phosphate, ^{90}yttrium, ^{186} rhenium, ^{198}gold) have been used; as none of them has the ideal physical and biological profile (i.e. pure β emitter with short half-life and with tissue penetrance limited to cover only the cyst wall), there is no consensus on which is the most suitable therapeutic agent. Based on studies with the largest series of patients and with relatively long follow-up periods, brachytherapy seems to offer a good prospect for the reduction/stabilization of cystic craniopharyngiomas. This combined with its reported low surgical morbidity and mortality render intracavitary irradiation an attractive option for predominantly cystic tumours, and particularly the monocystic ones. Its impact on the quality of survival and long-term morbidity (particularly vision, neuroendocrine and cognitive function) remain to be assessed [1, 18, 19].

The intracystic installation of the antineoplasmatic agent bleomycin has been proposed for the management of cystic tumours. However, in published reports the tumour control rates range between 0% and 100%. Direct leakage of the drug to surrounding tissues during the installation procedure, diffusion though the cyst wall or high drug dose have been associated with various toxic (hypothalamic damage, blindness, hearing loss, ischaemic attacks, peritumoral oedema), or even fatal effects. The value of this treatment option in the tumour control or even in the delaying of potentially harmful surgery and/or radiotherapy, as well as the optimal protocol and the clear-cut criteria predicting the long-term outcome remain to be established in large series with appropriate follow-up [1, 20, 21].

Stereotactic radiosurgery delivers a single fraction of high dose ionizing radiation on precisely mapped targets keeping the exposure of adjacent structures to a minimum. Tumour volume and close attachment to critical structures are limiting factors for its application, with 10 and 15 Gy being the maximum tolerated doses to the optic apparatus and the other cranial nerves, respectively. Published studies suggest that achieves tumour control in a substantial number of patients with small volume lesions (complete/partial resolution: 67–90%). Stereotactic radiosurgery may be particularly useful for well-defined residual disease following surgery or for the treatment of small solid recurrent tumours, particularly after failure of the conventional radiotherapy. In cases of large cystic portions multimodality approaches with instillation of radioisotopes or bleomycin may offer further benefits. Studies with long-term follow-up evaluating the optimal marginal dose, its role in the prevention of tumour growth and its effects on the neurocognitive and neuroendocrine functions are required [1, 22–24].

Systemic chemotherapy has been offered in a limited number of patients mainly with aggressive tumours with relative success [1]. Its application remains rather experimental and its place, particularly in the treatment of aggressive tumours, remains to be assessed.

The finding that most papillary craniopharyngiomas harbour a *BRAF* (V600E) mutation has opened avenues in using pharmacological agents specifically targeting and inhibiting mutant *BRAF* in resistant to treatment cases. Recent case reports have shown reduction in tumour volume suggesting the promising potential of this approach which, however, remains to be validated with clinical trials [4].

Long-Term Outcome After Surgery ± Conventional External Beam Irradiation

Morbidity

Patients with craniopharyngioma suffer from significant long-term morbidity (mainly endocrine, visual, hypothalamic, neurobehavioural, and cognitive) attributed to the damage of critical neuronal structures by the primary or recurrent tumour and/or to the adverse effects of the therapeutic interventions (Table 2.4.2.4). Notably, the severity of the radiation-induced late toxicity (endocrine, visual, hypothalamic, neurocognitive) is associated with the total and per fraction doses, the volume of the exposed normal tissue and the young age in childhood populations [1].

In series including subjects with various treatment modalities and follow-up periods, the frequency of pituitary hormone deficits ranges between 88% and 100% for growth hormone (GH), 80–95% for FSH/LH, 55–88% for ACTH, 39–95% for thyroid-stimulating hormone (TSH), and 25–86% for antidiuretic hormone (ADH). Apart from symptomatic diabetes insipidus (DI), which is probably more common in surgically treated patients, the long-term endocrine morbidity is not affected by the type of tumour therapy. Interestingly, restoration of pre-existing hormone deficits after surgical removal, is absent or uncommon. The phenomenon of growth without growth hormone

Table 2.4.2.4 Probability of various morbidities and compromised functional outcome at 10-years follow-up in patients with craniopharyngioma

Outcome	Rate at 10-year follow-up
Major visual filed defects (i.e. at least quadrantanopia)	48%
Hyperphagia-excessive weight gain	39%
Hemiparesis or monoparesis	11%
Epilepsy	12%
Complete dependency for basal daily activities	9%
Unable to work in previous occupation	23%
School status behind the expected level	28%
Depression or mood disorders necessitating treatment for various periods	15%
GH deficiency	88%
FSH/LH deficiency	90%
ACTH deficiency	86%
TSH deficiency	80%
Diabetes insipidus	65%

Adapted with permission from Karavitaki N, Brufani C, Warner JT, *et al.* (2005). Craniopharyngiomas in children and adults: systematic analysis of 121 cases with long-term follow-up. *Clin Endonol*, 62, 397–409.

has been reported in some children with craniopharyngioma, who show normal or even accelerated linear growth, despite their untreated GH deficiency. The pathophysiological mechanism has not been clarified; the obesity-associated hyperinsulinemia or the presence of hyperprolactinaemia have been proposed as factors stimulating growth by affecting serum concentrations of IGF-I or by binding directly to the IGF-I receptor. Finally, a number of studies support the view that GH replacement in children and adults does not increase the risk of tumour recurrence [1, 6, 25, 26].

Compromised vision has been reported in up to 62.5% of the patients treated by surgery combined or not with radiotherapy during observation period of 10 years. The visual outcome is adversely affected by the presence of visual symptoms at diagnosis and by daily irradiation doses above 2 Gy [1].

Hypothalamic damage may result in hyperphagia and uncontrollable obesity, disorders of thirst and water/electrolyte balance, behavioural, and cognitive impairment, loss of temperature control, and disorders in the sleep pattern.

Obesity is the most frequent manifestation affecting 26–61% of the patients treated by surgery combined or not with radiotherapy. It is a consequence of the disruption of the mechanisms controlling satiety, hunger, and energy balance and it often results in devastating metabolic and psychosocial complications. Possible contributing mechanisms include lack of sensitivity to endogenous leptin, vagally mediated hyperinsulinaemia, and autonomic imbalance, as well as reduced physical activity (rather than increased energy intake), which is exaggerated by the neurological defects, the visual failure, and the somnolence. Notably, in adults with craniopharyngioma, the basal metabolic rate adjusted to the total body weight is significantly lower compared with controls and children with surgically treated craniopharyngioma have decreased aerobic capacity during an exercise test related to hypothalamic involvement [27]. Hypothalamic obesity often results in devastating metabolic and psychosocial complications, necessitating provision of dietary and behavioural modifications, encouragement of regular physical activity and psychological counselling. Bariatric surgery is a management option for these patients. In a recent systematic review and meta-analysis of 21 cases of bariatric surgery for hypothalamic obesity in patients with craniopharyngioma (6 with adjustable gastric banding, 8 with sleeve gastrectomy, 6 with Roux-en-Y gastric bypass, and 1 with biliopancreatic diversion), the maximal mean weight loss was achieved in the gastric bypass group after 12 months [28]. Medical therapies including dextroamphetamine, combination of diazoxide and metformin (aiming to reduce the hyperinsulinaemia), octreotide (aiming to reduce hyperinsulinaemia and simultaneously enhance the insulin action) and glucagon-like peptide-1 analogues have been proposed as a medical approach [29]. Studies with large number of patients and longer follow-up are needed to establish the benefits and safety of these surgical and medical management options.

Diabetes insipidus with an absent or impaired sense of thirst confers a significant risk of serious electrolyte imbalance and is one of the most difficult complications to manage. In this group of patients, the maintenance of the osmotic balance has been shown to be precarious with recurrent episodes of hyper- or hyponatraemia contributing to morbidity and mortality. Careful fluid balance in and out and regular weighting are important. Factors associated with significant hypothalamic morbidity have been proposed to be young age at presentation in children, manifestations of hypothalamic disturbance at diagnosis, hypothalamic invasion, tumour height greater than 3.5 cm from the midline, attempts to remove adherent tumour from the region of hypothalamus (emphasizing the importance of conservative surgical resection when hypothalamic involvement is present), multiple operations for recurrence and hypothalamic radiation doses of more than 51 Gy [1, 6, 7, 9].

The compromised neuropsychological and cognitive function in patients with craniopharyngioma contributes significantly to poor academic and work performance, disrupted family and social relationships, and impaired quality of life. In a series of 121 patients treated by surgery with or without adjuvant radiotherapy and followed-up for a mean period of 10 years, 40% had poor outcome (the assessment was based on motor and visual deficits, dependence for activities of daily living, Karnofsky Performance Scale, school and work status, debilitating psychological or emotional problems) [7]. It has also been shown that the mean morbidity scores (based on endocrine deficiencies, vision, motor disorders and epilepsy, learning difficulties, behavioural problems, IQ, hypothalamic dysfunction) of children with additional surgery for recurrence were higher than the ones after their initial surgery and higher than those of children without recurrence [9]. There is no consensus on the therapeutic option with the least adverse impact on the neurobehavioural outcome necessitating prospective studies with formal neuropsychological testing and specific behavioural assessment prior and after any intervention [1]. These data are particularly important for the young children, in which the uncertainties of whether delaying irradiation is a reasonable policy, and whether the neurotoxicity of the recurrent disease and the subsequent surgery is higher than the one associated with irradiation offered to prevent relapse, need to be answered.

Mortality

The overall mortality rates of patients with craniopharyngioma have been reported to be 3–9 times higher than that of the general population with survival rates range between 83% and 92.7% at 10-years. Apart from the deaths directly attributed to the tumour (pressure effects to critical structures) and to the surgical interventions, the risk of cardio-/cerebrovascular and respiratory mortality is increased. It has also been suggested that in childhood populations the hypoadrenalism and the associated hypoglycaemia, as well as the metabolic consequences of ADH deficiency and absent thirst may contribute to the excessive mortality. The impact of tumour recurrence on the long-term mortality is widely accepted and the 10-year survival rates in such cases range between 29% and 70% (depending on the subsequent treatment modalities) [1, 6, 30].

Treatment Algorithm

The proposed treatment algorithm which is based on the significant available literature is shown in Figure 2.4.2.5 [1]. Surgical removal is suggested for all craniopharyngiomas causing compressive signs or symptoms (if a predominantly cystic lesion, the resection may be facilitated by previous aspiration of the cyst fluid). Gross total removal is a reasonable aim provided it is m performed by experienced neurosurgical hands and hazardous manipulations to vital brain structures (particularly the hypothalamus) are avoided. If residual tumour remains following surgery, adjuvant irradiation is recommended; this is because of the high risk of recurrence and its adverse impact on morbidity and mortality. Although this strategy may be debated for the young children, the radiation toxicity to the developing brain needs to be balanced with the consequences of relapse and subsequent possible multiple surgical procedures. In small tumours not causing pressure effects (visual, neurological, hypothalamic), radiotherapy (preceded by biopsy for confirmation of the diagnosis) is an attractive approach avoiding the risks of surgery. In predominantly cystic tumours, previous fluid aspiration may reduce the adverse sequelae of possible cyst enlargement during irradiation.

The treatment of recurrent disease depends on the previous interventions and the severity of the clinical manifestations. In recurrent lesions not previously irradiated, radiotherapy provides satisfactory local control rates. In view of the high morbidity and mortality of a second surgery, such an intervention is advocated only in cases of acute pressure effects. The treatment of further recurrence(s) should be individualized and could include gamma knife radiosurgery, cyst controlling procedures, surgical debulking (for significant solid life-threatening component) and systemic chemotherapy or for the papillary variant BRAF (V600E) inhibitors [1, 4].

2.4.3 Perisellar Tumours Including Cysts, Hamartomas, and Vascular Tumours

Jürgen Honegger, Ulrike Ernemann, and Rudi Beschorner

Introduction

Approximately 80% of symptomatic tumours in the pituitary region are pituitary adenomas and further 10% are craniopharyngiomas. Among the remaining 10%, a considerable number of rare tumour entities have to be considered (Table 2.4.3.1). Endocrinological, neuroradiological, and ophthalmological evaluation is the indispensable diagnostic triad to identify typical features in non-adenomatous perisellar tumours, and to provide diagnostic accuracy.

The typical clinical aspects of non-adenomatous perisellar tumours and the differential-diagnostic value of specific symptoms are presented in the following. The current therapeutic strategies and outcomes are described.

Table 2.4.3.1 Perisellar tumours

Pituitary and hypothalamic Tumours	Solitary fibrous tumour
	Spindle cell oncocytoma
Craniopharyngioma	**Extradural tumours**
Ganglioglioma	Bone 'tumour' (f.e. Paget's disease, fibrous dysplasia, osteoid osteoma)
Germ cell tumour (f.e. Germinoma)	
	Chordoma
Granular cell tumour	Chondrosarcoma
Haemangiopericytoma/solitary fibrous tumour	Chondrosarcoma
Hypothalamic hamartoma	Esthesioneuroblastoma
Lipoma, hypothalamic	Multiple myeloma
Lymphoma	Naso-pharyngeal carcinoma
Meningioma	Plasmacytoma
Metastasis	**Perisellar cysts**
Mixed ganglioglioma-adenoma	Arachnoid cyst
Neuroblastoma	Dermoid cyst
Optico-hypothalamic glioma	Epidermoid cyst
Paraganglioma	Rathke's cleft cyst
Pituicytoma	Sellar colloid cyst
Pituitary adenoma	**Vascular 'tumours'**
Pituitary carcinoma	Aneurysm
Pituitary blastoma	Cavernous sinus haemangioma
Schwannoma	Cavernous haemangioma of the optic chiasm
Sellar ependymoma	

Rathke's Cleft Cysts

It is assumed that Rathke's cleft cysts (RCC) are related to embryonal pituitary development and consist of remnants of Rathke's pouch. Microscopically small RCC are found during autopsies in 30% of normal pituitary glands. Patients with clinically symptomatic RCC usually present during adulthood.

Symptoms and endocrinological findings: Among the rare symptomatic cases, headache and visual loss are the most common presenting symptoms [1]. A meta-analysis showed hypopituitarism in 46% of the cases [2] (see Figure 2.4.3.1). The reported frequency of diabetes insipidus varies between 0% and 21% (Figure 2.4.3.2).

Neuroradiological imaging: The hyperintense appearance of the protein-rich cyst contents on T1-weighted MRI is characteristic but not obligatory. The two typical localizations are intrasellar with possible suprasellar extension and above the pituitary gland adjacent to the pituitary stalk (Figure 2.4.3.3).

Therapy: Indication for surgery is given for these benign cysts only when there is proof of deficits or a large space-occupying cyst is found. The vast majority of RCC can be removed by transsphenoidal surgery (TSS). The objective of surgery is drainage of the cyst and biopsy or partial excision of the cyst wall. Radical resection of the often adherent and thin capsule is usually not performed due to the increased morbidity (e.g. nasal cerebrospinal fluid (CSF) fistula, hypopituitarism, or diabetes insipidus). Histologically, the wall of the cyst is mainly lined by columnar ciliated and goblet cells as well as occasional pituitary hormone-producing cells. Additionally, squamous metaplasia may occur.

Outcome: Headache and visual impairment mostly abate postoperatively and hyperprolactinaemia frequently resolves [3, 4]. Preoperative hypopituitarism improves in some patients while diabetes insipidus usually persists. Recurrence rates of 0%-33% have been reported. RCC with squamous metaplasia are more likely to recur. Only a minority of recurrences become symptomatic and require re-operation [3].

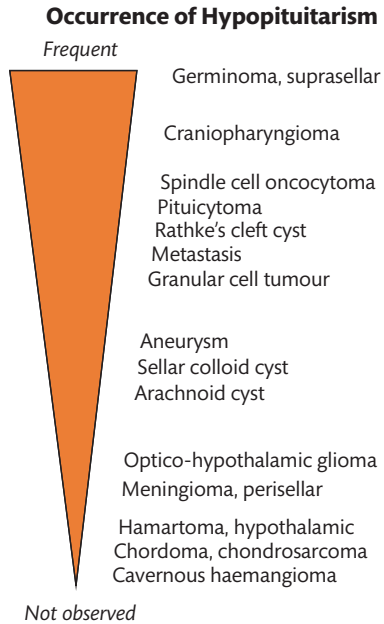

Figure 2.4.3.1 Frequency of hypopituitarism in perisellar tumours.

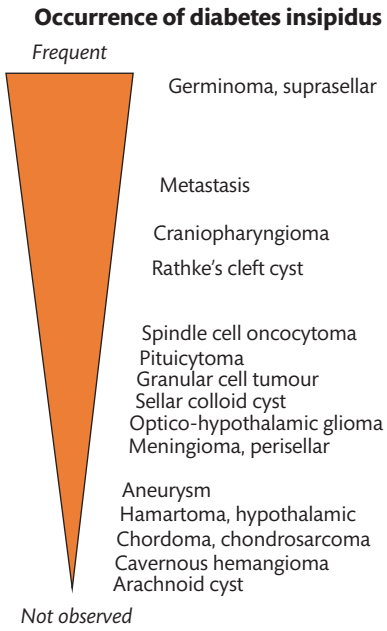

Figure 2.4.3.2 Frequency of diabetes insipidus in perisellar tumours.

Sellar Colloid Cysts

Sellar colloid cysts (SCC), arise from the intermediate lobe of the pituitary gland and must be regarded as 'pseudocysts'. They are relatively frequent sellar lesions and represent a clearly distinct clinical entity. It has been suggested that SCC are a result of cellular degeneration [5]. SCC are often misinterpreted as pituitary adenomas.

Symptoms and endocrinological findings: Usually, SCC are a chance finding and there are no endocrinological impairments.

Figure 2.4.3.3 Suprasellar Rathke's cleft cyst. The sagittal T_1-weighted MRI shows the hyperintense signal of the cyst (arrow) above the pituitary gland (asterisk).

In neurosurgical series, the patients are mostly women with menstrual period disruption, galactorrhoea, and headache as the main clinical complaints. Endocrine deficits are usually mild. Formal endocrinological examination revealed hyperprolactinemia and hypogonadism in 72% of the symptomatic cases [5].

Neuroradiological imaging: The oval configuration (like an American football) and localization between the anterior lobe and the posterior lobe of the pituitary are characteristic and reliable in the differential diagnosis (see online Figure 2.4.3.4). No contrast enhancement is found. It should be looked for the characteristic dark signal of colloidal cyst content on T_2-weighted MRI.

Therapy and outcome: Surgical removal of colloidal cyst content is performed in symptomatic SCC by TSS. As they do not exhibit an epithelial lining, normal pituitary is usually found in the biopsy of the adjacent tissue [5]. Headaches often abate postoperatively. The endocrinological deficits mostly regress and normal prolactin levels are restored. No recurrence is to be anticipated.

Arachnoid Cysts

Arachnoid cysts (AC) constitute a non-proliferative anomaly of the arachnoidea. An expansive, 'tumour-like' cyst can arise due to a circumscribed collection of CSF within reduplication of the arachnoidal membrane. Intrasellar AC are relatively uncommon [6].

Symptoms and endocrinological findings: Visual impairment and headache are predominant presenting symptoms in sellar AC [6]. Hypogonadism and growth hormone deficiency were described in 50% of previously untreated cases [6] (Figure 2.4.3.1). Diabetes insipidus is not mentioned in the relevant literature as a symptom of sellar AC (Figure 2.4.3.2).

Neuroradiological imaging: MRI shows the typical findings of cystic space-occupying lesion. AC may be localized intrasellar with secondary suprasellar arching or in the suprasellar region. In the differential diagnosis of pituitary cysts, attention must be paid to the signal of the cyst. The signal of the AC contents corresponds to the CSF signal (see online Figure 2.4.3.5). Due to the thin arachnoidal capsule, no peripheral contrast enhancement is found.

Therapy: Surgical treatment of sellar AC is challenging. Most neurosurgeons prefer TSS despite the high risk of postoperative rhinorrhoea. Broad fenestration of the cyst wall toward the suprasellar CSF spaces with meticulous sellar floor reconstruction has been recommended for communicating AC that refill with CSF after cyst evacuation [6]. Alternatively, obliteration of the cyst cavity with graft implantation can be performed [7]. Cyst drainage and broad fenestration of the cyst wall by a small craniotomy is a good alternative to the transsphenoidal evacuation as it avoids the risk of nasal CSF leakage and is particularly recommended in large AC.

Outcome: Visual deficits usually improve postoperatively [6]. Partial hypopituitarism often recovers, whereas panhypopituitarism frequently persists [6].

Perisellar Meningiomas

Meningiomas are by far the most frequent non-pituitary tumours with secondary spread into the pituitary fossa and encroachment upon the pituitary gland or stalk. In meningiomas, the ratio of

women to men is 5:1. Meningiomas arise from arachnoid cover cells of the meninges. Benign World Health Organization (WHO) grade I meningiomas numerically dominate. Mutations in the TERT promoter [8] or in the breast cancer (BRCA)1-associated protein-1 tumour suppressor gene (BAP1) are associated with a worse prognosis.

In addition to the histological classification, meningiomas are also subdivided according to their localization. The most common meningiomas in the pituitary region are the tuberculum sellae meningiomas (TSM) and the cavernous sinus meningiomas (CSM).

Tuberculum Sellae Meningiomas

Symptoms and endocrinological findings: The main symptom of TSM is visual loss, whereby the impairment can be one-sided due to a prechiasmatic lesion or bilateral due to a chiasmal syndrome. Pituitary failure is rare in TSM despite the often considerable size [9]. In some cases, hypogonadism is observed, or hyperprolactinemia due to displacement of the pituitary stalk.

Neuroradiological imaging: A frequent differential-diagnostic error is misdiagnosing a TSM as a pituitary adenoma. Therefore, precise inspection of sagittal MR images is paramount and reveals that the meningioma sits broad-based on the tuberculum sellae and above the pituitary gland, but does not grow in the confines of the pituitary gland (see online Figure 2.4.3.6). In contrast to pituitary adenomas, meningiomas often show dural enhancement (so-called **dural tail**) which is explained by tumour spread but also by increased vascularization of the neighbouring meninges.

Therapy: Traditionally, TSM are operated by a transcranial approach. The extended transsphenoidal approach has become an alternative for removal of TSM [10]. In the majority of cases, TSM can be completely resected.

Outcome: With 10%, the recurrence rate is relatively low [10]. High rates of visual improvement have been reported. However, postoperative visual decline is observed in 10% of the operated patients (8). The risk of postoperative pituitary deficits is low [9].

Cavernous Sinus Meningiomas

Symptoms and endocrinological findings: The main symptom of CSM is double vision due to ocular motor nerve palsies. Often retroorbital pain is reported due to dural involvement and distension of the cavernous sinus. Hormone abnormalities occur when the direction of growth is medial. The most frequent endocrine abnormality is hyperprolactinemia [11].

Neuroradiological findings: Neuroradiologically, the expansive tumour within the cavernous sinus shows strong contrast enhancement. The marked dural tail, which extends to the tentorium, is characteristic in CSM.

Therapy: Meningiomas are usually slow-growing tumours and two-third of meningiomas remained stable in size during observation [12]. Therefore, asymptomatic or oligosymptomatic meningiomas of the cavernous sinus can initially be managed conservatively with regular control MRI. Symptomatic or growing CSM are treated these days primarily by radiotherapy. Single-shot radiosurgery is particularly suitable for meningiomas confined to the cavernous sinus. Hypofractionated radiosurgery or fractionated radiotherapy has advantage in large meningiomas with proximity to the optic system. The radical cavernous sinus surgery of the 1980s has been abandoned due to the high morbidity and tendency to recurrence. Surgical debulking is made in cases of exophytic tumour expansion and in compression of the optic pathways or growth into the optic canal.

Outcome: Tumour control rates of more than 90% can be achieved with radiation modalities [13]. In light of the close proximity to the hypothalamo-pituitary system, radiation of perisellar meningiomas requires close attention to radiation-related endocrinological deficits, which may manifest several years after treatment.

Diaphragma Sellae Meningiomas

The rare variant of diaphragm sellae meningioma originates immediately anterior or posterior to the pituitary stalk and grows above the diaphragm sellae. Visual symptoms but also endocrine deficits prevail at presentation. Due to the location of these meningiomas, operative removal which is performed via a craniotomy is challenging and carries a risk of endocrine deficits.

Intrasellar Meningiomas

Purely intrasellar meningiomas are rare [11]. It is assumed that this entity arises from the lower side of the diaphragma sellae. Thus, it is a special variant of diaphragma sellae meningiomas. Most intrasellar meningiomas have been treated by TSS [11], but resection of these often highly vascular tumours is more difficult than resection of pituitary adenomas.

Pituitary Metastases

Pituitary metastases are reported in published autopsy series of patients with malignant disease with a frequency of 1% to 11.8%. By contrast, metastases in the pituitary and hypothalamus are relatively rare in surgical series. Predilection sites of metastasizing are the bone, in particular the clivus, with secondary spread to the pituitary, but also the pituitary itself and the pituitary stalk. Breast and lung cancer are predominant among metastases in the pituitary region followed by prostate and renal cancer [14].

Symptoms and endocrinological findings: It is important to differentiate from pituitary adenomas since metastases require rapid therapy. About half of the patients presenting with pituitary metastasis have a history of malignoma. Eye muscle paresis up to ophthalmoplegia are characteristic of malignomas in the sellar region. Other frequent complaints are retroorbital pain and visual impairment. In a literature review, the incidence of diabetes insipidus was 33% [14]. Diabetes insipidus is an important endocrinological hint as it points to a pituitary lesion other than a pituitary adenoma. Anterior pituitary insufficiency was found in 40% of the patients [14].

Neuroradiological imaging: MRI usually shows strong, homogeneous contrast enhancement. Other than in pituitary adenomas, pituitary metastases often show tumour expansion along the hypophyseal stalk. Parasellar extension into the cavernous sinus is frequently encountered. Osteodestructive growth is an important differential-diagnostic criterion indicating a malignant tumour.

Therapy: The main indications for surgery are relief of visual deficits and pain, confirmation of diagnosis, and removal of the tumour mass if considered beneficial for the overall outcome. The transsphenoidal approach is most often used [15]. Usually, the indication is given for adjuvant radiation therapy after surgical treatment and confirmation of diagnosis [15]. Administration of

chemotherapy or targeted therapy depends on the underlying malignant disease.

Outcome: While ophthalmological symptoms are likely to improve after surgical decompression, endocrinological deficits are usually not reversible. The overall prognosis for patients with pituitary metastasis is poor. In the individual case, however, it decisively depends on the origin and type of malignoma and the stage of disease.

Clivus Chordomas

Chordomas arise from persisting remnants of the notochord and consist of so-called physaliphorous tumour cells (see online Figure 2.4.3.7). They occur along the neuraxis. The clival region is the second most frequent location after the sacral region [16]. Clivus chordomas (CC) may expand toward the pituitary fossa and suprasellar toward the pituitary stalk and hypothalamus.

Symptoms and endocrinological findings: The patients mean age is 40–50 years [16]. The main symptom of chordoma in the upper clivus area is a one- or two-sided abducens nerve palsy as the nerve runs in Dorello's canal in proximity to the clivus. Hypothalamo-hypophyseal endocrinological deficits are relatively rare (Figures 2.4.3.1 and 2.4.3.2).

Neuroradiological imaging: On MRI, CC are commonly hyperintense on T2-weighted images and enhance inhomogeneously after contrast administration. CC primarily grow in the bone with osteodestructive character. Expansive growth with convex arching of the clivus dura toward the brain stem and pons cerebri is typical.

Therapy and outcome: The primary treatment is surgical. A meta-analysis showed gross total resection (GTR) in 39.9% of CC [16]. In CC near the midline, resection is initially by extended, endoscopic, or microscopic TSS. CC are often soft tumours facilitating resection. Depending on the expansion, other skull base approaches or combined procedures may be necessary. CC are characterized by a high tendency to local recurrence. Metastases are relatively rare, but the risk increases with advanced disease. Radiotherapy is effective and is used as adjuvant therapy. Radiation with heavy particles, such as proton or carbon ion radiation, is preferred [17]. CC are not responsive to cytotoxic chemotherapy. It has recently been shown that patients with advanced CC can benefit from novel targeted therapy. These include tyrosine kinase inhibitors or epidermal growth factor receptor inhibitors. Five-year progression-free survival (PFS) is approximately 50% and 5-year overall survival (OS) is 75% [16].

Petroclival Chondrosarcomas

Petroclival chondrosarcomas (PCS) arise from primitive mesenchymal cells of the chondral matrix originating from the petroclival synchondrosis and can extend to the pituitary fossa.

Symptoms: Similar to CC, patients typically present with cranial nerve palsies among which diplopia due to abducens nerve palsy prevails. Headache is another common symptom.

Therapy: PCS are typically slow-growing with locally invasive behaviour. Initial observation is an option for selected patients [18]. The mainstay of primary therapy is surgical resection. Because of the common eccentric growth, TSS is used less frequently than in CC. Various transcranial approaches have been used depending on the precise location [18]. A good chance of postoperative recovery of abducens nerve palsy exists [18]. Radiation for PCS has been shown to be effective and proton or photon beam radiation has commonly been used [18]. It can be used as adjuvant therapy following initial surgery or can be withheld until recurrence occurs [18].

Outcome: In a large series of skull base chondrosarcomas treated by surgery and consecutive fractionated radiation therapy, the 5- and 10-year PFS was 99% and 98%, respectively [19].

Optico-Hypothalamic Gliomas

Low-grade optic pathway gliomas (OPG) account for approximately 5% of all brain tumours in children and are frequently associated with neurofibromatosis type 1 (NF-1). Gliomas with posterior extension and hypothalamic involvement are named optico-hypothalamic gliomas (OHG).

Symptoms: 20% of children with NF-1 harbour an OPG which is frequently an incidental finding during neuroradiological work-up. In sporadic cases, unsystematic visual impairment is in the foreground.

Endocrinological findings: Preoperative differentiation of OHG from craniopharyngiomas may be difficult. Contrary to craniopharyngiomas, hypopituitarism and diabetes insipidus are rarely seen preoperatively [20] (Figures 2.4.3.1 and 2.4.3.2). In OHG, hypothalamic syndrome occurs in about 20% of the patients. Cachexia prevails among hypothalamic disorders [20].

Neuroradiological imaging: Intrinsic growth within the optic system should be watched for on MRI (Figure 2.4.3.8). Sometimes the tumour has already attained gigantic size at the time of diagnosis and hydrocephalus secondary to Foramen Monroi occlusion may occur. The numerically dominant pilocytic astrocytomas show both cystic portions and solid portions with areas of high contrast uptake.

Therapy: The attitude is most commonly conservative with observation and therapy withheld if tumour size and vision are stable. Spontaneous remissions have been described.

Chemotherapy is currently the predominant treatment modality for OPG [21], and carboplatin and vincristine are mostly used. Surgical tumour debulking has to be considered in large and progressive OPG with exophytic growth.

Radiotherapy is often used as second-line treatment. In very young patients, radiotherapy is avoided where possible due to the adverse long-term sequelae on the developing brain including neuroendocrine deficits, neurodevelopmental delay, and cognitive impairment [21].

Outcome: Sporadic cases of OPG have an inferior prognosis compared to OPG in NF-1. A 10-year OS of patients with OPG of 94% has been reported [22]. Survival rates are inferior if the optic chiasm and the hypothalamus are involved. The rare malignant OHG are an entity of adulthood.

Suprasellar (Hypothalamic) Germinomas

Intracranial germinomas arise from extragonadal primordial germ cells and account for approximately 70% of central nervous system

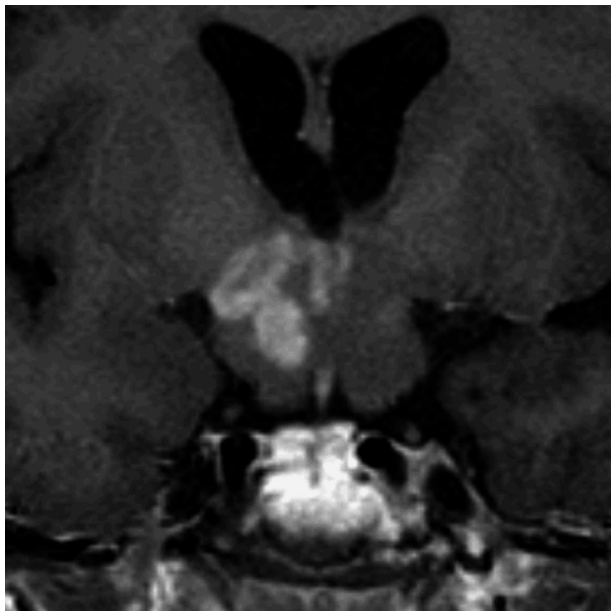

Figure 2.4.3.8 Optico-hypothalamic glioma. The coronal T_1-weighted MRI with contrast shows the intrinsic growth of the glioma within the optic system and hypothalamus.

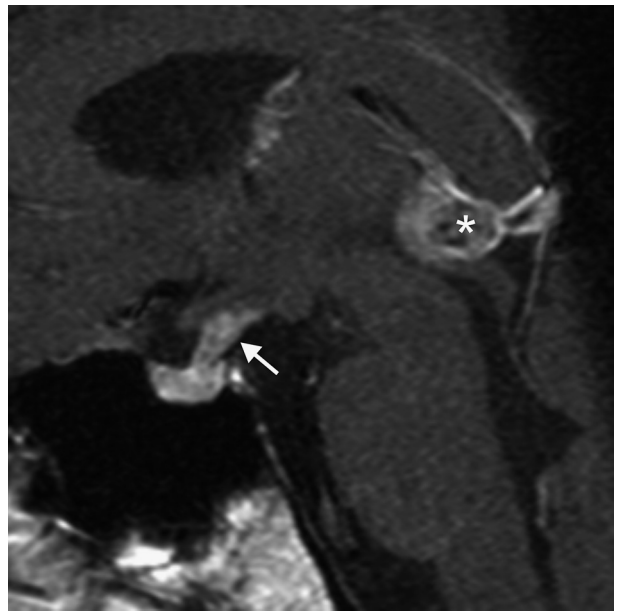

Figure 2.4.3.9 Suprasellar germinoma. The sagittal T_1-weighted MRI with contrast demonstrates the suprasellar germinoma at the pituitary stalk (arrow). A second manifestation is shown in the pineal region (asterisk).

germ cell tumours (CNS-GCT). While most germinomas are located in the pineal region, 10–20% grow in the suprasellar region.

Symptoms and endocrinological findings: The triad of anterior pituitary insufficiency, diabetes insipidus and visual compromise is a characteristic finding in suprasellar germinomas [23]. Often, panhypopituitarism is present. Diabetes insipidus with no imaging proof of a lesion may be evidence of a germinoma in status nascendi and requires close-meshed MRI control examinations.

Neuroradiological imaging: MRI reveals a tumour with marked contrast uptake in the area of the pituitary stalk and infundibulum. In some cases, a second lesion is found in the area of the pineal gland and raises strong suspicion for the diagnosis of a germinoma (Figure 2.4.3.9).

Further diagnostics: The differential-diagnostic delineation from other lesions with contrast uptake in the area of the pituitary stalk, such as infundibulo-hypophysitis, Langerhans cell histiocytosis, or metastases is often not possible by means of MRI. A subtle CSF analysis with examination for tumour cells, inflammatory cells, and tumour markers is demanded in such cases. All patients with suspected CNS-GCT should have the tumour markers α-fetoprotein (AFP) and ß subunit of human chorionic gonadotropin (ß-HCG) measured in CSF and serum [24]. Proof of α-fetoprotein and ß-HCG indicates the presence of a non-germinomatous CNS-GCT. Further tumour markers including placental alkaline phosphatase (PLAP) and soluble c-Kipt can be used to characterize CNS-GCT.

Therapy and outcome: Histo-pathological confirmation of the diagnosis by biopsy is obligatory in patients with suspected suprasellar germinoma. Radical operation is not justified in light of sensitivity to radiotherapy and chemotherapy. Localized intracranial germinomas are treated with whole-ventricle radiotherapy plus a boost to the tumour region [24]. Neoadjuvant chemotherapy followed by radiotherapy is another accepted therapeutic concept [24, 25] and allows a reduction of the radiation dose. Five-year survival rates exceeding 90% have been shown for intracranial germinomas.

In contrast, 5-year survival rates of non-germinomatous CNS-GCT is only 44%. However, they are extremely rare in the pituitary region.

Hypothalamic Hamartomas

Hypothalamic hamartoma (HH) is a non-neoplastic, malformative mass which consists of atypically differentiated glial and neural tissue.

Symptoms: HH usually become symptomatic in early childhood either because of precocious puberty or because of gelastic ('laughing') seizures [26]. The laughing seizures constitute a specific epileptic disorder (so-called **gelastic epilepsy**), which is pathognomonic for the presence of a HH. Gelastic epilepsy is pharmaco-resistant and leads to secondary epileptogenesis with additional types of seizures. In addition, cognitive impairment and behavioural disturbances ranging up to serious psychiatric symptoms occur.

Neuroradiological imaging: MRI reveals a lesion without contrast uptake in the area of the tuber cinereum or the mamillary bodies, which appears isointense to grey matter on T1-weighted images. Pediculated and small hamartomas lead more often to precocious puberty, while broad-based and large hamartomas with intrahypothalamic expansion and involvement of the third ventricle more often elicit gelastic epilepsy [26].

Therapy of precocious puberty: Precocious puberty is usually treated these days with gonadotropin-releasing hormone (GnRH) analogues. The outcome in terms of fertility and final height is favourable.

Therapy of epilepsy: Pharmaco-resistant epilepsy can be treated surgically by transcranial resection or disconnecting of the HH.

From 15% to 67% of the patients have been reported to be seizure-free postoperatively. Postoperative endocrinological and neurological deficits may occur.

Endoscopic disconnection after insertion of the endoscope via the foramen of Monro is used especially for HH with expansion into the third ventricle [27]. Rates of seizure freedom of 50% or greater have been reported in larger series.

Single-session radiosurgery is especially suited for the treatment of small and medium-sized hamartomas. In a prospective trial on Gamma Knife radiosurgery in 48 patients, 39.6% became seizure free (Engel class I) and 29.2% experienced worthwhile improvement (Engel class 2) [28].

Further treatment options are interstitial radiotherapy (brachytherapy), radiofrequency thermocoagulation, and laser thermocoagulation.

Gangliocytomas

Gangliocytomas consist of neural cells. In addition to gangliocytomas in the brain, gangliocytomas are also observed in the hypophysis. The precise aetiology has not finally been uncovered. 65% of sellar gangliocytomas are associated with adjacent pituitary adenomas which are mostly hormone-secreting (Figure 2.4.3.10). Associated growth hormone-secreting pituitary adenomas, leading to acromegaly, prevail [29]. The mainstay of therapy is TSS. A review of the literature found a 63% chance to normalize the associated hypersecretory endocrinopathy by surgery [29].

Tumours of the Posterior Pituitary

Granular cell tumour of the sellar region, pituicytoma, and spindle cell oncocytoma represent a distinct group of low-grade tumours (WHO grade I) arising from pituicytes, specialized glial cells in the infundibulum and neurohypophysis. Expression of TTF-1 which is also found in non-tumorous pituicytes is a clue to the diagnosis of a pituicyte-derived tumour [30] (see online Figure 2.4.3.11). Presumably, they represent three morphological variants of a single entity [30]. Granular cell tumours are more common than pituicytomas. Spindle cell oncocytomas are least frequent [31]. In tumours of the posterior pituitary, the preoperative diagnosis of a pituitary adenoma is a frequent misinterpretation.

Symptoms and endocrinological findings: Visual disturbances are the predominant presenting symptoms for all three types [31]. Partial hypopituitarism is present in one-third of patients with granular cell tumours and one-half of patients with pituicytomas at the time of diagnosis [32]. Panhypopituitarism is particularly frequent in spindle cell oncocytomas. Diabetes insipidus is surprisingly rare despite the infundibular or posterior lobe origin.

Neuroradiological imaging: Strong contrast enhancement is a frequent MRI finding. Purely intrasellar location is only found in pituicytomas. Intrasellar und suprasellar location can be observed in all three entities (Figure 2.4.3.12). Purely suprasellar location is common in granular cell tumours and is found in about 40% of pituicytomas [31, 33]. Spindle cell oncocytomas tend to show infiltrative growth impairing differentiation from the pituitary gland.

Therapy and outcome: TSS is mostly performed. However, transcranial surgery is indicated for purely suprasellar tumours. Tumours of the posterior pituitary tend to be highly vascular impeding radical removal. Massive intraoperative bleeding has been repeatedly reported.

Symptomatic granular cell tumours can progress rapidly and require timely surgical treatment. Gross total removal of pituicytoma has been reported in approximately 50% of the cases and is mostly curative [33]. New endocrine deficit is the most frequent inadvertent sequela of surgery for pituicytomas [33].

Radiotherapy appears to be beneficial in cases with less than total resection [32]. In pituicytomas, the overall outcome is favourable. The outcome in granular cell tumours is inferior. Death

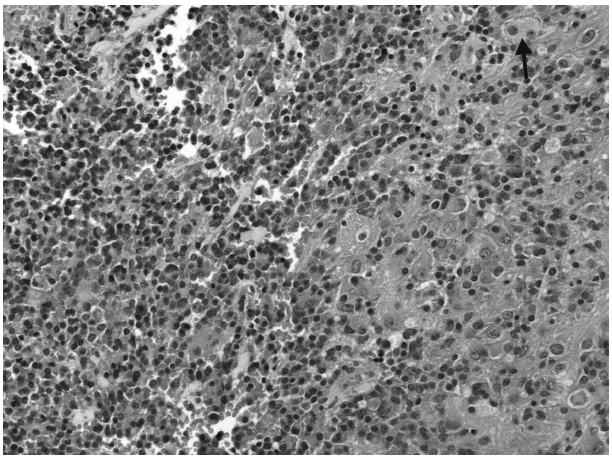

Figure 2.4.3.10 Pituitary gangliocytoma and adenoma. Histology shows the border zone between distinct parts of two tumours. On the right, the tumour consists of mature ganglion cells including single binucleated ganglion cell (arrow). On the left, small epithelial cells are seen as part of a pituitary adenoma. H&E-staining. Original magnification ×200.

related to the tumour has been reported in 9% of cases following surgery without radiotherapy and in 16% following surgery with radiotherapy [32]. Unfavourable clinical outcome has also been described in some spindle cell oncocytomas.

Aneurysms

After passing the skull base, the carotid artery has a close proximity to the pituitary over a long distance. Intrasellar (infradiaphragmatic) aneurysms usually originate from the clinoid or cavernous segment of the carotid artery. Suprasellar aneurysms originate from the distal carotid artery after it has entered the intradural space or from the anterior communicating artery [34].

Symptoms: Headache is a frequent complaint of patients with unruptured aneurysms of the perisellar region [34]. Visual deficits are common in supradiaphragmatic aneurysms. Anterior pituitary dysfunction was found in 60% of infradiaphragmatic, intrasellar aneurysms [34]. Diabetes insipidus was not observed.

Neuroradiological imaging: On MRI, aneurysms can be recognized by their direct relationship to the vessels and by their flow signal (see online Figure 2.4.3.13). It is extremely important to recognize the neuroradiological signs, since aneurysms may imitate pituitary tumours. The transnasal operation of a wrongly interpreted aneurysm could have fatal consequences. If an aneurysm is suspected, digital subtraction angiography (DSA) is the gold standard to confirm the diagnosis (see online Figure 2.4.3.13). CT angiography and MR angiography are increasingly used alternative non-invasive methods.

Therapy and outcome: Symptomatic or growing extradural, infradiaphragmatic aneurysms of the carotid artery are usually treated by endovascular coil-embolization (often requiring additional stenting of the parent vessel) or by flow-diversion stents [35]. Supradiaphragmatic, intracranial carotid artery aneurysms require treatment because of the risk of spontaneous aneurysm rupture causing potentially fatal subarachnoid haemorrhage (SAH). Occlusion of the intracranial aneurysm is usually performed by endovascular coil-embolization or by microsurgical aneurysm clipping. Many patients are only diagnosed when SAH has occurred and require emergency treatment.

Beyond the possible deleterious neurological sequelae, SAH can cause endocrinological deficits. A review on pituitary function in the chronic stage after SAH showed a high variability of hypopituitarism between 0% and 55% [36]. Single pituitary hormone deficiency is more frequent than deficiency of multiple hormonal axes. The proximity of the ruptured aneurysm to the hypothalamus and pituitary region increases the risk for developing hypopituitarism.

Haemangiomas

In the perisellar region, there are two rare but well-defined entities of haemangiomas, namely *cavernous sinus haemangiomas* and *cavernous haemangiomas of the optic chiasm*.

Cavernous Sinus Haemangiomas

Cavernous sinus haemangiomas (CSH) are vascular neoplasms that account for 2% of cavernous sinus tumours.

Figure 2.4.3.14 Cavernous haemangioma of the cavernous sinus with lateral expansion toward the temporal lobe and medial expansion with displacement of the pituitary gland (arrow). The lesion appears strongly hyperintense on the axial T_2-weighted image.

Symptoms: Clinically, cranial neuropathies, visual compromise, and headaches are in the foreground [32].

Neuroradiological findings: CSH appear strongly hyperintense on T_2-weighted MRI (Figure 2.4.3.14), and show marked contrast uptake.

Therapy and outcome: In contemporary surgical series, resection of CSH was mostly performed by a transcranial, extradural approach with total resection in more than 80% of the cases [37]. A high blood loss must be anticipated in these highly vascular lesions. A high efficacy and safety have recently been shown with primary radiosurgery or fractionated radiotherapy for CSH. A 100% control rate has been reported with frequent postprocedural recovery of cranial neuropathy [38]. The recent literature indicates that radiotherapy is superior to surgery in the treatment of CSH. No valid data on endocrinological outcome with the different treatment modalities exist.

Cavernous Haemangiomas of the Optic Chiasm

Cavernous haemangiomas of the optic chiasm are vascular malformations composed of closely apposed dilated vascular channels. They are a rare differential diagnosis in suprasellar tumours. Clinically, acute or subacute visual impairment due to acute bleeding occurred in most of the cases described. MRI may reveal bleeding into the optic chiasm, and a berry-shaped 'tumour' arising in the optic chiasm is found. Therapeutically, evacuation of a haematoma and resection of the lesion is performed via a transcranial approach.

2.4.4 Lymphocytic Hypophysitis and other Inflammatory Conditions of the Pituitary

Mark E. Molitch and Jelena Kravarusic

Introduction

Inflammatory conditions of the pituitary are far less common than pituitary adenomas. However, their incidence may be rising due to increased recognition based on symptomatology, laboratory tests, better radiology methods and new immune therapies for cancer whose immune-related adverse effects (IRAE) include hypophysitis.

Although the most common of these, lymphocytic hypophysitis, is limited to the pituitary and pituitary stalk, many of the other lesions are usually part of a systemic process. Nonetheless, even these lesions, such as Langerhans' cell histiocytosis, sarcoidosis and newly recognized immunoglobulin G4-related hypophysitis (IgG4-RH) sometimes are limited to the central nervous system (CNS) and, rarely, present as isolated lesions of the hypothalamic/pituitary area. When lesions are located in the base of the hypothalamus or in the stalk, they commonly present with a combination of diabetes insipidus (DI) and hypopituitarism. In some cases, hypothalamic infiltration may be more widespread, affecting a variety of additional hypothalamic functions, such as satiety, sleep, and temperature regulation. These inflammatory lesions tend to be progressively destructive, resulting ultimately in fibrosis, but the rate of progression is highly variable. When hypopituitarism or DI occur, they rarely recover even if the underlying process is directly treated. Thus, these lesions present more with endocrine hypofunction than with mass effects, although in early stages lymphocytic hypophysitis, may well present with mass effects to the point where it can be confused with a pituitary adenoma.

Although hypophysitis is usually thought of as a primary process, it may occur secondarily in relation to infection (viral, bacterial, fungal, tuberculosis, syphilis) or other processes such as Langerhans cell histiocytosis, sarcoidosis, Wegener's granulomatosis, Crohn-Takayasu disease and ruptured cysts [1, 2–4] and increasingly recognized since 2004, as a part of immunoglobulin G4-related disease (IgG4RD).

Lymphocytic Hypophysitis

Lymphocytic hypophysitis is associated with hypopituitarism and a sellar mass. It is most commonly seen in the peri- or postpartum period but it has also been reported after menopause [1]. The diagnosis may be challenging, as the clinical and radiographic distinction from pituitary adenomas and other sellar masses is often not obvious. The disease is presumably autoimmune in aetiology, although there has never been a specific target antigen identified [1].

