7.1.4 Growth Disorders with No Defined Aetiology

Minu George and Steven Chernausek

Introduction

Short stature or slowing of linear growth are frequent problems presenting to providers of healthcare for children. While a comprehensive history and physical examination, with review of the growth record, and limited laboratory testing occasionally reveals an aetiology, more commonly the cause is not obvious and the patient is classified as having either idiopathic short stature, familial short stature, or constitutional delay of growth and adolescence. These are largely diagnoses of exclusion where one relies on characteristic clinical features and the absence of signs of a defined condition. The 2008 Consensus Workshop on the Diagnosis and Treatment of Children with Idiopathic Short Stature (ISS) defined ISS as a condition where the height is below –2 standard deviations for age and sex when compared to appropriate normative data for the population, where there is no evidence for 'systemic, endocrine, nutritional, or chromosomal abnormalities', and in whom birth weight is normal [1]. Individuals are further subcategorized as to whether the short stature has a familial basis (i.e. those whose current stature is within the range expected for parents' height, and those with delayed bone age, which is assumed a harbinger of delayed adolescence).

Previous consensus statements have addressed idiopathic short stature and the short child born small for gestational age (SGA) separately [1, 2]. Although nearly 90% of individuals born small for gestational age will experience accelerated growth following birth and reach heights in the normal range by age 2 years, those who do not show such 'catch-up growth' constitute a significant proportion of individuals seen by healthcare providers for short stature. Similar to idiopathic short stature, the reason short stature persists in these individuals remains an enigma. Thus, separation of the short child born SGA from those classified as isolated idiopathic short stature is arbitrary and in part reflects the licensing and approval processes for recombinant human growth hormone (rhGH) therapy as each have separate indications. In this chapter, we briefly describe the epidemiology and clinical presentation of children with growth deficits. We discuss the impact of the disorder on the patients' well-being and adult height and propose an approach to diagnosis that incorporates newer available genetic testing. Lastly, we review the risks and benefits of pharmacologic interventions that would stimulate growth and/or increase adult height. We occasionally include data concerning short children born small for gestational age along with those classified as ISS according to consensus guideline when relevant. The reasons for a broad-based approach are the overlap of phenotypes, the lack of evidence that these entities are entirely physiologically distinct, and the fact that the issues concerning prognosis and response to therapy are shared.

Demographics

It is disconcerting to parents and healthcare providers alike that the majority of children who stand below –2 SDS for height fall into the category of ISS. Both would like an explanation for the condition and clarity with regards to expected adult stature. From population studies it is estimated that approximately 5% of short children have a pathological condition [3–5]. In another 15% a low birth weight or length for gestational age (SGA) is found [6]. The 2008 consensus statement for ISS estimated that about 60–80% of children presenting to a paediatric endocrinologist with short stature would have ISS. Since that time there has been tremendous progress in applying molecular genetic approaches to evaluation of short stature. As such, we now suggest that 25–40% of children diagnosed with idiopathic short stature could receive a molecular diagnosis [7]. The shorter the stature, the greater the prevalence of organic disease, and therefore the better chance of finding a pathological cause with advanced genetic testing.

Pathophysiology

Normal somatic growth requires the secretion of growth-controlling hormones, along with the appropriate response of growing tissues via cognate receptors and signal transduction pathways, and the expression of genes regulating cell division and protein synthesis, all in the context of adequate nutrition and oxygenation. Thus, the causes of aberrant growth are many and result from a wide variety of hormonal, genetic, or nutritional disturbances. It seems an oxymoron to consider 'causes' of something 'idiopathic', but in fact the term translates to 'one's own suffering' (Gr. idios + pathos), describing a condition intrinsic to an individual. There is always an explanation for a growth deficit; it may just not be obvious at the outset. In fact, the mechanisms involved in the pathophysiology of idiopathic short stature are frequently in play in more pronounced disorders recognized as distinct diseases. The various conditions can be categorized as follows (see Table 7.1.4.1).

Defects in the Growth Hormone/Insulin-Like Growth Factor (GH/IGF) Axis

For the purposes of this discussion the GH/IGF axis will consist of GH and the IGFs (1 and 2), their respective receptors, the factors directly controlling their secretion (e.g. GHRH), bioactivity (e.g. IGF binding proteins) and the intracellular signalling pathways that follow receptor activation (e.g. STAT5B for GHR, AKT for IGF1R). The relevance of this axis to ISS is based on several

Table 7.1.4.1 Idiopathic short stature and related conditions: examples of genes involved

Classification	Gene	Classic disease	Non-classic/hypomorphic	Est ISS prevalence	Refs
GH/IGF Axis	*GH1, GHRHR GHSR*	Isolated GH deficiency	Normal prenatal growth, slow postnatal growth	Rare	[44, 75]
	IGF1	IGF deficiency with severe pre and postnatal growth failure. Microcephaly. Sensorineural deafness	Both pre and postnatal growth affected, low circulating IGF1	Rare	[10, 12, 75]
	IGF1R	IGF resistance syndrome, severe pre an postnatal growth failure	Both pre and postnatal growth affected, normal or increased circulating IGF1	1–2%	[10, 12, 75]
	IGFALS	Modest reduction in postnatal growth—low circulating IGF1	Unknown	2–10%	[16, 75]
	PAPPA-2	Modest short stature, increased circulating IGF1, Skeletal abnormalities	Unknown	Unknown	[76]
Growth Plate/Skeleton	*ACAN*	Spondyloepiphyseal or metaphyseal dysplasias-	Short stature with advanced bone age	2%	[21, 75, 77, 78]
	FGR3	Achondroplasia	Hypochondroplasia, idiopathic short stature	1–2%	[75]
	NPR2	Acromesomelic dysplasia	Idiopathic short stature +/– disproportionate	2–6%	[79–82]
	SHOX	Leri-Weill dyschondrosteosis, Turner syndrome	Idiopathic short stature +/– disproportionate	3–15%	[23, 83, 84]
Intrinsic Cellular Growth	*BLM*	Bloom syndrome	Prenatal growth failure—syndromic features may be subtle—propensity for malignancy	Rare	[85]
	FANCA	Fanconi anaemia	Prenatal growth failure, GH deficiency in some, propensity for malignancy	Rare	[86]
	CUL7, OBSL1, CCDC8	3-M syndrome	Probable pre and postnatal growth failure +/– syndromic features	unknown	[44]
	KRAS, MAPK2, PTNP11	Noonan spectrum	Not SGA, ISS +/– syndromic features	~ 1–2%	[44]

Genes noted here are only representative of a much larger number that have been implicated in short stature/growth failure. For a more extensive listing of genes associated with monogenic disorders, see Wit *et al*. [87].

factors. First, the GH/IGF axis is the major controller of growth in mammals. Studies in mice show that up to 70% of adult size is determined by the combination of GH and IGF1 action [8]. Genetic mutations in humans confirm that human growth is also profoundly influenced by GH and IGF [9]. Second, there is evidence that subtle defects in GH or IGF secretion or action are frequently found in children with idiopathic short stature and related conditions [10]. Third, rhGH hormone and rhIGF1 are presently the main therapeutic options for treating individuals with short stature of any cause.

Several lines of evidence suggest that impairment of GH action or IGF secretion is restraining growth in a significant proportion of ISS children. Up to 50% of individuals classified as ISS have subnormal circulating concentrations of IGF1 even when indices of GH release are normal [10]. In addition, ISS patients with low IGF1 levels appear less sensitive to GH administration in terms of both growth stimulation and IGF1 production [11]. These patients could be considered to have 'Non-classical' GH/IGF defects. Such data has provoked examination of relevant genes in patients with ISS, revealing that mutations in *SHOX* and *IGF1-R* are more frequent in children with ISS [12], although still not explaining the condition in most patients.

There is also a potential causative role of genetic variants in the type 1 IGF receptor (IGF1R) for short stature of undetermined aetiology. Patients with definitive molecular defects characteristically manifest with substantial pre- and postnatal growth failure accompanied by normal or elevated circulating concentrations of IGF1 [13]. *IGF1R* mutations are found in up to 2% of short children born SGA [14]. The IGF1R is a critical element in the pathway of cellular growth control and heterozygous variations that are less disruptive are present in the normal population and appear to impact growth [15].

Recent studies have identified novel defects in the IGF axis that influence stature. The vast majority of IGF1 in the bloodstream circulates as a ternary complex composed of IGFBP-3, the acid labile subunit (ALS), and IGF1 itself. Genetic defects in *IGFALS* lead to low circulating levels of IGF1 and generally modest short stature [16]. A growth deficit is also present in patients with mutations in pregnancy-associated plasma protein A2 (PAPPA2). PAPPA2 selectively cleaves IGF binding proteins 3 and 5 and thereby facilitates the release of IGF1 from the IGFBPs, which is required for IGF receptor interaction. Individuals with *PAPPA2* mutations have short stature in addition to other skeletal findings. Mutations in *IGFALS* have been reported in surveys of individuals with ISS. The frequency of *PAPPA2* variations is unknown.

Intrinsic Defects in Growing Tissues

Certain growth disorders are the result of aberrations in basic mechanisms of cellular growth and consequently affect all growing tissues. Conditions that retard the cell cycle or increase apoptosis would be expected to result in global reduction in growth and be expressed by both pre- and postnatal growth failure. Fanconi anaemia and Bloom syndrome are examples of such disorders. They are characterized by DNA instability and are manifest by low birthweight, slow growth, and a propensity to malignancy. Other conditions in this category are the RASopathies (RAS/MAPK pathway syndromes [17]) which include Noonan and Noonan-like syndromes and the 3-M syndrome (typically mutation of *CUL7, OBSL1* or *CCDC8*) [18]. Though uncommon, mutations in these pathways can be found in individuals in whom common genetic and endocrine conditions have been excluded.

Disorders of the Growth Plate and Skeleton

Growth in stature is the sole result of division, maturation, and expansion within the growth plates of the axial skeleton. Thus, it is not surprising that the cause of short stature in many, including those with ISS, involve defects in chondrocyte response to hormonal stimuli or its division and maturation within the growth plate itself [19]. Genome-wide association studies have identified 700 distinct loci that determine adult stature [20]. A large number of these involve genes that are active within the growth plate. In addition, genetic defects that cause severe short stature and obvious skeletal dysplasia in some present with a much more modest phenotype when the mutation results in a lesser change in function. Conditions associated with aberrations in *ACAN* and *SHOX* are illustrative. Mutations in *ACAN* (encoding a matrix protein) are the basis for spondyloepiphyseal and spondyloepimetaphyseal dysplasia but are also found in approximately 2% of individuals with ISS. Those affected typically show modest changes in body segment proportion and an advanced bone age, which is characteristic of the syndrome [21, 22]. SHOX is a transcription factor located on the X chromosome and is the main reason why girls with Turner syndrome are short. The severe form of SHOX haplo-insufficiency results in Leri-Weill dyschondrosteosis but SHOX defects are also found in approximately 5% of individuals with ISS [23, 24].

Psychological Aspects of Short Stature

Shortness during childhood could be perceived as a disadvantage and might interfere with normal psychological development. No clear-cut relationships have been established between reduced stature and psychological distress. The question of psychosocial morbidity as a justification for treatment in ISS has been asserted by proponents of rhGH treatment in non-GH deficient children but continues to be a contentious subject. There is a (mis)perception among children and adults that taller is better and that short people who are assertive have a 'complex' that attempts to compensate for their size.

Psychosocial Stress and Adjustment

The belief that short stature is an impediment to social adjustment due to more negative social experiences, including teasing, being treated younger than your age (juvenilization), having fewer friends, and less social acceptance is pervasive [25]. Studies of patients referred for short stature (normal variants as well as those with pathological conditions) showed slightly more than half were regularly teased about being short. This is about the same proportion as juvenilization [26]. As adults, those with short stature also experience more problems driving a car, have less income, hold fewer higher-level academic degrees, and have problems with dating and marriage; the latter being particularly the case for shorter men [27]. Therefore, it is not surprising that children and adults of both genders desire to be taller [28]. There are reports that suggest short children are more likely to be bullied than their taller peers [5]. Paediatric endocrinologists also share these beliefs; more than 50% report the emotional well-being of children and adults with heights less than third percentile is sometimes impaired and more than a quarter believe it is always or often impaired [29]. Therefore these children and adolescents may experience more psychosocial stress. However, not all short children are equally affected and furthermore the stressors are not directly related to the degree of short stature [26].

In contrast to studies of children or families seeking medical care, community-based studies reach different conclusions. A large, longitudinal, non-interventional study of 7–9-year-old children conducted in a single region in the UK (the Wessex study) showed no evidence that stature of less than third percentile was associated with significant psychosocial or academic disadvantages [30]. Despite the desire to be taller and reports of bullying there was no measurable effect on self-esteem or school performance. A similar study in the United States of 11–18-year-olds showed height was unrelated to popularity, total number of friends, or whether friendships were reciprocated. Although children were often judged younger than they actually were, this was unrelated to social acceptance among peers. In addition, the findings did not vary based on gender. [31].

Educational Attainment and Economic Status

The effects of adult height on educational attainment and the type of employment and income level achieved have been explored is some detail [32]. Studies of stature and income frequently report that taller men and women earn more than their shorter peers do [33]. Upon further scrutiny, it appears that taller people earn more because of stronger cognitive abilities throughout their lives. Height is associated with better mental and physical health and cognitive function in adult life [34]. Secondary analysis supports the hypothesis that stronger cognitive ability explains the difference in occupational status and income and that height only serves as a proxy measure for an attribute of greater importance (i.e. cognitive ability). Thus, height is a marker of early childhood health and nutrition, both of which affect cognitive development. This suggests that childhood nutrition and environment contribute to cognitive development which subsequently influences educational attainment, school achievement and, later, occupational choice. All of these may in turn affect health and cognitive function in old age [34].

Health-Related Quality of Life

Examination of health-related quality of life (HrQoL) is a novel analytical approach to provide a better understanding of the psychosocial consequences of short stature and can help clinicians identify vulnerable groups of paediatric patients that could benefit from further assessment and referral. Use of the instrument in a study of 345

children aged 8–18 years showed that children with short stature, particularly those with current height below –2 SD, are at increased risk for internalizing problems. Children/adolescents with short stature presented more parent-reported internalizing problems and lower self- and parent-reported condition-specific HrQoL, compared to patients with an achieved height above –2 SD. GH treated children self-reported better HrQoL than the GH untreated group [35].

Functional Impairment

An association between short stature and functional impairment (e.g. decreased intelligence, poor academic achievement, and behaviour problems) has long been postulated, but there is no consensus as to whether such a cause-and-effect relationship exists. In the Wessex Growth Study short children up to 13 years of age achieved significantly lower scores on measures of intelligence quotient, reading attainment, and basic number skills, and were less satisfied with their height. However, they did not differ significantly from the control children of average stature on measures of self-esteem, self-perception, parents' perception, or behaviour. Furthermore, the short children more frequently came from working class homes and therefore their attainment scores were predicted by class and IQ together rather than by height alone. These results provide only limited support for the hypothesis that short children are disadvantaged [36]. A systematic review of the association of short stature and functional impairments showed most short children scored within the normal range in functional tests; however, within studies, short stature was often associated with decreased intelligence, academic achievement, and visual-motor skills. On average, children with short stature score lower than their peers on functional tests but few short children scored outside the normal range. Among six studies examining academic achievement in children with ISS or constitutional delay of growth and adolescence, all short children scored at least within approximately 1 SD of normal scores. However, most of these same studies found that children with short stature were more likely to have lower academic achievement scores than children of average height. These studies show no evidence regarding whether treatment of short stature improves functional impairment adaptation [37]. Therefore, while treatment of short stature has been justified by potential improvements in functional impairment, quality of life, and economic status due to increased stature, the data remain inconclusive, and the subject controversial.

Approach to the Patient

Certain diagnoses must be excluded to categorize a patient as having ISS (see Table 7.1.4.2). Those listed are conditions that have the potential to slow growth with few outward manifestations. In addition, the growth pattern for ISS typically has an onset of the growth attenuation either before birth or within the first years of life. A growth chart that displays normal growth for several years after which the growth rate markedly slows is atypical for ISS and indicates an acquired cause of growth failure should be pursued.

Defining short stature as 2 SD or more below the mean for age and sex will identify many children with healthy variations in height and lacking underlying pathology. The condition is simply benign normal variation. A smaller number of children will have a pathologic condition affecting growth and perhaps other aspects of their health. It can be a challenge for the clinician to identify those and therefore many children receive the nebulous diagnosis of idiopathic or familial short stature after routine studies. Thus, assuming the conditions listed in Table 7.1.4.2 have been eliminated, several questions must be addressed. To what extent is the patient's stature compromising quality of life? What is the likelihood that the patient will reach an acceptable adult stature? Should additional testing be conducted in an attempt to reach a definitive diagnosis? Is treatment of the growth deficit warranted and, if so, with what modality?

Table 7.1.4.2 Diagnoses to exclude before classification as ISS and related conditions

Condition	Standard Testing	Comment
Growth hormone deficiency	IGF1, IGFBP3, GH stimulation	
Hypothyroidism	T4, TSH	Thyroid dysgenesis may mimic ISS
Turner syndrome in girls	Karyotype or sex chromosome FISH	May present with short stature as the only obvious clinical finding
Bone dysplasias & chondrodystrophies	Anthropometry, consider skeletal survey	Probably underdiagnosed
Occult GI disease (e.g. inflammatory bowel disease), malnutrition	CBC, ESR, or CRP, celiac screen	
Renal disease	Electrolytes, BUN, Cr, UA	Rare—prenatal onset can be SGA
Other chronic systemic diseases (e.g. asthma, cyanotic congenital heart disease)	Specific tests prompted by history and physical examination	In most cases, cause would be obvious

A foreknowledge of future growth and ultimate height as an adult would be helpful in addressing those questions. Assessment of growth velocity over 6–12 months is an essential element in the evaluation. It is especially relevant for those born SGA as the majority have accelerated growth following birth and reach a normal size by age 2 years [38]. A below average growth velocity after age 2 years would be a concern for any patient.

Accurately predicting adult height in a young child is difficult. Most methods rely primarily on bone age determination and were derived from individuals with variants of normal stature, not from those with pathologic conditions [39]. However, as a group, about two-thirds of children with ISS ultimately reach an adult stature within the lower normal range [40], the increase in SD score from childhood to final height being attributed to a delay in pubertal onset that prolongs the growing period. Thus, those with modest height deficits early in life (e.g. –2 to –2.5 SD) and who maintain near normal growth rates may need no treatment other than reassurance and perhaps androgen therapy for those with constitutional delay of growth and adolescence.

Figure 7.1.4.1 illustrates an approach to pursue specific diagnoses that might not be evident following standard testing in the short child. Because of the tremendous technical advances allowing the detection of meaningful variations in the human genome at reasonable cost, we believe that a genetic approach to uncovering the cause short stature is warranted for many [7]. Five distinct clinical scenarios that encompass the majority of patients with the initial diagnosis of ISS are described in Figure 7.1.4.1. Each scenario

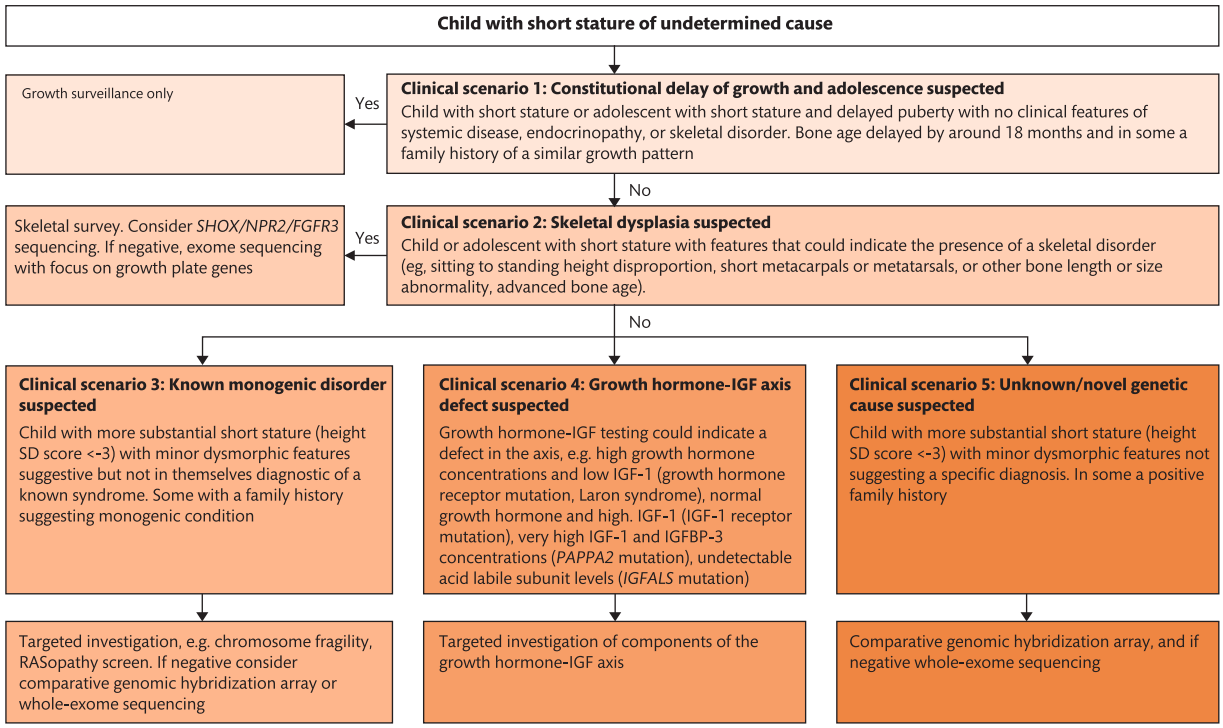

Figure 7.1.4.1 Proposed schema for molecular diagnosis in a child with short stature of undetermined cause. Each box contains a potential clinical scenario leading to an investigative strategy. Short stature of undetermined cause is defined as short stature more than −2 SDs below the mean, with or without being born small for gestational age, with no readily recognizable syndrome diagnosis, no substantial microcephaly, normal screening investigations (e.g. karyotype [in females], routine blood testing to exclude occult systemic disease, and thyroid function), and no growth hormone deficiency by standard growth hormone stimulation testing. SHOX-short stature homeobox. IGF-insulin-like growth factor.

corresponds roughly to the pathophysiologic groups described previously and is associated with specific diagnostic steps. For example, patients with modest short stature and a history and physical examination consistent with constitutional delay of growth and adolescence (scenario 1) are simply observed. Those showing subtle features of skeletal dysplasia would have assessment of select genes such as *SHOX* and *NPR2,* as mutations in those are consistent with that phenotype. Box 7.1.4.1 delineates features that would increase the likelihood of attaining a genetic diagnosis.

Another group includes those patients with evidence for defects in the GH/IGF axis based on measures of circulating IGF1 and the GH response to stimuli. The increase in circulating IGF1 following GH administration (the IGF generation test) has been suggested as a way to identify intermediate forms of GH resistance. Although attractive in concept, it has not proved sufficiently sensitive and is of limited value [41]. Instead, a molecular genetic approach is indicated, with the hormonal measures dictating which genes are analysed. Low levels of IGF1 in the face of normal or elevated GH release are consistent with defects in *GHR, IGF1, IGFALS*, whereas if both IGF1 and GH are increased, defects in *IGF1R* are more likely. A recent report supports the value of this approach by identifying genetic defects for half the cases when a problem with GH/IGF axis is suspected on clinical/hormonal grounds [42].

The fifth scenario addresses those individuals who appear to have a pathologic condition affecting growth by virtue of dysmorphic features or severe short stature, but for whom no specific diagnosis or pathway is suspected. Those individuals would undergo an untargeted survey of their genome starting with comparative genome hybridization and ending with whole exome sequencing. Diagnostic yields may approach one-third depending on selection of subjects [43, 44].

Reaching a specific diagnosis has several benefits. Foremost, it ends the diagnostic odyssey and can provide the family with additional information regarding prognosis, the potential value of treatment, and the risk for relatives and offspring. However, there remain drawbacks and limitations to pursuing specific diagnoses in this way. In many cases involving novel or modest changes in genetic structure, solid information about height prognosis or response to growth-promoting agents is lacking. In countries where ISS is an approved indication for rhGH therapy, it is possible that reaching a specific diagnosis removes the patient from the ISS category and

Box 7.1.4.1 Factors favouring genetic studies in ISS

- Severe growth deficit (Ht. <−3 SD)
- Height much below target ht. (e.g. mid-parental height + 2 SD, patient −2SD)
- Pedigree suggestive of monogenic disorder
- Dysmorphic features
- Developmental delay
- Disproportionate short stature

makes acquiring treatment more difficult. In addition, there are circumstances where the genetic basis of the condition will not be uncovered using whole exome sequencing. Epigenetic changes or mutations in non-coding regulatory regions will not be detected. In certain cases short stature will be the result of a combination of genetic variations each of which alone would have a modest effect on stature, but when combined interact to yield a more pronounced phenotype. The current approaches typically seek a monogenic explanation and are inadequate to deal with more complex situations [45]. Despite this, the advantages of reaching a specific diagnosis outweigh the disadvantages.

Treatment to Increase Stature

Medical treatments that influence stature either involve increasing the growth rate (e.g. rhGH, rhIGF1), prolonging the growth period (e.g. GnRH agonists, aromatase inhibition), or combine the two effects (e.g. rhGH and aromatase inhibition). At the current time, the only treatment approved by national regulatory agencies for ISS or the short child born SGA is rhGH. Moreover, approvals are not uniform across the continents. For example, rhGH is approved for ISS by USFDA, but not EMEA and the criteria for treatment of the short SGA patient also differs by agency. Data relevant to ISS for both approved and off-label therapies are discussed in the following section. The reader should review current literature, regulatory agency publications, and professional society guidelines for specific prescribing information and recommendations.

Human Growth Hormone

Human growth hormone has been prescribed since 1957 initially to treat GH deficiency and later for short stature due to other causes. It was first isolated from cadaveric pituitary glands, requiring arduous and costly collection of glands, followed by extraction and purification of the hormone. This limited supply restricted its use to children with severe GH deficiency who were treated with low doses and suboptimal schedules. The use of pituitary-derived GH was discontinued in 1985 following an outbreak of Creutzfeldt-Jakob disease and all subsequent treatment has been with recombinant hormone (r-hGH). The development of recombinant DNA-derived GH, allowed the production of virtually unlimited amounts of GH, leading to the approval as therapy for additional childhood conditions characterized by short stature.

The story of GH treatment in children for ISS begins in 1983 when 15 non-GH deficient short children were treated with cadaveric GH for 6 months and increased their growth rates by more than 2 cm per year [46]. Subsequent trials (see Table 7.1.4.3) demonstrated efficacy and led to the 2003 US FDA approval for GH treatment of children with ISS with heights at or less than −2.25 standard deviations (≤1.2 percentile) below the mean for age and sex and pretreatment growth rates unlikely to permit attainment of adult height in the normal range. The effectiveness of GH therapy in ISS was affirmed at the 2008 ISS Consensus Workshop which concluded that children with ISS whose heights were less than −2 SDS for age and sex and were more than 2 SDS below their mid-parental target height or had a predicted height less than -2 SDS warrant consideration for treatment [1].

Controversy persists despite the consensus statement as to the effectiveness and value of GH treatment for children with ISS [47]. A detailed meta-analysis of the rhGH trials examined the impact of rhGH therapy of children with ISS [48]. Out of the 19 GH ISS trials to reach adult height (mean duration of 5.4 years), 10 met the criteria for controlled trials; of which three were randomized

Table 7.1.4.3a Summary of results from the randomized controlled trials of GH therapy in children with ISS treated to final height

Study & group	N	GH dose (mg/kg/day)	Mean age at start of therapy (yrs)	Mean (SD) years of therapy (yrs)	Height at baseline (SD score)	Mean adult height (SD score)	Mean height gain (SD score)	Difference between case and control in adult height (SD score)

trials and seven were non-randomized. The three randomized controlled trials included 115 children, 79 cases, and 36 controls whereas the seven non-randomized control included 477 children, 181 cases, and 296 controls. Analysis of the randomized trials showed that the adult height of the GH-treated exceeded that of untreated children by 0.65 SDs, or about 4 cm, after 5.4 years of rhGH therapy [48]. In the non-randomized controlled studies, the adult height of the rhGH-treated patients exceeded that of controls by only 0.45 SDS or about 3 cm on average. The relationship between height gain and quality of life or psychosocial outcomes was not addressed in this analysis. These authors concluded that: (1) no single, high quality evidence RCT has been carried out up to the achievement of adult height; (2) the overall magnitude of rhGH effects on reducing the adult height deficit in children with ISS is on average less that achieved with other conditions for which rhGH was licensed; and (3) the individual response to therapy is highly variable.

GH treatment of the short child born small for gestational age. The definition of 'small for gestational age' has varied from less than the 10th percentile for birth weight to less than −2 SDs for weight or length. The latter definition is more commonly accepted as indicating prenatal growth restraint and is the definition applied in a 2007 consensus statement [2]. Children born SGA represent a heterogeneous group at risk for multiple long-term complications including short adult stature along with other metabolic and endocrine disorders. For the 10–15% of SGA children who do not experience catch up growth within the first few years, rhGH is effective in increasing adult height, particularly when started early in life and at a sufficient dosing. In addition, rhGH treatment also positively affects body composition with an increase in lean mass leading to a decreased risk of metabolic complications in SGA [49]. Additional information concerning children born small for gestational age can be found in Chapter 7.1.3.

Safety during rhGH treatment. Human growth hormone is a safe drug when prescribed as recommended with adverse events rarely observed (78 per 100 000 treatment years for patients with ISS) [50]. Adverse effects are related to the stimulation of skeletal growth (e.g. slipped capital femoral epiphysis and scoliosis), the water retentive action of growth hormone (e.g. intracranial hypertension) or the effect of GH on glucose metabolism (e.g. decreased insulin sensitivity) [51]. See Box 7.1.4.2. In children, the frequency of adverse effects depends on the underlying disorder and is similar or lower in patients with ISS when compared to other rhGH-treated conditions [52]. At dosages of 0.24–0.37 mg/kg/week, rhGH treatment in children with ISS does not cause hyperglycaemia. At dosages ≥0.3 mg/kg/week, a dose-dependent increase in fasting and stimulated insulin levels is observed [50]. Current evidence derived from 'on-treatment' surveillance studies in GH deficient children indicates that rhGH does not increase the risk for new malignancies nor is there an increased risk of recurrence of primary cancer in cancer survivors. For the latter group there is suggestive evidence that the development second malignancies may be increased by GH treatment [53]. Thus, the safety profile of rhGH at doses ≤0.37 mg/kg/week for the treatment of children with ISS is similar to or better

Box 7.1.4.2 Effects of growth hormone treatment in children

Known adverse effects of growth hormone treatment in children

- Intracranial hypertension
- Slipped capital femoral epiphysis
- Progression of scoliosis

Potential/theoretic adverse effects of growth hormone treatment in children

- Pancreatitis
- Increased risk for adverse cardiovascular events during adulthood
- Increased risk of second malignancy in cancer survivors

than that seen in other rhGH-treated conditions and is not associated with any predictable adverse events [50].

Long-term safety of rhGH. With the expanded use of rhGH in children and the higher doses employed, concerns about the potential for adverse effects developing long after the completion of GH therapy have arisen. Studies that address this problem have been extremely limited until recently. The SAGhE (Safety and Appropriateness of Growth Hormone Treatments in Europe) cohort is the largest and longest follow-up study of GH-treated patients independent of industry [54, 55]. This ongoing study assesses the cause-specific mortality and cancer incidence of now over 24 000 patients from eight European countries treated during childhood with GH since 1984. As such, it is a major resource for investigating cancer and mortality risks in rhGH patients.

The first reports from SAGhE were discordant, with some indicating increased mortality and risk for stroke [56, 57] while others found no excess deaths due to cancer or cardiovascular events [58]. The overall all cause standardized mortality ratios were noted to be increased in a subsequent systematic review, but malignancy and cardiovascular standardized mortality ratios were not significantly increased [59]. The validity of these early SAGhE data was questioned by many, especially since in the cohort from Belgium, Netherlands and Sweden there was no convincing evidence for the induction of new cancers or relapse of pre-existing malignancies following GH treatment [58]. Most recently a combined registry analysis of the long term safety of rhGH has shown no increased risk of mortality in children or adults treated with rhGH. No evidence of increased risk of stroke, new malignancy, leukaemia, non-leukaemic extracranial tumours or recurrence of malignancy in patients without predisposing risk factors was seen [60]. In children and adults it can be stated with certainty that rhGH given by the current dose ranges and indication especially the idiopathic short stature indication for this medication is considered remarkably safe [53].

Patient selection and dosing for rhGH. Treatment of ISS with rhGH assumes that the patient will benefit from having a stature that approximates that of peers during childhood and as an adult. The benefits may be psychosocial or functional in those with severe short stature, but there are no data that indicate GH-treated patients are otherwise healthier. Thus, it can be a challenge to determine which patients are most likely to benefit given the variability in response and concerns about long-term safety. The 2016 guidelines developed by the Pediatric Endocrine Society suggest 'a shared decision-making approach to pursuing GH treatment for a child with ISS. The decision can be made on a case-by-case basis after assessment of physical and psychological burdens, and discussion of risks and benefits'. These guidelines also recommend a starting dose of 34 µg/kg daily, increasing up to 67 µg/kg daily if needed. However, studies comparing dose regimens are limited. Typically the response to treatment is best in the first year, so for some patients a higher initial dose may be warranted. Lastly, patient's growth should be monitored closely given the unpredictability of response to treatment and GH discontinued in those who do not show a meaningful increase in growth rate above baseline. The response required to justify continued treatment may differ among providers, but a growth velocity of at least +1.0 SD for age and sex or an increase of at least 3 cm per year above baseline have been suggested as reasonable cut points [1].

Recombinant Human Insulin-Like Growth Factor 1 (rhIGF1)

Regulatory agencies within the United States, Japan, and Europe have approved rhIGF1 for treatment of short stature due to severe primary IGF1 deficiency, defined as height and circulating IGF1 concentrations 3 SD or more below means for age and sex with adequate GH secretion. Most reports of treatment largely reflect results from patients with GH insensitivity due to GH receptor deficiency (Laron syndrome) [61]. However, studies that are more recent have demonstrated short-term growth response to rhIGF1 alone and in combination with hGH in less severely affected individuals [62]. Because of the generally suppressed levels of IGF1 in ISS [10, 63], some children will qualify for treatment and could potentially respond. In ISS children who do not respond to GH treatment, rhIGF1 therapy is a theoretical option; however, data are lacking regarding efficacy and safety in this population [64].

Sex Steroids

Testosterone esters are commonly prescribed for boys with constitutional delay of growth and puberty (CDGP) as both short stature and lack of secondary sexual characteristics are of frequent concern to the patient. Treatment will accelerate growth and induce a masculine phenotype and body composition [65]. Testosterone esters at doses of 50–100 mg as intramuscular injections per month are effective in stimulating growth and puberty without attenuating adult height when used in boys older than 13 years with no signs of puberty and a predicted adult height in the normal range [66]. A 3–6 month course of these low doses of testosterone may suffice to induce spontaneous development of puberty and subsequent psychological well-being in this subgroup of CDGP. The oral preparation testosterone undecanoate (40 mg/day) can also be used, although its effect is considered more variable than that of intramuscular preparations. No data are available for newer cutaneous forms of androgens, for example gels or patches.

Oxandrolone is an anabolic androgenic steroid, which has a theoretical benefit of having less androgenic effects than testosterone

and additionally does not aromatize to oestrogen. It has been shown to increase height velocity in the short term in several studies but does not lead to increase in predicted or measured final adult height [67]. While it does offer the advantage of oral administration over IM for testosterone, it does have the disadvantages of being only weakly androgenic and carrying a small risk for hepatotoxicity. While European and US regulatory agencies have approved oxandrolone for treatment of short stature in girls with Turner syndrome, approval is currently lacking specifically for ISS. Given the lack of an effect on adult height and the scarcity of data for use in the population, its place in the management of ISS is uncertain.

Characteristics of growth in girls with CDGP is less well known. A proportion of CDGP girls do not attain adult height consistent with their mid-parental target height. Those with a lower height SDS in childhood have a reduction in final adult height. Low-dose oestrogen treatment, which might seem a logical approach, does not seem to influence adult height in girls with CDGP [68].

Aromatase inhibitors. Males with mutations in the aromatase enzyme CYP19A1 exceed their adult target heights because they cannot synthesize oestrogens from androgens which, in turn, delays growth plate maturation. This observation gave rise to the notion that aromatase inhibitors used during puberty could augment adult height by blocking oestrogen production and thereby prolonging growth during adolescence. Small controlled trials have been conducted in adolescent boys, the first of which was with letrozole in constitutional delay in growth and puberty with adult height increase [69] and afterwards in children with ISS alone [70] or in combination with rhGH [71]. Combination therapy with AI/GH for up to 36 months increases height in pubertal boys with ISS more than either GH or AI alone. Height gains from baseline stature for those treated for 36 months were: AI, mean, +23.8 cm; GH, +26.7 cm; and AI/GH, +30.7 cm. These gains in height compare favourably with the expected height gain from 14.1 to 17.4 years of +13.0 cm for boys with a height SDS of −2.0 [71]. AIs alone and in combination with GH were well tolerated without adverse effects for up to 3 years. They concluded that AIs are an alternative treatment to enhance linear growth in adolescent boys with ISS, particularly in combination with GH [71]. This treatment modality is not used in girls due to a risk for ovarian cyst development and the potential for subsequent ovarian torsion. Concerns about adverse effects such as aberrant bone turnover leading to vertebral anomalies, reduced HDL cholesterol, increased insulin resistance, impairment of cognitive function, and long-term effects on spermatogenesis remain. These concerns coupled with a lack of larger studies put the use of aromatase inhibitors in the category of experimental drugs; they should be used cautiously and ideally in clinical trials that continue to evaluate safety and efficacy.

Gonadotropin Releasing-Hormone Analogues

Gonadotropin releasing-hormone analogues (GnRHa) block luteinizing hormone and follicle-stimulating hormone secretion, thereby decreasing gonadal production of androgens and oestrogens resulting in prolongation of growth. Although GnRHa treatment effectively delays epiphyseal fusion, it renders patients hypogonadal at a critical time of development. When administered to children with ISS, 3.5 years of GnRHa resulted in approximately 4 cm of increased adult height compared to controls [72]. The modest height gain compared to controls is due in part to the slowing of growth rate that accompanies the treatment. In an attempt to counteract this, rhGH and GnRHa have been administered in combination to patients with ISS and short children born SGA. Adolescents with Tanner stage 2–3, age and bone age less than 12 years for girls or less than 13 years for boys, height SD less than −2.0 SDS or between −1.0 and −2.0 SD plus a predicted adult height less than −2.0 SD were randomly allocated to receive GH plus GnRHa or no treatment for 3 years. FH was assessed at the age of 18 years or older in girls or 19 years or older in boys. Initial growth rates are increased by the rhGH addition, but the effect on final height is either modest or insignificant after stopping treatment as 50% of the predicted height gain at treatment withdrawal was lost at treatment withdrawal [73]. Most recently, a randomized control study treating patients with ISS at puberty onset with either GH with leuprorelin in combination or GH alone. Although promising, a new treatment adverse event emerged as more frequent bone fractures occurred in combination than GH [74]. These modest increases in adult height probably do not outweigh the disadvantages of delaying puberty. Therefore, while GnRHa are the standard treatment for central precocious puberty and are safe, its use alone or in combination with GH is controversial and not generally recommended for treatment of ISS when pubertal onset is at a normal age.

In summary, administration of rhGH continues to be the principal treatment to address compromised stature in children with ISS. In recent years, long-term benefits of the growth achieved from rhGH has been questioned because of modest or variable height gains and limited evidence of psychological benefit. That said, studies to date have not always used optimal doses and were conducted in relatively older children (i.e. 11+ years) for whom efficacy and benefit may be constrained. Therefore, for each child with substantial non-GH deficient short stature a risk to benefit ratio assessment must be made and a decision reached in conjunction with parent and patient wishes. Many ethical concerns such as the duty to provide appropriate assent and re-assent at critical junctions such as pubertal onset, protecting children from unnecessary treatment, considering fairness to non-treated children, and allocating healthcare resources responsibly should also be considered. Less expensive and invasive treatments or perhaps no growth enhancing treatment at all along with counselling remain viable options.

Conclusions

The slow-growing, short child of undetermined aetiology continues to challenge healthcare providers. A decade ago most were categorized simply as ISS after testing that typically included assessments of GH secretory status. In some cases, GH was administered to improve stature. Although the value of GH treatment for ISS is a matter of persistent debate, it is clear that the response is highly variable among individuals, with some showing remarkable response. Certainly, treatment may be warranted in children with severe short stature to alleviate restrictions on activities of daily living [75].

The availability of newer genetic tests and the appreciation for a much wider range of conditions attenuating growth has improved

our ability to make specific diagnoses and reduced the population of those labelled ISS. However, uncovering novel diagnoses presents additional challenges as we frequently lack information on the prognosis for adult height or response to growth-promoting therapies. Despite this, we believe that reaching a specific diagnosis is worthwhile and that with time a better understanding of the distinct conditions will lead to appropriate management and therapy.

7.1.5 Tall Stature

Lars Sävendahl and Emelie Benyi

Introduction

Tall stature can be defined as a height above the 97th percentile (corresponding to a standard deviation score (SDS) of +1.88). Extreme tall stature is commonly defined as a height exceeding +3 SDS. Even though tall stature is constitutional in most cases, growth disorders causing excessive growth are important to rule out since they can be associated with other health implications. There are several physical and developmental signs to look out for which could be associated with a growth disorder. These can be either primary or secondary, a division that is further detailed next.

Growth and Growth Plate Regulation

Many signalling pathways, local and systemic, have been demonstrated to regulate longitudinal bone growth [1, 2]. Systemic factors include growth hormone (GH), insulin-like growth factors (IGFs), insulin, thyroid hormone, leptin, sex steroids, vitamin D, and glucocorticoids. There are also local regulators in the growth plate such as fibroblast growth factors (FGFs), and bone morphogenetic proteins (BMPs). Dysregulation of these signalling pathways may cause excessive growth and tall stature.

Growth Hormone and IGF-I

Growth hormone (GH) is a single polypeptide chain produced by the pituitary gland. Secretion is regulated by the hypothalamic peptides, growth hormone-releasing hormone (GHRH) and the inhibitory hormone somatostatin. It is also stimulated by ghrelin produced in the stomach while IGF-1 exerts negative feedback control. Growth hormone stimulates longitudinal bone growth both via direct stimulation of the growth plate, and indirectly by stimulating the hepatic production of IGF-1 [3]. IGF-1 is also ubiquitously expressed in many other tissues such as fat, muscle and in the growth plate. It has systemic effects on amino acid uptake, bone mineral density, muscle mass, and lipolysis [4]. In addition, it has local effects in the growth plate under the influence of GH stimulating both proliferation and hypertrophy of chondrocytes as well as ossification by affecting the osteoblasts [5, 6]. In a growing individual, a GH secreting pituitary adenoma will cause accelerated growth and tall stature which is referred to as pituitary gigantism.