Epidemiology

About 500 patients with primary lymphocytic hypophysitis have been described in the literature [5]. It affects women more frequently than men, with a reported ratio of about 5:1; however, the female:male ratio is decreasing in recent years as more men are reported. The mean age at diagnosis is approximately 35 years for women and 45 years for men [5]. Of the 57% of patients developing the disorder in association with pregnancy, most occur during the last month of pregnancy or during the first 2 months postpartum [1, 2]. It has rarely been described in children [6].

Classification and Pathology

Anatomically, the most common form is lymphocytic adenohypophysitis, where anterior pituitary cells and hormones are affected but posterior pituitary involvement is absent or minimal. With the much less common lymphocytic infundibuloneurohypophysitis, the posterior pituitary is primarily involved, causing DI and anterior pituitary function is usually preserved [1, 3, 4]. Lymphocytic infundibulopanhypophysitis is even more rare, with lymphocytic infiltration and destruction present in both the anterior and posterior pituitary. These patients present with a combination of DI and anterior pituitary deficiency [1, 3, 4].

Pathologically, primary hypophysitis has been described in three forms: lymphocytic, granulomatous, and xanthomatous. Lymphocytic hypophysitis is characterized by a dense lymphocytic infiltration of the anterior pituitary with destruction of the normal pituitary architecture and replacement with fibrosis [1, 3, 4, 7] (Figure 2.4.4.1). The lymphocytes are predominantly cytotoxic T lymphocyte (CD8+) cells, suggesting that T-cell-mediated cytotoxicity is critical in the pathogenesis of the disorder [8].

Pathogenesis

The aetiology of lymphocytic hypophysitis is unknown but it has been speculated to have an autoimmune basis [1, 3, 4, 8]. Nearly 30% of patients have a history of coexisting autoimmune diseases such as Hashimoto's thyroiditis, Addison's disease, type 1 diabetes and pernicious anaemia [1, 3, 4, 7], and the condition is now considered a component of the type 1 polyglandular autoimmune syndrome [1, 3, 4]. In one recent prospective study antinuclear and antiextractable nuclear antigens (Ro, La, Sm, RNP, Scl-70, and Jo1) were detected; thus, perhaps all patients with autoimmune hypophysitis should be evaluated for other organ specific and nonspecific antibodies [9].

Although antipituitary antibodies have been demonstrated in some patients with lymphocytic hypophysitis, their specificity for

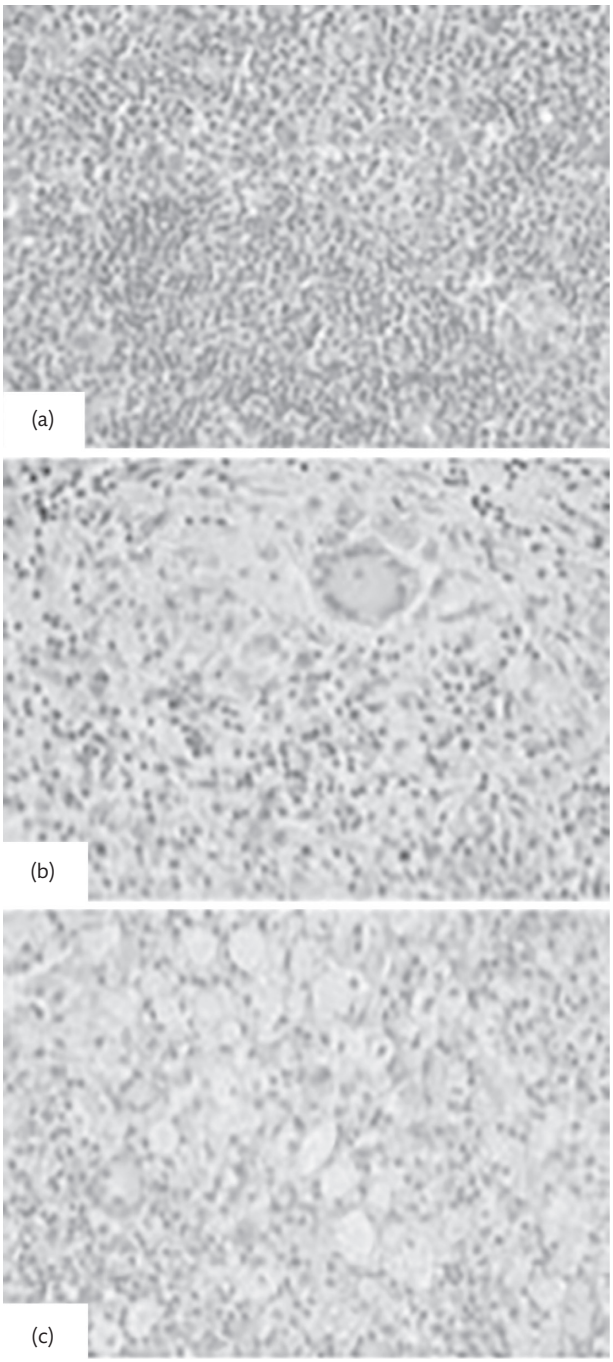

Figure 2.4.4.1 Histologic subtypes of primary hypophysitis. (a) Lymphocytic hypophysitis. Note massive lymphocytic infiltration of pituitary with scattered islands of preserved pituitary cells. (b) Idiopathic granulomatous hypophysitis. Characteristic multinucleated giant cells and granuloma surrounded by fibrosis, sparse infiltration of plasma cells. (c) Xanthomatous hypophysitis. Predominance of foamy macrophages, a few lymphocytes, and single plasma cells (haematoxylin and eosin, original magnification ×40).

hypophysitis is poor, as they are also present in patients with non-autoimmune pituitary disease, other non-pituitary autoimmune disease [10, 11] and in normal postpartum women who do not develop hypophysitis. The pathogenic pituitary autoantigen(s) remain to be elucidated, although several candidates have been proposed [5].

Presentation

When associated with pregnancy, lymphocytic hypophysitis typically presents in the third trimester of pregnancy or within 1 year postpartum, with symptoms usually related to a pituitary mass (headaches or visual symptoms) or hypopituitarism. The disorder often comes to attention due to failure of either lactation or menses following delivery [1, 2–4, 12]. Neurohypophyseal involvement, manifesting as DI, occurs in 15% of cases [1, 2–4, 7, 12]. Other rare presentations of lymphocytic hypophysitis include meningeal irritation, diplopia due to cavernous sinus involvement and occlusion of the internal carotid arteries.

Symptoms resulting from partial or panhypopituitarism occur in approximately 80% of cases, and multiple deficiencies are found in approximately 75% of cases [1, 2–4, 8, 12] as illustrated in the Table 2.4.4.1.

There is an inexplicable unique predilection for the corticotrophs and thyrotrophs to be affected while the gonadotrophs may be spared. Prolactin (PRL) levels range from unmeasurable to elevated; low levels are attributable to destruction of the lactotrophs, while hyperprolactinaemia is expected during pregnancy and the early postpartum period. However, elevated prolactin levels have been reported in cases of lymphocytic hypophysitis in men and non-pregnant women [7, 13, 14], which is likely secondary to compression of the pituitary stalk.

Radiology

Magnetic resonance imaging (MRI) in hypophysitis commonly shows an enlarged pituitary gland, often with suprasellar extension and stalk thickening [1, 2–4] (Figure 2.4.4.2).

The gland is generally symmetrically enlarged and administration of gadolinium homogeneously enhances the gland.

Table 2.4.4.1 Lymphocytic hypophysitis: clinical presentation

Symptoms	Frequency
Mass effects	
Headache	60%
Visual disturbance	40%
Bitemporal hemianopsia	32%
Impaired visual acuity	16%
Diplopia	<5%
Endocrine dysfunction	80%
Adrenal insufficiency	65%
Hypothyroidism	60%
Growth hormone deficiency	54%
Hypogonadism	40%
Hyperprolactinaemia	30%
Diabetes insipidus	15%

Data abstracted from Beressi *et al.* [12] based on analysis of 145 cases of clinically suspected and biopsy-proven lymphocytic hypophysitis.

Figure 2.4.4.2 Lymphocytic hypophysitis on coronal section in T1 phase. The pituitary gland is diffusely and symmetrically enlarged extending into the suprasellar region. The floor of the sella is intact.

In contrast, in adenomas gadolinium enhances the gland more focally as described in the Table 2.4.4.2. In lymphocytic hypophysitis, the pituitary displays a relative low signal on T_1- and a relatively high signal on T_2-weighted images. By comparison, in macroadenomas a low signal on T_1-weighted images is uncommon, but a high signal on T_2-weighted images is occasionally seen. Often, the dura mater adjacent to the mass in lymphocytic hypophysitis shows a unique, marked contrast enhancement referred to as a 'dural tail'. In late stages, these MRI findings may be absent due to shrinkage of the mass with resolution of the inflammatory process, and fibrotic changes and an empty sella may be seen [14, 15].

Diagnosis

Lymphocytic hypophysitis should be considered in the differential diagnosis of pituitary masses and/or hypopituitarism in females who are pregnant or in the early postpartum period. This is especially true in cases associated with other autoimmune diseases or unusual patterns of hormone deficiencies. In the past many individuals with postpartum hypopituitarism who lacked a history of hypovolemic shock were inadvertently labelled as having Sheehan's syndrome when, in fact, they had hypophysitis.

A definitive diagnosis of lymphocytic hypophysitis requires tissue biopsy. However, it may be possible to make a presumptive clinical diagnosis in patients who meet the following criteria: (1) a history of gestational or postpartum hypopituitarism, especially after a delivery uncomplicated by haemorrhage or hypotension; (2) a contrast enhancing sellar mass with imaging features characteristic of lymphocytic hypophysitis; (3) a pattern of pituitary hormone deficiency with early loss of adrenocorticotrophic hormone (ACTH) and thyroid stimulating hormone (TSH) unlike that typically found with macroadenomas (i.e. sequential loss of growth hormone [GH], luteinizing hormone [LH]/follicle-stimulating hormone [FSH], ACTH, and TSH); (4) relatively rapid development of hypopituitarism in contrast to the expected slow development of hypopituitarism that would be expected with an adenoma; and (5) a degree of pituitary failure disproportionate to the size of the mass. Nevertheless, biopsy may be required in situations in which a distinction cannot be made between lymphocytic hypophysitis and a non-functioning macroadenoma or prolactinoma and when neurologic signs develop.

Lymphocytic Infundibuloneurohypophysitis

Lymphocytic hypophysitis and infundibuloneurohypophysitis likely represent distinctly separate pathologic entities, as the latter tends to occur in older patients and is less likely to be associated with pregnancy [1, 2–4]. Lymphocytic infundibuloneurohypophysitis causes central DI and spares the anterior pituitary as a result of an inflammatory process confined to the stalk and posterior pituitary [16]. The radiologic features are generally more clearly delineated: thickening of the pituitary stalk or neurohypophysis and homogeneous enhancement of the pituitary stalk or neurohypophysis after the administration of contrast material [17].

Table 2.4.4.2 MRI characteristics of lesions of the hypothalamus/pituitary

Type of lesion	Signal intensity on T_1	Signal intensity on T_2	Contrast enhancement	Pattern of enhancement	Shape	Dural enhancement
Hypophysitis	Relatively low	High	Marked	Homogeneous	Symmetric	Common
Histiocytosis	Isointense	Hyperintense	Moderate	Non-specific	Stalk thickening	Common
Sarcoidosis	Isointense	Hyperintense	Moderate	Non-specific	Stalk thickening	Leptomeningae
Wegener's granulomatosis	Isointense	Hyperintense	Intense	Homogenous	Superior infundibulum thickening	Common, linear
Immune checkpoint related	Isointense to hypointense	Hyperintense	Marked	Non-specific	Nodular stalk thickening	Common
IgG4 related	Iso to hypointense	Hyperintense	Marked	Non-specific	Stalk thickening	Not reported
Pituitary Adenoma	Isointense	Usually isointense	Moderate	Focal	Dumbbell	Rare

Data abstracted from [3, 15, 16, 31, 39, 42, 43].

Management

The natural history of lymphocytic hypophysitis is variable and unpredictable. Typically, the pituitary initially becomes inflamed, oedematous, and enlarged, and the patient develops symptoms secondary to mass effects. Progressive fibrosis develops, causing destruction of the parenchyma leading to hypopituitarism. In some cases, the course is aggressive and neurologic and hormonal deficits progress rapidly [1, 2–4, 7]. However, cases of spontaneous partial or full recovery of pituitary function, as well as resolution of pituitary masses in the absence of any intervention, have been well documented [18–20]. Because the natural history of lymphocytic hypophysitis is so variable, appropriate management remains controversial.

Controlled therapeutic trials are not feasible due to the rarity of hypophysitis, an inability to make definitive diagnosis without histologic proof, and the considerable variability in the natural history of the disorder. Until recently, preoperative suspicion of the diagnosis was rare due to under-recognition, and the traditional diagnostic and therapeutic approach involved transsphenoidal biopsy, exploration, and/or pituitary resection. Consequently, cases illustrating only transient compressive effects and endocrine dysfunction support the concept of conservative management. With a greater knowledge of the course of lymphocytic hypophysitis and the ability to make a presumptive diagnosis in highly suggestive cases, it is possible to avoid routine neurosurgical exploration in many cases.

Corticosteroid therapy has been advocated as a means of attenuating inflammation and, in some patients, has been associated with return of pituitary function and reduction of the mass [21, 22]. Conversely, cases have also been reported in which lymphocytic hypophysitis failed to improve with glucocorticoid therapy [7, 23]. There are also a few documented cases of improvement in symptoms with administration of corticosteroids followed by a relapse when therapy was discontinued [24]. It is unclear, however, whether improvement in the clinical course is directly attributable to corticosteroid treatment or simply reflects the natural course of the disease [18–20]. Given the uncertainty regarding the efficacy of corticosteroid treatment and its known adverse effects, such therapy does not seem justified for most patients.

Patients with a presumed diagnosis of lymphocytic hypophysitis should be observed closely and undergo serial visual field examinations or an MRI if they are managed medically. Surgical decompression of the pituitary mass may be required if the patient fails conservative therapy, as demonstrated by progressive radiologic or neurologic deterioration or by signs of optic nerve compression. However, in this situation, some would argue for a short course of steroids [1, 2–4, 7]. The optimal surgical strategy involves only partial resection of the mass to decompress the surrounding structures via a transsphenoidal approach rather than an attempt at complete resection, because surgery rarely improves endocrine dysfunction. All patients with lymphocytic hypophysitis require appropriate replacement therapy for deficient hormones. Long-term follow-up is mandatory to monitor for the development of other hormonal deficits. Because hypopituitarism is temporary in a subset of patients, a careful attempt should be made to withdraw hormone replacement after resolution of the inflammatory stage if progression to fibrosis does not result in irreversible hypopituitarism.

Langerhans Cell Histiocytosis

Langerhans cell histiocytosis (LCH) is a rare disorder characterized by clonal proliferation of abnormal dendritic antigen-presenting histiocytes, known as Langerhans cells, with an accompanying infiltrate of lymphocytes, eosinophils, and neutrophils resulting in the destruction of a variety of tissues. LCH is also regarded as an inflammatory disease because an altered expression of cytokines and cellular adhesion molecules important for the migration and homing of Langerhans cells has been demonstrated [25, 26].

Epidemiology

LCH is usually considered to be a disease of childhood, with a peak incidence at the ages of 1 to 3 years [27]. Overall, the incidence is 3–5 cases per million per year, with a male to female ratio of 2:1 [27]. In adults, the mean age at diagnosis is 33 years and it is seen even more rarely, the estimated prevalence being 1–2 cases per million [28].

Presentation

In adults, LCH has a predilection for the hypothalamus and pituitary. When only patients with multisystem disease are included, the prevalence of DI can be as high as 40% and DI is considered to be the most common endocrine disease-related permanent consequence [29]. DI can also be the presenting feature, predating the diagnosis of LCH. Established DI is generally permanent and does not respond to any disease-modifying treatment; hence the only treatment is desmopressin [30]. DI associated with structural abnormalities of the hypothalamus and pituitary often heralds the development of anterior pituitary hormone deficiencies and CNS involvement [31]. Anterior pituitary dysfunction is found in up to 20% of patients with LCH, and is almost always associated with DI [30, 32]. Once established, anterior pituitary deficiencies seem to be permanent and are not affected by any form of LCH disease-modifying treatment [31]. The most frequent anterior pituitary hormone deficiency is that of growth hormone, which is found in up to 42% of patients and generally diagnosed with a latency of 1 year from the diagnosis of DI. Deficiencies of LH/FSH are next most common, with a latency of 7 years from the diagnosis of DI [32]. Therefore, if a partial pituitary hormone deficiency is identified in a patient with LCH, regular monitoring for the remaining hormones is advised. In addition to pituitary involvement, up to 40% of patients with DI have hypothalamic infiltration which results in non-endocrine hypothalamic manifestations, including abnormal eating patterns, morbid obesity, and disturbances in social behaviour, temperature, sleep pattern, and thirst. DI may be particularly difficult to manage in patients with impaired memory.

Radiology

Patients with LCH and DI commonly demonstrate a loss of the hyperintense signal of the posterior pituitary on T_1-weighted images ('bright spot') on MRI [30]. Infundibular enlargement is present in up to 71% of patients at the time of diagnosis of DI [33] as illustrated in Figure 2.4.4.3 [34].

Hypothalamic mass lesions have been described in 8–18% of patients exhibiting one or more pituitary hormone deficiencies [33].

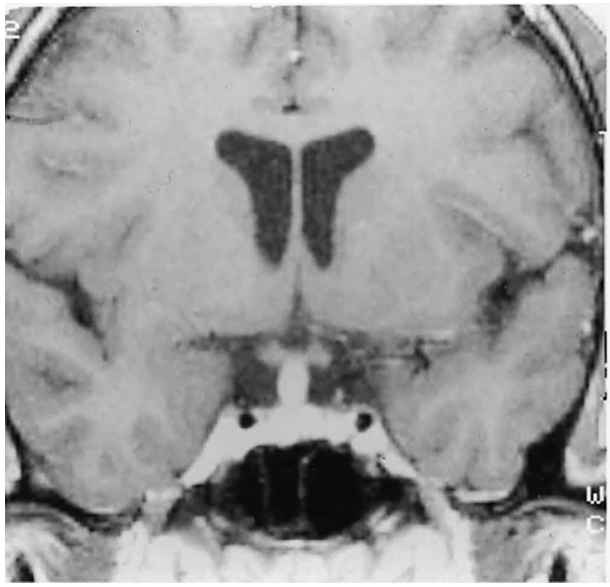

Figure 2.4.4.3 Thickening of pituitary stalk (arrow) due to biopsy-proven Langerhans cell histiocytosis.

Reproduced with permission from Purdy LP, Molitch ME (1998). Sudden onset of diabetes insipidus in an adolescent. *EndoTrends*, 5, 1–7.

The LCH lesions typically are isointense on T_1 images, hyperintense on T_2 images and enhance with gadolinium [33].

Diagnosis

In order to make the diagnosis of LCH, one must search for extracranial manifestations of LCH with a radiographic skeletal survey, skull series, chest X-ray, and bone scan so that these lesions can be biopsied. Osteolytic lesions due to LCH may be present in the jaw or mastoid, so radiographs of the jaw are a worthwhile part of the diagnostic evaluation. When biopsies of other tissues show LCH and the MRI and clinical picture are compatible, biopsy of the hypothalamic/stalk lesion is rarely necessary.

To establish a diagnosis according to the published criteria of the Histiocytosis Society, a tissue biopsy must either show presence of pathognomonic Birbeck granules on electron microscopy or stain positive for CD1a [35]. Birbeck granules are pentalaminar cell inclusions that sometimes have a 'tennis racquet' dilated terminal appearance [36]. Their exact function is unknown, but some studies implicate them in antigen processing.

Management

The course of LCH is often unpredictable, varying from spontaneous regression and resolution to rapid progression and death or repeated recurrence with a considerable risk of permanent sequelae. Patients with disease that is localized to one organ system, usually in the bone, skin, or lymph nodes, have a good prognosis, and need minimal or even no treatment. In contrast, multiple organ involvement carries a risk of a poor outcome, including 10–20% mortality and a 50% risk of life-impairing morbidity. Therefore, an early diagnosis and close follow-up is critical. The mainstays of treatment of LCH have been surgery and radiation over the years. However, vinblastine in combination with steroids is now the most frequently used initial therapy for multisystem disease [32]. Cladribine (2-chlorodeoxyadenosine) can be effective for adults with recurrent and/or disseminated disease [37].

Anterior and posterior pituitary hormonal deficits are replaced as necessary. As with other infiltrative diseases of the hypothalamus, the anterior pituitary hormone deficits may gradually appear. Therefore, periodic testing for many years and then treatment of new deficits may be necessary.

Sarcoidosis

The prevalence of CNS involvement in sarcoidosis is 5–15% and most of these patients are found to have non-caseating granulomas in the hypothalamo–pituitary region in addition to the leptomeninges and cranial nerves [38]. The most commonly found hormonal abnormality is DI (17–90% of patients), followed by hyperprolactinaemia (3–32%) [39]. Hypothalamic involvement may also cause obesity, somnolence with disruption of sleep cycle, alteration in the thirst centre and loss of short-term memory [40].

MRI usually shows pituitary stalk thickening and enhancement as well as pituitary enlargement. Periventricular lesions and leptomeningeal enhancement can be seen in sarcoidosis and this can help distinguish it from lymphocytic hypophysitis. Significant laboratory findings that may aid in diagnosis are elevated levels of serum and cerebrospinal fluid angiotensin converting enzyme (ACE). As with LCH, a search for other systemic tissue involvement is important, so that a biopsy can be obtained.

Management of sarcoidosis frequently involves the use of steroids, but recovery of anterior and posterior pituitary function usually does not occur [39]. Recently, cladribine was also found to reverse DI caused by sarcoidosis [41]. The hypothalamic/pituitary involvement may be gradual and progressive, so that periodic testing is necessary and hormonal deficits treated as they develop.

Granulomatosis with Polyangiitis (GPA, Formerly Known as Wegener's Granulomatosis)

Wegener's granulomatosis is a systemic vasculitis affecting small and medium sized vessels, most commonly in the respiratory tract and kidneys; the pituitary is involved in less than 1% of cases [42]. Involvement of the pituitary can occur via direct extension from nasal, paranasal, or orbital disease, from remote granulomatous involvement, or from vasculitis of the hypothalamus. Patients most frequently present with DI but hyperprolactinaemia and panhypopituitarism have also been reported [3].

The finding of high titres of antineutrophil cytoplasmic antibody (c-ANCA) can be diagnostic but in some cases biopsy of affected tissue is required. When there is hypothalamic/pituitary involvement, MRI reveals an enlarged pituitary with homogeneous enhancement, thickening and enhancement of the pituitary stalk, and enhancement of the optic chiasm [3, 43].

Wegener's granulomatosis is usually treated with glucocorticoids and/or cyclophosphamide. However, such treatment does not usually lead to reversal of the hypopituitarism. Similar to other infiltrative disease, the destruction may be gradual, necessitating repeated testing and treatment of hormonal deficits as they develop.

Immune Checkpoint Therapy-Related Hypophysitis

Ipilimumab is a monoclonal IgG1 antibody against CTLA4 (cytotoxic T lymphocyte antigen 4), an inhibitory molecule expressed on activated and regulatory T cells, ultimately dampening T cell activation. If CTLA4 is blocked, T cells remain active, and this effect is used in cancer destruction. Additionally, there are other immune checkpoint inhibitors, monoclonal antibodies antiprogrammed cell death protein 1 (PD-1) nivolumab and pembrolizumab and antiprogrammed cell death-ligand 1 (PD-L1) atezolizumab, durvalumab, and avelumab, which also cause IRAE, but notably less commonly hypophysitis.

IRAE hypophysitis due to ipilimumab given for therapy of metastatic melanoma was first reported in 2003 [44], and is now observed in approximately 10–15% of patients receiving agents targeting CTLA4 [45–47]. Hypophysitis is significantly less common following use of PD1 antibodies [48]. IRAE hypophysitis seems to favour older men; however, this observation is limited by epidemiology of cancers these medications are used to treat. Some reports show a higher incidence of hypophysitis in combination PD1 plus CTLA4 therapy [47] but others found no difference or a lower rate compared to ipilimumab alone [49].

Pathogenesis

The pathogenesis of cancer immune therapy-related hypophysitis is unclear. One hypothesis is that CTLA-4 blocking antibodies bind pituitary cells expressing CTLA4 antigen and cause hypophysitis through type IV (T-cell dependent) and type II (IgG dependent) immune mechanisms, as evidenced by finding macrophage infiltration, complement fixation, and lymphocyte activation [50]. Antibodies towards PD1 are from the IgG4 class, which cannot activate complement and are not effective mediators for antibody dependent cell mediated cell toxicity [6]. Interestingly, patients treated with PD1 and/or PDL1 IgG4 antibodies instead of IgG1 used in ipilimumab rarely developed pituitary damage [48]. Also, hypophysitis occurs less frequently in patients receiving tremelimumab, an IgG2 antibody which blocks CTLA4 [50].

Presentation

The clinical presentation is similar to other forms of hypophysitis, with a headache, less commonly with visual disturbances and DI and usually presents approximately 2–3 months after starting therapy.

Radiology

Radiological findings are not specific, and may show mild-to-moderate diffuse enlargement of the pituitary gland, with either homogeneous or heterogeneous enhancement after contrast administration on pituitary MRI [45, 51]. Radiological changes can precede the clinical diagnosis by several weeks [45]. Many case reports have highlighted the incidental detection of hypophysitis when positron emission tomography (PET) is used for surveillance. Importantly a normal MRI does not rule out hypophysitis and management should be based on clinical presentation and evaluation of pituitary hormone levels [52].

Management

Corticosteroids have been used for immune therapy-related hypophysitis treatment. High-dose steroids do not seem to improve outcome [53], but can be considered for critically ill patients, either due to hypophysitis or hypopituitarism, significant hyponatraemia, severe headache, or pituitary enlargement with mass effect on the optic chiasm. Hydrocortisone in doses 15–25 mg daily [48] can help with the headache and fatigue, treat adrenal insufficiency and still not prevent the patient from enrolment in a study protocol which may exclude patients treated with high-dose steroids due to their immunomodulatory effect [54].

The clinical response to cancer immunotherapy has been linked with development of IRAEs; in several studies a direct correlation was observed between relapse free survival and development of IRAEs [44, 45]. However, this observation may be biased against patients who don't survive long enough to be observed. This phenomenon needs further investigation, for its potential benefit in prognosis, if any, to be considered.

IGG4-Related Hypophysitis

IgG4-related disease (IgG4RD) is a systemic autoimmune disease characterized by inflammatory pseudotumour (IPT) infiltrates containing IgG4 rich-plasma cells, storiform (cartwheel or whirling pattern) fibrosis, obliterative vasculitis, and often but not always elevated IgG4 serum levels [55]. IgG4 is the least abundant of all IgG antibodies and is associated with several autoimmune and allergic diseases such as Mikulicz disease, retroperitoneal fibrosis, autoimmune pancreatitis, and Riedel thyroiditis [56, 57]. It is unclear what the role is of IgG4, as it is not found in normal pituitaries [58] and has a role in immune downregulation [59]. It has been postulated to possibly be a by-product of an exaggerated immune response [60].

Pathogenesis

Iwata *et al.* showed antipituitary antibodies in 5 out of 17 patients with IgG4-related hypophysitis (IgG4RH) (29%), and in none of the pituitaries of healthy controls. Antibodies were of the IgG1 subclass rather than IgG4 in all five cases, suggesting that IgG4 does not have a direct role in the pathogenesis of the hypophysitis [61].

The prevalence of IgG4RHs unknown, and it depends on the diagnostic criteria and mostly retrospective analyses. As this condition was not previously recognized, some cases previously classified as lymphocytic hypophysitis may have been IgG4RH. Bernreuther *et al.* used histological and immune staining to retrospectively analyse cases previously reported as primary hypophysitis and found that 12 of 29 (41.4%) fulfilled the criteria for IgG4RH [62].

Presentation

It is most commonly seen in older men, in contrast to lymphocytic hypophysitis, which is more common in younger women. Presenting symptoms can mimic any sellar mass with compressive symptoms: headache, visual disturbances, and hypopituitarism [63].

Diagnosis

In an effort to make a correct diagnosis and avoid an invasive tissue biopsy, diagnostic criteria have been proposed that don't require histopathology by Leporati *et al.* [64] and are as follows: (1) mononuclear cell infiltration of the pituitary gland, rich in lymphocytes

and plasma cells, with more than ten IgG4-positive cells per high-power field or IgG4-positive/IgG-positive cells > 40% on pituitary histopathology; (2) sellar mass and/or thickened pituitary stalk on MRI; (3) a biopsy proving the involvement in other organs (association with IgG4-positive lesions in other organs); (4) an increased serum IgG4 level (>140 mg/dl); and (5) a prompt shrinkage of the pituitary mass and symptom improvement with steroids. The diagnosis of IgG4-RH is established when any of the following is fulfilled: (1) or (2) and (3) or (2), (4) and (5). For this reason, these criteria have been widely accepted followed by an increase in reports of IgG4RH. Caution should be exercised in diagnosing IgG4RH solely based on histopathology of IgG4 rich infiltrate because this can be present in other inflammatory, autoimmune, infectious, and neoplastic conditions. FDG-PET scanning may be useful in characterizing systemic involvement of tissues.

Management

The mainstay in therapy of IgG4RH are glucocorticoids, which replace deficient cortisol and lower serum IgG4 levels. There is no consensus for the optimum dose and duration, Yuen *et al.* proposed prednisolone at a dose 0.6 mg/kg for 1 to 2 months and tapered at a rate of 5 mg per week. If the disease relapses after glucocorticoid therapy discontinuation, it can be resumed and addition of rituximab can be considered [58].

Other Rare Forms of Hypophysitis

Granulomas and multinucleated giant cells are not found in lymphocytic hypophysitis and, if observed, suggest an alternative diagnosis of granulomatous hypophysitis. This rare disorder has an incidence of 1/1 000 000. Granulomatous hypophysitis occurs in men and women with equal frequency and is not particularly associated with pregnancy. It may also present as a mass lesion with hypopituitarism and pathologically is characterized by giant cell granulomas [1, 2–4, 7, 8].

Xanthomatous hypophysitis, is exceedingly rare, with only 28 cases reported to date. The pathology of xanthomatous hypophysitis is characterized by a predominance of foamy macrophages, lymphocytes, and single plasma cells [1, 8].

Other rarer types of hypophysitis appear to be part of a more generalized inflammatory process and include Rosai–Dorfman disease and fibrosing inflammatory pseudotumour (also called Tolosa–Hunt syndrome and parasellar chronic inflammatory disease) [65].

Pineal Physiology and Pathophysiology, Including Pineal Tumours

Susan M. Webb, Anna Aulinas, Cristina Colom, and María-José Barahona

Pineal Physiology

The pineal gland is innervated mainly by sympathetic nerve fibres which inform the gland of the prevailing light-dark cycle and acts as a neuroendocrine transducer; it is located behind the third ventricle in the centre of the brain, is a highly vascular organ formed by neuroglial cells and parenchymal cells or pinealocytes; the latter synthesize melatonin, as well as other indoleamines and peptides.

The main pineal hormone melatonin (N-acetyl 5-methoxytryptamine) exhibits an endogenous circadian rhythm, reflecting signals originating in the suprachiasmatic nucleus; environmental lighting entrains the rhythm, by altering its timing. Independently of sleep, pineal melatonin is inhibited by light and stimulated during darkness, thanks to the neural input by a multisynaptic pathway which connects the retina, through the suprachiasmatic nucleus of the hypothalamus, preganglionic neurons in the upper thoracic spinal cord and postganglionic sympathetic fibres from the superior cervical ganglia, with the pineal gland.

Melatonin deficiency may produce sleeping disorders, behavioural problems, or be associated with precocious or delayed puberty in children, while chronically elevated melatonin has been observed in some cases of hypogonadotropic hypogonadism [1, 2].

Pineal Tumours

The main clinical problem related to the pineal gland is that of pineal tumours (Box 2.5.1). They are rare, ten times more common in children than in adults and mainly derive from the three types of cells: neuroglial, parenchymal, and germinal cells [3–5]. For the first time, the 2016 WHO classification of central nervous system (CNS) tumours uses molecular parameters in addition to histology to define tumour entities, formulating a concept for how CNS tumour diagnoses should be structured in the molecular era [6].

1. **Neuroglial cell tumours (20%)** may affect children and adults of any age. Low-grade, pilocytic astrocytomas usually present before the age of 20 years, with no sex predilection, while other types are more frequent in adults (intermediate diffuse and anaplastic astrocytomas or high-grade malignant glioblastomas; Box 2.5.1).
2. **Parenchymal tumours (15–30%)** secrete melatonin and differ in their degree of malignancy. The 2016 WHO classification grade them from I (pineocytomas, being mostly benign) to

Box 2.5.1 Classification of pineal tumours

Neuroglial cell tumours (20%)
- Low-grade astrocytomas (juvenile pilocytic)
- Intermediate diffuse and anaplastic astrocytomas
- High-grade malignant glioblastomas

Parenchymal tumours (15–30%) (See **Table 2.5.1**)

Germ cell tumours (80% in Japan, 30–50% in Western Europe and USA)
- Germinomas
  - Non-germinomatous germ cell tumours
  - Embryonal carcinoma
  - Yolk sac tumour
  - Choriocarcinoma
  - Teratomas
    - Benign teratomas
      - Immature
      - Mature
    - Teratoma with malignant transformation

Mixed germ cell tumours

Table 2.5.1 Parenchymal pineal tumour classification [3, 4, 7, 8]; the current WHO classification does not provide strict criteria to distinguish grade II and III tumours.

WHO grade	Histological type	Indicators of differentiation (from more to less)	Prognosis
I	Pineocytoma	No mitoses/very positive NF	Good
II III	Intermediate differentiation (20%)	Moderate nuclear atypia/low to moderate mitotic activity/<2 mitoses per HPFs/positive NF protein staining /MIB-1 proliferation indices 3–10% >6 mitoses per HPF/necrosis/negative NF protein staining	↓
II or III	Papillary tumour of the pineal region		
IV	Pineoblastoma	Variable plus positive or negative NF	Bad

WHO, World Health Organization; NF, neurofilaments; HPF, high power field.

IV (pineoblastomas, being highly malignant) (Table 2.5.1). However, most parenchymal tumours are either mixed or show intermediate differentiation (WHO grades II and III, Table 2.5.1) [7]. Histologically, **pineocytomas** characteristically present pineocytomatous rosettes, while pineoblastomas are populated by small, highly undifferentiated cells, often present with haemorrhagic or necrotic components, but rarely calcifications. The major prognostic factor is the extent of surgery. **Pineoblastomas** are highly malignant, aggressive and of rapid growth (similar to other primitive neuroectodermal tumours like neuroblastomas or medulloblastomas). **Papillary tumours** of the pineal region (PTPR) were included as a new entity in the 2007 WHO classification. They are very rare neuroepithelial tumours, macroscopically indistinguishable from pineocytomas, combining papillary and solid areas; however, microscopically, these tumours are easily distinguished. Recently it has been shown that PTPR have ependymal differentiation and are phenotypically more similar to the circumventricular subcommissural organ of the posterior third ventricle than to the pineal gland [8]. The biological and clinical behaviour of these tumours is variable and may correspond to WHO grades II or III, but definite histological grading criteria remain to be defined. Intermediate grades II and III represent different degrees of differentiation and prognosis (Table 2.5.1).

3. **Germ cell tumours (30–50%)**, histologically and biologically homologous to gonadal germ cell neoplasms, will characteristically present positive markers for alpha fetoprotein (AFP) and beta human chorionic gonadotrophin (β-hCG), with more (**teratomas**) or less differentiation (**germinomas**), as well as intermediate degrees (yolk sac tumours).

Very rarely, pineal region tumours may derive from meningothelial, mesenchymal, ependymal, choroid plexus elements and peripheral nerves giving rise to **gangliogliomas, melanocytic neoplasms, atypical teratoid/rhabdoid tumours, meningiomas, cavernous angiomas, hemangiopericytomas** or **neurinomas/neurofibromas**, apart from **lymphomas** or **metastases**.

Clinical Presentation

Clinical presentation of pineal tumours depends on age at onset and histology [9, 10]. Over 90% present with raised intracranial pressure, often with obstructive hydrocephalus; initial symptoms are frequently headache, nausea, vomiting and decreased vision; 50–70% of patients refer visual signs like diplopia, cranial nerve palsies, papilledema and ptosis or Parinaud's syndrome (failure of upward gaze, pupillary dilatation and diminution of pupillary light reflex) due to pressure on the pretectal region. Compression on the brain, cerebellum, hypothalamus, and pituitary may cause paralysis of other cranial nerves, ataxia, diabetes insipidus, and hypopituitarism. Pineal tumours may interfere with puberty, due to either pressure of the tumour on the hypothalamic centres which govern gonadotrophin secretion, excessive melatonin secretion by pinealocyte tumours causing delayed puberty in adolescents, or reduction of the potential antigonadotrophic effect of melatonin, which, together with β-hCG secretion by destructive germ cell tumours could explain precocious puberty in prepubertal children.

The 2016 WHO classification of **parenchymal tumours** (that characteristically secrete melatonin) [11–16] grade them from I to IV (Table 2.5.1) [3, 4, 7]. **Pineocytomas** (grade I) present more often in adults with a mean age of 43 years, with a male to female ratio of 0.6/1, evolve slowly locally (interval between onset of symptoms and surgery may be of several years), do not invade contiguous tissue or seed the cerebrospinal fluid (CSF). Non-specific presenting manifestations reflect compression of neighbouring structures (tectal plate, aqueduct of Sylvius, cerebellum, brainstem, hypothalamus, pituitary) like increased intracranial pressure, changes in mental status, neuroophthalmologic, brain stem, and/or cerebellum dysfunction, hypopituitarism, and hyperprolactinemia. Rarely intratumoural haemorrhage (pineal apoplexy) with subarachnoid extravasation may occur. Concurrent uveoretinitis in occasional patients with pineocytomas probably reflect the common photoreceptor activity of pineal and retinal cells. No metastases and a 5-year survival > 90% have been reported. The major prognostic factor is the extent of surgery.

Pineoblastomas (grade IV) typically appear before the age of 20 years, most often in young children, but there are reports in adults, with a slight male preponderance. Presenting symptoms of this least differentiated and most aggressive pineal parenchymal tumour are more rapidly progressive and of shorter duration (interval between initial symptoms and surgery may be less than a month). Median postsurgical survival varies from 24 to 30 months. They are locally invasive and prone to disseminate through the CSF, often fatal, but may be controlled in some cases by a multimodality combination of aggressive surgery, radiotherapy, and chemotherapy. They may occur in familial bilateral retinoblastoma (due to a germline retinoblastoma gene mutation) known as a trilateral

retinoblastoma syndrome, with a median survival of only 6 months; or in patients with familial adenomatous polyposis. They may also present in patients with *DICER1* germline mutations [7, 17]. Recent studies suggest that in addition to the tumour predisposition syndrome DICER1, the appearance of sporadic pinealoblastomas due to a somatic mutation leading to the inactivation of DICER1 and dysfunction/dysregulation of one of its precursor RNA strands (miRNA) is also possible [18]. Negative prognostic predictors are disseminated disease at diagnosis, the patient's young age and partial surgical resection.

Intermediate grades II and III represent different degrees of differentiation and prognosis (Table 2.5.1).

Papillary tumours present with a variable clinical behaviour, median age at diagnosis of 35 years, but may affect children and adults, with no sex predilection [7, 12–14, 19–22]. Local recurrences are common, especially if resection is incomplete, but spinal dissemination is rare. Gross total resection and younger age are associated with overall survival, while radiotherapy and chemotherapy have no significant impact. Higher Ki-67 proliferation index (>10%) or more than 3 mitoses per 10 high power fields have shown to be related with a shorter progression-free survival [7].

Germ cell tumours arise around the third ventricle, most commonly in the pineal region, but may also be seen in the suprasellar, hypothalamic compartment; 5–10% of patients harbour lesions in both locations. Ninety per cent (90%) appear under the age of 20 years and are more frequent in boys than girls (2.5:1), except suprasellar lesions more common in girls. An increased risk of intracranial germ cell tumours has been associated with Klinefelter's syndrome, Down's syndrome, and neurofibromatosis type 1 [23, 24].

Other tumours, like pineal meningiomas, gangliogliomas, ependymomas, lipomas, and pineal metastases, most frequently of breast or lung origin may occur, often with other brain metastases; symptoms and signs reflect the extent of the disease [20, 25].

Diagnosis

An appropriate tissue specimen for accurate histological diagnosis and determining tumour type is critical to optimize subsequent management. Serum alpha fetoprotein (AFP; synthesized mainly by yolk sac tumours, and teratomas) and β-hCG (in choriocarcinomas or germinomas) concentrations are of diagnostic utility if markedly elevated in serum and/or CSF. Measurement of these markers in CSF for initial staging, and if positive, for follow-up are useful. CSF cytological examination should be delayed at least 2 weeks after surgery to increase the chance of reflecting true dissemination of viable tumour rather than postoperative tumour spillage. If these markers are clearly raised, histological verification may not be required.

Biopsies may be obtained by classical surgical routes (posterior interhemispheric transcallosal, suboccipital transtentorial and infratentorial-supracerebellar routes) or by microsurgical techniques, with significantly reduced perioperative mortality rates (<2%); a neuroendoscopic or stereotactic biopsy are reasonably safe and well tolerated [9, 26], in experimented hands, but the diagnosis of mixed or intermediate tumours may be difficult without extensive tissue sampling, and especially may miss detecting a possible teratoma component. In any case, operative risk should be balanced with the risk of not obtaining an accurate histological diagnosis, with prognostic implications. In cases of non-diagnostic or equivocal biopsies or indicative of a benign tumour (mature teratoma, meningioma), surgery is recommended.

Imaging

MRI is the gold standard imaging technique for evaluating pineal tumours and detecting intradural extramedullary metastases [27]. An MRI will disclose the size and extension of the tumour and possible metastases, but cannot accurately identify the histological nature, which relies on biopsy or serum/CSF tumour markers. In the more malignant tumours (pineoblastomas, germinomas, teratomas) the spine as well as the brain should be imaged, since spread into the subarachnoid space and the spine are frequent.

Neuroimaging of **astrocytic tumours** can vary; MRI usually shows hypodensity on T_1-weighted images and hyperintensity on T_2-weighted images; gadolinium enhancement is uncommon, except if active tumour progression occurs.

Among **parenchymal tumours**, pineocytomas appear as non-invasive, solid masses in the posterior third ventricular region, and tend to be smaller (<3 cm in general), rounder, hypodense, homogeneous masses with dispersed calcifications, particularly peripheral, which enhance heterogeneously or diffusely on computed tomography (CT) and MRI, and present a lesser degree of hydrocephalus. Macrocystic presentation is rare but small cysts may be present. T_1-weighted images are hypointense while T_2 are hyperintense. Haemorrhage and necrosis are exceptional.

Pineoblastomas are larger, lobulated, homogeneous tumours, rarely calcified and present with a greater degree of hydrocephalus and local invasion of contiguous brain or leptomeninges; they may exhibit distant subarachnoid and extracranial metastases, more frequently in young females; they are hyperdense and enhance homogeneously on CT (Figure 2.5.1), while on MRI they appear as hypo-to isointense on T_1-weighted images and enhance diffuse- or heterogeneously with contrast (Figures 2.5.2, 2.5.3, and 2.5.4). Haemorrhage and necrosis are common (Figure 2.5.5).

Germ cell tumours (except teratomas) appear as solid masses on MRI, iso- or hyperdense, which enhance after contrast (Figures 2.5.6 and 2.5.7); small nodular calcifications may be seen on CT scans. Teratomas tend to contain intratumoural cysts next to calcifications and low attenuation signals, typical of fat. Haemorrhages are common in choriocarcinomas and mixed neoplasms.

Treatment

Surgery, chemotherapy, and radiation are used in the treatment of pineal region tumours. Surgery, either open, stereotactic, or endoscopic, is used to obtain a biopsy, mandatory in the majority of cases to obtain a definite histological diagnosis [9]. Morbidity and cure rates have improved over the last years thanks to a greater understanding of the nature of the different tumours, more accurate neurosurgical experience, selective use of chemotherapy, and the introduction of modern irradiation techniques. However, the rarity of pineal tumours, make the obtaining of large prospective multicentre international studies to define their optimal management, difficult.

Figure 2.5.1 Contrast-enhanced CT scan of a recurrent pineoblastoma in a 16-year-old boy with ventricular shunt.

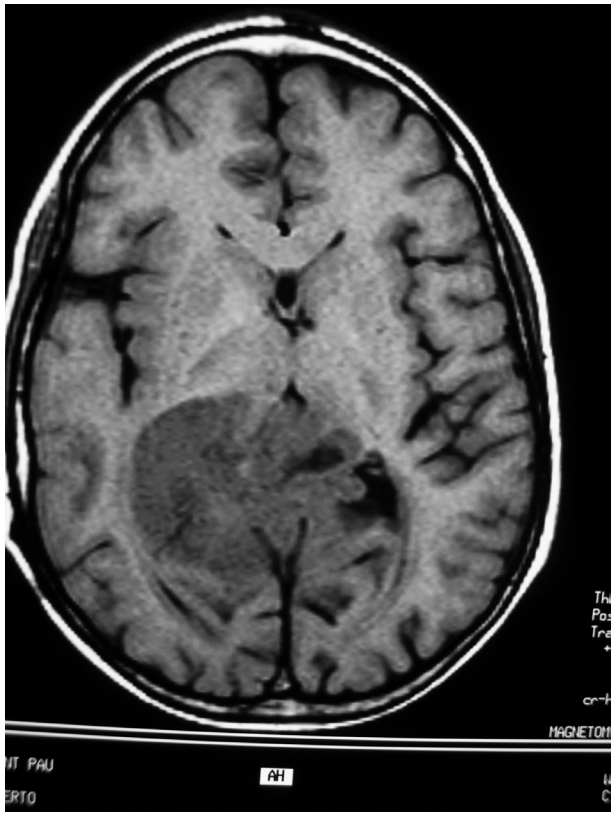

Figure 2.5.2 T_1-weighted MRI of a recurrent pineoblastoma in a 16-year-old boy without contrast.

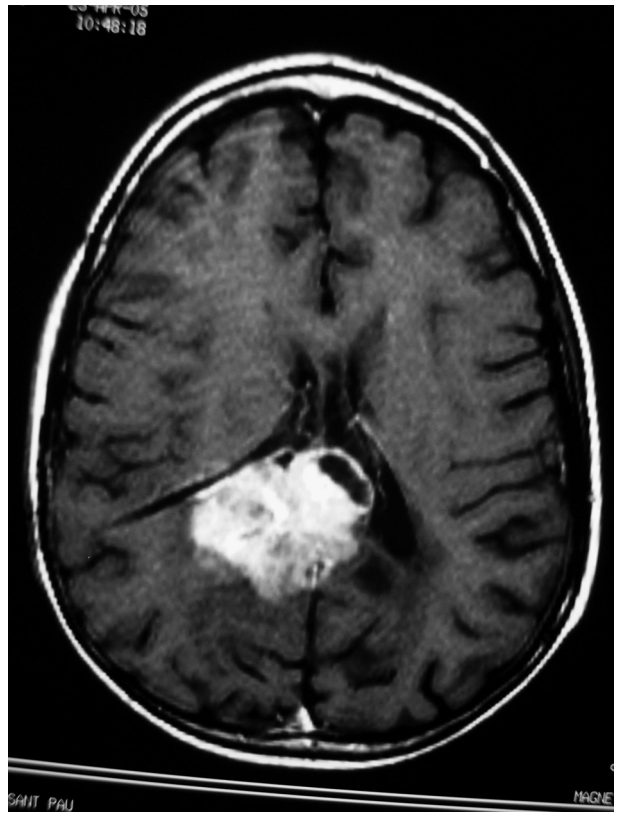

Figure 2.5.3 T_1-weighted gadolinium-enhanced MRI of a recurrent pineoblastoma showing the ventricular shunt.

Treatment depends on histology obtained after surgery, which apart from the biopsy can resolve intracranial hypertension with a ventricular shunt (atrial or peritoneal) and perform partial debulking of the tumour if possible; total resection is rarely possible (Table 2.5.2).

Astrocytomas: Treatment for astroglial derived malignant gliomas is local radiotherapy to the tumour (54 Gy), either conventional or stereotaxic, while surgery may be curative for the more benign pilocytic astrocytomas.