Sex Steroids

Sex steroids including oestrogen and testosterone are mainly produced by the gonads. Oestrogens play an important role for growth in both girls and boys. In girls, oestrogens are mainly produced in the ovaries. In boys, the main production occurs in peripheral tissues through aromatization of androgens. Oestrogens affect growth by reducing IGF-1 mediated negative feedback which regulates the effect of GH and its secretion [7]. Oestrogens stimulate growth during puberty but are also the factor that finally leads to growth plate fusion at the end of puberty in both genders [8]. Testosterone increases the effect of GH on IGF-1 secretion [7]. Androgen receptors are expressed in the human growth plate but any local direct effects of androgens on longitudinal bone growth have not been established [9].

Oestrogens act by binding two different nuclear receptors in the growth plate, oestrogen receptor (ER)α and ERβ, and a more recently discovered G protein-coupled oestrogen receptor 1 (GPER1) [10, 11]. ERα and ERβ are both expressed throughout the different zones of the growth plate [12]. The abundance of both receptors increases as the cells differentiate [13]. Oestrogens stimulate osteoblasts and inhibit osteoclasts but the exact mechanisms through which they promote bone growth are not clear [14]. Open growth plates at 28 years of age were observed in a 204 cm tall male who had an ERα inactivating mutation [15]. Patients with aromatase deficiency exhibit similar phenotypes with a lack of pubertal growth spurt and growth plates which remain open into adulthood leading to tall stature. Patients with aromatase deficiency respond to oestrogen treatment which improves bone mineralization and closes the growth plates. Such therapy has no effect in an ERα-mutated patient suggesting that ERα has an important role for growth plate fusion in humans.

Local Regulators of Growth in the Growth Plate

One type of local regulator in the growth plate are fibroblast growth factors (FGFs) which have important roles at every stage of endochondral bone formation. Fibroblast growth factor-1 and FGF-3 are growth-inhibiting whereas FGF-2 is growth promoting [2, 16]. Bone morphogenetic proteins (BMPs) are also present throughout the endochondral ossification process and seem to have antagonizing effects to FGFs in some of the stages [17]. Parathyroid hormone-related peptide (PTHrP) has a stabilizing role in the growth plate by maintaining chondrocytes in a proliferative stage and also inhibiting hypertrophy [18]. C-type natriuretic peptide (CNP) is a local positive regulator of growth [19]. Activating mutations or overexpression of CNP can cause tall stature [20, 21].

Diagnosis of Tall Stature

Even though tall stature is constitutional in the vast majority of cases, growth disorders causing excessive growth are important to rule out in patients seeking medical attention for tall stature since they can be associated with other health issues. There are several physical and developmental signs to look out for which could be associated with a growth disorder. To give some examples, an increased birth length may be a sign of Beckwith-Wiedemann syndrome. A large head circumference, on the other hand, may indicate an underlying syndrome such as Sotos syndrome or Weaver syndrome. Developmental problems are common in individuals with homocystinuria and several syndromes including Klinefelter, Triple X, Fragile X, Loeys–Dietz, Sotos, and Weaver syndrome. There is a common division into primary and secondary growth disorders which are summarized in Table 7.1.5.1. Primary growth disorders affect the growth process itself and may have a prenatal onset. Secondary growth disorders are caused by external factors and affect growth indirectly.

Constitutional Tall Stature

Constitutional tall stature is also known as familial tall stature. It is genetic, hence dependent on the height of the mother and father of

Table 7.1.5.1 Overview of growth disorders associated with tall stature

	Major clinical findings (in addition to tall stature)	Diagnostic testing
Primary growth disorders		
Marfan syndrome	Long extremities, aorta dilatation, scoliosis, flexible joints, ectopia lensis	Ghent criteria, genetic testing for FBN-1 mutation, echocardiography, and ophthalmology evaluation
Loeys–Dietz syndrome	Long extremities, aorta dilatation, scoliosis, flexible joints, cleft palate	Genetic testing for mutations of the TGFß signalling pathway
Homocystinuria	Long extremities, scoliosis, ectopia lensis, developmental delay	Blood test for homocysteine concentration
Multiple endocrine neoplasia 2B	Long face, scoliosis, joint laxity, alacrima, mucosal neuromas on the tongue, lips, oral cavity, and conjunctivae	Genetic testing for mutations in the *RET* gene
Klinefelter syndrome	Small testes, muscle weakness, cognitive disabilities, infertility, gynaecomastia	Chromosome karyotyping (XXY or variants with ≥2 X chromosomes)
Fragile X	Protruding forehead and large ears, autism, developmental delay	Genetic testing for FMR1 mutation
Sotos syndrome	Large skull, cognitive disabilities	Genetic testing for NSD1 mutation
Weavers syndrome	Dysmorphic facial features, learning difficulties	Genetic testing for EZH2 mutation
Beckwith–Wiedemann syndrome	Neonatal hypoglycaemia, macroglossia, hemihyperplasia, embryonic tumours	Clinical assessment and genetic testing
Secondary growth disorders		
Pituitary gigantism	Frontal bossing, prominent jaw, large hands and feet, delayed puberty, muscle weakness	Blood test for basal GH and IGF-1; GH suppression test
Precocious puberty (central and peripheral)	Early onset of puberty and pubertal growth spurt (tall stature in childhood)	Blood test for LH, FSH, oestrogen and testosterone, bone age
Familial glucocorticoid deficiency	Failure to thrive, hypoglycaemia	Blood test for plasma ACTH and cortisol. Genetic testing

the child. Height is highly heritable in a polygenic manner. It has been estimated in a sibling study that the heritability of height is 80% [22]. Through genome-wide association studies (GWAS) over 400 loci associated with height have been identified, explaining approximately 20% of the phenotypic and 25% of the genetic height variation [23, 24]. Elevated levels of GH and IGF-1 have been observed in studies of individuals with constitutional tall stature but the results are inconclusive [25–28]. One study showed higher peak GH concentrations in tall children when compared to those of short and normal height [25]. Another study showed higher IGF-2 levels in tall individuals when compared to controls whereas no difference in IGF-1 levels was found [26]. IGF-1, IGF-2, and GH levels were compared between tall and normal/short army recruits (six in each group) and even though a tendency towards higher levels was seen in taller individuals, differences were not statistically significant which can however relate to a small number of study participants [28].

Constitutionally tall children often grow more rapidly in the first 4 years of life, after which growth drops to more normal rates [29]. Dickerman *et al.* studied the growth patterns from birth to 9 years of age in 65 children diagnosed with constitutional tall stature. Their mean birth lengths were 52.1 and 53.5 cm in girls and boys, respectively, corresponding to the 75th percentile. At 4 years of age, their heights had increased to 111.7 and 113.0 cm, respectively, corresponding to 2.5 SD above the mean. Between four and nine years, the growth curves were parallel with the 50th percentile, but 2.75 SD above on average. The authors suggest that the fact that the birth length does not deviate from normal indicates that factors leading to tall stature are postnatal.

Primary Growth Disorders

Marfan Syndrome

Marfan syndrome is a connective tissue disorder caused by a mutation in the fibrillin-1 gene (FBN1) located on chromosome 15 (15q21.1). This gene encodes a glycoprotein called fibrillin-1 which is essential for connective tissue formation. Marfan syndrome affects approximately two to three per 10 000 individuals [30, 31]. It is usually inherited in an autosomal dominant pattern although approximately 25% of affected individuals have a de novo mutation. The most serious abnormality associated with this syndrome is dilatation of the aorta which can lead to aortic dissection and rupture, a fatal condition. Other clinical features include ectopia lentis, scoliosis, crowded teeth as well as flexible and painful joints. Children with Marfan syndrome may grow extremely tall with especially long arms, legs, fingers, and toes. In 1986, an expert panel developed a set of diagnostic criteria, called the Berlin nosology, aimed to facilitate accurate diagnosis [32]. This was later revised due to overdiagnosis and the commonly used Ghent criteria were developed [33], with further revisions in 2010 [34]. These diagnostic criteria are mainly focused on the family history of Marfan, ectopia lentis, aortic dilatation, and FBN-1 mutations. Additional criteria include body disproportions and musculoskeletal abnormalities.

Loeys–Dietz Syndrome

Loeys–Dietz syndrome is an autosomal dominant genetic disorder affecting the collagen production in the connective tissue caused by a mutation of the transforming growth beta signalling pathway. It has similarities to Marfan syndrome such as an increased risk of aorta dissection due to an aneurysm. Other clinical features beside overgrowth are hypertelorism and cleft palate [35].

Homocystinuria

Homocystinuria is an autosomal recessive disorder caused by a mutation in the cystathionine-beta-synthase (CBS) gene on chromosome 21 (21q22.3) affecting approximately one in 6000 newborn children [36]. Individuals with homocystinuria have a deficient elimination of homocysteine and its metabolites. There are two types, B_6-responsive and B_6-nonresponsive homocystinuria, the first usually being milder than the second. Homocystinuria affects connective tissues in the body, including fibrillin. Affected individuals may exhibit clinical features similar to those in Marfan syndrome including tall stature with long legs and arms, scoliosis, and ectopia lentis. They might also suffer developmental delay (especially the B_6-nonresponsive type) and thromboembolic complications which can lead to an early death [37].

Multiple Endocrine Neoplasia Type 2B

Another differential diagnosis in patients with Marfanoid habitus is multiple endocrine neoplasia type 2B (MEN2B) which is a rare autosomal dominant disorder caused by mutations in the *RET* gene. Clinical manifestations include mucosal neuromas on the tongue, lips, oral cavity, and conjunctivae which are white-yellow papules a few millimetre in size and may be present at birth and can usually be found by age 10 years [38]. Gastrointestinal complaints caused by diffuse gastrointestinal ganglioneuromatosis may be present from infancy or early childhood. Affected individuals are at high risk of developing medullary thyroid cancer at a very young age and have an increased risk of pheochromocytoma.

Klinefelter Syndrome

Klinefelter syndrome, also called 47,XXY, affects one to two boys per 1000 [39]. Due to an extra X-chromosome, these patients have excess expression of certain genes. One of these is the short stature homeobox (SHOX) gene, which has been shown to influence the phenotype seen in Klinefelter syndrome [40, 41]. Clinical features include tall stature, small external genitalia, muscle weakness, cognitive disabilities, behavioural problems, infertility, and gynecomastia. Affected boys also have a higher risk of developing diabetes mellitus, cancer, and cardiovascular disease. Klinefelter syndrome is often diagnosed late, when affected men fail to conceive [42].

Fragile X

Fragile X affects approximately one in 5000 males and one in 10 000 females and is caused by a mutation in the fragile X mental retardation 1 (FMR1) gene located on the X-chromosome. Symptoms include tall stature, intellectual disability, developmental delay, autism and a characteristic appearance with a protruding forehead, and large ears [43].

Sotos Syndrome

Sotos syndrome affects one in 10 000 to 14 000 newborns and is caused by mutations in the nuclear receptor binding SET domain protein 1 (NSD1) gene in 90% of the cases. The skull is large and affected individuals have an increased height velocity during the first 4 years of life and an increased adult height. Cognitive disabilities are common [44].

Nevo Syndrome

Nevo syndrome is caused by a NSD1 deletion and is inherited in an autosomal recessive pattern. It shares clinical features with the more common Sotos syndrome described earlier [45].

Weaver Syndrome

Mutations in the oncogene EZH2 causes Weaver syndrome which is associated with tall stature, dysmorphic facial features, and learning difficulties [46]. Due to the similar clinical picture it is often mistaken for Sotos syndrome.

Trisomy X

Trisomy X is a sex chromosome aneuploidy affecting approximately 1 in 1000 girls. It is associated with tall stature as well as behavioural problems and learning difficulties [47].

Simpson–Golabi–Behmel Syndrome

The overgrowth condition Simpson–Golabi–Behmel syndrome (SGBS) is caused by a mutation in the X-linked SGBS gene. In addition to tall stature affected individuals may exhibit supernumerary nipples, muscular hypotonia and an increased risk of tumours in infancy has been seen [48].

Beckwith–Wiedemann Syndrome

Most affected individuals with Beckwith–Wiedemann syndrome (BWS) have an imprinting disorder of one or two gene clusters that contain the *IGF2* and *H19* genes, under control of chromosome 15 imprinting centre 1 (IC1), and the *CDKN1C* and *KCNQ1OT1* genes, under control of imprinting centre 2 (IC2). Approximately 65% of children with BWS have a birth weight above the 90th percentile [49]. They are tall in childhood and mean adult height has been reported to be 1.8 ± 1.2 SDS above normal [50]. Congenital anomalies such as macroglossia, ear creases or pits, naevus flammeus, and abdominal wall defects are characteristic of BWS as is hemihyperplasia [49]. Affected individuals may develop hypoglycaemia due to hyperinsulinism in the neonatal period and also have an increased risk of developing embryonic tumours, especially Wilms tumour.

PTEN Hamartoma Tumour Syndromes

This group of growth disorders includes Cowden disease and Bannayan–Riley–Ruvalcaba syndrome and affects approximately one in 200 000–250 000 [51]. They are caused by a mutation of the PTEN tumour suppressor genes and are inherited in an autosomal dominant pattern.

Perlman Syndrome

Perlman syndrome is a rare autosomal recessive genetic disorder caused by a mutation in the *DIS3L2* gene. It is characterized by overgrowth, dysmorphic facial features, renal dysplasia, and an increased risk of developing Wilms tumour. It has a poor prognosis with a high neonatal mortality.

Secondary Growth Disorders

Pituitary Gigantism

Pituitary gigantism causes abnormal growth in childhood due to excessive secretion of GH. The most common cause is a benign pituitary tumour but the incidence is unknown [52]. In some cases, underlying causes are Carney complex, McCune–Albright syndrome (MAS), multiple endocrine neoplasia type 1 (MEN-1), and neurofibromatosis [53, 54]. Pituitary gigantism causes bones as well as muscles and internal organs to grow excessively. Other physical features associated include frontal bossing, a prominent jaw, large hands, and feet. It can also cause delayed puberty, headache, muscle weakness, double vision, and sleeping problems. Different treatment methods are available including transsphenoidal surgery, somatostatin analogues, and GH antagonists [55].

Obesity

Obese children often experience tall stature due to early adrenarche, early puberty, and advanced skeletal maturation. The mechanism is thought to be related to hyperinsulinemia. Insulin binds to the IGF-1 receptor and increases height velocity. It also increases free IGF-1 in the circulation [55]. However, adult height is usually not affected due to a more blunted pubertal growth spurt and earlier growth plate closure [56].

Hyperthyroidism

Thyrotoxicosis in childhood may cause an acceleration of skeletal maturation and linear growth. It is unclear whether this acceleration affects the final height or if it is compensated by an accelerated bone maturation [57, 58].

Precocious Puberty

Children are considered to experience premature puberty if onset is before 8 years of age for girls and 9 years for boys [59]. Precocious puberty affects approximately one in 500 girls and one in 2000 boys [60]. These girls and boys are tall during childhood, but due to the advancement in skeletal maturation and early growth plate fusion, adult height is usually unaffected or if left untreated sometimes can be reduced [39, 55].

Familial Glucocorticoid Deficiency

Familial glucocorticoid deficiency (FGD) is characterized by a failure of the adrenal cortex to produce glucocorticoids in spite of normal levels of ACTH [61]. There are different types of this condition caused by different mutations. FGD type 1 is caused by a mutation in the ACTH receptor. Mutations in accessory or regulatory proteins can give the same clinical picture with failure to thrive and hypoglycaemia in early childhood and later an association with tall stature where the mechanism is unclear [62].

Aromatase Deficiency

Aromatase deficiency is a rare autosomal recessive disease caused by a mutation of the gene *CPY19* affecting the aromatization of androgens into oestrogens. This leads to delayed skeletal maturation and open growth plates even after adolescence resulting in extreme tallness unless the patient is treated with oestradiol. Affected girls are born with ambiguous genitalia [63].

Psychosocial Aspects of Being Tall

The most common complaint with tall stature is psychosocial problems. Tall individuals may experience social difficulties at school and parents are sometimes concerned of their tall child's ability to

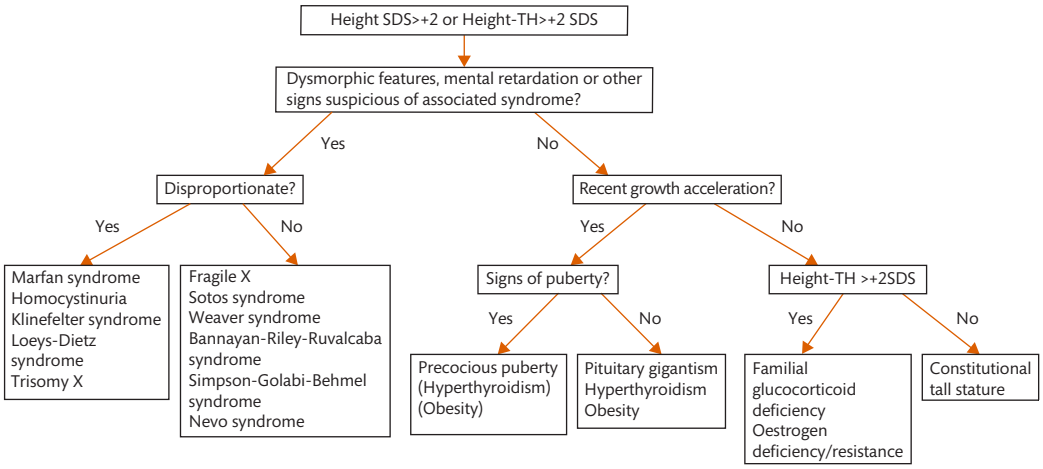

Figure 7.1.5.1 Flow chart for the assessment of a tall child.

find a partner. In an Australian cohort of 650 tall women (approximately one third were previously treated with high-dose sex steroids to reduce their heights), no difference in mental or physical health was found between treated and untreated individuals. However, both these groups had a significantly higher risk of developing major depression compared with population-based studies [64].

In a public school in the United States, social outcomes in relation to height were studied in 956 pupils in grade 6–12 in order to establish whether or not there were grounds for intervention in extremes of height. They found that there were minimal effects from height on social behaviour and popularity [65].

There are also studies reporting positive traits associated with tall stature. Higher income in tall individuals has been reported [66]. Another study in which the 45 210 study participants were divided into fifths according to their heights reported that the shortest 20% had a lower mood than the taller participants except for those financially disadvantaged. In this group the association between height and mood was surprisingly reversed [67].

A Swedish study of the risk of suicide in association with fetal and childhood growth reported that short adults are more prone to commit suicide and tall adult stature is protective [68].

Assessment of the Tall Child

The assessment of tall stature can be facilitated by using a flow chart (Figure 7.1.5.1). A thorough history and physical examination is essential as summarized in Box 7.1.5.1. It is important to assess the child's height against standard growth charts and to decide whether the child has normal body proportions or not. Where disproportionate growth occurs, it is more likely that there is an underlying genetic syndrome. Furthermore, it is necessary to establish whether one or even both parents are tall, and if so whether there is a dominant growth abnormality such as Marfan syndrome. Also, children with heights close to average might need investigation if their heights are well above their mid-parental target height or if they experience sudden growth acceleration. Some conditions can cause excessive growth during childhood with a normalization of height before adult age, such as obesity and precocious puberty.

Auxological measurements should include total height as well as sitting height and arm span. Sitting height percentage is usually calculated as the proportion of the upper body segment compared to total height (including the lower extremities). Patients with Klinefelter or Marfan syndrome usually have disproportionally long legs and arms. Even individuals with constitutional tall stature often have relatively long legs with a lower sitting height percentage than individuals of average height. Body mass index (BMI) should be calculated and pubertal staging performed including measurement of testicular volumes in boys. Bone age can be determined from an X-ray image of the left hand and wrist. This should not be done until the patient has entered puberty as final height predictions based on bone age are unreliable at prepubertal ages. Box 7.1.5.1 summarizes suggested initial investigations at the primary care level.

Of vital importance is to exclude potentially serious conditions which might require treatment, such as Marfan syndrome. If this is suspected, the patient should be referred for echocardiography to assess for possible aorta dilatation which can lead to aortic rupture. In some cases, clinical geneticists are consulted and specific genetic

Box 7.1.5.1 History and examination in assessment of tall children

History

- Pregnancy and birth information including birth weight, length, head circumference
- Early development (speech, motor skills, social development)
- Cognition and learning difficulties
- Family history including pubertal timing, growth, and heights, cardiovascular- and other disorders
- Medical history
- Nutrition

Physical examination and tests

- Auxology (plotted onto a growth chart) including height, weight, head circumference, sitting height, leg length, arm span
- Dysmorphic signs
- Pubertal stage
- Signs of thyroid disease
- Musculoskeletal abnormalities including laxity in joints, spinal deformation
- Neurological examination
- Cardiovascular examination
- Ophthalmology examination/consultation
- Bone age X-ray (left hand and wrist): only of value for adult height prediction once the patient has entered puberty
- Lab tests or genetic karyotyping if suspicion of specific disorders (see Table 7.1.5.1)

Box 7.1.5.2 Referral to specialist

Consider referral if:

- Marked height (but not weight) acceleration after 1 year of age
- Tall stature atypical for the family (height >2 SD over SD for target height)
- Patient/parental concern of extreme adult height

Information to include in referral:

Patient history

- Who initiated investigation?
- Growth chart including height and weight from birth until present
- Other health issues including any back or joint problems, previous lens dislocation
- Time of pubertal onset and menarche (girls)
- Any school difficulties

Hereditary factors

- Sudden deaths in the family
- Parental heights and timing of puberty

Physical examination

- Pubertal stage
- Testicle volumes (boys)

testing requested. Karyotyping is performed when, for example Klinefelter syndrome is suspected. Some diagnoses can be confirmed with blood tests, for example pituitary gigantism (GH and IGF-1) and homocystinuria (plasma homocysteine). Box 7.1.5.2 indicates when referral to a paediatric endocrinologist should be considered.

In the clear majority of cases, tall children will be diagnosed with constitutional tall stature. Reassurance is often sufficient in the management of constitutionally tall patients and their families. In rare cases, an intervention might be called for. Following an algorithm may facilitate the management of a tall child being considered for surgical treatment to reduce further growth (Figure 7.1.5.2).

Height Prediction in Tall Girls and Boys

As an individual's height is 80% heritable, calculations have been proposed to predict adult height based on parental heights (i.e. 'target height', TH). However, this method has a large margin of error and more reliable is a prediction based on skeletal maturation assessed by hand and wrist X-ray. The so called bone age can be determined with the atlas of Greulich and Pyle [69]. Based on the bone age, the remaining growth is then estimated with methods such as the tables of Bayley and Pinneau [70] or Tanner–Whitehouse [71]. De Waal *et al.* evaluated different methods of adult height prediction in tall individuals and concluded that the precision was clinically acceptable in girls but not in boys. In both tall girls and tall boys, the tables of Bayley–Pinneau overestimates while Tanner–Whitehouse underestimates final height. The absolute error was on average approximately 2 cm in girls and 3 cm in boys for each of these methods [72]. There are also automated options for bone age determination from X-ray images including BoneXpert (Visiana, Denmark) [73]. This software has been found to be reliable in several different patient groups, resulting in predictions similar to those made by experienced clinicians [74–76]. However, it has to our knowledge not been studied specifically in tall individuals.

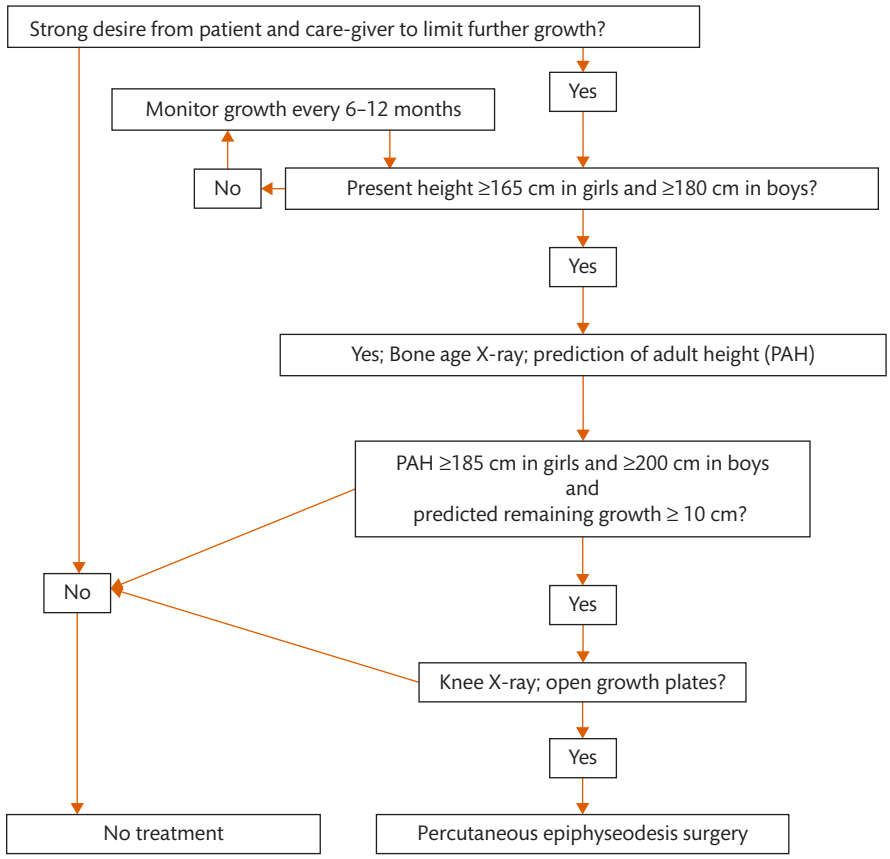

Figure 7.1.5.2 Flow chart for monitoring a tall child considered for surgical treatment.

Growth-Reducing Therapy

The use of growth reduction therapies is declining, possibly due to more acceptance of tall stature in the society and fear of side effects [77]. Historically, sex steroids have been the most common treatment method to reduce growth in tall girls and boys. Other therapies which have not reached the same popularity are somatostatin analogues (inhibits GH release from the pituitary gland) and bromocriptine (dopamine agonist) [78–82]. Surgical options have been introduced in the last decades which may replace medical methods of growth reduction [83–85].

High-Dose Sex Steroid Therapy in Girls

Oestrogens cause growth plate fusion during normal pubertal development. Sex steroid therapies to reduce growth in tall children were developed in the 1950s. It has been demonstrated that administration of high-dose oestradiol accelerates skeletal maturation which causes premature fusion and reduced adult height [86–88]. The daily doses of ethinyl oestradiol have gradually decreased from approximately 500 to 100 μg during the following decades, in some with the addition of medroxyprogesterone acetate.

Treatment efficacy varies greatly in literature which is partly explained by difficulties in final height prediction in tall individuals. A study of 56 treated girls showed a treatment effect of up to 6 cm height reduction [89]. This study included a control group to estimate the prediction error and found it to be 1.2 cm. Drop *et al.* reported 1.1–2.4 cm reductions in adult height compared to prediction in high-dose oestrogen treated girls depending on which method that was applied to predict adult height [90]. Another study showed a mean growth reduction in 159 treated women of between 1.7 and 4.2 cm depending on prediction method. They also found a linear relationship between bone age at start of treatment and the degree of effect. Treatment needed to be started before 14 years of age to have any effect at all [72]. In 279 tall girls treated with diethylstilboestrol or ethinyl oestradiol, their adult heights were reduced by 2.5 cm on average and the effect decreased by one cm per year of delay in treatment start [91]. A more recent Danish study of 60 girls treated with 17β-oestradiol girls showed a reduction in adult height of 1.6 cm [92].

Reported short-term side effects of high-dose oestrogen treatment include acne, weight gain, nausea, and headache [93–96]. With regards to long-term side effects, infertility in women treated with high-dose oestrogens for tall stature has been reported [97, 98]. The treated women had decreased fecundity, were more likely to have used fertility drugs and had more advanced aging of their ovaries compared to those untreated. There are also indications of possible risk increases in thrombosis and cancer [99, 100].

High-Dose Sex Steroids in Boys

Boys have also been treated with high-dose sex steroids to reduce adult height and the testosterone compounds used were generally long-acting esters such as testosterone propionate, enanthate and decanoate [90]. Testosterone doses of 250–500 mg were usually administered through intramuscular injections every second week and the treatment duration was typically 1.5 years [90, 101].

A final height reduction of 4.4 cm was reported in 33 treated boys [94]. Others reported a final height reduction of 4.8 cm when using the Bayley and Pinneau tables for height prediction but as low as 0.5 cm with the Tanner-Whitehouse prediction methods [72]. Height reductions of approximately seven centimetres were found in another study of 25 treated tall boys [102]. Other important factors affecting the efficacy were timing of initiation and duration of the treatment. Failure in optimizing these conditions appears in some cases to have led to an effect opposite to that desired. Drop *et al.* reported that when treatment was started at a bone age of 14 years or later, final height was increased instead of decreased [90]. Van den Bosch *et al.* reported that an addition of what the authors considered to be a low dose of ethinyl oestradiol (50 μg daily) at the beginning of testosterone therapy in tall boys caused an instant decrease in height velocity [103]. Decker *et al.*, on the other hand, found no additional effect of ethinyl oestradiol in this combination [104].

Reported short-term side effects of high-dose sex steroid therapy in boys include acne, weight gain, gynecomastia, and aggression [93–94]. Male infertility after testosterone treatment has not been shown even though lower serum testosterone levels have been reported [105, 106].

Surgical Methods

Epiphysiodesis is a surgical method to stop growth by destruction of the epiphyseal growth plate. It was first described by Phemister in 1933 for correcting leg length discrepancy [107]. With an open approach a block of bone was removed from the physis in the longer leg and put back in a rotated position, in which bony bridges formed and prevented further bone growth. In the 1980s a less invasive method was developed, so called percutaneous epiphysiodesis [108, 109].

Bilateral epiphysiodesis to reduce height in tall adolescents was first described in 1997 [85]. The Phemister method was used and they reported a height reduction of nine centimetres and no serious side effects in six treated boys. The first report on bilateral percutaneous epiphysiodesis to reduce height was published in 2006 and included 17 treated tall boys [84]. It was performed on the growth plates of the distal femur, proximal tibia, and proximal fibula. In boys, the procedure was found to be safe and reduced final heights by on average 7 cm (range 1.2–13.8 cm). Another study on both girls and boys showed a growth reduction of 4.1 and 6.4 cm, respectively, and no serious side effects were reported [83]. The authors recommend treatment when the patient has at least 15 cm of predicted remaining growth which likely results in a reduction of adult height by at least 5 cm. As an example, a girl with a predicted adult height of 190 cm should be treated before having reached a height of 175 cm and a boy with a predicted adult height of 205 cm should be treated before having reached a height of 190 cm. In recent years, radiofrequency application has been proposed as a new method for epiphysiodesis but has so far only been tested in rabbits [110, 111].

With a surgical approach to reduce height, many of the reported or potential side effects of pharmacological treatments mentioned earlier can be avoided [72, 94, 95, 98]. On the downside, surgery always brings a risk of infection and complications associated with anaesthesia. Also, skeletal deformities including leg length difference are other potential side effects.

Ethical Considerations Regarding Growth-Reducing Therapies

There are important ethical considerations to address before offering any treatment to reduce height. When a child presents for evaluation of tall stature it is important to establish whether it is

the child, the parents, or someone else who are most concerned. Other important questions are: what is the long-term value of the treatment? Is it possible that the psychosocial impact of being extremely tall is pronounced only during adolescent years due to peer pressure and reluctance to stand out, factors for which the importance diminishes with age? Treated individuals are generally healthy adolescents. Few side effects or long-term complications are acceptable under such circumstances. There are no known significant physical problems associated with height *per se* that could be avoided by reducing further growth potential. Sex steroid treatment in girls has been shown to impair future fertility and its use has since diminished. For surgical options, long-term complications are yet to be investigated. In the case of percutaneous epiphysiodesis, however, the procedure has been used within the field of paediatric orthopaedic surgery for many decades to treat leg length discrepancy and is regarded as safe. Also, the acceptance in society of extreme height seems to be increasing and any psychosocial impact of standing out because of being tall may be diminishing.

Summary

Tall stature is usually constitutional but might be caused by a growth disorder. Assessment of children and adolescents seeking medical attention for tall stature must be thorough and exclude any associated condition, such as Marfan syndrome, which might need medical treatment and monitoring. Other disorders associated with tall stature are Klinefelter syndrome, homocystinuria and the rare condition pituitary gigantism where there is an overproduction of growth hormone. In those few cases where an intervention is considered to reduce further growth, it is crucial to establish if it is the patient her- or himself who has a genuine desire to be treated and to carefully weigh up potential gains against risks. Any psychosocial advantage from such treatment has not been established, while the impact of height reduction on mental health has also not been adequately defined. In the past, tall boys and girls have been treated with high dose sex steroids but it has been shown to reduce fertility in girls and the use of this therapy has decreased markedly. New surgical methods are becoming more common including percutaneous epiphysiodesis. With this method the growth plate cartilage around the knee is destroyed surgically and the impact on height is certainly comparable, if not better than hormonal treatment. Overall, however, acceptance of tall stature is improving in society and in future it is likely that intervention for height reduction will rarely be required.

7.2

Sex Development

7.2.1 Sex Determination and Differentiation

Physiology Leading to Male and Female Development

Olaf Hiort and Ralf Werner

Introduction

The biological sex of a human being is dependent on a genetic pathway that determines the differentiation of the gonads to develop either into a testis or an ovary. This pathway usually starts with the initial setting of either a 46,XX or a 46,XY karyotype. Subsequently, a tightly regulated cascade of both sex chromosome and autosome derived genetic expression is initiated. From the bipotent gonadal anlagen, ovarian or testicular cells develop, which set the stage for hormone synthesis and allow the shaping of the individual phenotype into either male or female. These processes occur in a precise step-wise and time-dependent manner and any disruption at sensitive time intervals will allow deviation from the usual pathways.

These conditions are described as 'disorders or differences of sex development (DSD)', and the clinical approach of professionals towards people affected by DSD is described in the next Chapter 7.2.2. DSD encompasses mostly rare to very rare genetically determined variants of a discrepancy between chromosomal, gonadal, and phenotypic sex. It is unclear at this time if external, non-genetic factors may disrupt the endocrine pathways and thus lead to DSD. Sex development is not only related to development of genital structures, but also includes sexually dimorphic development of brain structures. Therefore, DSD will affect not only the appearance of primary genital structures and subsequent sexual maturation at puberty, but also gender identity. Furthermore, the initial genetic components of gonadal development may be involved in differentiation and function of other organs, such as the adrenal, the heart, the skeletal system or even the neurological system. Therefore, patients with DSD conditions may have associated endocrine illnesses and other system disorders.

Chromosomal Sex

The chromosomal sex of an individual is determined with the fusion of egg and sperm at the time of conception. Usually, one X chromosome is inherited from the mother, while the sperm from the father may provide either an X or a Y chromosome to account for the 46,XX or 46,XY karyotype of the embryo. This genetic layout is seen as a starting point of sex development in the principally 'un-sexed' child. The chromosomes themselves may harbour sex-specific and sex-nonspecific, pseudoautosomal genes. Sex chromosome division may be altered either prior to conception or during the first cell divisions of the blastocyst, leading to numerical aberrations. Well-known are sex chromosome trisomies such as 47,XXY (Klinefelter syndrome) or monosomies such as 45,X (Turner syndrome), but also higher numbers of sex chromosomes (such as 48,XXXY, 49,XXXXY etc.) have been described in humans [1]. Mosaicism (e.g. 45,X/46,XY) arises from the loss of a sex chromosome during the first cell cycles. Also, chimeric alterations (e.g. 46,XX/46,XY) may occur. It is believed that the presence of Y-chromosomal material expressing *SRY* (*sex determining region Y*) in any 46,XX or mosaic individual may lead to testicular or partial testicular development of the gonadal structures and, hence to a range of phenotypes.

Development of the Bipotential Gonad

Most information regarding the development of the gonads and the genes involved in their development in mammals come from mouse genetics and humans presenting with DSD. The gonadal primordium is believed to arise as part of a common adrenogonadal primordium from the urogenital ridge, which develops as a paired structure at 10.5 days post-coitum (dpc) in mice and around the fifth week post-conception (p.c.) in humans. A gubernaculum forms at the cranial and caudal ends to allow the descent of the gonad during later development (Figure 7.2.1.1). The bipotential gonads harbour two distinct cell types, somatic cells and germline cells, that differ in their embryologic origin. The somatic part is composed of cells developing

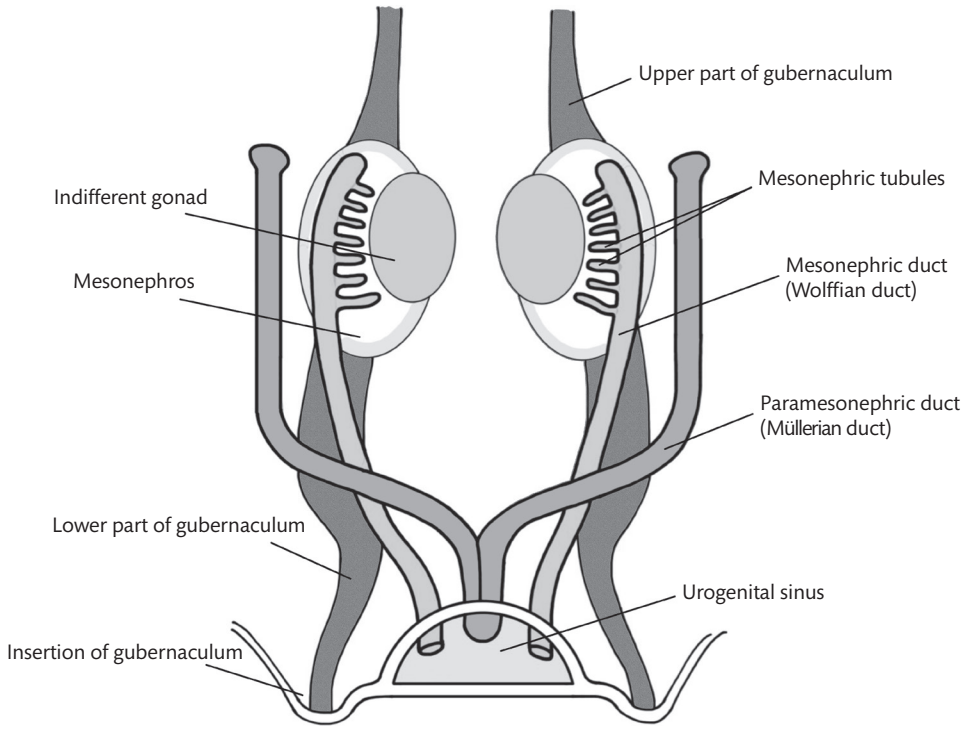

Figure 7.2.1.1 The indifferent or bipotent gonads with the gubernaculum and the mesonephric and paramesonephric ducts.

from the coelomic epithelium and the mesenchyme beneath. It originates from the intermediate mesoderm and partly from the mesonephros. Genital ridge formation starts with increased proliferation of epithelial cells on the surface of the mesonephros forming a dense and pseudostratified layer. Its underlying basal membrane becomes disintegrated and allows the epithelial cells to invade the mesonephros. The germ line, however, comes from the primordial germ cells which derive from the ectoderm. In the mouse, induction of primordial germ cells from the proximal epiblast is first visible as a cluster of about 45 cells around 6.25 dpc [2]. The primordial germ cells proliferate and migrate to the gonadal ridge after which they undergo epigenetic reprogramming and erasure of parental imprints [3]. In humans, at the end of the fifth week p.c. (10.5 dpc in mice), the primordial germ cells migrate to the surface of the gonadal ridge joining the somatic cells. The growing coelom epithelium is now in very close contact with the primordial germ cells, maintaining the integrity of germ cells and the somatic part of the gonadal ridge. The germ cells proliferate and no differences between male or female gonads are visible in mice up to 12 dpc, and the sixth week p.c. in humans (Figure 7.2.1.2).

Genes Involved in Formation of the Bipotent Gonad

Studies of knock out mice and people with gonadal dysgenesis provided information on genes involved in genital ridge development. A set of genes including *GATA* binding protein 4 (*Gata4*), nuclear receptor subfamily 5 group A member *1* (*Nr5a1,* also known as steroidogenic factor 1, Sf1), Wilms tumour 1 (*Wt1*), Lim homeobox protein 9 (*Lhx9*) and empty spiracles homeobox 2 (*Emx2*) have all been shown to be vital to the development of the genital ridge [4]. *Wt1* is expressed as early as 9.5 dpc in the whole urogenital ridge [5] and plays an important role in the development of the gonad as well as the kidneys. This zinc finger transcription factor has 24 isoforms. Alternative splicing leads to an insertion or omission of three amino acids (+/– KTS; lysine, threonine, serine) between the third and fourth zinc finger. The Wt1-KTS isoform seems to have a key role in gonadal ridge development since ablation of the *Wt1*-KTS leads to a lack of broadening of the genital ridge due to increased apoptosis [6].

GATA4 is a zinc finger transcription factor that is necessary for genital ridge initiation and is expressed in the genital ridge in an anterior-posterior direction preceding immediately the thickening of the coelomic epithelium. *Gata4* knock-out is embryonic lethal due to defects in early ventral morphogenesis [7]. Therefore, conditional *Gata4* knock-out mice have been created that display no gonadal initiation. Their coelomic epithelium remains a monolayer and the basement membrane underneath persists unfragmented preventing migration [4]. Knock out mice for *Emx2* also show gonadal dysgenesis and a decrease of epithelial cells migrating to the mesenchymal part of the gonadal ridge [4, 8, 9]. In humans, haploinsufficiency caused by deletions encompassing *EMX2* have been linked to a wide spectrum of DSD ranging from hypospadias to complete sex reversal [10]. *Lhx9* KO mice show agenesis of the gonads in both sexes. The genital ridge develops, but the coelomic epithelium fails to proliferate and gonads are not formed. Nevertheless, germ cells migrate normally to the presumptive gonadal region at the expected time [11]. Although mice lacking *Lhx9* do not exhibit further severe defects, to date no mutations in this

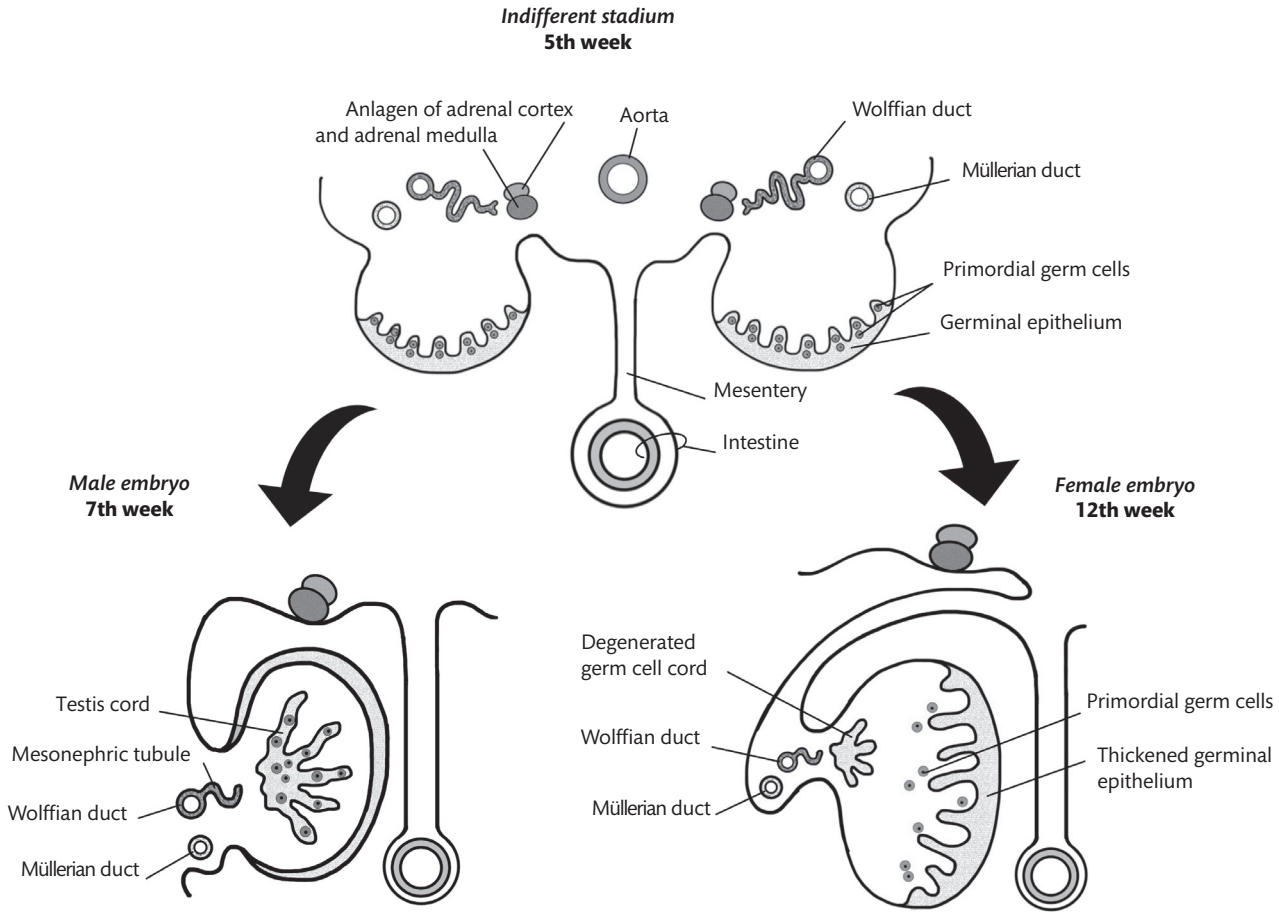

Figure 7.2.1.2 Differentiation of testis and ovary from the indifferent stage.

gene in humans have been described. *Nr5a1* expression follows *Gata4* expression and is restricted to the genital ridge and the adrenal primordium. Mice lacking *Nr5a1* have a similar phenotype to *Lhx9* KO mice. They lack adrenal glands and gonads and both male and female mice have female internal genitalia [12]. Interestingly, expression of *Nr5a1* in *Lhx9* –/– mice is greatly reduced, suggesting that LHX9 might be a regulator acting upstream of *Nr5a1*.

After fragmentation of the basement membrane some proliferating SF1 positive cells of the coelomic epithelium undergo epithelial-mesenchymal transformation (EMT) and migrate inwards into the mesenchyme forming the gonadal somatic precursor cells.

Testis Determination

The presence and expression of the master switch gene *Sry* (sex-determining region of the Y chromosome) leads to an upregulation of its target *Sox9* and drives the bipotential precursors into the Sertoli cell lineage leading to testis development. In mice, XY genital ridges with a deletion or malfunction of *Sry* or *Sox9* can differentiate into an ovary and forced expression of *Sry* or overexpression of *Sox9* in XX genital ridges can induce development of testes [13–15]. This demonstrates that the cell types in the genital ridge are equally capable of expressing both male and female pathway genes resulting in testis or ovary development with a high dependency on the presence of a Y-chromosome (including the *Sry* gene). *Sry* expression is the trigger to activate the testis determining pathway and to suppress the ovarian determining pathway [16]. In mice, *Sry* is expressed only in a small-time window from 10.5 dpc to 12.5 dpc starting in the centre of the gonad. The expression expands rapidly to its poles, reaches its maximum around 11.5 dpc and extinguishes from the centre to the poles. An accurate spatiotemporal expression of *Sry* is necessary since delayed or reduced *Sry* expression impairs testis development [17]. In humans *SRY* expression starts in the seventh week of gestation (41–44 days post ovulation, d.p.o.) in XY gonads but persists at low levels throughout the embryonic phase and beyond [18]. Studies in mice have shown numerous factors regulating *Sry* expression. Recently, these factors have been integrated into a model consisting of three regulatory modules that modify the activity of the three key transcription factors SF1, GATA4, and WT1 binding to the *Sry* promoter [17]. Mutations that affect the level of *SRY* expression or its timing during sex determination might also be responsible for some idiopathic cases of gonadal dysgenesis [19]. One of the earliest morphological changes after *Sry* expression is an increase in proliferation that results in an increase of the size of the XY gonad compared to the XX gonad. This increase in proliferation is dependent on SRY and occurred in two phases. In the first phase enhanced proliferation is observed in SF1 positive cells of the

coelomic epithelium contributing to the Sertoli-cell population, and in a second phase proliferation occurs in SF1 negative cells of the genital ridge that are not precursors of Sertoli cells [20].

The transcription factor SRY binds to and activates the testis specific enhancer (TES) on *Sox 9* [21, 22]. After *Sry* is downregulated, SOX9 maintains its expression in Sertoli cell precursors by binding to its own TES via the same binding motif as SRY [21]. SOX9 also directly or indirectly upregulates the proliferation-promoting factor FGF9 that maintains *Sox9* expression via its FGF receptor 2 (FGFR2). FGFR2 was detected at the plasma membrane of proliferating coelomic epithelial cells and in the nucleus of Sertoli precursors [23, 24]. In *Fgf9* or *Fgfr2* KO mice *Sox9* expression is reduced and all testis specific events in the developing gonad are disrupted such as cell proliferation, Sertoli cell differentiation or testis cord formation [24–27]. Recently, a first patient with a heterozygous mutation in *FGFR2* displaying craniosynostosis with 46,XY DSD due to gonadal dysgenesis has been reported [28] and gave a first indication that FGF9 levels may also play a role in human testis development. SRY and SOX9 also bind to the promoter of the *Ptgs* gene encoding prostaglandin D synthase mediating the synthesis of PGD2 [29, 30] initiating a paracrine feed-forward loop. PGD2 binds to its DP-receptor and activates an intracellular cascade that leads to activation of cAMP-dependent protein kinase A and phosphorylation of SOX9 protein. Phosphorylated SOX9 translocates into the nucleus and binds to its own promoter thereby maintaining its expression [31]. This pathway is a second SOX9 amplification pathway independent of the FGF9 pathway [32] contributing to Sertoli cell differentiation and may play a role in *Sox9* upregulation of neighbouring SRY negative cells to reach a threshold of SOX9 positive Sertoli precursors to force testis development.

One of the early target genes of SOX9 is anti-Müllerian hormone (AMH), a signalling molecule of the TGF (transforming growth factor) superfamily responsible for the regression of the Müllerian ducts in XY embryos (see next). In the genital ridge, *Amh* expression is limited to pre-Sertoli cells after *Sry* is expressed and testis cord formation becomes visible [33]. Once *Amh* expression is initiated its expression level continues at high levels during gestation. Several transcription factors that are also important for the development of the gonadal ridge and the first steps of sex determination such as WT1, GATA4, SF1, and SOX9 are recruited to the *Amh* promoter and control *Amh* transcription [34, 35].

Differentiation of Sertoli cells is the first step towards testis determination. Sertoli cells are the organizing centres in the developing testes. They influence testis cord formation and the differentiation of other important cell types of the testis, like peritubular myoid cells, fetal Leydig cells and endothelial cells [16]. Testis cord formation starts with the aggregation of pre-Sertoli cells around clusters of germ cells, but does not depend on the presence of germ cells, since cords devoid of germ cells develop normally. The cords tubularize and attach with both ends to a common junction, the rete testis. Peritubular myoid cells (PMC) form the outer layer of the seminiferous tubules and are in direct contact with the surface of Sertoli cells. In mice, this is a monolayer, but in humans it typically consists of multiple layers that are separated by an extracellular matrix, which is deposited by both PMC and Sertoli cells [36, 37]. PMC are first visible at 13.5 dpc in mice or 12 weeks in humans [38, 39].

In mice, Sertoli cells express *Desert Hedgehog* (*Dhh*) shortly after *Sry* and its expression persists into adulthood. DHh is one of three secreted mammalian hedgehog proteins (Sonic Hedgehog, SHh; Indian Hedgehog IHh, and DHh) that acts as a morphogenic ligand via its receptor patched1 to regulate Leydig cell and PMC differentiation. *Dhh* KO-mice show affected PMC and Leydig cell differentiation with disrupted testicular cord structure, fewer fetal Leydig cells in the embryo and absence of adult Leydig cells [40]. The phenotype of the XY mice depends on the genetic background and ranges from infertile males to complete sex reversal [41, 42]. In humans homozygous mutations in *DHH* are associated with partial or complete gonadal dysgenesis with and without polyneuropathy [43–45]. Interestingly, ectopic activation of the hedgehog pathway in SF1 positive somatic precursors of fetal mouse ovaries transformed these cells into fetal Leydig cells. These cells produce androgens and INSL3 (insulin-like growth factor 3) and lead to virilization of the female embryos and ovarian descent, but the female reproductive system is left intact [46]. Leydig cells appear at least in two phases (three phases in humans) as two distinct Leydig cell populations: In the fetal testis as fetal Leydig cells (FLC) and in the adult testis as adult Leydig cells (ALC). In humans, there is a third phase of Leydig cell amplification in the neonatal phase (neonatal Leydig cells, NLS) during minipuberty between one and six months of age [47]. It is believed that fetal Leydig cells decline in the postnatal testis and are replaced by another population of adult Leydig cells, but recent lineage tracing experiments in mice have shown that FLC may persist in the adult testis. In mice, fetal and adult Leydig cells differ in the androgens they produce. An example is the expression of *Hsd17b3*, which converts androstenedione to testosterone. *Hsd17b3* is expressed in ALC but not FLC, therefore the main androgens produced by FLC and ALC are androstenedione and testosterone, respectively. In the fetus, androstenedione is converted by Sertoli cells to testosterone required for masculinization of the embryo [48]. Another difference between FLC and ALC in rodents is the ability of FLC to produce glucocorticoids [49]. Nevertheless, recent studies support the hypothesis that FLC and ALC arise from stem Leydig cells (SLC) that have their origin in the fetal testis, but it is unclear if they arise from common progenitors. The initial steroidogenesis of FLC is independent of gonadotrophins, but human FLC become dependent on placental human chorionic gonadotrophin (hCG) and human LH/CG receptor (LHCGR), which is expressed at the 11th week of gestation. In humans, testosterone secretion peaks between week 12–14 and the concentration of hCG is 10-fold higher than that of LH. During the second trimester, hCG concentration falls significantly followed by a decrease of testosterone secretion while LH concentration remains constant [50]. Human mutations in the LH/CG-receptor show the importance of gonadotrophin stimulation of fetal Leydig cells, since 46,XY patients with homozygous inactivating mutations in the *LHCGR* gene present with Leydig cell hypoplasia or Leydig cell agenesis [51]. In contrast mutations in the *LHB* (luteinizing hormone beta polypeptide) gene in 46,XY individuals lead to normal virilization at birth, but cause pubertal delay and hypogonadism [52, 53] indicating that FLC are dependent on hCG but not LH.

Ovary Determination

Sex determination is regulated by a molecular antagonism between testis and ovary pathways. The cell fate decision in the supporting cells, that determine a Sertoli or granulosa cell line, is a key step in sex determination. Since *Sry* is absent in a XX gonosomal

background, *Sox9* is not upregulated in the gonadal ridge. Therefore, SF1 positive supporting cell precursors are not recruited to the Sertoli cell lineage. Instead the *Wnt/ß-catenin* pathway is activated by R-spondin1 (*Rspo1*), Wingless-related MMTV integration site 4 (*Wnt4*), and Forkhead box L2 (*Foxl2*) [54]. *Wnt4* and *Rspo1* are expressed in the early somatic precursor cells of the genital ridge and, if not downregulated by the testis pathway, maintained in the mouse ovary. RSPO1 is involved in the female-specific upregulation of *Wnt4* and therefore knockout of either *Wnt4* or *Rspo1* in mice leads to a similar phenotype with partial female to male sex reversal, associated with a presence of steroidogenic cells with ectopic androgen production and formation of coelomic vessels [55, 56]. In humans, a heterozygous *WNT4* missense mutation was detected in a 46,XX patient with regressed Müllerian structures and elevated androgen production suggesting partial gonadal dysgenesis [57]. Homozygous disruption of WNT4 is associated with SERKAL syndrome (46,XX **Se**x **R**eversal with dysgenesis of **K**idneys, **A**drenals and **L**ungs) including 46,XX DSD (OMIM # 611812) [58]. Disruption of *RSPO1* causes a syndrome characterized by 46,XX ovotesticular DSD (female to male sex reversal), palmoplantar hyperkeratosis and predisposition to squamous cell carcinoma of the skin (OMIM #610644) ([59, 60]. In contrast, a 46,XY patient with sex reversal carrying a chromosome 1p31–35 duplication including *WNT4* and *RSPO1* genes has been identified [61]. Signalling through the canonical WNT pathway by WNT4 and RSPO1 induces stabilization and nuclear translocation of ß-catenin and activation of target genes. ß-catenin is expressed in the gonads of both sexes, but specific ablation of ß-catenin in SF1 positive somatic cells of the gonadal ridge affects only ovarian development and the phenotype is similar to that seen in *Wnt4* or *Rspo1* knockouts [62]. Conditional knock-in mice that express a stabilized form of ß-catenin in Sf1 positive somatic cells of XY gonads also override the male programme and show a male to female sex reversal [63]. The Rspo1/Wnt4/ß-catenin and the Fgf9 signalling pathway repress each other [23]. Interestingly, *Sox9* and *Fgf9* are not upregulated in *Ctnnb1* (ß-catenin) XX knock out mice [62] demonstrating that masculinization is a direct effect of loss of ß-catenin and other genes must be repressed by ß-catenin. This is supported by several studies of double knock-out mice affecting male and female pathway genes like *Wnt4/Fgfr2, Wnt4/Fgf9* [64], *Rspo1/Sox9* [65], and *Ctnnb1/Sox9* [66]. While knock-out of *Sox9* or the *Fgf9* pathway could be rescued in XY-mice by additional knock-out of the *ß-catenin* pathway, possibly by expression of other SRY target genes like *Sox8*, XX-mice still show partial masculinization. These results suggested that *Sox9* might be dispensable and that some other pro-testis genes require repression by the Wnt/ß-catenin pathway [66].

Surprisingly, once the ovary or testis is determined, its maintenance needs further lifelong expression of pro-ovarian or pro-testis genes. Conditional ablation of the transcription factor *Foxl2* in the adult mouse ovary leads to somatic ovary to testis trans-differentiation with reprogramming of granulosa and theca cells into Sertoli-like and Leydig-like cells capable of testosterone production at a level consistent with normal males [67]. FOXL2 maintains the ovarian phenotype mainly by repression of *Sox9* together with oestrogen receptor 1/ESR1 [67]. In humans, heterozygous mutations in *FOXL2* cause the blepharophimosis/ptosis/epicanthus inversus syndrome (BPES, OMIM #110100) associated with ovarian failure [68]. Recently, BPES in conjunction with congenital heart failure was also detected in two of three children with 46,XX ovotesticular/testicular DSD (OTDSD/TDSD) harbouring a heterozygous frame shift mutation in Nuclear receptor subfamily 2 group F member 2 (*NR2F2,* also known as Chicken ovalbumin upstream promoter transcription factor 2, Coup-TFII) indicating that NR2F2 might be a new pro-ovary and anti-testis sex determining factor [69].

In contrast, loss of the double-sex and mab-3 related transcription factor 1 (*Dmrt1*) in XY mice activates *Foxl2* expression and re-programmes Sertoli cells into granulosa cells, even if ablated conditionally in adults [70]. Under the influence of transdifferentiated Sertoli cells, theca-like cells form and produce oestrogen and even germ cells are feminized in the mutant gonads [70]. This plasticity of Sertoli and granulosa cells after terminal differentiation demonstrates that the molecular antagonism between male and female sex determination continues into adulthood and indicates that DMRT1 and FOXL2 are essential for postnatal sex maintenance of the testis or ovary, respectively. Interestingly, XY *Dmrt1* mutant mice are born as males with testes and feminize only after birth [71]. However, chromosome 9p deletions in humans removing *DMRT1* or partial deletions of *DMRT1* can cause 46,XY DSD with feminization at birth (OMIM #154230) [72, 73].

Sex Differentiation

Sex differentiation refers to the development of the phenotypic features of sex, namely the development of the internal and external male or female structures. This is mostly a hormone driven process, depending on the presence or absence of either anti-Müllerian hormone (AMH) or androgenic sex steroids. This finally results in the male or female somatic sex.

While the female somatic sex at birth does not seem to be dependent on ovarian endocrine activity, male sex differentiation has to be seen as the active, hormone-dependent, and irreversible modification of the primarily bipotent tissue structures of the internal and external genital anlagen. Androgenic steroids such as testosterone will lead to irreversible downstream expression patterns of genes corresponding to induction of the male phenotype in cells of the genital tubercle. Thus, these androgenic steroids program the transcriptome and epigenome of the cells in a so-called male programming window in the developing embryo [74]. Clinically, the effects are seen as the anogenital distance, the development of the scrotum and penile differentiation and length. These effects are also likely to account for reproductive issues such as sperm count and long-term testosterone levels in the adult male. We have to presume that the androgenization effects are also major players in the determination of facets such as body composition (muscle:fat ratio) and bone mineral density.

Development of Internal Genital Structures

In both sexes the internal genital structures arise again from bipotent anlagen, the Wolffian ducts and the Müllerian ducts. Under the influence of AMH secreted from the Sertoli cells of the testes during the critical period, the Müllerian ducts regress. So in the typical male development, the differentiation and growth of the uterus, upper third of the vagina, and fallopian tubes is actively suppressed. AMH acts through the AMH II receptor in the Müllerian duct mesenchyme [75].

In contrast, the Wolffian ducts develop under the influence of testosterone, giving rise to the epididymis, the seminal vesicles, and some parts of the prostate. The human fetal testes synthesize testosterone from the eighth week of gestation. The timing of development for testosterone-dependent structures, however, is very distinct. The prostate forms around the tenth to thirteenth week of gestation, while the seminal vesicles develop later, around week 14–16 (for a review, see [74]). Testosterone initially stabilizes the Wolffian ducts and elongation and convolution of the cranial end leads to formation of the epididymis, the middle portion forms the vasa deferentia and the caudal part differentiates into the seminal vesicles. The prostate develops from the urogenital sinus, which arises in humans around the seventh week of gestation from the cloaca. Androgens, namely testosterone, will lead to differentiation into zonal subdivisions to form the prostate. Female development does not depend on hormonal influences to mediate differentiation. In the absence of AMH, the Müllerian duct will differentiate into the uterus, fallopian tubes, cervix, and upper vagina. The lack of androgens causes the Wolffian duct to regress.

Again, the male development is dominant and hormone dependent. In some types of DSD with high amounts of testosterone formed in the adrenal, such as 21-hydroxylase deficiency leading to congenital adrenal hyperplasia, there are residues of prostate tissue even in 46,XX individuals.

Development of External Genital Structures

The external genital anlagen is in a bipotent stage around the seventh week of gestation. If no sex steroids are acting on the tissue, female external structures will arise with a clitoris, labia minora and majora. Under the influence of androgens, namely dihydrotestosterone converted peripherally from testosterone through 5alpha-reductase type 2, the phallic structure arising from the genital tubercle will form into a penis with elongation of the urethra to the tip of the phallus. Likewise, the urogenital folds will fuse and form the scrotal folds, while the labia minora are equivalent to parts of the shaft of the phallus in the male. This differentiation will be finished by the end of the twelfth week of gestation and thereafter, high amounts of dihydrotestosterone are needed for the growth of the phallus and of the prostate. Interestingly, these differentiation processes can only take place during very defined and strict time intervals, which represent the previously described 'male programming window'. Elaborate animal model experiments demonstrate that the lack of androgens will lead to a female phenotype regardless of karyotype while androgenization leads to a male phenotype regardless of karyotype.

Thus, human sex development depends to a large extent on the systematic and local synthesis and action of specific hormones, which act in a very distinct spatial and time-dependent manner [76]. The precursor of sex steroids is cholesterol, which is metabolized through a variety of enzymes, which may in part be dependent on adequate co-enzymes and co-factors. The majority of steroidogenic enzymes are P450 (CYP) enzymes, which catalyse redox reactions relying on electron supply via specific electron transfer. Typically, these enzymes are localized in the mitochondria. This applies for instance to the first critical enzyme P450 side-chain cleavage (CYP11A1), 11beta-hydroxylase (CYP11B1), and aldosterone synthase (CYP11A1); in contrast 17alpha-hydroxylase (CPY17A1), 21-hydroxylase (CYP21A2), and aromatase (CYP19A1) are localized to the endoplasmic reticulum. The latter enzymes depend on P450 oxidoreductase (POR) for electron transfer.

The initial step of cholesterol conversion to pregnenolone is crucial and of special interest, because it not only relies on the P450 side-chain cleavage enzyme (P450scc), but in selected organs such as adrenal and testis it needs a specific transporter, the Steroidogenic Acute Regulatory (StAR) protein; StAR promotes a rapid trans-membranous crossing of cholesterol into the mitochondrium. Two very rare conditions have been described due to mutations of either P450scc or StAR. The description of deleterious mutations in P450scc came as a surprise, because it had been thought that this would also hamper severely the placental steroid production and thus not be compatible with life [77, 78]. However, recently mutations have been described which only partially affect P450scc function and lead to minor phenotypes in the DSD spectrum [79, 80]. StAR defects have initially been described in infants with grossly enlarged adrenals, 'congenital lipoid adrenal hyperplasia' [81], due to accumulation of cholesterol within the cytoplasm, but these findings have been challenged in part by other case descriptions [82].

CYP17A1 is an interesting protein with actually two enzymatic capacities, namely the 17alpha-hydroxylase activity and an additional 17,20 lyase activity. The first converts pregnenolone or progesterone to their 17alpha-hydroxylated products, the latter metabolizes these compounds into dehydroepiandrosterone (DHEA) or androstenedione, respectively. The differentiation of the two enzymatic capacities of CYP17A1 is important in the diagnosis of DSD, because of the presence or absence of alterations of the mineralo- and glucocorticoid pathways. Isolated 17,20 lyase deficiency is mostly due to defects in the cytochrome b5, which is an allosteric factor promoting the interaction with POR and CYP17A1 and thus enhancing the 17,20 lyase activity without influencing 17alpha-hydrolyse activity [83].

The 3beta-hydroxysteroid dehydrogenase type 2 (HSD3B2) enzyme is critical, because of its ability to convert pregnenolone and its 17alpha-hydroxylated form into progesterone and 17-OH progesterone, therefore playing an important role in the adrenal for mineralo- and glucocorticoid synthesis. In addition, HSD3B2 converts DHEA directly into androstenedione and thus controls the complete Δ4 steroid synthesis pathway. Mutations affecting HSD3B2 are associated with rare forms of congenital adrenal hyperplasia, but due to its capacity to convert DHEA to androstenedione it should be considered in the differential diagnosis of DSD.

Mainly in 46,XY DSD, defects of the down-stream cascade of testosterone synthesis play an important role. The enzymes are crucial and necessary for male phenotypic development. 17beta-hydroxysteroid dehydrogenase (HSD) type 3 (HSD17B3) synthesizes testosterone from androstenedione. This enzyme is mostly expressed in the testes and primarily acts during fetal development.

However, currently, a number of isoenzymes are known, for instance 17beta HSD type 5 (AKR1C3, aldo-keto reductase family 1 member C3) which may be involved in substantial testosterone synthesis in the testes postnatally, especially at the time of puberty [84]. This may support virilization in patients with 17beta HSD type 3 deficiency during pubertal development despite underlying deleterious mutations [85]. Conversion of testosterone to the more potent dihydrotestosterone (DHT) is mainly not localized in the testes, but directly in the androgen target tissues. Here 5-alpha reductase type 2 (SRD5A2) is the main enzyme, in particular during prenatal development. Lack of DHT due to mutation of *SRD5A2* will lead to

variable phenotypes of under-androgenization from almost completely female external genitalia to only slightly diminished penile size [86]. These patients have a high virilization potential at the time of puberty, mainly due to the effects of testosterone; however, some of DHT may also be synthesized via the 5-alpha reductase type 1 (*SRD5A1*) pathway in these patients. Genetic alterations of *HSD17B3* and *SRD5A2* play a role only in 46,XY male development; in females with homozygous or compound heterozygous mutations, no abnormality in sex development is seen and these women are presumably fertile.

It has recently been demonstrated that 5-alpha reduction of testosterone is not the only pathway of DHT synthesis. Via the so-called backdoor pathway DHT may be produced from androstanediol, a compound that is converted through several steps directly from 17-alpha-hydroxy progesterone and requires CYP17A1 and 17-beta HSD type 3 and type 5, with the latter also known as 3alpha hydroxysteroid dehydrogenase type 2. This alternative mode for DHT synthesis could explain some of the virilization in patients with congenital adrenal hyperplasia due to 21 hydroxylase deficiency, because of the very high substrate levels of 17-OH progesterone [87] (Figure 7.2.1.3).

In humans and other mammals, androgens act via a single androgen receptor (AR) in a very specific manner. Both sexes express the AR, therefore the appropriate levels of androgens promote male sex development of an individual. The AR is a single-copy gene localized on the X-chromosome at Xq11–12. Due to the hemizygous state of the gene in 46,XY individuals, mutations in the AR gene directly affect male sex development. The AR acts as a typical nuclear receptor via transcriptional regulation of defined target genes. The genetic and functional structure of the AR is of interest as numerous studies have been performed to explain a genotype-phenotype correlation in androgen insensitivity syndrome (OMIM #300068), but also in conditions relating to other functions of the AR, such as spinobulbar muscular atrophy (SBMA, OMIM #313200) or the role of the AR in prostate cancer. The gene is composed of 8 exons, where the first large exon encodes for the variable N-terminal domain, exons 2 and 3 for the DNA-binding domain, and exons 5–8 for the ligand-binding domain. The N-terminal domain contains two variable repeat regions, a CAG and a GGN repeat, which have been associated with aspects of androgen action. Elongation of the CAG-repeat has been associated with sub- or infertility [88], and very expanded CAG repeats may lead to spinal and bulbar muscular atrophy [89].

The AR initially resides in the cytoplasm and is bound to a complex of heat-shock proteins, chaperones, and co-chaperones. Ligand-binding induces a conformational switch, involving N- and C-terminal interaction, which eventually unmasks a nuclear localization signal. The ligand-bound AR translocates rapidly into the nucleus, which again may involve a number of heat-shock proteins and immunophilins. Within the nucleus, the AR forms a homodimer and binds to androgen-response elements within the target DNA. Some of these elements may also be recognized by other steroid receptors, but the AR can bind to selective androgen-response elements, also involving specific co-regulator proteins, which enhance

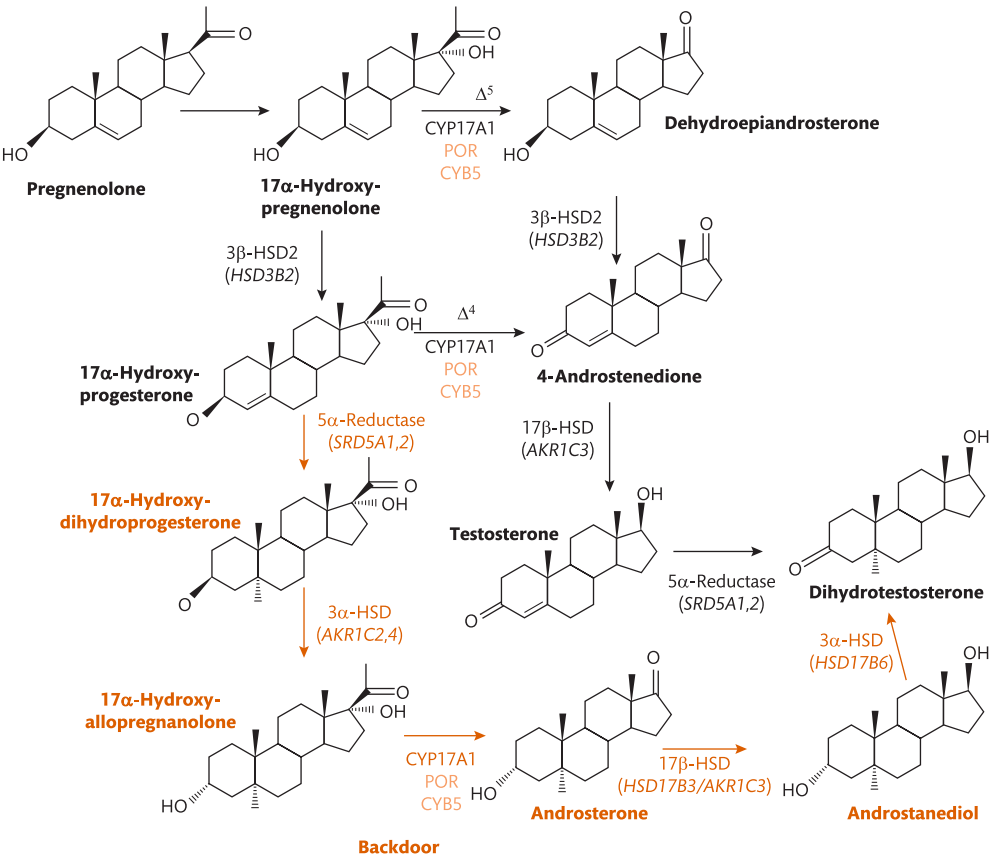

Figure 7.2.1.3 The 'backdoor' pathway of dihydrotestosterone synthesis.

or supress AR-dependent transcription of target genes. Many co-factors possess enzymatic activities that lead to post-translational modifications including phosphorylation, acetylation, methylation, ubiquitination, sumoylation, and ADP-ribosylation. More than 300 different AR-interacting proteins have been described, but their role in DSD conditions remains unclear. Analysis of AR-dependent transcription of target genes demonstrates that cell-specific classes of genes may be up- or downregulated.

Interestingly, different androgens can elicit different effects via the single AR, as has been shown in elegant cellular model studies [90]. This is also seen in normal sex development with the different actions of testosterone and DHT or even androstenedione and is exemplified by DSD conditions due to mutations in the aforementioned enzymatic pathways.

This may be due to the different binding capacities of the various androgens, but also due to cellular metabolism within the target cells, as demonstrated by DHT synthesis in cells harbouring the 5-alpha reductase enzyme. Furthermore, AR action is, in common with other nuclear receptors, dependent on cell- or tissue-specific coregulators, which may also be expressed in a time-dependent manner [91]. Hence, androgen-related genital and sex development will arise from very specific gene expression patterns regulated through the AR [92, 93]. This effect is irreversible, and genetic signatures will be present throughout life representing the sexual phenotype of an individual. Each individual may have a specific 'androgen response index', which may reflect the variability in all humans, but may be specifically altered in people with DSD conditions [76].

The Role of Oestrogens in Prenatal Development

Currently, little is known about the role oestrogens play in prenatal sex development. We know from patients with complete gonadal dysgenesis, who presumably have no gonadal function and therefore should have a lack of systemic oestrogen synthesis, that sex development is comparable to other 46,XX females. However, the fetus is usually exposed to oestrogenic steroids via the placenta and therefore should receive some general effects through these compounds. Some endocrine disrupting compounds are actively enriched in the fetus, such as bisphenol A, and we are now recognizing their effects both on fertility and sexual behaviour of exposed fetuses [94].

Brain Sexual Differentiation

Mammalian sex development is not restricted to genital tissues. Functional studies in mouse models demonstrate that up to three quarters of all genes will be transcribed in a sex-dimorphic expression pattern [95]. This includes also the brain, which is of course of high interest in DSD, because this will influence the psychological aspects of sex including gender identity, gender role behaviour and sexual orientation. The latter are developed through biological factors (genes and hormones) as well as through modification of psychological, social, and cultural factors. In part, a sex-specific gene expression signature is already present in the brain before gonadal differentiation sets in [96]; however, for more than 30 years the additional influence of perinatal androgens on the sex-specific development of certain brain regions has been recognized [97]. Sex differences may characterize specific neural regions, such as the pre-optic area, the bed nucleus of the stria terminalis, the medial nucleus of the amygdala, the ventromedial nucleus of the hypothalamus, the arcuate nucleus, and the cerebral cortex.

In general, sex steroids will play an activating and an organizational role in brain and behavioural development. While activating influences are transient and correspond to a waxing and waning of hormone levels (e.g. associated with sexual interest), organizational aspects are permanent and will, as in sex determination and development in general, not be changed throughout life. Significant differences in DNA methylation are encountered between males, females, and also masculinized females [98]. This aspect is also the core understanding of those increasing voices that describe people with DSD living as intersex persons, and has already led to the recommendation not to assign a usual sex to affected persons or even to develop further positions on variant sex assignment.

Perinatal hormone exposure may influence behavioural patterns. For instance, if female rats are treated with testosterone during the first days of life, they lose the typical female reproductive behaviour and instead develop male behavioural patterns. This demonstrates that early post-natal androgens may influence permanently organizational structures in the brain. In contrast, peripheral oestrogens may play only a minor role in female-typical behavioural patterns, with levels modulating qualitative behavioural aspects. However, there are suggestions that testosterone may pass the blood–brain barrier and may be aromatized in the brain to local oestrogens, which then promotes masculinizing brain effects [98].

Throughout life, the diminishing of sex hormone levels may lead to different peripheral and central patterns of change in stress response systems in male and female rats [99], thereby implying a sex difference for different mood disorders like depression.

Conclusion

Recently it has become increasingly clear that sex development is not a simple pathway leading to robust different poles of male and female. Rather, sex development starts from a common trunk allowing numerous alterations of phenotype through genetic and endocrine programming and is also susceptible to cultural and social influences in humans. While the identification of the effects of sex and gender factors from molecular to genomic sciences has led to recognition of male and female differences in health and disease, a general appreciation and acceptance of broad variability within and between the sexes is only partially acknowledged at this time. It will need further understanding of the developmental processes and a linkage with social sciences to comprehend the continuum of human sex development.

7.2.2 Disorders of Sex Development (DSD) in the Newborn

S. Faisal Ahmed and Salma R. Ali

Introduction

The birth of a new baby is one of the greatest wonders of nature and one of the most exciting events known to humankind. The first question that is usually posed by the new parent is 'is it a boy or a girl?'; without this information the parents cannot even formulate the second question which is usually 'is he/she alright?'. It is no wonder that the birth of a child with an abnormality of genital development where the sex of rearing is uncertain at birth, presents difficult clinical and ethical issues. However, the recognition of genital ambiguity may depend on the expertise of the observer. Whilst the prevalence of genital anomalies at birth may be as high as 1 in 300 births [1], the prevalence of complex anomalies that may lead to true genital ambiguity may be as low as 1 in 5000 births [2]. Rather than treating every affected child as a medical emergency, it is paramount that such a child is assessed by an expert with adequate knowledge about the range of variation in the physical appearance of genitalia, the underlying pathophysiology of disorders of sex development and the strengths and weaknesses of the tests that can be performed in early infancy. This expert should ensure that the parents' needs for information are comprehensively addressed while appropriate investigations are performed in a timely fashion. This expert needs to have immediate access to the multidisciplinary team that is essential for the management of such a child. In the field of rare conditions, it is imperative that the clinician shares the experience with others through national and international clinical and research collaboration. The I-DSD registry is an example of how registries can facilitate international collaboration to address issues ranging from fundamental mechanisms to clinical outcomes [3].

Terminology

The use of terminology which is clear, easy to use and understood by all health professionals, patients and their families is fundamental to the management of affected newborns and children. In addition, terminology should respect the individual and avoid terms which might cause offense. The term 'intersex' has had variable connotations even within professionals; some employed it as a term that covered all affected newborns whilst at the other end of the spectrum, some believed that the term should only apply to those where there is complete mismatch between chromosomal and anatomic sex. The consensus reached in 2005 on management of these patients, stressed the importance of the aspect of terminology and recommended substitution of the term 'intersex' with 'disorder of sex development (DSD)' which is defined as any congenital condition in which development of chromosomal, gonadal or anatomic sex is atypical [4]. It also recommended the abandonment of terms such as 'pseudohermaphroditism' and 'true hermaphroditism'. Whilst, the new nomenclature (Table 7.2.2.1) is easier to use and understand, and helps the professional planning investigations, it will nevertheless evolve over time as our understanding of long-term outcome, as well as molecular aetiology, improves. Given that atypical genitalia may occur as commonly as 1 in 300 births and may not always be associated with a functional abnormality, some have advocated the use of 'differences' in preference to the term 'disorder' [5, 6]. The strength of the acronym 'DSD' is that it can be used to cover both differences and disorders of sex development. The likelihood of this difference existing as a disorder will depend on the functional implications of the condition which may be heavily influenced by the social and cultural framework within which the child exists [7].

General Principles of Management

Optimal clinical management of infants with DSD should comprise the following principles:

- All newborn infants should receive a male or female sex assignment.
- When there is any doubt about sex assignment, a hasty decision must be avoided prior to expert evaluation.
- Whilst all specialist neonatal units should be expected to be able to stabilize the critically unwell infant with a DSD, comprehensive evaluation and the development of a plan for long-term management must be performed at a specialist centre with an experienced multidisciplinary team.
- The specialist centre should be able to complete first-line investigations quickly which are sufficient for deciding sex assignment and excluding immediate medical concerns. The centre should be able to develop a plan for second-line investigations that will guide long-term management.
- Management should be patient-centred, holistic, and as far as possible, evidence-based. Decisions which are not evidence-based should be explained to the family.
- Patient and family concerns should be respected and addressed in strict confidence.
- Open communication with patients and families is essential and participation in decision-making is encouraged. The multidisciplinary specialist team should have the ability to arrange, or preferably, provide, long-term care from infancy to adulthood in the affected individual.

Communication

The initial contact with the parents of a child with a DSD is important as first impressions from these encounters often persist. A key point to emphasize is that the child with a DSD has the potential to become a well-adjusted, functional member of society. The use of the phrase 'differences in sex development' may be particularly beneficial in introducing the concept of the range of variation in sex development that can be encountered to those with little prior knowledge of the field. It should be emphasized that DSD is not shameful. In those cases where there are no doubts about sex assignment, it should not be assumed that the parents' need for information and psychological help are any less (Table 7.2.2.2). The parents' perception of risk may be quite different from the clinical perception of the severity of illness [8]. In those cases where there is true genital ambiguity, it should be explained to the parents that the best course of action may not initially be clear, but the healthcare team will work with the family to reach the best possible set of decisions in the circumstances. The healthcare team should discuss with

Table 7.2.2.1 The classification of DSD

Disorder of gonadal development	Disorder of androgen synthesis	Disorder of androgen action	Disorder of androgen excess	Leydig cell defect	Persistent Müllerian duct syndrome	Defects of Müllerian development	Non-specific disorder of undermasculinization	Other

the parents what information to share in the early stages with family members and friends. It is essential that the parents do not register the birth until the sex of rearing is established. Parents need to be informed about sex development; they should be provided with written information and directed to internet-based information (Box 7.2.2.1). Ample time and opportunity should be made for continued discussion with review of information previously provided.

The Multidisciplinary Team

Optimal care for children with DSD requires an experienced multidisciplinary team that is generally found in regional centres. The team may exist as a clinical network with links to other children's centres (Scottish DSD Network, https://www.sdsd.scot.nhs.uk). Ideally, the team includes paediatric subspecialists in endocrinology, surgery and/or urology, psychology/psychiatry, gynaecology, genetics, neonatology, nursing and, if possible, social work, and medical ethics. Core composition will vary according to DSD type, local resources, developmental context, and location. The team has a responsibility to educate other healthcare staff in the appropriate initial management of affected newborns and their families and should also have the ability to review and discuss its own performance through audit of clinical activity and attendance at joint clinics and education events. For new infants with a DSD, the team should develop a plan for clinical management with respect to diagnosis, gender assignment and treatment options before making any recommendations. Ideally, ongoing discussions with the family are conducted by one professional with appropriate communication skills. Transitional care should be organized with the multidisciplinary team operating in an environment comprising specialists with experience in both paediatric and adult practice. Support groups have an important role to play, and their contact details should be supplied to the parents, it is possible that affected parents may prefer to talk to local families

Table 7.2.2.2 Themes, subthemes, and percentage of parents who raised the theme during qualitative interview about the parents' own experience during the early years of their affected child's life

affected in a similar way. The availability of such a local pool of voluntary helpers who had some support from the specialists would complete the composition of the multidisciplinary team.

Clinical Evaluation of the Infant with a Suspected DSD

The infant with a suspected DSD may need evaluation for a few reasons. Firstly, there may be a need to determine the sex of rearing. Secondly, there may be concerns about immediate, life-threatening metabolic conditions that are more likely to be associated with certain diagnoses that are, for instance, associated with adrenal insufficiency. Thirdly, an improved knowledge of the aetiology of the underlying condition may allow the development of a long-term management plan. Fourthly, continued evaluation over the longer-term will allow the affected individuals and their care-providers to understand issues such as fertility, sexual function and the risk of tumour development and help with informed disclosure of the diagnosis itself. Finally, the process of evaluation also allows the creation of rapport with the patient and the parents.

Initial Approach

It is very likely that the clinician from whom a specialist opinion is sought will encounter the infant and the parents after the family have already been seen by other health professionals. Their anticipation of meeting someone who can answer all their questions, provide them with reassurance and solve all the problems can be a daunting and impossible task for a single clinician, irrespective of their level of expertise. It is likely that this clinician will form a long-lasting relationship with this family and over time with the help of the multidisciplinary team will be able to address most of the issues mentioned. It is, therefore, very important to have a positive and systematic approach for the first encounter with the family with emphasis on the general well-being of the child.

History

An adequate history should concentrate particularly on:

Family history: Parental consanguinity, history of an infant with salt-losing, unexplained infant deaths, or DSD in relatives. These elements may indicate autosomal recessive genetic disorders associated with disturbed steroidogenesis (usually CAH). In contrast, an X-linked recessive mode of inheritance is suggestive of androgen insensitivity syndrome (AIS).

Antenatal history: Maternal ingestion of drugs which may cause fetal virilization (androgens), or signs of maternal androgen excess which may indicate a maternal androgen secreting tumour; Exposure to specific environmental factors able to inhibit virilization of the fetus. Some assisted conception techniques include progestogen-containing drugs and these methods increase the likelihood of male offspring with genital anomalies.