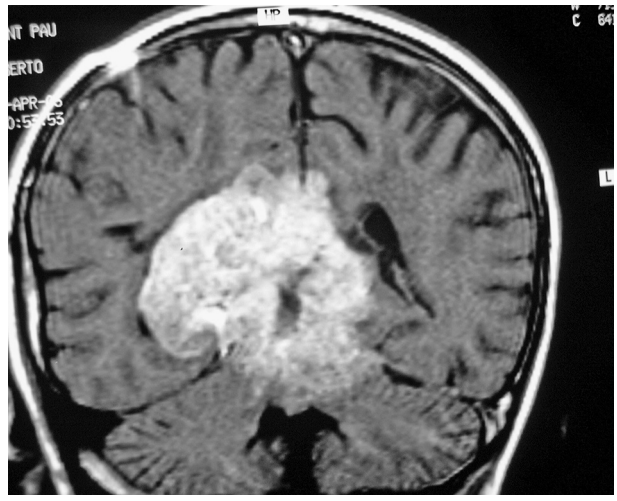

Figure 2.5.4 Coronal T_1-weighted gadolinium-enhanced MRI of a recurrent pineoblastoma.

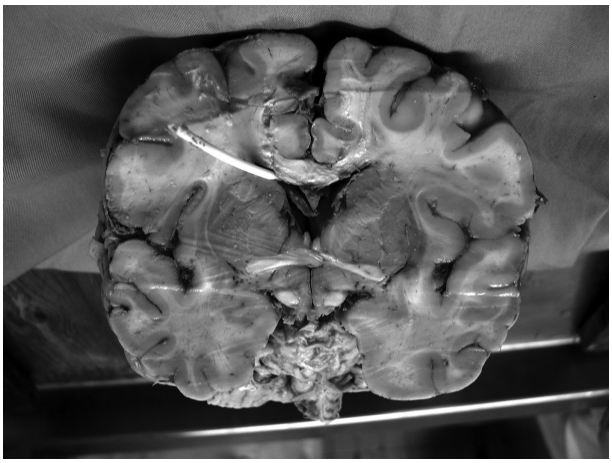

Figure 2.5.5 Coronal slice of the brain corresponding to Figure 2.5.1, showing the pineoblastoma and ventricular shunt.
Courtesy of Dr. E Guardia.

Pineal parenchymal tumours: Pineocytomas only require local radiotherapy to the tumour (54 Gy). In pinealoblastomas, a high probability of spinal seedlings should lead to craniospinal radiotherapy, since they are radiosensitive (25–30 Gy on the neuroaxis with a pineal boost of 40 Gy aimed at more effective local disease control). However, routine craniospinal irradiation has been questioned and may not be necessary in patients with negative staging. Stereotaxic radiosurgery may control local progression and minimize

Figure 2.5.6 CT scan of a recurrent pineal germinoma in a 57-year-old man, with a ventriculoperitoneal shunt.

Figure 2.5.7 Contrast-enhanced CT scan of a recurrent pineal germinoma in a 57-year-old man.

damage to the surrounding brain, especially important in prepubertal patients, in whom total brain irradiation is associated with neurocognitive dysfunction, endocrinopathy, second malignancies, vascular complications, and spinal growth impairment. However, it may be associated with a high risk of marginal recurrence and distant metastases, and is not considered the treatment of choice for infiltrative but curable tumours. Furthermore, complications such as ataxic gait and gaze palsy have been reported after radiosurgery. In young children chemotherapy with cisplatinum, etoposide, cyclophosphamide, and vincristine, which alone is not curative, may allow a lower dose of radiotherapy to have similar effects. In older children with pineoblastoma, craniospinal irradiation is followed by chemotherapy (even though its role on final outcome is not fully defined). Age at diagnosis ≥4 years and administration of radiotherapy as initial therapy are considered favourable prognostic factors for progression-free survival [28]. Autologous haematopoietic stem-cell-supported high-dose chemotherapy has been proposed with some initial promising results, although experience is limited [29].

In mixed or intermediate pineal parenchymal cells (Grade II or III, Table 2.5.1), apart from local radiotherapy, craniospinal irradiation and chemotherapy should be considered, when increasing number of mitoses and less differentiation are observed [9, 11–16].

In PTPR, the optimal treatment remains controversial, as no definitive treatment strategy exists for this lesion. It has been described that a minimally invasive strategy (radiotherapy or stereotactic radiosurgery) resulted in a favourable response to treatment, avoiding the risks of aggressive surgical removal. However, incomplete resection tended to be associated with decreased survival and

Table 2.5.2 Treatment guidelines for pineal tumours. Surgery for histologic biopsy and subtyping and if necessary CSF diversion (ventriculoperitoneal shunt or ventriculostomy) should always be performed, with the possible exception of germ cell tumours with diagnostically elevated tumour markers

Tumour type	Radiotherapy	Chemotherapy[1]	Surgery
Glial origin			
Juvenile pilocytic astrocytoma	No	No	Complete resection
Intermediate/diffuse/anaplastic/ Astrocytomas/glioma	Local	No	Debulking
Malignant glioblastoma	Local	No	Debulking
Parenchymal tumours			
Pineocytoma	Local	No	Biopsy
Intermediate or mixed tumour	Local ± craniospinal	Yes, in more undifferentiated tumours	Biopsy
Pineoblastoma	Local Routine craniospinal not always indicated. Age <5 yrs: Lower dose, after initial chemotherapy	Yes (role on final outcome unclear)	Biopsy
Papillary tumours	Local	No	Complete resection
Germ cell tumours			
Germinoma	Local + craniospinal (unless convinced of negative staging)	Yes (alone not curative)	Biopsy
Non-germinatous tumours	Local + craniospinal	Yes (pre- or post-surgery)	Resection as much as possible, without ↑ morbidity

[1] Chemotherapy includes cisplatin, etoposide, and cyclophosphamide or ifosfamide.

with recurrence. In an updated retrospective series of 44 patients, only gross total resection and younger patient age were associated with overall survival; radiotherapy and chemotherapy had no significant impact [7].

Germ cell tumours. Surgery is not considered curative in germinomas, which are radiosensitive and should therefore receive local radiotherapy [9, 23, 24]. Unless firmly confident of negative staging (by negative tumour markers—AFP and β-hCG—in blood and CSF, and negative MRI), craniospinal radiotherapy should be offered given the high probability of spinal seedlings. Germinomas are also highly chemosensitive, and excellent responses to postoperative cisplatin and cyclophosphamide have been reported. Survival is high (>90% at 5 years) in patients with localized pure germinomas, using either chemotherapy or focal radiotherapy or craniospinal irradiation, while focal irradiation alone has a worse outcome. In metastatic germinomas, craniospinal irradiation is the treatment of choice (25–35 Gy to the spine and a local pineal boost of 40 Gy). Lower irradiation doses are currently being considered, especially if adjuvant chemotherapy is offered [23]. Bifocal lesions in the pineal and hypothalamus should be considered localized germinomas rather than metastatic disease, and receive irradiation to both locations.

Other germ cell tumours are less radiosensitive than germinomas, with a poor survival after radiotherapy alone (median survival of under 2 years) and require multimodality treatment [23, 24]. Surgical resection after tumour reduction with initial chemotherapy with cisplatin, etoposide, and ifosfamide is an alternative. Tumour markers are useful for follow-up. Combining chemotherapy with radiotherapy (local up to 54 Gy or craniospinal up to 36 Gy) may increase long-term survival to 80%.

Surgery is the treatment of choice of **pineal meningiomas** and **other localized pineal** tumours if possible; alternatively, localized stereotactic radiosurgery may be offered with good long-term prognosis [9].

Pineal cysts. Masses in the pineal region are most commonly non-neoplastic cysts incidentally discovered at autopsy or on a radiographic work-up for symptoms not reasonably attributed to the cyst. Very rarely they act as a mass lesion and produce signs of increased intracranial pressure, by compressing the aqueduct (obstructive hydrocephalus) or tectal plate (Parinaud's syndrome). On MRI they appear as a 1–3 cm mass, equally or slightly more dense than CSF in T_1-weighted image studies and which brightly enhance in T_2-weighted images, reflecting their fluid nature; evidence of haemorrhage and peripheral calcification may be found. If asymptomatic, pineal cysts do not generally require treatment; if large enough to increase intracranial pressure, resection may be necessary, with an excellent long-term outcome [9, 30]. Patients with growing lesions, contrast enhancement, and haemorrhage are more likely to develop hydrocephalus and should be followed-up with serial MRI. However, no specific management guidelines exist regarding follow-up of these lesions and whether patients need to be monitored over time [31].

SECTION 3

Thyroid Disease

3.1

Evaluation of the Thyroid Patient

3.1.1 The History and Iconography Relating to the Thyroid Gland

Robert Volpé† *and Clark Sawin*†

This chapter is reproduced from the previous edition.

Introduction

This chapter is a brief summary of the history and art related to the thyroid gland. The reader is referred to other sources for an exhaustive exposition of these matters [1–3].

Early Years

Knowledge of goitre (which was not known to be a thyroid enlargement until about the sixteenth century) goes back into antiquity. In 1600 BC, burnt sponge and seaweed was used for the treatment of goitre in China [2]. In the fourth century BC, the Ayur Veda, a Hindu system of medicine in India, contained a discussion of goitre [1, 2]. In Greece, in the days of Hippocrates, goitre was regarded purely as a deformity, and was attributed to the drinking of snow water [2]. In ancient Greece, swellings in the region of the thyroid gland (and presumably swellings elsewhere in the neck) were referred to as 'bronchocoele' or 'struma'. Galen (AD 130–200), considered the greatest medical practitioner in antiquity after Hippocrates, regarded the thyroid as a lubricant for the larynx [2]. Later, Julius Caesar [2] noted that Gauls had large necks as one of their characteristics. Celsus (25 BC to AD 50) in Rome defined bronchocoele (a tumour in the neck, most likely goitre) and he also described cystic goitre, as well as surgery for these lesions [2]. At the same time, in Egypt, Egyptian coins showed the presence of goitres, [4] and an Egyptian relief of Cleopatra likewise depicted her with what appears to be a goitre.

Even in these early years several writers [1, 2] referred to epidemics of goitre in the Alps, which was a forerunner to a wide literature from this region regarding goitres and their relationship to Alpine culture. The Chinese also were well aware of goitre in those early years, and recommended seaweed for the treatment of goitre as early as AD 340. Much later, the treatment of goitre with desiccated thyroid was advocated as early as AD 1475 by Wang Hei in China [2].

In Switzerland in the sixteenth century, Paracelsus [5] (1493–1541) recognized the connection between cretinism, endemic goitre, and congenital idiocy. He attributed goitre to mineral impurities in the drinking water. Later in that century and the next century, also in Switzerland, many writers described cretins in Swiss cantons and related them to the presence of goitre [3]. In 1656 [6] at St Thomas's Hospital, London, Thomas Wharton named the lobes of the thyroid, 'glandulae thyroidiaeae' because of their anatomical proximity to the thyroid cartilage, and not because of their shape. He felt that the fact that women generally had larger thyroid glands than men was for the purpose of making their necks 'more even and beautiful'.

During the mid and late medieval period in Europe, goitre and cretinism played a significant part in the social history of middle Europe, particularly in Alpine areas where these conditions were quite prevalent. Indeed, there was a connotation that those people with goitres were somehow inherently evil, and this was reflected in the folk art of the period. Indeed, depictions of goitre and cretinism in art and sculpture at that time were commonplace, and form the subject of an entire volume [3].

The discovery of iodine at the beginning of the nineteenth century was a landmark event in relation to the thyroid gland. In 1811, Bernard Courtois (1777–1838), a self-taught chemist and dealer in chemicals and manufacturer of saltpetre in Paris, was using vitriol to clean the vats used for making potash from seaweed, when he noted violet fumes. This violet gas condensed into crystals on cooling; he called the crystals substance X. The substance was soon identified as a new halogen element by Sir Humphrey Davy

† It is with regret that we report the deaths of Dr Robert Volpé and Clark Sawin.

(1778–1829) [7], who happened to be in Paris at the time (despite the ongoing Napoleonic War). As just mentioned, seaweed or burnt sponge had been employed in the treatment of goitre for centuries [2]. However, the credit for using iodine itself in the treatment of goitre appears to go to Coindet (1774–1834) [8] of Geneva in 1820, after he had determined that the substance in burnt sponge that acted against 'bronchocoele' was actually iodine. In his 'tincture of iodine', he used 48 grains of iodine to one ounce of spirit of wine. For adults, he prescribed 10 drops of the tincture in half a tumbler of 'syrup of capillaire' and water three times a day, the dose being increased after a few weeks to 15 or even 20 drops. He noted that bronchocoele would usually subside and be destroyed within the space of 6–10 weeks. A few years later, Lugol (1786–1851) in 1829 [2] also recommended and used (what we now call) Lugol's solution for the treatment of goitre, with considerable success.

With the spread of iodine usage, toxic effects soon appeared, as described by Coindet in 1821, and later by Frederic Rilliet (1814–61) [9]. These ill effects of iodine led to a great deal of anxiety about its use for goitre under any circumstance; for some, it was completely proscribed.

Surgical treatment of goitre had been mentioned by Celsus (25 BC to AD 50) [2]. It was also mentioned in the Turkish manuscript of Charaf Eddin in 1465. Johann A.W. Hedenus (1760–1836) [2] reported in 1822 on six cases of successful excision of a goitre for impending suffocation. Joseph Henry Green (1791–1863) reported the removal of the right lobe of the thyroid gland in St Thomas's Hospital, London, in 1829, but the patient died of sepsis 2 weeks later.

Structure and Function

In a paper by T.W. King (1809–47) [10] of Guy's Hospital, London, there is a description of what was thought to be the secretion of the thyroid as passing into its lymphatics and so into the great veins. King noted that this had been indirectly surmised by Morgagni. He also remarked prophetically that we should be able one day to show that a particular material is slowly formed and partially kept in reserve and that this principle is also supplementary, when poured into the descending inferior vena cava, to important functions in the course of the circulation. Thus, he had a conception of the internal secretion by the thyroid. In notes appended to King's paper, Astley Cooper (1768–1841), a surgeon at the same hospital, agreed with King about this idea.

John Simon (1818–97) [1] in 1844, while assistant surgeon at King's College Hospital and demonstrator of anatomy at King's College, London, published a paper on the comparative anatomy of the thyroid. He stated that in addition to its copious vascular supply, it had the structure of a secreting gland. Several decades later, based on thyroidectomies performed on monkeys and other mammals, Victor Horsley (1857–1916) [11] in 1885 supported the generalization of Felix Semon (1849–1921) in 1883 that myxoedema, cretinism, and operative cachexia strumipriva were all due to thyroid deficiency, and not due to chronic asphyxia (as Theodor Kocher, a surgeon in Bern, Switzerland, originally believed) or due to injury of the sympathetic or other nervous structures. Horsley thought that the thyroid controlled the metabolism of mucus, and that the effects of thyroid insufficiency were due to an accumulation of mucus. Others thought that the function of the thyroid was to neutralize or remove poisons, and so thyroid insufficiency was presumed to produce toxaemia. Horsley, in his report to the Clinical Society's Committee on Myxoedema (1888) divided the effects of complete thyroidectomy on monkeys into (1) the acute effects, which consisted of nervousness, tremor, clonic spasm, contracture, paresis, paralysis, and which came on between the second and the twelfth day (now in retrospect clearly the result of damage to the parathyroid glands); and (2) chronic experimental myxoedema. After Gley's [12] rediscovery in 1891 of the parathyroid glands, it became evident that the effect of complete removal of the thyroid resulted in myxoedema, and that removal of the parathyroids was responsible for what had previously been called tetania thyreopriva.

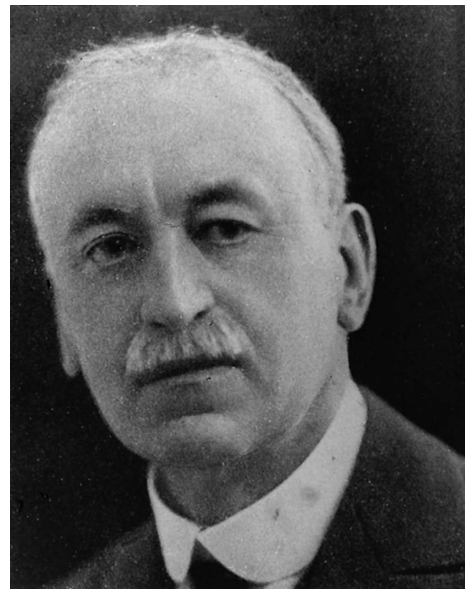

Figure 3.1.1.1 Professor George R. Murray (1865–1939), Newcastle-upon-Tyne, England, who first used extracts of sheep thyroid for the treatment of myxoedema in 1891.

Reproduced with permission from Rolleston HD. *The Endocrine Organs in Health and Disease, with a Historical Review*. London: Oxford University Press, 1936.

The dramatic results of replacement treatment of myxoedema by thyroid preparations by George Murray (1865–1939) [13] (**Figure 3.1.1.1**) in the United Kingdom in 1891, and Magnus-Levy's [14] demonstration in France in 1895 that thyroid medication accelerated metabolism, led to the conclusion that the thyroid and its internal secretion had definite powers other than detoxification.

Theodor Kocher (1841–1917) [2] suggested in 1895 that the thyroid might contain iodine. In the same year, Tschirch [2] was unable to establish this point. However, Eugen Baumann (1846–96) [15] apparently quite independently of Kocher's suggestion, investigated the chemistry of the thyroid, and was much surprised to find iodine. He published his findings in 1896 [15] called the extracted compound that contained iodine 'thyreo-iodin', and considered it to be the active principle of the thyroid. This led to the isolation by Kendall [16] in 1914 of an active principle which was initially called thyroxyindole and later thyroxin. In 1926, Harington (1897–1972) [17] proved that it was derived from tyrosine and not, as Kendall thought, from tryptophane, and was found to be a basic substance, now called thyroxine. Thyroxine was subsequently shown by Harington [2] and Salter [2] to be less powerful than desiccated thyroid. It was of interest that Harington was not able to accept the

possibility that a principle other than thyroxine might exist to explain the metabolic effects of desiccated thyroid. It was not until 1952 that Gross and Pitt-Rivers [18] discovered triiodothyronine, which proved to be that elusive second principle.

Cretinism

The term 'cretin' is thought by some to derive from Christianus, in that the cretinous patients were 'incapable of sin' [2]. They were considered as simple, innocent creatures, 'gens du bon Dieu' [2]. Cretinism was one of the diseases first recognized in early life before it was realized that adults were also affected. The observation that cretinoid conditions occurred in adult life in women occurred much later, and was particularly recognized by Sir William Gull (1816–90) [19] in 1873. He was instrumental in leading the commission (which he initially chaired) to the conclusion that myxoedema was actually due to thyroid deficiency. William Ord (1834–1902) [20] gave the name 'myxoedema' to the adult form in 1877 and was the chairman of the commission at the time of the report (1888).

Significant differences were noticed between the adult and the childhood form. In the latter, there was arrest of development in growth both in body and brain. Because cretinism was found more commonly in the deep mountain valleys, there were many theories as to the relationship of air, water, and food, as noted by Hoefer (1614–81), DeSaussure (1740–99), and Malacarne (1744–1816) [1]. A Royal Commission in Sardinia (1) in 1848 found that the incidence of cretinism was 28% of the population in the District of Aosta but much lower elsewhere.

Causes of Hypothyroidism

The causes of the hypothyroidism were not fully understood throughout the nineteenth century. W.M. Ord [20, 21] described the appearance of the thyroid gland in this condition in 1878, and 13 cases were examined after death in the Report of the Clinical Society of London in 1888. The thyroid showed fibroid atrophy and great diminution in size and weight. There was evidence of chronic inflammation, lymphocytic infiltration, fibrosis, and disappearance of the acini and colloid. However, in 1912, it was Hakaru Hashimoto (1888–1934) [22, 23] a surgeon from Fukuoka, Japan, who described four cases of goitre associated with hypothyroidism in which lymphocytic infiltration of the thyroid gland was an important feature. The most common cause of spontaneous hypothyroidism in areas of the world where there is no iodine deficiency is that of (what is now termed) Hashimoto's thyroiditis or autoimmune thyroiditis. Only much later, in 1956, was autoimmune thyroiditis produced experimentally by Rose and Witebsky in Buffalo, New York [24] and in that same year, thyroid antibodies were found in the circulation of patients with Hashimoto's thyroiditis by Roitt and Doniach [25] in the United Kingdom. These findings helped to usher in the era of autoimmunity.

Toxic Goitre

Few diseases can have more synonyms and none more eponyms. C.P. Howard [26] collected more than 20 such terms.

Looking back into antiquity, the Persian writer, Sayyid Ismail Al-Jurjani in 1136 [1, 2] may have been the first to connect exophthalmos with goitre. Flajani's (1741–1808) [27] description in 1802 in Ascoli, Italy, failed to associate the goitre, exophthalmos, and palpitations as one disease, and his account failed to attract much attention. Indeed, Antonia Testa's (1756–1814) [28] reference in 1800 to the coincidence of prominent eyes and a cardiac disorder likewise did not attract much attention. Testa was the professor of medicine and surgery at Bologna and was said to be a learned theorist, but a mediocre clinician. Caleb Hillier Parry [29, 30] (1755–1822) of Bath, England observed a case in August 1786, but his description of eight cases of 'enlargement of the thyroid gland in connection with enlargement or palpitation of the heart' was not published until 1825, 3 years after his death. His second case, seen in 1802, was of particular interest as it seemed to be precipitated by an acute stress, a factor that still exercises the interest of many observers. He considered that the thyroid was acting as a reservoir for the blood being pumped out by the hyperactive heart. This posthumous report in 1825 still preceded Graves' publication by a decade.

Robert J. Graves [31–33] (1796–1853) of Dublin, Ireland, gave a clinical lecture at the Meath Hospital in Dublin and subsequently published a short article on 'palpitation of the heart with enlargement of the thyroid gland' in 1835. He then included these accounts in textbooks that he later wrote. These texts drew considerable attention to the disorder. This attention was later amplified in 1840 by Karl Adolf von Basedow (1799– 1854) [34] of Merseburg, Germany, who described four patients with exophthalmos, goitre, and palpitations; his description eave rise to the phrase 'the Merseburg triad'. William Stokes (1804–78), a colleague and friend of Graves in Dublin, actually described hyperthyroidism much more fully than Graves in his text, Diseases of the Heart in 1854 [35].

In France, the first description of the disease was provided in 1856 by Jean-Martin Charcot (1825–93) [36]. employing the term 'cachexia exophthalmica' to describe the condition. Charcot's older colleague, Armand Trousseau (1801–67) mentioned in a lecture at the Hotel Dieu in Paris in 1860, that iodine, which had been 'inappropriately' prescribed for hyperthyroidism had actually caused marked amelioration of the disease [37]. Nevertheless, he felt that the use of iodine in toxic goitre was dangerous, and warned against it.

The credit for the precedence for the description of this disease is scarcely resolved to this day. Sir William Osler [38, 39] in his third edition of his famous textbook of medicine belatedly gave the credit for the first important description of this disease to Parry. However, Trousseau [37] had been impressed with the books written by Graves (who was highly regarded as an academic physician) and felt that Graves should be given the credit. In mid-Europe, many observers have given that honour to Basedow. Thus, although the term Graves' disease is in common usage in English-speaking countries, Basedow's disease is generally used in Europe. In Italy, the term, Flajani's disease is sometimes heard. At international meetings, the term Graves' disease is most commonly heard.

The cause of Graves' disease remained unknown, and led to many interesting hypotheses, most notably the importance of psychological factors. Rolleston [1] has summarized the various influences which were thought to be at work in causing this condition. In 1907, Charles Mayo [2] of Rochester, Minnesota, first used the term 'hyperthyroidism', to conform to the idea we hold today,

namely that the disorder represents an excess of thyroid hormone. In 1910, Kocher [1, 2] coined the term 'Jod-Basedow' to describe hyperthyroidism precipitated or aggravated by excess iodine. David Marine [2] also suggested that iodine might actually be a treatment for Graves' disease. A few years later, in 1913, Henry Plummer (1874–1937) [40] was able to separate Graves' disease from hyperthyroidism related to toxic nodular goitre (Plummer's disease). In 1924, Plummer and Boothby [41] showed that the preoperative use of iodine greatly simplified the operative management of Graves' disease.

Treatment of Graves' disease remained mainly surgical until 1942, when Hertz and Roberts [42, 43] introduced radioactive iodine for the diagnosis and treatment of Graves' disease. The following year, Astwood [44] used thiourea and thiouracil in the medical treatment of Graves' disease, thus initiating the era of antithyroid drug therapy. In 1956, the year that thyroid autoantibodies were first identified, Adams and Purves [45] in New Zealand described the presence of an abnormal stimulator of the thyroid in Graves' disease which later proved to be an antibody directed against the thyroid-stimulating hormone receptor (thyroid-stimulating antibody). Thus, Graves' disease, as well as Hashimoto's thyroiditis, proved to be an autoimmune disorder.

Other Conditions

In 1896, Riedel [46, 47] described invasive fibrous thyroiditis, a rare fibrosing condition of the thyroid gland and de Quervain [48] described subacute non-suppurative thyroiditis in 1896.

3.1.2 Biosynthesis, Transport, Metabolism, and Actions of Thyroid Hormones

W. Edward Visser

Introduction

In healthy humans with a normal iodine intake, the thyroid follicular cells produce predominantly the prohormone thyroxine (3,3′,5,5′-tetraiodothyronine; T_4), which is converted in peripheral tissues to the bioactive hormone 3,3′,5-triiodothyronine (T_3) or to the inactive metabolite 3,3′,5′-triiodothyronine (reverse T_3). The bioavailability of thyroid hormone in target tissues depends to a large extent on the supply of plasma T_4 and T_3, the activity of transporters mediating the cellular uptake and/or efflux of these hormones, as well as the activity of deiodinases and possibly other enzymes catalysing their activation or inactivation. The actions of thyroid hormone are mediated by binding of T3 to the nuclear thyroid hormone (or T3) receptors (TRs). Thyroid function is regulated most importantly by the hypophyseal glycoprotein thyroid-stimulating hormone (TSH), also called thyrotropin. In turn, TSH secretion from the anterior pituitary is stimulated by the hypothalamic factor thyrotropin-releasing hormone (TRH). TSH secretion is downregulated by negative feedback action of thyroid hormone on the hypothalamus and the pituitary. The contribution of locally produced T_3 versus uptake of plasma T_3 is much greater for some tissues such as the brain and the pituitary than for most other tissues. Plasma TSH is an important parameter for the diagnosis of thyroid dysfunction but is not representative for the thyroid state of all tissues. In this chapter various aspects will be discussed of: (a) the neuroendocrine regulation of thyroid function, (b) the biosynthesis of thyroid hormone (i.e. the prohormone T_4), (c) the activation and inactivation of thyroid hormone in peripheral tissues, (d) cellular transport of thyroid hormone and (e) the mechanism by which T_3 exerts it biological activity. A schematic overview of the hypothalamus– pituitary–thyroid–periphery axis is presented in Figure 3.1.2.1.

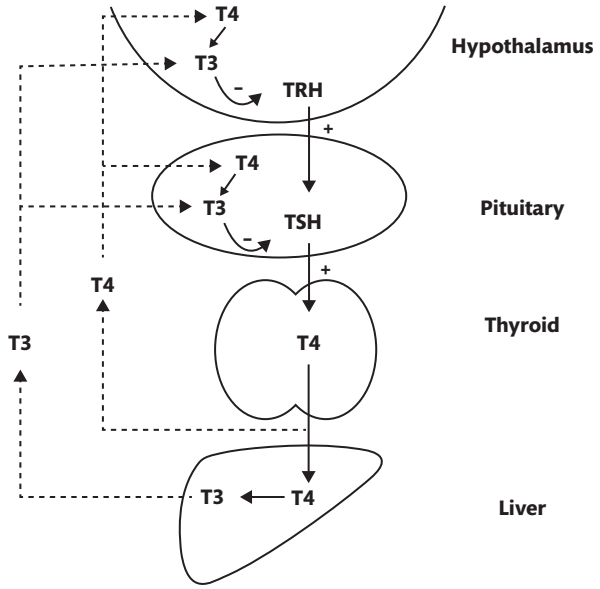

Figure 3.1.2.1 Overview of the regulation of the production and metabolism of thyroid hormone in the hypothalamus–pituitary–thyroid–periphery axis, showing the liver as a major T_3-producing tissue.

Regulation of Thyroid Function

Thyrotropin-Releasing Hormone

TRH is a tripeptide with the structure pyroglutamyl-histidyl-proline amide (pGlu-His-Pro-NH_2) in which the C-terminal carboxyl group is blocked by amidation and the N-terminal α-amino group is blocked by cyclization. Beside stimulating TSH secretion,

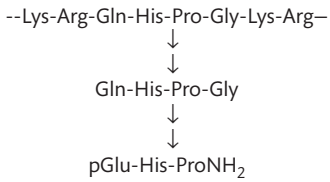

Figure 3.1.2.2 Biosynthesis of TRH. The figure shows the several steps by which the TRH progenitor sequences in proTRH are processed to mature TRH.

TRH also stimulates prolactin secretion. TRH is not only produced in the hypothalamus but is widely distributed through the central nervous system where it functions as a neurotransmitter. TRH is also detected in the posterior pituitary and in different other tissues, but little is known about its role there.

Hypophysiotropic TRH is produced in neurons, the cell bodies of which are located in the paraventricular nucleus of the hypothalamus [1]. The biosynthesis of TRH involves the production of a large precursor protein (proTRH) which, in humans, consists of a sequence of 242 amino acids. This proTRH contains six copies of the TRH progenitor sequence Gln-His-Pro-Gly, flanked at both sides by pairs of the basic amino acids Arg and/or Lys (Figure 3.1.2.2). Cleavage of proTRH at the basic amino acids by prohormone convertases (e.g. PC1 and PC2) and further removal of remaining basic residues by carboxypeptidases results in the liberation of the progenitor sequences. A specific glutaminyl cyclase catalyses the formation of the pGlu ring at the N-terminus and a so-called peptidylglycine α-amidating mono-oxygenase converts Pro-Gly to $ProNH_2$ at the C-terminus [2]. The processing of proTRH takes place in vesicles that transport mature TRH and intervening peptides along the axons of the TRH neurons to the median eminence, where they are released into the portal vessels of the hypophyseal stalk.

TRH is transported over a short distance through the hypophyseal stalk to the anterior lobe of the pituitary, where it stimulates the production and secretion of TSH (and prolactin). These actions of TRH are initiated by its binding to the type 1 TRH receptor (TRHR1), which is expressed on both the thyrotrope (TSH-producing cell) and the lactotroph (prolactin-producing cell) [3]. This receptor belongs to the family of G-protein-coupled receptors, characteristically containing seven transmembrane domains. Human TRHR1 is a protein consisting of 398 amino acids, and binding of TRH induces a change in its interaction with the trimeric G-protein, resulting in the stimulation of phospholipase C activity. The activated phospholipase C catalyses the hydrolysis of phosphatidylinositol-4,5-diphosphate to the second messengers inositol-1,4,5-triphosphate and diacylglycerol, which initiate a cascade of reactions, including an increase in cellular Ca^{2+} levels and protein kinase C activity, that ultimately stimulates the release as well as the synthesis of TSH (and prolactin) [3]. TRH stimulation of TSHβ gene expression is also dependent on the pituitary-specific transcription factor 1.

TRH is subject to rapid degradation in the blood as well as in different tissues. Although multiple enzymes are involved, a very important role is played by the TRH-degrading ectoenzyme TRHDE, which catalyses the cleavage of the pGlu-His bond [4]:

$$pGlu\text{-}His\text{-}ProNH_2 \rightarrow pGlu + His\text{-}ProNH_2.$$

This enzyme has been characterized as a zinc-containing metalloproteinase, which in humans consists of 1024 amino acids. It has a single transmembrane domain and is inserted in the plasma membrane such that most of the protein is exposed on the cell surface (ectopeptidase), in particular in brain, pituitary, liver, and lung. Enzymatic cleavage of the protein close to the cell membrane releases most of the protein in a soluble and enzymatically active form into the circulation, representing the origin of plasma TRHDE. Plasma TRHDE appears to be derived mostly from the liver. In the brain and the pituitary, where the enzyme is probably located in close vicinity of the TRH receptor, TRHDE supposedly plays an important role in the local regulation of TRH bioavailability. TRHDE activity in the pituitary and in plasma is increased in hyperthyroidism and decreased in hypothyroidism, which may contribute to the negative feedback control of TSH secretion by thyroid hormone [4].

Thyroid-Stimulating Hormone

TSH is a glycoprotein produced by the thyrotropic cells of the anterior pituitary. Like the other hypophyseal hormones luteinizing hormone and follicle-stimulating hormone, it is composed of two subunits. The α-subunit is identical and the β-subunit is homologous among the three hormones [5]. Although hormone specificity is conveyed by the β-subunit, dimerization with the α-subunit is required for biological activity. Human TSH consists of 205 amino acids; 92 in the α-subunit and 113 in the β-subunit. It has a molecular weight of 28 kDa, 20% of which is contributed by three complex carbohydrate groups: two on the α-subunit and one on the β-subunit. The structure of these carbohydrate groups is important for the biological activity of TSH and is dependent on the stimulation of the thyrotrope by TRH [5]. Changes in TSH glycosylation underlie the altered TSH bioactivity under certain circumstances, such as pituitary stalk compression.

In addition to the stimulation by TRH and negative feedback by thyroid hormone, TSH production and secretion is also subject to negative regulation by hypothalamic somatostatin and dopamine and by steroids such as cortisol [6].

TSH binds to a specific TSH receptor located in the plasma membrane of the follicular cell. The human TSH receptor is a G-protein-coupled receptor which, is a protein consisting of 764 amino acids with an exceptionally long extracellular N-terminal domain [7]. The TSH receptor is preferentially coupled to a $G_s\alpha$-subunit of the trimeric G-protein. Binding of TSH to its receptor induces the dissociation of the G-protein subunits, resulting in the activation of the membrane-bound adenylate cyclase and, thus, in the stimulation of cAMP formation as second messenger. The increased cAMP levels induce a series of events, including the activation of protein kinase A activity, that ultimately results in the stimulation of the biosynthesis and secretion of thyroid hormone [8]. In particular, the expression of genes coding for key proteins for hormone production (e.g. the iodide transporter, thyroglobulin, and thyroid peroxidase) is increased through mechanisms that also involve different thyroid-specific transcription factors such as TTF1, TTF2, and PAX8.

As discussed elsewhere in this section, hyperthyroidism is often caused by an autoimmune process in which TSH receptor-stimulating antibodies play an important role. Hyperthyroidism may also be caused by a hyperfunctioning adenoma. In most patients with a toxic adenoma, somatic mutations have been identified

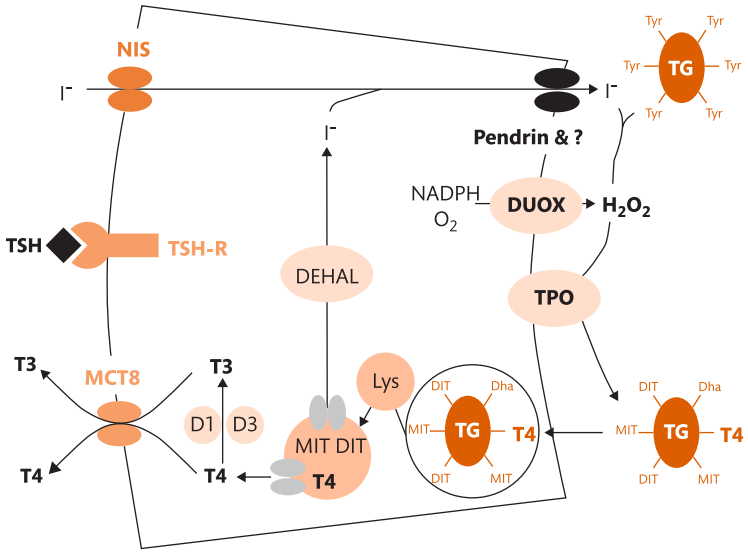

Figure 3.1.2.3 Schematic presentation of a thyroid follicular cell and important steps in the synthesis of thyroid hormone. DIT, 3,5-diiodotyrosine; MIT, monoiodotyrosine.

in the TSH receptor, which result in the constitutive activation of this receptor [9]. In other patients, somatic mutations have been found in the $G_s\alpha$-subunit that result in the constitutive activation of the G-protein in the absence of TSH. Together, mutations in the TSH receptor and the $G_s\alpha$-subunit account for the majority of toxic adenomas. Also, germline, gain-of-function mutations have been identified in patients with congenital, non-autoimmune hyperthyroidism. Conversely, germline, loss-of-function mutations have been described in patients with TSH resistance [9]. However, patients with TSH resistance may be clinically euthyroid because the partial defect in TSH receptor function is compensated by increased plasma TSH concentrations [9].

Biosynthesis of Thyroid Hormone

The functional unit of the thyroid gland is the follicle, composed of a single layer of epithelial cells surrounding a colloidal lumen in which thyroid hormone is stored as an integral part of its precursor protein thyroglobulin. The biosynthesis of thyroid hormone comprises the following steps, which are depicted schematically in Figure 3.1.2.3 [8, 10]:

1. Uptake of iodide through the basolateral membrane and export through the apical membrane.
2. Clustering of thyroglobulin, thyroid peroxidase (TPO) and the dual oxidase DUOX2 in a 'thyroxisome' at the luminal surface of the apical membrane [11].
3. Formation of H_2O_2 by DUOX2.
4. H_2O_2-dependent iodination of tyrosine residues in thyroglobulin by TPO.
5. H_2O_2-dependent coupling of iodotyrosine to iodothyronine residues in thyroglobulin by TPO.
6. Resorption of thyroglobulin from the lumen and hydrolysis in lysosomes.
7. Deiodination of iodotyrosines and reutilization of iodide.
8. Secretion of iodothyronines, predominantly T_4, into the bloodstream.

Iodide Uptake

Iodine is an essential trace element required for the synthesis of thyroid hormone. The basolateral membrane of the follicular cell requires an active transporter that mediates uptake of I^- together with Na^+. This human sodium-iodide symporter (NIS) consists of 618 amino acids and 13 transmembrane domains [12]. Supposedly, these domains form a channel through which I^- and Na^+ are transported in a stoichiometry of 1:2. The surplus of positive charge indicates that I^- transport is electrogenic and further driven by the Na^+ gradient. TSH stimulates the expression of the *NIS* gene to such an extent that the intracellular iodide concentration is about 30–50 times higher than its extracellular level. NIS can also bind other anions, some of which are even transported [12].

An important example is perchlorate (ClO_4^-) which potently inhibits iodide uptake by the NIS, an effect utilized in the perchlorate discharge test used for the diagnosis of an organification defect (i.e. impaired incorporation of iodine in thyroglobulin). Perchlorate inhibits the uptake but not the release of iodide from the thyroid. Therefore, if perchlorate is administered after a dose of radioactive iodide, it will provoke a marked release of radioactivity from the thyroid in case of an organification defect but not from a normal thyroid gland. Pertechnetate (TcO_4^-) is another anion transported by the NIS, and this observation is utilized in the scanning of the thyroid gland using radioactive $^{99m}TcO_4^-$.

Since the iodination of thyroglobulin takes place at the luminal surface of the apical membrane, iodide also has to pass this membrane. A transporter putatively involved in this process has been identified and termed pendrin, since the gene coding for this

protein is mutated in patients with Pendred's syndrome [13]. This is a congenital condition characterized by deafness due to a cochlear defect and hypothyroidism due to an organification defect as indicated by a positive perchlorate discharge test. Pendrin is capable of transporting bicarbonate, chloride, and iodide [13], and is expressed only in the thyroid and the cochlea. The exact function of pendrin in the transport of iodide across the follicular apical membrane is subject to debate. There is likely another protein capable of releasing iodide into the follicular lumen of which anoctamin is a likely candidate [14]. Efflux of iodide from thyroid follicular cells is acutely stimulated by TSH, which may involve recruitment and/or activation of an iodide exporter such as pendrin.

Thyroglobulin, DUOX2, and TPO

Thyroglobulin is an exceptionally large glycoprotein consisting of two identical subunits. Each mature subunit in human thyroglobulin contains 2748 amino acids and has a molecular weight of approximately 330 kDa [15]. The *TG* gene is located on human chromosome 8q24.2-q24.3; it covers about 300 kb of genomic DNA and consists of 48 exons.

DUOX2 is a large glycoprotein embedded in the apical membrane of the thyrocyte. Mature human DUOX2 contains 1527 amino acids and has seven putative transmembrane domains, an NADPH-binding domain, an FAD-binding domain, a haem-binding domain, two calcium-binding EF hands, and a peroxidase domain [16]. It catalyses the oxidation of NADPH from the cytoplasm and delivers its product H_2O_2 to the luminal surface of the membrane. Functional expression of DUOX2 requires the presence of the maturation factor DUOXA2, a protein consisting of 320 amino acids and five putative transmembrane domains [17].

TPO is a glycoprotein consisting of 933 amino acids and featuring a single transmembrane domain. A short C-terminal domain is located in the cytoplasm but most of the protein is exposed on the luminal surface of the apical membrane, which also contains a haem-binding domain, the active centre of the enzyme [18]. The human *TPO* gene covers about 150 kb on chromosome 2p25, distributed over 17 exons.

Formation of Iodothyronines

Thyroid hormone synthesis takes place at the luminal surface of the apical membrane in the scaffold of the thyroglobulin molecule and consists of two important reactions that are both catalysed by TPO (i.e. the iodination of Tyr residues and the subsequent coupling of iodotyrosine to iodothyronine residues) [18]. The structures of these compounds are illustrated in Figure 3.1.2.4. The prosthetic haem group of TPO undergoes a two-electron oxidation by H_2O_2 (supplied by DUOX2) to the intermediate compound 1 (Cpd1). Cpd1 may carry out either a one-electron oxidation reaction, by which it is converted to the intermediate Cpd2, or a two-electron oxidation by which native TPO is regenerated. TPO-catalysed iodination probably involves a two-electron oxidation of I^- to I^+ with subsequent electrophilic substitution of Tyr residues in thyroglobulin, producing 3-iodotyrosine (monoiodotyrosine, MIT). Substitution of MIT residues with a second iodine produces 3,5-diiodotyrosine (DIT).

Coupling of two suitably positioned iodotyrosine residues results in the formation of an iodothyronine residue at the site of the acceptor iodotyrosine, leaving a dehydroalanine residue at the site of the donor iodotyrosine [18]. Coupling of the diiodophenol moiety

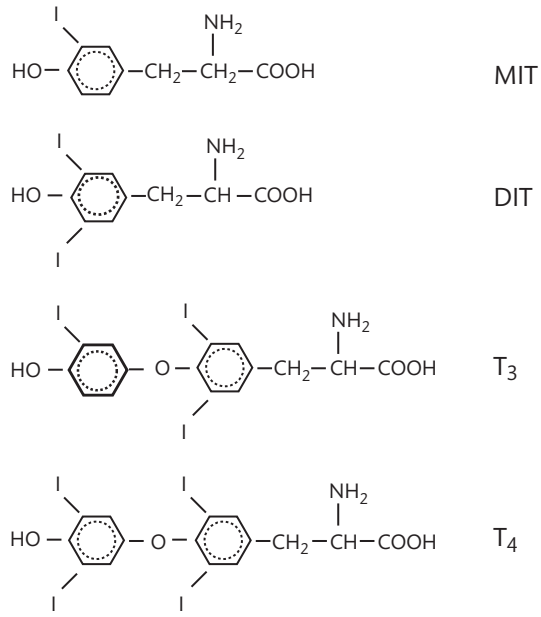

Figure 3.1.2.4 Structures of the iodotyrosines MIT and DIT and the iodothyronines T3 and T4.

of one DIT residue to the phenolic oxygen of a second DIT residue results in the formation of T_4, while coupling of the iodophenol moiety of MIT to a DIT residue yields T_3. Coupling of DIT and MIT to generate reverse T_3 or MIT and MIT to form 3,3′-T_2 are apparently rare events, since thyroidal secretion of reverse T_3 and 3,3′-T_2 are negligible.

Although Tyr is the building block of thyroid hormone, the Tyr content of thyroglobulin is not greater than that of most other proteins. Each thyroglobulin subunit has only four hormonogenic sites, Tyr residues that can ultimately be transformed into iodothyronines. At three sites (positions 5, 1290, and 2553 in the mature protein) T_4 can be formed, while at the fourth site (position 2746) T_3 is preferentially produced. However, at normal levels of iodination the average yield is 1–1.5 molecules of T_4 and approximately 0.1 molecule of T_3 per thyroglobulin subunit. The ratio between T_3 and T_4 formation is under control of TSH. At this stage the iodothyronines are still in peptide linkage with the thyroglobulin backbone and remain stored as such in the lumen until their secretion is required.

Release of Thyroid Hormone

In response to TSH stimulation, thyroglobulin is resorbed from the lumen largely by both macro- and micropinocytosis [8, 10]. The former type of endocytosis is associated with the formation of large pseudopodia that engulf colloid and the thyroglobulin contained therein, resulting in the formation of large cytoplasmic vesicles also known as colloid droplets. The second process concerns the receptor-mediated endocytosis of thyroglobulin, involving the binding of thyroglobulin to apical membrane proteins. Megalin, a very large (*c.*600 kDa) cargo protein located in the apical membrane of different cell types, including thyrocytes, may be involved although it appears to function primarily in the transcellular transport of poorly iodinated thyroglobulin [19].

Both types of endosomes fuse with lysosomes, generating so-called phagolysosomes. In these vesicles thyroglobulin is

hydrolysed by lysosomal proteases, (i.e. cathepsins) [20], resulting in the liberation of T_4, a small amount of T_3, as well as excess MIT and DIT molecules. MIT and DIT are probably exported from the vesicles via a specific transporter [21]. Thus, they have access to the iodotyrosine dehalogenase (DEHAL1), located in the endoplasmic reticulum, which catalyses their deiodination by NADH [22, 23]. The iodide thereby released is reutilized for iodination of thyroglobulin.

Human DEHAL1 is a homodimer of a 289-amino acid protein containing an N-terminal membrane anchor and a conserved nitroreductase domain with an FMN-binding site [22, 23]. The *DEHAL1* gene is located on chromosome 6q24-q25 and consists of five exons. Since DEHAL1 lacks an NADH-binding sequence, iodotyrosine deiodinase activity requires the involvement of a reductase, which has not yet been identified.

The most important mechanism of thyroid hormone secretion involves the secretion from the gland through membrane transporters. This requires iodothyronines to be released via transporters from the vesicles into the cytoplasm, and subsequently secreted through transporters located in the basolateral membrane. In the latter route, some T_4 may be converted before secretion to T_3 by iodothyronine deiodinases present in the thyrocyte (see next). The thyroid hormone transporter MCT8 (see next) is crucial for the excretion of the hormones from the gland into the circulation.

In an average human subject, T_4 and T_3 are secreted in a ratio of about 15:1 (i.e. about 100 μg (130 nmol) T_4 and 6 μg (9 nmol) T_3 per day). The latter represents approximately 20% of daily total T_3 production [24]. Hence, most T_3 is produced by deiodination of T_4 in peripheral tissues.

Inhibitors of Thyroid Hormone Production and/or Secretion

Administration of a large amount of iodide usually results in an acute but transient decrease in thyroid hormone secretion [8, 10]. The mechanism of this inhibition of thyroid hormone secretion by excess iodide is unknown. Excess iodide will also induce an inhibition of the synthesis of thyroid hormone; this phenomenon is known as the Wolff–Chaikoff effect [8, 10]. The mechanism appears to involve, among others, the formation of an iodinated lipid (iodolactone) that inhibits several steps in thyroid hormone synthesis. This includes the inhibition of iodide uptake by the NIS, which results in a decrease in the intracellular iodide concentration and, thus, a decrease in iodolactone formation. This relieves the inhibited hormone synthesis, known as the escape from the Wolff–Chaikoff effect, that occurs despite the continued administration of excess iodide.

Thiourea derivatives have been known since long as potent inhibitors of thyroid hormone synthesis [25]. Two of these, 6-propyl-2-thiouracil and particularly methimazole are widely used in the medical treatment of patients with hyperthyroidism (Figure 3.1.2.5). Their antithyroid activity is based on the potent inhibition of TPO, the mechanism of which depends on the available iodide concentration [18]. In the presence of iodide, the thiourea inhibitors compete with the Tyr residues in thyroglobulin for the TPO–I^+ iodination complex, preventing the formation of thyroid hormone. The thiourea inhibitors are thus converted to the sulfenyl iodide derivatives which undergo further oxidation of the sulphur ultimately to sulphate.