Information about antenatal counselling and results of prenatal tests: Knowledge of what has already been discussed with the parents by health professionals, and their understanding of the information, is essential.

Social history: An enquiry about the family social network, parents' general understanding of DSD and their current concerns.

General Examination

The general physical examination should determine whether there are any dysmorphic features and the general health of the baby. Affected infants, particularly those who have XY DSD, are more likely to be small for gestational age and may display other developmental anomalies [1, 9, 10]. In addition to a systematic examination, the affected infant should be examined for mid-line defects which may point towards an abnormality of the hypothalamo–pituitary axis. The state of hydration and blood pressure should be assessed as various forms of adrenal steroid biosynthetic defects can be associated with differing degrees of salt loss, varying degrees of masculinization in girls or under-masculinization

in boys, or hypertension. The cardiovascular collapse with salt loss and hyperkalaemia in congenital adrenal hyperplasia does not usually occur until the second week of life (with salt loss usually evident from day 4) and so will not be apparent at birth in a well neonate, however, it should be anticipated in a suspected case. Jaundice (both conjugated and unconjugated) may be observed in cases of hypopituitarism or cortisol deficiency. The urine should be checked for protein as a screen for any associated renal anomaly (e.g. Denys–Drash/Frasier syndromes) and a pre-feed blood glucose should be checked for hypoglycaemia (suggestive of hypopituitarism, or occasionally in CAH e.g. 3βHSD deficiency). Renal tract anomalies such as ureteropelvic junction obstruction, vesicoureteric reflux, pelvic or horseshoe kidney, crossed renal ectopia, and renal agenesis may occur in as many as 1% and 5% of cases with isolated distal and proximal hypospadias, respectively [11].

Examination of the External Genitalia

A detailed physical examination and documentation of the genitalia is necessary to evaluate the degree of genital anomaly. The first step is careful inspection and palpation. In a number of infants, gonads or swellings may be visible in the labioscrotal folds or the inguinal regions but they may disappear on palpation. In those presenting with apparently normal female external genitalia, bilateral hernias containing testes (and, rarely uterus or fallopian tubes) should be sought by palpation. In any case, if gonads are palpated externally, these will be testes (ovaries tend to remain in the pelvic position) or, rarely, ovotestes. A careful measurement of the phallus (stretched dorsal length) and comparison to published normative data [4] is recommended to assess the extent of deviation of the appearance from normal and to explain this difference to the parents. The presence or absence of a chordee should be noted; the location of two (urethral and vaginal) or one orifice (urethral or urogenital sinus) that opens on the dorsal (epispadias) or ventral surface (hypospadias) of the phallic structure should be noted. An epispadias is a very rare condition and is usually part of a spectrum of conditions (bladder and cloacal exstrophy) where there can be a failure of fusion of a number of lower abdominal and pelvic organs including external genitalia. Hypospadias is a much commoner condition where the location of the urethral orifice may be proximal and close to the perineum, mid-shaft or distal and close to the coronal sulcus or the glans. A shorter anogenital and anoscrotal distance may correlate with the severity of hypospadias [12]. The description of the degree of labioscrotal fold fusion, i.e. complete absence of scrotal fusion, a posterior fusion of labia majora, a partially fused hemiscrotum or completely fused scrotum is also very important. Finally, the nature of the skin of the genitalia and labioscrotal folds (texture and pigmentation) and the shape of the folds and whether they are sac-like provides helpful information on androgenization and the possibility of finding testes.

Although scoring systems such as the Prader scoring system for XX DSD [13] and modifications of this system for XY DSD [14, 15] may provide an integrated summary description of the genitalia, these scoring systems are not sufficiently discriminatory to portray the full spectrum of the variation encountered in the external genitalia. The external masculinization score (EMS) which scores external genitalia individually for scrotal fusion, microphallus, location of urethral meatus and location of each gonad may be a more objective method of describing the external appearance [16] (Figure 7.2.2.1).

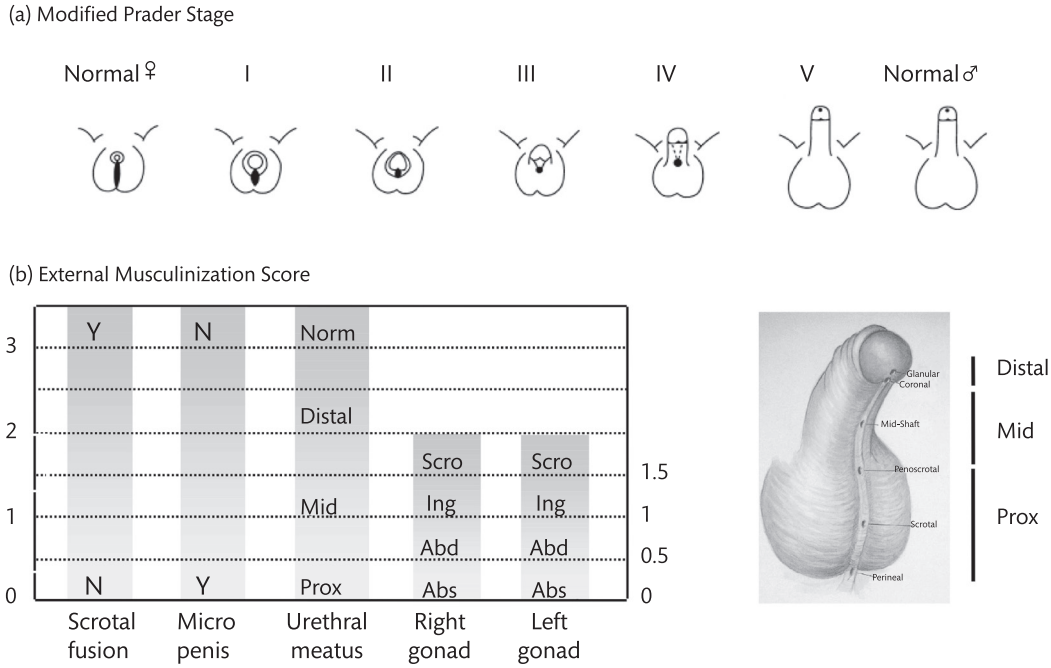

Figure 7.2.2.1 Scoring external genitalia.

Why Investigate

There are clear reasons for investigating an infant with genital anomalies and these include determination of sex of rearing, concerns about early medical problems, concerns about medical and surgical problems in later childhood and development of a long-term plan that anticipates future health issues such as sexual development and function, tumour risk and fertility. A clear knowledge of the underlying aetiology may also facilitate explanation of the condition to the parent and the older child. Thus, investigations should be performed with these different objectives in mind and should be split into first-line and second-line investigations. First-line investigations should, in most cases, be sufficient to guide sex of rearing, exclude early medical problems and provide an idea of the nature of the problem. In the newborn infant, detailed dynamic endocrine investigations should only be performed if they can alter the management of the child; in most cases these investigations can be performed after 3 months when many reproductive and adrenal-related hormones have reached a status quo and the results are easier to interpret. Furthermore, collecting blood samples may be simpler in the older child and collection of multiple blood samples from an otherwise well infant may exert unnecessary stress on the child's parents.

Which Infant Should be Investigated?

Most infants with a suspected DSD will present with:

- overt genital ambiguity
- a family history of DSD such as complete androgen insensitivity syndrome
- a discordance between genital appearance and a prenatal karyotype
- apparent female genitalia with an enlarged clitoris and posterior labial fusion
- apparent female genitalia with an inguinal/labial mass
- apparent male genitalia with bilateral undescended testes
- apparent male genitalia with a microphallus
- apparent male genitalia with proximal hypospadias
- apparent male genitalia with distal or mid-shaft hypospadias with undescended testis

The greatest amount of debate regarding the need for investigation involves the case of the boy presenting with hypospadias and/or cryptorchidism (i.e. the undermasculinized boy). Considerable variation exists about the extent to which these infants should be investigated [17]. Routine systematic examination of 423 consecutive newborn boys in one hospital revealed that 412 (98%) had an EMS of 12. The median (tenth centile) EMS for the group of 11 infants with an EMS of less than 12 was 11 [10, 16]. One infant with isolated micropenis had an EMS of 9; three infants with isolated glandular hypospadias had an EMS of 11; three infants with absent unilateral testis also had an EMS of 11; four infants with a unilateral inguinal testis had an EMS of 11.5. Thus, an EMS of less than 11 was only encountered in 1/423 boys [16]. These data are similar to population data suggesting that genital anomalies occur in about 1:300 total births and 75% of these patients have an associated hypospadias [1]. Population studies also suggest that approximately 50% of hypospadias cases affect the distal penis (glandular or coronal) [18]. The largest study to date of karyotype analysis in children with isolated cryptorchidism, isolated hypospadias or a combination of the two anomalies revealed chromosomal anomalies in 27 of the 916 patients with cryptorchidism (2.94%) and in 7 of the 100 with hypospadias (7%) and in 4 of the 32 with a combination of cryptorchidism and hypospadias (12.5%) [19]. The incidence of chromosome anomalies was 1.8% in cases of isolated cryptorchidism and 6.7% in those with other associated anomalies. In patients with hypospadias, abnormal karyotypes were only detected when there were additional congenital abnormalities. In one specialist centre, out of 63 unselected cases with proximal hypospadias (penoscrotal, scrotal, perineal) who were studied for all known causes of hypospadias with clinical as well as molecular biological techniques, an underlying aetiology was identified in 31% of cases. Of these 31% of cases, 17% were due to complex genetic syndromes, 9.5% were due to chromosomal anomalies and 1 involved the vanishing testes syndrome, the androgen insensitivity syndrome and 5 alpha-reductase type 2 deficiency, respectively [20]. Thus, infants who require further evaluation and investigation should include all children with EMS of less than 11 and all children with familial hypospadias. This will avoid detailed investigations of boys with isolated glandular hypospadias and boys with isolated inguinal testes.

First-Line Investigations

Typically, in the young infant with DSD, gonadal palpability combined with karyotyping, ultrasound examination for Müllerian structures and determination of 17-hydroxyprogesterone level should provide a reasonable guide for the initial practical management of the newborn with a DSD (Figure 7.2.2.2). Karyotype is indicated in all such cases of atypical genitalia and even when prenatal karyotype is available. The results of the karyotype and the ultrasound should be available within 48hrs of presentation. Whilst FISH or PCR analysis using X and Y specific probes is sufficient for initial management it is recommended that these tests are confirmed by a formal karyotype. It also needs to be borne in mind that any mosaicism that is evident may be tissue dependent. Ultrasound is the imaging modality of choice in newborns and if this is difficult to perform, then a laparoscopy should be considered especially as dysgenetic gonads are not clearly delineated by MRI. Genitograms are not as frequently carried out and have been replaced with cystoscopy/genitoscopy in most specialist centres [21, 22].

Due to the effects of stress of labour, and insufficient time for accumulation of hormone in CAH, a sample for 17-hydroxyprogesterone may be difficult to interpret in an infant who is less than 36 hours old. Besides 17-hydroxyprogesterone, biochemistry tests should include serum testosterone, anti-Müllerian hormone (AMH), cortisol, androstenedione, ACTH, gonadotropins, a sample for DNA extraction, and urine for analysis and steroid profile. It is likely that the biochemistry results will be available within a week. Any spare sample should be stored for analysis at a later date. Given that steroid hormones and gonadotrophins fluctuate over the first few weeks of life, serial measurements are particularly valuable. Infants with salt-losing forms of congenital adrenal hyperplasia may start to show biochemical signs of salt loss from day 4, with a rise in potassium being the earliest sign. Whilst it is safest to provide salt and mineralocorticoid where salt loss is suspected, it is also important to establish the diagnosis for long-term management. Urinary electrolytes are unhelpful. Sending a sample for plasma renin activity or measuring renin concentration prior to treatment can be helpful retrospectively,

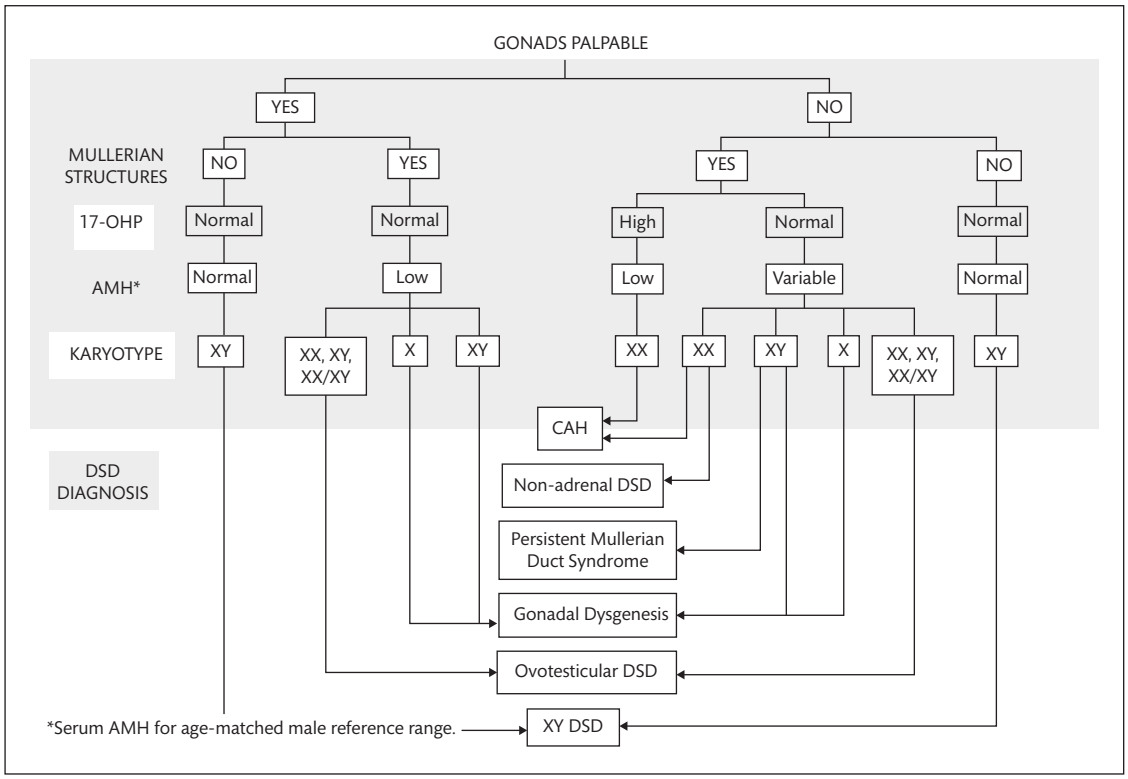

Figure 7.2.2.2 The use of first-line investigations in the newborn.

A 5-year-old boy with cryptorchidism and pubic hair: investigation and management of apparent male disorders of sex development in mid-childhood. *Horm Res.* 2009 Jan;71 Suppl 1:87–92. doi: 10.1159/000178046. Epub 2009 Jan 21.

and genetic analysis in CAH is informative. Monitoring weight is useful in any infant where there is a risk of salt loss.

Serum testosterone estimation has often been used as a marker of functioning testes as well as a sign of intact pathways for the synthesis of testosterone. However, given that many commercially available testosterone assays are non-specific in the early neonatal period [23] and can cross-react with other conjugated steroids, it is possible that for the newborn infant serum AMH level is a more diagnostically reliable marker of testes than serum testosterone. AMH is a useful tool to assess Sertoli function in suspected DSD and may have diagnostic utility in conditions associated with androgen deficiency or insensitivity [24]. There is a clear difference between AMH concentration in boys and girls, especially in early childhood. In boys under the age of 8 years, a serum AMH concentration of 200 pmol/L may be an appropriate cut-off to denote normality, given that it was the approximate tenth centile for this age range. However, AMH concentrations are generally higher in the young boy before they fall in late childhood (Figure 7.2.2.3). It should also be noted that AMH concentrations tend to rise over the first 3 months in some young infants [25] and may in some cases be lower than 200 pmol/L at initial

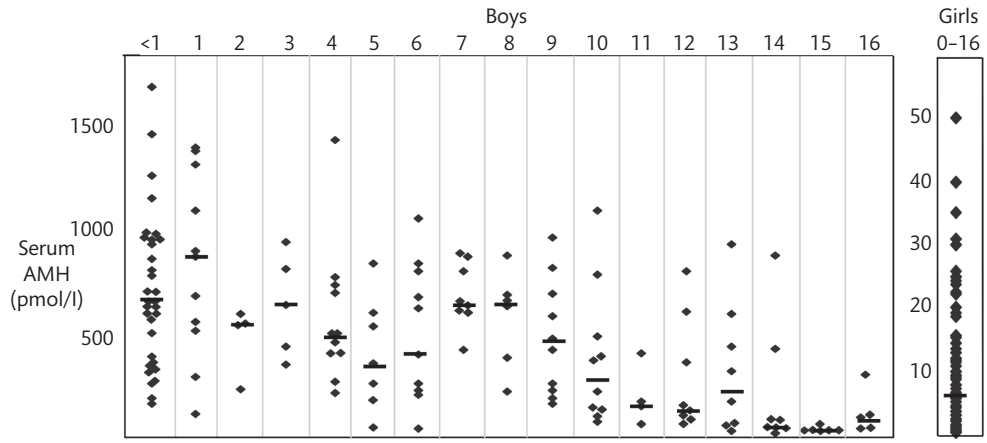

Figure 7.2.2.3 AMH concentration in boys and girls.

evaluation, although still above 25pmol/L which approximately represents the 90th centile for girls [26].

Second-Line Investigations

In most cases these tests are performed to investigate the underlying aetiology but are usually not necessary to determine the sex of rearing.

These investigations could include:

- Biochemistry to assess the gonadal and adrenal axes- hCG Stimulation to assess production of testosterone, androstenedione, dihydrotestosterone (DHT), 11-deoxycortisol and 17-hydroxypregnenolone. To detect abnormalities of the last three steroids, it may be more effective to analyse a urine steroid profile (spot or 24 hr) by gas chromatography-mass spectrometry (GC-MS). Other biochemical investigations that may need to be considered include LHRH, ACTH stimulation, renin, and aldosterone. Measurement of serum cholesterol and 7-dehydrocholesterol are indicated in the child who has features consistent with Smith–Lemli–Opitz syndrome.
- Imaging: ultrasound scan, MRI, genitogram.
- Internal surgical examination: cystourethroscopy, laparoscopy.
- Pathology: gonadal biopsy; there are, however, unresolved questions as to whether one biopsy represents the whole gonad. In addition, it is unclear as to what is the minimum amount of ovarian or testicular tissue that should be present to classify the gonad as an ovotestis.
- Genetics: high resolution karyotype, karyotype from different tissues (blood, skin, gonads), DNA for storage and analysis. Molecular genetic investigations are increasingly being performed at an earlier stage (Figure 7.2.2.4) in the diagnostic process [27].
- Functional studies of androgen sensitivity: a functional assessment of androgen sensitivity can be performed by assessing the clinical response of testosterone on the phallus. Secondly, androgen sensitivity can be assessed by measuring change in an androgen-responsive circulating protein such as sex hormone binding globulin (SHBG); SHBG levels should fall following androgen exposure and a failure to show this reduction may be indicative of androgen insensitivity [28]. The utility of this test in the young infant is unclear given that circulating SHBG is very variable in the young infant. Androgen binding studies involve evaluation of the concentration of androgen receptors; the number of receptors and their affinity for testosterone are measured on cultured genital skin fibroblasts. However, the results may depend on the site from which the skin is originally collected. Over 80% of cases with a phenotype consistent with complete androgen insensitivity syndrome and abnormal androgen binding may have a variant in the androgen receptor (*AR*) gene [29]. However, in cases consistent with a partial androgen insensitivity syndrome phenotype, only 50% of cases with abnormal binding may have a variant in the androgen receptor gene. Given that AR analysis may reveal a variant in over 80% of cases with a CAIS phenotype anyway, there probably is no need to perform androgen binding studies in this group of infants. However, the yield of AR variants in PAIS is much lower at less than 30%. Boys with PAIS and a variant in the *AR* may have poorer clinical outcomes, thus, routine genetic analysis of *AR* to confirm PAIS will inform long-term prognosis and management [30]. It is also possible that in some cases of AIS, the gene variant may exist beyond the *AR* coding region. Identification of such cases of AIS will be challenging and may require more complex tools such as measurement of androgen responsive proteins in genital skin fibroblasts [31] or measurement of androgen responsive peripheral transcriptome [32].

The hCG Stimulation Test

Although controversy exists regarding the optimal regimen, stimulation with human chorionic gonadotrophin (hCG) has been used to assess the presence of functioning testicular tissue and the detection of defects in testosterone biosynthesis and action for over 40 years [33]. In the UK, a number of different protocols are used for hCG stimulation but most use intramuscular hCG 1000–1500 units on 3 consecutive days for a standard test [17]. If there is a poor response, this test can be followed by prolonged hCG stimulation 1500 units on 3 consecutive days for the first week followed by 1500 units on 2 days a week for the 2 following weeks. The definition of a normal response may depend on the age of the child and the regimen itself. In infants and older children, who have a more active gonadotrophin axis, the Leydig cells may be more responsive to hCG stimulation and the shorter duration of hCG stimulation may be sufficient [34]. Recently, in an older group of children with suspected hypogonadotropic hypogonadism, cut-off for a normal testosterone response has been reported to be at 3.5 nmol/L after 3 days of stimulation and 9.5 nmol/L after the 3 week stimulation regimen [35]. Besides testosterone, other androgens that should be assessed include dihydrotestosterone and androstenedione. For these two metabolites, the day 4 sample is more important than the day 1 sample. There is no additional benefit of collecting a sample for these two metabolites on day 22.

Aetiology of XX DSD

46,XX DSD can be divided into disorders of ovarian development, disorders of androgen synthesis, disorders of Müllerian development and other conditions affecting sex development.

The most common cause of 46,XX DSD with ambiguous genitalia in newborns is congenital adrenal hyperplasia (CAH). It is characterized by androgen excess and a variable alteration in glucocorticoid and mineralocorticoid function and a specific profile of steroid hormones. This profile can identify enzyme defects including deficiency of 21α-hydroxylase (90–95% of cases), 11β-hydroxylase (4–8% cases), 3β-hydroxysteroid dehydrogenase type 2 (rare), and P450 oxidoreductase (unknown prevalence). Other causes of androgen excess leading to masculinization of XX individuals including P450 aromatase deficiency, maternal androgen excess, and androgenic tumours in pregnant mothers (e.g. luteoma) are relatively infrequent, however, these should be considered in the differential diagnosis of maternal/fetal virilization.

Disorders of Gonadal Development

46,XX Ovotesticular DSD (Formerly Known as 'True Hermaphrodites') and 46,XX Testicular DSD ('46,XX Males')

Rarely, the developing ovary may contain some testicular tissue (Ovotesticular DSD) or may develop as a functioning testis that secretes adequate amounts of testosterone for adequate virilization and AMH for regression of the Müllerian ducts (testicular

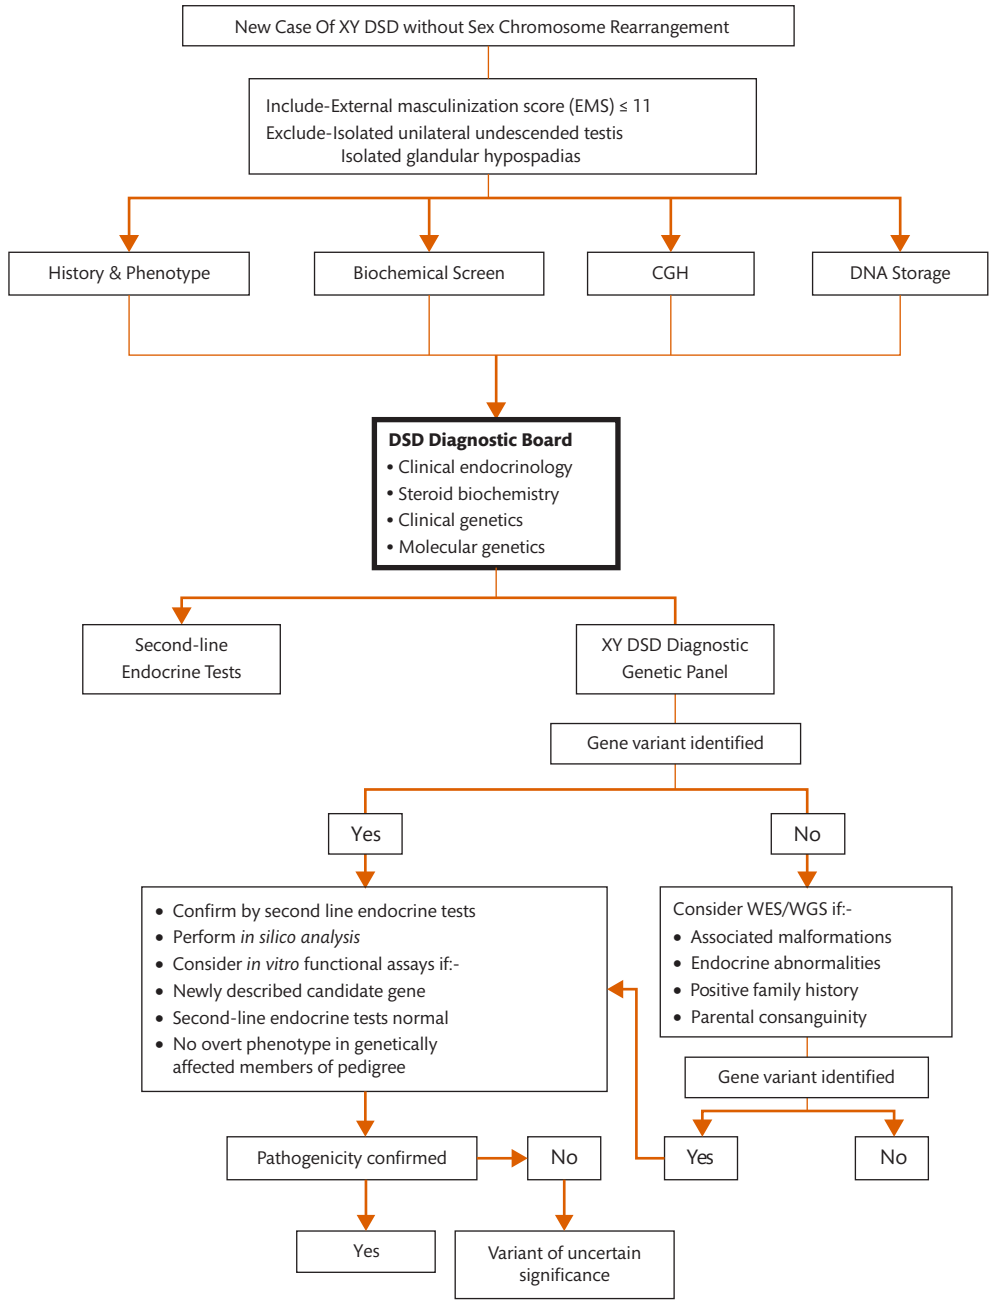

Figure 7.2.2.4 Suggested pathway for investigating cases of 46,XY disorder of sex development (DSD) through an integrated endocrine and genetic approach that relies on a joint DSD diagnostic board with expertise in endocrinology, steroid biochemistry, clinical genetics and molecular genetics.

Reproduced with permission from Alhomaidah D, McGowan R, Ahmed SF. The current state of diagnostic genetics for conditions affecting sex development. *Clin Genet*. 2017 Feb;91(2):157–62. doi: 10.1111/cge.12912.

DSD). The incidence of 46,XX testicular DSD is estimated to be 1 in 20 000. Ovotesticular DSD can be subclassified according to the type and location of the gonads. Lateral cases (20%) have a testis on one side and an ovary on the other. Bilateral cases (30%) have testicular and ovarian tissues present bilaterally as ovotestes. Unilateral cases (50%) have an ovotestis present on one side and a normal ovary or testis present on the other side. In ovotesticular DSD, the initial manifestations are ambiguous genitalia in almost all cases and the internal duct structures display gradations between male and female. There is often a urogenital sinus and a uterus or a hemi- or a rudimentary uterus on the side of the ovary or ovotestis. Breast development will occur in puberty and even menses may occur in a significant proportion when ovarian tissue is present. However, without removal of testicular tissue, these children will also proceed to virilize at puberty. Presence of functional testicular tissue can be investigated by checking AMH or testosterone levels following hCG stimulation. Assessment of functioning ovaries by biochemical markers has not been thoroughly explored and the utility of measuring oestradiol after repeat FSH stimulation or measurement of an ovarian specific marker such as Inhibin A requires further study. Two-thirds of affected children are raised as boys (see section, 'Sex Assignment in the Affected Newborn'). If the testicular components

are removed, serial AMH levels may allow adequate confirmation of complete removal of functioning testicular tissue. In contrast, 46XX testicular DSD is usually associated with a normal male phenotype or a relatively mild abnormality of the male genitalia, such as distal or mid-shaft hypospadias. In adulthood, although testosterone synthesis is not affected, spermatogenesis is usually severely affected.

Ovarian Dysgenesis

Ovarian dysgenesis is most frequently seen in association with sex chromosome aneuploidy such as Turner syndrome and related variants. However, these conditions do not present in infancy with physical abnormalities of sex development.

Disorders of Androgen Excess

21α-Hydroxylase (CYP21) Deficiency

Congenital adrenal hyperplasia due to 21-hydroxylase deficiency is the commonest cause of 46XX DSD, accounting for up to 95% of all cases. Consensus guidelines exist for the management of this condition in infancy as well as in the older child [36]. The newborn girl with this condition can be virilized to a varying extent, as illustrated by the Prader classification (Figure 7.2.2.1). High serum concentration of 17OH-progesterone (>300 nmol/L) after the first 48 hours of birth and high androstenedione and testosterone in the early neonatal period are the biochemical hallmarks of this condition. More than 75% of these infants will also be salt losers because of a deficiency of mineralocorticoid synthesis and the affected child will present with a salt losing crisis in the second or third week of life.

3β-Hydroxysteroid Dehydrogenase (HSD3B2) Deficiency

3β-hydroxysteroid dehydrogenase type 2 catalyses the conversion of Δ^5 steroids to Δ^4 steroids and a deficiency of this enzyme results in adrenal insufficiency as well as accumulation of pregnenolone, dehydroepiandrosterone (DHEA), and androstenediol. In peripheral tissues, as well as the placenta, the accumulating steroids, and particularly DHEA, can be converted to more potent androgens, such as testosterone, by the Type 1 isoenzyme. Most girls with this condition present with relatively mild signs of virilization such as clitoromegaly, associated with adrenal deficiency.

P450 Oxidoreductase (POR) Deficiency

Defects in P450 oxidoreductase can cause combined deficiencies of 21α-hydroxylase, 17α-hydroxylase, and aromatase enzymes and this can be associated with abnormal genital development in both girls and boys. Children with this condition usually have cortisol deficiency, but have normal mineralocorticoid function.

11β-Hydroxylase (CYP11B1) Deficiency

This is the second commonest cause of virilizing congenital adrenal hyperplasia accounting for approximately 5% of all cases. Apart from a DSD, this condition may also be associated with hypertension and hypokalaemia, but these abnormalities are not universally present, particularly, not in infancy. These abnormalities are due to the accumulation of 11-deoxycorticosterone which is a weak mineralocorticoid. They may be associated with a low renin. Children with this condition usually have cortisol deficiency.

Familial Glucocorticoid Resistance

This is a rare condition, usually due to a heterozygous mutation in the glucocorticoid receptor α gene. The partial end-organ insensitivity leads to high ACTH, cortisol, mineralocorticoids, and androgens. One case of a girl with a homozygous mutation in this gene and a coexisting heterozygous mutation in CYP21 has been described with marked virilization at birth.

P450 Aromatase Deficiency

Aromatase deficiency is inherited as a rare autosomal recessive condition caused by CYP19A1 gene mutation. There is often a history of maternal virilization after the second trimester of pregnancy coupled with elevated maternal androgen levels which resolve after the pregnancy. Urine from these mothers has elevated levels of 16α-hydroxyandrostenedione (16OH-D4A) and its metabolites. In infancy and subsequently during puberty, these girls have high serum androgens and low oestrogen concentrations as affected individuals cannot synthesize endogenous oestrogens. Girls show no signs of feminization and progressively virilize. Inadequate oestrogen supplementation may be associated with osteoporosis and a failure of timely epiphyseal fusion. Molecular testing of the *CY19A1* gene is available.

Maternal Androgen Excess

Any maternal source of elevated androgens can induce virilization of the female fetus. Ovarian tumours include luteoma of pregnancy, arrhenoblastoma, hilar-cell tumour, masculinizing ovarian stromal cell tumour, and Krukenberg tumour. Discrepancy between the marked virilization of the mother and the minimal androgen effect in female offspring can be explained by the placental aromatase activity, which converts androgens to oestrogens, or to the metabolism of androgen, which thus becomes less active. Apart from untreated maternal virilizing CAH, androgen-secreting adrenal tumour in the mother is rare. In both cases, investigation of abnormal androgen production by the mother must be performed immediately after delivery. Maternal ingestion of androgens, progestogens, or other drugs is another cause of fetal virilization. Exogenous steroids administered during the pregnancy may cause posterior fusion of the labia, clitoral enlargement, and even increased degrees of androgenization. In the past, several oral progestational compounds, given because of threatened abortion, have been implicated, such as 19-nor testosterone. Other drugs, like danazol or stilbestrol that are used in pregnancy, have also been associated with abnormalities of the genitalia.

Disorders of Müllerian Development

Abnormalities in uterine development can result in bicornuate uterus, uterine hemiagenesis, hypoplasia, or agenesis. These can be associated with renal, cardiac or spine abnormalities as part of the Mayer–Rokitansky–Küster–Hauser (MRKH) syndrome or MURCS (Müllerian agenesis, renal aplasia, cervical spine anomalies) syndrome. MRKHS (1:5000 females) is thought to be the second commonest cause of primary amenorrhoea after ovarian dysgenesis. The MURCS syndrome occurs in approximately one-third of all MRKH patients. On rare occasions, absence of Müllerian structures

and the presence of coexisting hyperandrogenaemia, has been associated with a mutation in the WNT4 gene [37]. Other conditions such as maturity onset diabetes of the young, the hand–foot–genital syndrome and Laurence–Moon–Biedl syndrome have also been associated with abnormalities of Müllerian development.

Other 46,XX DSD

Complex urogenital abnormalities, such as cloacal anomalies, can affect both sexes and require major reconstructive surgery.

Variations That May Present as DSD

Clitoral lengths are variable and when in doubt should be compared to published norms [4]. In addition, the clitoris may be enlarged in conditions such as neurofibromatosis. In any newborn girl, the labial folds may be very swollen and oedematous immediately after birth and may look like scrotal sacs. In premature babies, the lack of labial adipose tissue may make the relative size of the clitoris more pronounced so that it is mistaken for clitoromegaly. Labial adhesions and vaginal bleeding in the newborn are signs of the normal oestrogen surge in the newborn period.

Aetiology of XY DSD

46,XY DSD can be divided into disorders of testis development, disorders of androgen synthesis, disorders of androgen action and other conditions affecting sex development. Biochemically, based on AMH and the hCG stimulation test, these disorders can also be divided into conditions where (1) AMH levels are low and testosterone levels do not rise following hCG stimulation—abnormalities of testes development or maintenance; (2) AMH levels are normal and testosterone levels do not rise following hCG stimulation—abnormalities of testosterone synthesis; (3) AMH levels are normal and testosterone levels do rise following hCG stimulation—abnormalities of testosterone action, dihydrotestosterone synthesis, persistent Müllerian duct syndrome or non-specific disorder of masculinization; (4) AMH levels are low and testosterone levels do rise following hCG stimulation—persistent Müllerian duct syndrome (Figure 7.2.2.5). However, in many cases, the biochemical assessment will not clearly delineate the case into any of these four categories.

Disorders of Testis Development

These disorders can have a spectrum of phenotypes and presentations. In the most extreme case, complete testicular dysgenesis, infants raised as girls do not present until adolescence with primary amenorrhoea. These girls will have normal external female genitalia and Müllerian structures and this condition is often called Swyer's syndrome. Partial gonadal dysgenesis may be associated with a variable and internal phenotype even extending to a phenotype of simply male infertility. Accordingly, there will be a variable reduction in AMH and testosterone response to hCG stimulation. Given that several single gene disorders, as well as chromosomal rearrangements have been described to be associated with the clinical picture of gonadal dysgenesis, the latter should not necessarily be considered the final diagnosis. These disorders are often associated with abnormalities in other systems and a thorough clinical evaluation of the affected infant will prove very useful in directing appropriate genetic analysis that can lead to the correct diagnosis. Currently, a genetic diagnosis is only reached in approximately 30% of cases of gonadal dysgenesis. The importance of reaching a genetic diagnosis in these cases is highlighted by conditions such as those associated with a mutation in the steroidogenic factor (*SF1*) gene which may occasionally be associated with adrenal deficiency or a mutation of the Wilms' tumour-related gene-1 (*WT1*), where the DSD may be the first sign of conditions such as WAGR syndrome, Denys–Drash syndrome, and Frasier syndrome.

Disorders of Androgen Synthesis

Defects anywhere along the pathway of androgen synthesis and target organ action can result in an XY DSD.

Cholesterol Synthesis Defects

A deficiency of 7-dehydrocholesterol reductase (DHCR7) results in a failure of cholesterol synthesis and results in the Smith–Lemli–Opitz syndrome. This is associated with a wide range of clinical features including microcephaly, cardiac defects, micrognathia, cleft palate, polydactyly, and syndactyly. In childhood, these children may display intellectual disability and growth failure. The genitalia in the affected XY infant may range from hypospadias to completely normal female external genitalia with no Müllerian ducts. The condition is diagnosed by low levels of cholesterol and elevated levels of its precursor, 7-dehydrocholesterol, as well as an androgen deficiency and a normal AMH. Adrenal insufficiency may occur in some cases and needs evaluation. Mutational analysis of the *DHCR7* gene will provide further confirmation of the diagnosis.

Leydig Cell Hypoplasia

A defect of the luteinizing hormone-choriogonadotropin receptor (*LHCGR*) gene leads to impaired sensitivity to hCG and LH and Leydig cell agenesis or hypoplasia. The genitalia in the affected XY infant may range from isolated hypospadias or micropenis to completely normal female external genitalia with no Müllerian ducts. The biochemical picture may include high basal and luteinizing hormone-releasing hormone (LHRH)-stimulated luteinizing hormone (LH) and follicle-stimulating (FSH) levels. There is a poor response to hCG stimulation and the AMH levels should be normal. Histology of the testes in the prepubertal child will show a marked lack of Leydig cells. Mutational analysis of the LH/hCG receptor gene provides further confirmation of the diagnosis.

Congenital Lipoid Adrenal Hyperplasia

Defects in the steroidogenic acute regulatory (StAR) protein lead to deranged intracellular transport of cholesterol and abnormalities of steroid biosynthesis. Affected XY infants have severe adrenal failure and the external genitalia are unambiguously female with no Müllerian structures. The testes may be palpable in the labioscrotal folds but are usually undescended. CT or MRI imaging of the adrenal glands, as well as histology, may reveal lipid accumulation. This condition is commoner in Japan and Korea. A non-classical form of this condition also exists and is associated with progressive adrenal insufficiency in early childhood but without any overt abnormalities of androgen synthesis. Mutational analysis of the StAR gene will provide further confirmation of the diagnosis.

P450 Side Chain Cleavage Deficiency

Defects in the P450scc enzyme result in a failure of conversion of cholesterol to pregnenolone which is the first common step in steroid biosynthesis. Affected XY infants have a phenotype which is very similar to congenital lipoid adrenal hyperplasia due to defect of StAR protein. Mutational analysis of the P450scc gene (also called *CYP11A1*) will provide further confirmation of the diagnosis.

3β-Hydroxysteroid Dehydrogenase (3β-HSD) Type 2 Deficiency

Defects in 3β-HSD Type 2 results in a failure to convert Δ^5-steroids to Δ^4-steroids. The genitalia in the affected XY infant may range from isolated hypospadias or micropenis to more severe undermasculinization but not completely normal female external genitalia. There are no Müllerian ducts. Besides a poor androgen response to hCG stimulation, affected infants will have adrenal deficiency which may not necessarily include salt wasting. A urine steroid profile that shows high concentrations of Δ^5-steroids (e.g. 17OH-pregnenolone, pregnenolone, dehydroepiandrosterone) and low concentrations of Δ^4-steroids (e.g. progesterone and cortisol) is helpful. However, there is a need for careful analysis and interpretation of the steroid profile as extra-adrenal/gonadal 3β-HSD type 1 may raise the levels of some Δ^4-steroids such as androstenedione and 17OH-progesterone. In addition, raised 17-OHP can lead to an erroneous diagnosis of 21 hydroxylase deficiency. Mutational analysis of the 3β-HSD Type 2 gene (also called *HSD3B2*) will provide confirmation of the diagnosis.

17α-Hydroxylase/17,20-Lyase Deficiency

Defects of the P450c17 enzyme can lead to a variable extent of a combined deficiency of 17α-Hydroxylase and 17,20-Lyase activity. In the affected XY infant, this will be associated with a variable degree of undermasculinization ranging from mild abnormalities of the genitalia to unambiguously female external genitalia. These account for around 1% of cases of 46,XY DSD. Besides a poor androgen response to hCG stimulation, affected infants will have a poor cortisol response to adrenal stimulation but may not display adrenal insufficiency as they have highly raised deoxycorticosterone levels which may lead to a state of low renin hypertension and hypokalaemic alkalosis in the older child. Mutational analysis of the P450c17 gene (also called *CYP17*) will provide confirmation of the diagnosis.

P450 Oxidoreductase Deficiency

The P450 oxidoreductase enzyme is necessary for electron transfer from NADP to many P450 enzymes and its deficiency can affect the activity of a number of P450 enzymes. Infants with XY DSD and an abnormality of this enzyme tend to present with a clinical picture consistent with combined deficiency of 21α-hydroxylase deficiency and 17,20-lyase deficiency. The genitalia in the affected XY infant may range from isolated hypospadias or micropenis to more severe undermasculinization but not completely normal female external genitalia. There are no Müllerian ducts. Besides a poor testosterone response to hCG stimulation, affected infants will have adrenal deficiency which is usually restricted to glucocorticoid deficiency. The deficiency of this enzyme may be associated with a condition called Antley–Bixler syndrome which is a skeletal dysplasia classically characterized by radiohumeral stenosis and craniosynostosis. This syndrome is not universally associated with abnormalities of the P450 oxidoreductase enzyme. Mutational analysis of the P450 oxidoreductase gene (also called *POR*) may provide confirmation of the diagnosis.

17β-Hydroxysteroid Dehydrogenase (17β-HSD) Type 3 Deficiency

17β-HSD has 6 isoenzymes which convert androstenedione, DHEA and estrone to testosterone. Deficiency of 17β-HSD Type 3 is

associated with XY DSD and affected infants often present with female external genitalia or sometimes ambiguous genitalia. However, these children can undergo spontaneous virilization during puberty with a rise in testosterone levels, possibly due to increased activity of the other isoenzymes. Thus, early accurate diagnosis of this condition is important as the affected infant may need sex reassignment if initially raised as a girl (see section, 'Sex Assignment in the Affected Newborn'). These infants shall have a poor testosterone response to hCG but may have a relatively high level of serum androstenedione such that the testosterone:androstenedione ratio may be less than 0.8. However, this is not an invariable finding in this condition; furthermore, a low ratio may also be found in poorly functioning testes. Mutational analysis of the 17β-HSD type 3 gene (also called *HSD17B3*) will provide confirmation of the diagnosis.