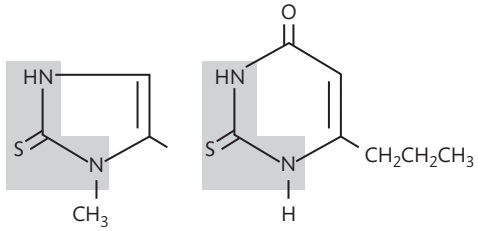

Figure 3.1.2.5 Structures of the TPO inhibitors methimazole and propylthiouracil. The thiourea moiety of the drugs is shaded.

Methimazole is a more potent inhibitor of TPO than propylthiouracil [18], and lower doses of methimazole (or the prodrug carbimazole) are required for the treatment of hyperthyroidism compared with propylthiouracil. Besides inhibiting thyroid hormone (i.e. T_4) synthesis by TPO, propylthiouracil also inhibits conversion of T_4 to T_3 by the type 1 iodothyronine deiodinase located not only in the thyroid but also in liver and kidney (see next).

Transport of Thyroid Hormone

Plasma Transport

In plasma, thyroid hormone is bound to three proteins, thyroxine-binding globulin (TBG), transthyretin (TTR, previously known as thyroxine-binding prealbumin (TBPA)), and albumin (Table 3.1.2.1) [25, 26]. Human TBG is a 54-kDa glycoprotein produced in the liver and consists of 395 amino acids and four carbohydrate residues. The *TBG* gene is located on the human chromosome Xq22.2, spans about 5.5 kb, and contains five exons [27]. Among the different thyroid hormone transport proteins, it shows by far the highest affinity for T_4, with an equilibrium dissociation constant (K_d) of approximately 0.1 nM, but also the lowest plasma concentration (*c.*15 mg/L) [26].

TTR is composed of four identical subunits, each consisting of 127 amino acids. The *TTR* gene is located on human chromosome 18q11.2-q12.1, covers about 7 kb, and contains four exons [28]. TTR can bind two T_4 molecules, with a K_d value of approximately 10 nM of the first T_4 molecule, and the plasma concentration of TTR amounts to approximately 250 mg/L [26]. Plasma TTR is produced in the liver, but the protein is also expressed in the choroid plexus where it is probably involved in T_4 transfer from plasma to the cerebrospinal fluid. Furthermore, TTR is expressed in trophoblasts where it may participate in the transplacental transfer of maternal T_4 to the fetus.

Albumin has multiple low-affinity binding sites for thyroid hormone, with K_d values for T_4 of 1–10 μM, but it has by far the highest plasma concentration (*c.*40 g/L) [26].

The resultant of the concentrations and affinities of the different thyroid hormone-binding proteins is that in normal human subjects approximately 75% of plasma T_4 is bound to TBG, approximately 15% is bound to albumin, and approximately 10% is bound to TTR [26]. The total binding capacity of these proteins is so high that only approximately 0.02% of plasma T_4 is free (non-protein-bound). The affinity of T_3 for the different proteins is roughly 10% of that of T_4. Therefore, plasma T_3 shows a similar distribution to T_4 over the different proteins, and the free T_3 fraction in normal plasma amounts

Table 3.1.2.1 Characteristics of T_4-binding proteins in human plasma

Protein	Concentration in plasma (mg/L)	Concentration in plasma (μmol/L)	Dissociation constant (K_d) (mol/L)	T_4 distribution (%)
TBG	*c.*15	*c.*0.3	*c.*10^{-10}	75
TTR	*c.*250	*c.*5	10^{-8}	10
Albumin	*c.*40 000	*c.*600	10^{-6} to 10^{-5}	15

TBG, T_4-binding globulin; TTR, transthyretin (formerly known as T_4-binding prealbumin, TBPA).

to approximately 0.2%. Thus, while the mean normal plasma total T_4 (*c.*100 nmol/L) and T_3 (*c.*2 nmol/L) levels differ about 50-fold, the difference in the mean normal free T_4 (*c.*20 pmol/L) and free T_3 (*c.*5 pmol/L) is only about fourfold. Reverse T_3 binds with intermediate affinity to the plasma proteins [26].

Since it is the plasma free T_4 and free T_3 concentrations that determine the tissue availability of thyroid hormone, they are more important parameters than the plasma total T_4 and T_3 concentrations in the assessment of thyroid status. Both concentration and thyroid hormone-binding affinity of the different plasma proteins are influenced by a variety of (patho)physiological factors [26]. Beside genetic variation resulting in deficiency or excess, TBG levels are also influenced by various endogenous and exogenous factors [27]. Notably, plasma TBG levels are increased by oestrogens. Different endogenous factors, such as free fatty acids, and drugs, such as salicylates, competitively inhibit T_4 binding to TBG [26].

A large number of mutations have also been identified in the *TTR* gene, some of which are associated with a decrease in T_4 binding affinity, whereas others result in an increased affinity for T_4 [29]. *TTR* mutations often cause neuropathic or cardiomyopathic amyloidosis, resulting from the deposition of insoluble TTR fibrils in nerves or the heart [29]. Finally, binding of thyroid hormone to albumin is subject to genetic variation. In particular, a specific increase in the binding of T_4 to albumin is frequently observed in otherwise healthy subjects, which may lead to the false diagnosis of hyperthyroidism if inadequate methods for analysis of plasma free T_4 are used [26]. This phenomenon of familial dysalbuminaemic hyperthyroxinaemia has been attributed to mutations in the albumin gene (typically R218H mutation), resulting in a marked increase in T_4 affinity [30].

Perturbation of plasma iodothyronine binding provokes an adaptation of the hypothalamus–pituitary–thyroid axis until normal free T_4 and free T_3 concentrations are again obtained. Therefore, measurement of plasma free T_4 rather than total T_4 levels is, together with analysis of plasma TSH, the cornerstone of the diagnosis of thyroid disorders.

Tissue Transport

Because iodothyronines are lipophilic compounds, it was assumed for decades that they readily pass the plasma membrane by simple diffusion. However, the polar nature of the alanine side chain ('zwitterion') is a serious obstacle for passage through the lipid bilayer of the cell membrane. Studies in recent years have established that tissue uptake of thyroid hormone does not take place by diffusion but is mediated by specific plasma membrane transporters [31]. Most early studies have been carried out in isolated rat hepatocytes, but carrier-mediated uptake of iodothyronines has been demonstrated in a variety of cells [31].

The mechanisms of thyroid hormone uptake appear to differ between tissues as studies in rat pituitary cells suggest a common transporter for T_4 and T_3, whereas neonatal rat cardiomyocytes show preferential uptake of T_3 over T_4 [31]. In view of the iodothyronine structure, it is not surprising that thyroid hormone uptake can be mediated by amino acid transporters showing partial (L-type) or complete (T-type) preference for aromatic amino acids [32, 33].

Thyroid Hormone Transporters

Since 2000, a number of thyroid hormone transporters have been identified at the molecular level. These include the Na-taurocholate cotransporting polypeptide (NTCP), different members of the organic anion transporting polypeptide (OATP) family, the L-type amino acid transporters (LATs), members of the monocarboxylate transporter (MCT; SLC16) family and SLC17A4 [34, 35].

Of these transporters, only NTCP (SLC10A1) transports its ligands in a Na^+-dependent manner [36]. It is exclusively expressed in liver and transports primarily bile acids. Human NTCP consists of 349 amino acids and has seven transmembrane domains. The *NTCP* gene is located on chromosome 14q24.1 and has five exons. There are no other thyroid hormone transporters in the SLC10 family. NTCP shows a preference for sulphated over non-sulphated iodothyronines.

Different human OATP members have been shown to transport iodothyronine derivatives [37]. In general, they are multispecific, transporting a variety of ligands. OATPs are glycoproteins containing around 700 amino acids and 12 transmembrane domains. The human OATP1 subfamily contains four members (OATP1A2, 1B1, 1B3, 1C1) with interesting properties. They are encoded by a gene cluster on chromosome 12p12 containing 14–15 exons. OATP1B1 and 1B3 are expressed only in liver and show preference for sulphated over non-sulphated iodothyronines as ligands [38]. The latter also holds for OATP1A2, which is expressed in different tissues. OATP1C1 is an exceptional transporter in this subfamily, showing a high preference for T_4 as the ligand and almost exclusive expression in the brain, especially in choroid plexus and capillaries in mice and in astrocytes in humans [37]. Recently, a young patient with progressive neurodegeneration associated with a defective OATP1C1 was identified [39].

T_4 and T_3 are also transported by two members of the heterodimeric amino acid transporters LAT1 and LAT2 [40]. These transporters are glycoproteins consisting of two subunits, a heavy chain and a light chain. The heavy chains contain a single transmembrane domain, and the light chains contain 12–14 transmembrane domains. LAT1 is composed of the SLC3A2 (4F2hc or CD98hc) heavy chain and the SLC7A5 light chain, and LAT2 is composed of the same heavy chain and the SLC7A8 light chain.

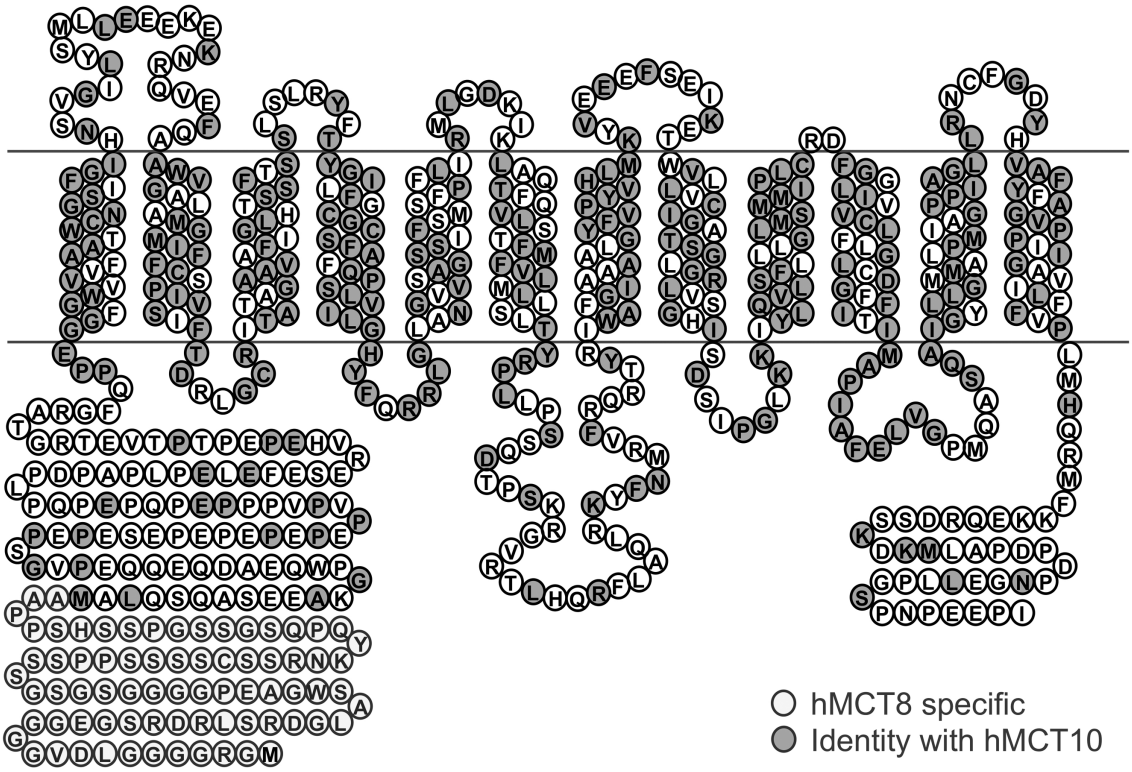

Figure 3.1.2.6 Protein structure of human MCT8 and MCT10.

These transporters are expressed in various tissues and facilitate the bidirectional transport of a variety of aliphatic and aromatic amino acids as well as iodothyronines over the plasma membrane [40].

Two important thyroid hormone transporters belong to the monocarboxylate transporter (MCT) family [41, 42]. MCT8 and MCT10 have been identified as important thyroid hormone transporters. Of these, MCT10 also transports the aromatic amino acids Trp, Tyr, and Phe, but so far only iodothyronines have been identified as ligands for MCT8.

Human MCT8 consists of 613 or 539 amino acids, depending on which of the two possible translation start sites is used, and MCT10 has 515 amino acids. They are homologous proteins with about 50% amino acid identity between 'short' MCT8 and MCT10 (Figure 3.1.2.6). Like the other MCTs, both MCT8 and MCT10 have 12 transmembrane domains. They have identical gene structures; the *MCT8* gene is located on human chromosome Xq13.2, and the *MCT10* gene is located on chromosome 6q21-q22. Both consist of six exons and five introns, with a large approximately 100 kb first intron. MCT8 and MCT10 show wide but different tissue distributions.

MCT8 and MCT10 are the most active and specific thyroid hormone transporters known today [35, 43, 44]. MCT8 is importantly expressed in brain, in particular in the endothelial cells of the blood-brain barrier, but is also expressed in astrocytes, neurons, and in the choroid plexus. MCT8 is essential for thyroid hormone uptake in the brain and into neural cells and, thus, for the crucial action of thyroid hormone during brain development. Mutations in MCT8 have been identified as the cause of Allan–Herndon–Dudley syndrome (AHDS). AHDS or MCT8 deficiency occurs in male patients and comprises a severe intellectual and motor disability and a peripheral thyrotoxicosis resulting from highly elevated serum T_3 levels [35, 43, 44] (see Chapter 3.4.5).

SLC17A4 transports T3 and T4 to a similar extent as MCT8 and is expressed in the human gastrointestinal tract. Although genetic variation is related to fT_4 concentrations, the precise function in physiology is unknown.

Several compounds may affect thyroid hormone uptake through inhibition of transporters (e.g. amiodaron) or changing the expression (e.g. non-thyroidal illness) and as such affect intracellular thyroid hormone bioavailability.

Metabolism of Thyroid Hormone

Deiodination

The thyroid gland of a healthy human adult with an adequate iodine intake produces predominantly the prohormone T_4 and only a small amount of the bioactive hormone T_3. It is generally accepted that, in humans, approximately 80% of circulating T_3 is produced by enzymatic outer ring deiodination (ORD) of T_4 in peripheral tissues [24]. Alternatively, inner ring deiodination (IRD) of T_4 produces the inactive metabolite reverse T_3. Deiodination is also an important pathway by which T_3 and reverse T_3 are further metabolized. T_3 largely undergoes IRD to the inactive compound T_2, which is also the main metabolite produced from reverse T_3 by ORD (Figure 3.1.2.7). Thus, the bioactivity of thyroid hormone is determined to an important extent by the enzyme activities responsible for the ORD (activation) or IRD (inactivation) of iodothyronines.

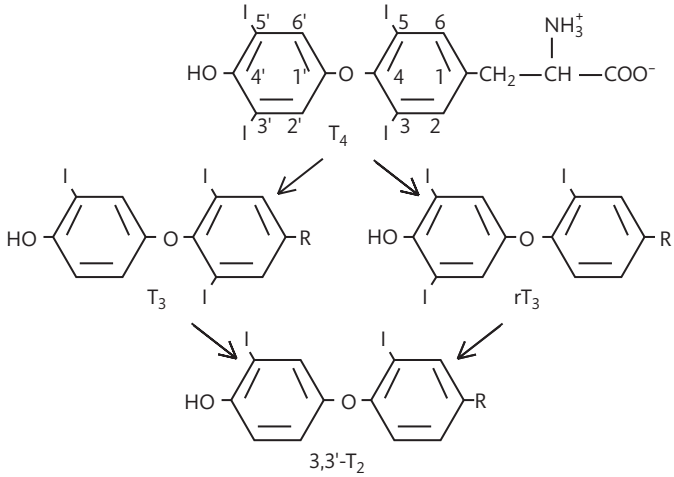

Figure 3.1.2.7 Conversion of the prohormone T_4 by outer ring deiodination (ORD) to the bioactive hormone T_3 or by inner ring deiodination (IRD) to the metabolite reverse T_3, and further conversion of T_3 by IRD and of reverse T_3 by ORD to the common metabolite T_2.

Three iodothyronine deiodinases (D_{1-3}) are involved in the reductive deiodination of thyroid hormone (Figure 3.1.2.8) [45]. They are homologous proteins consisting of 249–278 amino acids, with a single transmembrane domain located at the N-terminus. The deiodinases are inserted in cellular membranes such that the major part of the protein is exposed on the cytoplasmic surface. This is consistent with the reductive nature of the cytoplasmic compartment required for the deiodination process.

The most remarkable feature of all three deiodinases is the presence of a selenocysteine (Sec) residue in the centre of the amino acid sequence. As in other selenoproteins, this Sec residue is encoded by a UGA triplet, which in mRNAs for non-selenoproteins functions as a translation stop codon. The translation of the UGA codon into Sec requires the presence of a particular stem-loop structure in the 3′-untranslated region of the mRNA, termed Sec-insertion sequence (SECIS) element, Sec-tRNA, and several cellular proteins, including SECIS-binding protein (SBP2). A bona fide SECIS element has been identified in the mRNA of all deiodinases [45].

D_1 is a membrane-bound enzyme expressed predominantly in liver, kidneys, and thyroid [45]. It catalyses the ORD and/or IRD of a variety of iodothyronine derivatives, although it is most effective in the ORD of reverse T_3. In the presence of dithiothreitol (DTT) as the cofactor, D_1 displays high K_m and V_{max} values. Hepatic D_1 is probably a major site for the production of plasma T_3 and clearance of plasma reverse T_3. D_1 activity in liver and kidney is increased in hyperthyroidism and decreased in hypothyroidism, representing the regulation of D_1 activity by T_3 at the transcriptional level.

The Sec residue is essential for the function of D_1 since substitution with Cys reduces enzyme activity to 1%, while substitution with Leu yields a completely inactive protein. Rapid inactivation of D_1 by iodoacetate is probably due to modification of the highly reactive Sec residue. Thus, Sec is the catalytic centre of D_1.

The different deiodinases require thiols as cofactor. Although reduced glutathione is the most abundant intracellular thiol, its activity is very low compared with the unnatural thiol DTT, which is often used in *in vitro* studies. Alternative endogenous cofactors include dihydrolipoamide, glutaredoxin, and thioredoxin. D_1 shows ping-pong-type kinetics in catalysing the deiodination of iodothyronines by DTT. D_1 activity is potently inhibited by propylthiouracil, and this inhibition is uncompetitive with substrate and competitive with cofactor. Together, these findings suggest that the catalytic mechanism of D_1 involves the transfer of an iodonium ion (I^+) from the substrate to the selenolate (Se^-) group of the enzyme, generating a selenenyl iodide intermediate which is reduced back to native enzyme by thiols such as DTT or converted into a dead-end complex by propylthiouracil.

D_2 is expressed primarily in brain, anterior pituitary, brown adipose tissue, thyroid, and to some extent also in skeletal muscle [45, 46]. In brain tissue, D_2 mRNA has been localized in astrocytes, in particular also in tanycytes lining the third ventricle in the arcuate

Type	D1	D2	D3
			Tissues, e.g.	liver, kidney, thyroid	Brain, pituitary, BAT, thyroid, skeletal muscle	Brain, placenta, fetal tissues
Substrates	rT3 >> T4 = T3	T4 > rT3	T3 > T4
Km	~0,1–10uM	~1 nM	~1 nM
Effects of TH	↑	↓	↑
Function	rT3 clearance plasma T3 production	Local T3 production	T3 and T4 clearance

Figure 3.1.2.8 Properties of the three iodothyronine deiodinases.

nucleus–median eminence region. D_2 is a low-K_m, low-capacity enzyme possessing only ORD activity, with a preference for T_4 over reverse T_3 as the substrate. The amount of T_3 in brain, pituitary, and brown adipose tissue is derived to a large extent from local conversion of T_4 by D_2 and to a minor extent from plasma T_3 [24, 45]. The enzyme located in the anterior pituitary and the arcuate nucleus of the hypothalamus appears very important for the negative feedback regulation of TSH and TRH secretion [1].

In general, D_2 activity is increased in hypothyroidism and decreased in hyperthyroidism. This is explained in part by substrate-induced inactivation of the enzyme by T_4 and reverse T_3 involving the ubiquitin-proteasome system [45]. However, inhibition of D_2 activity and mRNA levels by T_3 has also been demonstrated in the brain and pituitary. The substrate (T_4, reverse T_3) and product (T_3)-dependent downregulation of D_2 activity is important to maintain brain T_3 levels in the face of changing plasma thyroid hormone levels.

In mammals, D_2 mRNA contains a second UGA codon just upstream of a UAA stop codon [45]. It remains to be determined to what extent this second TGA codon specifies the incorporation of a second Sec residue or acts as a translation stop codon. The amino acid sequence downstream of this second Sec is not required for enzyme activity.

D_3 activity has been detected in different human tissues, brain, skin, liver, and intestine, where activities are much higher in the fetal stage than in the adult stage [45]. D_3 is also abundantly expressed in placenta and pregnant uterus. D_3 has only IRD activity, catalysing the inactivation of T_4 and T_3 with intermediate K_m and V_{max} values. D_3 in tissues such as the brain is thought to play a role in the regulation of intracellular T_3 levels, while its presence in placenta, pregnant uterus, and fetal tissues may serve to protect developing organs against undue exposure to active thyroid hormone. Indeed, fetal plasma contains low T_3 (and high reverse T_3) concentrations. However, local D_2-mediated T_3 production from T_4 is crucial for brain development. Also in adult subjects, D_3 appears to be an important site for clearance of plasma T_3 and production of plasma reverse T_3. In brain, but not in placenta, D_3 activity is increased in hyperthyroidism and decreased in hypothyroidism, which at least in brain is associated with parallel changes in D_3 mRNA levels [24, 45].

In contrast to the marked decrease in hepatic and renal (but not thyroidal) D_1 activities, there are only minor effects of selenium deficiency on tissue D_2 and D_3 activities [47]. This may be explained by findings that the selenium state of different tissues varies greatly in selenium-deficient animals. In addition, the efficiency of the SECIS element to facilitate read-through of the UGA codon may differ among selenoproteins, which could result in the preferred incorporation of Sec into D_2 or D_3 over other selenoproteins.

The presence of Sec in a strongly conserved region of the proteins suggests the same catalytic mechanism for the different deiodinases. However, D_2 and D_3 are much less susceptible than D_1 to the mechanism-based inhibitors propylthiouracil, iodoacetate, and gold thioglucose [45]. This could be explained if the reactivity of the selenol group in D_2 and D_3 is much lower than that in D_1. Indeed, substitution of Sec in D_1 with the much less reactive Cys is associated with a dramatic decrease in its sensitivity to inhibition by gold thioglucose and propylthiouracil. Interestingly, the amino acid two positions downstream of the catalytic Sec residue (Ser in D_1, Pro in D_2 and D_3) plays an important role in determining the reactivity of the catalytic Sec residue [45].

Mutations in SBP2 cause a multisystem disorder including abnormalities in deiodinase activity [48]. Patients present growth and developmental delay, myopathy, infertility, and metabolic abnormalities. Some of these features are caused by increased accumulation of reactive oxygen species as a result from deficiencies of antioxidant selenoenzymes such as glutathione peroxidase. Thyroid function tests typically show normal TSH concentrations, elevated fT_4 and rT_3, accompanied by decreased T_3 concentrations. The exact mechanisms underlying the abnormal thyroid parameters are not well understood, but the elevated T_4 and rT_3 levels over T_3 levels indicate that ORD is predominantly affected.

Alanine Side Chain Modification

Intriguing metabolites are generated by side chain metabolism of iodothyronines (Figure 3.1.2.9). By action of decarboxylases such as ornithine decarboxylase (ODC) iodothyronines can be converted into iodothyronamines. In particular two of these, 3-iodothyronamine (T_1AM) and thyronamine (T_0AM), can exert acute and dramatic effects on heart rate, body temperature, and physical activity, inducing a torpor-like state [49]. Thus, these thyroid hormone metabolites appear to have neurotransmitter-like properties, adding a novel dimension to the already diverse effects of the conventional thyroid hormone structures.

The iodothyroacetic acid metabolites 3,3′,5,5′-tetraiodothyroacetic acid (Tetrac) and 3,3′,5-triiodothyroacetic acid (Triac) are generated from T_4 and T_3, respectively presumably by further conversion of iodothyronamines by the monoamine oxidases MAO-A or MAO-B, the (Figure 3.1.2.9) [50]. An alternative, iodothyronines can be converted to their aceto-acidic acid derivatives via an α-keto acid intermediate by the α-aminoadipate aminotransferase/kynurenine aminotransferase II (AADT/KAT II or AADAT), which transaminates halogenated tyrosines [51]. Although, in general, oxidative deamination is an inactivating pathway for monoamines, Triac has significant thyromimetic activity and its affinity for the T_3 receptor TRα1 is equal to that of T_3 and for the TRβ receptor it is even higher that of T_3 (see next section). Triac has a role in selective cases of resistance to thyroid hormone due to mutations in TRβ [52]. Preclinical studies suggest the potential of Triac to improve the neurological phenotype in MCT8 deficiency [53]. There may be multiple pathways leading from T_4 and T_3 to T_1AM and T_0AM with different orders for the successive decarboxylation and deiodination steps. Iodothyronamines are deiodinated by the different deiodinases [54], but it is unknown which iodothyronines are substrates for different decarboxylases or which iodothyronamines are converted by MAO-A or MAO-B. Also, the exact biological functions of the iodothyronamine and iodothyroacetic acid metabolites remain to be established.

Sulphation

In addition to deiodination, iodothyronines are metabolized by conjugation of the phenolic hydroxyl group with sulphate or glucuronic acid (Figure 3.1.2.9). Sulphation and glucuronidation are so-called phase II detoxification reactions, which increase the water solubility of substrates and, thus, facilitate their biliary and/or urinary clearance. However, iodothyronine sulphate levels are normally very low in plasma, bile, and urine, as these conjugates

are rapidly degraded by D_1, suggesting that sulphate conjugation is a primary step leading to the irreversible inactivation of thyroid hormone [55, 56]. Thus, the IRD of T_4 sulphate to reverse T_3 sulphate and of T_3 sulphate to T_2 sulphate is orders of magnitude faster than the IRD of non-sulphated T_4 and T_3, whereas the ORD of T_4 sulphate to T_3 sulphate is completely blocked. Plasma levels (and biliary excretion) of iodothyronine sulphates are increased if D_1 activity is inhibited by drugs such as propylthiouracil, and during fetal development, non-thyroidal illness, and fasting. Under these conditions, T_3 sulphate may function as a reservoir of inactive hormone from which active T_3 may be recovered by action of tissue sulfatases and bacterial sulfatases in the intestine.

Sulfotransferases represent a family of enzymes with a monomer molecular weight of approximately 34 kDa, located in the cytoplasm of different tissues, in particular liver, kidney, intestine, and brain. They catalyse the transfer of sulphate from 3′-phosphoadenosine-5′-phosphosulfate to usually a hydroxyl group of the substrate. Different phenol sulfotransferases have been identified with significant activity towards iodothyronines. These include human SULT1A1, 1A2, 1A3, 1B1, and 1C2 [55]. They have a large substrate preference for T_2, which is sulphated orders of magnitude faster than T_3 or reverse T_3, whereas sulphation of T_4 is hardly detectable.

Surprisingly, human oestrogen sulfotransferase (SULT1E1) is an important isoenzyme for sulphation of thyroid hormone. Although human SULT1E1 shows much greater affinity for oestrogens (K_m *c.*nM) than for iodothyronines (K_m *c.*μM), it sulphates T_2 and T_3 as efficiently as other SULTs, and is much more efficient in sulphating reverse T_3 and T_4 [55]. Human tissues expressing SULT1E1 include liver, uterus, and mammary gland [57]. In particular, the enzyme expressed in the endometrium may be a significant source of the high levels of iodothyronine sulphates in human fetal plasma. Different human SULTs have also been shown to catalyse the sulphation of iodothyronamines [58].

Glucuronidation

In contrast to the sulphates, iodothyronine glucuronides are rapidly excreted in the bile. However, this is not an irreversible pathway of hormone disposal since, after hydrolysis of the glucuronides by bacterial β-glucuronidases in the intestine, part of the liberated iodothyronines is reabsorbed, constituting an enterohepatic cycle [56, 59]. Nevertheless, about 20% of daily T_4 production appears in the faeces, probably through biliary excretion of glucuronide conjugates. Glucuronidation is catalysed by UDP-glucanosyltransferases (UGTs) that utilize UDP-glucuronic acid as cofactor. UGTs are localized in the endoplasmic reticulum of predominantly liver, kidney, and intestine. Most UGTs are members of the UGT1A and UGT2B families [60].

Glucuronidation of T_4 and T_3 is catalysed by different members of the UGT1A family, 1A1, 1A3, and 1A7–10. Usually, this involves the glucuronidation of the hydroxyl group (Figure 3.1.2.9), but human UGT1A3 also catalyses the glucuronidation of the side chain carboxyl group, with formation of so-called acyl glucuronides [61]. Interestingly, Tetrac and Triac are much more rapidly glucuronidated in human liver than T_4 and T_3, and this occurs predominantly by acyl glucuronidation [62].

In rodents, metabolism of thyroid hormone is accelerated through induction of T_4-glucuronidating UGTs by different classes of compounds, including barbiturates, fibrates, and polychlorinated biphenyls [63, 64]. This may result in a hypothyroid state as the thyroid gland is not capable of compensating for the increased hormone loss. In humans, thyroid function may be affected by induction of T_4 glucuronidation by antiepileptics, but overt hypothyroidism is rare [65]. Administration of such drugs to T_4-replaced hypothyroid patients may necessitate an increase in the T_4 substitution dose.

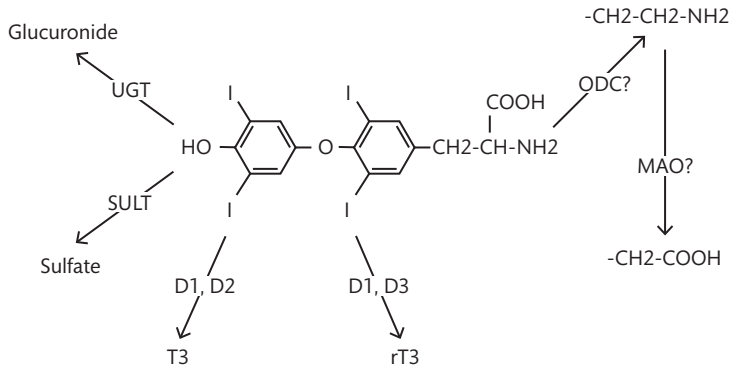

Figure 3.1.2.9 Pathways of thyroid hormone metabolism.

Thyroid Hormone Actions

Role of Thyroid Hormone in Thermogenesis

Thyroid hormone is critical for the development of different tissues, in particular the brain, but it is also essential for an optimal function of most tissues in adult life [66]. It is probably the most important factor regulating thermogenesis, as reflected by the increase in the basal metabolic rate in hyperthyroid subjects and the decrease observed in hypothyroid individuals [67–69]. Thyroid hormone increases the synthesis as well the degradation of proteins, lipids, and carbohydrates, predominantly by stimulating the expression of key enzymes involved in these processes. Examples of these are the lipogenic enzymes, malic enzyme, fatty acid synthase, and glucose-6-phosphate dehydrogenase, and the gluconeogenic enzyme phosphoenolpyruvate carboxykinase.

Special forms of substrate cycling take place between the cytoplasm and the mitochondrion, such as the glycerol-3-phosphate/dihydroxyacetone phosphate shuttle in which cytoplasmic and mitochondrial α-glycerophosphate dehydrogenase (αGPD) isoenzymes participate [67, 68]. This represents one way to enable oxidation of cytoplasmic NADH in the mitochondrion, which is impermeable to this cofactor. Thyroid hormone stimulates the expression of mitochondrial αGPD, and the increased electron flow via this enzyme is associated with an increased heat production relative to adenosine triphosphate (ATP) synthesis.

Thyroid hormone also increases the activity of Na^+,K^+-ATPase, an enzyme located in the plasma membrane of all tissues, in particular kidney, heart, and skeletal muscle, which is responsible for the maintenance of the Na^+ and K^+ gradients across this membrane. In myocytes, the increased Na^+,K^+-ATPase activity accelerates the repolarization of the sarcolemma following a depolarization stimulus that contributes to the tachycardia induced by thyroid hormone.

Another important target for thyroid hormone action is the Ca^{2+}-ATPase located in the sarcoplasmic reticulum of muscle cells [69]. Innervation of the myocyte triggers the release of large amounts of

Ca^{2+} from the sarcoplasmic reticulum into the cytoplasm, where it binds to the actomyosin complex that initiates contraction. There are two Ca^{2+}-ATPase isoenzymes, SERCA1 that is characteristic for fast-type skeletal muscle and SERCA2 that is characteristic for slow-type skeletal muscle and heart. T_3 increases Ca^{2+}-ATPase activity by stimulating the transcription of both *SERCA1* and *SERCA2* genes, which explains the increased relaxation rate of the muscle induced by T_3 [69].

It has been estimated that excess Ca^{2+} cycling in contracting muscle may account for up to 50% of the T_3-dependent energy expenditure during work or shivering [69]. The remainder of the T_3-induced energy turnover in contracting muscle is largely accounted for by the change in the expression of two forms of the myosin heavy chain which are characterized by high (MHCα) and low (MHCβ) ATPase activities and contraction rates. T_3 stimulates the expression of the *MHC*α gene, whereas it inhibits the expression of the *MHC*β gene [69]. A similar T_3-induced shift in MHC expression is also observed in the heart [70].

In addition, T_3 increases the expression of the uncoupling protein UCP1 in brown adipose tissue (BAT) [67, 68]. This is an important mechanism by which T_3 stimulates non-shivering cold-induced thermogenesis. UCP1 is an ion transporter located in the inner mitochondrial membrane which dissipates the proton gradient over this membrane generated by the respiratory chain, producing heat instead of ATP. Significant BAT depots have been demonstrated in the neck and shoulder region of normal adults, especially in cold-adapted subjects and more so in younger females than in older males [71]. Cold exposure leads to a dramatic stimulation of D_2 expression in BAT, and the resultant induction of local T_3 production plays an important role in the stimulation of BAT activity. This includes increased mobilization and burning of lipids as well as stimulated UCP1 expression, together resulting in a major increase in heat production [67, 68].

UCP1 is expressed exclusively in BAT. Other members of the UCP family are expressed in other human tissues, including UCP2 in a variety of tissues including heart and skeletal muscle, UCP3 in skeletal muscle, and UCP4 and UCP5 in brain. The expression of UCP2 and UCP3 is also under positive control of thyroid hormone, but their role in T_3-induced thermogenesis has not been established [72].

The regulation of the mitochondrial proteins UCP1 and αGPD by thyroid hormone is mediated predominantly by interaction of the nuclear T_3 receptor with the promoters of these genes [67, 72]. However, there is also evidence for direct effects of thyroid hormone on the mitochondria, the mechanism of which is incompletely understood but may involve interaction of T_3 and other iodothyronines such as 3,3'-T_2 and 3,5-T_2 with cytochrome *c* oxidase [73]. Many studies have reported effects of thyroid hormone on cellular processes that are not mediated by the nuclear T_3 receptor, including stimulation of transport of glucose, amino acids, and ions over the cell membrane, stimulation of actin polymerization in neurons, and stimulation of mitogen-activated protein kinase activity. The last is mediated by the binding of iodothyronines to integrin, a plasma membrane receptor. The interested reader is referred to an extensive review of these extranuclear actions of thyroid hormone [74].

Specific thyroid hormone-binding sites have also been detected in the cytoplasm in different tissues. A notable example is the NADPH-dependent cytoplasmic thyroid hormone-binding protein present in rat liver, which appears to be important for the trafficking of thyroid hormone to the nucleus or mitochondria [75].

Mechanism of T3 Action

Most biological actions of T_3 are initiated by its binding to nuclear T_3 receptors [76–78]. These proteins are members of the superfamily of ligand-dependent transcription factors, which also includes the receptors for steroids (e.g. cortisol, oestradiol, and testosterone), 1,25-dihydroxyvitamin D_3, retinoic acid, and 9-*cis*-retinoic acid. The last, so-called retinoid X receptor (RXR) is an important member of this gene family, because it forms functional heterodimers with a number of other nuclear receptors, including T_3 receptors. Two T_3 receptor genes have been identified; the *THRA* gene encoding TRα is located on human chromosome 17 and the *THRB* gene encoding TRβ on human chromosome 3. By alternative exon utilization of both genes, four major receptor isoforms, TRα1, TRα2, TRβ1, and TRβ2, are generated, which consist of 410–514 amino acids (Figure 3.1.2.10). Although the *THRB* gene (150 kb) is much larger than the *THRA* gene (*c.*30 kb), they have similar genomic structures, comprising 10 (*THRB*) or 11 (*THRA*) exons, and their coding sequences show a high degree of homology [76–78].

As in the other members of the nuclear receptor family, functional key domains have been recognized in the T_3 receptors, in particular the DNA-binding domain (DBD), which is approximately 100 amino acids long, and the ligand-binding domain (LBD), which

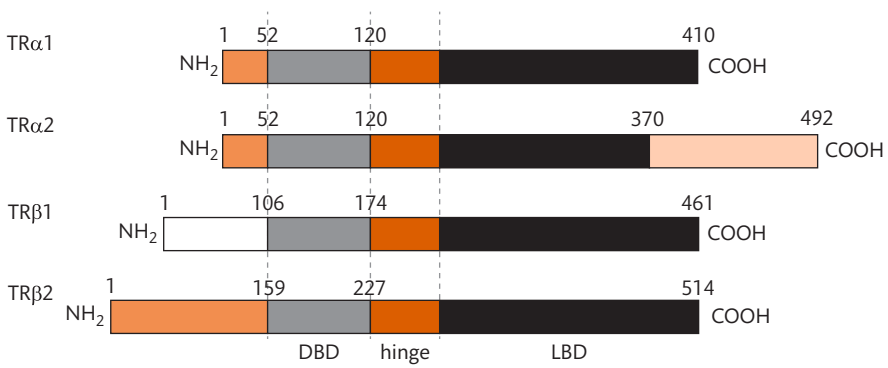

Figure 3.1.2.10 Domain structures of the different T_3 receptor (TR) isoforms. The TRα2 variant is incapable of binding T_3. DBD, DNA-binding domain; LBD ligand-binding domain.

is approximately 250 amino acids in length [76–78]. The amino acid sequences of the TRα and TRβ subtypes are most homologous in their DBD and LBD and least homologous at their N-terminus. The latter contains the ligand-independent AF1 transactivation domain, while an AF2 domain necessary for homo- and heterodimerization and ligand-dependent activation is located at the C-terminus. The short sequence between the DBD and the LBD is usually referred to as the hinge region.

The structural difference between TRα1 and TRα2 is located at the C-terminus of the proteins, where the sequences of the last 40 amino acids in TRα1 and 122 amino acids in TRα2 differ completely due to alternative splicing. The alteration in the LBD of TRα2 is associated with a complete loss of T_3 binding. Therefore, this splice variant is not a *bona fide* T_3 receptor, but for convenience it will still be referred to here as TRα2. TRα2 has a weak negative effect on the action of T_3 through the other T_3 receptors. The N-terminal domains of TRβ1 (106 amino acids) and TRβ2 (159 amino acids) differ almost completely due to utilization of alternative transcription start sites. Apparently, this domain provides TRβ2 with specific properties required for T_3-induced downregulation of *TRH* and *TSH* genes [76–78].

The high homology between the LBDs of TRα1 and TRβ explains their very similar ligand specificity, with affinities much higher for T_3 than for T_4. However, the metabolite Triac also binds to the T_3 receptors with an affinity equal to (TRα1) or even greater than (TRβ1) that of T_3 [79]. Nevertheless, T_3 is the major endogenous iodothyronine occupying the nuclear thyroid hormone receptors, which are thus true T_3 receptors. Several TRβ-specific agonists have been developed with pharmacologically interesting and selective effects on the liver, resulting in lowering of body weight, lipid, and cholesterol without detrimental effects on the heart [78, 79]. Most likely, the tissue-specific effects of these compounds are not only determined by their affinity for the T_3 receptor isoforms but also by the diverse ligand-preference of thyroid hormone transporters in different tissues. Interestingly, non-selective T_3 receptor antagonists have been developed as well [78, 79].

The different T_3 receptor isoforms show distinct tissue distributions [76–78]. The TRα1 is the predominant T_3 receptor expressed in brain, heart, and bone, whereas TRβ1 is the major receptor in other tissues, including liver, skeletal muscle, kidney, and fat. TRβ2 is preferentially expressed in the anterior pituitary and the hypothalamic area of the brain. These locations suggest the particular involvement of TRβ2 in the feedback inhibition of TSH and TRH secretion by thyroid hormone. Exon utilization specifying TRβ2 expression in the anterior pituitary is under the control of pituitary-specific transcription factor 1, response elements for which are located in the TRβ gene promoter [80]. Regulation of the expression of T_3-responsive genes involves the binding of the T_3 receptors to so-called T_3 response elements (TREs) in the promoter region of these genes [76–78]. TREs usually consist of two half-sites arranged as repeats or palindromes. The most prevalent TRE half-site sequence is AGGTCA, and the direct repeat of this half-site spaced by four nucleotides (DR4) is a particularly powerful TRE. However, some TREs show marked deviation from this 'consensus' half-site sequence, which, moreover, is also recognized by other receptors such as RXR and the retinoic acid receptor. This may be the basis for 'cross-talk' between different nuclear receptors and their target genes. Although T_3 receptors may bind as homodimers to the TREs, T_3 effects on gene expression are usually mediated by T_3 receptor/RXR heterodimers.

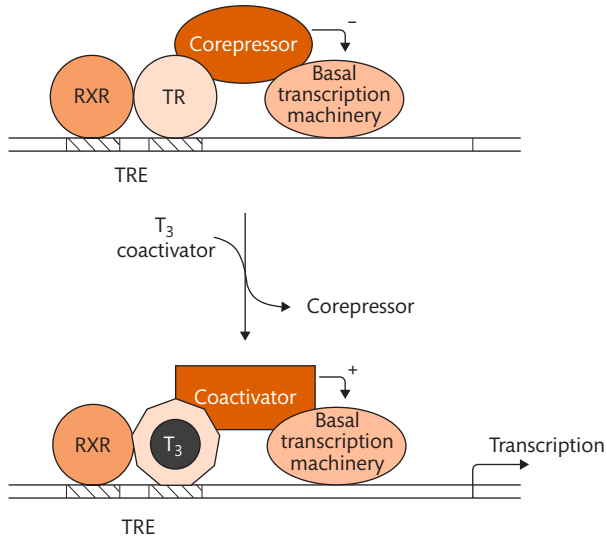

Figure 3.1.2.11 Simplistic model of the regulation of gene transcription by T_3. RXR, retinoid X receptor; TR, T_3 receptor; TRE, T_3 response element in the promoter of a T_3-responsive gene.

Binding of the T_3 receptor/RXR heterodimer to TRE does not require T_3 or 9-*cis*-retinoic acid, the ligand for RXR. The DBDs of these (and other) nuclear receptors contain two 'zinc fingers' (peptide loops that chelate a zinc atom) that fit in the grooves of the DNA and are, thus, very important for the specificity of the receptor-promoter interaction [76–78]. In the absence of T_3 and irrespective of the presence of 9-*cis*-retinoic acid, binding of the T_3 receptor/RXR heterodimer to the TRE results in suppressed gene transcription mediated by the binding of corepressor proteins such as NCoR (nuclear corepressor) or SMRT (silencing mediator of retinoid and thyroid hormone receptors) to a specific region (CoR box) of the unliganded T_3 receptor (Figure 3.1.2.11). These corepressors directly or indirectly inhibit the activity of the basal transcription machinery.

Binding of T_3 induces a conformational change in the T_3 receptor, which results in the release of the corepressors and the recruitment of coactivator proteins such as SRC1 (steroid receptor coactivator-1) and CBP (cAMP response element-binding protein (CREB)-binding protein) [76–78]. The AF2 domain, a highly conserved 9-amino acid sequence located at the C-terminus of the different nuclear receptors, plays an important role in the binding of the coactivators. The latter directly or indirectly stimulate the activity of the basal transcription machinery. One mechanism by which transcription is stimulated involves the histone acetyltransferase activity of the coactivators or of other proteins with which they interact. Acetylation of histones loosens the chromatin structure and thus facilitates interaction of the transcription machinery with the DNA. Conversely, corepressors may recruit proteins with deacetylase activity.

T_3 Inhibition of TSH and TRH Gene Expression

The earlier discussion of the mechanism of action of T_3 concerns the expression of genes which are under positive control of thyroid hormone. However, a roughly equal number of genes are negatively regulated by T_3, in particular those involved in the negative feedback regulation of the hypothalamus–pituitary–thyroid axis (i.e. the *TSH*β and the *TRH* genes). In the promoter regions of these genes

negative TREs have been identified that often consist of only one half-site. In the *TSH*β gene such a negative TRE has been found in close proximity to the AP-1 site which mediates the stimulation of *TSH*β gene transcription by TRH. As just mentioned, there appears to be a specific role for TRβ2 in the regulation of the negative TREs in the *TSH*β and *TRH* genes [76–78]. In contrast to gene regulation through positive TREs, binding of TRβ2 to negative TREs in the absence of T_3 probably results in the activation of gene transcription. In the presence of T_3, transcription is inhibited. The exact mechanism of this negative regulation of gene expression by T_3 and any T_3 receptor is still unclear.

*TSH*β gene transcription is also strongly inhibited by 9-*cis*-retinoic acid, and this effect is mediated by the pituitary-specific RXRγ1 subtype, and involves both TRE-dependent and TRE-independent interactions with the *TSH*β gene promoter. The clinical relevance of this effect is underscored by a recent study showing that treatment of patients with T-cell lymphoma with bexarotene, another RXR-selective ligand, induces central hypothyroidism [81]. It is also interesting to mention that the *TRH* gene promoter contains a glucocorticoid response element. Hypothalamic TRH-producing cells also express the glucocorticoid receptor, and the interaction of this receptor with its response element appears to mediate the inhibition of TRH synthesis by glucocorticoids [82].

In addition to the regulation of TSHβ and α-subunit gene expression, T_3 also acutely inhibits TSH secretion, the exact mechanism of which is still unresolved. Although T_3 is the active hormone exerting the inhibition of TSH production and secretion, serum T_4 appears to be a major player in the negative feedback regulation of the hypothalamus–pituitary–thyroid axis by acting as a precursor for local D_2-mediated generation of T_3 at these central sites [45, 83].

Recent research in two particular areas has led to important advances in our understanding of the mechanism of action of T_3. One type of study has utilized T_3 receptor knockout and mutant mice in which one or more of the different T_3 receptor isoforms is deleted or mutated [78]. These studies reveal which organ functions critically depend on the type of T_3 receptors they express. Similarly, mice mutant for NCoR or SMRT have revealed important insights in the function of corepressors in thyroid hormone signalling [84]. Much knowledge regarding the molecular mechanisms of T_3 receptor/T_3 action has also been gained from studies in patients with thyroid hormone resistance associated with mutations in TRβ (resistance to thyroid hormone; RTH). In recent years, patients with mutations in TRα have been identified. For a thorough discussion of RTHα and RTHβ, the reader is referred to Chapter 3.4.5.

3.1.3 Clinical Assessment of the Thyroid Patient

Inge Bülow Pedersen and Stig Andersen

Introduction

Thyroid disorders are common and their occurrence increase with age. The number of structural abnormalities rise with age reaching 20–40% in women [1, 2] and functional abnormalities are 20–30% in old people [3]. This makes evaluation of thyroid function, size, and structure an important part of any complete history taking and physical examination of a patient.

Deficient or excessive thyroid hormone secretion affects nearly all body systems, and examination of a patient with a proven or suspected thyroid abnormality should include a more general evaluation of the patient. For example, an episode of thyrotoxicosis in an old person may provoke atrial fibrillation and impair cardiac function. The abnormality may persist after treatment of the thyrotoxicosis, and there may be a need for supplementary therapy directed against the atrial fibrillation. Similarly, symptoms of arteriosclerotic heart disease may worsen after initiation of treatment in a patient with hypothyroidism. Both hypothyroidism and heart disease should be diagnosed to make an appropriate plan for therapy.

The three key abnormalities of the thyroid gland are: [1] thyrotoxicosis with excessive thyroid hormone that affects the body; [2] hypothyroidism with thyroid hormone deficiency; [3] and goitre with a general or focal abnormal enlargement of the thyroid gland. A fourth but less common abnormality is the painful thyroid. Examination of the thyroid patient should lead to a conclusion based on symptoms and signs related to these abnormalities.

Clinical symptoms and signs of hyper- and hypothyroidism are many and they are given and detailed in subsequent chapters. However, symptoms and signs of a clinical condition requiring more than usual observation or even acute therapy should be identified during the initial assessment. The risk of thyrotoxic crises should be included in the evaluation of a thyrotoxic patient. The risk of myxoedema coma is very low in the patient with hypothyroidism. Still, the condition certainly should not develop during the period of diagnostic work-up. **Box 3.1.3.1** lists some symptoms and signs that should raise attention to the development of a severe thyroid condition, including factors that signify risk of thyroid malignancy in a patient with goitre. The presence of these symptoms and signs guide the decision to accelerate further diagnostic evaluation.

A number of different thyroid diseases may cause various thyroid abnormalities. Any clinical finding that rise the suspicion of a thyroid functional or structural abnormality should initiate a systematic evaluation of the disease underlying the abnormality (nosological diagnosis). For example, if the patient seems to be thyrotoxic the examination should lead to a provisional conclusion on the

Box 3.1.3.1 Warning symptoms and signs in thyroid patients

- Untreated hyperthyroidism[a]
  - Fever
  - Diarrhoea
  - Severe tachycardia (resting pulse rate >110 beats/min)
  - Complication severe disease
  - Resting dyspnoea
- Untreated hypothyroidism[b]
  - Somnolence
  - Hypothermia
  - Complicating severe disease
- Goitre[c]
  - Hard solitary nodule
  - Growth of nodule
  - Stridor or hoarseness
  - Fixed to surroundings
  - Enlarged lymph nodes
  - Radiation to the neck as a child

[a] In untreated hyperthyroidism imminent thyrotoxic crisis should be looked for. Another severe complication is pulmonary embolism, in part due to dehydration.
[b] Somnolence and hypothermia may be warnings of myxoedema coma.
[c] Symptoms and signs indication a higher risk of malignancy in a goitre.

disease causing the thyrotoxicosis. The four most common causes of thyrotoxicosis are Graves' disease, multinodular toxic goitre, toxic adenoma, and subacute thyroiditis [4]. The diagnosis should be substantiated by further biochemical tests and imaging procedures.

Some of the diseases leading to thyroid abnormalities may have other manifestations. It is important to look out for these. A common example is the orbitopathy that may present even prior to abnormal thyroid function, and some may not develop thyroid dysfunction despite manifest orbitopathy. The pretibial myxoedema of Graves' disease is a rare example, as is the retroperitoneal fibrosis with ureteral obstruction encountered in some patients with Riedel's thyroiditis.

The history and clinical examination may point directly to a specific thyroid disorder and the diagnostic sensitivity and specificity may be nearly 100% in some cases. However, the symptoms and signs of hypo- or hyperthyroidism overlap considerably with complaints and abnormalities commonly seen in other diseases and in apparently healthy people (e.g. fatigue, weight alterations, nervousness, lack of concentration, constipation). Importantly, the diagnostic accuracy of symptoms decreases with age and are no longer valid past the age of 65 years [5]. Biochemical testing of thyroid function is thus essential in the evaluation of the thyroid patient.

Laboratory test results of thyroid function may be influenced by a number of clinical conditions and by medication. Interpretation of test results depend on information on medication and clinical conditions and it is important to obtain this information. One important example is pregnancy [6]. Both total and free thyroid hormones in serum vary during normal pregnancy, and pregnancy-induced modulations of the immune system may modify autoimmune thyroid abnormalities.

Transient hypo- or hyperthyroidism are seen in 5–10 % of women 3–10 months after delivery as part of autoimmune postpartum thyroiditis. Another example is severe general illness [7], which may be accompanied by various alterations in total and free thyroid hormones and thyroid-stimulation hormone (TSH) in serum even if the thyroid gland is not affected.

Medication may alter thyroid function tests [8]. Some important examples are oestrogens (high thyroxin-binding globulin with high total thyroxine (T4) and triiodothyronine (T3)), carbamazepine, and phenytoin (low total and free T4 and T3), and amiodarone (high total and free T4, slightly depressed total and free T3, and TSH in the upper part for the reference range). These are the variations seen in patients without thyroid abnormalities. Amiodarone has high iodine content and is also a frequent cause of thyroid disease.

Excess iodine may induce hypo- or hyperthyroidism in susceptible individuals. The disease is transient in most cases, and the sources may be iodine-containing medications, over-the-counter 'health products' with iodine, intake of seaweed, or iodine-containing radiocontrast agents. The type of dysfunction depends on the general iodine intake of the population. Hypothyroidism is the common abnormality induced in geographical areas with a high iodine intake, while thyrotoxicosis predominates in areas with a low basic iodine intake. This difference in type of abnormality induced be excess iodine intake reflects the underlying difference in the epidemiology of thyroid abnormalities in low and high iodine intake areas. Low iodine intake areas see frequent non-toxic and multinodular toxic goitres, whereas autoimmune diseases with subclinical and clinical hypothyroidism are common in high iodine intake areas. Hence, history taking should include information on excess iodine intake and additional information on the general iodine intake level in the area. This will provide clues to the probability of the various thyroid abnormalities to look out for.

Thyroid diseases cluster in some families and a family history is a valuable contribution to the risk estimation for a patient. Information on more specific genetic defects such as those leading to thyroid hormone resistance syndromes or to alterations of hormone binding proteins in serum is important to avoid diagnostic errors. The presence of autoimmune disorders such as vitiligo, rheumatoid arthritis, type 1 diabetes, Addison's disease and pernicious anaemia in a patient considerably enhances the risk of an autoimmune thyroid disorder in the patient and may guide the focus of the diagnostic work-up.

Previous thyroid disease raises the risk of current thyroid abnormality. For example, both hyper- and hypothyroidism may be transient if induced by excessive iodine intake (see Chapter 3.2.4). However, there may be an underlying subclinical thyroid abnormality such as autonomous thyroid nodules in hyperthyroidism or autoimmune thyroiditis in hypothyroidism and re-exposure to excess iodine commonly causes relapse. Still, spontaneous development of a thyroid function abnormality may also occur.

Patients with postpartum thyroiditis typically harbour an underlying autoimmune thyroiditis. Hence, a new episode of thyroiditis is common following a subsequent pregnancy, and the risk of a permanent thyroid hypofunction increases considerably. The risk of relapse is high (in the order of 50%) in a patient in remission after previous medical treatment for the hyperthyroidism of Graves' disease. Some patients treated with radioiodine or surgery for hyperthyroidism develop immediate or early hypothyroidism, though it may develop later and occur even after decades in others. Patients who have received external radiation of the neck have an increased risk of hypothyroidism. Patients treated with radiation to the neck or exposed to radioactive fallout during childhood have a markedly increased risk of malignant and benign thyroid nodules.

The history of tobacco smoking is pertinent to history taking in the patient with thyroid disease because smoking may aggravate the

orbitopathy of Graves' disease [9], and lead to a high frequency of goitre by interacting with iodine in the thyroid in iodine deficiency [10].

Physical Examination of the Thyroid Gland

Any complete physical examination of the thyroid gland includes inspection and palpation of the anterior region of the neck. Auscultation of the thyroid gland can be used to evaluate bold flow in a goitre and percussion of the upper part of the sternum may be used as an indicator for the presence of a large retrosternal goitre.

The normal thyroid is situated with the upper poles of the lobe at the level of the cricoid cartilage. The lower poles are 1–2 cm above the sternoclavicular junction in young adults, but the thyroid gland tends to be located more caudally on the neck in elderly people.

Inspection of the Thyroid Gland

The patient is examined sitting or standing with light from a window or a lamp at an obliquely angle on the anterior of the neck. The chin of the patient is raised moderately. Inspection of the skin may reveal scars after thyroid surgery and vascular changes suggesting impaired venous flow or pervious radiation of the neck.

Do careful inspection of the thyroid region for signs of thyroid enlargement, nodules, and asymmetry (Figure 3.1.3.1a). The normal thyroid gland is not or only barely visible in most people. The exception is young women with a slender neck, in whom a high and medially situated normal thyroid gland may give the clinical impression of goitre ('pseudo-goitre').

The next step is inspection of the region while the patient is swallowing. In lack of drinking water, the patient may be asked to imagine chewing a piece of lemon. This may induce salivation and facilitate swallowing. The thyroid gland will normally move upwards during swallowing following the trachea (compare the thyroid region before swallowing (Figure 3.1.3.1b) with the region during swallowing (Figure 3.1.3.1c)). Small thyroid enlargements and nodules may be identified in this way. Inspection during swallowing is an important part of characterization of a goitre. If the goitre remains fixed to the surroundings and does not move it may be a sign of malignancy (Box 3.1.3.1). If still uncertain, inspect the

Figure 3.1.3.1 Clinical examination of the thyroid gland in a young woman with a small goitre. (a) Inspection with oblique light, (b) inspection while the patient drinks water before swallowing, and (c) during swallowing. Note the change in position of the small goitre. (d) Palpation of the superficial part of the thyroid gland with flat fingertips. (e) Displacement of the thyroid to the left by pressure on the larynx (pressure on the trachea is more irritant). (f) Bidigital palpation of the deep parts of the left thyroid lobe behind the sternocleidomastoid muscle.

thyroid region while the patient swallows, with light from various angels and with the neck of the patient more or less extended.

Palpation of the Thyroid Gland

Palpation can be performed while the examiner and the patient are sitting or standing in front of each other or while the examiner is standing behind the sitting patient. The patient should hold the head upright but the neck should not be hyperextended. Palpation involves a superficial and a deep examination of the gland. In addition, thorough palpation for enlarged cervical lymph nodes should be performed. The superficial part of the thyroid is examined by moving the flat fingertips systematically across the thyroid region searching for swellings and nodules (Figure 3.1.3.1d). When special care is needed, the examination may be facilitated by using lubricant (e.g. gel for ultrasound examination). It may also be helpful to ask the patient to swallow while palpating the gland softly. Nodules and enlarged lobes may be identified when they are moving.

Palpation of the thyroid lobes between the fingers is achieved by displacing the larynx (and thereby the trachea and the thyroid gland) to one side (Figure 3.1.3.1e) and palpating the thyroid lobe behind the sternocleidomastoid muscle as illustrated in Figure 3.1.3.1f. Nodules in the deeper parts of the thyroid lobes can be detected in this way.

If goitre or one or more nodules are found they should be examined and described with respect to size, hardness, location, mobility, and tenderness. Proper description of location is important as it aids interpretation of the findings on the scintigrams, particularly for support of the suspicion of a cold nodule. Lack of mobility during swallowing may be a sign of malignancy but several other possibilities exist. Fixation could be caused by inflammation surrounding an acute or subacute thyroiditis. Such lesions tend, however, to be painful, which is rare in case of a cancer.

Auscultation of the Thyroid Gland

The goitre of patients with active Graves' disease may have a very high blood flow. The flow can occasionally be heard upon auscultation as a systolic murmur over the gland. When present in the medically treated patient it indicates persistent activity of the disease despite medication, and it is often accompanied by a high T_3/T_4 ratio. If surgery is planned, pretreatment with iodine for 7–10 days prior to surgery is recommended [11].

A similar clinical pattern may occasionally be seen in patients with Graves´ disease grossly overtreated with thyroid blocking drugs. The treatment causes a lowering of serum T_3 and T_4 with subsequent excessive TSH secretion. Such high TSH can induce a 'blocking goitre' with a high blood flow.

A systolic murmur over the thyroid does not always originate from the thyroid gland. Other diagnostic options include referred sound from the heart in a patient with aortic stenosis or sclerosis and a systolic murmur from an arteriosclerotic carotid artery.

Reliability of Clinical Assessment in Thyroid Disease

The typical patient with Graves´ disease is a young or middle-aged woman with a family history of thyroid disease, complains of nervousness, heat intolerance, palpitations, weight loss, high pulse rate, agility, and a diffuse goitre. The diagnosis based on clinical assessment is nearly 100% reliable in this case. The occurrence of eye symptoms further supports the diagnosis. However, both hyper- and hypothyroidism may be difficult to diagnose from clinical findings especially in elderly people where the diseases may be monosymptomatic with, for example, slow cerebration in hypothyroidism and weight loss in thyrotoxicosis. Biochemical evaluation of thyroid function is necessary and TSH measurement should be a first-line test.

The diagnosis of goitre is a separate challenge. Classically, goitre is a thyroid gland, which is palpable or visible due to focal or general enlargement. Occasionally the goitre is not visible or palpable because the growth and extension of the gland occurred behind the sternum causing a retrosternal goitre.

A visible and/or palpable thyroid gland is not a goitre if there is no general or focal enlargement. In young women, this may be seen as a 'pseudo-goitre'. Ultrasound examination of the thyroid gland with measurement of volume and identification or exclusion of thyroid nodules is an important supplement to the clinical evaluation. The interobserver variability of thyroid volume determinations by ultrasonography is around 10% and the reproducibility of identifying nodules is high.

The size of the thyroid gland of apparently healthy people is highly dependent on the iodine intake level of the geographical area of the investigation. Upper normal values of 18 ml for women and 25 ml for men have been suggested [12].

However, there is a marked discrepancy between the 'true' thyroid volume determine by ultrasound examination and the finding of no goitre or a small goitre by clinical examination. This is illustrated in Figure 3.1.3.2, which also shows that clinical goitre may not be present despite thyroid volumes several times the upper normal. Systematic studies of the clinical assessment of goitre have shown that estimation of thyroid size by inspection and palpation is imprecise and large intra- and interobserver variations are present [14, 15].

The estimation of thyroid size by clinical examination is imprecise. Evaluation of nodularity of the thyroid gland faces similar difficulties. Solitary thyroid nodules identified by palpation are often part of multinodular glands when examined by ultrasonography. This is seen in up to 50% of cases [16]. Thyroid nodules are identified more frequently in patients when using ultrasound compared to clinical examination. Only around 50% of nodules larger than 1.5 cm detected by ultrasonography were identified by palpation in a follow-up study of patients who had received neck irradiation as children and therefore had a high risk for developing thyroid cancer later in life [17].

A clinical investigation of the thyroid and surroundings remains first-line investigation of the thyroid gland. Clinical investigation is also the initial investigation used for goitre detection. Increased volume of the thyroid gland by ultrasound examination is of limited clinical importance if thyroid function is normal and the patient has no signs or symptoms of goitre.

The situation differs when it is necessary to add test for thyroid function abnormalities and/or investigations for abnormalities of thyroid structure and size. The first-line test for thyroid function is TSH in serum. This should be performed in many patients presenting various complaints of some duration, even with limited clinical suspicion of thyroid disease. On the other hand, clinical examination of the thyroid gland remains an important first-line evaluation for goitre and thyroid nodules. Sensitive imaging procedures including ultrasound should be used for patients with abnormal clinical and/

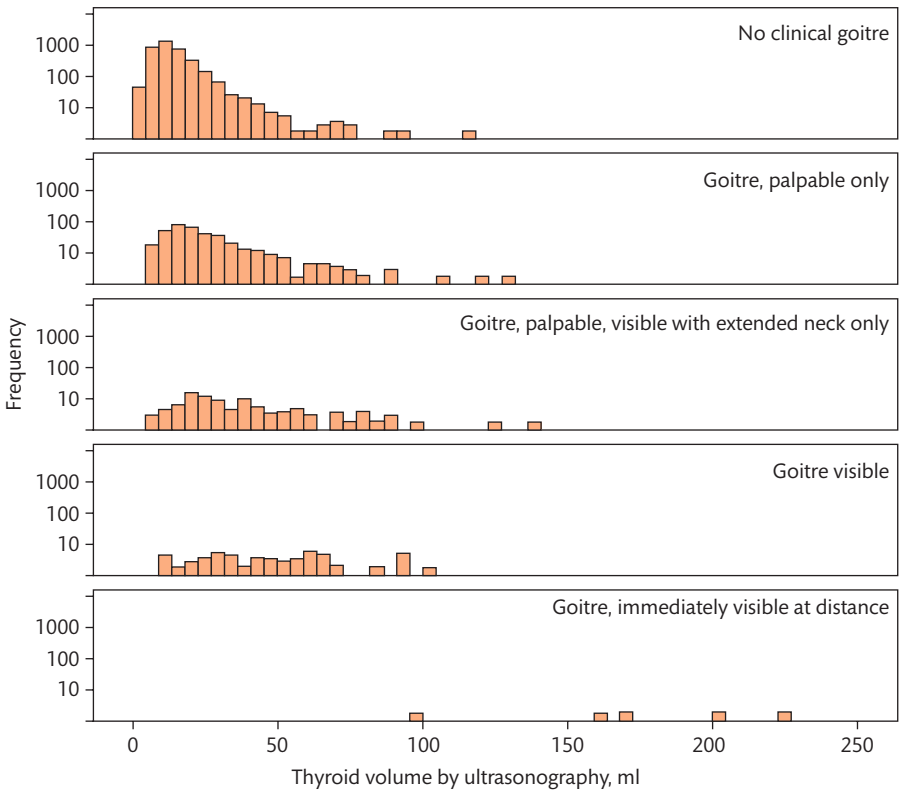

Figure 3.1.3.2 Goitre by clinical examination and thyroid volume measured by ultrasonography in a population study of 4649 people living in an area with mild to moderate iodine deficiency. Data from the DanThyr cross-sectional study performed before the Danish iodine fortification programme [13].

or biochemical findings suggesting thyroid disease, as well as for patients at increased risk of developing thyroid cancer.

3.1.4 Thyroid Function Tests and the Effects of Drugs

Ulla Feldt-Rasmussen

Introduction

Basal metabolic rate followed by protein-bound iodine were the first laboratory tests of thyroid function until the introduction of radioimmunoassay methods [1], which made it possible to quantify both circulating thyroxine (T_4), triiodothyronine (T_3) and thyroid-stimulating hormone (TSH). However, none of the methods had sufficient sensitivity and precision for diagnosing hypo- or hyperfunction of the thyroid gland. Development of third generation immunometric TSH assays with highly improved functional sensitivity allowed suppressed serum TSH concentrations to be clearly distinguished from normal. Different ingenious techniques to estimate the minute free fraction of total serum T_4 have been developed over the years, but even the best free T_4 methods offer only marginal diagnostic advantage over the measurement of total T_4 when the concentration of thyroxine-binding globulin (TBG) and other binding proteins are abnormal. Current enthusiasm for free T_4 and T_3 estimation needs to be tempered by an understanding of the method-dependent limitations of these techniques, particularly where assessment of thyroid function is most difficult.

While there is little doubt that circulating TSH and T_4 should both be measured when an abnormality of thyroid function is clinically suspected, recent recommendations suggest testing a wide range of patient groups with an increased risk of thyroid dysfunction (**Box 3.1.4.1**). Thus, neonatal screening for congenital hypothyroidism is firmly established. Routine testing of thyroid function with a single measurement of serum TSH in women over 50, a group most likely to have significant thyroid dysfunction [2, 3] has become widely recommended. The recognition that adequate maternal T_4 in the first trimester of pregnancy is a crucial determinant of fetal brain development, has led to increased assessment of thyroid function before pregnancy, especially in women with impaired fertility or risk factors for thyroid dysfunction. The frequency of postpartum thyroid dysfunction places a high priority on assessing thyroid function for any suggestive clinical features in the first year after childbirth [4].

There is a trend for peripheral thyroid hormones to be estimated in primary care only if TSH is abnormal. In case of uncertainty of the diagnosis, other biochemical methods such as circulating TBG, thyroid autoantibodies, thyroglobulin as well as genetic

Box 3.1.4.1 Conditions with an increased likelihood of thyroid dysfunction where thyroid function testing should be considered

- Previous thyroid disease or surgery
- Goitre
- Non-thyroid autoimmune disease(s)
- Other endocrine deficiencies
- Atrial fibrillation
- Down's syndrome, Turner's syndrome
- Type 1 diabetes
- Metabolic syndrome, morbid obesity
- Irradiation of head and neck
- Impaired reproductive function in women
  - Polycystic ovarian syndrome; Endometriosis
  - Premature ovarian failure
  - Recurrent miscarriage
- Postpartum ill health
- Preterm infants
- Pituitary abnormality
- Severe head injury

Drug therapy
- Cytotoxic therapy
- Contrast agent or other iodine exposure
- Amiodarone
- Lithium
- Highly active antiretroviral therapy
- Mitotane
- Sunitinib
- Retinoids
- Biological agents (interferon α, interleukin 2, interferon β 1a or 1b, monoclonal antibody treatment; denileukin diftitox)

testing and imaging techniques can assist in defining the thyroid function disturbance [1]. The value of routine testing needs to be compared with sensitivity and accuracy of clinical assessment, which was in unselected patients assessed by primary care physicians and even specialists inferior to laboratory results in up to one-third of patients evaluated for suspected thyroid disease [5]. Finally, many drugs can influence both thyroid function *per se* while some affect the biochemical thyroid function measurements without function disturbance (i.e. spurious and often uninterpretable. This chapter is an update from the previous edition written by the late Jim Stockigt [5]).

The T_4–TSH Relationship

Regardless of the strategy used for first-line testing, serum TSH and a valid serum T_4 estimate are both necessary for definitive assessment of thyroid status. As shown in Figure 3.1.4.1, the common types of thyroid dysfunction can be identified by diagonal deviations from the normal T_4–TSH relationship, which depends on the negative feedback interaction between target gland secretion and trophic hormone. The figure shows primary hypothyroidism due to target gland failure (high serum TSH with low free T_4: A), failure of TSH secretion (both low: B), autonomous or abnormally stimulated target gland function (high serum free T_4 with low TSH: C), and primary excess of TSH or thyroid hormone resistance (both high: D). Abnormal results that fall outside these areas suggest that some other factor has disturbed this relationship, or that the sample has been collected under non-steady state conditions (e.g. altered trophic-target hormone relationship, medications, TSH receptor mutations, hormone resistance syndromes, inaccurate estimates of active hormone concentrations, inaccurate reference ranges, or low assay sensitivity). The figure shows serum free T_4 rather than T_3 because T_4 is the major circulating determinant of TSH secretion.

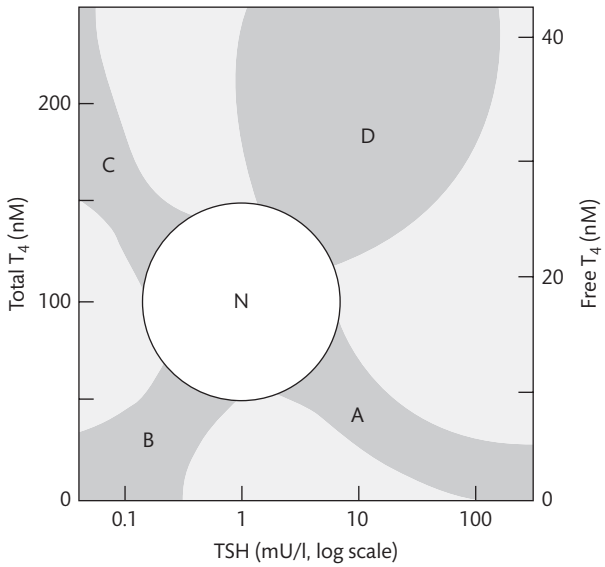

Figure 3.1.4.1 The relationship between serum TSH and total free T_4 concentrations is shown in normal subjects (N) and in various typical abnormalities of thyroid function: primary hypothyroidism (A); central or pituitary-dependent hypothyroidism (B); thyrotoxicosis due to autonomy or abnormal thyroid stimulation (C); and TSH-dependent thyrotoxicosis or generalized thyroid hormone resistance (D). Note that linear free T_4 responses correspond to logarithmic TSH changes. Areas A and C represent primary thyroid abnormalities, while results that fall in areas B and D suggest a primary pituitary abnormality. Abnormal findings that fall in the intermediate areas suggest non-steady state sampling conditions due to the large difference in half-lives of TSH and T_4, an assay artefact, an altered T_4–TSH relationship, or the presence of another agonist (e.g. T_3).

The assumption of steady state condition should always be questioned when associated illness or medications perturb the pituitary–thyroid axis. The large difference between the half-lives of TSH (1 h) and T_4 (1 week) accounts for many transient non-diagnostic abnormalities in the T_4–TSH relationship, such as acute effects of medications, early response to therapy, evolution of disease, and diurnal variations. Optimal assessment of thyroid function depends on collaborative communication across the laboratory–clinical interface [1].

Screening and Case-Finding

In the absence of associated disease, where there are no clinical features to suggest thyroid dysfunction, a normal serum TSH concentration has over 99% negative predictive value in ruling out primary hypothyroidism or thyrotoxicosis [3]. Assessment of untreated subjects with no features of thyroid dysfunction and therefore with low prediagnostic probability now commonly begins with initial measurement of TSH alone, with T_4 and/or T_3 assays added only if TSH is abnormal, or if an abnormality of TSH secretion is suspected. According to this algorithm, free T_4 is measured to distinguish between overt and subclinical hypothyroidism when serum TSH is elevated, while a suppressed or subnormal TSH level should be followed by measuring both free T_4 and T_3 to distinguish subclinical from overt thyrotoxicosis and to identify T_3 toxicosis.

Clinical Suspicion of Thyroid Dysfunction

The use of serum TSH as the sole initial test of thyroid function may lead to incorrect or incomplete assessment of thyroid status in a number of situations [1, 5]. Initial measurement of both T_4 and TSH is appropriate whenever thyroid dysfunction is clinically suspected, because thyroid dysfunction due to pituitary disease, either hypopituitarism, or the less common situation of TSH-dependent hyperthyroidism, may be missed if TSH alone is used for initial assessment [6]. The far-reaching consequences of missing these disorders are not reflected by a small percentage deficit in diagnostic sensitivity.

Evaluating and Adjusting the Response to Treatment

In patients with newly treated thyrotoxicosis, TSH may remain suppressed for months or even longer after normalization of serum T_4 and T_3; serious overtreatment may result if TSH alone is used for adjustment of antithyroid drug dosage. Further, thyrotoxicosis may persist due solely to T_3 excess. Therefore, a reassessment of serum

free T_4 and free T_3 levels is recommended after about 3 weeks of antithyroid drug therapy to allow appropriate dose adjustment.

During standard T_4 replacement therapy a TSH value in the lower normal range usually coincides with an optimal symptomatic response. Serum TSH is the best single index of appropriate replacement of hypothyroidism during long-term T_4-therapy, but during the early phase of treatment, free T_4 should also be measured, because TSH may remain inappropriately elevated long after normalization of T_4. In elderly patients, especially with cardiac ischaemia, dose adjustment is a clinical not a laboratory decision. During T_4 suppressive therapy (e.g. after treatment for thyroid cancer), periodic assessment of free T_4 (but not T_3 [7]), in addition to TSH, is appropriate to identify and avoid thyroid hormone excess that may have adverse effects on the cardiovascular system or bone density.

During treatment of hypothyroidism for hypothalamo-pituitary disease, serum TSH is of limited value in assessing T_4 dosage, which should be based on serum free T_4 and clinical response. However, serum TSH needs to be suppressed to avoid under-replacement [8].

Difficult Diagnostic Situations

Interpretation of thyroid function tests may be compromised by intercurrent illness and medications. There is a high prevalence of abnormal thyroid function tests in patients with acute medical [9] and sometimes acute psychiatric illness [10]. However, when TSH and free T_4 are considered together, as in **Figure 3.1.4.1**, most of these abnormalities do not indicate true thyroid dysfunction. However, the consensus has moved away from routine testing during critical illness without a strict clinical indication [5]. If not due to medications, the combination of low free T_4 and TSH indicates a poor prognosis [5], although these findings cannot usefully influence individual management decisions.

During any severe illness, one or more of the assumptions of hypothalamo–pituitary–thyroid stability may not be valid. Serum TSH values are frequently subnormal in the absence of thyrotoxicosis, but the large majority of thyrotoxic subjects have values below 0.01 mU/L, whereas hospitalized patients with non-thyroidal illness do not show this degree of TSH suppression [11]; serum free T_4 estimates during critical illness are prone to multiple method-dependent interfering influences, due to heparin and other medications. Notably, serum total T_4 measurements are much less prone to such artefacts [12].

In late pregnancy, there are clearly unresolved methodological problems in estimating serum free T_4, with strong negative bias in some methods [4, 13, 14], which has questioned the wisdom of continuing to rely on free thyroxine estimates during pregnancy [13]. In contrast to various free T_4 methods [4, 13] total serum T_4 and its derivative, the free thyroxine index, showed a more robust inverse relationship with serum TSH, with consistent results in numerous reports [13]. Thus, total T_4 measurement may be superior to free T_4 estimates as a guide to therapy during pregnancy, provided modification of the reference values to the normal oestrogen-induced increase in TBG. If free T_4 estimates continue to be used in pregnancy, clinicians should interpret results according to trimester- and method specific reference intervals. Problems inherent in free T_4 measurement during pregnancy and otherwise can possibly be resolved by using isotope dilution liquid chromatography tandem mass spectrometry after ultrafiltration [15].

Measurement of Serum TSH Concentrations

The secretion of TSH, a 24–30 kDa glycoprotein composed of two subunits, from the anterior pituitary is regulated by negative feedback from circulating free T_4 and T_3 concentrations. In normal subjects, serum TSH concentrations show pulsatile and diurnal variation, with approximate mean maximum concentrations of 3 mU/L at 02.00 with nadir values about 1 mU/L at about 16.00 without significant sex difference [16]. This TSH fluctuation with an amplitude of 20–50% makes it difficult to establish the significance of serial changes during follow-up of patients with subclinical hypothyroidism, because a 40% change due to pulsatile secretion can be misread as progression of disease [17].

TSH is measured by immunometric assays using two antibodies against different epitopes on the α- and β-subunits of TSH [11], and serum TSH can be precisely measured at least to 0.03 mU/L. Important factors when clinical decisions are based on values close to the detection limit include between-assay reproducibility or precision profile, composition of assay matrix, possible appearance of non-specific interference during sample storage, as well as possible carryover from one sample to the next during automated sampling [5]. Analytical sensitivity defined as 2 or 3 SD above the zero point is often too optimistic. Functional sensitivity defined as 20% between-assay coefficient of variation has become accepted [11], but assay performance may vary between laboratories despite apparently identical technique. Laboratories should therefore establish their own detection limit from the between-assay precision profile in the subnormal range.

While immunometric TSH assays offer enhanced sensitivity, they may be liable to non-specific interference (e.g. in methods that use mouse monoclonal antibodies). An antimouse immunoglobulin in the test serum allows formation of a false bridge between the solid phase and the signal antibody, thus generating a spuriously high assay value. Inclusion of mouse immunoglobulin in the assay usually blocks this effect, although persistent false-positive serum TSH values are still found in some samples [18].

Most patients with TSH-secreting pituitary tumours have increased serum α -subunit concentrations [19], but values can also be elevated in postmenopausal women and in hypogonadal men.

The TSH Reference Range: Current Controversies and Uncertainties

Between 08.00 and 21.00, reference values for serum TSH are generally in the range 0.3–4 mU/L, following a logarithmic Gaussian distribution and with higher values in the immediate postnatal period. Median values are generally about 1 mU/L with a long tail to the right, so the upper limit of the reference range is contentious. Widespread application of thyroid function testing has identified large numbers of asymptomatic subjects with abnormal TSH and with normal serum T_4, who may merit the designation 'subclinical thyroid dysfunction' [20]. A sustained abnormality should be demonstrated before definite categorization [21]. The

merits and limitations of initiating therapy for these individuals are controversial.

These considerations have become complicated because of lack of consensus on the limits of the TSH range [20, 22], in particular on whether the upper limit of the TSH reference range should be reduced from about 4 mU/L to 3 mU/L or even lower. Similarly, for subclinical hyperthyroidism there is lack of consensus as to classification of subnormal TSH values according to the NHANES III study [11] (TSH values below 0.1 mU/L) or to other guidelines in favour of using values below the lower normal limit of 0.45 mU/L [20]. Since the gradation from normality to severe thyroid dysfunction is a continuum, studies of outcomes from intervention will be critically dependent on uniform cut-off points and terminology.

Until these uncertainties are resolved, it is likely that most clinicians will recommend a period of observation rather than immediate intervention. If a trend towards overt disease is to be the cue to intervention, it is critical to establish what constitutes a significant change in serum TSH value. From an analysis of serial individual variation over 1 year, the difference required for two test results to be convincingly different was 40% for TSH and 15% for free T_4 and free T_3 [17].

Indications for TRH Testing

Thyrotropin-releasing hormone (TRH) testing in clinical practice has almost been eliminated by the highly sensitive TSH assays. However, measurement of serum TSH 20–30 min after intravenous injection of 200–500 µg TRH is still useful for some purposes: (1) when basal serum TSH is out of context (TSH assay artefacts); (2) apparent thyroid hormone resistance or pituitary-dependent thyrotoxicosis (patients with TSH-secreting pituitary tumours show no TSH increase after TRH [19], while those with thyroid hormone resistance usually do); and (3) central hypothyroidism where low serum free T_4 may be associated with normal serum immunoreactive TSH concentration with impaired biological activity [23].

Assays for Serum T_4 and T_3

Concentrations of total serum T_4 and T_3 reflect not only hormone production, but also the number and affinity of plasma protein binding sites. Total concentrations vary in direct relationship to protein binding, while serum free T_4 and free T_3 concentrations should not, if measured by valid methods. Serum total and free T_3 concentrations are higher in children [24]. In pregnancy, reference ranges for free T_4 show marked method-dependent variation; quoted ranges should be both trimester and method specific [25].

Estimation of Serum Free T_4 and Free T_3

There have been many approaches to assay serum free T_4 and T_3 concentrations, with detailed analysis of the validity of various methods [1, 11, 15]. Two-step methods that separate a fraction of the free T_4 pool from the binding proteins before assay are generally least prone to analytical artefacts. No current method conveniently measures the free T_4 concentration in undisturbed, undiluted serum similarly to *in vivo* conditions. Equilibrium dialysis is widely considered the reference method for free T_4 measurement, but is also subject to error. Evaluation of novel serum free T_4 methods should include testing with various protein binding abnormalities, as well as sera that contain substances competing for serum protein binding sites. Unexpected interference may only be noted after methods have been used for some time, as, for example, in the effect of rheumatoid factor [26], or drug competitors for protein binding [27].

Recent reports suggest that methods based on liquid chromatography/tandem mass spectrometry after ultrafiltration, or equilibrium dialysis may improve measurement of free T_4 [15]. Further evaluations, in particular details of long-term reproducibility of these techniques, as well as serial dilution studies to evaluate the effect of circulating inhibitors of T_4 binding are awaited. In many countries the price per sample is prohibitive for routine use, even if the assay quality appears to be superior in terms of sensitivity, precision, and accuracy.

Measurement of Serum T_3

Assays for total or free T_3 have no place in diagnosing hypothyroidism, but should be included in the diagnostic protocol in the following situations:

1. Suspected thyrotoxicosis when serum T_4 is normal and serum TSH is suppressed, to distinguish T_3 thyrotoxicosis from subclinical thyrotoxicosis
2. Antithyroid drug therapy to identify persistent T_3 excess, despite normal or subnormal serum T_4 values
3. Amiodarone-induced thyrotoxicosis, which should not be based on T_4 excess alone
4. Early recurrence of thyrotoxicosis with suppressed TSH, after cessation of antithyroid drug therapy
5. Establish the extent of hormone excess when an intentional T_4 overdose has been taken

The serum T_3 concentration is not useful in assessing T_3 replacement (e.g. because of its short plasma half-life).

Variant Binding Proteins and Antireagent Antibodies

Molecular changes in TBG, transthyretin (TTR), or albumin may result in altered serum concentrations of these binding proteins, or may alter their binding affinity for T_4 and/or T_3. The X-linked structural TBG variants have either normal or reduced affinity for T_4 and T_3. Most X-linked variants cause complete TBG deficiency, while some are associated with subnormal concentrations of immunoreactive serum TBG, often with reduced affinity for T_4 [28]. In complete absence of TBG, total serum T_4 is reduced to 20–40 nmol/L (normal 50–140 nmol/L), whereas in hereditary TBG excess the concentration may increase up to 250 nmol/L [28]; free T_4 should remain normal, but some estimated free T_4 methods do not

correct quantitatively for TBG abnormalities, whether hereditary or acquired.

Familial dysalbuminaemic hyperthyroxinaemia (FDH) [29], shows a selective increase in binding affinity for T_4 resulting in total serum T_4 in the range 180–240 nmol/L. The variant protein has increased affinity for some T_4-analogue tracers, resulting in spuriously high serum free T_4 estimates; equilibrium dialysis, two-step free T_4 methods, and serum TSH and thyroglobulin confirm that people with FDH are euthyroid. The diagnosis is verified by genetic analysis.

Circulating T_3- or T_4-binding autoantibodies can cause methodological artefacts in both total and free measurements of T_4 and T_3 [11, 12]. Tracer bound to the endogenous human antibody will be falsely classified as 'bound' or 'free', leading, respectively, to spuriously low or high serum values. Assay after ethanol extraction establishes the true total hormone concentration.

Interference can also result from antibodies against assay reagents (e.g. antiruthenium, antistreptavidin, or antibiotin) [11]. High dose biotin ingestion has also been shown to result in serious distortion of analyte-specific, platform specific assay results, and is now a frequent cause of false results due to the current popularity of biotin ingestion [11].

Euthyroid Hyperthyroxinaemia and Hypothyroxinaemia

These terms are used when the total or free T_4 concentrations are increased or decreased without evidence of thyroid dysfunction. The effects of medications and alterations in the T_4 binding proteins are the commonest causes. Hypothyroxinaemia is a normal response when TSH secretion is inhibited by another thyromimetic such as T_3 or triiodothyroacetic acid. During critical illness serum T_4 may be subnormal due to inhibition of TSH secretion [30], decreased production of binding proteins, or accelerated T_4 clearance. Hypothyroxinaemia without increase in TSH is also seen in low birthweight premature infants, reflecting hypothalamic–pituitary immaturity [31].

Integration of Tests of Thyroid Function with Other Investigations

When thyroid function is abnormal, additional diagnostic information can be gained from the technologies described here next.

Antibody Measurements

In subclinical hypothyroidism, presence of thyroid peroxidase and/or thyroglobulin antibodies indicates a substantial increased risk of developing overt hypothyroidism [2], and also indicates an increased likelihood of postpartum thyroiditis or amiodarone-induced hypothyroidism. Persistently positive thyrotropin receptor antibody (TRAb) is useful in indicating that apparent remission of Graves' disease is unlikely to be sustained, while negative TRAb are not predictive of permanent remission. TRAb measurement can indicate the possibility of neonatal thyrotoxicosis in the infant of a mother with autoimmune thyroid disease and may also define the aetiology of atypical eye disease.

Thyroid Imaging

The use of isotope imaging techniques in thyrotoxicosis due to Graves' disease varies widely between different centres. While some now regard routine radioisotope imaging as redundant in typical Graves' disease, negligible uptake can be a key feature in confirming thyrotoxicosis due to thyroiditis, iodine contamination, and factitious ingestion of thyroid hormone. Imaging also can confirm a 'hot' nodule as the predominant source of thyroid hormone excess. Computed tomography (CT) is valuable in identifying retrosternal extension, but contrast agents should be avoided. Colour flow Doppler has been reported to differentiate between, for example, type 1 and type 2 amiodarone-induced thyrotoxicosis [32].

Thyroglobulin

In the follow-up of differentiated thyroid cancer, an undetectable serum thyroglobulin concentration (in absence of thyroglobulin antibodies), in presence of high serum TSH indicates effective ablation and may justify less rigorous T_4 suppression of TSH. Thyroglobulin is undetectable in thyrotoxicosis factitia, and generally extremely high in subacute thyroiditis and in amiodarone-induced thyrotoxicosis of the thyroiditis type [5, 11].

Assay of thyroglobulin in the needle wash from suspect neck lymph nodes has a higher sensitivity and specificity than cytology in diagnosing metastatic thyroid tissue [33].

Indices of Thyroid Hormone Action

While there is no reliable laboratory index of peripheral thyroid hormone action, some tests [34], including sex steroid-binding globulin, serum ferritin, serum angiotensin-converting enzyme, as well as oxygen consumption, systolic time interval, and cardiac contractility [35], may be useful in following individual response in situations of suspected thyroid hormone resistance or during long-term suppressive therapy with T_4.

Drug Effects on Serum T_4 and TSH

The multiple effects of medications on the pituitary–thyroid axis have been reviewed elsewhere [1, 28, 36]. Medications that present special problems include amiodarone, heparin, lithium, phenytoin, highly active antiretroviral therapy, immune-mediated therapies [36], and drugs that displace T_4 from TBG. Oestrogen, endogenous or exogenous, most commonly affects tests of thyroid function by increasing total T_4 due to an increase in TBG concentration by increased glycosylation and slower clearance. Free T_4 remains normal. Transdermal oestrogens do not show this effect [28].

Amiodarone

Amiodarone is the most complex and difficult of drugs affecting thyroid status [32]. The clinical entities include two forms of thyrotoxicosis, one due to iodine excess and one attributed to thyroiditis. In iodine-replete regions the predominant amiodarone-induced thyroid abnormality is hypothyroidism, especially in those with associated autoimmune thyroiditis. The drug also causes benign euthyroid hyperthyroxinaemia in up to 25% of treated patients. There is often poor correlation between circulating thyroid

hormone levels and the clinical manifestations of amiodarone-induced thyroid dysfunction, and criteria such as muscle weakness and weight loss are more relevant for severity assessment.

Heparin

In serum obtained from heparin-treated patients, the measured concentration of serum free T_4 may be higher than the true *in vivo* concentration, due to *in vitro* generation of non-esterified fatty acids as a result of heparin-induced lipase activity during sample storage or incubation [27]. Low-molecular-weight heparin preparations have a similar effect [37].

Lithium

Lithium, used in the management of manic-depressive illness, has multiple effects on the pituitary–thyroid axis, the most important being inhibition of thyroglobulin hydrolysis and hormone release [38]. It can exacerbate or initiate autoimmune thyroid disease with development of goitre and hypothyroidism; there are also rare reports of lithium-induced thyrotoxicosis. Serum TSH, T_4, and T_3 assays give a true index of thyroid status during lithium treatment.

Phenytoin and Carbamazepine

The antiepileptic phenytoin and carbamazepine commonly result in subnormal serum total T_4, with an apparent lowering of free T_4, not accompanied by the anticipated increase in TSH [39]. This discrepancy, which is not easily distinguishable from central hypothyroidism due to pituitary deficiency, is a methodological artefact related to underestimation of true free T_4 in diluted serum samples that contain inhibitors of T_4 protein binding [1, 11, 36, 39].

Antiretroviral Therapy

Infection with human immunodeficiency virus may influence tests of thyroid function by various mechanisms, occasionally as result of direct infection of the thyroid gland or alteration of immunological function, but more frequently from effect of medications that alter metabolism of thyroxine or as a non-specific effect of debilitating illness. Although some studies [40] show a higher than expected prevalence of hypothyroidism, predominantly subclinical, during treatment with highly active antiretroviral therapy, a recent study indicates that current treatment is associated with normal thyroid function measurements. There are reports of reduced effectiveness of T_4 replacement or transient over-replacement during treatment with antiviral drugs [41, 42]. There is no consensus as to whether thyroid function should be routinely monitored in infected patients, but testing will frequently be required to assess features that could be due to thyroid dysfunction.

Effects of Drug Competitors for Thyroid Hormone Binding to Plasma Proteins

Both TBG and TTR show extensive cross-reactions with a wide range of drugs [1, 28, 36]. As reviewed elsewhere [12], the failure of current free T_4 and T_3 methodology to reliably reflect the effect of drug competitors that increase free T_4 and T_3 *in vivo* by displacement, remains a major limitation in the general applicability of free hormone assays. These effects are poorly reflected by standard free hormone assays because samples are generally assayed after dilution, which underestimates the free hormone concentration in the presence of competitors. This discrepancy occurs because of dissociation of bound ligand with progressive sample dilution [12, 39]. Important drug competitors have a much smaller proportional reservoir of bound ligand than does T_4, so that their free concentration becomes negligible with progressive dilution while the free T_4 concentration remains unaltered [12]. Since competition is a function of relative free ligand concentrations, the effect of a competitor to increase free T_4 is underestimated, the error being greatest in assays with the highest sample dilution.

Drug Interactions

Drug effects on thyroid function may be especially potent when several agents are given together. For example, infusion of furosemide in high dosage lowers serum T_4, while concurrent dopamine infusion inhibits TSH secretion; together they can result in profound hypothyroxinaemia. Combinations of rifampicin or ritonavir or other medications that accelerate T_4 clearance, with glucocorticoid-induced inhibition of TSH secretion can have a similar effect.

Diagnostic Approach to Anomalous or Discordant Laboratory Results

When there is discordance between laboratory results and clinical findings, a distinction needs to be made between anomalous assay results due to assay interference and those that indicate previously unsuspected or subclinical disease. Consideration of the fundamental assumptions that underlie the diagnostic use of the trophic-target hormone relationship may give a clue to the discrepancy. Anomalous or unexpected assay results can be approached in the following sequence:

1. Clinical re-evaluation with particular attention to medication history and long-term features suggestive of thyroid disease (e.g. weight change, goitre).
2. Measurement of serum TSH by alternative method.
3. Estimation of free T_4 and T_3 by alternative methods with particular attention to method-dependent artefacts and medications.
4. Follow-up sampling to establish whether the abnormality is transient or persistent.
5. Measurement of serum total T_4 to establish whether the free T_4 estimate is disproportionately high or low in relation to total T_4 (e.g. heparin artefact, oestrogen). (Arguably, measurement of total T_4 with correction for variations in TBG, interpreted in conjunction with TSH, could now be regarded as the gold standard where free T_4 estimates are inconclusive).
6. Search for an unusual binding abnormality or hormone resistance syndrome in the propositus and family members.

3.1.5 Non-Thyroidal Illness (NTI)

Robin P. Peeters and Anita Boelen

Serum and Tissue Thyroid Hormone Concentrations in NTI

Within 2 hours after the onset of acute illness (and after 24–36 hours of fasting), T_3 levels decrease and rT_3 levels rise [1]. The magnitude of these changes is related to the severity of the disease. T_3 levels decrease progressively with increasing severity of disease without reaching a nadir, whereas rT_3 increases in relation to severity of disease, but reaches a plateau. rT3 is not invariably elevated in all causes of NTI [2, 3].

In mild illness, total and free T_4 (fT_4) levels may rise initially after the onset of disease but in severely ill patients, T_4 levels drop as well. Both low T_4 and T_3, as well as high rT_3 are associated with a worse prognosis [1, 4]. Thyroid-stimulating hormone (TSH) may rise briefly for ~2 hours after the onset of disease, but despite the drop in serum T_3 (and eventually also in T_4), TSH usually remains within the (low) normal range.

Duration of illness is another important determinant of the thyrotropic profile in NTI [5, 6]. Patients requiring intensive care enter a more chronic phase of NTI, and the low levels of thyroid hormone in prolonged illness have a more neuroendocrine origin. Pulsatility and circadian variation in TSH secretion is diminished in prolonged illness and hypothalamic thyrotropin-releasing hormone (TRH) mRNA expression in patients who died from chronic severe illness is low compared to patients who died from an acute trauma [7]. Low TSH secretion and TRH expression correlate with low serum T_3. Reverse T_3 levels remain elevated or may return back to normal with the decrease in serum T_4 (see **Figure 12.1.2.2b** in Chapter 12.1.2 for a simplified overview of the major changes occurring within the thyroid axis during the acute and chronic phase of critical illness.). Type of illness and feeding status are also important [2, 3, 8].

Both low T_4, low T_3, and high rT_3 levels are associated with a worse prognosis. A study in 451 patients who received intensive care for at least 5 days, showed that TSH, T_4, T_3, and the T_3/rT_3 ratio increased in patients who survived, but not in non-survivors [4] (see **Figures 3.1.5.1–3.1.5.3**). Patients who died after critical illness had lower tissue T_3 compared to patients who had died acutely, but the severity varies from one organ to another [9]. Low serum T_4 and T_3 correlated well with local concentrations in liver and skeletal muscle [10].

Neuroendocrine Changes in NTI

Acute Illness

After the onset of acute disease, TSH levels may rise briefly for ~2 hours, despite the ongoing decrease in circulating T_3 (and T_4), TSH usually remains within the (low) normal range. It suggests an altered feedback at the level of the hypothalamus and/or pituitary. The physiological nocturnal TSH surge is absent in the acute phase of illness [5] (see **Figure 3.1.5.3**). These changes cannot be attributed to exogenous glucocorticoids or dopamine, since serum TSH is also in the low-normal range in patients without these drugs.