Steroid 5α-Reductase (5α-RD) Type 2 Deficiency

5α-RD exists as two isoenzymes. Type 1 is expressed in skin and type 2 in the genitalia. In XY DSD infants may present with a variable phenotype ranging from micropenis or hypospadias to female external genitalia. This phenotype is due to reduced activity of 5α-RD type 2 and a failure to convert testosterone to dihydrotestosterone. The classical biochemical profile includes a high testosterone:dihydrotestosterone ratio following hCG stimulation (normal ratio is <25:1) although many affected cases have a lower ratio. An additional diagnostic feature is a urinary steroid profile which shows a decreased ratio for 5α:5α-reduced C_{21} and C_{19} steroids. It may not be possible to detect this abnormality in the urine until late infancy. Like 17β-HSD type 3 deficiency, these children can undergo spontaneous virilization during puberty with a rise in testosterone levels, possibly due to increased activity of the Type 1 isoenzymes. Thus, early accurate diagnosis of this condition is important as the affected infant may need sex reassignment if initially raised as a girl (see section, 'Sex Assignment in the Affected Newborn').

Disorders of Androgen Action

In XY DSD, a disorder of the androgen receptor leads to a phenotype that can range from a man with infertility through to a range of abnormalities of the genitalia in the newborn boy (partial androgen insensitivity syndrome, PAIS) to completely female external genitalia (Complete Androgen Insensitivity Syndrome, CAIS). The exact prevalence of PAIS and CAIS are unknown and estimates vary widely. Older estimates give prevalence rates of CAIS in 46,XY individuals of approximately 1:20 000 to 1:64 000. Children with AIS should have normal testosterone and dihydrotestosterone response to hCG stimulation and should have a normal urinary steroid profile. However, a number of children with a confirmed genetic diagnosis of AIS may have a poor response to hCG stimulation, and this may be related to associated abnormalities of the testes or the test itself. The AMH level should be normal; sometimes it has been shown to be somewhat high for age-matched standards. Similarly, LH levels may be high especially following LHRH stimulation. There are no Müllerian ducts. In the older infant, fixed treatment with testosterone may not be accompanied by changes in testosterone responsive effects, such as a fall in SHBG or change in the size of the phallus. Mutational analysis of the androgen receptor gene (also called *AR*) will provide confirmation of the diagnosis. Androgen binding studies may be helpful in directing mutational analysis, particularly in cases of PAIS. As the condition is inherited in an X-linked pattern, a consistent family history is very helpful. Furthermore, exploration of X-linked markers in affected and non-affected family members can indicate the likelihood of the condition. A number of cases of XY DSD are incorrectly labelled as 'PAIS' when no firm biochemical or genetic abnormalities are identified in gonadal function, androgen synthesis or androgen action. Strictly speaking, the term PAIS should be reserved for those children who have XY DSD and a genetic abnormality of the AR gene. The children without a genetic abnormality may be better described as 'XY DSD with a non-specific disorder of under-masculinization'.

Persistent Müllerian Duct Syndrome (PMDS)

AMH is secreted by the Sertoli cells from around 7 weeks gestation and subsequently acts through the AMH Type 2 receptor to lead to regression of the Müllerian ducts. PMDS is a rare condition occurring due to a variant of the AMH gene or its receptor. In XY infants with PMDS, boys are born with male external genitalia but have persistence of internal Müllerian structures. The diagnosis is usually suspected when a child has a repair of an inguinal hernia, orchidopexy, or coincidental intrabdominal surgery. There are two anatomic forms. In the commoner type, there is one inguinal hernia which contains the ipsilateral testis and the ipsilateral fallopian tube and the uterus. In some of these herniae, the contralateral testis may also be present. In the less-commoner form, all the structures including the testes are present in the pelvis. Affected children have a normal testosterone response to hCG but fertility and, sometimes Leydig cell function may be compromised in adulthood due to unsuccessful attempts at orchidopexy and anatomical abnormalities of the epididymis and the vas deferens. Surgical opinion about the timing of salpingectomy and hysterectomy vary.

Disorders of Testes Maintenance

A number of different terminologies (bilateral vanishing testes, embryonic testicular regression, rudimentary testes, congenital anorchia) are used to describe a group of conditions which are characterized in infants with a XY karyotype and absent or rudimentary testes. The syndrome entails the presence of testes which vanish during embryogenesis. The aetiology of this syndrome is unclear: regression of the testes *in utero* may be due to a genetic variant, a teratogen factor, or a bilateral torsion. Clinically, the syndrome encompasses a spectrum of phenotypes, ranging in severity from genital ambiguity to a male phenotype with an empty scrotum. The management of patients with a defect of testes maintenance is dictated by their position in the clinical spectrum of the disorder. Patients with rudimentary testes have a male phenotype with micropenis, small atrophic testis with pre-Sertoli and Leydig cells. Some patients present with perineal hypospadias and persistent Müllerian derivatives. Congenital anorchia is characterized by the complete absence of testicular tissue at birth, but normal male sexual differentiation without Müllerian derivatives.

Gender and Its Development

Unlike the sex categories, male and female, gender has several aspects: gender assignment, gender role, gender identity, gender attribution, and sexuality. In most societies, gender assignment occurs at birth, long before we have a say in the matter, marking the beginning of the process of gender socialization. The process of gender socialization also includes society's expectations of how males or females should behave, as expressed in their gender role behaviour. Gender identity is distinct from gender role behaviour and refers to the individual's perception of one's own gender and how it conforms to the male or female gender role in society. Gender attribution is what we all do when we meet someone and want to decide whether they are a man or a woman. This is often based on obtaining a number of cues which are symbolic manifestations of gender and that have traditionally included clothing, mannerisms, physical appearance, gait, and occupational choice. Finally, sexuality refers to erotic desires, sexual practices, or sexual orientation. In some cultures, individuals are often socially identified as homosexuals or heterosexuals as if a person's sexual orientation encapsulates the total personality and identity. For most people, their gender identity, gender role, and the symbolic gender manifestations are congruent and, in addition, they will be sexually attracted to the opposite sex. However, it is also possible that a man may have gender manifestations that do not completely converge with his male gender identity and remains sexually attracted to a member of the opposite sex; of course, a number of other permutations may also exist. Some aspects of gender, such as role, assignment, the symbolic manifestations, as well as the different types of sexuality, may differ markedly from one society to another and continue to evolve within respective societies. In some cultures, the distinction is becoming less absolute and it may be better to consider these aspects as a continuum, with female characteristics at one extreme and male ones at the other. The development of gender identity is the result of a complex interaction between genetic, prenatal, and postnatal endocrine influences and postnatal psychosocial and environmental experiences. Gender development consists of gender identity formation such as gender knowledge, self-perception, preferences (toy, playmate), and gender role behaviours [38]. By the end of the first year of life, infants may already be able to discriminate between the sexes, and some may be able to display sex related toy preferences. By 2–3 years of age children are able to correctly label themselves and others according to gender. By the age of 3 years, preference for one sex role has emerged with the child having a clear sense of whether he/she is a boy or girl. Children fix on cues such as clothing and hair in gender labelling exercises; even when genital cues are available they are used far less to make categorization decisions than these other cues, at least until the age of 8 years or so, possibly reflecting insufficient biological understanding of gender differences. By the age of 5 years, children learn that gender remains stable over time, becoming preoccupied with categorical differences between males and females. However, it is not until children have mastered the concept that gender remains constant (despite superficial changes in appearance), at the age of between 5 and 7, that many argue is when a gender identity has been fully attained. Theorists have suggested that once 'gender constancy' has been mastered, this becomes a motivator to shaping sex appropriate gender behaviour [38].

Sex Assignment in the Affected Newborn

Initial gender uncertainty is unsettling and stressful for families as well as the health professionals. Given that gender development is a relatively long-term process, clinical professionals involved in management need to be clear of the distinction between sex assignment and gender assignment; the latter cannot be achieved by the clinical team and should be considered intrinsic to the child's own development. However, expediting a thorough assessment and reaching a decision on sex assignment is required. Factors that influence sex assignment include the diagnosis, genital appearance, surgical options, need for lifelong replacement therapy, the potential for fertility, views of the family and sometimes, circumstances relating to cultural practices. More than 90% of 46,XX CAH patients and all 46,XY CAIS assigned female in infancy identify as females. Evidence supports the current recommendation to raise markedly virilized 46,XX infants with CAH as female. In the late presenting virilized 46,XX child who has been raised as a boy, there are cases where gender reassignment has not been undertaken and there is a need for long-term outcome studies in these cases as well as those where gender reassignment has occurred [39]. Approximately, 60% of 5α-reductase (5αRD2) deficient patients assigned female in infancy and virilizing at puberty (and all assigned male) live as males. In 5αRD2 and possibly 17β-hydroxysteroid dehydrogenase (17βHSD3) deficiencies, where the diagnosis is made in infancy, the combination of a male gender identity in the majority and the potential for fertility (documented in 5αRD2, but unknown in 17βHSD3) should be discussed when providing evidence for gender assignment. Among patients with PAIS, androgen biosynthetic defects, and incomplete gonadal dysgenesis, there is dissatisfaction with the sex of rearing in about 25% of individuals whether raised male or female; recent data have shown a trend towards these affected infants being raised as boys [40]. The decision on sex of rearing in ovotesticular DSD should consider the potential for fertility based on gonadal differentiation and genital development, and assuming the genitalia are, or can be made, consistent with the chosen sex. In the case of mixed gonadal dysgenesis (MGD), factors to consider include prenatal androgen exposure, testicular function at and after puberty, phallic development, and gonadal location. Individuals with cloacal exstrophy reared female show variability in gender identity outcome, but more than 65% appear to live as women.

Surgical Management

The surgeon has a responsibility to outline the surgical sequence and subsequent consequences from infancy to adulthood. Only surgeons with expertise in the care of children and specific training in the surgery of DSD should perform these procedures. Parents now appear to be less inclined to choose surgery. As orgasmic function and erectile sensation may be disturbed by clitoral surgery, the surgical procedure should be anatomically based to preserve erectile function and the innervation of the clitoris. Emphasis should be placed more on functional outcome, rather than a strictly cosmetic appearance. It is generally felt that surgery that is performed for cosmetic reasons in the first year of life relieves parental distress and improves attachment between the child and the parents. However, systematic evidence for this belief is lacking. It is anticipated that surgical reconstruction in infancy will need to be refined at the time of puberty.

Vaginal dilatation should not be undertaken before puberty. The surgeon must be familiar with a number of operative techniques in order to reconstruct the spectrum of urogenital sinus disorders. An absent or inadequate vagina (with rare exceptions) requires a vaginoplasty in adolescence when the patient is psychologically motivated and a full partner in the procedure. In the case of a DSD associated with hypospadias, standard techniques for surgical repair include chordee correction, urethral reconstruction, and the judicious use of testosterone supplementation. The magnitude and complexity of phalloplasty in adulthood should be taken into account during the initial counselling period. It should also be explained to parents that sexual contentment is not simply dependent on penetrative sex. Parents must not be given unrealistic expectations about penile reconstruction, including the use of tissue engineering. The testes in patients with CAIS and those with PAIS, raised female, need to be removed to prevent malignancy in adulthood, but this can be deferred until adolescence which allows spontaneous feminization and an opportunity for the patient to have a say in the timing of removal. The streak gonad in a patient with MGD raised male should be removed in early childhood. Bilateral gonadectomy is performed in early childhood in females (bilateral streak gonads) with gonadal dysgenesis and Y chromosome material. In patients with androgen biosynthetic defects raised female, gonadectomy should be performed before puberty. A scrotal testis in patients with gonadal dysgenesis remains at risk for malignancy and there is little consensus on screening besides regular palpation in adolescence and adulthood.

Psychosocial Management

Psychosocial care should be an integral part of management in order to promote positive adaptation and allow parents to express and resolve their concerns. The early concerns of parents may be less to do with the long-term implications of the condition and more to do with coping and adjustment during infancy (Table 7.2.2.2). Experienced healthcare staff including the mental healthcare services who work as part of a clinical network with access to others with more specialist knowledge and experience may be particularly valuable in providing generic psychosocial support. A common issue seems to be related to how the condition should be explained to friends and relatives [8]. This expertise can facilitate team decisions about gender assignment/reassignment, timing of surgery and sex hormone replacement. Psychosocial screening tools that identify families at risk for maladaptive coping with a child's medical condition should be considered [41]. Once the child is sufficiently developed for a psychological assessment of gender identity, such an evaluation must be included in discussions about gender reassignment. Gender identity development begins before the age of 3 years, but the earliest age at which it can be reliably assessed remains unclear. The generalization that the age of 18 months is the upper limit of imposed gender reassignment should be treated with caution and viewed conservatively. Atypical gender role behaviour is more common in children with DSD than in the general population, but should not be taken as an indicator for gender reassignment. It is important to emphasize the distinction between sex-typical behaviour, sexual orientation, and gender identity. Thus homosexual orientation (relative to sex of rearing) or strong cross-sex interest in an individual with DSD is not an indication of incorrect gender assignment. In the longer-term, most current studies suggest that affected individuals lead productive lives, but a small proportion may have functional problems and may also suffer from gender identity disorders [42]. Parents do need to be aware of these issues. It should be explained that the process of disclosure concerning facts about karyotype, gonadal status, and prospects for future fertility is a collaborative ongoing action which requires a flexible individual-based approach.

7.3

Pubertal Disorders

7.3.1 Recognizing Normal and Disordered Pubertal Development

Alan D. Rogol and John S. Fuqua

Definition of Pubertal Maturation

Puberty (Latin *pubertas*, of ripe age, adult) is 'the condition of being or the period of becoming first capable of reproducing sexually that is brought on by the production of sex hormones and the maturing of the reproductive organs (such as the testes and ovaries), development of secondary sex characteristics (such as male facial hair growth and female breast development), and in humans and the higher primates by the first occurrence of menstruation in the female' [1].

We shall use pubertal maturation, a process, to define the physical and hormonal changes as the child becomes an adolescent and then an emerging adult. The psychological/behavioural changes associated with pubertal development will not be further discussed in this chapter.

Pre-pubertally the hypothalamic-pituitary-gonadal (HPG) axis is active during the second trimester of gestation but relatively quiescent following mini-puberty in the first few months of life and preceding pubertal maturation. The outward signs differ in boys and girls. One evaluates pubic hair (both sexes), breast maturation (females), and penile and testicular maturation (boys). These are noted in detail in Table 7.3.1.1 and shown in Figure 7.3.1.1. Individuals vary in the level of maturity attained at a given point in time (maturity status at a given age), in timing (when maturational events occur) and in tempo (rate of maturation) [2]. Thus, in individuals of the same sex and chronological age, wide variations of biological age occur as indicated by physical examination and bone age determination. Not only is there variability in the age of attainment of one or another stage, but there may be significant variability between the stages for breast and pubic hair or genital development and pubic hair within any individual (Tables 7.3.1.2 and 7.3.1.3)

Table 7.3.1.1 Pubertal maturation in males and females

Stage	Physical characteristics
Pubic hair in males and females	
1	Prepubertal
2	Sparse growth of long, slightly pigmented hairs at the base of the penis (males) or mons veneris/labia majora (females)
3	Further darkening and coarsening of hair, with spread over the symphysis pubis
4	Hair is adult in character, but not in distribution, has not spread to the lower abdomen (males) or to the medial surface of the thighs (males and females)
5	Hair is adult in distribution, with extension to the lower abdomen (males) and/or the medial surface of the thighs (males and females)
Breast development in females	
1	Prepubertal
2	Breast budding, widening of the areola with elevation of both breast and nipple as a small mound
3	Continued enlargement of both breast and areola, but without separation of their contours
4	Formation f the areola and nipple as a secondary mound projecting above the contour of the breast
5	Adult shape with the areola and nipple recessed to the contour of the breast
Genital development in males	
1	Prepubertal
2	Enlargement of the testes and scrotum, thinning and reddening of the scrotal skin, penis remains prepubertal
3	Further growth of testes and scrotum; enlargement of the penis, predominately in length
4	Further growth of testes and scrotum with pigmentation of the scrotal skin; further enlargement of the penis, especially in circumference, and development of the glans
5	Testes, scrotum, and penis are adult in size and shape

[2–4]. Some boys complete the process of moving from G2 to G5 in two years and others may take up to 4.5 years. Boys may enter G2 only 6 months after girls are at stage 2 for breast development, but they differ by almost 2 years in age at peak height velocity (PHV), a maturational benchmark or biological anchor of pubertal maturation. This translates to girls having PHV often at B2 and boys in the latter part of G3 or G4.

Tables 7.3.1.2 and 7.3.1.3 show the variability of entry into a stage and progression on to the next stage. However, one of the limitations of the data is that they are cross-sectional and it requires a longitudinal study to evaluate the 'kinetics' or trajectory of an individual. Additionally, there are limitations of the sexual maturity rating (SMR) process, especially at the earliest stages when palpation is mandatory to distinguish breast budding from

Table 7.3.1.2 Percentages of Swiss girls in each stage of breast development when they reached each stage of pubic hair development (top); and in each stage of pubic hair development when they reached each stage of breast development (bottom)

Pubic hair stage	Percentage in each breast stage				
	B1	B2	B3	B4	B5
PH2	49	46	5	0	0
PH3	0	36	51	12	1
PH4	0	4	47	33	16
PH5	0	1	6	34	59

	PH1	PH2	PH3	PH4	PH5
B2	16	67	16	1	0
B3	2	26	50	20	2
B4	0	4	28	43	25
B5	0	0	7	29	64

B, breast; PH, pubic hair.

adipomastia or as the testis changes from a prepubertal volume. The prepubertal testis has a volume ≤3 ml, or ≤2.5 cm in longest diameter, while at stage 5 the testis is 12–25 ml or 2.8–5 cm in longest diameter.

The sequence of pubertal progression is predictable and once entrained usually goes to completion. However, there is variability in the rate of progression just as there is in its onset. Thelarche is usually the first sign in more than 90% of girls, followed by sexual hair a year or more later. However, pubarche may occur first (and/or simultaneously with breast development) in a small percentage of girls [5].

There are very significant changes in the shape and composition of the adolescent body as it progresses through male or female maturation. These changes include the maturation of body tissues such as increases in haemoglobin concentration (much later in boys than girls, at SMR 4 or 5); alkaline phosphatase, especially the bone fraction as an indicator of bone osteoblastic activity during rapid bone growth; a small increase in blood pressure [2]; the amount and the distribution of adipose tissue; and both bone mass and fat-free lean tissue mass [6]. Significant increases in total energy requirement (boys greater than girls) accompany, and likely drive, the changes in body composition. Body measurements at any one time do not indicate the state of maturity; however, longitudinal data that span adolescence may be evaluated for specific growth parameters that do indicate maturity status: age of onset of the growth spurt and age at PHV [2]. Growth spurts in other dimensions also occur but not necessarily in synchrony, as may be seen in Table 7.3.1.4 [2, 7]. In both sexes the peak velocity in weight, lean mass, and bone mineral content occur after peak height velocity. These parameters reach their young adult values often in the late second or early third decade, especially for males. This pattern has physical performance implications for both sexes, as the strength of adolescent boys accelerates markedly compared to girls relatively early in pubertal maturation [8, 9] and to a greater degree in males. In any event it is more strongly correlated to the biological parameter of peak height velocity than to chronologic age [8]. The development of muscle strength not only depends on the neuroendocrine axes for growth hormone and the gonads, but also depend on neural and biomechanical factors. Sex differences emerge during puberty, with boys demonstrating accelerated increases in strength, but girls continuing to increase strength at a similar rate as in prepuberty, allegedly due to neuromuscular facilitation rather than increased muscle bulk [10]. By late puberty boys and girls may differ in strength by ~50% [11].

It should be remembered that there are consequences of pubertal body composition changes that remain as risk factors for common diseases in the adult, for example, cardiovascular disease. Some of these, especially increased fat mass, often track into adulthood [6].

Table 7.3.1.3 Percentages of Swiss boys in each stage of genital development when they reached each stage of pubic hair development (top); and in each stage of pubic hair development when they reached each stage of genital development (bottom)

Pubic hair stage	Percentages in each genital stage				
	G1	G2	G3	G4	G5

Hormones of Puberty

Regulation of Gonadal Steroid Production

Gonadotropin releasing hormone (GnRH) is secreted from the hypothalamus in a pulsatile fashion. A complex neuroendocrine regulatory mechanism involving multiple stimulatory and inhibitory inputs contributes to GnRH secretion. GnRH secretion in prepubertal children as measured by LH concentration is characterized by low and irregular pulses occurring every 3–4 hours, and serum concentrations of LH and FSH are low. As the child approaches puberty, both the amplitude and frequency of GnRH pulses increase during the night-time hours, with pulse frequency approximating once per hour and returning to baseline by morning (Figure 7.3.1.2). This phenomenon leads to a diurnal variation in testosterone secretion in boys and to a lesser extent, oestradiol concentrations in girls. As puberty progresses, the changes in GnRH pulses extend to the daytime hours, stabilizing at a period of every 90–120 minutes, with corresponding increases in afternoon concentrations of sex steroids [12]. However, the diurnal variation in testosterone remains noticeable in adult men throughout the lifespan. Changes in GnRH pulse frequency alter relative production of FSH and LH, with slower pulsatility increasing FSH production. In adult women, pulse frequency varies over the menstrual cycle, ranging from every 60–100 minutes [13].

An interesting phenomenon is the transient activation of GnRH, gonadotropin, and sex steroid secretion that occurs in the first few months of life, termed the 'minipuberty of infancy'. In boys, testosterone concentrations fall in the first weeks after birth. By 4 weeks of age, however, testosterone levels rise and peak in boys at 7.2 ± 2.3 nmol/L at about 1–3 months of age, approximating levels seen in early-mid puberty [14]. By 5–6 months of age, testosterone concentrations fall and reach otherwise normal prepubertal ranges in the second half of the first year. In girls, oestradiol levels do not have an obvious peak but fluctuate over time, decreasing by 6–12 months of age [15]. Gonadotropin levels in boys are sufficient to cause increases in testicular volume, and testosterone concentrations are high enough to cause penile growth and acne [16]. In girls, oestradiol levels during the minipuberty contribute to breast bud and uterine growth [17].

As puberty approaches, increases in GnRH pulsatility can be measured in both boys and girls as subtle increases in LH levels years before the clinical onset of puberty. These increases have been detected in serum as well as in urine [18, 19]. As clinically apparent

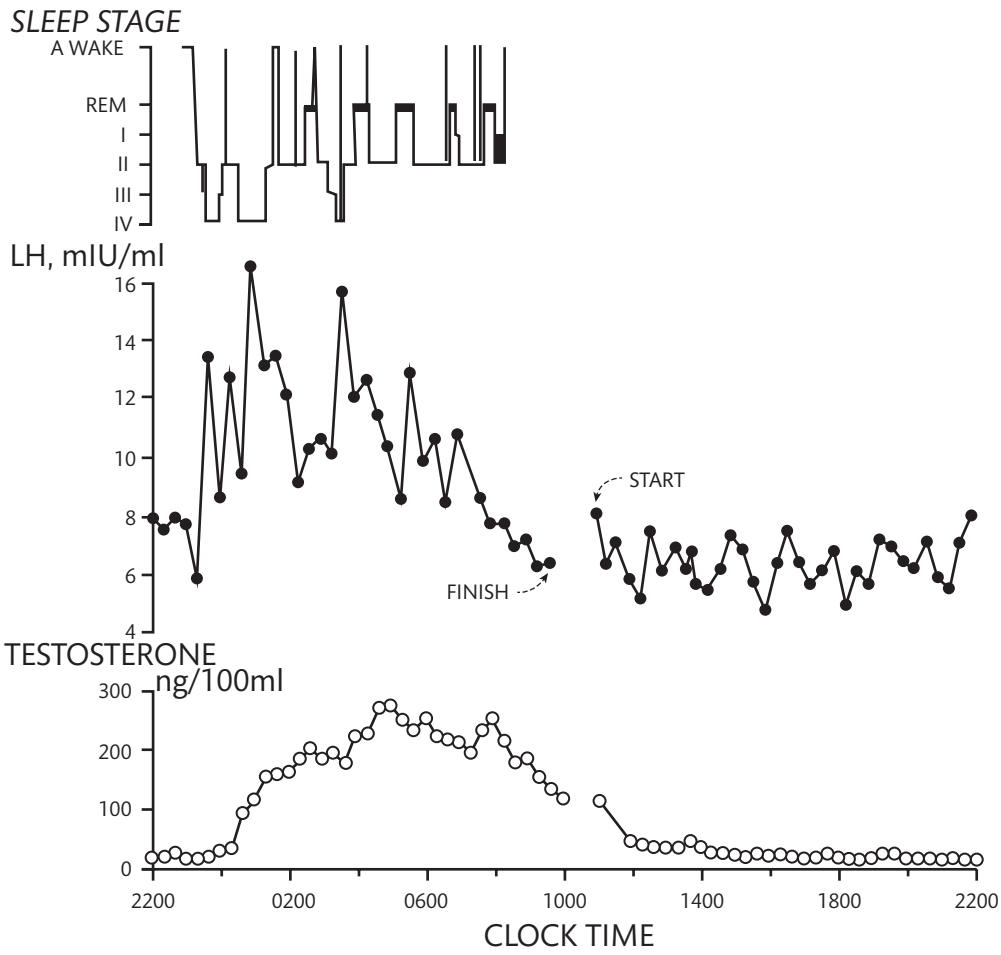

Figure 7.3.1.2 LH and testosterone secretion in a boy in the early stages of pubertal maturation demonstrating increased testosterone concentration and LH pulse amplitude and frequency during sleep, with decreases in both amplitude and frequency in the morning.

changes occur with pubertal maturation, concentrations of sex steroids increase concurrently [20] and eventually reach adult levels.

Gonadal Peptide Hormones

In addition to the sex steroids testosterone and oestradiol, other important products of the testes and ovaries are the peptide hormones inhibin and anti-Müllerian hormone (AMH). Both are products of the Sertoli cells of the testes and the ovarian granulosa cells. Inhibin exists in two major isoforms, inhibin B and inhibin A, with inhibin B produced primarily during the follicular phase and inhibin A during the luteal phase [21]. Inhibin secretion is stimulated by FSH and functions in both males and females as part of a negative feedback loop to suppress pituitary release of FSH. Anti-Müllerian hormone plays an important role in the development of the male internal genitalia in the early weeks of gestation. In the adult ovary, AMH appears to decrease the growth of primordial follicles. Measurement of AMH has clinical utility as a reflection of the number of primordial ovarian follicles and possibly in the assessment of polycystic ovary syndrome.

Serum concentrations of AMH and the inhibins change between infancy and adulthood. In boys, AMH concentrations are high at birth and gradually decline during prepubertal life, with levels averaging 90–100 ng/ml at age 7–10 years. At the onset of puberty, concentrations fall rapidly to reach levels similar to those seen in females. In girls, AMH concentrations are low at birth and remain modest in comparison to males. Levels increase slightly around the time of puberty, but average 2–3 ng/ml in adolescent girls [22]/

By contrast, concentrations of inhibin B gradually rise during the prepubertal years. Several investigators have studied this relationship of the rise in inhibin B to the clinical manifestations of puberty. In a prospective, longitudinal study of a small number of boys and girls, Crofton *et al*. found progressive increases in inhibin B from genital Tanner stages 1 through 3 in boys and increases in both inhibin A and B between breast Tanner stages 1 and 4 in girls [23]. In a series of much larger cross sectional studies of data derived from NHANES III, Lee and colleagues [24, 25] found a gradual increase of inhibin B in both boys and girls through late childhood and into early adolescence, with the majority of prepubertal girls having levels below the limit of detection. On a population basis in girls, inhibin B was modestly useful for predicting the onset of puberty as established on clinical grounds, with an optimal cut-point on receiver operating characteristic (ROC) analysis of 17.9 pg/ml, but relatively high false positive and negative rates [24, 25]. However, in boys the degree of interindividual variation rendered inhibin B alone unhelpful to establish the onset of puberty [20].

Growth Hormone/Insulin-like Growth Factor-1 (IGF-1)

A hallmark of puberty is acceleration of height velocity, often called the pubertal growth spurt. Growth hormone is released in a pulsatile fashion, with more than 75% of daily release occurring at night. The most reliable pulse of growth hormone secretion occurs 45–90 minutes after the onset of the first cycle of deep sleep, with a variable number of lesser pulses through the night [26]. With the onset of puberty and the rise in oestradiol and testosterone concentrations, the amount of growth hormone released increases by a factor of approximately three. Serum concentrations of IGF-1 increase by a similar amount [27]. In addition to directly stimulating growth hormone secretion, aromatizable androgens potentiate the effect of growth hormone on IGF-1 release. Additionally, growth hormone has a direct effect on ovarian granulosa cells to increase steroidogenesis, and IGF-1 acts to increase ovarian FSH receptors [28]. With progression of puberty, oestrogen concentrations rise in both sexes, ultimately resulting in maturation of the epiphyseal growth plates and cessation of linear growth. The higher concentration and earlier secretion of oestrogens in girls appears to account for the earlier occurrence of the pubertal growth spurt and the shorter average adult height in girls vs. boys [29].

Regulation of Pubertal Timing

The timing of puberty is a complex trait, with a Gaussian distribution in the general population. It is a dynamic interaction between genes and the environment, with influences including nutritional factors, environmental influences, and genetic input. It is estimated that between 50% and 80% of the variance of normal pubertal timing is explained by genetic factors [30, 31]. Efforts to understand the genetics of pubertal timing have led to the discovery of many genes that are clearly necessary for pubertal maturation. Many of these genes, when mutated, lead to specific syndromes of delayed or absent puberty. However, it is not clear that these genes individually or as a group explain much of the variability of the onset of **normal** puberty, and despite the identification of these involved genes, our understanding of the genetic trigger(s) for the onset of pubertal maturation remains incomplete. Genome-wide association studies and other high throughput technologies have shown promise in elucidating regulatory systems for complex traits. Additionally, systems biology approaches have demonstrated multi-layered networks of genetic control [32]. These networks comprise lower level primary mechanisms of GnRH secretory control and higher levels of transcriptional regulation, theorized as a system of network 'nodes' [33]. Primary GnRH secretory control is exerted through stimulatory and inhibitory neuronal inputs as well as excitatory glial-neuronal interactions. Higher level control networks seem to be largely inhibitory and may themselves be controlled in part by epigenetic mechanisms. Putative members of higher-level control networks include *IRF2BPL* (*EAP1*), *CADM1* (*SynCAM*), *POU2F2* (*OCT2*), and *TTF1* [33].

In 2003, the kisspeptin/GPR54 system was discovered to be a key regulatory factor in the initiation of increased GnRH pulsatility at the onset of puberty [34]. In the human, kisspeptin is produced in neurons in the infundibular nucleus and preoptic area of the hypothalamus and interacts with its receptor, GPR54, on GnRH secreting neurons. A subpopulation of kisspeptin neurons, termed KNDy neurons, coexpress neurokinin B and dynorphin, Multiple factors influence kisspeptin secretion, including neurokinin B and dynorphin, which are thought to be stimulatory and inhibitory factors, respectively [35]. Kisspeptin expression increases with the physiologic onset of puberty in several mammalian species. In multiple animal species, including humans, exogenous administration of kisspeptin increases the pulse amplitude of GnRH. Administration of kisspeptin to healthy male and female volunteers increases gonadotropin concentrations [36, 37]. In humans, inactivating mutations of this system have been associated with delays in puberty, while activating mutations lead to precocious puberty [38]. The kisspeptin/GPR54 system

may also be involved in the negative and positive feedback effects of sex steroids on GnRH secretion. Despite these lines of evidence, it remains unestablished if kisspeptin is the primary trigger of puberty or if it acts as an amplifier [35].

GnRH secretion is negatively regulated by makorin ring finger protein 3 (MKRN3), a hypothalamic factor that may act directly on GnRH secreting neurons or may act via the KNDy neurons [39]. Serum concentrations of MKRN3 decrease as normal puberty progresses in boys and girls [40]. *MKRN3* is an imprinted gene on chromosome 17q11–q13 that is silenced on the maternal allele. Thus, inactivating mutations lead to autosomal dominant precocious puberty, but only when paternally inherited. Methylation defects appear to be uncommon. *MKRN3*-related precocious puberty affects both girls and boys, with a median age at pubertal onset of 6 and 8.25 years, respectively [41].

Gamma-aminobutyric acid (GABA)-secreting neurons play an inhibitory role in puberty and may be involved in the juvenile pause, the temporary suppression of the hypothalamic-pituitary-gonadal axis that occurs during childhood. Suppression of GABAergic neuronal input may lead to the initiation of puberty [42]. Additional factors may include increased glutamate stimulation of N-methyl-D-aspartate (NMDA) receptors, which are stimulatory to GnRH release [43], and an decreased negative feedback effect of low levels of circulating sex steroids. Investigation of this phenomenon is difficult due to species specificity [44].

Epigenetics

Multiple lines of evidence suggest that epigenetic changes may play roles in the timing of puberty. Major epigenetic mechanisms include DNA methylation as well as acetylation and methylation of histones. In rodent models, all three mechanisms alter the activity of kisspeptin neurons and GnRH neurons. Alterations in epigenetic markers may occur during pubertal maturation, including increases in histone acetylation that increase kisspeptin mRNA transcription and methylation changes in promotor region of the *GNRH* gene in rodents and non-human primates [35].

MicroRNAs (miRNAs) provide an additional epigenetic mechanism for regulation of gene expression and translation. MicroRNAs are approximately 22 nucleotide-long non-coding RNAs that transcriptionally silence target genes by increasing mRNA degradation. Individual miRNAs may affect dozens of target genes, while target genes may each be controlled by several miRNAs, creating a diverse network of regulatory control. Evidence for miRNA control of pubertal timing comes primarily from studies of mice. Several distinct miRNAs either activate or suppress hypothalamic–pituitary–gonadal function, both at the level of the hypothalamus and by altering gonadal maturation [35]. There is limited evidence suggesting a role of miRNAs in human pubertal maturation. GWAS demonstrated an association between age at menarche and changes at chromosome 6q21 near the *LIN28B* gene, implicated in processing of the let-7 family of miRNAs, shown in animal studies to be a pubertal activator [45].

Environmental Effects

Because development and maintenance of reproductive competency is an energy-intensive process, it is unsurprising that puberty is metabolically gated. In general, factors that result in negative energy balance delay the onset or progression of pubertal maturation, while positive energy balance, such as occurs with obesity, tends to accelerate the process.

Studies of the relationship of obesity to the timing of pubertal maturation in girls have demonstrated earlier onset of breast development in obese girls. A recent meta-analysis reviewing 11 studies of a total of 4841 subjects showed a relative risk of 2.44 for obese girls to have early breast development. Interestingly, although some of the analysed studies showed a relationship between obesity and the age at menarche, this did not reach statistical significance in the combined meta-analysis [46]. Data in boys were less consistent, and the investigators were unable to demonstrate a relationship between obesity and genital development. This was due in part to the low number of male subjects in included studies. It is likely that in boys different degrees of obesity produce different effects on the timing of pubertal maturation.

A key factor that links body fat stores to reproductive maturation is leptin, an adipocyte-derived signalling molecule. Indeed, humans carrying mutations in either the gene encoding leptin or its receptor demonstrate disruption of puberty, and leptin replacement in deficient individuals helps to restore hypothalamic–pituitary–gonadal function [47]. Leptin appears to be a permissive factor for puberty in both males and females, in that threshold levels are required for pubertal initiation. However, leptin in and of itself is not sufficient. The mechanism of action for this permissive effect of leptin is not well-understood. Kisspeptin expression is increased by leptin [48], but whether this is due to a direct effect on KNDy neurons or is driven by intermediary cells is unclear. Such intermediates may include POMC neurons and GABAergic neurons [35]. Other possible links between energy stores and reproductive maturation include ghrelin, proposed to have inhibitory effects, and insulin, which may act within the CNS as a permissive or stimulatory factor.

In addition to classical endocrine and neuroendocrine systems, overfeeding may lead to earlier pubertal maturation by inducing epigenetic changes, especially during key points in development, such as fetal life, early post-natal life, and puberty. Evidence for this comes predominately from animal studies, with limited human data [49].

An interesting phenomenon is the higher prevalence of early puberty in girls who have been internationally adopted. Theories for why this occurs have included the effects of early nutritional deprivation with later catch up weight gain, a response to psychologic stress, lack of accurate age determination, or as a result of environmental endocrine disrupting chemical exposure [50–52].

Environmental Endocrine Disruptors

Endocrine disrupting chemicals (EDCs) are broadly defined as naturally occurring or synthetic chemicals that have stimulatory or inhibitory effects at hormone-responsive tissues leading to alterations in normal developmental or physiologic processes. From a reproductive standpoint, most EDCs have estrogenic or anti-estrogenic actions, anti-androgenic actions, or a combination and may have effects at the level of the brain, gonads, or target tissues. They have been linked to alterations in decreased sperm counts, infertility, gonadal cancers, and genital malformations. Although a single EDC may have minimal measurable effects at environmental concentrations, human exposures are typically multiple, and the possibility of additive or synergistic effects is a concern [35]. Most of our understanding of the estrogenic effects of EDCs comes from animal studies, although there are both prospectively and retrospectively collected human data.

Exposure to EDCs has been postulated to contribute to earlier age at onset of puberty [53]. Interpretation of human studies is challenging as a result of variations in the aspects of puberty that were assessed and characteristics of the exposures, such as the specific EDCs studied, times of exposure, exposure doses, and the effects of other EDCs, either those assessed or unknown exposures. In a study of 200 adolescents living in a polluted area of Belgium, delays in genital development and pubic hair growth in boys were associated with serum concentrations of polychlorinated biphenyls (PCBs), and delayed breast development in girls occurred when serum dioxin concentrations were high [54]. Similarly, Leijs *et al.* reported results from a prospective study that related prenatal and perinatal exposure to dioxin-like compounds with delayed onset of breast development in girls and a trend to delayed age at first ejaculation in boys [55]. Other investigators have been unable to demonstrate large effects of similar EDCs [56, 57].

Many of the action of EDCs are thought to occur through their direct effects on oestrogen receptors (ER), particularly for high-dose exposures. However, in animal studies very low-level exposure has been shown to cause abnormal development through alternative mechanisms. Bisphenol A (BPA) is a plasticizer found in many bottles, cans, and other items that come in contact with food. It is estimated that 90% of the US population has detectable BPA concentrations in urine [58]. BPA is a selective oestrogen receptor modulator (SERM) that acts both at ERα and ERβ. Low dose in utero BPA exposure in mice altered expression of DNA methyltransferases in the fetal CNS, enzymes involved in epigenetic gene methylation. These alterations were associated with changes in methylation of the ERα gene in the same brain regions, which led to altered ERα gene expression. Exposed female offspring demonstrated disrupted sexually dimorphic behaviours, indicating long-lasting effects even at low doses [59].

Secular Trends in Pubertal Maturation

Secular or long-term temporal trends for human puberty, menarche, and reproduction have been of interest for centuries. One should distinguish the issue of *timing*—the chronological ages at which certain events within the pubertal maturation scheme occur—from *tempo*, which refers to the time taken to pass through the various stages of pubertal maturation. In terms of an evolutionary/developmental model, data from skeletal ages of remains (e.g. limb length) suggest that in Palaeolithic women menarche occurred at ages between 7 and 13 years (slightly younger or comparable to present ages), early sexual maturation being an evolutionary trade-off of a reduced life expectancy [60]. There was an apparent stabilization at age 12–15 years through the Classical and Medieval times, which are not so different from the present era. During the mid-nineteenth century Industrial Revolution there was an increase to 15.5 to 17.4 years [61, 62], with adolescents from the higher socioeconomic strata at the lower end of that age range, perhaps reflecting good general health and nutritional status. The increase in the age at menarche during the mid-nineteenth century was considered to be related to deleterious living conditions in which hygiene deteriorated, the population density increased, nutrient availability was diminished, and infectious diseases were common.

Investigators have since shown a secular trend toward a decreasing age at menarche from the mid-19th century (~16–17 years) as sanitation and living standards improved and the burden of infectious diseases diminished, especially water and food borne illnesses [60]. This general trend occurred at a rate as high as 12 months per decade, decreasing to perhaps 3 months per decade in the early and mid-twentieth century. Over the last 4–6 decades, this trend has levelled off, except for continuing small decreases in age at menarche in some areas of the developing world [60]. A similar trend was noted in boys using the timing of voice breaking as the criterion for pubertal maturation.

More recently, there has been interest in other indicators of pubertal maturation besides menarche, including indicators for boys. Trends have been noted in adult height, with a gain of 1–3 cm per decade as well as in weight, although the latter has been more variable [63]. There is significant heterogeneity in these changes related to ethnic, geographical, and socioeconomic factors, including 'modernization' that has included decreases in family size and child/early adolescent labour. Stress and endocrine disrupting chemicals (EDC) have also been implicated [64]. It is likely that early nutritional alterations have also played a role. There is a significant influence of birth weight as an output variable of environmental factors acting *in utero* [63]. Especially strong is the influence of the rate of weight gain in the first 1000 days from conception (developmental origins of health and disease, DOHaD, or Barker hypothesis) [63, 65] on the timing and tempo of pubertal maturation and subsequent menarche in girls [66]. During these first 2 years the child maintains developmental plasticity [65] or the ability to modify structure and function in response to environmental cues, especially those present *in utero* [63]. These permanent effects are thought to occur by epigenetic mechanisms in response to the mismatch of the initial environment (e.g. poor nutrition *in utero)* to the later environment (e.g. a surfeit of energy availability). Some girls with lower birth weight and rapid early, post-natal weight gain enter puberty early and mature more rapidly than peers of normal birth weight, often resulting in short stature as adults [67].

Recent trends show slightly more than a year earlier start of pubertal maturation in girls, but a much smaller decrement in the age at menarche, indicating a slower tempo from the start of maturation to its completion [68]. Are there longer-term effects of this modern trend? There likely are, with respect to earlier menopause; reproductive system neoplasia, breast cancer; and the metabolic syndrome linked to the long-term consequences of obesity [64].

Secular changes can occur even over the span of several decades, especially within an isolated society that may undergo demographic and epidemiological shifts. Demographic shifts include a change from relatively low population growth and a small difference between birth and death rates to a rapid population growth and a divergence of births and deaths. Epidemiologic shifts include a change from high infectious disease mortality to an increase in mortality from degenerative (non-communicable) diseases in older adults [69]. This is precisely what has happened in the Valley of Oaxaca in southern Mexico, with a direct correlation between changes in maturation and demographic and epidemiological transitions within the Zapotec-speaking indigenous population as chronicled over 4 decades by Malina and his coworkers [69]. The data show changes in body size (height, weight, and BMI all increase) and in the age of menarche over the time of observation. The age at menarche (15 years) was stable in those born between 1896 and 1954 before the demographic change. However, there was a decrease of ~0.51 yr/decade for those born from 1955 to 1981 (14 years) at the

onset of the demographic transition and an accelerated decrement of 0.78 yr/decade for those born between 1983 and 1992, with subsequent menarche at approximately 13 years [69]. This insular and very well evaluated and reported population is likely a microcosm for the more broad-based populations for which there are data over centuries.