Different mechanisms have been proposed for this altered feedback. Studies in rodents during fasting and after lipopolysaccharide (LPS) injection, which is a model for acute inflammation, show no compensatory rise in TRH in contrast to hypothyroid animals [11]. Local expression of thyroid hormone-activating type 2 deiodinase (D_2) is increased resulting in higher local concentrations of hypothalamic T_3 [12, 13]. Inflammatory mediators are involved in the inflammation-induced rise in D_2 expression; RelA (the p65 subunit of NF-κB) is able to bind the Dio2 promoter and increases D_2 expression in primary tanycytes after LPS stimulation *in vitro* [14]. Targeting RelA in tanycytes of mice results in reduced hypothalamic Dio2 and TRH mRNA expression after LPS. These changes are not required for the downregulation of TSHβ expression and serum thyroid hormone (TH) [15]. The role of local T_3 in the hypothalamus is supported by the observation that $TR\beta^{0/0}$ mice display an impaired illness-induced TRH decrease and TRβ signalling important for the feedback of T_3 on TRH neurons [16, 17], and in agreement with a downregulation of TRH in fasting and acute illness. Animal data suggest that an altered transmembrane transport of thyroid hormone at the pituitary and/or hypothalamus may be involved in the altered setpoint of the HPT-axis as well as an enhanced occupancy of nuclear T_3 receptors in the pituitary thyrotrophs.

In the acute phase of NTI, serum cytokines are usually high. Injection of cytokines such as IL-1, IL-6, and TNF-α is at least partially able to mimic the thyrotropic alterations of the acute stress response. Studies in IL-12 and IL-18 knockout mice show that these cytokines are also involved. However, cytokine antagonists fail to restore thyroid hormones, both in animals (IL-1, IL-6, TNF, Interferon) and in humans (IL-1) [18, 19].

High endogenous cortisol may also contribute to the blunted TSH response in acute illness.

Chronic Illness

Patients with prolonged NTI have more severe central dysfunction. In addition to the absent nocturnal TSH surge, TSH pulsatility diminishes dramatically, and hypothalamic TRH expression is reduced [5, 6]. Both correlate with low serum T_3 [7]. Patients who die after severe illness have less than 50% of hypothalamic and pituitary T_3 content compared to patients who die acutely [9]. The positive correlation of TSH secretion and TRH expression with serum T_3 levels suggests a more central origin of the low T_3 syndrome in prolonged illness. Vice versa, an increase in TSH is a marker for recovery, suggesting recovery from the low T_3 syndrome is also initiated centrally (see Figure 3.1.5.2 in which the recovery of TSH precedes the recovery of the T_3/rT_3 ratio). In addition, continuous infusion with TRH (especially when combined with a growth hormone secretagogue) is able to (partially) restore serum TSH, T_4, and T_3 in prolonged critical illness, both in humans and in animals [20].

The pathophysiology of the suppressed HPT-axis is incompletely understood. Circulating cytokines are usually low in the chronic phase of NTI and other mechanisms must be involved. Upregulation of hypothalamic D_2, and/or a downregulation of D_3 could suppress TRH expression via relatively high hypothalamic T_3. However, hypothalamic and pituitary T_3 levels are low in patients who die after prolonged illness [9]. This makes an important contribution of hypothalamic and pituitary deiodinases and/or transporters to central suppression less likely.

Other pathways, such as the melanocortin signalling pathway and neuropeptide Y (NPY), might be involved in regulating hypothalamic TRH [6, 21, 22]. However, their exact role is not yet elucidated [22]. Exogenous glucocorticoids and dopamine are known to suppress the hypothalamus–pituitary–thyroid axis, and perhaps prolonged hypercortisolism and/or endogenous dopamine in these patients may also play a role (see Box 3.1.5.1).

Extrathyroidal (Peripheral) Changes in NTI

In the acute phase of critical illness and after starvation, changes in thyroid hormone levels are mainly caused by changes in peripheral metabolism of thyroid hormones and serum binding proteins [1]. In the chronic phase these changes persist but decreased thyroidal T_4 production is superimposed. The serum T_3/rT_3 ratio is the most accurate reflection of peripheral metabolism, since this ratio is independent of variations in binding proteins and independent of decreased thyroidal T_4 production.

Box 3.1.5.1 Essential information

- In critical illness, a decrease in serum T_3 and increase in serum rT_3 are the most characteristic and persistent abnormalities.
- The magnitude of these changes is related to severity of disease and associated with a worse prognosis.
- Feeding status also seems important with regard to the changes in peripheral thyroid hormone levels, an altered feedback setting at the hypothalamus-pituitary level, a decreased activation, and an increased inactivation of thyroid hormone occur in NTI.
- The acute and more chronic phase of NTI should be seen as two separate entities. An altered peripheral metabolism is the major player in the acute situation, whereas central dysfunction is more important in the chronic phase of severe illness.
- There is currently no evidence that NTI (in the acute or in the chronic phase) should be treated with thyroid hormone.
- Possible benefits of treatment with hypothalamic releasing factors should be the subject of future studies.

Deiodination of Thyroid Hormones in NTI

The fall in serum T_3 and increase in serum rT_3 in the acute phase of critical illness and in fasting are largely due to a decreased conversion of T_4 to T_3 and of rT_3 to T_2 [1]. Recent data suggest that the immediate fall in T_3 is related to concomitant fasting rather than to illness *per se*. The randomized controlled trial 'Early versus Late Parenteral Nutrition in Critically Ill Adults (EPaNIC)' showed that not feeding critically ill patients early, (thereby accepting pronounced macronutrient deficit that in these patients), improved clinical outcome [23]. Early feeding prevented a large part of the early drop in plasma TSH, T_4, and T_3, and also prevented the rise in rT_3 [24]. Similar data were obtained in a rabbit model of NTI, in which early feeding also reversed the low liver D_1 and high liver D_3 [25]. Fasting-induced NTI may thus be an adaptive beneficial response [8].

Liver and skeletal muscle biopsies obtained within minutes after death of intensive care unit patients demonstrate low liver D_1 activity compared to healthy individuals, except for patients who died acutely from severe brain damage (Figure 3.1.5.1) [3]. Low D_1 activity clearly correlated with high rT_3 and a low T_3/rT_3 ratio, independent of duration of illness. D_1 activities also correlate with local T_3 and T_3/rT_3 ratios in liver [10].

Altered D_2 activity may not play a role in the pathogenesis of the low T_3 syndrome in prolonged critical illness [26].

Induction of D_3 activity was demonstrated in liver and muscle samples of NTI patients, whereas these tissues normally do not express D_3 (Figure 3.1.5.1). High liver and high muscle D_3 activity was associated with high serum and local tissue rT_3 levels. D_3 induction was independent of duration of illness. Animal studies showed that the decrease of serum T_3 was independent of D_3 activity [27]). Thus, a downregulation of D_1 (and in the acute phase of illness also D_2) is the important factor contributing to low levels of T_3, whereas the high levels of rT_3 seem to be due to a combination of low D_1 and high D_3. D3 is also expressed in granulocytes during infection (see Figure 3.1.5.4) [28–30]. Bacterial meningitis results in a strong increase of T_4 and rT_3 concentrations in cerebrospinal fluid (CSF). This altered thyroid hormone profile is consistent with elevated D_3 activity in infiltrating neutrophils at the site of infection [31].

Tissue deiodinase activities and serum thyroid hormone levels are significantly associated with cause of death [3]. A post-mortem study in over 60 patients demonstrated that liver D_1 activity and serum T_3/rT_3 were highest in patients who died from severe brain damage, intermediate in those who died from sepsis or excessive inflammation and were lowest in patients who died from cardiovascular collapse (see Figure 3.1.5.5). Liver D_3 showed an opposite relationship. There was no relation between deiodinase activities and a marker of inflammation (C-reactive protein) but patients who needed inotropes and/or those requiring dialysis because of acute renal failure had a lower liver D_1 activity and higher liver and muscle D_3 activity. This suggests that poor tissue perfusion and cellular hypoxia may be an important determinant regulating deiodinase activities *in vivo*. D_3 activity and D_3 mRNA are increased

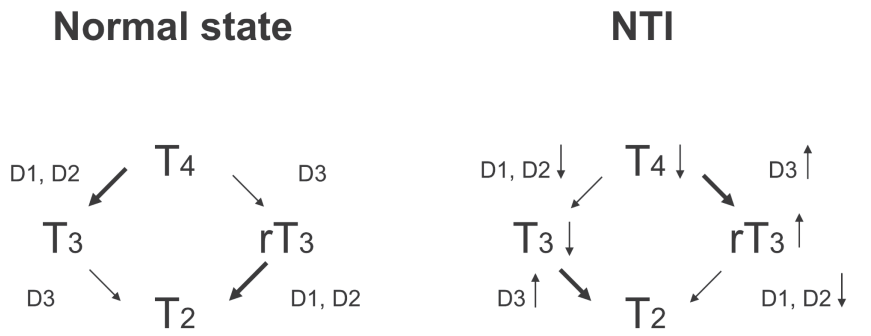

Figure 3.1.5.1 Relationship between the different iodothyronines and the outer (D_1, D_2) and inner ring (D_3) deiodination by the three deiodinases on the left. Like D_3, D_1 has some inner ring deiodination capacity *in vitro*, but there is currently no evidence that this is of any significance *in vivo* (see also Chapter 3.1.2). This is therefore omitted from the figure. Observed changes in deiodinase activities and iodothyronine levels during critical illness, both in the acute and chronic phase of critical illness on the right.

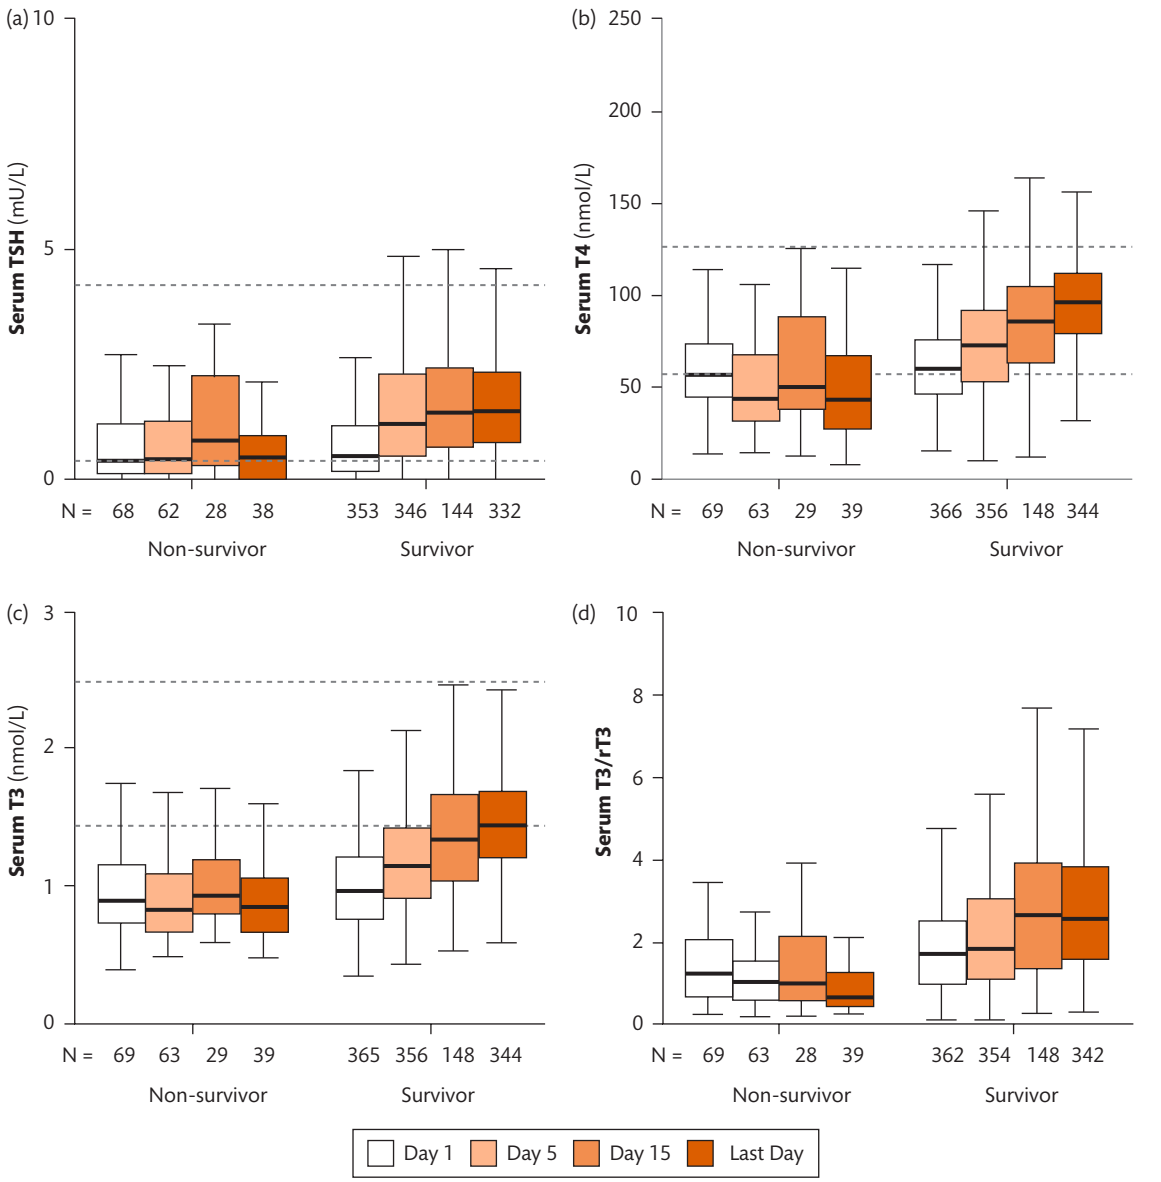

Figure 3.1.5.2 Serum TSH, T_4, and T_3 levels and the T_3 to rT_3 ratio at day 1, 5, 15, and the last day of ICU stay in survivors and non-survivors. From day 5 onward, serum TSH, T_4, and T_3 increased in patients who survived, whereas there was no such pattern in patients who died (a–c). The serum T_3 to rT_3 ratio increased in survivors from day 5 to the last day, whereas it did not alter or even decreased in non-survivors (d). On the last day of ICU stay, the majority of patients had TSH and T4 levels within the normal range, whereas T_3 was still low. The blocked line represents the normal values.

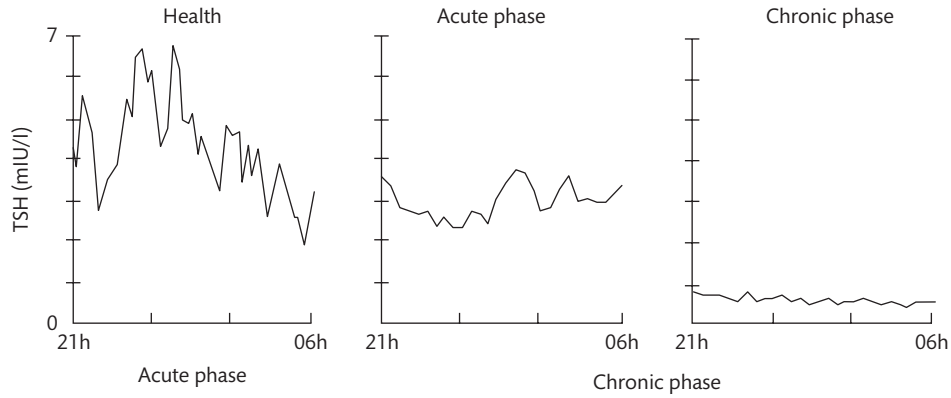

Figure 3.1.5.3 The nocturnal serum concentration profiles of thyrotropin in critical illness are abnormal and differ markedly between the acute and chronic phase of the disease.

by hypoxia, and hypoxia-inducible factor 1 induces local thyroid hormone inactivation [32].

Transmembrane Transport of Thyroid Hormones in NTI

Cellular uptake of thyroid hormones is rate limiting for subsequent intracellular metabolism and nuclear T_3 binding [33]. Kinetic studies have shown that fasting and non-thyroidal illness result in attenuation of uptake of liver T_4 and rT_3, probably via decreased concentrations of intracellular adenosine triphosphate (ATP). Inhibition of thyroid hormone uptake can also be caused by non-esterified fatty acids and bilirubin, both elevated in critical illness, and certain drugs such as amiodarone.

In critically ill patients, neither liver, nor skeletal muscle MCT8 expression were related to the ratio of the serum over tissue concentration of T_4, T_3, or rT_3 [10]. This suggests MCT8 is not crucial in the transport of these iodothyronines over the plasma membrane in liver and skeletal muscle. Liver TH transporter expression differs between several NTI models; acute illness lowers MCT8 and MCT10 expression whereas chronic inflammation decreases MCT8 mRNA and increases MCT10 mRNA. Lethal bacterial sepsis affects hepatic TH transport marginally without modulating liver TH concentrations [34]. However, this does not exclude an important role of other transporters.

Thyroid Hormone Receptors in NTI

Little is known about the regulation of thyroid hormone receptors (TR) in NTI. In rats, starvation results in a decreased expression and occupancy of hepatic TR [35]. In peripheral mononuclear cells in humans, an increased expression of both TRα and TRβ has been demonstrated in patients with chronic liver and renal disease, whereas in patients in the intensive care unit only TRβ mRNA was increased [36]. In patients with liver disease, both liver TRα (20-fold) and liver TRβ (5-fold) were increased compared to healthy liver controls. A post-mortem study in 58 subjects who had died in the intensive care unit showed an increased expression of the TRα1/TRα2 ratio (active isoform/dominant negative isoform), which was positively related to severity of disease and age [37]. In this study, no relation between severity of disease and TRβ1 expression was observed.

The clinical relevance of these changes is not clear. An increase in the expression of active receptor isoforms might be an adaptive response to decreasing levels of thyroid hormone. On the other hand, a higher TR expression with low levels of T_3 will lead to an increase

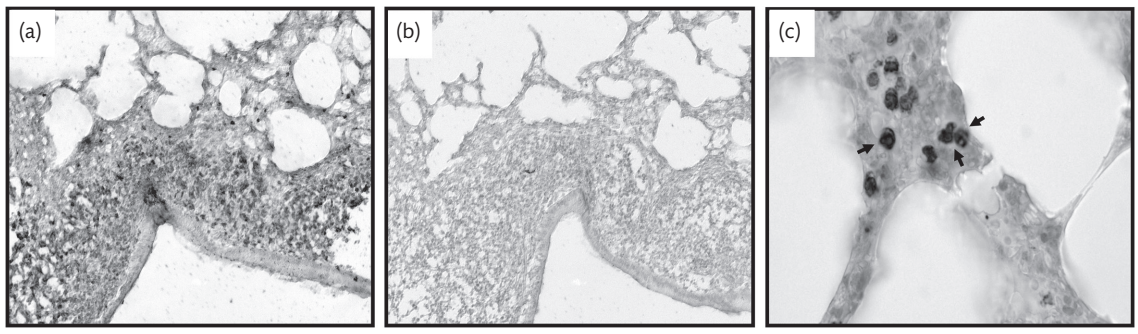

Figure 3.1.5.4 An overview of a lung section showing *S. pneumoniae* induced infiltrate after 48 hours stained both with anti-D_3 antibody (a) and pre-immune serum (b). Note clearly stained D3-positive granulocytes in the infiltrated area that are shown in more detail (indicated by arrows) (c).

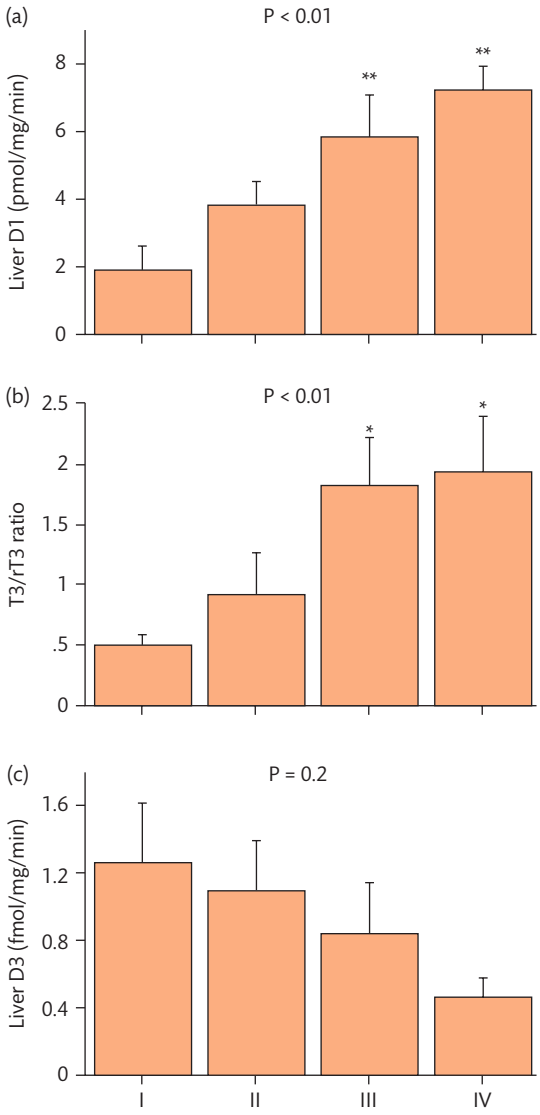

Figure 3.1.5.5 Correlation of liver D_1 (a) and liver D_3 (b) activities, and the T_3/rT_3 ratio (c) with cause of death. Patients are divided into four different groups based on cause of death. I, Cardiovascular collapse (n = 5); II, multiple organ failure with sepsis (n = 21); III, multiple organ failure with systemic inflammatory response syndrome (n = 14); IV, severe brain damage (n = 4). Liver D_1 activity and serum T_3/rT_3 ratio showed a significant relation with cause of death (P <0.01), whereas liver D_3 activity showed an opposite trend. **, P <0.01 vs. group I; *, P <0.05 vs. group I. Data represent means ± SEM and P values were obtained with ANOVA and Fisher's least significant difference for multiple comparisons.

in the proportion of unliganded receptors, which would have an opposite effect. Interestingly, no relation was demonstrated between liver TRβ1 mRNA and serum thyroid hormones in critically ill patients, although D_1 expression is regulated by T_3 via TRβ1 [37].

Other Metabolic Pathways in NTI

Sulphation mediates the rapid and irreversible degradation of iodothyronines by D_1. Inner ring deiodination of T_4 and T_3 by D_1 is markedly facilitated after sulphation, whereas outer ring deiodination of T_4 is completely blocked after sulphation.

Elevated levels of T_4S and T_3S/T_3 ratios have been reported in NTI patients, and post-mortal serum T_4S in critically ill patients are positively correlated with the length of stay in the intensive care unit [38, 39]. Low hepatic D_1 activity in these patients plays an important role in the increased levels of T_4S.

Glucuronidation in NTI may be important with regard to the use of several drugs. Carbamazepine, phenytoin, and rifampicin particularly induce hepatic glucuronidation. This may lower T_4, but T_3 and TSH are usually unaffected.

Ether linked cleavage (ELC) involves the breaking of the ether bridge in between the two tyrosines, yielding diiodotyrosine (DIT) as a main product, and catalysed by peroxidases such as myeloperoxidase (MPO) in leukocytes. Its role is rather limited, but DIT increases during sepsis [40] attributing to TH clearance.

Alterations in Thyroid Hormone Binding

Thyroxine binding globulin (TBG), transthyretin (TTR), and albumin are decreased in NTI reflecting the catabolic state of the patient. However, increased TBG levels can be present in liver disease. Various drugs cause alterations in serum binding, either by decreasing TBG (e.g. glucocorticoids), or by displacing thyroid hormones from binding proteins (e.g. acetyl salicylic acid, furosemide). In heparin-treated patients, the measured concentration of serum fT_4 can be higher than the true *in vivo* concentration. This is the result of heparin-induced lipase activity during sample storage and incubation, resulting in *in vitro* generation of non-esterified fatty acids (NEFA) which displace T_4 and T_3 from TBG (see also Chapter 3.1.3). Low molecular weight heparin preparations have a similar effect.

Low serum binding of thyroid hormone in NTI due to the presence of a circulating binding inhibitor has been proposed in older studies [1]. However, exogenous T_4 administration can easily replenish the T_4 pool in patients with prolonged illness, making it unlikely that such a binding inhibitor is an important cause of low serum T_4 [41].

The Diagnosis of Thyroid Disease in Critical Illness

Evaluation of thyroid status in NTI can be very difficult, especially in patients in the intensive care unit. The value of clinical examination should not be underestimated. Thus, the presence of eye signs (ophthalmic Graves' disease), goitre, and a family history of thyroid disease or autoimmune disease in general, are important points that may support the diagnosis of autoimmune thyroid disease (see Box 3.1.5.2).

Because of the numerous changes in serum thyroid hormones in NTI, and because there is currently no evidence that these changes should be treated, thyroid function should not be tested in critically ill patients, unless there is strong suspicion of thyroid disease. In unselected hospitalized patients, TSH was less than 0.1 mU/L in 3.1%, whereas TSH was above 20 mU/L in 1.6% of patients [42]. When thyroid function is tested, measurement of TSH alone is often not sufficient. Most fT_4 assays are unreliable

Box 3.1.5.2 The diagnosis of thyroid disease in critical illness

- In critical illness, thyroid function should only be tested if there is a strong suspicion of thyroid disease.
- A normal TSH virtually excludes thyrotoxicosis or hypothyroidism. However, when thyroid function is tested, measurement of TSH alone is often not sufficient.
- Most fT_4 assays are unreliable in critical illness.
- Dopamine and glucocorticoids suppress TSH secretion.
- Hyperthyroidism:
  - A low TSH is compatible with both NTI and thyrotoxicosis.
  - Nearly all patients with a low but detectable TSH will have normal thyroid function tests after recovery from illness.
  - Approximately 75% of patients with NTI and a TSH <0.01 mU/L have hyperthyroidism.
  - Serum T_4 and T_3 should be high (or high-normal) in hyperthyroidism, and low (or low-normal) in NTI.
- Hypothyroidism:
  - In patients recovering from NTI, TSH levels may become temporarily elevated.
  - Most patients with an elevated TSH <20 mU/L will have normal thyroid function tests after recovery from illness, especially when thyroid peroxidase and thyrogobulin antibodies are negative.
  - In patients with TSH >20 mU/L, hypothyroidism is permanent in only 50%.
  - Hypothyroid patients have serum T_4 and T_3 (and a relatively higher T_3/T_4 ratio) compared to patients recovering from NTI.
  - Low serum rT_3 suggests hypothyroidism, whereas high rT_3 supports of NTI.
- If no definite diagnosis can be made, thyroid function tests should be repeated after recovery from illness.

in critical illness, due to alterations in binding proteins, increased use of heparin in an ICU setting, and the possible presence of circulating binding inhibitors. Therefore, the total thyroid hormone should be measured as well.

Hyperthyroidism

In an NTI patient, suspected of hyperthyroidism, serum TSH is the most helpful test. If serum TSH is still within the normal range, the presence of thyrotoxicosis is virtually excluded. But when serum TSH is low, it could be a consequence of NTI or of hyperthyroidism. However, NTI almost never results in TSH less than 0.01 mU/L [43, 44]. Nearly all patients with a low but detectable TSH, will have normal thyroid function tests after recovery from illness. On the other hand, approximately 75% of patients with the low T_3 syndrome and a TSH less than 0.01 mU/L have hyperthyroidism [45]. Interpretation of serum TSH becomes more difficult in patients treated with TSH-suppressing agents such as dopamine and corticosteroids. Additional measurement of T_4 and T_3 levels is mandatory, but should be interpreted with care. T_4 levels are low in approximately 50% of critically ill patients, and T_3 levels are low in the majority of patients, which could mask active hyperthyroidism. However, serum T_4 and T_3 levels should be high (or high-normal) in hyperthyroidism, and low (or low-normal) in NTI.

Hypothyroidism

The diagnosis seems straightforward for a critically ill patient, with suspected hypothyroidism if serum TSH is elevated. However, in patients recovering from NTI, TSH levels may become temporarily elevated. Even in patients with TSH of more than 20 mU/L, hypothyroidism is permanent in only ~50% of cases [42]. Patients with permanent hypothyroidism have significantly lower levels of T_4 and T_3. Most patients with an elevated TSH less than 20 mU/L will have normal thyroid function tests after recovery, especially if thyroid peroxidase and thyroglobulin antibodies are negative.

In central hypothyroidism serum TSH is usually low, and differentiation from NTI becomes very difficult. Other pituitary deficiencies and related clinical signs are commonly present in these patients, but prolonged critical illness often leads to suppression of other neuroendocrine axes as well [5]. Serum rT_3 may be helpful in some cases, but rT_3 assays are rarely available. In general, a high T_3/T_4 ratio and a low rT_3 favour the presence of hypothyroidism. If no definite diagnosis can be established, thyroid function test should be repeated after recovery from illness.

Should Patients with NTI Be Treated with Thyroid Hormone?

Both in acute and in prolonged critical illness, low levels of thyroid hormone are associated with a higher mortality rate, but it remains controversial whether NTI is an adaptation protecting against catabolism or a maladaptation. It is important to re-emphasize the teleological differences between the acute and chronic phase of severe illness (see Figure 12.1.2.2b in Chapter 12.1.2). Acute changes within the thyroid axis after the onset of critical illness (low T_3 and elevated rT_3) are similar to the changes observed in starvation. These changes have been interpreted as an attempt to save energy expenditure and protein wasting which does not need intervention. This is supported by recent studies suggesting that (at least part of) the immediate changes in thyroid function tests during acute critical illness are related to the concomitant fasting rather than the illness *per se*. Thyroid hormone replacement in fasting subjects results in an increased nitrogen excretion and negative nitrogen balance, suggesting catabolism. Whether this also applies to the changes in the acute, and especially in the more chronic phase of critical illness, is controversial. However, the improved prognosis of ICU patients that were not fed early suggests that this fasting-induced NTI in the acute phase of critical illness may be an adaptive beneficial response which should not be corrected [8]. In humans, only few studies with T_4 treatment have been performed, with rather low sample sizes. So far, no clear beneficial effect has been demonstrated.

Because of the decreased T_4 to T_3 conversion in NTI, T_3 treatment may be a better choice. However, T_3 treatment may be harmful as well (see [46]). In the chronic phase of critical illness, altered thyroid hormone levels appear to have a more central origin, although peripheral metabolism is also altered. Studies performed in fasting subjects and in patients with acute critical illness should therefore not be extrapolated to the chronic phase of severe illness.

Tissue thyroid hormones were measured in patients who stayed on the intensive care unit for more than 5 days [10]. Some patients were treated with a combination of T_4 and T_3 if they had a serum T_4 of less than 50 nmol/L, a normal TBG, and clinical signs of hypothyroidism. Higher serum T_3 levels in treated patients were associated with higher tissue T_3 contents. However, the fourfold increase in liver T_3 in treated patients was disproportional compared to the

twofold increase in serum and muscle T_3. TSH levels were suppressed in treated patients suggesting overtreatment although their serum T_3 was still in the low or low-normal range. So, if patients are substituted with thyroid hormone, should we aim for thyroid hormone levels within or still below the normal range?

Intervention with hypothalamic releasing factors in patients with chronic critical illness has the advantage that the negative feedback inhibition of thyroid hormone on the pituitary is maintained, thereby providing a safer therapy option. It has been shown in patients with prolonged critical illness and in an animal model, that continuous infusing of TRH in combination with a growth hormone secretagogue is able to restore thyroid hormone levels. In these patients, therapy resulted in a reduction of catabolic markers. Whether this would also result in a beneficial effect on mortality remains to be addressed in future studies.

3.1.6 Thyroid Imaging: Nuclear Medicine Techniques

Steen Joop Bonnema and Laszlo Hegedüs

Introduction

Nuclear medicine techniques, used for many decades in the management of thyroid patients, are based on the principle that a radionuclide or radiopharmaceutical agent ('tracer') is administered orally or intravenously, and then taken up by the target tissue after minutes or hours. By the decay of the isotope, gamma rays are emitted, which can be detected by sensitive equipment located outside the body, mostly by a gamma camera with a pinhole collimator. Detecting sufficient decays ('counts') a pixilated image, referred to as a scintigram, can be produced. This does not have the resolution of images obtained by ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI), and is therefore not suitable for detailed morphological evaluation of the thyroid. More importantly, nuclear medicine techniques reflect the functional status of the thyroid, sometimes in a quantitative manner, which none of the other methods are able to. The radiation burden imposed by most nuclear medicine techniques is low, and usually less than that imposed by a plain X-ray of the thorax. Nevertheless, administration of radioisotopes during pregnancy or breastfeeding is contraindicated.

Table 3.1.6.1 Commonly used radioactive isotopes for thyroid imaging and therapy

Isotope	Half-life	Administered activity	Clinical use	Comments
^{123}I	13 h	Routine scan: 3.7–11.1 MBq	Routine thyroid imaging	High-quality images Enables uptake measurements
		Whole-body scan: 74–185 MBq	Imaging residual tumour tissue after thyroidectomy in patients with thyroid cancer	High-quality images Enables dosimetry Low radiation to patient
^{124}I	4.18 days	Whole-body PET/CT: 148–185 MBq	Whole-body PET/CT, mostly in patients with thyroid cancer	High resolution PET images Enables dosimetry
^{131}I	8.1 days	Whole-body scan: 74–148 MBq	Pre- or post-therapeutic residual tumour tissue imaging after thyroidectomy in patients with thyroid cancer	Low-resolution images Higher radiation, as compared with ^{123}I
		For therapy: 185–7400 MBq	Used for treatment of hyperthyroid diseases, non-toxic goitre, and differentiated thyroid cancer	Emits primarily β-particles, which act locally in the thyroid tissue
$^{99m}TcO_4$	6 hours	37–370 MBq (i.v.)	Routine thyroid imaging	Produced locally by molybdenum generator. Only evaluates trapping and not organification
FDG	110 min	370–550 MBq (i.v.)	Whole-body PET/CT in patients with thyroid cancer	Most often used for the thyroglobulin-positive iodine-negative patient

The iodine isotopes can be administered intravenously, or more commonly orally.
FDG, 18F-deoxy-glucose.

Radioactive Tracers

The thyroid is unique in its ability to trap and organify iodine. The energy-requiring sodium-iodide symporter (NIS), located in the membrane of the thyrocyte, provides the mechanism for trapping, while the intracellular enzyme thyroid peroxidase is central in incorporating iodine into thyroglobulin (Tg). NIS does not differentiate between various isotopes of iodine, and this enzyme is crucial for thyroid scintigraphy and uptake measurements. Besides iodine, NIS can also trap technetium (^{99m}Tc), as pertechnetate ($^{99m}TcO_4$). This isotope can be produced locally using a molybdenum generator, and is therefore easier to produce and handle than iodine isotopes. However, as $^{99m}TcO_4$ is not organified it leaks out of the thyroid gland. Therefore, the increased concentration gradient of $^{99m}TcO_4$ across the cellular membrane of the thyrocyte is dependent on continuous NIS activity. Consequently, imaging and uptake measurements using $^{99m}TcO_4$ as tracer must take place 10–20 min after i.v. injection of this radiopharmaceutical, rather than after hours or days, as with radioactive iodine.

The unit of radioactivity is expressed in Becquerel (decay/s) or Curie (3.7×10^{10} decays/s). Radioactivity of the nuclide should not be confused with the dose, measured in Gray (Gy), which is the term applied to the absorbed radiation by the exposed tissue. The radioactivity administered for clinical purposes is in the order of megabecquerels (MBq) or gigabecquerels (GBq). The radioactivity used for uptake measurements is up to 100 times lower than that used for therapeutic purposes (i.e. ^{131}I therapy).

^{123}I has a half-life of 13 hours and a γ -photon energy of 159 keV, which is readily detectable by a gamma camera. Almost similar characteristics apply to ^{99m}Tc, which emits γ -photon energy of 140 keV, and with a half-life of 6 hours. However, these characteristics make ^{99m}Tc as well as ^{123}I suitable only for diagnostic and not therapeutic purposes. ^{131}I is an excellent isotope for therapy because it has a half-life of 8 days, and the emitted β -particles act locally due to a path length of only 1–2 mm. These properties are, however, disadvantageous for imaging because the radiation dose is higher while the resolution of the image is poorer. Thus, the γ -photon flux produced by 3.7 GBq ^{131}I can be obtained by merely 148 MBq of ^{123}I. Table 3.1.6.1 lists the clinically useful radioisotopes and some of their properties.

Thyroid Iodine Uptake Measurement

This test is based on oral or intravenous administration of a radioactive iodine isotope to determine the iodine uptake of the thyroid tissue. Once in the body, the tracer is gradually taken up by the thyroid similar to the endogenous iodine pool. At a given time point, the amount of the tracer within the thyroid equilibrates with the rate of iodine uptake and thyroid hormone synthesis, and the release of the isotope into the circulation, incorporated in the thyroid hormones. Importantly, the test does not measure thyroid hormone synthesis and secretion, but merely the avidity of the thyroid gland for iodine, and its clearance rate relative to the renal iodine excretion. Thus, a clear inverse relationship exists between the dietary intake of iodine and the thyroid iodine uptake.

Procedure

An uptake measurement is usually performed 24 hours after oral administration of 3.7–7.4 MBq of ^{123}I. The intrathyroidal amount of tracer can be measured with a gamma scintillation counter, placed at a fixed distance in front of the neck. The number of radioactive counts emitted from the thyroid is compared with the radioactivity administered to the patient. Mostly, the uptake value at 24 hours after radioiodine administration is used for practical reasons, and because most thyroid glands have reached the plateau of isotope accumulation at this time. A high 24 hour thyroid iodine uptake, usually in the range 40–85%, is observed typically in patients with hyperthyroidism, but may be seen after recovery from thyroid failure or severe iodine deficiency leading to elevated thyroid-stimulating hormone (TSH) serum levels and hypothyroidism. In severe hyperthyroidism, seen in some patients with Graves' disease, the thyroid uptake must be measured within 2–6 hours after the radioiodine administration due to a very high iodine turnover rate. ^{99m}Tc instead of iodine isotopes may be used in this situation since

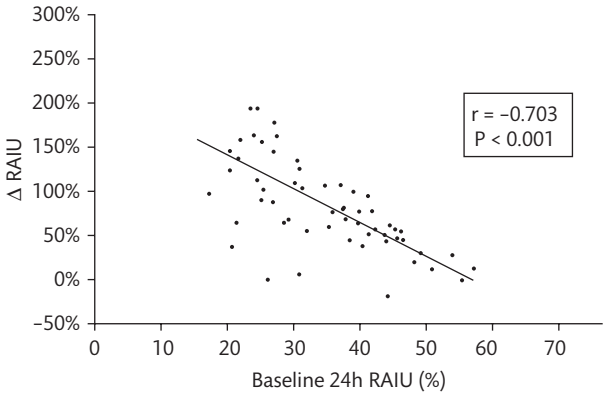

Figure 3.1.6.1 The positive effect of rhTSH stimulation on the thyroid ^{131}I uptake (RAIU) in patients with multinodular non-toxic goitre is clearly inversely related to the initial RAIU.

Reproduced with permission from Fast S, Nielsen VE, Grupe P, *et al*. Optimizing 131I Uptake After rhTSH Stimulation in Patients with Nontoxic Multinodular Goiter: Evidence from a Prospective, Randomized, Double-Blind Study. *J Nucl Med* 2009;50:732–37. Copyright © 2009 the Society of Nuclear Medicine, Inc

the thyroid iodine uptake in the very early period following the nuclide administration mainly reflects the NIS activity [1].

Indication for Thyroid Iodine Uptake Measurement

With accurate thyroid function markers, valid serological tests, and widely accessible ultrasound facilities, most thyroid patients can be diagnosed correctly. In patients with non-toxic benign goitre, an uptake measurement may indicate whether ^{131}I therapy is a therapeutic option, since the 24-hour thyroid iodine uptake should be at least 20%. In hyperthyroid patients treated with ^{131}I, the 24-hour uptake value—and sometimes the ^{131}I half-life—is mandatory for calculation of the administered ^{131}I activity at some centres.

Recombinant Human TSH Stimulation

Stimulation with 0.1 mg recombinant human TSH (rhTSH; doses of 0.005–0.9 mg have been used)—given as a single intramuscular injection 24 hours before ^{131}I administration—increases the 24-hour thyroid iodine uptake by 100% or more, even in iodine-loaded subjects [2]. This effect correlates inversely with the baseline thyroid iodine uptake [3], with the implication that patients with the lowest baseline uptake potentially benefit the most from rhTSH stimulation in relation to ^{131}I therapy (Figure 3.1.6.1). The effect on the 24-hour thyroid iodine uptake from rhTSH stimulation correlates inversely also with serum TSH [3].

Perchlorate Discharge Test

Some ions, like thiocyanate (SCN–) and perchlorate (ClO_4–), inhibit the NIS, resulting in leakage from the thyroid, if the iodine is not intracellularly organified. Thus, the iodine loss from the thyroid gland following NIS inhibition correlates inversely with the thyrocyte's ability to bind iodine.

The test is performed by administering a tracer dose of ^{123}I, and measurement of the thyroid ^{123}I uptake after 4 hours. Thereafter, 500–1000 mg of $NaClO_4$ (or $KClO_4$) is administered orally, and the uptake measurement is repeated after 1 hour. Perchlorate acutely blocks the NIS, allowing non-organified ^{123}I to leak out of the thyrocyte. A thyroid organification defect is very likely to be present if the ^{123}I uptake after perchlorate administration shows a reduction of 15% or more. An ^{123}I uptake value in the range 10–15% is considered borderline, and may be due to a partial organification defect. An abnormal perchlorate discharge test is seen in inborn defects of iodine organification, for example, human thyroid peroxidase (TPO) gene mutations or Pendred's syndrome.

Thyroid Scintigraphy

Thyroid scintigraphy is a rapid and relatively low-cost method. A normal thyroid scintigraphy shows a homogeneous isotope distribution in both lobes. Usually, the isthmus and the pyramidal lobe are not visualized well in a euthyroid individual, but these structures become more apparent in hyperthyroid conditions. A vague isotope uptake in the submandibular glands is often seen due to ability of these structures to actively concentrate iodine intracellularly. Thyroid scintigraphy gives an overall impression of the thyroid volume. However, this technique is inaccurate in comparison with ultrasound, CT, and MRI, which should be used instead [4].

Single Photon Emission Computed Tomography

In line with the principle behind a radiological CT, 3D scintigraphic images can be constructed, if the gamma camera rotates around the region of interest; this technique is termed single photon emission computed tomography (SPECT). By SPECT, the resolution can be enhanced to 6–7 mm, and allows identifying small thyroid nodules. However, SPECT is more time consuming than planar scintigraphy, and the latter method is usually sufficient in a clinical setting. For thyroid volume estimation, SPECT performs better than planar scintigraphy but is less accurate than thyroid ultrasound [4].

The clinical application of thyroid scintigraphy and other nuclide imaging techniques in various thyroid disorders is described in the remaining part of this chapter, and summarized in Table 3.1.6.2.

Thyrotoxicosis

Thyrotoxicosis is defined as elevated serum levels of thyroid hormones, while hyperthyroidism specifically is caused by an active hormone synthesis and secretion from the thyroid gland (or ectopic thyroid tissue). Thyroid scintigraphy can easily differentiate between the two conditions.

In the majority of cases (>90%), the aetiology of hyperthyroidism is either Graves' disease or toxic nodular goitre (solitary or multinodular). Both conditions are characterized by high uptake and turnover rate of iodine in the actively hormone producing thyroid tissue, and the scintigraphic appearance reflects the differences in tissue texture and functionality. There is no need to discontinue antithyroid drugs prior to ^{99m}Tc scintigraphy, as these agents do not affect the NIS function.

Graves' Disease

In Graves' disease, the entire gland, and the pyramidal lobe if present, shows a scintigraphically uniform thyroid isotope uptake. The size of the gland may range from normal to grossly enlarged. In some cases, superimposed activity in the central part of the thyroid lobes due to the greater depth of thyroid tissue may raise suspicion

Table 3.1.6.2 Application of nuclear medicine techniques in the most common thyroid diseases

Thyroid diseases	Indication for nuclear medicine techniques
Graves' disease	• Scintigraphy is not mandatory if TRAB is positive • Thyroid volume assessment for prognostication is more accurately performed by ultrasound • Prior to ^{131}I therapy, measurement of the ^{131}I kinetics for dose calculation is done at some centres
Toxic nodule(s)	• In case of negative TRAB, thyroid scintigraphy is indicated in order to confirm the presence of autonomously functioning nodule(s) suitable for ^{131}I therapy
Non-toxic goitre	• Scintigraphy detects whether a nodule is hypofunctioning (cold), in which case fine-needle aspiration biopsy may be considered • 24 h thyroid iodine uptake measurement can guide whether ^{131}I therapy is a therapeutic option
Thyroiditis (postpartum or subacute)	• Scintigraphically low isotope uptake during the thyrotoxic phase supports the presence of thyroiditis • In the hypothyroid patient, whether permanent or transient, there is normally no indication for scintigraphy
Thyroid cancer	• Whole-body ^{123}I or ^{131}I scintigraphy, performed pre- or post-^{131}I treatment, may detect residual differentiated thyroid cancer tissue • FDG-PET/CT is indicated on suspicion of residual radioiodine non-avid tumour tissue • In medullary thyroid cancer, ^{18}F-DOPA-PET seems the most sensitive method for detection of persistent tumour tissue

TRAB, TSH receptor antibody.

of thyroid nodules, but this can easily be ruled out by an ultrasound examination.

Thyroid scintigraphy can be omitted in patients with a clinical presentation typical of Graves' disease, and in the presence of TSH-receptor antibodies in serum. If a measure for the thyroid volume is needed, thyroid ultrasound is more accurate than scintigraphy.

Toxic Nodular Goitre

In patients with autonomously functioning thyroid nodules, the thyroid scintigraphy shows one or more marked areas with high isotope uptake. Uptake in the normal paranodular thyroid tissue depends on the thyroid status. In patients with moderately hyperactive 'warm' nodules, leading to subnormal serum TSH levels, some isotope uptake may be seen in the paranodular thyroid tissue (Figure 3.1.6.2a). In very hyperfunctioning 'hot' nodules, completely suppressing serum TSH, the remaining part of the thyroid may not be scintigraphically visualized. Thus, a toxic multinodular goitre (Figure 3.1.6.2b), sometimes being disconfigured due to nodular degeneration, may harbour coexisting hyperactive (warm/hot) and hypoactive (cold) nodules, as well as hypofunctioning normal thyroid tissue. If the patient has been treated with antithyroid drugs for some time, achieving a normal serum TSH level, the isotope may be more uniformly distributed within the gland.

Since ^{131}I therapy usually is a first line treatment in patients with one or more thyrotoxic nodules, scintigraphy is always indicated in such cases to confirm the presence of nodular functional autonomy. Importantly, Graves' disease may develop *de novo* in a patient with nodular goitre. In fact, such a coexistence occurs in as many as 10–15% of unselected hyperthyroid patients [5]. Based on thyroid ultrasound only, the clinician may get the impression that the hyperthyroidism is due to a multinodular goitre rather than Graves' disease (Figure 3.1.6.3). However, the presence of TSH-receptor antibodies, and a thyroid scintigraphy showing a more diffuse distribution of the isotope throughout the thyroid gland, will clarify the aetiology of the hyperthyroidism.

Other Thyrotoxic Conditions

Thyrotoxicosis characterized by a low thyroid isotope uptake is most often caused by subacute, silent, or postpartum thyroiditis. These conditions are discussed in section 3.3.

Exposure to excess iodine (e.g. X-ray contrast media) or amiodarone (an antiarrhythmic drug with high iodine content) sometimes leads to thyrotoxicosis. The very high whole-body iodine pool and the iodine load of the gland block for further thyroid iodine uptake. Therefore, the scintigraphy shows low or no thyroid isotope uptake. In fact, knowing that the patient has been exposed to iodine-containing agents, there is rarely indication for thyroid scintigraphy. The clearance of excess iodine, and especially of amiodarone, may take several months, with slow recovery of a normal thyroid function. If the thyrotoxicosis persists, thyroid scintigraphy may be indicated, provided the iodine exposure has ceased.

In patients who factitiously ingest thyroid hormones in excessive amounts, the thyrotoxic state and a faint thyroid scintigram will

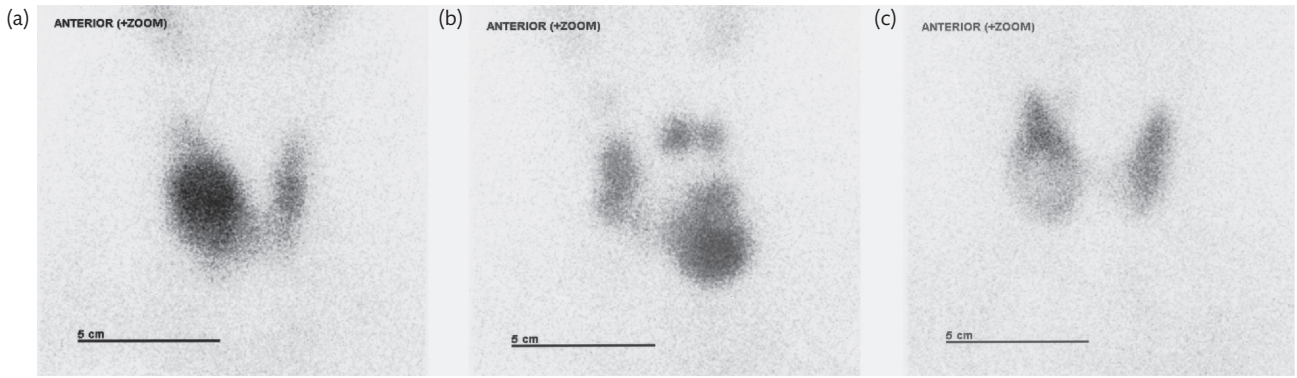

Figure 3.1.6.2 Examples of thyroid scintigrams in various disorders. (a) Solitary warm nodule in the right thyroid lobe. (b) Toxic multinodular goitre with several hot nodules and suppression of the paranodular thyroid tissue. (c) Solitary cold nodule in the right thyroid lobe.

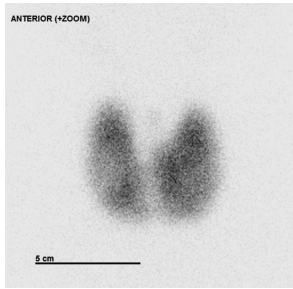

Figure 3.1.6.3 Thyroid scintigraphy in a 57-year-old woman with Graves' disease and coexisting multinodular goitre. From a euthyroid state 6 months earlier the woman became severely hyperthyroid due to Graves' disease, which was confirmed by high serum levels of TSH-receptor autoantibodies. Thyroid ultrasound showed a classical bilateral multinodular configuration. The isotope is irregularly distributed as the immune stimulation affects nodular and paranodular tissue to a different extent.

raise suspicion of thyroiditis. However, excess exogenous thyroid hormone leads to suppression and inactivation of the thyroid gland, reflected by low levels of serum Tg, while this biomarker is usually high in conditions with thyroiditis.

Hypothyroidism

Thyroid imaging is not mandatory and often superfluous in the diagnostic work-up and during follow-up of hypothyroid patients, independent of the aetiology. When goitre is suspected in Hashimoto's thyroiditis, ultrasound examination should be preferred over scintigraphy. In early stages of autoimmune thyroiditis, even with severe thyroid failure, thyroid scintigraphy may show some thyroid uptake in a diffuse or patchy pattern. This is due to preserved function of the NIS, further stimulated by a high serum TSH, whereas the thyroid failure primarily results from defects in iodine organification and thyroid hormone synthesis.

Thyroiditis

The term thyroiditis covers several conditions, the most common being autoimmune (Hashimoto's) thyroiditis. Thyroid scintigraphy is often superfluous in thyroiditis, with a few exceptions as discussed next.

Autoimmune Thyroiditis

Autoimmune thyroiditis may give rise to thyrotoxicosis due to exacerbation of the autoimmune inflammation, which may be clinically apparent as silent thyroiditis and postpartum thyroiditis. In particular, it is important to differentiate between postpartum thyroiditis and Graves' disease. In postpartum thyroiditis, an inflammatory destructive condition with no active thyroid hormone synthesis, thyroid scintigraphy shows universally very low or no isotope uptake. However, the distinction between the two conditions can often be made without thyroid imaging. Nearly all patients with Graves' disease harbour TSH-receptor antibodies, which are absent in typical cases of postpartum thyroiditis. In addition, the dynamics of the two diseases are very different, as the thyrotoxic phase in postpartum thyroiditis is followed by hypothyroidism, before recovery of the thyroid function takes place within some months. With such a course, the diagnosis is usually settled, and thyroid scintigraphy is of no value at this late phase of the disease. Importantly, radioactive isotopes should not be administered to a breastfeeding woman. If necessary, breast milking in advance (with storage in the refrigerator), and no breastfeeding during 24–48 hours after the scintigraphy complies with the safety regulations.

Subacute Thyroiditis (de Quervain's Thyroiditis)

The course of the thyroid hormone serum levels in subacute thyroiditis is similar to that seen in silent or postpartum thyroiditis. Accordingly, thyroid scintigraphy initially shows a very low or no thyroid uptake. Subacute thyroiditis may affect the gland unilaterally, with initially no isotope uptake in a single thyroid lobe, and with subsequent progression to the entire gland within weeks.

Occasionally, typical symptoms like neck pain may be absent in subacute thyroiditis. In the undiagnosed patient, this may prompt an ^{18}F-deoxy-glucose positron emission tomography (FDG-PET). If performed in the thyrotoxic phase, an increased FDG uptake in the thyroid and skeletal muscle is seen, while the uptake in the liver is decreased [6].

Goitre and Thyroid Nodules

Scintigraphy provides a rough estimate of the size and configuration of the gland, and its possible extension into the mediastinum. However, its primary role in patients with thyroid nodules is to discriminate hyperactive from hypoactive nodules (Figure 3.1.6.2c). Fine-needle aspiration biopsy (FNA) should be considered only in cold nodules, since hyperactive nodules with rare exceptions never represent a carcinoma.

The fraction of cold nodules constitutes more than 75% of nodules in consecutive series of thyroid scintigrams, with an á priori risk of 8–25% for these lesions to harbour malignancy [7]. Such risk estimates are most probably influenced by selection bias, since cold nodules ≥10 mm are found in 2–3% of unselected individuals residing in regions with borderline iodine deficiency [8]. The risk of malignancy in a cold nodule is similar, regardless of whether it is solitary or part of a multinodular goitre [7]. Importantly, a toxic multinodular goitre does not exclude the possibility that cold nodules, located in other parts of the goitre, may be malignant. Scintigraphy is of great help in identifying such coexisting lesions.

Choice of Tracer for Scintigraphy of Nodular Goitre

^{99m}Tc used as tracer may result in false-positive uptake in 5% of thyroid nodules ('trapping only nodules'), as compared with ^{123}I scintigraphy [9]. However, comparative studies have been unable to demonstrate any clinically significant differences between the two tracers [7]. In case of substernal goitre, ^{123}I rather than ^{99m}Tc scintigraphy is recommended, since the background activity in the mediastinum attenuates the emission from the isotope (Figure 3.1.6.4).

^{99m}Tc-MIBI is a lipophilic radiopharmaceutical that accumulates in the thyroid, independent of iodine trapping and organification. ^{99m}Tc-MIBI uptake reflects both the number and

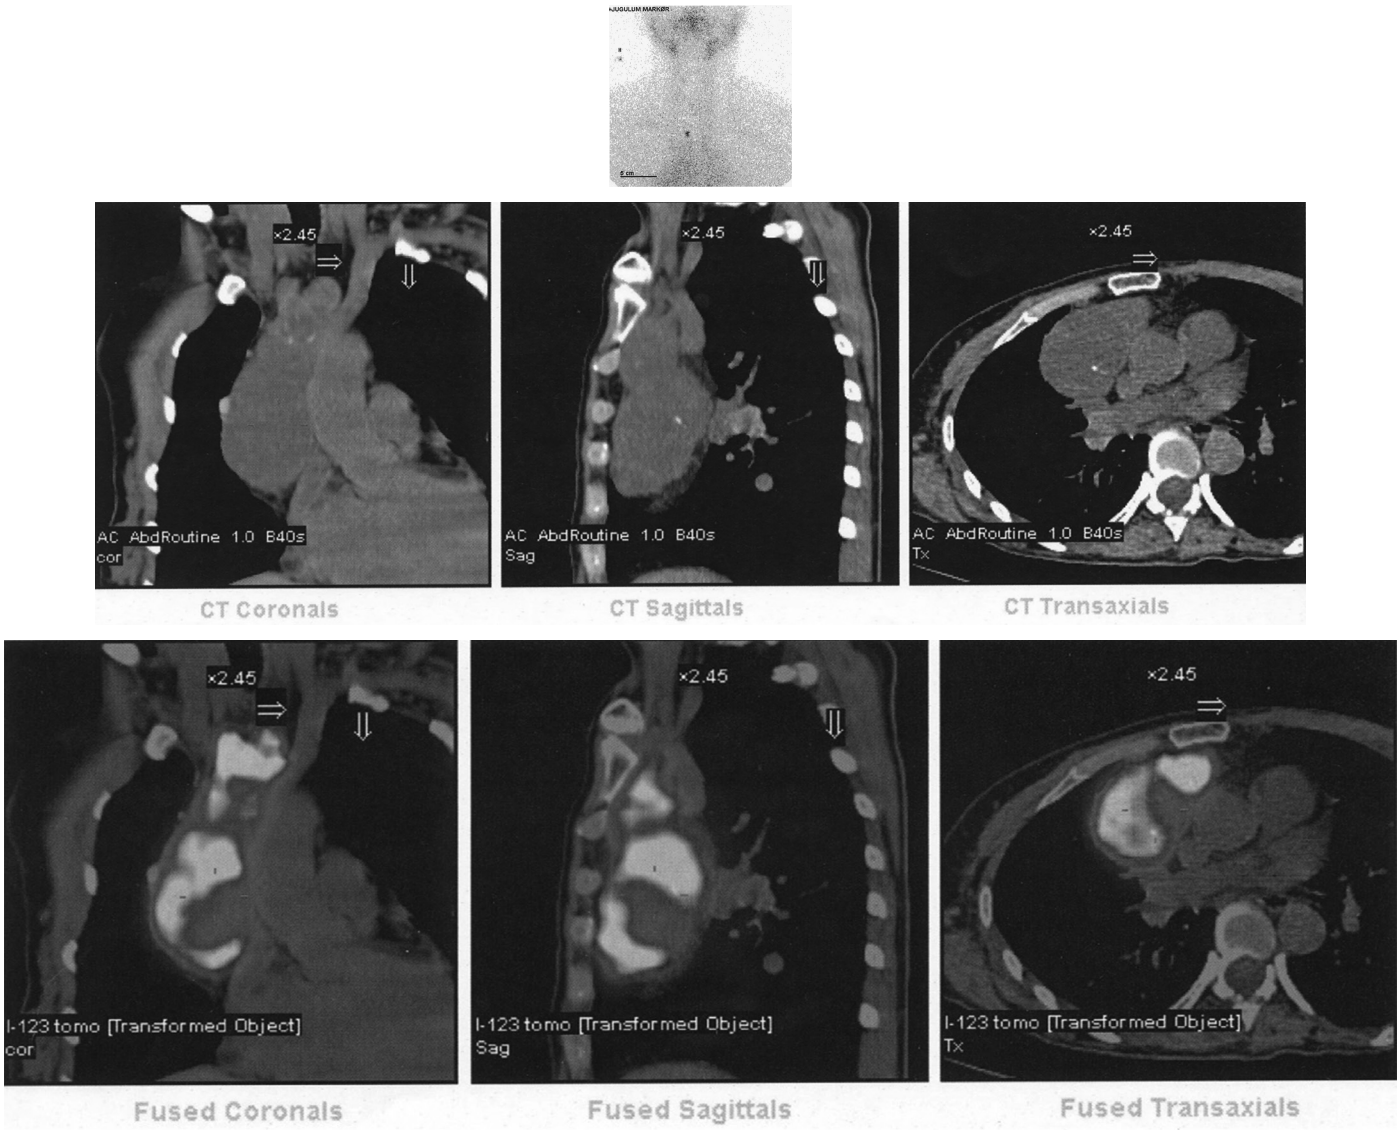

Figure 3.1.6.4 A 51-year-old woman with swallowing difficulties due to a large intrathoracic goitre. A large tumour mass in the mediastinum was detected by CT scan (middle), but no thyroid tissue could be visualized by conventional ^{99m}Tc scintigraphy (top). A ^{123}I SPECT/CT was performed 24 hours after i.m. injection of 0.1 mg of recombinant human TSH. A convincing ^{123}I uptake is seen in the right-anterior part of the mediastinum (bottom), confirming that the mass represents an intrathoracic goitre. The volume was measured to 193 ml, and the 24-hour ^{123}I uptake was 57%.

function of mitochondria, and thus the oxidative burden of the thyroid nodule [10]. Nodules with increased uptake and late retention of ^{99m}Tc-MIBI are suspicious for malignancy, but based on a meta-analysis [11]—demonstrating 82% sensitivity and 63% specificity for detection of malignancy in hypofunctioning thyroid nodules—^{99m}Tc-MIBI scintigraphy as an adjunctive test seems unjustified.

Indication for Thyroid Scintigraphy in Patients with Goitre

Despite the aforementioned potential advantages, thyroid scintigraphy is generally not included in the initial evaluation of goitre patients. Hyperthyroidism is a definite indication for scintigraphy in the setting of nodular goitre, in order to visualize warm or hot nodules if ^{131}I therapy is considered. Even with a normal serum TSH, scintigraphy may detect autonomously functioning nodules in 50% of patients [12]. Thyroid scintigraphy is recommended in cases where FNA has shown follicular neoplasia, particular if serum TSH is below normal. Such a lesion is with great certainty benign, despite the cytological diagnosis, if scintigraphy confirms that the nodule is autonomously functioning.

Positron Emission Tomography

PET scan, combined with CT, has proven very helpful for managing a wide variety of cancers. Different kinds of tracers are used for PET scans, with FDG as the most widely employed. This agent is taken up by the cells, proportional to the rate of glucose metabolism. Because malignant tissue generally is metabolically more active, FDG uptake is a potential indicator of even small areas with malignant tissue. A hindrance for a widespread use of PET is the need of a cyclotron for ^{18}F production, and limitation of transport distances due to a half-life of 110 minutes.

PET in Patients with Thyroid Nodules

^{124}I is transported intracellularly by NIS, like other iodine isotopes. Its half-life is 4.2 days, and 22% of its emission consists of positrons. ^{124}I-PET/CT specifically visualizes the thyroid gland, resulting in better thyroid images than provided by conventional nuclear medicine techniques. In patients with benign thyroid disease, ^{124}I-PET/CT detects significantly more nodular lesions, functional as well as non-functional, than does ^{99m}Tc scintigraphy or ^{99m}Tc-SPECT [13]. The main indication for PET/CT, however, is in situations where thyroid cancer is suspected, or already diagnosed.

FDG-PET may be useful in the evaluation of scintigraphically cold nodules with indeterminate FNA findings. The sensitivity and specificity of FDG-PET/CT for detection of thyroid carcinoma are in the ranges 77–100% and 33–64%, respectively [10]. A meta-analysis found a negative predictive value of 96% in indeterminate thyroid nodules larger than 15 mm [14]. Thus, FDG-PET/CT seems to rule-out malignancy in indeterminate nodules, except in those smaller than 10–15 mm, probably due to limited spatial resolution. The method also has its limitations in Hürthle cell lesions, in which benign as well as malignant lesions can be PET positive [15]. With these exceptions, application of FDG-PET can potentially decrease the number of unnecessary diagnostic hemithyroidectomies, in some studies by 35% [10], and may in fact be cost-effective [16].

Contrasting the generally high sensitivity of FDG-PET, the specificity is consistently poor due to mechanisms not fully understood. The maximum standardized uptake value (SUV_{max}) is significantly higher in malignant than in benign thyroid nodules but with huge overlap, and therefore not useful in a clinical setting [17]. Moreover, SUV_{max} calculations strongly depend on the type of PET-scanner and other external factors.

FDG-PET is currently not routinely recommended in patients with FNA indeterminate thyroid nodules.

Thyroid Incidentalomas Detected by PET

Focal thyroid lesions, detected incidentally, are seen in 1–2% of patients undergoing FDG-PET for non-thyroid reasons. Approximately 35% of these incidentalomas harbour thyroid cancer [17], depending on the selection of patients. The majority of these FDG-PET positive lesions are small papillary carcinomas, often resulting in thyroid cancer surgery and year-long monitoring. It remains to be established whether such an active approach is justified in terms of increased survival, quality of life, and cost. At present, it is recommended that FDG-avid thyroid incidentalomas larger than 10 mm are evaluated by FNA [18].

If FDG-PET shows diffuse uptake of the thyroid, this typically represents an inflammatory condition, like autoimmune thyroiditis, and the patient can be reassured about the benign nature.

Thyroid Cancer

At diagnosis, and before neck surgery, nuclear medicine techniques are not routinely employed. After total thyroidectomy, whole-body scan (WBS) after administration of either ^{123}I or ^{131}I might detect iodine-avid tissue. NIS expression is decreased in more than 90% of thyroid carcinomas due to tumorigenic degeneration, and by as much as 1200-fold [19]. However, NIS remains expressed at a level that allows imaging as well as therapy by radioactive iodine isotopes. Although serum Tg is the primary cancer marker used in the follow-up [18], WBS helps in the stratification of the patient [19]. WBS can be performed either with (post-treatment WBS) or without (diagnostic WBS) prior ^{131}I therapy given for ablative or adjunctive purpose. For a diagnostic WBS, a low dose of ^{123}I (or ^{131}I) is used (Figure 3.1.6.5). A post-treatment WBS is obtained 5–10 days after the therapeutic ^{131}I is administered.

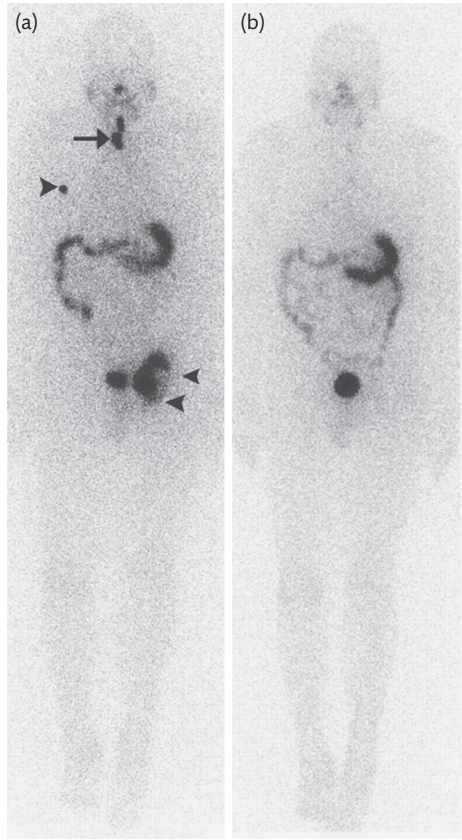

Figure 3.1.6.5 A 67-year-old man with papillary thyroid cancer. (a) Pretreatment whole-body ^{123}I scan shows residual thyroid tissue in the neck (arrow), as well as right rib and left hip metastases (arrowheads). (b) No abnormal uptake is seen on the ^{123}I scan taken at the 1-year follow-up.

A diagnostic WBS is used to detect local and distant metastases, and to tailor the therapeutic ^{131}I dose as well as excluding patients for ^{131}I therapy in case of no uptake suggestive of non-radioiodine avid disease. In fact, diagnostic WBS may provide important information that leads to change in management strategy in up to 50% of cases [20]. Diagnostic WBS is less used at many centres given the fact that ^{131}I therapy is administered according to a risk stratification strategy, or empirically in case of abnormal serum Tg levels during follow-up. According to the American Thyroid Association guidelines, postsurgical diagnostic WBS may be beneficial if the extent of residual tumour tissue cannot be determined by conventional imaging, or the management of the patient may be altered by the additional information [18].

Details of thyroid cancer surveillance and treatment algorithms are given in Chapter 3.5.6.

Optimizing Radioiodine Uptake

Iodine restriction for 1–2 weeks increases the radioiodine uptake during WBS as well as the efficacy of the ^{131}I therapy, but it is unknown whether such iodine restriction has impact on the long-term recurrence rate [21].

A high serum TSH stimulates the radioiodine uptake of residual thyroid cancer tissue. This can be achieved either by thyroid hormone withdrawal—4 weeks for levothyroxine, and two weeks for triiodothyronine—or by the administration of rhTSH. The main advantage of rhTSH stimulation is avoidance of a prolonged hypothyroid state and an improvement of the patient's well-being [22]. The two regimens have proved to be equally effective in terms of the cancer ablation rate. Importantly, rhTSH stimulation is more cost-effective and leads to a lower whole-body irradiation, as compared with the withdrawal regimen [2].

Thyroid Stunning

Thyroid stunning is the phenomenon where the radioiodine uptake is attenuated due to prior irradiation. Stunning, dose-related and detectable even at a very low level of radiation, is associated with decreasing levels of NIS-mRNA and signs of cell cycle arrest but not cell death [2]. It is unclear whether stunning constitutes a significant clinical problem. The discrepancy between a positive diagnostic ^{131}I-WBS and a subsequent negative post-treatment ^{131}I-WBS has been attributed to the impact of stunning. However, what seems to be stunning may in fact be a cell killing effect by the WBS or the ^{131}I therapy [23]. To minimize stunning, ^{123}I should be used for WBS, since the required activity is lower than that needed with ^{131}I. However, the clinical relevance of stunning can be questioned since patients show similar ablation rates, independent of the iodine isotope used prior to the ^{131}I therapy [2]. The potential negative effect of stunning by a diagnostic WBS adds further support to a strategy where ^{131}I ablative therapy is given on an empiric basis.

Interpretation of the Whole-Body Scan

In patients thyroidectomized and devoid of persistent cancer tissue, the 24–72 hours radioiodine uptake in the thyroid region should be no more than 0.2–0.5% of the administered radioactivity. Most iodine is excreted in the urine, and the bladder is easily identified on a WBS. There is almost no radioiodine uptake in muscles, skeleton, brain, heart, and lungs, unless there are iodine-avid metastases. ^{123}I diagnostic and ^{131}I post-treatment WBS concordance rates are approximately 87% and 72% for a positive and negative WBS, respectively [24]. Post-treatment WBS may visualize additional lesions, compared to the diagnostic WBS, in as many as 40% of cases [19]. Before the advent of PET techniques, post-treatment ^{131}I-WBS was thus considered the definite test to visualize iodine-avid thyroid cancer tissue.

A false-positive WBS can result from radioiodine uptake in a non-thyroidal organ expressing NIS (i.e. the stomach, the salivary, and the mammary glands). Conversely, dedifferentiated cancer cells might have lost their ability to trap iodine, resulting in false-negative WBS. Lack of radioiodine uptake in residual thyroid cancer cells may also be due to an erroneous intake of thyroid hormone or high dietary iodine content.

PET in Differentiated Thyroid Cancer

FDG-PET

In patients with abnormally elevated serum Tg, FDG-PET is superior to both diagnostic and post-treatment ^{131}I-WBS for the localization of remnant cancer tissue (Figure 3.1.6.6). Well-differentiated thyroid cancers—with a metabolic rate not significantly different from that in normal thyroid tissue—might fail detection by FDG-PET/CT. In contrast, poorly differentiated and more aggressive cancers demonstrate a high uptake of FDG. Indeed, NIS expression is decreased while the glucose transporter Glut1 is upregulated in poorly differentiated thyroid tumour cells [25]. On functional imaging this is called a "Flip-flop" phenomenon, which can be reversed by some tyrosine kinase inhibitors, inducing re-expression of NIS in the tumour cells [25].

The serum Tg cut-off level for the maximum sensitivity and specificity for FDG-PET/CT is in the range 12–32 ng/ml, but positive lesions can be detected even with Tg levels below 10 ng/ml [19]. RhTSH stimulation prior to FDG-PET/CT might improve the diagnostic sensitivity, but this rarely leads to change in disease management [26].

^{124}I-PET

Results have been variable when ^{124}I-PET is compared to post-treatment ^{131}I-WBS. Differences in the radioactivity and the regimen used for enhancing ^{124}I uptake may explain the lack of agreement across studies. Nevertheless, ^{124}I-PET/CT visualizes residual disease

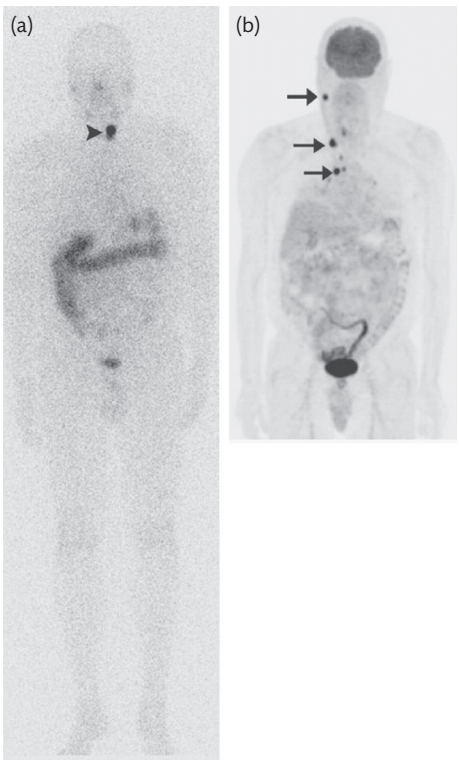

Figure 3.1.6.6 A 74-year-old man with papillary thyroid cancer. (a) Whole-body ^{123}I scan shows thyroid tissue in the neck (arrowhead). (b) FDG-PET/CT (carried out on the same day) shows extensive metastatic disease in cervical and mediastinal lymph nodes (arrows).

with a very high sensitivity, as well as lesions not detected by post-treatment ^{131}I-WBS [27]. The precise role of ^{124}I-PET/CT in the management of patients with differentiated thyroid cancer remains to be established. For dosimetry, which relies on quantification and estimation of the tracer residence time, ^{124}I-PET/CT is superior to SPECT/CT [25].

Imaging in Medullary Thyroid Cancer

As medullary thyroid cancer (MTC) originates from the iodine-independent para-follicular C-cells nuclear imaging techniques are based on non-iodine isotopes. PET/CT is probably the technique mostly used. ^{18}F-DOPA-PET appears to be a more sensitive method than FDG-PET for localizing persistent MTC, but its sensitivity varies from 47% to 83%, depending on the calcitonin level [25]. In particular, ^{18}F-DOPA-PET/CT has high sensitivity for detection of primary MTC and lymph node metastases, as compared to ultrasonography, and lymph node resection during neck surgery may be more successful if guided by ^{18}F-DOPA-PET/CT [28].

MTC expresses one or more types of somatostatin receptors. While ^{68}Ga-labelled somatostatin receptor PET/CT is helpful in the management of patients with neuroendocrine tumours, the diagnostic performance of this method is lower in MTC [25]. Although this method is particularly efficient for detection of bone metastases [29], functional imaging seems to be of limited value in the management of MTC.

New Tracers for Cancer Detection

Prostate-specific membrane antigen (PSMA) is expressed on the endothelial cells of tumour neo-vasculature, not only in prostate tissue but also in many non-prostate cancers. Thus, radioiodine-refractory thyroid cancer tissue expresses PSMA, which might be visualized with ^{68}Ga-PSMA-PET/CT [19]. Another new agent is ^{18}F-tetrafluoroborate that has a bio-distribution characteristic of NIS expression, and may hold promise in the treatment guidance of differentiated thyroid cancer [27].

Despite the potential benefit from new and often expensive nuclear medicine technologies, it remains to be shown that their use improves the prognosis in thyroid cancer patients. Most thyroid malignancies have a good prognosis, and the increased surveillance and application of imaging during the last decades do not seem to have influenced the overall survival [30].

3.1.7 Thyroid Imaging: Non-Isotopic Techniques

Laszlo Hegedüs and Finn N. Bennedbæk

Box 3.1.7.1 Clinical settings for the use of thyroid imaging

- Patients with thyroid enlargement or tenderness or with the finding of a cervical lump at physical examination
- Patients with an incidental finding of thyroid nodule(s), e.g. on PET-CT, CT, or MRI not performed for thyroid purposes
- Patients with laboratory abnormalities indicating a thyroid disease
- Patients at high risk for thyroid malignancy (history of familial thyroid carcinoma, previous neck irradiation)
- Stratification of the risk of malignancy of thyroid nodules
- Guidance for thyroid nodule fine-needle aspiration (FNA) or for minimally invasive procedures
- Presurgical staging of patients who undergo surgery for thyroid malignancy or symptomatic goitre
- Postsurgical surveillance of neck recurrences after resection of thyroid carcinoma
- Detection of developmental abnormalities and ectopia varieties of the thyroid gland

Introduction

Clinical examination and evaluation of thyroid function remain fundamental in the evaluation of thyroid disorders, but observer variation leads to a considerable heterogeneity in the evaluation of patients with suspected thyroid disease [1]. Thus, it is not surprising that imaging of the thyroid is often performed. Although it most often cannot distinguish between benign and malignant lesions, and its clinical value is thought to be limited [2], a recent survey confirms the value of ultrasonography (US) in euthyroid patients with a solitary thyroid nodule [3].

The thyroid gland can be evaluated by several non-isotopic imaging techniques. The most commonly used are US, CT, and MRI. Each method has advantages and limitations, and there is no absolute clinical indication for performing any of these imaging procedures in most patients (see Box 3.1.7.1) [4].

Thyroid US examination with high-frequency transducers provides an unmatched spatial and time resolution for the detection of focal lesions, the stratification of the risk of malignancy, and the assessment of diffuse structural abnormalities [5]. Thyroid radioisotope scan is of use for the characterization of the gland's functional status in clinically and subclinically hyperthyroid patients, especially if candidates for radioiodine treatment, and for the detection of hyperfunctioning nodules that do not need fine-needle aspiration biopsy (FNA), in toxic nodular goitre [6]. CT and MRI offer valuable information in patients with a large goitre or an invasive tumour in the presurgical evaluation of whether eligible or not for surgery. These cross-sectional imaging techniques provide a detailed definition of the relationship of the thyroid with the anatomical structures located in the neck or the mediastinum.

This chapter will focus on the clinical use of these methods and, as far as this is possible, compare their advantages and disadvantages.

Techniques

Ultrasonography

Examination of the neck is performed with high-frequency transducers (7–15 MHz), and the patient in the supine position with the

Box 3.1.7.2 Possible applications of US in thyroid disorders

- Size determination
- Morphology (diffuse, uni-, or multinodular, cyst)
- Echogenicity (hypo-, normo-, or hyperechogenic)
- Flow determination
- Determination of tissue elasticity
- Aid in diagnostic biopsies
- Aid in minimally invasive procedures (cyst aspiration, ethanol, and thermal ablation procedures*) [7]
- Evaluation of regional lymph nodes

* Thermal ablation procedures include laser, radiofrequency, high-frequency US, and microwave therapy.

neck hyperextended. The transducer is coupled to the skin with gel since ultrasound does not pass through air. The technique can detect thyroid lesions as small as 2 mm and distinguish solid nodules from simple and complex cysts. It enables the accurate determination of thyroid size, gives a rough estimate of echogenicity, visualizes vascular flow and velocity (colour flow Doppler), provides information on tissue elasticity of lesions, and aids in the accurate placing of needles, be it for diagnostic or therapeutic purposes (see Box 3.1.7.2)

The main drawbacks are the high degree of observer dependency and the inability to visualize retroclavicular or intrathoracic extension of the thyroid [2, 5]. The average investigation rarely takes more than 5–10 min.

The normal thyroid is a bilobed gland, located in the lower anterior neck, with two pear-shaped lobes connected anteriorly by a central rim of tissue (the isthmus). The left and right lobes are located immediately to the left and right of the trachea, respectively. The internal carotid arteries and internal jugular veins are located postero-laterally to the thyroid lobes, whereas the strap muscles of the neck are located anteriorly. Usually, the thyroid gland size is 20 mm or less in both the transverse and the anteroposterior diameter with a length of 40–60 mm.

The normal thyroid parenchyma has a characteristic homogeneous medium-level echogenicity (see Figure 3.1.7.1). The surrounding muscles have a lower echogenicity.

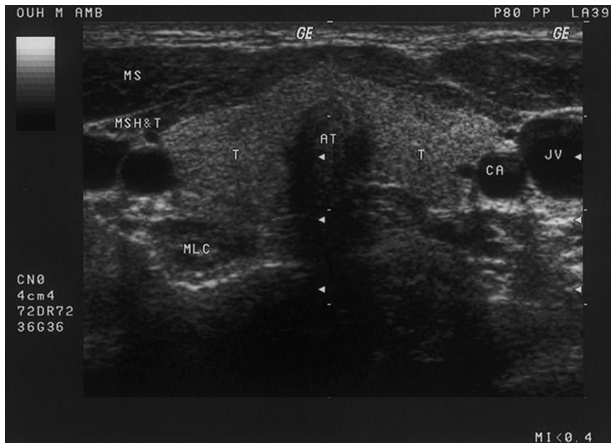

Figure 3.1.7.1 Transverse sonogram of the normal thyroid gland. AT, trachea; CA, common carotid artery; JV, jugular vein; MLC, longus colli muscle, MS, sternocleidomastoid muscle; MSH&T, sternohyoid and thyrohyoid muscle; T, thyroid.

A high proportion of people with a normal thyroid gland have small (1–3 mm) cystic or solid lesions, the frequency being higher in women, increasing with age, and varying between countries [5, 8]. The importance of these abnormalities is unclear, but since incidental sonographic nodules ('incidentalomas') are very common, whereas thyroid cancer is not, a conservative/expectant approach is generally recommended.

Goitre (i.e. an enlarged thyroid gland), remains a clinical diagnosis. But this evaluation carries an inaccuracy of approximately 40% and cannot reliably be used for size determination [1]. Thyroid volume may be estimated with the ellipsoid formula (length × width × thickness × π/6 for each lobe) or, more precisely, with a dedicated tridimensional software. The normal thyroid size (5–20 ml in adults) is positively related to weight and age, increases with decreasing iodine intake, and is influenced by a number of physiological as well as environmental factors [2, 5]. US is the most sensitive technique for screening populations for goitre and is widely used for field studies [2, 5, 9].

Computed Tomography and Magnetic Resonance

US examination is the primary imaging modality for thyroid disease, but other cross-sectional techniques used for the evaluation of neck or chest disease may commonly reveal thyroid abnormalities. The diagnostic accuracy of CT and MRI for thyroid malignancy is low, and these imaging methods should not be used in the routine diagnostic work-up of thyroid nodules, but be reserved for the assessment of intrathoracic goitres as well as for evaluation of the extension of the disease in patients with aggressive thyroid malignancy [2]. Today, multidetector CT allows multiplanar reconstructions (axial, sagittal, coronal planes) with slice thickness of 2 mm or less. Acquisition should include a volume from the skull base to the tracheal bifurcation [2]. At the CT evaluation, when without contrast medium, the thyroid appears as a homogeneous and mildly hyperattenuating gland when compared to the surrounding neck muscles and has an average attenuation of 80–100 Hounsfield Units. After injection of contrast material, the gland shows an intense and homogeneous enhancement. For large goitres, a study without contrast injection may disclose a relevant intrathoracic growth. For invasive thyroid carcinomas, the use of CT contrast media is usually needed to reliably rule out an infiltrative growth or the presence of nodal metastases in cervical regions (e.g. the retrotracheal area) that cannot be reliably visualized by US [10]. In such patients with aggressive disease who are candidates for rapid radioiodine ablation and post-dose whole-body scintigraphy, MRI with gadolinium should be used as the first-choice cross-sectional imaging method because the iodide load of CT contrast media may interfere with thyroid iodide uptake for a few months. MRI examination is commonly performed with axial and coronal T_1-weighted and with fat-saturated T_2-weighted images, followed by postcontrast axial and coronal T_1-weighted images. When compared with the cervical muscles, the thyroid gland is faintly hyperintense on T_1-weighted MR images and iso- to slightly hyperintense on T_2-weighted images. Analogously to contrast-enhanced CT imaging, gadolinium-enhanced MRI shows the thyroid gland characterized by an intense and homogeneous enhancement [10]. Both MRI and CT imaging provide precise anatomic information regarding the position of the thyroid relative to adjacent vascular, respiratory, and muscular structures. Still, despite the better contrast resolution of MR imaging and the elevated spatial resolution of CT, B-mode US examination

remains the best option for the evaluation of thyroid nodules and cervical lesions.

Thyroid Imaging for the Assessment of Diffuse Thyroid Disease: Ultrasound

Non-autoimmune non-toxic diffuse goitre appears diffusely enlarged with a uniform or discretely irregular echo pattern without nodules. Various degrees of hypoechogenicity may be evident, but, when marked, suggest the presence of autoimmunity. In Hashimoto's thyroiditis, hypoechogenicity is always marked but may be inhomogeneous. US cannot reliably differentiate between benign autoimmune thyroiditis and lymphoma or carcinoma. Therefore, goitre growth, especially in the L-thyroxine-treated patient, should raise suspicion of lymphoma and lead to biopsy or operation. In Graves' disease, the thyroid is most often enlarged and the echo pattern homogeneous. Echogenicity can be normal to markedly decreased and the latter suggests a decreased probability of achieving remission on antithyroid drugs. Colour flow Doppler can demonstrate the rich vascularity and increased flow related to the degree of hyperthyroidism. Subacute thyroiditis leads to thyroid enlargement and areas of marked hypoechogenicity probably related to areas that are affected. Remission leads to normalization of size, but areas of hypoechogenicity may remain long after remission is obtained [11].

Computed Tomography and Magnetic Resonance

The normal thyroid gland is easily visualized on CT and its density is always higher than surrounding tissues. Differences in density reported from various countries reflect differences in iodine intake. Disease in the thyroid usually leads to decreased ability to concentrate iodine, therefore, reduced density on CT is the hallmark of thyroid disease [2]. The exact density measurements have not proved useful in distinguishing between various thyroid disorders. Thus, the CT image may be compatible with a certain diagnosis but rarely specific for it.

Non-autoimmune non-toxic diffuse goitre appears to be homogeneously enlarged with various degrees of hypodensity. Graves' disease is characterized by a 50–70% decrease in density and may be slightly inhomogeneous. Hashimoto's thyroiditis typically demonstrates an inhomogeneous iodine distribution and a 50% decrease in CT density which is lowest in hypothyroid individuals. Increasing goitre size is characteristically associated with decreasing density. Asymmetrical hypodense areas should raise the suspicion of lymphoma or carcinoma.

Subacute thyroiditis is also characterized by hypodensity and is focal or diffuse depending on the extent of the disease. In the initial phases, acute suppurative thyroiditis has no characteristic CT image; however, as infection progresses, loculated abscesses with hypodensity may appear.

MRI is highly sensitive but just as non-specific as US and CT in differentiating benign from malignant lesions [2]. It can distinguish solid from simple and complex cysts. It allows thyroid size determination and, as with CT and in contrast to US, it can visualize the retrotracheal area and retroclavicular or intrathoracic goitre and is less operator dependent [12]. The paramagnetic contrast agent gadolinium allows visualization of tumour vascularity. The drawbacks are cost, very limited availability for this purpose, length of the investigation, and cooperability (5% of patients cannot cooperate due to claustrophobia and some, especially children, need to be sedated). Patient and tissue movement (e.g. swallowing) decreases image quality and calcifications are better visualized with CT.

On T_1-weighted images the normal thyroid gland is clearly seen on MRI and shows a nearly homogeneous signal with an intensity as the adjacent neck muscles. On T_2-weighted images, the normal thyroid has a much greater signal intensity than adjacent muscles. Blood vessels, lymph nodes, fat, and muscle are clearly identified and distinguished from the thyroid. In Graves' disease the thyroid has slightly heterogeneous diffusely increased signal on both T_1- and T_2-weighted images. Hashimoto's thyroiditis causes a heterogeneous signal intensity on T_1-weighted images and a diffusely increased signal on T_2-weighted images.

Currently, the only indication for CT or MRI in diffuse, non-neoplastic thyroid disease is the presurgical characterization of

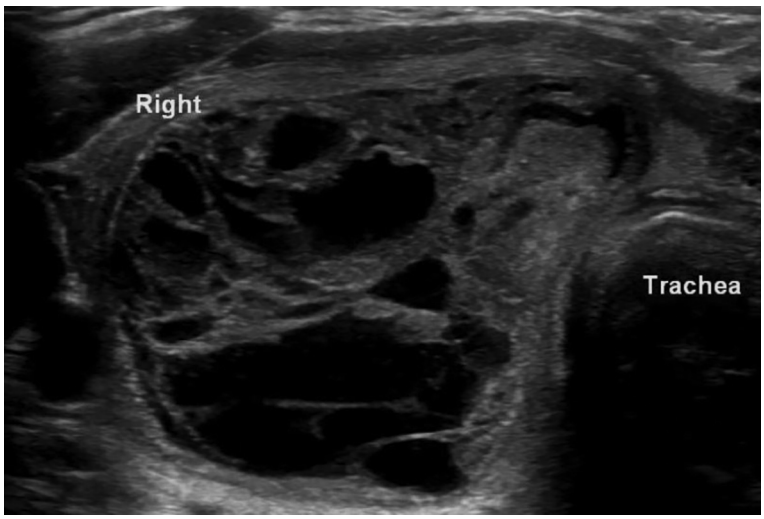

Figure 3.1.7.2 Trans-sectional greyscale US image of the right thyroid lobe showing a cystic–solid nodule with a spongiform appearance.

Box 3.1.7.3 Recommended variables to be included in a US reporting system

- Thyroid volume
- Echogenicity and vascularity of the gland
- Nodules (above 5 mm unless highly suspect)
- Location (side, superior, medial, inferior)
- Size (3 diameters +/– volume), and change in size in case of follow-up US
- Shape, margins, echogenicity, composition
- TIRADS score (see below)
- Retrosternal extension
- Tracheal deviation
- Study of lymph nodes (levels II, III, IV, V, VI)

Based on US features the categorization in five groups correlates to a malignancy risk (see Table 3.1.7.2) [14].

large goitres that are associated with local pressure symptoms. Large goitres may variably affect the trachea and oesophagus, and this may result in stenosis of the upper airway and/or swallowing dysfunction that may be clinically ill-defined unless appropriately evaluated [13]. In these patients presurgical cross-sectional imaging should be performed for a better definition of the indication and timing of surgical resection and for an appropriate planning of the surgical approach [13]. Indeed, both CT and MRI may accurately define the extent of the intrathoracic growth of the goitre, the displacement of the vascular structures of the neck, and the severity of the airway lumen reduction [10, 13].

Thyroid Imaging for the Assessment of Nodular Thyroid Disease: Ultrasound

In case of detection of thyroid nodule(s), a neck US should be performed with the evaluation of: (a) size and number; (b) texture and echogenicity (see Figure 3.1.7.2); (c) shape and margins; (d) presence and type of calcifications; and (e) vascularization and stiffness pattern [2]. Based on this evaluation, a risk stratification rating the probability of malignancy of the nodule can be performed [14]. The US TIRADS (Thyroid Imaging Reporting and Data System) categorization of thyroid nodules is based on an analytical and detailed categorization of US patterns, organized in different classes and subclasses of thyroid nodules [14]. It is recommended that assessment in a standardized reporting system is performed (see Box 3.1.7.3)

Enlarged lymph nodes may represent a benign reactive process or malignancy. Benign lymph nodes typically are oval, with a hyperechoic central stripe and vascular flow being present in the centre of the node. Loss of the hilum is felt to represent interruption of lymphatic flow by tumour invasion. However, the hilum may not always be easily defined by US in a benign lymph node, and the specificity for lack of a hilum has been reported to be only 29% for predicting the presence of cancer [15]. Malignant lymph nodes tend to become rounded in shape, distinguishing them from fusiform benign lymph nodes, but may also become irregular with microcalcifications (see Figure 3.1.7.3). Central and lateral neck lymph nodes are affected by metastatic papillary thyroid carcinoma (PTC) in up to 70% of cases [15]. US is acknowledged to be the first-line imaging modality for node assessment. The sensitivity of US in detecting abnormal lymph nodes ranges from 25% to 60% for the central neck and from 70% to 95% for the lateral neck [15]. US features predictive of malignant lymph node involvement are summarized in Table 3.1.7.1 [15].

Computed Tomography and Magnetic Resonance

CT and MRI are less accurate than US for the evaluation of risk of malignancy in focal thyroid lesions. Small size nodules may be undetectable by CT and/or MRI evaluation, and the presence of microcalcifications may easily be overlooked. Thus, after US characterization, no further imaging is needed for thyroid lesions that are not associated with signs of infiltrative growth of the cervical structures. Primary thyroid lymphoma is usually diagnosed in elderly subjects with a long-standing history of nodular goitre or Hashimoto's thyroiditis and often present with compressive symptoms of the airways and oesophagus. The disease commonly

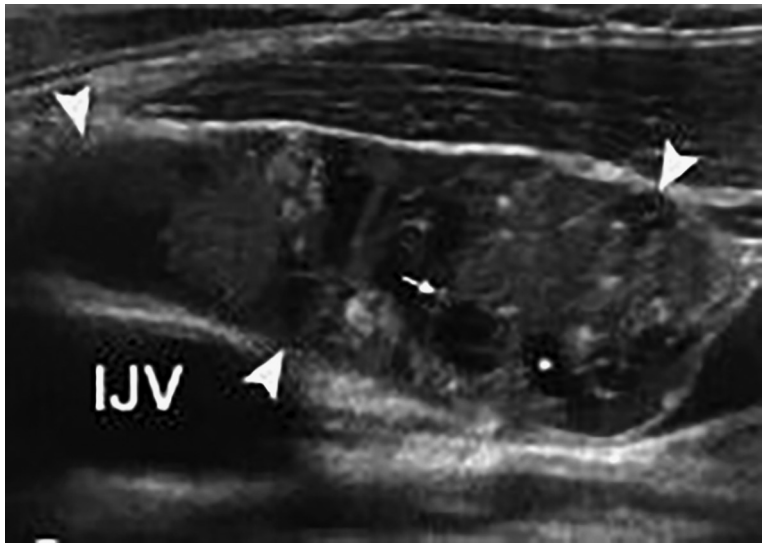

Figure 3.1.7.3 Transverse sonogram of a metastatic lymph node. Irregular heterogeneous echo texture with several microcalcifications. IJV, internal jugular vein.

Table 3.1.7.1 US features predictive of malignant lymph node involvement

Criterion	Sensitivity	Specificity
Size >1 cm	68%	75%
Shape (ratio of long axis to short axis <2.0)	46%	64%
Microcalcifications	46%	100%
Peripheral hypervascularity	86%	82%

Source: Data from Leboulleux S, Girard E, Rose M, Travagli JP, Sabbah N, Caillou B, Hartl DM, Lassau N, Baudin E, Schlumberger M. 2007. Ultrasound criteria of malignancy for cervical lymph nodes in patients followed up for differentiated thyroid cancer. *J Clin Endocrinol Metab* 92:3590–4.

manifests as a spreading mass that is hypoattenuating at CT examination [2], and like in anaplastic carcinoma, abnormal regional lymph nodes are commonly seen.

Multinodular goitre is often an enlarged asymmetrical gland with multiple low-density areas of varying degrees of discreteness (see Figure 3.1.7.4). CT density is decreased but in an inhomogeneous way. After intravenous contrast, enhancement is obtained except for areas containing haemorrhage, necrosis, or cysts. Calcifications are seen in up to 50% of goitres. Compression of the trachea, oesophagus, and great vessels is easily ascertained, and CT has found use especially in patients with monstrous and partly intrathoracic goitres, where it is ideal for the estimation of tracheal compression and quantitation of the intrathoracic extension of the goitre. Anatomical continuity with the cervical thyroid as well as a CT density greater than muscle, provides evidence of its thyroidal origin. Mediastinal lymphoma, lymphadenopathy, or thymus usually has markedly lower CT densities.

On CT imaging simple cysts are hypodense lesions, smooth-walled, and surrounded by normal thyroid tissue. The density of cyst fluid is always less than muscle and contrast injection does not lead to enhancement. Complex cysts are easily distinguished from simple cysts.