An interesting set of data have come from the Fels Longitudinal Study [6] in which two cohorts of females were followed longitudinally. One cohort was born in the years 1929–1954 and the second in 1955–1982. All had data obtained until at least age 21 years, and there was an average of 21 serial observations. The initial BMI 6 years before menarche was indistinguishable between the two cohorts. The final BMI 6 years beyond menarche was 1.2 kg/m^2 greater in the more recently born women. This difference was statistically significant. In fact, the later-born cohort began to have greater BMI four years before menarche. Yet at all times the heights at each year were indistinguishable between cohorts. This is consistent with those in the later cohort having more adipose tissue compared to those in the earlier cohort. There were no significant differences between the two cohorts (that is, no secular trend) in attaining ages at early childhood minimum height velocity (MHV), prepubertal MHV, PHV, or age at menarche. From a larger database, Chumlea and colleagues concluded that there is no secular trend in the age at menarche in US girls over the past few decades [70]. Thus, it seems in the general US population that the secular trend in menarche has vanished over the past 4 or more decades; however, that does not mean that in isolated populations, as noted by Malina *et al*. [69], rapid changes in socioeconomic variables can still support secular changes in pubertal maturation, including age at menarche.

Tempo of Pubertal Maturation

Pubertal tempo is a measure of the rate of individual change over time. It may refer to passage between individual stages or across multiple stages; for example, from the beginning (B2) to the end (B5 or menarche). The data of Marshall and Tanner showed that traversing genital stage 2 to stage 5 in boys required approximately 3 years, with a range of 1.86–4.7 years. In girls the transition from B2 to B5 took an average of 4 years, but with a striking range, 1.51 to nearly 9 years. It should be noted that some girls mature to B4 but not B5 and others may 'skip' B4 maturation stage [71, 72].

Flor and colleagues noted the synchrony of the magnitude of skeletal age maturation and the magnitude of pubertal acceleration or delay in their study of boys with sexual precocity due to congenital adrenal hyperplasia, familial male-limited precocious puberty, or delayed sexual maturation due to constitutional delay of growth and puberty [73]. The synchronous maturation was not related to weight, height nor BMI. The hypothesis, at least in boys, is that skeletal maturation influences the HPG axis maturation.

Quantitative data for girls were presented by Pantsiotou and colleagues, who noted differences in first to third quartile maturation compared to the slowest fourth quartile for passage through several stages of sexual maturation (Table 7.3.1.5) [74]. These data are concordant with those of Rosenfield and colleagues, who showed that those girls who began pubertal development early had a slower course through pubertal maturation to menarche [68].

Table 7.3.1.5 Rates of pubertal maturation in girls. Data presented as years (IQR)

Maturation stages	Early	Average	Late
B2 to PHV	1.6 (1.0–2.2)	1.1 (0.7–1.7)	0.9 (0.3–1.1)
PHV to menarche	0.8 (0.6–1.2)	0.8 (0.4–1.3)	0.9 (0.5–1.3)
B2 to menarche	2.3 (2.0–2.8)	2.1 (1.7–2.8)	1.6 (1.4–2.4)

B2, Breast Tanner stage 2; IQR, interquartile range; PHV, peak height velocity.

Activity in sport has been proposed as a modifier of growth and pubertal maturation; however, at least in some aesthetic sports, for example, artistic gymnastics, distance running, and ice skating, body size is apparently a selection criterion [75]. In small subsets of male and female adolescents in the Wroclaw, Poland Longitudinal Growth Study, Malina and Bielicki found that the heights and weights of boys who were active in sport and training followed the growth trajectory of early maturing boys [76]. The growth trajectories for girls who were active in sport and training were indistinguishable from those of the normal, non-training girls [76].

Distinction of Early Normal Puberty from Precocious Puberty

At times, the challenge for the clinician is to determine whether a patient's pubertal changes occur because of normal maturational processes that happen at the younger end of the age spectrum or because of pathological processes occurring later in childhood. Precocious puberty may take numerous forms, as discussed in Chapter 7.3.3, and an extensive discussion is beyond the scope of this chapter. However, there are a number of considerations when trying to distinguish pathologic vs. early normal pubertal maturation.

1. **Age at onset**. Much has been published about the younger end of the normal range of pubertal onset. Traditional teaching has been that it is abnormal for signs of puberty to occur before age 8 years in girls and 9 years in boys. However, the data upon which these ages are based were derived from relatively racially and ethnically homogenous populations and were obtained before the dramatic increase in the prevalence of childhood obesity. More recent studies of racially/ethnically diverse children show that puberty may begin earlier in African-American and Mexican-American children than in White children and that pubertal maturation in general may begin earlier [77]. While the younger end of normal is a subject for further debate, the clinician should have a high index of suspicion when pubertal changes occur before these ages.
2. **Pattern of maturation**. Physiological puberty usually follows a characteristic sequence in which breast development and testicular enlargement occur in temporal relationship to pubic hair and other signs of maturation. Physical changes occurring out of sequence or missing elements of maturation (e.g. pubic hair without testicular growth) should be viewed with suspicion.
3. **Tempo of maturation**. Pubertal changes that progress more rapidly than normal may indicate a pathological cause (e.g. adrenal tumour).

4. **Rate of linear growth**. There is a predictable relationship of the pubertal growth acceleration to the other physical changes in boys and girls, with peak height velocity occurring earlier in the maturational process in girls than in boys. When signs of pubertal maturation are noted without accompanying normal growth acceleration, a normal variant such as premature adrenarche or premature thelarche may be present.
5. **Skeletal maturation**. There is a close relationship between skeletal maturation (bone age) and the onset of the pubertal growth spurt. Both boys and girls with normal puberty begin the pubertal growth spurt when 85% of adult height is attained [78]. When translated into bone age, this corresponds to a bone age of 11.0 years for girls and 13.5 years for boys using the methods of Bayley and Pinneau and Greulich and Pyle [79]. Thus, an obvious linear growth acceleration at significantly younger bone ages should raise concern for abnormal puberty.
6. **Laboratory testing**. Endocrine testing may confirm the presence of pathologic causes of early puberty, such as suppression of LH secretion in response to GnRH analogue administration in cases of peripheral precocious puberty or high concentrations of 17-hydroxyprogesterone in the 21-hydroxylase deficiency variant of congenital adrenal hyperplasia. Of note, there is a large degree of overlap in gonadotropin concentrations between normal prepubertal children and those in the early stages of normally timed or precocious central puberty, making the measurement of LH and FSH levels an insensitive approach to assessing the onset of puberty. Additionally, demonstration of normal pubertal changes in endocrine testing will not by itself distinguish central precocious puberty from normal timing.
7. **Imaging**. Similar to laboratory testing, imaging of the CNS, adrenal glands, or pelvis may identify pathologic causes of puberty. Demonstration of ovarian enlargement on pelvic imaging suggests gonadotropin-mediated puberty, but will not distinguish central precocious puberty from normal timing.

Distinction of Late Puberty (Physiologic) from Pathologic Delay

When evaluating a child with delayed puberty, it is important to distinguish those with true pathology, for example, idiopathic hypogonadotropic hypogonadism, from those with 'late blooming' or constitutional delay of growth and puberty (CDGP). The latter is characterized by a *delay* in the timing and potentially the tempo of maturation. Height velocity appears slow as affected children continue to grow at their previous prepubertal rate or slower, compared to their peers who are undergoing the pubertal growth spurt. The evaluation should include determination of a child's bone age, which appears younger than chronological age [80]. When plotted on the growth chart against bone age rather than chronological age, the height of a child with CDGP appears normal and more consistent with mid-parental target height. A family history of CDGP is not uncommon, and children often reach their genetic potential *without* intervention. Spontaneous puberty occurs by 18 years of age; however, testosterone therapy has the potential to reduce some of the psychosocial distress that frequently accompanies delayed puberty.

Although some studies have shown little effect of CDGP on psychosocial well-being [81], others demonstrate an association with poor psychological outcomes. Some of these negative outcomes may persist into adolescence and emerging adulthood. The Oakland Growth Study, for example, found that late maturing boys were not only perceived as less mature and less attractive than peers, but also had more feelings of inadequacy, which persisted into emerging adulthood [82]. Delayed pubertal timing has also been associated with higher rates of depression, anxiety, and substance use in adolescence and young adulthood. Academic achievement may be adversely affected as well [81].

Delayed puberty may also occur in those with permanent hypogonadism, caused by failure to produce sufficient levels of testosterone, sperm, or both [83]. The differential diagnosis between these two categories, especially the latter, is complex and discussed in greater detail in other chapters (7.3.2 and 2.3.1) in this text. Clinical and laboratory findings to distinguish those with CDGP from those with idiopathic hypogonadotropic hypogonadism are noted in Table 7.3.1.6.

Nutritional and Other Non-Hormonal Causes of Delayed Puberty

Worldwide, malnutrition caused by inadequate intake of calories, protein, or both is by far the largest factor in poor growth, stunting, and delayed puberty. The greatest impact is on infants and toddlers, often with lifelong consequences of stunting and inadequate psychological and intellectual development. This may manifest by being born small-for-gestational age or as infectious diseases and diarrhoea during infancy. Although these factors may continue through childhood and manifest as delayed pubertal maturation (and development), there is less documentation.

Table 7.3.1.6 Clinical and laboratory findings in IHH and CDGP

Feature	IHH	CDGP
Hormonal profiling during 'mini-puberty' at 4–8 weeks of life	Lack of appropriate rise in LH and testosterone	Elevated LH and testosterone levels
Pubertal onset	Absent or pubertal arrest (less common)	Delayed; spontaneous progressive maturation by age 18
Puberty pattern	Absent or arrested gonadarche	Delayed pubarche and gonadarche
Growth	Prepubertal growth; +/– eunuchoid proportions (delayed growth plate fusion)	Normal growth for bone age
Family history of delayed puberty	+/–	+/–
Sense of smell	+/– Anosmia (30–50%)	Normal
Testicular size	Small testes (1–2 ml); +/– history of cryptorchidism	Normal for bone age
Stretched penile length	+/– micropenis	Normal for bone age
Possible associations	Bilateral synkinesia (mirror movements), dental agenesis, renal anomalies, hearing impairment, midline defects (cleft lip/palate)	None

In this section, we will highlight some acquired causes of delayed growth and maturation that are seemingly 'primary' as opposed to those resulting from chronic diseases and their treatments. Adolescent eating disorders include anorexia nervosa, an extreme dissatisfaction with one's body (size or shape or even certain parts). This dissatisfaction may lead to pathologic phobias and food aversion [84]. Bulimia nervosa reflects a fear of fatness and attempts to lose weight by fasting and binge eating but then purging to avoid weight gain. Patient with bulimia nervosa are usually not as underweight as those with anorexia nervosa. Both disorders are more commonly seen in adolescent girls.

Similarly, there is a large group of adolescents, mainly female, with perhaps a 'sub-clinical' form of anorexia nervosa, designated as 'fear of obesity'. These adolescents practice many of the same dietary strategies to remain thin, often with goals of a fraction of their ideal weight [85]. Slowing of growth and maturation is one consequence of this eating behaviour, which may occur in over 50% of 12th grade girls, especially in affluent areas [86].

'Excessive' Energy Expenditure

Energy availability and growth and pubertal maturation may be better understood through a dissection of the mechanism of relative energy deficiency in sport, formerly known as the female athlete triad, as this concept also affects males [87]. The triad originally referred to the relationship between three inter-related components: energy availability (EA), menstrual function, and bone health [88]. There is often a trajectory over time: healthy athlete to the opposite end of the spectrum—low EA, amenorrhea, and osteoporosis [87]. The broadened definition now includes a clinical syndrome that results from relative energy deficiency including alterations in metabolic rate, protein synthesis, menstrual function, bone health, immunity, and cardiovascular and psychological health [87]. The more direct connection to puberty was shown in two elegant reports by Loucks who noted alterations in LH pulsatility within 5 days of decreasing the daily energy balance from 45 kcal/kg lean body mass (LBM)/day to 30, 20, and 15 kcal/kg LBM/day. Although no significant slowing of the GnRH pulse generator occurred at 30 kcal/kg LBM/day, significant slowing—as defined by number of LH pulses—was noted at 20 kcal/kg/LBM/day, with further slowing at 10 kcal/kg LBM/day [89]. That this was relevant to the hypothalamic–pituitary–gonadal axis at puberty was shown by Loucks, noting that susceptibility to the effects of the energy deficit was attenuated as adolescent women 'aged', and was gone by 14 years post-menarche [90]. These data fit well with the known 'physiologic' disorders of menstrual cycles within the first 2 years following menarche. The data may be interpreted as an exquisite sensitivity to nutritional or psychologic stressors.

A similar mechanism may be operative in the male, as states of chronic undernutrition can cause profound suppression of reproductive function, including diminished pulsatile LH secretion. Using the male rhesus monkey as an example, Cameron and colleagues showed that a brief period of fasting suppressed LH secretion, commencing a few hours after a missed meal. This was considered to be due to an energy deficit and not non-specific 'stress', since naloxone, an opioid antagonist, did not reverse the alteration to the central gonadal axis [91].

An example in the human is that short stature of youth artistic gymnasts has been attributed to the effects of intensive training, especially from an early age. The data from a conference devoted to this issue are noted by Malina *et al.* [75], and may be summarized as follows:

1. Near adult or adult height of female and male artistic gymnasts is not compromised by intensive training at a young age or during the pubertal growth spurt
2. Gymnastics training does not attenuate growth of the upper (sitting height) or lower (legs) body segment lengths.
3. Gymnastics training does not appear to attenuate pubertal growth and maturation, including skeletal age, secondary sex characteristics, age at menarche, rate of growth, and timing and tempo of the growth spurt.
4. Present data are insufficient to address the issue of intensive gymnastics training and alterations within multiple endocrine systems
5. Though shorter and lighter than their average peers, gymnasts have an appropriate weight for height, making it less likely that malnutrition is an important factor.
6. Given the individuality of physical growth and biological maturation and the variety of factors known to influence these processes, it is difficult to specify effects attributable to systematic training in artistic gymnasts.
7. Artistic gymnasts show patterns of growth characteristics comparable to short, late-maturing youth with short parents.
8. Other variables that may affect growth and maturation should be considered and include: dietary intake, family size and related characteristics, and quantitative indicators of training time, intensity, and environment (e.g. 'toxic' stress).

Although these data were gathered and debated specifically for artistic gymnastics, their reach goes far beyond this very select group of adolescents; for the effects of some of the factors listed here, especially #8, may have profound effects on far larger groups of adolescents from many backgrounds.

Stress

In day-to-day activities the stress response is meant to be transient. Its accompanying anti-growth, anti-reproductive, catabolic, and immunosuppressive effects are temporarily beneficial and/or of no adverse consequences to the individual [92]. On the other hand, chronic activation of this system may affect growth, maturation, and reproduction due to its effects on the hypothalamic–pituitary–adrenal (HPA) axis. In the realm of growth and maturation, prolonged activation of the HPA axis may lead to:

- Suppression of GH secretion
- Glucocorticoid-induced effects on IGF-I action
- CRH-induced increases in somatostatin, indirectly inhibiting GH secretion [92]
- Inhibition of gonadotropin secretion

These hormonal effects are manifest in the clinical realm as the syndrome of psychosocial short stature, a term that was originally used to describe severely compromised height in children or adolescents due to emotional deprivation and/or physical/psychological abuse [93]. The original description included a syndrome simulating idiopathic hypopituitarism, with apparent GH deficiency or secondary adrenal failure. What was of great surprise was that removal from the inciting environment led very quickly to reversal of the signs and symptoms.

Within a month of convalescent 'therapy' away from the initial environment, a number of the children grew at an accelerated rate and had reversal of their abnormal pituitary stimulation tests [94, 95].

The syndrome is seemingly far less common in the adolescent, but one of us (ADR) followed such a patient through late adolescence and into young adulthood [96]. Growth failure and delayed sexual maturation developed in an adolescent male after severe emotional trauma at age 12 years. He had an eating disorder, was profoundly malnourished for several months, and then resumed eating spontaneously. When evaluated at age 17 years 8 months, he was entirely prepubertal, tested multiple times as GH deficient, and had low gonadotropin levels. The hormonal deficits persisted for many years despite good nutrition and lack of abuse, a course inconsistent with psychosocial short stature or effects of malnutrition *per se.* In his third decade the patient spontaneously grew to a normal adult stature compatible with his mid-parental target height and had full maturation of primary and secondary sexual characteristics. The conclusion was that psychologic trauma induced a deranged hormonal state that persisted for almost a decade [96].

Disorders (Differences) of Sex Development (DSD)

Most individuals with DSDs present at birth or during infancy. However, some of the milder DSDs, especially those that change at adolescence, present with differences in the development or progression of pubertal maturation. Chapter 7.2.2 ('Disorders of Sex Development (DSD) in the Newborn') presents the subject in depth. In summary, the following groups of adolescents may present with a suspected DSD:

1. Girls with primary amenorrhea, with or without breast development
2. Girls who virilize at puberty
3. Boys with pubertal delay (very small percentage of the far more prevalent group with CDGP)

Summary and Conclusions

Puberty is the time for major changes in sexual maturation and psychosocial development. We emphasize the physical changes and their hormonal and regulatory concomitants as the immature, prepubertal boy and girl traverse multiple adolescent stages to become emerging adults at nearly full adult height and sexual maturation. Fully developed body composition usually does not occur until the third decade. Genetic and environmental factors, including the social environment, nutrition, and endocrine disrupting chemicals, are noted as modifiers or modulators of these physiologic processes, with emphasis on the timing, tempo, and longer-term secular trends. We finish with describing some common variants of pubertal maturation, which are more fully described in Chapters 7.3.2 and 7.3.3.

7.3.2 Pubertal Delay and Hypogonadism

Alan D. Rogol and John S. Fuqua

Introduction

Puberty may be defined as the physiologic process resulting in the attainment of sexual maturity and reproductive capacity. An assessment of puberty is an integral component of the evaluation and treatment of endocrine disorders in children and adolescents. Not only does it impact sexual maturation, but it has other effects with lifelong consequences, including linear growth, changes in body composition, and skeletal mineralization. Patients with disorders of puberty, including precocious and delayed puberty, make up a large percentage of the children and adolescents who consult paediatric endocrinologists. An understanding of delayed or absent puberty requires a foundation in the normal processes regulating the onset of puberty and factors essential for its progression and completion. In this chapter, we will first review normal growth and puberty, particularly with regard to their interdependence. We shall then discuss the differential diagnosis of delayed or absent puberty and present diagnostic algorithms for hypergonadotropic and hypogonadotropic hypogonadism, emphasizing some gender-specific aspects.

Physical Changes of Puberty

Concurrent with the secretion of sex steroids during puberty, major physical changes, physiologic adaptations, and social and emotional challenges occur. The measurement and assessment of these changes are critical for determining when pubertal maturation is progressing normally or not and to monitor the efficacy of treatment.

Puberty in Boys

In boys, the earliest physical change associated with puberty is testicular enlargement, although a subset of boys has pubic hair growth due to adrenal androgens prior to testicular enlargement. Testicular size is commonly assessed by using a series of calibrated, testis-shaped ellipsoids (beads) called the Prader orchidometer. If this is not available, the long axis of the testis can be measured using simple callipers or an ordinary tape measure. Prepubertal testes are <4 ml in volume and less than or equal to 2.5 cm in length. As puberty ensues, the testes gradually enlarge, mainly due to increases in volume of the seminiferous tubule content, and eventually reach the adult volume of 15–25 ml or length of 4–5 cm. Physical changes accompanying testicular enlargement include thinning of the scrotal skin, apocrine sweating and odour, and the growth of sexual hair. Additional changes present in boys include an increase in muscular size and strength and body hair growth in a typical adult male pattern. Deepening of the voice occurs during the second half of pubertal maturation.

Genital development in boys is often assessed using the method of Tanner. Two rating scales are used in males: one for pubic hair growth and another for enlargement of the testes, penis, and scrotum. Tanner stages for boys are reviewed in Table 7.3.1.1 in Chapter 7.3.1. Briefly, pubic hair growth starts as fine, straight, lightly pigmented hairs generally located on the pubic symphysis at the base of the penis. As puberty progresses, the hair becomes coarser and curly, with darker pigmentation. At Tanner stage 5, the growth extends down the medial thighs and up the lower abdomen. Genital Tanner stages are somewhat more subjective. The earliest stage of puberty consists of testicular enlargement only, followed by gradual enlargement of the penis, first in length and then in circumference, and enlargement of the testes to reach full adult maturity [1].

Puberty in Girls

In girls, the first clinically apparent sign of puberty is breast development, although pubic hair growth precedes breast development by up to 6 months in approximately 30%. It is common for one breast to grow for several months before the other, and mild asymmetry is often present. Pubic hair growth usually begins within 6 months of the onset of breast development. As oestrogen levels increase, changes occur in the vaginal mucosa. In the prepubertal girl, the vaginal epithelium is thin with a dark red colour and consists mainly of basal and parabasal cells. With advancing pubertal maturation, the epithelium proliferates and thickens. Intermediate and superficial cornified squamous cells overlay the parabasal cells and give the mucosa a pink, opalescent appearance. This is often accompanied by a physiologic vaginal discharge.

The progression of puberty in girls is also assessed with Tanner staging. Pubic hair in girls is assessed using the same hallmarks as in boys, although normal girls with Tanner stage 5 pubic hair do not have extension up the lower abdomen (Table 7.3.1.1 in Chapter 7.3.1). Some physicians add a Tanner stage 6 in girls to describe those with pubic hair extension both to the medial thighs and in the midline of the lower abdomen. Breast development is commonly measured using Tanner staging as well, and this is also depicted in Table 7.3.1.1 in Chapter 7.3.1. Breast development begins at Tanner stage 2 with budding, in which there is a firm palpable disk of tissue not larger than the areola. In stage 3, the diameter of the tissue exceeds the areola but does not have stage 4 morphology. Stage 3 encompasses a large range of development, from very early in puberty up to the later stages of maturation. With stage 4, there is a 'double contour' in which the profile of the areola is distinct from the profile of the breast. Although stage 5 is considered to be full adult development, some normal adult women do not progress beyond stage 4, and some never develop a double contour, skipping stage 4 altogether [2].

Growth and Pubertal Maturation

The clinical hallmark of puberty as it relates to body size is the pubertal growth spurt. In boys, the peak of the growth spurt is timed to Tanner stage III–IV, whereas in girls the peak occurs earlier in puberty, typically at Tanner stages II–III. The average peak growth velocity in boys is 9.5 cm/year, and in girls it is somewhat less, 8.3 cm/year. The later onset of puberty, the later occurrence of the growth spurt within puberty in boys, and the greater magnitude of the growth spurt result in an average height difference between the sexes of 13 cm.

Puberty also has effects on skeletal maturation, and the timing of puberty is more closely correlated with the bone age than with chronologic age. In European girls, the average bone age at the time of thelarche is 10.5 years (95% confidence limits 8.5–13.2), and at the time of menarche it is 12.8 years (11.3–13.6). In girls, the peak height velocity occurs at a bone age of 12 years. In boys, the average bone age at stage 2 of puberty is 11.5 years (9.0–14.2). At peak height velocity in boys, the bone age ranged between 11.9 and 15.5 years in one study and between 12.5 and 16 years in another study [3, 4].

Children with advanced bone ages typically enter puberty earlier than their peers, while those with delayed bone ages enter puberty later. Factors that alter the bone age also alter the timing of puberty, and these may include sex steroids and the GH/IGF-1 system [4].

Age at Onset of Puberty

There is a great deal of disagreement about the age at which pubertal maturation is normal. Most of this disagreement relates to the lower age limit of normal. There is evidence that the age of onset of puberty has decreased in the last several decades in both girls and boys. For boys, data show that the average age at Tanner stage 2 maturation is between 11.2 and 12.4 years. The normal range of attainment of stage 2 puberty in boys is commonly considered to extend from 9 years up to 13.5 years. For girls, there is more disagreement. Historically, the normal range of onset of puberty has been between 8 and 13 years, but the lower limit of normal may extend down to 7 years for white girls and 6 years for black girls. An analysis of data from the Third National Health and Nutrition Examination Survey (NHANES) in the United States revealed that body mass index (BMI) is an independent predictor of the age of onset of puberty, with earlier occurrence of breast and pubic hair development and earlier menarche in girls with BMI above the 85th percentile [5]. The upper limit of 13 years for girls remains generally accepted. The **tempo** of pubertal maturation is also important to consider. Girls starting puberty earlier than average tend to have a slower progression to menarche than girls starting puberty later. Hence, the age at menarche has less variability than the age at thelarche and is about 12.6 years. This phenomenon also probably occurs in males, but the lack of a clearly definable event such as menarche in male puberty makes study difficult [6–9].

Hypothalamic–Pituitary–Gonadal (HPG) Axis Maturation

A detailed discussion of HPG axis maturation is beyond the scope of this chapter but is discussed in more detail in Chapter 7.3.1. 'Recognizing Normal and Disordered Pubertal Development'. Briefly, the hypothalamic-pituitary-gonadal axis is active *in utero*, with peak secretion of gonadotropin releasing hormone (GnRH), luteinizing hormone (LH), and follicle stimulating hormone (FSH) occurring between 20 and 24 weeks' gestation. During later pregnancy, levels drop as the negative feedback effects of gonadal hormones intensify. There is a brief 'minipuberty of infancy' that occurs early after birth, but by 5–6 months of age GnRH secretion, LH and FSH levels, and gonadal steroid levels fall to their prepubertal levels. This cessation of activity is known as the juvenile pause. Over the course of the next several years, the juvenile pause persists, reaching the greatest degree of axis suppression in females at about age 6 years.

When measured using immunoassays, which lack sensitivity at low concentrations, the morning increases in testosterone and oestradiol may be difficult to detect during the very earliest stages of puberty. However, modern techniques, such as liquid chromatography/tandem mass spectrometry (MS) can usually detect even the lower prepubertal levels. In early puberty, gonadotropin levels also may be difficult to distinguish from normal prepubertal levels, in part due to the pulsatile nature of their secretion and in part due to the low amplitude of secretion during the daytime. These factors make the routine laboratory evaluation of delayed puberty difficult, because randomly obtained gonadotropin and sex steroid levels do not differentiate a patient who is nearing a normal but delayed puberty from one who will never enter puberty due to a pathological condition. However, as GnRH pulsatility increases in early puberty, pituitary stores of LH also increase. These stores may be released following acute stimulation by GnRH. This is the basis for the GnRH stimulation test, which may be positive even before physical changes of puberty become clinically apparent.

Over the course of puberty in girls, LH levels increase 25–40-fold relative to levels present before puberty. Oestradiol concentrations increase from <5 pg/ml (<18.4 pmol/L) before puberty up to >100 pg/ml (>367 pmol/L) in a post-menarchal girl. Testosterone concentrations in prepubertal males generally are below 10 ng/dL (0.35 nmol/L), and in young adults they are above 300 ng/dL (10.4 nmol/L).

Control of Pubertal Timing

The mechanisms underlying regulation of pubertal timing have been partially elucidated in recent years, but much remains poorly understood. There is a strong influence of genetics on the timing of puberty, and it is estimated that 50–80% of the variance can be attributed to genetic factors [10, 11]. Genome-wide association studies have demonstrated associations between a number of loci and age at menarche. A recent study of 11 000 samples with associated clinical data identified loci relevant to timing of both female and male puberty [12]. Interestingly, loci associated with increased body mass index (BMI) were also associated with early puberty in females, while those loci were variably associated with either early or delayed puberty in boys, reflecting the conflicting clinical data of the impact of this parameter on male puberty [13]. Additional environmental inputs on pubertal timing include endocrine disrupting chemicals. Although exposure to these substances is often associated with early pubertal maturation, they may also lead to delayed maturation in both males and females. Investigation

of these effects is confounded by the multiplicity of exposures. Additionally, differing levels of exposure may lead to opposite effects on pubertal timing. Further, there appears to be a window of vulnerability, with effects being particularly apparent after exposure in early life [14]. The effects of these and other environmental factors may be through direct genomic mechanisms, but also likely involve non-genomic (epigenetic) mechanisms, such as effects on DNA and histone methylation, histone acetylation, and microRNA expression. This topic is discussed in more detail in Chapter 7.3.1., 'Recognizing Normal and Disordered Pubertal Development'.

Delayed Puberty and Hypogonadism

The causes of delayed puberty and hypogonadism can be divided into those involving delays or defects in hypothalamic regulation of the initiation of puberty and those involving primary defects of the gonads. These groups of conditions are best differentiated by the serum concentrations of gonadotropins after the age when puberty is expected. Hypothalamic and pituitary deficiencies are termed hypogonadotropic hypogonadism or central hypogonadism, and primary gonadal disorders are termed hypergonadotropic hypogonadism or primary hypogonadism.

Constitutional Delay of Growth and Puberty (Transient Hypogonadotropic Hypogonadism)

Constitutional delay of growth and puberty (CDGP) is a common variant of physiologic (normal) maturation. Its major outward characteristics include a slowing of linear growth during the late preteen and early teen years as well as a delay in the timing (and perhaps tempo) of puberty. In the typical scenario, a boy (or his parents) seeks endocrinological evaluation in the early teenage years because of significant concern for the discrepancy in growth and pubertal maturation between the patient and his/her age peers (Figure 7.3.2.1). The condition must be distinguished from hypogonadotropic hypogonadism [15, 16] (Table 7.3.2.1).

Clinically, the height age (the age for which the patient's height is the 50th centile) is delayed with respect to the calendar age but is concordant with the 'biological age' as indexed by the bone age. Sexual maturation is either prepubertal or lagging behind that of their peers, although it is often appropriate for the bone age. The height velocity is normal for a **prepubertal** child, although it may decline to subnormal values if the delay is more than 2–3 years (prepubertal 'dip'). When the height is plotted on the standard growth curve, the height gain appears to be 'falling off' the previously defined height centile, since the standard growth curve incorporates the pubertal growth spurt at an 'average' age. This discrepancy in growth between the normal adolescent age peers and the one with CDGP only accentuates the difference between them. The height discrepancy and the delay in pubertal maturation are often compelling concerns of the patient or the family, bringing the adolescent to medical consultation. Tanner has devised longitudinal growth curves that account for the later growth and adolescent maturation, because this pattern is so common. The large majority of those with CDGP follow this 'custom' curve, emphasizing that the standard growth curves based upon cross-sectional data, although adequate for the population 'averages', do not necessarily describe the growth of an **individual**.

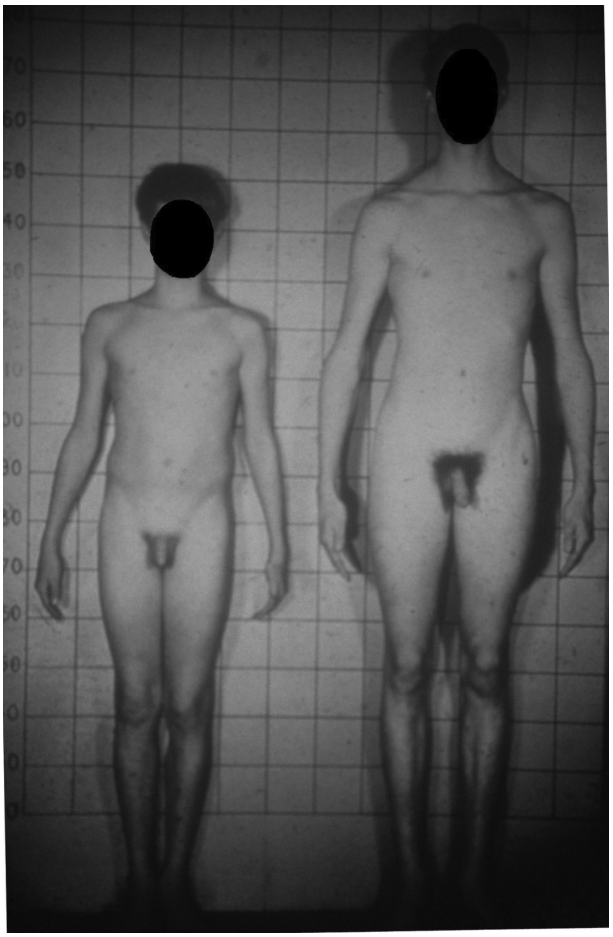

Figure 7.3.2.1 Healthy fraternal twin boys, age 15 years. The boy on the right has had normally timed pubertal development. His brother on the left has constitutional delay of growth and puberty.

Biochemically, adolescents with CDGP resemble their peers with comparable biological (bone) ages. Thus, the pubertal increases in haemoglobin, haematocrit, creatinine, and alkaline phosphatase will not be present. Serum levels of growth hormone (pulsatile pattern), IGF-I, IGFBP-3, LH, FSH, and the sex steroids may be diminished for chronological age, but normal when compared to younger adolescents of the same stage of pubertal maturation. The suppressed HPG axis found in adolescents with CDGP represents an extension of the physiologic hypogonadotropic hypogonadism (the 'juvenile pause') noted since infancy.

Without intervention with sex steroids, adolescents with CDGP will undergo spontaneous pubertal maturation and will reach their target height range as calculated from parental stature. Maturation occurs as much as several years after that of their peers. Failure to enter puberty spontaneously indicates long-term hypogonadism. Many adolescents with CDGP find the delay intolerable and suffer significant emotional distress because they differ in their appearance from their peers during these years. That is often the rationale for the **short-term** use of gonadal steroid therapy. Linear growth and a more mature 'appearance' are more objective outcomes of gonadal steroid administration.

Although some studies have shown little effect of CDGP on psychosocial well-being [17], others demonstrate an association with

Table 7.3.2.1 Comparison of CDGP and IHH

Clinical/lab test	CDGP	IHH
History of undescended testicles	–	±
Anosmia/hyposmia	–	+ (30–50% of patients)
Family history of delayed puberty	+	±
Presence of endogenous progressive pubertal maturation by age 18 years	+	–
Puberty pattern	Delayed adrenarche	More likely to have normal adrenarche
Height for age	Usually short	Usually normal
General physical exam	Normal	Usually normal but may have: Synkinesia Cleft lip and/or palate Sensorineural hearing loss Dental agenesis Skeletal malformations
Genital exam	Delayed pubertal maturation. Testicular and penile length appropriate for bone age	Small testes (1–2 ml) ± small phallus
Laboratory evaluation	Unreliable to distinguish between CDGP and IHH	

Table data obtained from Wehkalampi, *et al.* [16] and from Ambler [15].

poor psychological outcomes. Some of these negative outcomes may persist into adolescence and emerging adulthood. The Oakland Growth Study, for example, found that late maturing boys were not only perceived as less mature and less attractive than peers, but also had more feelings of inadequacy, which persisted into emerging adulthood [18]. Delayed pubertal timing has also been associated with higher rates of depression, anxiety, and substance use in adolescence and young adulthood. Academic achievement may be adversely affected as well [17].

Hypogonadotropic Hypogonadism

There are many causes of combined pituitary hormone deficiency, both congenital and acquired, that may include deficiency of GnRH or gonadotropins. These conditions are reviewed in subsections 2.3 and 2.4.

The neuroendocrine control of mammalian reproduction is governed by a single gene coding for gonadotropin-releasing hormone (GnRH). A neural network of approximately 1500 to 2000 neurons integrates various upstream genes that are responsive to environmental cues such as food (energy) availability, stress, and perhaps light-dark cycles (at least in seasonally breeding mammals).

A cascade of signalling molecules and transcription factors plays a crucial role in pituitary development, cell proliferation, patterning, and terminal differentiation [19]. Genes are expressed in an orderly sequence to activate or inhibit downstream processes (target genes) that have specific roles in the terminal differentiation of pluripotential precursor cells. Genes identified in association with isolated hypogonadotropic hypogonadism are listed in Table 7.3.2.2. It should be noted however, that there is increasing evidence that disorders of puberty may be caused by mutations in multiple genes in the same individual (oligogenicity), with some disorders presenting from the accumulative burden of mutations in genes such as FGFR1 and CHD7. In a recent large study of 116 subjects with Kallmann syndrome (KS) and normosmic isolated hypogonadotropic hypogonadism (nIHH), abnormalities in genes known to cause isolated hypogonadotropic hypogonadism (IHH) were identified in 51%. Fifteen per cent (15%) of subjects had abnormalities in two or more genes [20]. This oligogenicity, with synergism between gene defects, likely broadens the phenotypic spectrum and the endocrine profiles of the subjects.

Kallmann syndrome is the combination of hypogonadotropic hypogonadism (HH) and a diminished sense of smell—hyposmia or anosmia. It is mainly due to a failure of the GnRH-secreting neurons, which have an extra-CNS origin in the nasal placode, to leave their origin in the olfactory epithelium and migrate into the CNS. This is accomplished via the olfactory bulb and tract, finally ending at the arcuate nucleus of the hypothalamus. These neurons form a network among themselves and project dendrites toward the median eminence. Through an inadequately understood mechanism, the neural network generates pulses of GnRH, which travel to the median eminence, are secreted into the hypothalamic-pituitary portal system, and then cause the pituitary gonadotrophs to produce LH and FSH pulses in the general circulation. These activate the gonads to produce testosterone or oestrogen/progesterone. Genes involved in the migration of GnRH neurons may lead to KS, although not all patients with these genetic abnormalities will also have anosmia or hyposmia. Those with normosmic isolated hypogonadotropic hypogonadism (nIHH) have an intact sense of smell. They present with a lack of sexual maturation at the appropriate age associated with inappropriately low gonadotropin levels in the presence of prepubertal concentrations of sex steroid hormones, otherwise normal anterior pituitary function, findings on brain imaging, and appropriate response to exogenous pulsatile GnRH administration. Patients with nIHH may not have mutations in genes regulating GnRH neuron migration but may instead have defects in genes important in other aspects of gonadotropin secretion. Approximately 50% of patients presenting with IHH have KS, with the other half having nIHH [20]. Abnormalities of at least 30 genes have been shown to cause both Kallmann syndrome and/or nIHH, and gene mutations have been identified in 31–51% of affected patients [20–22]. Individuals with classic KS and nIHH may be found in the same kindred [23]. Many of the identified genes known to cause KS and nIHH encode receptor-ligand pairs or are involved in networks regulating developmental pathways.

Genetic Abnormalities Associated with Kallmann Syndrome and nIHH

Fibroblast growth factor-8 (FGF8), its receptor FGFR1, and related proteins have been identified as critical to the normal development and migration of GnRH precursor neurons from the fetal olfactory placode to the arcuate nucleus of the hypothalamus [21]. Mutations of some genes in this system (as listed in Table 7.3.2.2) have also been associated with defects in the ears and kidneys as well as additional areas of the CNS. Together, defects in genes involved in the FGF8 system account for approximately 23% of cases of congenital hypogonadotropic hypogonadism [24].

Table 7.3.2.2 Single gene defects leading to isolated hypogonadotropic hypogonadism

Mutations in the FGF8 gene in association with KS were first described in 2008 [24]. FGF8 is transcribed as four isoforms and is expressed in a variety of tissues, including the brain, limbs, heart, eye, and ear. Patients with loss of function mutations have hypogonadism, which may be anosmic or normosmic. Associated abnormalities include hearing loss, hyperextensibility of the digits, and cleft lip/palate [25]. Interestingly, one patient with an FGF8 mutation developed adult-onset hypogonadism, presenting with infertility and decreased libido. He responded normally to pulsatile GnRH therapy [24].

Fibroblast growth factor receptor 1 (FGFR1, aka KAL2) is one of four tyrosine kinase receptors for the much larger family of FGF ligands (at least 23 members) and binds FGF8. Although only approximately 10% of all persons with KS have mutations in this receptor, almost as many with nIHH have the same set of mutations. The inheritance is autosomal dominant. Mutations in FGFR1 may occur in association with mutations in CHD7 with increased frequency (oligogenicity) [20]. Interestingly, some who clearly met the criteria for nIHH subsequently had normal puberty, sexual maturation, and fertility **after** receiving sex-hormone replacement therapy. Ten per cent (5/50) of the subjects in one large series showed this phenotypic response, including increased testicular size suggesting sustained gonadotropin secretion, pulsatile LH secretion, adult levels of testosterone, and a normal ejaculate and sperm count [26, 27]. Isolated anosmia without hypogonadism has also been identified within families with FGFR1 mutations.

ANOS1 (also called KAL1) was the first gene discovered to cause KS. Its protein product, anosmin-1, has neural cell adhesion properties and is produced in a variety of neural tissues, including the developing olfactory bulb [26, 28]. Anosmin-1 modulates FGFR1 signalling on the cell surface and has roles in neurogenesis and the motility and migration of neural cells. It is an absolute requirement for the developing GnRH neurons to traverse the cribriform plate and take residence in the arcuate nucleus [29]. In addition to hypogonadism, individuals with ANOS1 deficiency lack olfactory epithelium and the olfactory bulb and tracts. Associated anomalies include synkinesia (mirror movements of the extremities), unilateral renal agenesis, oculomotor abnormalities, sensorineural hearing loss, and mid-line facial clefts. The mode of inheritance is X-linked recessive; as such it is approximately 10-fold more common in males. Approximately 10–20% of males with KS have mutations in the ANOS1 gene [30].

HS6ST1 is the gene encoding heparan sulphate 6-O-sulfotransferase 1 and is required for the modification of heparan sulphate. 6-O-sulfated heparan sulphate is part of a proteoglycan complex located on the cell surface that is required for normal FGF signalling. HS6ST1 mutations have been identified in kindreds with both KS and nIHH, some members of which have palatal abnormalities. Hypogonadism is inherited in a complex non-Mendelian pattern [31].

Other genes involved in the FGF8 system include FGF17, IL17RD, DUSP6, SPRY4, KLB, and FLRT3, each of which are found in relatively small percentages of patients with KS or nIHH [23].

The prokineticin system is composed of two very similar receptors (PROKR1 and PROKR2) within the rhodopsin receptor family, analogous to the kisspeptin receptor, GPR54. These receptors have two polypeptide ligands, PROK1 and PROK2. The former and its receptor, PROKR1, are primarily found in the gastrointestinal tract, but PROK2 and PROKR2 are located in neuroendocrine areas, including the arcuate nucleus, olfactory tract, and the suprachiasmatic (clock) nucleus. The phenotype includes abnormal development of the olfactory bulbs combined with hypogonadotropic hypogonadism. Humans with mutations in PROK2 or PROKR2 may have the Kallmann or the nIHH phenotype and endocrine profile [26].

Mutations in chromodomain helicase DNA-binding protein 7 (CHD7) are found in the majority of patients with CHARGE syndrome (Coloboma of the eye, Heart defects, Atresia choanae, Retarded growth and development, Genitourinary defects, and Ear abnormalities). Some affected patients have pituitary defects, including growth hormone deficiency and HH. Patients initially identified as having Kallmann syndrome have been subsequently reclassified as having CHARGE syndrome based on the presence of ear abnormalities and detection of mutations in CHD7 [32]. Mutations in CHD7 may occur in association with mutations in FGFR1 with increased frequency (oligogenicity) [20].

Mutations in the *SOX10* gene have been associated with Waardenburg syndrome, a constellation of deafness and pigmentation abnormalities of the eyes and hair. Investigation of the frequency of SOX10 mutations in patients with KS demonstrated gene defects in 38% of those with KS and hearing impairment. SOX10 mutations were found in only 2% of individuals with KS who had normal hearing [33].

Other genes implicated in KS include *WDR11, SEMA3A, SEMA3E, CCDC141, FEZF1, IGSF10, AXL, NELF*, and *SMCHD1* [23, 34, 35].

Genetic Abnormalities Associated Only with nIHH

The *KISS1* and *KISS1R* genes encode kisspeptin and the kisspeptin receptor. A few years after the discovery of the ANOS1 gene came the isolation of the kisspeptin receptor and its cognate ligand, a 54 amino acid peptide comprising residues 68–121 (also known as metastin) of the 145 amino acid precursor, kisspeptin-1 [26, 36]. *KISS1R* is a G-protein-coupled receptor gene that, when mutated, causes autosomal recessive nIHH in both mice and humans, suggesting that it is an obligatory upstream controlling mechanism for pulsatile GnRH secretion. A subset of kisspeptin-secreting neurons demonstrates paracrine or autocrine regulation by neurokinin B and dynorphin. Subjects with mutations in the *KISS1R* gene lack pubertal development at the appropriate time, but have an intact sense of smell. Male and female subjects with mutations in the *KISS1R* gene achieve fertility and normal pregnancy following either exogenous gonadotropin therapy or long-term, pulsatile GnRH administration. As more mutations have been found, the phenotype has expanded to delayed puberty rather than absent pubertal development. In humans, inactivating mutations of this system have been associated with delays in puberty, while activating mutations lead to precocious puberty [37]. These findings solidify the position of the kisspeptin/GPR54 system acting before (upstream of) GnRHR.

The GnRH receptor, GNRHR, is a G-protein coupled receptor expressed on the gonadotropes. Mutations result in impaired GnRH binding, intracellular trafficking, recycling, or signal transduction and cause a spectrum of defects from completely deficient to partial insufficiency of the HPG axis. The mode of inheritance is autosomal recessive. Reports of several series of subjects with nIHH have noted a frequency of GnRHR gene insufficiency ranging from 3.5% to 16.7% [38, 39]. Several patients with homozygous frame shift mutations in the *GNRH1* gene encoding GnRH have been reported [40, 41], but this appears to be a rare cause of nIHH. Affected males had cryptorchidism and microphallus, and both males and females exhibited a complete absence of pubertal development, low gonadotropin concentrations, and low serum levels of testosterone and oestradiol, respectively. The patients were normosmic, and there were no other associated abnormalities. In addition, Chan *et al.* identified several heterozygous variants in patients with nIHH which are of uncertain significance [41].

TAC3/TACR3 encode neurokinin B and its receptor. It has been estimated that mutations in this system may be responsible for over 5% of cases of nIHH [42, 43]. Neurokinin B is co-located in some neurons expressing kisspeptin, where it appears to be involved in autocrine/paracrine regulation of kisspeptin secretion in association with dynorphin. Neurokinin B and its receptor are also expressed in other reproductive tissues, including the uterus and ovary. The majority of the patients identified as having mutations in this system have had abnormalities in the receptor [43, 44]. Nearly all of the male patients had micropenis, but testicular volumes varied, suggesting some degree of testicular function. Interestingly, many affected individuals appear to have had partial or complete recovery of gonadal function in adulthood when observed following treatment [43]. A smaller number of patients with mutations in the *TAC3* gene have been described. However, the phenotype of these individuals is indistinguishable from those with mutations in the receptor, including the potential for gonadal recovery. Study of the TAC3/TACR3 genes in a group of Finnish patients with constitutional delay of growth and puberty did not reveal any abnormalities [45].

Deficiency of leptin leads to a phenotype of early and severe hyperphagia, accelerating weight gain, insulin resistance, impaired T-cell function and nIHH as an adolescent [46]. Circulating leptin concentrations are below the level of sensitivity of common leptin assays. Although thyroid, adrenal and somatotropic functions in adults are normal, the levels of gonadotropins and sex-steroids are within the prepubertal range as is the physical examination. Pulsatile LH secretion is absent; however, with administration of recombinant human leptin, marked changes in body composition (decreased fat mass) and adolescent maturation occurred [46]. Leptin administration to prepubertal children did not induce puberty, indicating that leptin is a permissive factor for puberty. Those with mutations of the leptin receptor have the same phenotype except that leptin levels are elevated and the response to exogenous leptin is absent or attenuated. Recombinant human leptin administration prevented the experimental disruption of LH pulsatility induced by fasting and restored menstrual cyclicity in **some** women with functional hypothalamic amenorrhea [47].

Mutation of the prohormone convertase 1/3 gene (PCSK1) leads to a monogenic obesity syndrome that may include nIHH. The gene is expressed primarily in endocrine glands and hypothalamus, and the protein product is needed to process a variety of prohormones into the mature hormones, including the cleavage of pro-opiomelanocortin (POMC) to α-melanocyte stimulating hormone (α-MSH). Additional conditions seen in patients with PCSK1 mutations include altered thyroid and adrenal function, abnormal glucose metabolism, and intestinal malabsorption. nIHH appears to occur in about 50% of affected individuals [38, 48].

NR0B1, located on the short arm of the X chromosome, encodes DAX1 (dosage-sensitive sex reversal-adrenal hypoplasia congenita) an orphan nuclear receptor predicted to be a transcription factor important in the development of the adrenal cortex and pituitary gonadotrophs. Loss of function of the DAX1 protein leads to an X-linked recessive disorder characterized by hypogonadotropic hypogonadism and adrenal failure without the hyperandrogenism

of virilizing congenital adrenal hyperplasia. Patients with this disorder, called adrenal hypoplasia congenita, have both glucocorticoid and mineralocorticoid deficiencies and hypogonadotropic hypogonadism that may not be manifest until the second decade of life. DAX1 is a negative regulator of SF1-mediated activity. Puberty is usually delayed, especially in boys, and a diagnosis of nIHH can be made at the appropriate age. Some may have a mixed picture of partial nIHH with an added defect at the gonad, illustrating the importance of DAX1 and SF1 for steroidogenesis [49]. Duplication of NR0B1 is associated with an XY disorder of sex development, either with a female phenotype or ambiguous genitalia.

Inactivating mutations of the human LHβ subunit (LHB) lead to nIHH in men and women [50]. All male subjects had normal genitalia at birth, but no pubertal development or fertility. The mode of inheritance is autosomal recessive. Circulating LH levels are undetectable, without an LH response to exogenous GnRH administration but with a normal response to hCG. Females have a milder presentation. One female subject with two brothers having nIHH due to LHβ deficiency presented with full sexual development and secondary amenorrhea and infertility. Menarche occurred at 13 years. She had premature menopause, but remained hypogonadotropic [50]. Thus there can be widely disparate phenotypes with the same mutation, especially as modified by sex. A specific explanation is lacking for the normal spontaneous pubertal development but subsequent premature menopause in the affected woman.

Females with isolated deficiency of the follicle stimulating hormone beta subunit (FSHB) present with delayed pubertal development and primary amenorrhea, normal or high levels of LH, and low or undetectable levels of FSH. Males have normal pubertal development but small testes and oligospermia. Exogenous GnRH administration raises LH, but not FSH levels [51].

Exercising Adolescent and Adult Women and Men

Exercise has an important impact on the HPG axis, and high levels of exercise can induce HH. The prevailing concept in this arena is that of energy conservation or the laws of thermodynamics. One must have 'enough' energy to support body growth and to store energy, predominantly fat, for longer-term energy requirements such as the menstrual cycle, pregnancy, and lactation [52]. The concept is that for current energy requirements:

$$\text{Energy retention} = [\text{energy intake } (\text{EI}) - \text{energy expenditure } (\text{EE})].$$

In experiments with female athletes, Loucks modified this to:

$$\text{Energy availability } (\text{EA}) = [\text{EI} - \text{exercise EE}]/\text{fat-free mass } (\text{FFM}).$$

The latter equation takes into account that it is the FFM that is the metabolically active (fuel burning) tissue and emphasizes how EA may be reduced by either restricting EI or increasing exercise EE (EEE) [52].

This latter equation may be rearranged to make the message clearer for experimental studies:

$$\text{EI} = \text{EEE} + [\text{EA x FFM}].$$

Randomized clinical trials controlling for both EI and EEE have shown that energy balance occurs at EA = 45 kcal/kg FFM *day in healthy young women and that there is damped pulsatile release of LH after 5 days with EA below 30 kcal/kg FFM*day, which roughly corresponds to the resting metabolic rate in healthy young adults. The susceptibility of the HPG axis to alterations in EA is strongly age dependent as might be hypothesized from the very high incidence of subclinical menstrual disorders shortly after menarche. This concept was experimentally tested by decreasing the energy availability to 25 kcal/kg FFM*day in gynecologically younger (5–8 years after menarche) and older (14–18 years after menarche) young women. After 5 days of caloric restriction and exercise, it was noted that only the gynecologically younger women had disrupted pulsatile release of LH. Thus, the gynecologically older women had a more 'robust' HPG axis, and the data likely explain the high incidence of 'athletic amenorrhea' in young women with the female athlete triad: eating disorder, osteopenia, and amenorrhoea [52].

This concept was updated for the International Olympic Committee in 2014 [53] which noted that compelling evidence existed that showed that the aetiologic factor underpinning the female athlete triad was an 'energy deficit relative to the intake and the energy expenditure required to support homeostasis, health and the activities of daily living, growth and sporting events'. They further noted dysregulation and dysfunction in many aspects of the body's physiologic functions. For these reasons they proposed changing the syndrome from Female Athlete Triad to Relative Energy Deficiency in Sport (RED-S) [53]. The authors neatly summarized the health consequences as shown in Figure 7.3.2.2. These include neuropsychiatric issues such as depression and irritability, difficulty concentrating, decreased coordination, and impaired judgment. Metabolic problems include decreases in glycogen stores, muscle strength, and endurance. Impacts on training lead to increased risk for injury and decreased training response.

The concept of high energy output and high psychological stress at low energy intake occurs in men as well, as noted in American Army Rangers during field training [54].

Treatment may be difficult and multiple options are outlined in the RED-S article [53]. The most straightforward approach would be to prescribe a greater caloric intake or to decrease exercise energy expenditure. This is a difficult treatment plan for a highly competitive athlete, likely a gymnast, dancer, or long-distance runner. The American Academy of Pediatrics Committee of Sports Medicine and Fitness, 1999–2000 has presented a series of recommendations [55]. Those relevant to the female athlete triad are shown in Box 7.3.2.1. A detailed update for the Female Athlete Triad (RED-S) taking into account the data shown earlier has been published [56]. Recommendations for screening, considerations for return to play and guidance for the clinician generally follow those in Box 7.3.2.1.

Hypergonadotropic Hypogonadism

The karyotype abnormality consisting of two or more X chromosomes and one or more Y chromosomes is known as Klinefelter syndrome. Klinefelter syndrome is the most common alteration of chromosome number, with a prevalence of 1:650 males in the general population [57]. It is thought that as many as 75% remain undiagnosed, even in adulthood. Infants and young children often have problems with expressive language development, and school aged children may have difficulty with reading. An assortment of

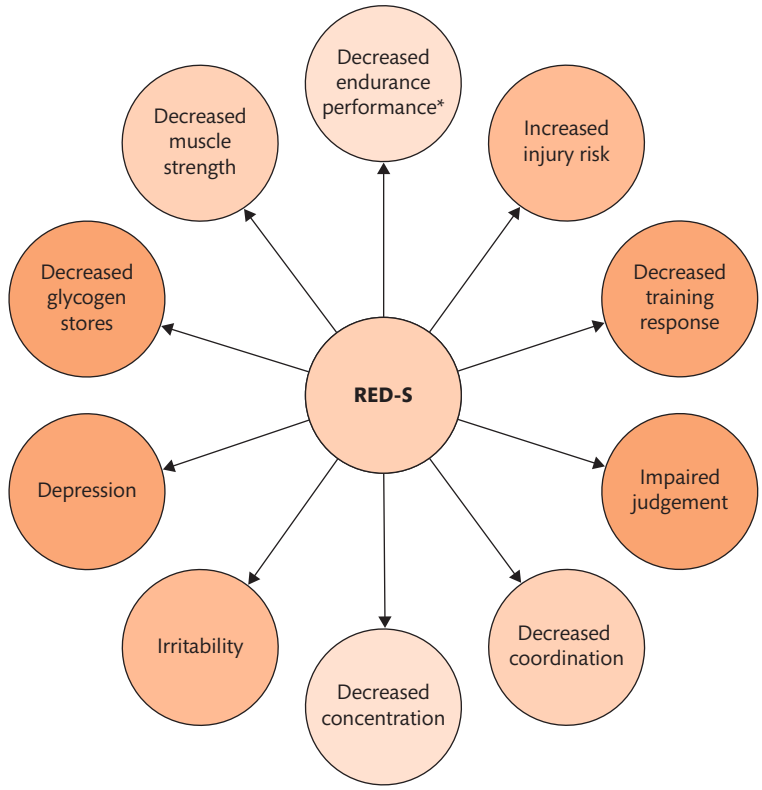

Figure 7.3.2.2 Health consequences of Relative Energy Deficiency in Sport (RED-S), including neuropsychiatric, metabolic problems, and impacts on training.

Box 7.3.2.1 Guidelines for assuring safe and healthy sports participation for children and adolescents

- Dietary practices; exercise intensity, duration, and frequency; and menstrual history should be reviewed during evaluations that precede participation in sports
- Amenorrhea should not be considered a normal response to exercise. That is, the underlying cause should be sought before denoting it as "athletic amenorrhea" in these gynecologically young women
- Disordered eating should be considered in adolescents with amenorrhea
- Education and counselling should be provided to athletes, parents, and coaches regarding disordered eating, menstrual dysfunction, decreased bone mineralization, and adequate energy and nutrient intake to meet energy expenditure and maintain normal growth and development.
- An adolescent with menstrual dysfunction attributed to exercise should be encouraged to increase energy intake and to modify excessive exercise activity to return to energy balance
- Oestrogen-progesterone supplementation may be considered in mature amenorrhoeic (late adolescent) athletes
- Measurement of bone mineral density and level of 25-hydroxyvitamin D should be considered tools to help make treatment decisions. The adolescent athlete is unlikely to have reached peak bone mass and thus, it is appropriate to use age-adjusted Z-scores rather than T-scores

Data derived in part from the American Academy of Pediatrics, Committee on Sports Medicine and Fitness, 1999–2000, with relevance to the female athlete triad. *Pediatrics*. 2000 Sep;106(3):610-3. (Ref 55)

behavioural challenges is often present. Psychological testing often shows disorders of executive function as well. Physically, the testes appear normal during infancy and childhood, and levels of FSH and LH are normal before puberty. As pubertal maturation unfolds, the testes do not increase in size normally, and the seminiferous tubules gradually become hyalinized, with loss of germ cells and Sertoli cells. Clinically, the testes remain small and may become very firm to palpation. In one study, the mean bitesticular volume (sum of the volume of both testes) was 4.6 ml [58]. LH and FSH levels begin to rise into the upper portion of the normal adult range early in puberty. By mid-puberty, LH and FSH concentrations are often abnormal. Although the onset of puberty is typically normally timed, 80% of affected individuals do not achieve normal adult concentrations of testosterone. The abnormal testosterone secretion results in a slow tempo of physical changes and lack of attainment of normal pubic hair and other sexual hair growth, as well as small penis size and lack of muscular development. The relatively low levels of testosterone and high concentrations of oestradiol predispose adolescents and adults to gynecomastia, which occurs in about 40% of affected individuals.

Essentially all affected men with Klinefelter syndrome have azoospermia or severe oligospermia and are infertile. However, intracytoplasmic germ cell injection (ICSI) has proven to be a feasible approach for those who have viable spermatozoa isolated from ejaculates or after microdissection testicular sperm extraction (mTESE). Additional health problems occurring with higher frequency in men

Table 7.3.2.3 Historical and physical examination features important in the evaluation of delayed puberty and hypogonadism

Historical findings	Physical examination
• Partial pubertal development • Family history of delayed puberty • Sense of smell • Dental development • Chronic disease • Head trauma • Chemotherapy • Radiation therapy • Headache • Visual problems • Galactorrhoea • Delayed language development • Poor school performance • Otitis media in females • Lymphedema in females • Congenital heart disease • Trauma of testes or ovaries • Undescended testes • Viral orchitis • Congenital malformations	• Height percentile • Height velocity • Weight percentile • Stigmata of Turner syndrome in girls • Stigmata of Prader–Willi syndrome • Other dysmorphic features • Delayed dentition • Anosmia or hyposmia • Visual fields • Funduscopy • Presence of thyromegaly • Breast development Tanner stage • Axillary hair • Pubic hair Tanner stage • Presence of other sexual hair growth • Genital Tanner stage • Testicular volume • Synkinesia

with Klinefelter syndrome include metabolic syndrome, type 2 diabetes, osteopenia, venous thromboembolism, ischemic heart disease, and a variety of autoimmune conditions including hypothyroidism. The risk for breast cancer, mediastinal cancers, and non-Hodgkin lymphoma is also higher than in the general population [58]. Men with higher-order aneuploidies such as 48,XXXY or 48,XXYY tend to have more severe and varied manifestations.

Partial or complete loss of one of the two X chromosomes in phenotypic females is known as Turner syndrome. Turner syndrome has an incidence of 1:2000 live born female infants. Turner syndrome is the most common cause of first trimester spontaneous abortions, and only about 1% of 45,X conceptuses are live born. The most common karyotype is 45,X, comprising about 50% of affected girls. Most of the remainder have various forms of mosaicism or partial deletion, usually including loss of at least the short arm of the second X chromosome.

The ovaries of fetuses affected with Turner syndrome show accelerated loss of germ cells [59]. At birth, the oocyte number is reduced to far below normal. The high rate of oocyte loss continues, and the ovaries of affected girls are typically depleted of germ cells within a few years of birth. Classically, girls with Turner syndrome fail to enter puberty, with an absence of breast development. Pubic and axillary hair typically develop normally due to adrenal androgen production. However, approximately 20% of girls will have spontaneous breast development, more commonly those with mosaic or partial forms of Turner syndrome. Spontaneous menses can occur, again most often in girls with mosaic forms, although secondary amenorrhea nearly always develops. Pregnancy may very rarely occur [60].

Gonadotropin levels in the neonatal period and infancy may be normal. In early and mid-childhood, LH and FSH concentrations are also normal, due to the high degree of negative feedback from low levels of oestrogen on the hypothalamus and pituitary. However, by late childhood and early adolescence, gonadotropin levels are often elevated well above the adult range. A karyotype is necessary to confirm the diagnosis and should be obtained regardless of the presence of physical stigmata of Turner syndrome.

The 47,XXX karyotype is common, with a prevalence of 1:900–1000 in the general population. There are few or no recognizable phenotypic features of the condition, although reports indicate that affected individuals are taller than average. There is a higher than normal incidence of neurodevelopmental disorders, such as poor attention span, academic difficulties, decreased verbal fluency, and poor spatial cognition. Although ovarian function is usually normal, primary ovarian dysfunction occurs in a subset of individuals. This may present as delayed puberty or as premature ovarian insufficiency. In studies of adult women with premature ovarian insufficiency, the 47,XXX syndrome occurs in approximately 3% of patients. Gonadotropin levels are elevated, and a karyotype analysis is diagnostic [61]. Females with larger numbers of additional X chromosomes (48,XXXX or 49,XXXXX) are more likely to have phenotypic and developmental abnormalities.

A large number of genes important for normal ovarian function reside on the long arm of the X chromosome. Deletions of portions of Xq and balanced translocations with breakpoints on Xq are associated with ovarian dysfunction. The location of breakpoints associated with hypergonadotropic hypogonadism cluster in two regions, Xq13.3-21.1 and Xq26-qter. The ovarian dysfunction may take the form of either primary or secondary amenorrhea [62].

XY and XX gonadal dysgenesis are terms describing heterogeneous groups of disorders of gonadal differentiation. These conditions are also discussed in Chapter 7.2.2, 'Disorders of Sex Development (DSD in the Newborn', with a focus on the newborn. Their effects on pubertal maturation are reviewed here. Individuals with XY and XX gonadal dysgenesis typically have normal female genitalia and are often not recognized until they fail to enter puberty. Those with XY complete gonadal dysgenesis (Swyer syndrome) have failure of testis determination early in fetal life, with formation of streak gonads and subsequent failure to secrete testosterone and anti-Mullerian hormone (AMH). In the absence of testosterone and AMH, both internal and external genitalia develop along female lines. If partial testis determination occurs, leading to partial Leydig and Sertoli cell function, incomplete masculinization of the internal and external structures occurs, resulting in ambiguous genitalia. Abnormalities of several genes have been implicated as causes of XY complete gonadal dysgenesis, including defects in SRY accounting for 10–15% of children (OMIM #480000) [63], defects in WT-1 associated with Denys–Drash and Frasier syndromes (OMIM #607102), abnormalities of SOX9 associated with campomelic dysplasia (OMIM #608160), NR5A1 encoding SF-1 associated with adrenal hypoplasia (OMIM #184757), and duplication of NR0B1 encoding DAX1 (OMIM #300473). Recently, a number of individuals with 46,XY gonadal dysgenesis have been found to have autosomal dominantly inherited activating mutations in MAP3K1 (OMIM #600982), which activate the genetic cascade leading to ovarian differentiation and inhibiting testis formation [64]. In addition to absent puberty, affected individuals have a 30% incidence of gonadal tumours, most commonly gonadoblastoma and dysgerminoma [65]. Spontaneous pubertal changes in a patient known to have XY complete gonadal dysgenesis should prompt a search for a sex steroid-secreting gonadoblastoma.

Girls with XX gonadal dysgenesis do not have physical features of Turner syndrome, but they are typically somewhat shorter than

average. Similar to individuals with Swyer syndrome, they have normal female internal and external genitalia. Ovarian histology ranges from fibrous streaks to hypoplastic ovaries. Gonadal tumours are uncommon in this population. Identified causes of 46,XX gonadal dysgenesis include mutations in NR5A1 (SF-1, OMIM #184757) and NOBOX (OMIM #610934) [66, 67], and FSH resistance caused by a mutation in the FSH receptor (OMIM #136435).

Those affected by either XY or XX gonadal dysgenesis have elevations of gonadotropin levels by the time of expected puberty. Karyotype analysis will reveal the diagnosis in 46,XY patients, and imaging studies of the pelvis will demonstrate the absence of ovaries. 46,XX gonadal dysgenesis must be distinguished from premature ovarian insufficiency caused by a number of other conditions, including autoimmune oophoritis or exposure to radiation or chemotherapeutic agents.

Complete androgen insensitivity syndrome (CAIS, OMIM #300068, see also Chapter 7.2.2, 'Disorders of Sex Development (DSD) in the Newborn') is caused by mutations in the androgen receptor gene. The prevalence of CAIS has been reported to be between 1:20 400 and 1:99 000 genetic males [68]. The effects on pubertal maturation are reviewed here.

At the time of puberty, the testes secrete testosterone, and testosterone levels typically rise into the adult male range or higher. Because of the androgen resistance, there are few or no clinical signs of androgen activity, such as pubic or axillary hair. Breast development appears to proceed normally, caused by aromatization of circulating testosterone. Primary amenorrhea occurs because of the absence of the uterus.

Gonadotropin levels are often normal at birth and typically are in the normal prepubertal range during childhood. As the individual reaches the age of normal puberty, LH secretion increases because of the lack of negative feedback from testosterone via the androgen receptor. High testosterone and LH concentrations in a female with primary amenorrhea and clinical signs of androgen resistance is virtually diagnostic, and the diagnosis is then confirmed with a karyotype demonstrating a 46,XY composition and genetic studies of the AR gene.

Galactosemia (OMIM #230400) is an inborn error of metabolism most commonly caused by a mutation in the GALT gene encoding galactose-1-phosphate uridyltransferase. Premature ovarian failure occurs in 75–96% of female patients with galactosemia. The age at onset of ovarian dysfunction ranges from childhood to adulthood, and patients may present with absent puberty or may have normal pubertal maturation and menarche but develop secondary amenorrhea later. Ovarian function may wax and wane, with periods of amenorrhea alternating with spontaneous ovarian cycles and possible fertility. Those individuals harbouring more severe mutations are more likely to experience consistent and lifelong ovarian failure. Patients with milder forms of galactosemia caused by defects in genes other than GALT may not have overt features of galactosemia but may present with primary ovarian insufficiency [69].

The mechanism of ovarian damage in cases of galactosemia is unknown. Ovarian tissue has a high content of galactose and its metabolites and normally has high galactose-1-phosphate uridyltransferase activity. In contrast, the testis has low enzymatic activity and low galactose content, presumably accounting for the absence of testicular dysfunction in males with galactosemia. It is thought that accumulation of galactose and galactose-1-phosphate in ovarian cells has direct cytotoxic effects by decreasing the activity of a number of metabolic pathways.

Defects in the receptors for LH and FSH are very rare causes of abnormal pubertal maturation. The LH receptor in the male is critical for normal testosterone secretion *in utero*. Hence, partial loss of LH receptor function (OMIM #152970) causes inadequate testicular secretion of testosterone and ambiguous genitalia in the 46,XY fetus. Alternatively, complete loss of the LH receptor leads to an inability to secrete any testosterone and a subsequent lack of masculinization of the 46,XY fetus leading to normal female external genitalia. If the individual is assigned to the female sex and not diagnosed early in life, there is complete absence of pubertal development and primary amenorrhea, as the testicular tissue will not secrete testosterone and there will be no aromatization to oestrogens. 46,XX females with loss of LH receptor function usually have normally timed breast development but experience primary or secondary amenorrhea and hypoestrogenemia. This highlights the importance of normal FSH activity for females in early puberty and the importance of LH activity to establish normal menses and oestrogen levels in later puberty and adulthood [70].

Abnormalities of the FSH receptor have mainly been described in the Finnish population. Females carrying mutations in the FSH receptor gene (OMIM #136435) usually present with 46,XX gonadal dysgenesis, with absent puberty and primary amenorrhea. Some affected individuals, however, will have spontaneous pubertal development and even menarche, although those identified as having the disorder have all become amenorrhoeic. Males with defects of the FSH receptor have normal pubertal development, normal testosterone levels, and normal or near normal gonadotropin levels. However, they may have oligospermia [71].

In addition to those discussed earlier, a large number of other single gene defects and genetic syndromes are associated with hypergonadotropic hypogonadism. Defects of steroidogenesis may cause disorders of sex development that are recognized in the newborn period as ambiguous genitalia. Some of these disorders, however, will result in a phenotypic female who is unable to synthesize either androgens or oestrogens. These disorders may cause congenital adrenal hyperplasia and include steroidogenic acute regulatory protein (StAR) deficiency (OMIM #600617) and 17-hydroxylase deficiency (OMIM #609300). Patients with carbohydrate-deficient glycoprotein syndrome produce abnormally glycosylated gonadotropins that are biologically inactive. The disordered puberty is more severe in females than males. Noonan syndrome, caused by a defect of the *PTPN11* gene in 50% of individuals (OMIM #176876), is a constellation of features including short stature, characteristic facies, and right-sided cardiac defects, as well as undescended testes. Although females with Noonan syndrome have normal ovarian function, some males may have abnormal Leydig cell function. Some boys with Noonan syndrome have delayed puberty with low gonadotropins. Aside from any evident dysmorphic features, these boys would not be distinguishable from those with CDGP or IHH. Other well-recognized genetic syndromes associated with hypergonadotropic hypogonadism include the fragile X pre-mutation (OMIM #300624), pseudohypoparathyroidism

type 1a (Albright hereditary osteodystrophy, OMIM #103580), autoimmune polyglandular syndrome type 1 (OMIM #607358), progressive external ophthalmoplegia, blepharophimosis syndrome, myotonic dystrophy, and ataxia-telangiectasia syndrome (OMIM #607585) [72, 73].

Vanishing testis syndrome refers to the case of the phenotypically normal male born with bilaterally absent testes. Normally functioning testicular tissue is presumably present in early gestation, as the external and internal genitalia are normally formed and there are typically no Müllerian remnants, implying normal secretion of testosterone and AMH *in utero*. This condition is thought to be due to antenatal bilateral torsion of the testes or other vascular events. This condition is uncommon, occurring in approximately 1:20 000 males. Careful physical examinations at birth and during childhood will reveal apparent bilateral undescended testes, and further evaluation by measuring AMH, inhibin B, or human chorionic gonadotropin (hCG)-stimulated testosterone will demonstrate the absence of functioning testicular tissue. However, if a good physical examination is not performed in childhood, this condition may remain undetected and present with delayed pubertal development. In some cases, the vascular insult may occur near the time of delivery, and bilateral testicular necrosis may be identified [74].

Gonadal tissue is very radiosensitive, with germ cells being particularly prone to radiation injury. Although loss of germ cells in the male leads to infertility, Leydig cells are more resistant to radiation-induced damage. Hence, at lower doses of radiation, there may be loss of fertility with preservation of endocrine function, diagnosed by elevation of FSH with normal LH and testosterone levels. At higher doses of radiation, both fertility and hormone secretion are affected, with elevation of both FSH and LH and low testosterone concentrations. With any degree of radiation exposure in the male child or adolescent, germ cell loss can occur, while Leydig cell injury does not usually occur until doses exceed 20–30 Gy. This situation contrasts with females, in whom germ cell loss is closely tied to loss of endocrine function due to loss of follicle development. The number of oocytes in the female is limited, and exposure later in adolescence or in adulthood, when there are normally fewer oocytes present, is associated with worse endocrine and reproductive outcomes than exposure early in childhood, when the number of oocytes present is larger. Radiation exposure in doses above 10 Gy in pubertal girls is associated with adverse reproductive outcomes, while doses above 15 Gy place prepubertal girls at risk [75].

Chemotherapeutic medications, especially alkylating agents, commonly cause gonadal injury in both prepubertal and pubertal patients. Higher dose protocols are more likely to cause gonadal dysfunction. This group of medications includes cyclophosphamide, ifosfamide, cisplatin, procarbazine, busulfan, chlorambucil, and others. Similar to the case of radiation exposure, females are at higher risk for chemotherapy-induced fertility and hormonal sequelae, while defects of testosterone secretion in males exposed to alkylating agents are uncommon. Overall, males who have survived cancer in childhood have a 24% decrease in fertility, while females have a 10-fold increase in the incidence of premature ovarian insufficiency [76].

A variety of approaches have been used to preserve gonadal function in children and adolescents undergoing cancer treatments. Oophoropexy, which refers to surgical relocation of the ovaries, may move at-risk ovaries out of the field of radiation but results in loss of spontaneous fertility and may make assisted reproductive techniques more difficult. Although oocyte and embryo cryopreservation are accepted techniques for preserving fertility in adults, these are not options for the prepubertal patient, as they require ovarian hyperstimulation with or without a sperm donor. Although these techniques may be available for post-menarchal adolescents, they require a 2–4-week interval of ovarian hyperstimulation before chemotherapy can begin. This may result in an unacceptable delay in many cases [77]. Other techniques, such as ovarian tissue cryopreservation, are being studied but are currently not available outside of clinical trials. Treatment with long acting GnRH analogues has been proposed for suppression of ovarian function with the goal of preserving fertility after cancer treatment. Data have shown variable degrees of success, and this approach is not recommended as the sole fertility preservation technique [78]. For male adolescents undergoing chemotherapy or radiation treatment, semen samples obtained before treatment may be frozen, and this should be offered to all those at risk [76]. Testicular tissue cryopreservation may be performed as part of clinical trials and is considered experimental at this time [78].

Autoimmune oophoritis (AO) presents as premature ovarian insufficiency or less commonly as absent puberty, arrested puberty, or primary amenorrhea. It is estimated that 1–5% of women with premature ovarian insufficiency have ovarian autoimmunity. AO is commonly reported in type 1 autoimmune polyglandular syndrome (APS, OMIM #607358), and may be less often found in type 2 APS. It is nearly always associated with autoimmune adrenalitis, and approximately 20% of females with primary adrenal insufficiency, will have AO. In the setting of type 1 APS, 36% of females will have AO, and 4% of males will have autoimmune orchitis. Affected individuals have clinical ovarian insufficiency, low oestradiol concentrations, and elevation of FSH. Anti-Müllerian hormone levels are low. Other manifestations of autoimmunity may be present, including hypothyroidism, systemic lupus erythematosus, Sjögren syndrome, rheumatoid arthritis, haemolytic anaemia, pernicious anaemia, inflammatory bowel disease, and others [79]. Antibodies to several cytochrome P450 steroidogenic enzymes have been documented in patients with AO, but assays for these autoantibodies are not commonly available. However, because of the close association between autoimmune adrenalitis and AO, antiadrenal antibodies directed against the 21-hydroxylase enzyme may serve as a surrogate marker in the patient with clinical ovarian insufficiency. Because primordial follicles are preserved early in the course of AO, treatment with immunosuppressive agents such as glucocorticoids may be effective [73, 80].

Viral orchitis is an uncommon problem that usually affects adult men. Infection with the mumps virus causes orchitis in 15–30% of postpubertal males, although orchitis is rare in children. In 15–30% of cases, orchitis is bilateral. Symptoms include pain, oedema, and erythema of the scrotum. After resolution, approximately half of affected men have decreases in testicular volume. Some patients will have minor alterations in endocrine function, but sterility is rare [81]. In women, mumps oophoritis is less common, affecting 5% of infected adult women. Mumps oophoritis is very rare in childhood, and rarely causes alterations of endocrine function or fertility in any affected female [82].

Other causes of orchitis and oophoritis include bacterial infections with *Chlamydia trachomatis, Neisseria gonorrhoea*, and *Escherichia coli*; other viral pathogens such as Coxsackie virus and varicella; and non-infectious causes such as Henoch–Schönlein purpura and other vasculitides.

Diagnosis of Delayed Puberty and Hypogonadism

Diagnostic algorithms for the evaluation of delayed puberty and possible hypogonadism are presented in Figures 7.3.2.3 and 7.3.2.4. The evaluation starts with a careful history and physical examination (Table 7.3.2.3). Important historical features include the presence or absence of any signs of puberty, including the age at onset and the tempo of progression. Inquiry about the patient's sense of smell is important, because patients and families will not volunteer this information in this setting. The growth pattern of the patient must be assessed by examination of a standard growth chart. Finally, the timing of puberty in the parents, siblings, and other relatives is critical, as many of the possible conditions are heritable.

Important physical features include the patient's height and weight, the presence or absence of any signs of puberty, and the quantification of these signs if possible. Quantification of pubertal development includes assessment of Tanner stages, measurement of testicular volume and penile length in males, and assessment of breast size in females or gynecomastia in males.

The laboratory diagnosis begins with determinations of LH and FSH concentrations. Normal or low gonadotropin levels direct the evaluation along the hypogonadotropic hypogonadism pathway, while elevations of gonadotropins suggest a diagnosis involving primary testicular or ovarian abnormalities. Sex steroid levels should be measured in the morning because of the diurnal variation, particularly for testosterone. Many commercially available assays for oestradiol are insensitive, and biologic effects of oestradiol may be present at serum concentrations below the detection limit. Serial measurements of gonadotropins and sex steroids may be helpful to quantify the progression of puberty or lack thereof.

Treatment of Delayed Puberty and Hypogonadism

The principle goal of treatment of adolescents with delayed or absent puberty is the attainment of sex steroid levels and physical

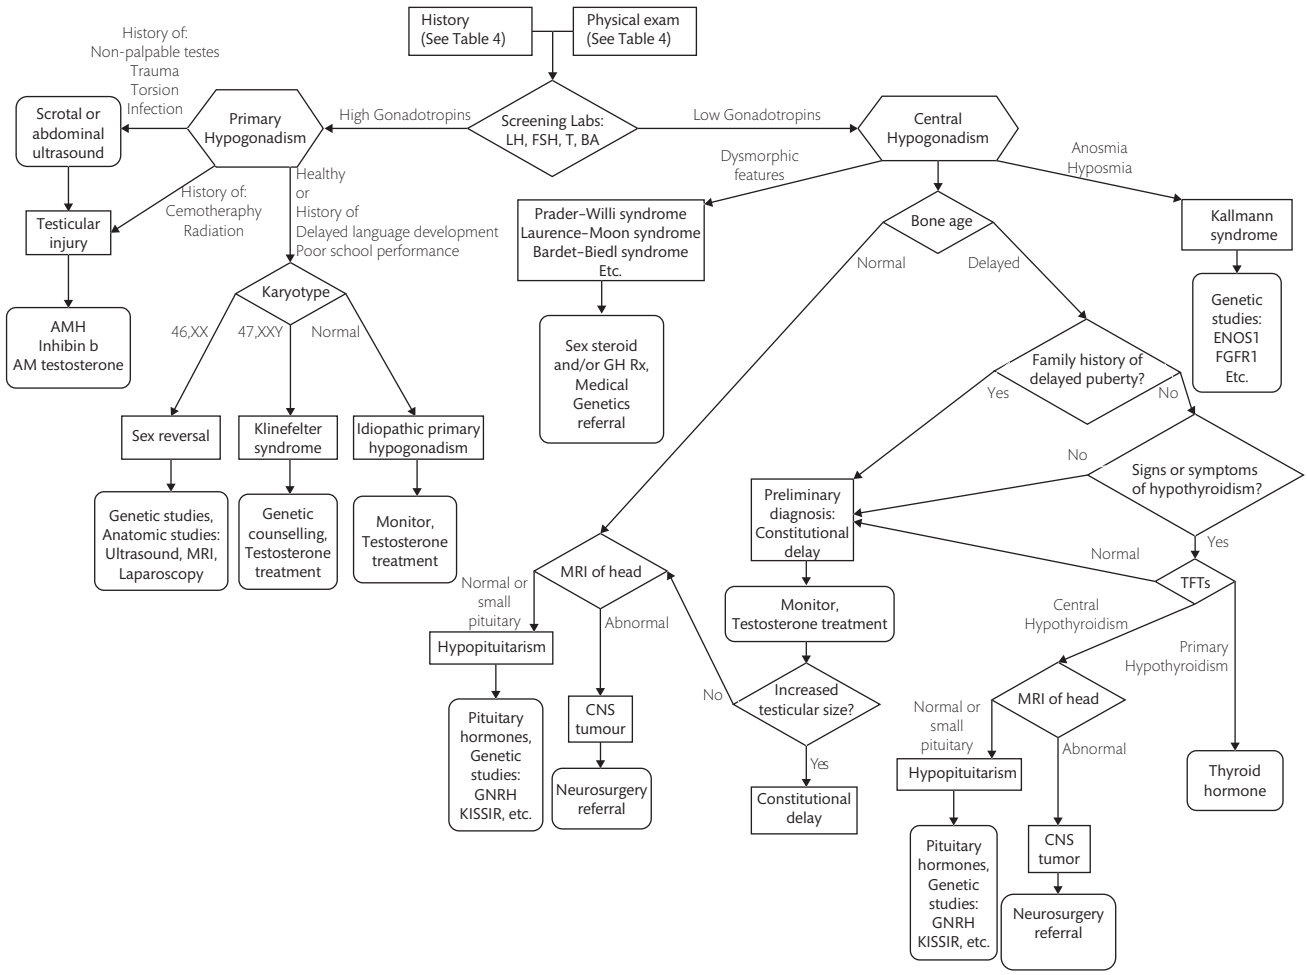

Figure 7.3.2.3 Algorithm for the evaluation and management of delayed puberty and hypogonadism in boys. AMH, Anti-Müllerian hormone; BA, bone age; CNS, central nervous system; FSH, follicle stimulating hormone; GH, growth hormone; LH, luteinizing hormone; MRI, magnetic resonance imaging; Rx, treatment; T, testosterone; TFTs, thyroid function studies.

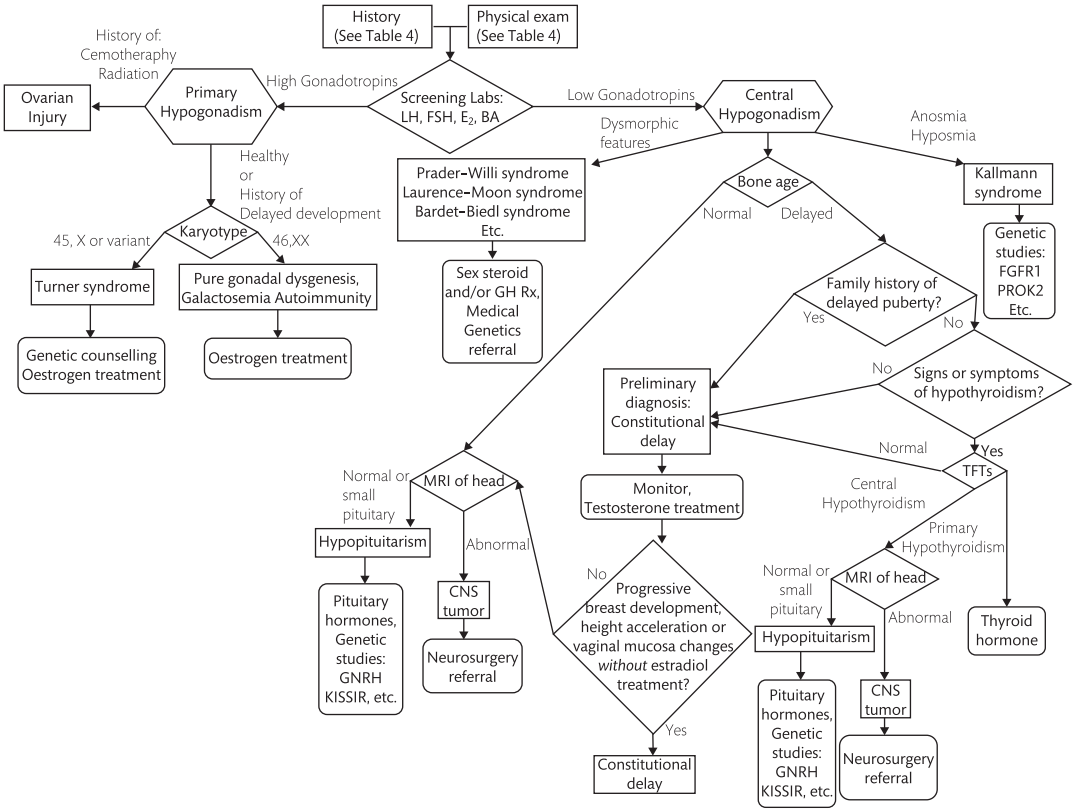

Figure 7.3.2.4 Algorithm for the evaluation and management of delayed puberty and hypogonadism in girls. BA, bone age; CNS, central nervous system; E2, oestradiol; FSH, follicle stimulating hormone; GH, growth hormone; LH, luteinizing hormone; MRI, magnetic resonance imaging; Rx, treatment; TFTs, thyroid function studies.

features that are appropriate for the stage of adolescent maturation. Replacement may be temporary in cases of transient delayed puberty, such as constitutional delay of growth and puberty (CDGP), or long-term in adolescents with permanent absence of pubertal maturation. Subsequent goals of sex steroid therapy in the adolescent are to promote physiological linear growth and development of secondary sexual characteristics and to permit the acquisition of normal body composition, including muscle mass and bone mineral content, to mimic the normal physiologic process. Regardless of whether the patient has hyper- or hypogonadotropic hypogonadism, long-term sex steroid replacement is accomplished similarly.

Androgen Preparations

Agents presently available for androgen replacement are listed in Table 7.3.2.4. Not all of the preparations are universally available, and treatment may need to be individualized using the locally available preparations. Few preparations are suggested for the induction of puberty, mainly because the dosage forms are metered to full androgen replacement for the adult. As most are drug delivery devices, they cannot be easily altered to deliver the small, and then increasing, doses of testosterone required to permit normal pubertal maturation in hypogonadal adolescents or in those with CDGP.

The oral 17α-hydroxylated preparations are virtually never used because of the concern of liver toxicity, and there is very little experience in adolescents with the buccal or nasal formulations. Testosterone undecanoate is not considered hepatotoxic. Unmodified testosterone, administered orally, is rapidly inactivated by first-pass hepatic metabolism.

Oxandrolone is a non-aromatizable, non-5-α reducible oral steroid hormone, which interacts directly with the androgen receptor. It augments height velocity in boys with CDGP without disproportionate advancement of skeletal maturation, which would theoretically decrease adult height [83]. In prepubertal boys, a marked increase in body mass index, a decrease in the triceps and subscapular skin folds, and an increase in the upper body muscle area have been noted following oxandrolone, 2.5 mg/day [84]. At that dose, oxandrolone was an anabolic steroid without significant virilizing action.

The primary clinical uses for androgen therapy in adolescent males are to induce pubertal maturation and as replacement therapy in those with permanent hypogonadism of either the hypogonadotropic or hypergonadotropic variety. The most common cause, although its precise incidence is unknown, is CDGP.

Without intervention, most adolescents with CDGP will undergo normal pubertal maturation spontaneously and most, but not all, will reach their genetically determined mid-parental height **range** [85]. Many adolescents suffer significant emotional distress because they differ in their appearance from their peers during these years. Androgen therapy was initially proposed for boys with CDGP to alleviate their psychological discomfort, in addition to the beneficial effects on bone mineral accrual, lean body mass (protein anabolism) and the regional distribution of body fat.

Table 7.3.2.4 Androgen preparations

Agent	Dosing route	Induction of puberty	Adult dose
Enanthate/cypionate	Intramuscular	50–100 mg IM every 4 weeks for 4–6 months 1. For CDGP: Dose can be increased after 3 months if no signs of pubertal maturation. Dose increase by 25–50 mg/month with evaluation at 3–4-month intervals until testes 8–10 ml 2. IHH: Increase dose by 25–50 mg/month at 4–6-month intervals until full adult replacement dose of ~200 mg/2 week or 100 mg/week	200 mg twice monthly
Mixture of esters (Sustanon)	Intramuscular	50–75 mg every 4 weeks for 4–6 months 1. For CDGP: Dose can be increased after 3 months if no sighs of pubertal maturation. Dose increased by 25 mg/month with evaluation at 3–4-month intervals until testicular volume reaches 6–8 mL 2. IHH: Dose may be escalated gradually to 100 to 150 mg/ month before changing to 250 mg/3 weeks, the approximate adult dose	250 mg every 2–3 weeks
Undecanoate	Intramuscular	Not recommended	750–1000 mg every 10–12 weeks (range 10–14 weeks)
Undecanoate	Oral	40 mg daily; titrate gradually to adult dose	80 mg twice daily
Testosterone	Transdermal patch	Begin with 2 mg/day patch for perhaps 12 h/day and gradually titrate to full adult dose	2.5–5 mg
Testosterone	Transdermal gel	0.5 gm/day increasing dose based on T levels (low level of evidence) Increase dose in stepwise fashion by 0.5 g increments to the full adult dose	5–10 g/day

The authors recognize that the majority of boys who have sought subspecialist evaluation are anxious to begin androgen therapy, and are generally pleased with the results, albeit subtle, even after 3 months of therapy with 50–75 mg long-acting testosterone esters per month. Their reasons to begin therapy fall into the appearance (too young), social (not considered a peer), and athletic (cannot compete because of size and lack of strength) spheres. The dose is increased by 25–50 mg per month every 3 months if spontaneous pubertal maturation has not occurred. This may be assessed by an increase in testicular size, indicating gonadotropin release despite the negative feedback effects of the exogenous testosterone, or by rising early morning levels of testosterone obtained at least 3 weeks following the previous testosterone injection. Therapy is discontinued when the testicular volume is approximately 6–8 mL. The longest acting ester available is testosterone undecanoate, and because of its ~3-month duration of action, it is not appropriate for adolescents with presumed CDGP.

For those with permanent hypogonadism, the escalation of the testosterone cypionate or enanthate ester continues until one reaches approximately 150 mg monthly, after which one might consider switching to twice monthly at 100 mg each administration, increasing to a maximum of 200 mg twice monthly, which is the average adult dose. At about the time of moving to twice monthly injections, one might consider the cutaneous gel which is available in sachet packages of 2.5 and 5 g or a metered pump dispensing 1.25 g, which we consider a mid-pubertal dose. The advantage of the gel is that the levels of testosterone, dihydrotestosterone (DHT), and oestradiol are all within the physiological range for the entire day. Subsequent alterations in dose can be made by measuring the circulating level of testosterone. Those receiving intramuscular testosterone have higher than normal levels of T, DHT, and oestradiol for the first part of the dosing interval and lower than normal for the latter part of the interval.

Oestrogen Preparations

Puberty can be induced using an oestrogen preparation started at approximately 12 years, an age appropriate to induce breast development without affecting the physiological rate of bone maturation or growth potential [86]. The initial dose should be low, one sixth to one quarter of the adult dose (Table 7.3.2.5), and increased gradually at intervals of 3–6 months. The administration of very low-dose depot oestradiol (initial dose of 0.2 mg/month, IM) permitted

Table 7.3.2.5 Oestrogen preparations

Agent	Dosing route	Induction of puberty	Adult dose
Oestradiol cypionate	Intramuscular	0.2 mg/month	~2.5 mg/month
Micronized oestradiol	Oral	0.25 mg/day	1–4 mg/day
Oestradiol	Transdermal patch*	6.25–12.5 µg twice weekly	100 µg twice weekly
Oestradiol	Transdermal gel	0.1 mg/day	1.5 mg/day

*The designated patch dosage is the amount delivered daily; how often one changes the patch depends on the manufacturer's specifications.

relatively age-appropriate (12–13 years of age) feminization without interfering with the effect of growth hormone on the enhancement of height potential [87].

In a study of girls with Turner syndrome, 56 subjects who were receiving rhGH therapy received low dose, oral micronized oestradiol (5 μg/kg*day) for 2 years followed by one year at 7.5 μg/kg*day and then 10 μg/kg*day [88]. The main purpose of the study was to induce feminization as close to physiologically as practicable without negatively affecting adult height. The majority had similar breast development and progression compared to a population of Dutch girls, but delayed by approximately 2 years. As previously reported, adult uterine size was not attained, likely due to the 45,X karyotype and not due to the protocol for the escalation of the oestradiol dose. No direct comparison with the transdermal application of oestradiol was made.

Transdermal oestradiol patches have been used with some advantages over the traditional oral administration of oestradiol or one of its synthetic analogues. Nocturnal application (3.1–12.5 μg/day of 17β-oestradiol) in girls with hyper- or hypogonadotropic hypogonadism produced levels of oestradiol that are similar to those measured in girls during spontaneous adolescent maturation [89]. Cutaneous administration of oestradiol in hydroalcoholic gel is another therapeutic possibility that can be used to induce puberty.

Detailed recommendations for low dose oestrogen treatment options for pubertal induction in adolescent girls with Turner syndrome and considerations for use may be found in [90]. The authors 'suggest the following practical approach to feminize girls with Turner syndrome: initiate puberty with low dose transdermal oestradiol, when available, starting with half of a 14 μg patch applied weekly or a whole 14 or 25 μg patch for one week per month at 11–12 years of age'. These investigators also recommend against the use of conjugated oestrogens unless other forms are unavailable. In general, the dose of oestrogen can be increased every 6–12 months to reach full replacement dose after two or three years of therapy.

Replacement therapy in most patients eventually involves cyclic oestrogen/progesterone therapy. Once full oestrogen replacement has been reached, cyclical progesterone (e.g. 5–10 mg of medroxyprogesterone acetate) can be added every month to induce monthly menstrual bleeding. Once full pubertal maturation has been reached, the oestrogen dosage should be the minimum that will maintain normal menstrual periods, prevent calcium loss from bone, and permit the accrual of peak bone mass early in the third decade [90]. At that time, low dose birth control pills are an alternative option; however, by definition the dose of oestrogen is greater than the physiologic dose for an adult woman.

7.3.3 Precocious Puberty

Diagnosis and Management

Juliane Léger and Jean-Claude Carel

Introduction

Precocious puberty (PP) may be caused by central or peripheral mechanisms. Precocious puberty leads to the progressive development of secondary sexual characteristics including breast development in girls and testicular enlargement in boys, together with the development of pubic hair, and an acceleration of growth velocity and bone maturation, resulting in premature fusion of the growth plates, potentially responsible for adult height deficit [1].

Premature sexual maturation is a frequent cause for referral to paediatric endocrinology. Clinical evaluation is generally sufficient to reassure the patient and family, but premature sexual maturation may reveal severe conditions and need a thorough evaluation to identify its cause and potential for progression, in order to propose an appropriate treatment [1]. Although the use of long-acting GnRH agonists has revolutionized the treatment of central precocious

puberty, questions remain regarding their optimal use [2]. One of the main ongoing controversial issues is the definition of normal pubertal development. The onset of puberty may also be subject to the effects of environmental (secular trends, adoption, absence of the father and possible exposure to estrogenic endocrine-disrupting chemicals), socioeconomic disadvantage, nutritional (body mass index), and constitutional (genetics, ethnicity) factors, with implications for the definition of precocious puberty [3, 4].

Normal and Premature Sexual Maturation

Normal pubertal development results from the activation of pulsatile hypothalamic GnRH secretion leading to activation of the pituitary-gonadal axis. The onset of puberty is marked clinically by breast development in girls and testicular enlargement in boys. Tanner stages (see Figure 7.3.1.1 in Chapter 7.3.1, 'Recognizing Normal and Disordered Pubertal Development') are used to evaluate pubertal development and the onset of puberty corresponds to Tanner 2 breast (B2) stage in girls (best assessed by both inspection and palpation) and Tanner 2 genital (G2) stage in boys (testicular volume greater than 4 ml or testicular length greater than 25 mm).

Defining the normal limits of pubertal development is difficult, given the paucity of truly normative data and the numbers of components to consider including not only pubertal onset, but also progression of puberty and onset of menarche. Although there have been discussions to decrease the cut-off defining early pubertal onset in girls, the traditional limits of 8 years in girls and 9.5 years in boys are still used by most paediatric endocrinologists [1]. Sexual hair development is a component of pubertal maturation that reflects the actions of androgen produced by the gonads or by the adrenals. Similarly, the traditional limits of pubic hair development have been set to 8 years in girls and 9.5 years in boys with wide ethnical variations.

There are several elements to remember when considering normal and abnormal pubertal development. First, the activation of the gonadotropic axis is not an all or nothing phenomenon, but evolves over several years, starting 2 to 3 years before the clinical onset of puberty. Second, the mean duration of the transition from one stage to the next is generally close to 6 months on average but varies among individuals. In slowly progressive puberty, pubertal development can remain at the B2 stage or revert to the B1 stage before resuming later. It is noteworthy that although the mean age at the B2 stage has decreased in the past decades, the age at menarche has been relatively stable, indicating a longer duration of puberty [5]. Third, the onset of puberty is affected by a number of factors in addition to ethnicity [6]. The prevalence of precocious puberty is about 10 times higher in girls than in boys and has been estimated at 0.2% of girls and less than 0.05% of boys. The number of cases increases with age for both sexes and onset of puberty below 6 years in girls and 7 years in boys accounts for only 15% of all cases [7, 8].

Aetiologies and Mechanisms Underlying Premature Sexual Development

Figure 7.3.3.1 summarizes the mechanisms underlying premature sexual development. Premature sexual development results from the action of sex steroids or compounds with sex steroid activity on target organs. The most common mechanism of progressive precocious puberty is the early activation of pulsatile GnRH secretion.

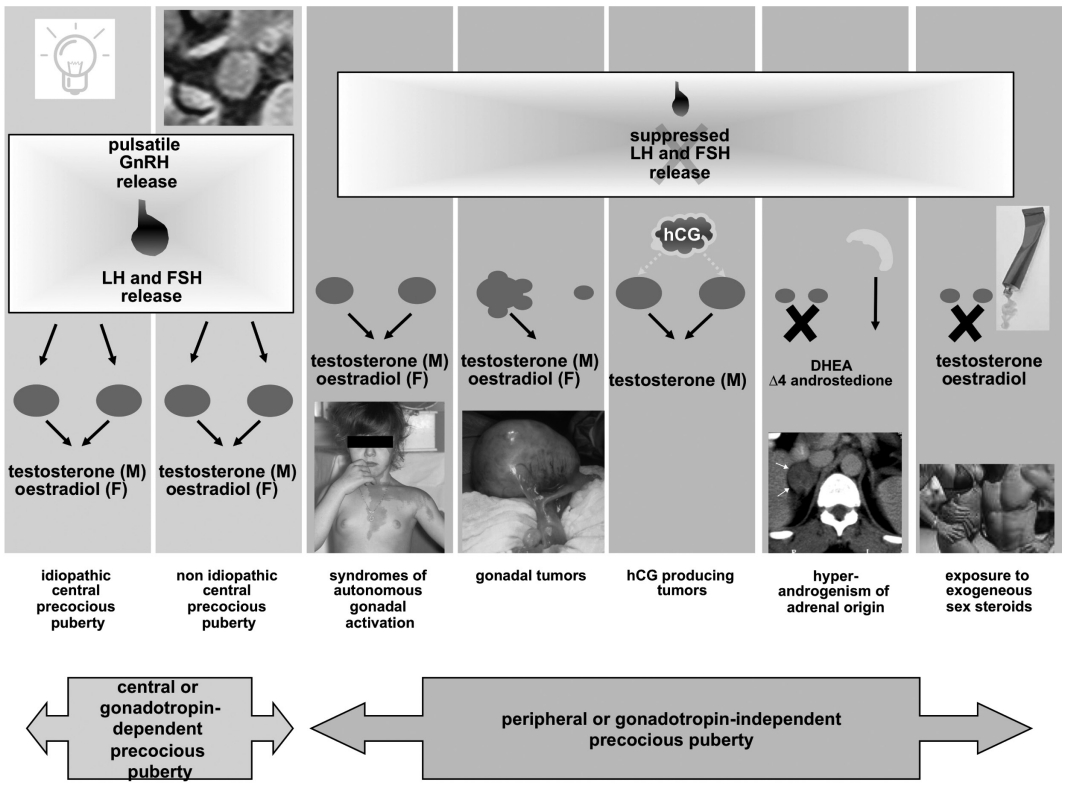

Figure 7.3.3.1 Principal mechanisms of premature sexual development.

Peripheral, or gonadotropin-independent precious puberty is due to the production of sex steroids by gonadal or adrenal tissue, independently of gonadotropins which are generally supressed. Exposure to exogenous sex steroids or to compounds with steroidal activity can also result in premature sexual development. It is also important to recognize variants of pubertal development that can mimic precocious puberty but do not lead to long-term consequences and are usually benign.

Central precocious puberty is due to the premature activation of GnRH secretion and results in a hormonal pattern that is similar to that of normal puberty, although early. Central precocious puberty can be due to hypothalamic tumours or lesions or be idiopathic in the majority of cases, in particular in girls (Table 7.3.3.1). Recent studies have implicated the inactivation of Makorin ring finger 3 (*MKRN3*) genes in 'idiopathic' CPP [9, 10]. *MKRN3* is an imprinted gene located on the long arm of chromosome 15, with a potentially inhibitory effect on GnRH secretion. *MKRN3* gene defects have been identified as a cause of paternally transmitted familial CPP, but such defects do not underlie maternally transmitted CPP and are rarely involved in sporadic forms [11, 12]. More recently, a paternally inherited DLK1 deletion has been reported in one family with isolated CPP [13]. Non-isolated idiopathic CPP has also been reported associated with complex and rare syndromic phenotypes such as Silver–Russell and Temple syndromes or encephalopathy disorders [14].

Peripheral precocious puberty can result from gonadal, adrenal or hCG-producing tumours, activating mutations in the gonadotropic pathway and exposure to exogenous sex steroids (Table 7.3.3.2). Peripheral precocious puberty can rarely lead to activation of pulsatile GnRH secretion and to central precocious puberty (Table 7.3.3.1).

It is essential to recognize that most cases of premature sexual maturation correspond to benign variants of normal development that can occur throughout childhood (Table 7.3.3.3). This is particularly true in girls below the age of 2 to 3 years where the condition is known as premature thelarche. Similarly in older girls, at least 50% of cases of premature sexual maturation will regress or stop progressing and no treatment is necessary [15]. Although the mechanism underlying these cases of non-progressive precocious puberty is unknown, the gonadotropic axis is not activated. Premature thelarche probably represents an exaggerated form of the physiological early gonadotropin surge that is delayed in girls relative to boys.

Consequences of Premature Sexual Maturation

Progressive premature sexual maturation can have consequences on growth and psycho-social development. Growth velocity is accelerated as compared to normal values for age and bone age is advanced in most cases. The acceleration of bone maturation can lead

Table 7.3.3.1 Clinical characteristics of the various forms of central precocious puberty

Cause	Symptoms and signs	Evaluation
Due to a CNS lesion		
Hypothalamic hamartoma	May be associated with gelastic (laughing attacks), focal or tonic-clonic seizures	MRI: Mass in the floor of the third ventricle iso-intense to normal tissue without contrast enhancement
Or other hypothalamic tumours: • Glioma involving the hypothalamus and/or the optic chiasm. • Astrocytoma, • Ependymoma, • Pinealoma, • Germ cell tumours.	May include headache, visual changes, cognitive changes, symptoms/signs of anterior or posterior pituitary deficiency (e.g. decreased growth velocity, polyuria/polydipsia), fatigue, visual field defects If CNS tumour (glioma) associated with neurofibromatosis, may have other features of neurofibromatosis (cutaneous neurofibromas, café au lait spots, Lisch nodules)	MRI: contrast-enhanced mass that may involve the optic pathways (chiasm, nerve, tract) or the hypothalamus (astrocytoma, glioma) or that may involve the hypothalamus and pituitary stalk (germ cell tumour), May have evidence of intracranial hypertension. May have signs of anterior or posterior pituitary deficiency (e.g. hypernatremia) If germ cell tumour: ßhCG detectable in blood or CSF
Cerebral malformations involving the hypothalamus: • Suprasellar arachnoid cyst, • Hydrocephalus, • Septo-optic dysplasia, • Myelomeningocele, • Ectopic neurohypophysis.	May have neurodevelopmental deficits, macrocrania, visual impairment, nystagmus, obesity, polyuria/polydipsia, decreased growth velocity.	May have signs of anterior or posterior pituitary deficiency (e.g. hypernatremia) or hyperprolactinemia
Acquired injury: • Cranial irradiation, • Head trauma, • Infections, • Perinatal insults.	Relevant history Symptoms and signs of anterior or posterior pituitary deficiency may be present	MRI may reveal condition-specific sequelae or may be normal
Idiopathic—no CNS lesion	≈ 92% of girls and ≈ 50% of boys History of familial precocious puberty or adoption may be present Syndromic/chromosomal disorders	No hypothalamic abnormality on the head MRI. The anterior pituitary may be enlarged *MKRN 3* gene evaluation if paternally transmitted
Secondary to early exposure to sex steroids		
Associated with any cause of gonadotropin-independent precocious puberty.	Relevant history	

Table 7.3.3.2 Clinical characteristics of the various forms of peripheral precocious puberty

Disorder	Characteristic symptoms and signs	Test results
Autonomous gonadal activation		
McCune–Albright syndrome and recurrent autonomous ovarian cysts due to somatic activating mutation of the GNAS gene resulting in increased signal transduction in the Gs pathway	Mostly in girls. Typically rapid progression of breast development and early occurrence of vaginal bleeding (before or within a few months of breast development) Precocious puberty may be isolated or associated with café-au-lait pigmented skin lesions (with irregular borders) or bone pain due to polyostotic fibrous dysplasia. More rarely other signs of endocrine hyperfunction (e.g. hypercortisolism, hyperthyroidism), liver cholestasis or cardiac rhythm abnormalities	Typically large ovarian cyst or cysts on pelvic ultrasound examination, Bone lesions of fibrous dysplasia May have laboratory evidence of hypercortisolism, hyperthyroidism, increased GH secretion, hypophosphatemia, liver cholestasis
Familial male-limited precocious puberty due to germinal activating mutations of the LH receptor gene	A familial history of dominant precocious puberty limited to boys (but transmitted by mothers) may be present but some cases are sporadic	Activating mutation of the LH receptor gene
Germline mutations of GNAS gene resulting in dual loss and gain of function. (rare)	Single case report of a boy with concomitant pseudohypoparathyroidism and gonadotropin-independent precocious puberty	
Tumours		
Granulosa cell tumours of the ovary.	Rapid progression of breast development, abdominal pain may occur. The tumour may be palpable on abdominal examination	Tumour detection on ultrasound or CT scan
Androgen producing ovarian tumours	Progressive virilization	Tumour detection on ultrasound or CT scan
Testicular Leydig cell tumours	Progressive virilization; testicular asymmetry (the tumour itself is rarely palpable)	Tumour detection on testicular ultrasound
hCG producing tumours	Tumours can originate in the liver or mediastinum. Pubertal symptoms in boys only. May be associated with Klinefelter syndrome	Elevated serum hCG
Adrenal disorders	Manifest with signs of androgen exposure	
Congenital adrenal hyperplasia	Increased androgen production leading to virilization in boys and girls	Increased adrenal steroid precursors in serum, mainly 17OH-progesterone (basal or after an ACTH stimulation test)
Adrenal tumour	Increased androgen production leading to virilization in boys and girls. Very rarely, oestrogen-producing adrenal tumour	Tumour on abdominal ultrasound or CT scan Elevated DHEAS, or adrenal steroid precursors
Generalized glucocorticoid resistance	Symptoms and signs of mineralocorticoid and adrenal androgen excess, such as hypertension and hypokalaemic alkalosis	Elevated free urinary cortisol and plasma cortisol
Environmental agents		
Exogenous sex steroids	Manifestations vary with the type of preparation (androgenic or estrogenic); most commonly described after topical exposure to androgens; tracing the source of exposure may be difficult	Endocrine evaluation can be misleading due to widely variable serum levels of sex steroids with time
Exposure to oestrogenic endocrine-disrupting chemicals	May play a role in precocious puberty in adopted children (by modulating the timing of pubertal gonadotropic axis activation) although this remains unproven	No validated biochemical test
Severe untreated primary hypothyroidism	Signs of hypothyroidism. No increase of growth velocity Manifest mostly with increased testicular volume in the absence of virilization. Due to a cross-reactivity of elevated TSH to the FSH receptor	Elevated serum TSH levels, low free T_4 level. No bone age advancement

to premature fusion of the growth plates and short stature. Several studies have assessed adult height in individuals with a history of precocious puberty. In older published series of untreated patients, mean heights ranged from 151 to 156 cm in boys and 150 to 154 cm in girls, corresponding to a loss of about 20 cm in boys and 12 cm in girls relative to normal adult height [16]. However, these numbers correspond to historical series of patients with severe early onset precocious puberty which are not representative of the majority of patients seen in the clinic today. Height loss due to precocious puberty is inversely correlated with the age at pubertal onset, and currently treated patients tend to have later onset of puberty than those in historical series [16].

Parents often seek treatment in girls because they fear early menarche [17]. However, there is little data to predict the age of menarche following early onset of puberty. In the general population, the time from breast development to menarche is longer for

Table 7.3.3.3 Benign variants of premature sexual maturation

Condition		
Non-progressive precocious puberty	See Table 7.3.3.5 for differential characteristics with progressive central precocious puberty	
Isolated precocious thelarche	Unilateral or bilateral breast development; particularly frequent before the age of 3 years	No further evaluation needed in most cases
Isolated precocious pubarche	Pubic hair development can be associated with adult body odour, axillary hair, or mild acne	Normal cortisol precursors in serum, including normal levels of 17OH-progesterone after ACTH stimulation
Isolated precocious menarche	Isolated vaginal bleeding without breast development or pubic hair, and no genital trauma. It is important to evaluate clinically for a vaginal lesion (sex abuse, foreign body, tumour)	

children with an earlier onset of puberty, ranging from a mean of 2.8 years when breast development begins at age 9 to 1.4 years when breast development begins at age 12 [18].

Adverse psychosocial outcomes are also a concern, but the available data specific to patients with precocious puberty have serious limitations [2]. In the general population, a higher proportion of early-maturing adolescents engage in exploratory behaviours (sexual intercourse, legal, and illegal substance use) and at an earlier age, than adolescents maturing within the normal age range or later [19]. In addition, the risk for sexual abuse seems to be higher in girls or women with early sexual maturation [20]. However, the relevance of these findings to precocious puberty is unclear, and they should not be used to justify intervention.

Evaluation of the Child with Premature Sexual Development

The evaluation of patients with premature sexual development should address several questions: (1) Is sexual development really occurring outside the normal temporal range? (2) What is the underlying mechanism and is it associated with a risk of a serious condition, such as an intracranial lesion? (3) Is pubertal development likely to progress? And (4) Would this impair the child's normal physical and psychosocial development?

Clinical Evaluation

A complete family history (age at onset of puberty in parents and siblings) and personal history including the age at onset and progression of sexual development should be taken. Any evidence suggesting possible central nervous system disorder, such as headache, increased head circumference, visual impairment or seizures should be sought. Growth should be evaluated by drawing a complete growth chart, because progressive precocious puberty is almost invariably associated with and sometimes preceded by an acceleration of growth velocity.

The stage of pubertal development should be classified according to Tanner (see Figure 7.3.1.1 in Chapter 7.3.1). Careful assessment is needed in obese girls to avoid overestimating breast development. The development of pubic hair results from the effects of androgens, which may be produced by testes or ovaries in central precocious puberty. Acne, oily skin, and hair may be present and result from the action of androgens. In girls, pubic hair in the absence of breast development is suggestive of adrenal disorders, premature pubarche or exposure to androgens. In boys, measurement of testicular volume may suggest the cause of puberty, as testicular volume increases in central precocious puberty as in normal puberty and in cases of peripheral precocious puberty due to testicular disorders (although generally less so), whereas it remains prepubertal in adrenal disorders, premature pubarche and other causes of peripheral precocious puberty. Physical examination should also assess for signs of specific causes of precocious puberty, such as hyperpigmented skin lesions suggesting neurofibromatosis or McCune–Albright syndrome. It is also important to recognize clinically the benign variants of precocious pubertal development with usually isolated and non-progressive secondary sexual characteristic (breast or pubic hair), normal or slightly increased growth velocity and no or slight bone age advancement, if performed (Table 7.3.3.3).

Premature sexual development can be associated with high levels of anxiety in girls and psychological evaluation of the child and of the familial environment may be useful.

Laboratory Evaluation and Imaging

Additional testing is generally recommended in all boys with precocious pubertal development, in girls who present with precocious Tanner 3 breast stage or higher or in girls with precocious B2 stage and additional criteria such as increased growth velocity, advanced bone age, symptoms or signs suggestive of central nervous system dysfunction or of peripheral precocious puberty.

Bone Age

Bone age measured using a reference atlas such as Greulich & Pyle evaluates the impact of sex steroids on epiphyseal maturation and is usually advanced in progressive precocious puberty. Caution should be taken in overinterpreting bone age, since there is a physiological scatter of approximately plus or minus one year of bone age vs chronological age in Caucasian children and a systematic advance of bone age in children of African descent when using references obtained in Caucasians. Bone age can also be used to predict adult height, although with a low precision (95% confidence interval of about ± 6 cm) and a tendency to overestimate adult height in precocious puberty.

Hormonal Measurements

Hormonal measurements that can be useful for the evaluation of premature sexual maturation are summarized in Table 7.3.3.4.

- Sex steroids should be determined in the morning, using assays with detection limits adapted to paediatric values. Most boys with precocious puberty have morning plasma testosterone values in the pubertal range. In girls, serum oestradiol levels are highly

Table 7.3.3.4 Hormonal evaluation for the evaluation of premature sexual maturation

	Technical requirements	Significance	Limitations	Usefulness
Serum oestradiol (girls)	Use morning values due to circadian variation. Use assay with a lower limit of detection of ≈ 5 pg/ml (18 pmol/L) or lower	Markedly elevated levels ≈ >100 pg/ml (367 pmol/L) suggest ovarian cyst or tumour	Levels can be normal in *bona fide* central precocious puberty. Difficulties in interpreting values measured with immuno-enzymatic methods (falsely high values close to the limit of detection of the assay)	First line test together with basal LH in girls. However, poor sensitivity to discriminate early pubertal from prepubertal levels
Serum testosterone	Use morning values due to circadian variation. Use assay with a lower limit of detection of ≈ 0.1 ng/ml (0.35 nmol/L)	Boys: reliable marker of testicular activation. Girls: use if signs of hyperandrogenism; elevated testosterone levels suggest adrenal disorders	Difficulties in interpreting values measured with immuno-enzymatic methods (falsely high values close to the limit of detection of the assay)	First line test with basal LH in boys. High sensitivity to confirm precocious puberty
Serum LH	Use morning values due to circadian rhythm Use ultrasensitive assays with a lower limit of detection of ≈ 0.1 UI/L or lower	Basal LH measurement poorly discriminates between prepubertal and early pubertal children Values >0.3 to 0.4 UI/L indicative of central precocious puberty with a high specificity and a low sensitivity in some series	Wide interassay variations; assay characteristics must be taken into account when interpreting the results	First line screening test in association with oestradiol or testosterone measurement. If clearly elevated can obviate the need for a stimulation test
Peak LH after stimulation with GnRH* or GnRH agonist	Can be performed at any time of the day Assay requirements similar to baseline measurements	Peak LH level above the pubertal cut off with elevated sex steroid levels indicate progressive central puberty Suppressed peak LH level with elevated sex steroid levels indicate peripheral precocious puberty	Wide interassay variations; assay characteristics must be taken into account when interpreting the results. Paucity of normative values to define cut-offs; values of5 to 8 UI/L are most often considered 'high' in children aged from 4 to 8 years. Higher cut-offs should be used in younger children due to transient activation of the gonadotropic axis. Peak values vary with the stimulating agent used (GnRH or GnRH agonist)	Gold standard for the diagnosis of central precocious puberty
Peak FSH after stimulation with GnRH* or GnRH agonist		Peak LH/FSH ratio typically increases during puberty; high ratios are used as a secondary criterion for progressive central puberty; this is less useful with more sensitive LH assays available	Poorly validated, in particular with sandwich-antibody assays for gonadotropin measurements	Can be useful as an additional criterion when a GnRH or GnRH agonist test is performed
Serum ßhCG		Produced by germ cell tumours. Can be detected in serum (peripheral tumours) or in CSF (intracranial tumour)	Peripheral production of ßhCG leads to pubertal development in boys and not in girls	Measurement warranted in boys with peripheral precocious puberty to identify a germ cell tumour and in the CSF when a lesion compatible with a germ cell tumour is detected by MRI.
Serum DHEAS		Produced by the adrenals, marker of androgen-producing adrenal tumours or of adrenal enzymatic defect	Also increased in precocious pubarche	Measure if androgenic signs (pubic hair) predominate
Serum 17OH-progesterone	Use morning (8 a.m.) values due to circadian rhythm or measure after ACTH stimulation.	Marker of adrenal enzymatic defects (congenital adrenal hyperplasia) Occasionally elevated with adrenal tumours	Borderline elevations are frequent in unaffected carriers of non-classical congenital adrenal hyperplasia	Measure if androgenic signs (pubic hair) predominate

variable and have a low sensitivity for the diagnosis of precocious puberty. Very high oestradiol levels are generally indicative of ovarian diseases (cysts or tumours).

- LH determinations are the key to diagnosis and should be based on ultrasensitive assays. Because prepubertal LH levels are <0.1 IU/L, LH assays used should have a detection limit near 0.1 IU/L. The measurement of gonadotropins following GnRH (or GnRH agonist) stimulation is considered the gold standard. However, normative values are scarce and cut-offs levels are not well validated. During normal puberty, the peak LH level increases progressively with a large overlap between successive pubertal stages resulting in an ability to fully discriminate only stage I and stage IV [16]. Peak LH levels of 5 to 8 IU/L suggest progressive central precocious puberty [17].
- Random LH measurements have been proposed as an alternative but variable cut-off values have been proposed. However, unless LH values are clearly elevated, we consider that it is preferable to confirm the diagnosis of progressive central precocious puberty by a stimulation test before initiating treatment. In girls below the age of 3 or 4 years, gonadotropin levels tend to be physiologically elevated and caution should be taken when interpreting the values to avoid over-diagnosing precocious puberty [21].
- FSH provides less information than LH measurements since FSH levels vary little through pubertal development. However, the stimulated LH/FSH ratio may help differentiate progressive precocious puberty (which tends to have higher LH/FSH ratios) from non-progressive variants that do not require GnRHa therapy.

Pelvic or Testicular Ultrasonography

In girls, pelvic ultrasonography can be used to detect ovarian cysts or tumours. Uterine changes due to oestrogen exposure can be used as an index of progressive puberty. A uterine volume greater than 2.0 ml and a uterine length of more than 34 mm have 89% and 80% sensitivity and 89% and 58% specificity respectively for precocious puberty in one series [22]. Testicular ultrasound scans should be performed if testicular volume is asymmetric or in peripheral precocious puberty, in order to detect Leydig cell tumours, which are generally not palpable.

Brain MRI

Neuroimaging is essential in the etiological evaluation of progressive central precocious puberty. Magnetic resonance imaging (MRI) is the examination of choice in the study of the brain and of the hypothalamic-pituitary region, for the detection of hypothalamic lesions. The prevalence of such lesions is higher in boys (30–80% of cases) than in girls (8–33%), and is much lower when puberty starts after the age of 6 years in girls, this population accounting for the majority of cases. It has been suggested that an algorithm based on age and oestradiol levels could replace MRI, but such an approach has not been clearly validated [23–25].

Differentiating Progressive and Non-Progressive Forms of Central Precocious Puberty

Clinical evaluation, hormonal measurements and imaging usually allow the identification of one of the following situations:

- **Progressive central or gonadotropin-dependent precocious puberty,** with high serum testosterone in boys, variable serum oestradiol in girls, peak serum LH after GnRH stimulation in the pubertal range, advanced bone age and oestrogenized uterus on ultrasound examination.
- **Peripheral or gonadotropin-independent precocious puberty,** with high serum testosterone in boys, generally high and occasionally markedly elevated serum oestradiol in girls, low (suppressed) peak serum LH after GnRH stimulation, advanced bone age and oestrogenized uterus on ultrasound examination.
- **Benign variants of precocious pubertal development**, with low serum sex-steroid levels, normal pelvic ultrasound examination and peak serum LH after GnRH stimulation in the prepubertal range (if done, not necessary in most cases).

Table 7.3.3.5 summarizes features reflecting the intensity and duration of the gonadotropic axis activation that are useful in distinguishing between progressive central precocious puberty and non-progressive forms of precocious puberty. Although these criteria are not fully evidence-based, and reflect personal experience

Table 7.3.3.5 Criteria to differentiate non-progressive forms and progressive central precocious puberty in girls

		Progressive central precocious puberty	Non progressive precocious puberty
Clinical	Pubertal stages	Progression from one stage to the next in 3 to 6 months	Stabilization or regression of pubertal signs
	Growth velocity	Accelerated (≈>6 cm/year)	Usually normal for age
	Bone age	Usually advanced by at least 1 year	Usually within one year of chronological age
	Predicted adult height	Below target height range or declining on serial determinations	Within target height range
Pelvic ultrasonography	Uterine development	Uterine volume >2.0 ml or length >34 mm Pearl-like shaped uterus Endometrial thickening (endometrial echo)	Uterine volume ≤2.0 ml or length ≤34 mm Prepubertal, tubular shaped uterus
Hormonal evaluation	Oestradiol	Usually measurable oestradiol level with advancing pubertal development	Oestradiol not detectable or close to the detection limit
	LH peak after GnRH or GnRH agonist	In the pubertal range	In the prepubertal range

as well as data obtained in cross-sectional and small-sized longitudinal studies, they can provide useful orientation. When discrepant results are obtained, it is recommended to wait a few months and reassess, to avoid unnecessary treatment [15].

The Normal Variants of Puberty

The distinction between early puberty and normal puberty is not clear-cut. There are several variants of normal puberty, which may pose problems for differential diagnosis, particularly as they have a high prevalence [26–28].

Isolated Premature Breast Development or Premature Thelarche

Premature thelarche is isolated breast development before the age of 8 years. There are two peaks in the frequency of premature thelarche: the neonatal period, which is marked by gonadotropin activation, this peak potentially lasting for 2 or 3 years, and the prepubertal period [29]. Premature thelarche differs from early puberty in the absence of any other aspect of sexual development, usually with a lack of scalability of breast development and no acceleration of height velocity or significant advance in bone maturation (≥2 years). Uterine ultrasound scans provide a simple means of checking that there is no change in the uterus. No further exploration or treatment is required and the outcome is the persistence of moderate breast development (in two-thirds of cases) or regression (one-third of cases). However, isolated premature breast development may precede the onset of central precocious puberty, which should not be ignored if patients develop other pubertal signs and an acceleration of height velocity.

Premature Development of Pubic Hair or Premature Pubarche

Premature pubarche is the appearance of pubic hair before the age of 8 years in girls and 9 years in boys. It may be accompanied by clinical signs of hyperandrogenism: acne, axillary hair, accelerated growth rate. It corresponds to adrenal maturation (adrenarche) and is not a differential diagnosis for central precocious puberty. Possible differential diagnoses to be systematically excluded include adrenal tumours and congenital adrenal hyperplasia [30, 31].

Slowly Progressive Forms of Precocious Puberty

Studies monitoring these benign variants of precocious puberty have shown that treatment with GnRH agonists is not appropriate because there tends to be either a total regression of pubertal signs or a slow progression towards puberty (Table 7.3.3.5)

Management

Central Precocious Puberty

GnRH Agonists

GnRH agonists are generally indicated in progressive central precocious puberty. GnRH agonists continuously stimulate the pituitary gonadotrophs, leading to desensitization and decreases in LH release and, to a lesser extent, FSH release [32]. Several GnRH agonists are available in various depot forms and their approval for use in precocious puberty varies between countries. Despite nearly 30 years of use of GnRH agonists in precocious puberty, there are still ongoing questions on their optimal use and an international consensus statement, has summarized the available information and the areas of uncertainty as of 2007 [2].

GnRH agonist treatments should be followed by experienced clinicians and result in the regression or stabilization of pubertal symptoms, decrease of growth velocity and bone age advancement [2]. GnRHa-injection dates should be recorded and adherence with the dosing interval monitored. A suppressed LH response to the stimulation by GnRH, GnRH agonist, or after an injection of the depot preparation (which contains a fraction of free GnRH agonist) is indicative of biochemical efficacy of the treatment but is not recommended routinely. Progression of breast or testicular development usually indicates poor compliance, treatment failure or incorrect diagnosis and requires further evaluation.

There are no randomized controlled trials assessing **long-term outcomes** of the treatment of central precocious puberty with GnRH agonists: at most, heightened outcomes have been evaluated. Among approximately 400 girls treated until a mean age of 11 years, the mean adult height was about 160 cm and mean gains over predicted height varied from 3 to 10 cm [16]. Individual height gains were very variable, but were calculated using predicted height, which is itself poorly reliable. Factors affecting height outcome include initial patient characteristics (lower height if bone age is markedly advanced and shorter predicted height at initiation of treatment) and, in some series, duration of treatment (higher height gains in patients starting treatment at a younger age and with longer durations of treatment).

Other outcomes to consider include bone mineral density, risk of obesity, and psychosocial outcomes. Bone mineral density may decrease during GnRH agonist therapy. However, subsequent bone mass accrual is preserved, and peak bone mass does not seem to be negatively affected by treatment [2]. There have been concerns that GnRH agonist use may affect BMI. However, childhood obesity is associated with earlier pubertal development in girls, and early sexual maturation is associated with increased prevalence of overweight and obesity. Altogether, the available data indicate that long-term GnRH agonist treatment does not seem to cause or aggravate obesity, as judged from BMI [2, 33]. However, the risk of obesity is a concern in girls with premature sexual maturation and BMI should be closely monitored. As discussed earlier, psychosocial evaluation data are scarce in patients with premature sexual maturation and there is little evidence to show whether treatment with GnRH agonists is associated with improved psychological outcome [2, 34, 35].

Although **tolerance** to GnRH agonist treatment is generally considered good, it may be associated with headaches and menopausal symptoms such as hot flushes. Local complications (3–13%) such as sterile abscesses may result in a loss of efficacy and anaphylaxis has been exceptionally described [36].

The **optimal time to stop treatment** has not been established and factors that could influence the decision to stop GnRH agonists include aiming at maximizing height, synchronizing puberty with peers, ameliorating psychological distress, or facilitating care of the developmentally delayed child. However, data only permit analysis of factors that affect adult height. Several variables can be used to decide on when to stop treatment including chronological age, duration of therapy, bone age, height, target height, growth velocity. However, these variables are closely interrelated and cannot be considered independently. In addition, retrospective analyses suggest

that continuing treatment beyond the age of 11 years is associated with no further gains [37]. Therefore, it is reasonable to consider these parameters as well as informed parent and patient preferences, with the goal of menarche occurring near the population norms [2]. Pubertal manifestations generally reappear within months of GnRH agonist treatment being stopped, with a mean time to menarche of 16 months [38]. Long-term fertility has not been fully evaluated, but preliminary observations are reassuring [38, 39].

The addition of growth hormone [40] or oxandrolone [41] when growth velocity decreases or if height prognosis appears to be unsatisfactory has been proposed. However, data are limited on the efficacy and safety of these drugs in children with precocious puberty.

Management of Causal Lesions

When precocious puberty is caused by a hypothalamic lesion (e.g. mass or malformation), management of the causal lesion has generally no effect on the course of pubertal development. Hypothalamic hamartomas should not be treated by surgery for the management of precocious puberty. Precocious puberty associated with the presence of a hypothalamic lesion may progress to gonadotropin deficiency.

Peripheral Precocious Puberty

Management of Causal Lesions

Surgery is indicated for gonadal tumours and postoperative chemo- or radiotherapy should be discussed as part of a multidisciplinary team including surgeons and oncologists.

Large ovarian cysts (greater than 20 ml or 3.4 