Table 3.1.7.2 TIRADS categories and malignancy risk

Category	US features	Malignancy risk, %
EU-TIRADS 1: normal	No nodules	None
EU-TIRADS 2: benign	Pure cyst Entirely spongiform	≅0
EU-TIRADS 3: low risk	Ovoid, smooth isoechoic/ hyperechoic No features of high suspicion	2–4
EU-TIRADS 4: intermediate risk	Ovoid, smooth, mildly hypoechoic No features of high suspicion	6–17
EU-TIRADS 5: high risk	At least one of the following features of high suspicion: • Irregular shape • Irregular margins • Microcalcifications • Marked hypoechogenicity (and solid)	26–87

EU-TIRADS, European Thyroid Imaging Reporting and Data System; US, ultrasound.

Source: Reproduced with permission from Russ G, Bonnema SJ, Erdogan MF, Durante C, Ngu R, Leenhardt L. European Thyroid Association Guidelines for Ultrasound Malignancy Risk Stratification of Thyroid Nodules in Adults: The EU-TIRADS. *Eur Thyroid J*, 2017; 6: 225–37.

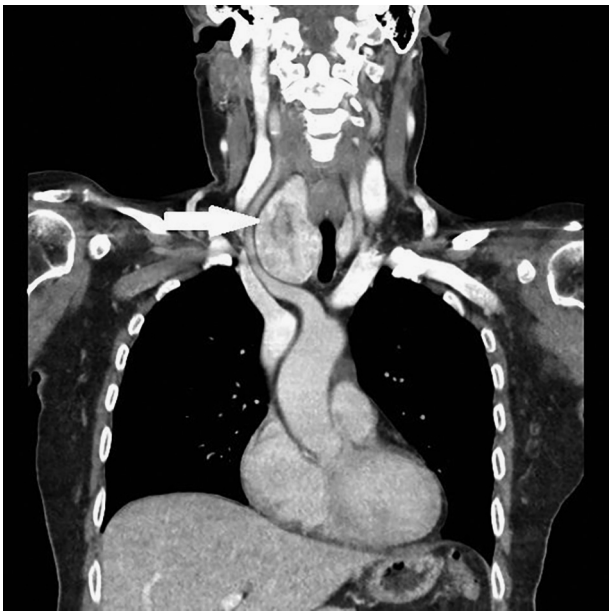

Figure 3.1.7.4 Coronal CT showing a partly intrathoracic multinodular goitre on the right side (the thyroid tissue being inhomogeneous with varying degrees of density) with slight compression of the trachea.

On MRI, simple cysts have a low-intensity signal on both T_1- and T_2-weighted imaging (see Figure 3.1.7.5). The intensity on T_1-weighted images increases with increasing protein and lipid content.

As with US, no CT characteristics will accurately separate benign from malignant lesions [2], although invasive growth into surrounding structures and metastases to cervical lymph nodes are suggestive of carcinoma. Papillary and follicular carcinomas are usually irregular low-density lesions and calcifications are present in the majority. There may be slight enhancement after contrast injection. The CT feature of medullary thyroid carcinomas is a single or multiple low-density lesions of variable size in one or both lobes. Lesions of 1–2 mm in size can be detected. Calcification is less often seen than in papillary carcinoma.

Large irregular masses of low attenuation with central cystic or necrotic areas are suggestive of anaplastic carcinoma especially if calcification is pronounced. Again, these features may also be seen in benign multinodular goitres. Invasion of the trachea, cricoid, or thyroid cartilage, and growth into the tracheal lumen is highly suggestive of carcinoma. Both Hashimoto's thyroiditis and thyroid lymphoma appear as masses of reduced density with little enhancement after contrast injection, and CT alone cannot make a distinction between them.

CT is of value in the follow-up of patients with thyroid cancer. Recurrence is evident as discrete low-density lesions within or outside the thyroid bed. Lymph node metastases typically have a regular rim, a core of central lucency, and no enhancement after intravenous contrast. CT is highly sensitive in detecting extrathyroidal spread of disease and therefore complementary to whole-body scanning with radioactive iodine.

Combined CT and positron emission tomography (PET) with [^{18}F]2-fluoro-2-deoxy-D-glucose (FDG) is a novel multimodality technology that enables a more precise anatomical localization of an area with increased focal uptake (potentially malignant lesion).

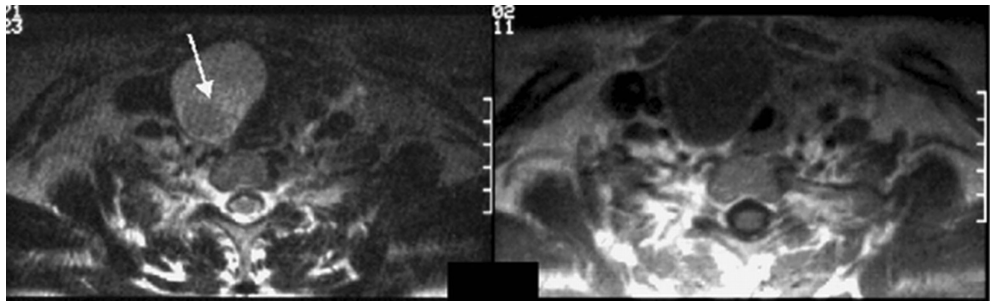

Figure 3.1.7.5 Axial MRI with T_2- (left) and T_1-weighted (right) scans of a cystic–solid thyroid nodule in the right thyroid lobe. A hypointense solid component (arrow) can be seen in comparison with the relatively hyperintense fluid. In the T_1-weighted picture, the lesion cannot be recognized in the hypointense fluid.

Its role in the initial evaluation of a thyroid nodule is limited but can be of value in case of indeterminate cytology [15]. It is increasingly used where there is suspicion of recurrence or spread of thyroid cancer [16].

On MRI follicular adenomas appear round or oval with a heterogeneous signal equal to or greater than that of normal tissue [2]. On T_2-weighted images the nodules have increased signal intensity. No MRI characteristics will accurately separate benign from malignant lesions. Thyroid carcinomas appear as focal or non-focal lesions of variable size; they are isointense or slightly hyperintense on T_1-weighted images and hyperintense on T_2-weighted images. The imaging characteristics of all types of thyroid carcinomas, including medullary carcinoma and lymphoma, are similar.

The extent of thyroid carcinoma can be determined preoperatively and may be useful in the planning of surgery. Extension into adjacent structures is usually evident. Gadolinium may be useful since metastatic nodes are enhanced centrally after gadolinium injection. Furthermore, in the postoperative follow-up recurrent carcinomas enhance with gadolinium, whereas scarring generally does not.

Magnetic Resonance Imaging

Please see Figure 3.1.7.5.

Conclusions and Recommendations

Thyroid imaging offers a relevant diagnostic and therapeutic contribution to the management of patients with thyroid disease. US is a sensitive tool for the evaluation of diffuse and focal thyroid disease and cervical masses. Thyroid US characteristics define the risk of malignancy in thyroid nodules and aids in making the decision of which nodules need FNA. Additionally, US examination confirms the presence of size abnormalities and/or possible changes in thyroid morphology in patients with clinical findings suggestive of thyroid dysfunction and/or inflammation. Thus, all patients suspected of thyroid disease benefit from a dedicated cervical US.

CT and MRI can provide much of the information that is obtained with US [2]. Their greater expense, limited availability, and other drawbacks argue against their use most of the time. CT is valuable in determining the extent of a substernal goitre or in the evaluation of a mediastinal mass. It can give valuable information in the evaluation of thyroid carcinoma and its spread. MRI may be useful in the same setting and is generally superior to CT in the evaluation of recurrent carcinoma, be it in the thyroid bed or in regional lymph nodes [2]. Therefore, a selective use of cross-sectional imaging with CT or MRI is recommended and should be based on clinical and sonographic indicators of extensive disease.

Preoperative PET-CT is not universally performed in patients with thyroid cancer because 18F-FDG uptake depends on the degree of tumour cell differentiation, such that uptake is higher in poorly differentiated than in well-differentiated thyroid tumours. In addition, well-differentiated thyroid tumours with iodine avidity have low glucose metabolism, and therefore PET is more useful for detecting recurrent or metastatic differentiated thyroid cancer in patients with negative radioiodine scans and elevated thyroglobulin levels during follow-up [17, 18].

3.1.8 Epidemiology of Thyroid Disease and Swelling

Mark P.J. Vanderpump

Introduction

Thyroid disorders are among the most prevalent of medical conditions. Their manifestations vary considerably from area to area and are determined principally by the availability of iodine in the diet. The limitations of epidemiological studies of thyroid disorders should therefore be borne in mind when considering the purported frequency of thyroid diseases in different communities [1, 2].

Iodine is an essential component of the thyroid hormones thyroxine (T_4) and triiodothyronine (T_3) produced by the thyroid gland. The ideal dietary allowance of iodine recommended by World Health Organization (WHO) in adults is 150 µg of iodine per day which increases to 250 µg per day in pregnancy and lactation. Iodine deficiency impairs thyroid hormone production and has adverse effects throughout life, particularly early in life as it impairs cognition and growth [3].

Iodine deficiency is a global problem with large populations at risk who are living in an environment where the soil has been deprived of iodine. The mountainous regions of Europe, the Northern Indian Subcontinent, the extensive mountain ranges of China, the Andean region in South America and the lesser ranges of Africa are all iodine deficient. Iodine deficiency remains a significant problem despite major national and international efforts to increase iodine intake, primarily through the voluntary or mandatory iodization of salt. In 2007, the WHO estimated that two billion people, including 285 million school-age children, still had iodine deficiency, defined as a urinary iodine excretion of less than 100 µg/L [4]. Iodine deficiency has emerged as issue in industrialized countries, previously thought of as iodine sufficient. International efforts to control iodine deficiency are slowing and reaching those that remains deficient poses major challenges [5].

In areas where the daily iodine intake is less than 50 µg, goitre is usually endemic, and when the intake falls below 25 µg per day, congenital hypothyroidism is seen. The prevalence of goitre in areas of severe iodine deficiency can be as high as 80%. Goitrogens in the diet, such as thiocyanate in incompletely cooked Cassava or thioglucosides in Brassica vegetables, can explain some of the differences in prevalence of endemic goitre in areas with similar degrees of iodine deficiency. Iodization programmes are of proven value in reducing goitre size and in preventing goitre development and cretinism in children [3].

The effects of mild-to-moderate iodine deficiency on cognition are less well known than those of moderate-to-severe deficiency but there is a continuum of disability with more subtle impairments of the intelligence quotient (IQ) and motor ability associated with less severe deficiency. A systematic review of available published studies from 1980–2011 found that, regardless of study design, iodine deficiency had a substantial impact on mental development of children five years old and under which translated into 6.9 to 10.2 IQ points lower in iodine deficient compared with iodine-replete children [6]. Autonomy can develop in nodular goitres, occasionally leading to thyrotoxicosis, and iodization programmes can also induce thyrotoxicosis, especially in those older than age 40 with nodular goitres [3].

In iodine-replete areas, most persons with thyroid disorders have autoimmune disease, ranging through primary atrophic hypothyroidism, Hashimoto's thyroiditis to hyperthyroidism

caused by Graves' disease. Cross-sectional studies have determined the prevalence of hyperthyroidism and hypothyroidism and the frequency and distribution of thyroid autoantibodies in different, mainly Caucasian, communities [1, 2]. United States (US) data revealed differences in the frequency of thyroid dysfunction and serum antithyroid antibody concentrations in different ethnic groups [7], whereas European studies revealed the influence of dietary iodine intake on the epidemiology of thyroid dysfunction [8]. Studies of incidence of autoimmune thyroid disease have only been conducted in a small number of developed countries [9]. Following a review of the available epidemiological data, the value of screening adult populations for autoimmune thyroid disease will be considered.

Hyperthyroidism

Hyperthyroidism has a significant short-term morbidity and long-term morbidity and mortality [10]. In epidemiological studies, the clinical diagnosis of thyrotoxicosis should be supported by measurements of serum T_4 or T_3 and thyrotropin (TSH) concentrations. Biochemical tests of thyroid function may reveal the diagnosis before it is clinically apparent. A rise in serum T_3 and fall in serum TSH are the earliest measures of thyroid overactivity, followed by a rise in serum T_4. The most common cause of hyperthyroidism in iodine-replete communities is Graves' disease, followed by toxic multinodular goitre, whereas rarer causes include an autonomously functioning thyroid adenoma, autoimmune or viral thyroiditis, excessive levothyroxine (L-T_4) replacement or drugs including amiodarone and lithium carbonate. In epidemiological studies, the aetiology is rarely ascertained.

Prevalence of Hyperthyroidism

The prevalence of hyperthyroidism in women is between 0.5 and 2% and is ten times more common in women than in men in iodine-replete communities [1, 2]. In the Whickham survey in Northeast England, the prevalence of undiagnosed hyperthyroidism was 4.7/1000 women [11]. Hyperthyroidism had been previously diagnosed and treated in 20/1000 women, rising to 27/1000 women when possible but unproven cases were included, as compared with 1.6 to 2.3/1000 men, in whom no new cases were found at the survey. The mean age at diagnosis was 48 years. In the US National Health and Nutrition Examination Survey (NHANES III), of those subjects who were neither taking thyroid medication nor reported a history of thyroid disease, 2/1000 had 'clinically significant' hyperthyroidism, defined as a serum TSH concentration less than 0.1 mU/L and serum total T4 concentration greater than 170 nmol/L [7]. A cross-sectional survey of 25 682 subjects aged over 18 years attending a Health Fair in Colorado, US found that overt hyperthyroidism, defined as serum TSH concentration less than 0.01 mU/L, was present in only 1/1000 of those not taking thyroid medication [12]. A higher prevalence is seen in iodine-deficient areas [8]. Prevalence data in elderly persons show a wide range between 0.4 and 2.0%. The reported prevalence rates for previously undiagnosed hyperthyroidism in hospitalized patients is between 0.3 and 1% and consistent with community surveys [1].

Table 3.1.8.1 The effect of environmental iodine intake on the prevalence of subclinical thyroid disease

Iodine status	Subclinical hypothyroidism	Subclinical hyperthyroidism
Deficient	1–4%	6–10%
Replete	4–9%	1–2%
Excess	18–14%	<1%

Subclinical Hyperthyroidism

The introduction of assays for serum TSH that were sensitive enough to distinguish between normal and low concentrations allowed subjects with subclinical hyperthyroidism to be identified. Subclinical hyperthyroidism is defined as a low serum TSH concentration and normal serum T_4 and T_3 concentrations, in the absence of hypothalamic or pituitary disease, non-thyroidal illness, or ingestion of drugs that inhibit TSH secretion such as glucocorticoids or dopamine [13]. Epidemiological studies differ in the definition of a low serum TSH concentration and whether the subjects included were receiving L-T_4 therapy.

The reported overall prevalence ranges from 0.5 to 6.3%, with men and women over 65 years having the highest prevalence and approximately half taking L-T_4 [1]. The Colorado study of 25 682 healthy volunteers (of whom 88% were white) found 2% had a subnormal serum TSH, with more than half on L-T_4 [12]. In the NHANES III study the prevalence was highest in those subjects aged 20 to 39 years and those aged greater than 79 years [7]. The percentage with serum TSH concentrations less than 0.4 mU/L was significantly higher in women than men, and black subjects had a higher prevalence (0.4%) than whites (0.1%) or Mexican Americans (0.3%). The prevalence is higher in iodine-deficient populations due to functional autonomy from nodular goitres [8] (Table 3.1.8.1).

Among subjects with subclinical hyperthyroidism, those with low but detectable serum TSH values may recover spontaneously when retested [13]. Non-thyroidal illness is an important cause of false-positive serum TSH test results. There are limited data on the risk of progression of subclinical hyperthyroidism to overt hyperthyroidism. Those with an undetectable serum TSH and confirmed aetiology as determined by thyroid scintigraphy due to Graves' disease or nodular disease have an annual incidence of approximately 5–8% [14]. A population study in Tayside, United Kingdom (UK) followed 2024 subjects with at least two serum TSH measurements below the reference range for at least four months for up to seven years [15]. Few subjects developed hyperthyroidism (0.5–0.7%) and the percentage of those reverting to normal increased with time and was more common if the baseline serum TSH was between 0.1 and 0.4 mU/L.

Incidence of Hyperthyroidism

The incidence data available for overt hyperthyroidism in men and women from large population studies are comparable, at 0.4/1000 women and 0.1/1000 men, but the age-specific incidence varies considerably [1, 2]. The peak age-specific incidence of Graves' disease was between 20 and 49 years in two studies but increased with age in Iceland and peaked at 60 to 69 years in Malmö, Sweden. The peak age-specific incidence of hyperthyroidism caused by toxic nodular goitre and autonomously functioning thyroid adenomas in the Malmö study was over 80 years. The only available data in a

black population, from Johannesburg, South Africa, suggest a ten-fold lower annual incidence of hyperthyroidism (0.09/1000 women and 0.007/1000 men) than in whites [2].

In the 20-year follow-up of the Whickham cohort, the mean annual incidence of hyperthyroidism in women was 0.8/1000 survivors (95% confidence interval (CI), 0.5–1.4) [16]. The incidence rate was similar in the deceased women. No new cases were detected in men. An estimate of the probability of the development of hyperthyroidism in women at a particular time averaged 1.4/1000 between the ages of 35 and 60 years (Figure 3.1.8.1) [16]. Serum antithyroid antibody status or goitre was not associated with the development of hyperthyroidism at follow-up. Other cohort studies provide comparable incidence data, which suggests that many cases of hyperthyroidism remain undiagnosed in the community unless routine testing is undertaken [9]. In Tayside, UK, 620 incident cases of hyperthyroidism were identified from medical records with an incidence rate of 0.77/1000 per year (95% CI, 0.70–0.84) in women and 0.14/1000 per year (95% CI, 0.12–0.18) in men [17]. The incidence increased with age, and women were affected two to eight times more than men across the age range. The incidence increased in women but not men between 1997 and 2001 [18].

Hypothyroidism

Hypothyroidism is an insidious condition with a significant morbidity, and the subtle and non-specific symptoms and signs may be mistakenly attributed to other illnesses, particularly in postpartum women and older people [19]. The earliest biochemical abnormality is an increase in serum TSH concentration associated with normal serum free T_4 and T_3 concentrations (subclinical hypothyroidism or mild thyroid failure), followed by a decrease in serum free T_4 concentration, at which stage, most patients have symptoms and benefit from treatment (overt hypothyroidism). In iodine-replete communities, the cause is either chronic autoimmune disease (atrophic autoimmune thyroiditis or goitrous autoimmune thyroiditis (Hashimoto's thyroiditis)) or destructive treatment for hyperthyroidism, which may account for up to one-third of cases of hypothyroidism in the community.

Congenital Hypothyroidism

Congenital hypothyroidism affects approximately 1 newborn in 3500 to 4000 births and is the most treatable cause of intellectual disability [20]. There is an inverse relationship between age at diagnosis and IQ in later life. In iodine-replete areas, 85% of the cases are due to sporadic developmental defects of the thyroid gland (thyroid dysgenesis), such as the arrested migration of the embryonic thyroid (ectopic thyroid) or a complete absence of thyroid tissue (athyreosis). The remaining 15% have thyroid dyshormonogenesis defects transmitted by an autosomal recessive mode of inheritance. Iodine deficiency (less than 25 μg per day), particularly in preterm infants, accounts for many cases in Eastern Europe, Asia, and Africa. Clinical diagnosis occurs in less than 5% of newborns with hypothyroidism because symptoms and signs are often minimal, so it is not possible to predict which infants are likely to be affected. Without prompt diagnosis and treatment, most affected children gradually develop growth failure, irreversible intellectual disability, and a variety of neuropsychological deficits. The apparent incidence of congenital hypothyroidism has more than doubled due to more inclusive diagnostic criteria, shifting demographics, and increasing survival of preterm infants [21]. The greatest increase has occurred in mildly affected children. Congenital hypothyroidism may be transient or persistent, but the natural history cannot be predicted by severity at diagnosis. In premature infants, who are especially vulnerable to hypothyroidism, the rise in serum TSH may be delayed and therefore detected only by routine follow-up screening.

Asymptomatic Autoimmune Thyroiditis

Raised serum concentrations of thyroid antibodies (antithyroid peroxidase (microsomal) (TPOAb) and antithyroglobulin (TGAb)) correlate with the presence of focal thyroiditis in thyroid tissue obtained by biopsy and at autopsy from patients with no evidence of hypothyroidism during life. Early post-mortem studies confirmed histological evidence of chronic autoimmune thyroiditis in 27% of adult women, with a rise in frequency over 50 years, and 7% of adult men, and diffuse changes in 5% of women and 1% of men [1]. Patients with hypothyroidism caused by either atrophic or goitrous autoimmune thyroiditis usually have high serum concentrations of these same antibodies. These antibodies also are often detected in serum of patients with Graves' disease and other thyroid diseases, but the concentrations are usually lower. There is considerable variation in the frequency and distribution of antithyroid antibodies because of variations in techniques of detection, definition of abnormal titres, and inherent differences in the populations tested.

A significant proportion of subjects in the community have asymptomatic chronic autoimmune thyroiditis of whom a substantial proportion have subclinical hypothyroidism (Figure 3.1.8.2) [11]. In the NHANES III survey the percentage of subjects with high serum thyroid peroxidase (TPO) and TG antibody concentrations increased with age in both men and women, and high concentrations were more prevalent in women than in men and less prevalent in blacks than in other ethnic groups [7]. Using a competitive immunoassay procedure, the reported prevalence of detectable TGAb and TPOAb levels were 10% and 12% in the healthy population.

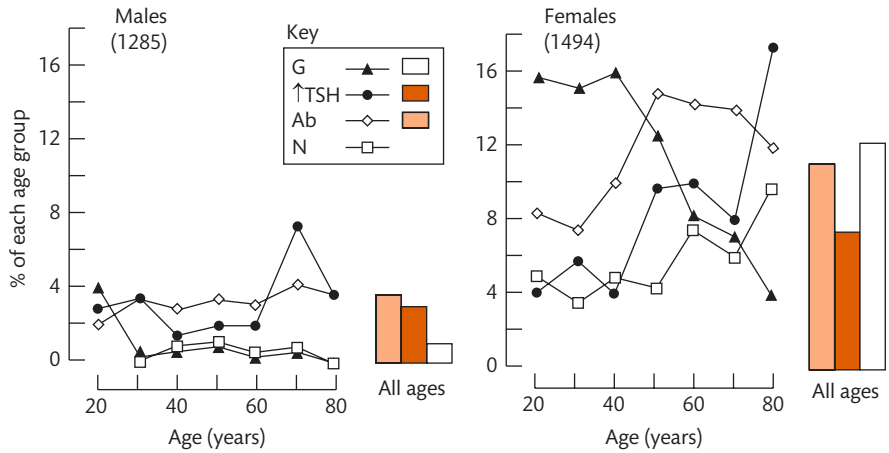

Figure 3.1.8.2 Age and sex distribution of thyroid microsomal antibodies (Ab), raised serum TSH greater than 6 mU/L (↑TSH), visible diffuse and multinodular goitre (G), and nodules (N) in the Whickham survey.

A hypoechoic ultrasound pattern may precede TPOAb positivity in autoimmune thyroid disease, and TPOAb may not be detected in more than 20% of individuals with ultrasound evidence of thyroid autoimmunity [13].

Prevalence of Hypothyroidism

In iodine-replete communities, the prevalence of spontaneous hypothyroidism is between 1% and 2%, and it is more common in older women and ten times more common in women than in men [1]. In the Whickham survey, the prevalence of previously diagnosed and treated hypothyroidism was 14/1000 women, increasing to 19/1000 women when possible, but unproven, cases were included [11]. The overall prevalence in men was less than 1/1000. One-third had been previously treated by surgery or radioiodine for thyrotoxicosis. The mean age at diagnosis was 57 years. The Whickham data are comparable with other studies where the prevalence of newly diagnosed hypothyroidism ranged between 0.6 and 12/1000 women and between 1.3 and 4.0/1000 in men investigated in Northern Europe, Japan, and the United States [1]. In the Colorado and NHANES III studies, the prevalence was 4/1000 and 3/1000, respectively [7, 12]. The prevalence is higher in surveys of older people in the community [1] and lower in areas of iodine deficiency [8]. The testing of hospital inpatients, predominantly elderly women, confirm a prevalence of 2% [1].

Subclinical Hypothyroidism

The term subclinical hypothyroidism represents a compensated state in which increased TSH output is required to maintain normal circulating thyroid hormone levels. An elevated serum TSH is a sensitive indicator of some degree of thyroid failure and, in contrast to below normal serum TSH levels, a clear inverse relationship is found with free T_4 levels. It is found either post radioiodine therapy or post surgery in up to 50% of apparently euthyroid patients. It may be evident for only a few months, but more often it represents a stage in the progression towards overt thyroid failure. Less frequent causes include external beam irradiation of malignant tumours of the head and neck, and drugs including lithium, amiodarone, and undiagnosed Addison's disease. In the community, the most common aetiology is chronic autoimmune thyroiditis [1, 13].

With respect to epidemiological studies, the definition of subclinical hypothyroidism varies from any increase in serum TSH to values more than 10 mU/L or, more stringently, a serum TSH value more than 10 mU/L and a positive test for circulating thyroid antibodies in serum. The term implies that patients should be asymptomatic, although symptoms are difficult to assess, especially in those in whom thyroid function tests have been checked because of non-specific complaints such as tiredness. Spontaneous recovery has also been described in subjects with subclinical hypothyroidism, although the frequency of this phenomenon is unclear. Normalization of serum TSH concentrations is more likely to occur in patients with negative antithyroid antibodies and serum TSH levels less than 10 mU/L, and within the first 2 years after diagnosis [13].

Controversy exists regarding the upper limit of the reference range for serum TSH [22, 23]. Reference ranges are derived from a reference population that comprises a large group of subjects who do not have thyroid disease and are otherwise well. By convention, a reference range usually only comprises 95% of a reference population. Thus, 2·5% of 'normal' individuals will fall above the reference range and 2·5% will fall below the range. For serum TSH, the reference population shows a log normal distribution and has a diurnal variation with the reference range in thyroid disease-free individuals typically cited as between 0.4 and 4.0 mU/L. The serum TSH reference range varies in different ethnic communities, trimesters of pregnancy, and progressively shifts towards higher concentration with age. Analysis of the NHANES III data suggest that the reference range for serum TSH rises with age as the 97.5 centile for those subjects aged more than 80 years was 7.49 mU/L and 70% had a serum TSH more than the population defined upper limit of the reference range of 4.5 mU/L of whom only 40% were antithyroid antibody positive [24].

In the original Whickham survey, 8% of women (10% of women over 55 years of age) and 3% of men had subclinical hypothyroidism [11]. In the Colorado study, 9.4% of the subjects had a high serum TSH concentration, of whom 9.0% had subclinical hypothyroidism

[12]. Among those with a high serum TSH concentration, 74% had a value of between 5.1 and 10 mU/L and 26% had a value greater than 10 mU/L. The percentage of subjects with a high serum TSH concentration was higher for women than men in each decade of age and ranged from 4% to 21% in women and 3% to 16% in men. The NHANES III study found that 11% of those aged 20 to 29 had a serum TSH greater than 2.5 mU/L, increasing to 40% in those aged 80 and over. Serum TSH concentrations were higher in whites than blacks, independent of serum antithyroid antibody concentrations [7]. Approximately 2% of adolescents aged 12 to 19 years had a serum TSH greater than 4.5 mU/L. Community studies of elderly persons have confirmed approximately 10% of subjects over 60 years having serum TSH values above the normal range [1]. Subclinical hypothyroidism is found at higher frequency in areas where iodine intake is high most cases are not of autoimmune origin [8] (Table 3.1.8.1). In surveys of hospital inpatients, the point prevalence rates were similar being between 3% and 6% with most subjects reverting to normal thyroid function three months following the acute illness [1].

Incidence of Hypothyroidism

After destructive treatment of hyperthyroidism with either radioiodine or surgery, the incidence of overt hypothyroidism is greatest in the first year. The incidence of hypothyroidism in patients with Graves' disease was higher than that in patients with nodular goitre (55% vs. 32%) and increased in those given higher doses of radioiodine [1]. If subclinical hypothyroidism is present one year or more after radioiodine or surgical treatment, then the annual rate of progression to overt hypothyroidism after either treatment is 2–6%. Treatment of Graves' disease with antithyroid drugs alone is also associated with the eventual development of hypothyroidism in 5–20% of cases from either autoimmune thyroiditis or the presence of TSH-blocking antibodies. The incidence of hypothyroidism after surgery, external radiation therapy of the neck, or both, in patients with head and neck cancer (including lymphoma) is as high as 50% within the first year after treatment, particularly in patients who underwent surgery and received high doses of radiation. The effect is dose-dependent, the onset is gradual, and subclinical hypothyroidism can be present for many years prior to the development of overt disease.

At the 20-year follow-up of the Whickham cohort the mean annual incidence of spontaneous hypothyroidism in the surviving women during the 20-year follow-up period was 3.5/1000 (95% CI, 2.8–4.5), increasing to 4.1/1000 (95% CI, 3.3–5.0) if all cases including those who had received destructive treatment for thyrotoxicosis were included [16]. The hazard rate increased with age to 13.7/1000 in women 75 to 80 years of age (Figure 3.1.8.1). The mean annual incidence during the 20-year follow-up period in men (all spontaneous except for one case of lithium-induced hypothyroidism) was 0.6/1000 (95% CI, 0.3–1.2). The risk of having developed hypothyroidism was examined with respect to risk factors identified in the first survey. Either raised serum TSH or positive antithyroid antibodies alone or in combination are associated with a significantly increased risk of hypothyroidism in surviving women (Table 3.1.8.2) [16]. The annual risk of spontaneous overt hypothyroidism was 4% in those who had both high serum TSH and antithyroid antibody concentrations, 3% if only their serum TSH concentrations was high, and 2% if only their serum thyroid antibody concentration was high; at the time of follow-up the respective rates of hypothyroidism were 55%, 33%, and 27%. The probability of developing hypothyroidism was higher in those women who had serum TSH concentrations above 2.0 mU/L and high serum titres of antithyroid microsomal antibodies at the first survey (Figure 3.1.8.3) [16]. Neither a positive family history of any thyroid disease, nor the presence of a goitre at either the first or the follow-up survey, or parity at first survey was associated with an increased risk of hypothyroidism.

Table 3.1.8.2 Development of spontaneous hypothyroidism in surviving women and men at 20-year follow-up of Whickham survey: odds ratios (with 95% CI)

Women	
TSH raised, regardless of thyroid antibody status	14 (9–24)
Thyroid antibody +, regardless of TSH status	13 (8–19)
If thyroid antibody -, effect of raised TSH alone	8 (3–20)
If thyroid antibody +, additional effect of raised TSH	5 (2–11)
If TSH normal, effect of thyroid antibody + alone	8 (5–15)
If TSH raised, additional effect of thyroid antibody +	5 (1–15)
TSH raised and thyroid antibody + combined	38 (22–65)
Men	
TSH raised, regardless of thyroid antibody status	44 (19–104)
Thyroid antibody +, regardless of TSH status	25 (10–63)
TSH raised and thyroid antibody + combined	173 (81–370)

Other incidence data for hypothyroidism are from short (and often small) follow-up studies [9] and confirm that serum TSH concentrations in the upper part of the normal range in this study have a predictive value. In Tayside, UK the standardized incidence of primary hypothyroidism remained between 3.90 and 4.89/1000 women per year between 1993 and 2001 [17, 18]. The incidence of hypothyroidism in men however significantly increased from 0.65 to 1.01/1000 per year ($P = 0.0017$) and the mean age at diagnosis of primary hypothyroidism decreased in women from 1994 to 2001.

Thyroid Disease in Pregnancy

Pregnancy has variable effects on thyroid hormone concentrations throughout pregnancy as well as being associated with goitre [25]. The latter is largely preventable by ensuring optimal iodine intake of at least 200 μg per day. Hypothyroidism in pregnancy usually characterized by a high serum TSH value has been found to occur in around 2–3% of otherwise normal pregnancies with the prevalence of overt hypothyroidism estimated to be up to 0.5% [26]. On a worldwide basis the most important cause of thyroid insufficiency remains iodine deficiency, while in iodine-replete communities the cause is usually chronic autoimmune thyroiditis. Untreated hypothyroidism may lead to obstetric complications, such as preterm delivery and fetal loss. Epidemiological data suggest that the children of women with hypothyroxinaemia may have psychoneurological

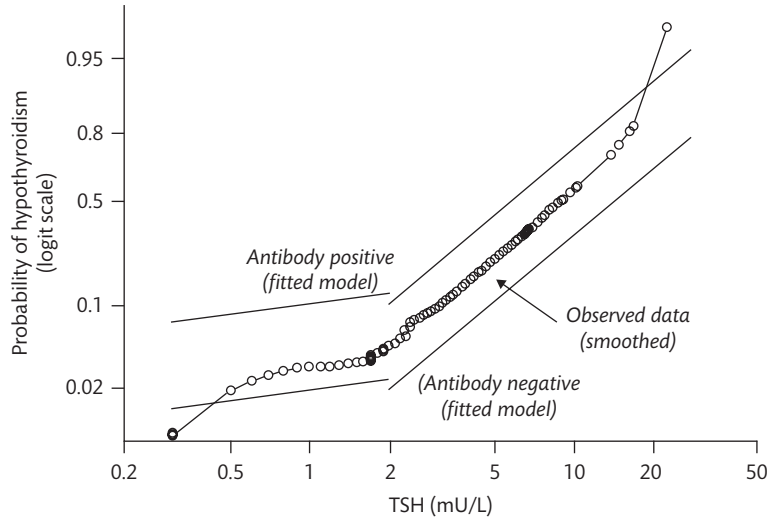

Figure 3.1.8.3 Probability for development of hypothyroidism within 20 years with increasing values of serum TSH at first Whickham survey in 912 survivors.

deficits. In classic areas of iodine deficiency, a similar range of deficits in children has been described where maternal hypothyroxinaemia rather than high serum TSH is the main biochemical abnormality [3]. In these areas, maternal iodine intake is often substantially less than the 200 μg per day currently recommended. Even in areas previously thought to be iodine sufficient, there is now evidence of substantial gestational iodine deficiency, which may lead to low maternal circulating thyroxine concentrations.

Hyperthyroidism is found in 0.1–0.4% of all pregnancies and is usually caused by Graves' disease characterized by TSH receptor (TSHR) antibodies, which usually decrease in titre throughout pregnancy. Maternal complications include miscarriage, placenta abruption, pre-eclampsia, and preterm delivery. High titres of TSHR antibodies predict a high risk of neonatal thyrotoxicosis [25].

Antithyroid antibodies, particularly TPOAb, occur in 10% of women at 14 weeks of gestation, which is compatible with the prevalence of antithyroid antibodies in community surveys [1, 13]. A proportion of these women will have subclinical hypothyroidism with a high serum TSH, but most will be euthyroid. However, after delivery a transient, destructive autoimmune thyroiditis that occurs between the twelfth and sixteenth week postpartum will develop in 50% of TPOAb positive women, as ascertained in early gestation, clinically apparent as postpartum thyroiditis (PPT) [26]. It presents as a temporary, usually painless, episode of hypothyroidism, occasionally preceded by a short episode of hyperthyroidism. Up to 25% of women progress to permanent hypothyroidism within approximately five years following an episode of PPT, particularly those with high antibody titres.

Goitre and Thyroid Nodules

The most common thyroid disease is simple (diffuse) goitre. The clinical grading of thyroid size is subjective and imprecise. The WHO grading system recognizes that an enlarged thyroid gland may be palpably but not visibly enlarged. Interexaminer variation may lead to differences in classifying a goitre as diffuse or multinodular. There is considerable overlap between the five WHO grades based on clinical criteria and thyroid volume estimated by ultrasonography. Ultrasonography has been used in epidemiological studies to assess thyroid size, resulting in much higher estimates of goitre prevalence than in studies in which goitre size was assessed by physical examination.

In cross-sectional surveys, the prevalence of diffuse goitre declines with age, the greatest prevalence is in premenopausal women, and the ratio of women to men is at least 4:1. In the Whickham survey, among the women 26% had a goitre; the frequency ranged from 31% in those aged less than 45 years (mostly diffuse) to 12% in those aged over 75 years (who had a higher proportion of nodular goitre) [11] (**Figure 3.1.8.2**). Longitudinal studies confirm the decreasing frequency of diffuse goitre with age [16]. This decline in frequency of diffuse goitres with age is in contrast to the increase in frequency of thyroid nodules and antithyroid antibodies with age. In the Whickham survey, less than 1% of the men but 5% of the women had thyroid nodules detected clinically, and the frequency increased to 9% in women more than age 75 [11]. A higher prevalence of nodular goitre is found in areas of iodine deficiency in Europe, such as Italy, Germany, and Denmark. Longitudinal data suggest an annual incidence for nodules of 1/1000 and that, once formed, they tend to remain present and benign for a long period of time [1].

With the increasing use of sensitive imaging techniques, an increasing proportion of thyroid nodules are detected incidentally. Many nodules are detected because of their size or anterior position in the neck, or the skill of the physician performing the examination but most thyroid nodules will not be clinically recognized. Up to 50% of nodules more than 1 cm detected by ultrasound are undetected by clinical examination. The prevalence of thyroid incidentaloma as an unexpected, asymptomatic thyroid nodule discovered during the investigation of an unrelated condition, is

67% with ultrasonography imaging, 15% with computed tomography or magnetic resonance imaging of the neck, and 1–2% with fluorodeoxyglucose positron emission tomography [27].

Thyroid Cancer

The clinical presentation of thyroid cancer is usually as a solitary thyroid nodule or increasing goitre size. Although thyroid nodules are common, thyroid cancers are rare. The four major histological types are papillary, follicular, medullary, and anaplastic, and each displays a different epidemiology. The annual incidence of all thyroid cancers ranges between 1 and 10/100 000 population in most countries and is two to four times more frequent in women than men [28, 29]. Papillary and follicular tumours, which comprise 60–90% of the total, are rare in children and adolescents but their incidence increases with age in adults.

Papillary thyroid carcinoma (PTC) is the most common thyroid malignancy and worldwide constitutes 50–90% of differentiated follicular cell-derived thyroid cancers. Papillary thyroid microcarcinomas (diameter less than 1 cm) are found in 4–36% of adults post-mortem in population-based studies. Most diagnoses of PTC occur in patients 30–50 years old (median age 44 years), and the majority (60–80%) occur in women. The reported increase in incidence of these carcinomas in recent years has been attributed to an improvement in pathological techniques and earlier and increased detection of small (subclinical) papillary cancers secondary to more widespread use of neck ultrasonography and fine-needle aspiration of very small thyroid nodules. However, a recent analysis of the National Cancer Institute's Surveillance, Epidemiology, and End Results database found an increase in the rates of differentiated thyroid cancer of all sizes, including tumours more than 4 cm and an increase in incidence-based mortality between 1974 and 2013, from 0.40 to 0.46/100 000 person-years [30]. External radiation exposure, particularly in childhood, is a major risk factor for papillary cancer. Four years after the nuclear accident at Chernobyl, a significant increase in the incidence of childhood thyroid cancer (almost exclusively papillary tumours in which a translocation of the *RET* gene occurs) was recorded in the regions most exposed [31]. There is no association between radioiodine therapy for thyrotoxicosis and subsequent development of thyroid cancer in adults.

Follicular thyroid cancer occurs relatively infrequently compared to papillary cancer and accounts for approximately 15% of all thyroid cancers. There is an increased frequency of follicular to papillary carcinoma (5:1) in iodine-deficient endemic goitre areas. It tends to be a malignancy of older persons, with a peak incidence of between ages 40 and 60 years and is approximately three times more common in women than in men. Medullary thyroid cancer (MTC) occurs in both sporadic and hereditary forms. The highest incidence of sporadic disease occurs in the fifth decade. Hereditary MTC can be inherited as an autosomal dominant trait with a high degree of penetrance associated with multiple endocrine neoplasia (MEN) type 2 syndrome or as familial MTC without any other endocrinopathies. It can be diagnosed before clinical presentation by genetic and biochemical screening. Anaplastic thyroid cancer is very rare and is more frequent in populations with endemic goitre. Thyroid lymphoma is also uncommon, constituting approximately 2% of extranodal lymphomas and occurring predominantly in older women. Up to one-third of patients have a history of goitre, whereas some have established autoimmune thyroiditis and may be taking L-T_4 therapy [29].

Screening for Thyroid Disorders

In the 1970s, screening programmes for congenital hypothyroidism were developed in which TSH was measured in heel-prick blood specimens to detect this condition as early as possible. The value of screening for congenital hypothyroidism is unquestioned, but only done routinely in approximately 30% of the world's birth population [20].

Certain groups within the adult population who should have an assessment of thyroid function at least once to detect thyroid dysfunction include those with a goitre or thyroid nodule, atrial fibrillation, dyslipidaemia, subfertility, osteoporosis, and assessing thyroid function in the annual review of people with diabetes mellitus appears cost-effective. There is no consensus on whether healthy pregnant women should be screened for thyroid disorders or PPT although it has been shown to be cost-effective in analytical models [32]. Women with type 1 diabetes are three times more likely to develop postpartum thyroid dysfunction so should be tested in the first trimester for thyroid antibodies.

Any woman with a history of PPT should be offered annual surveillance of thyroid function due to the long-term risk of permanent hypothyroidism. Because of the high prevalence of hypothyroidism in people with Down's syndrome and Turner's syndrome, an annual check of thyroid function is recommended. Thyroid function tests are indicated every six months for those receiving amiodarone, lithium, within three months of initiation of immune checkpoint inhibitor therapy and every 12 months following head and neck irradiation. All patients with hyperthyroidism who receive ablative treatment should be followed indefinitely for the development of hypothyroidism beginning 4–8 weeks after treatment, and then at three-month intervals for one year and annually thereafter. Among patients hospitalized for acute illness, testing should be limited but with a high index of clinical suspicion and with an awareness of the difficulties in interpreting thyroid function tests in the presence of acute illness.

Whether healthy adults living in an area of iodine sufficiency benefit from screening for thyroid disease remains controversial. The benefit from a screening programme must outweigh the physical and psychological harm caused by the test, diagnostic procedures, and treatment [33, 34]. The prevalence of unsuspected overt thyroid disease is low, but a substantial proportion tested will have evidence of thyroid dysfunction, with approximately 10% with subclinical hypothyroidism and 1% with subclinical hyperthyroidism. No appropriately powered prospective, randomized, controlled, double-blinded interventional trial of either L-T_4 therapy for subclinical hypothyroidism or antithyroid therapy for subclinical hyperthyroidism exists [13].

Epidemiological studies have shown an association between subclinical hypothyroidism and coronary heart disease in younger people (less than 65 years) and those with high serum TSH (more

than 10 mU/L) [35]. In older people, a higher serum TSH and lower free T4 concentrations within the euthyroid range are associated with lower risk of multiple adverse events including mortality [36]. Treatment in those who are symptomatic, pregnant or preconception, or aged less than 65 years appears justified [37]. Endogenous subclinical hyperthyroidism is associated with increased risk of total, coronary heart disease mortality and incident atrial fibrillation, with the highest risk being with serum TSH less than 0.10 mU/L [38]. Subclinical hyperthyroidism may be associated with an increased risk for hip and non-spine fractures [39]. Treatment may be indicated in those older than 65 years with serum TSH less than 0.1 mU/L to potentially avoid serious cardiovascular events, fractures, and the risk of progression to overt hyperthyroidism [40]. Any potential benefits of therapy in subclinical hyperthyroidism must be weighed against the morbidity associated with the treatment of hyperthyroidism.

From the available evidence, the following recommendations are suggested for an iodine-replete community:

- Screening for thyroid dysfunction in women younger than age 50 and in men is not warranted in view of the relatively low point prevalence of unsuspected overt thyroid dysfunction.
- Case-finding in women during menopause or during visits to a primary care physician with non-specific symptoms is justified due to the high prevalence of subclinical hypothyroidism.
- If increased serum TSH is found at screening, then measurement should be repeated two months later together with free T_4 measurement after excluding non-thyroidal illness, drugs, and so on.
- Treatment with L-T_4 is recommended if the serum TSH is greater than 10 mU/L, irrespective of whether free T_4 is low.
- Subjects with a serum TSH between 5 and 10 mU/L and normal free T_4 are at increased risk of developing hypothyroidism, and repeat measurement of serum TSH is warranted at least every three years if not annually.
- If a suppressed serum TSH is found at screening, it should be re-measured two months later, and if it is still suppressed, free T_3 should be measured.
- After L-T_4 replacement is initiated, for whatever indication, long-term follow-up with at least an annual measurement of serum TSH is required.

Aetiology of Thyroid Disorders

3.2.1 The Complex Genetics of Thyroid Disease

Terry F. Davies, Francesca Menconi, and Yaron Tomer

Introduction to Genetics

Genes and Chromosomes

The nucleus of each human cell encodes approximately 30 000 genes. More than 20% of the genes in each individual exist in a form that can vary between individuals. These variable genetic forms are termed polymorphisms among normal individuals, and they account for much of the normal variation in body traits, such as height and hair colour. The genetic information encoded in the DNA is stored on the chromosomes and each somatic cell contains 46 chromosomes (22 autosomes and two sex chromosomes), arranged in 23 pairs, one of each derived from each parent. Since each individual has two copies of each chromosome (for **autosomes**), one from each parent, there are also two copies of each gene; one of which is mostly suppressed (inactivated). The chromosomal location of a gene is termed the **locus** of the gene. The gene in a certain locus usually exists in two forms and these variants of the gene are termed **alleles**. When an individual's two alleles at a locus are identical, that individual is said to be a **homozygous** at that locus, and when the two alleles are different, the individual is a **heterozygous**.

Female somatic cells contain two X chromosomes, whereas male somatic cells contain only one X chromosome. Nevertheless, the activity of genes coded for by the X chromosome is not higher in females than in males. This is due to inactivation of most of the genes on one of the two X chromosomes. Thus, in female somatic cells only one X chromosome gene is usually expressed, and this process of suppression is called X-chromosome inactivation. X-chromosome inactivation occurs early in embryonic life and, thereafter, in each cell either the maternal or paternal chromosome is inactivated in what is often a random mechanism. This results in a tissue mosaic of paternally and maternally expressed X-chromosomal alleles, with an average of 1:1 distribution. As a result, a female who is heterozygous for an X-linked gene will show a mosaic-like distribution of cells expressing either one of the two alleles. Recently X-inactivation has been postulated to play a role in autoimmune diseases and may help explain their female preponderance (see next).

Inheritance

When genetic information is transmitted from parent to offspring the process is called inheritance. Germ cells undergo **meiosis**, a process in which 2 gametes with 23 chromosomes are generated. During meiosis paired chromosomes undergo recombination, a process in which paired chromosomes break at identical points along their length and switch genetic material on opposite sides of the breaking point. Recombination results in an exchange of matching segments of the chromosome between two homologous chromosomes (Figure 3.2.1.1). Since recombination is also a random event, the farther apart two genes are on the same chromosome, the greater the likelihood that a recombination will occur in the space between them. When two genes A and B are very far apart they are transmitted to the offspring independently, as if they were located on different chromosomes (i.e. the probability that a given parental allele of gene A will be transmitted to the offspring with the same parental allele of gene B is 50%, as would be expected to occur at random). On the other hand, if genes A and B are located *close* to each other, the probability that a given parental allele of gene A will be transmitted to the offspring with the same parents allele of gene B is greater than 50%, and the genes are said to be linked (Figure 3.2.1.1). In other words, if two gene loci are linked there is a greater than 50% probability that offspring will inherit the same combination of alleles that are present on the parental chromosome. If the genes were right next to each other then they would have a very high chance of being inherited together. This phenomenon is the basis for the concept of linkage analysis (see next).

Understanding Mutations

A mutation is an alteration in chromosomal DNA that is inherited from one generation to another. Mutations in genes may be silent or if located appropriately can change the structure and/or function of the encoded protein causing differences in enzyme function, receptor signalling, structural proteins, or regulatory proteins. When several mutations in two or more genes produce similar changes then **genetic heterogeneity** is said to exist. For example, in maturity onset diabetes of the young (MODY), similar clinical presentations (**phenotypes**) can be caused by mutations in the glucokinase gene or the hepatic nuclear factor 1∀ gene. However, in some diseases an individual may inherit the mutation but will not develop the disease phenotype. Such diseases are said to have reduced **penetrance**. The penetrance of the disease is defined as the probability that an individual inheriting the mutation will actually develop the disease phenotype. An example of a disease with reduced penetrance is multiple endocrine neoplasia type II (MEN 2) where not every individual inheriting the mutation in the RET proto-oncogene will develop the full phenotype of the disease.

Categories of Genetic Diseases

Genetic diseases can be caused by a variety of changes in our genetic code and for simplicity can be divided into broad categories:
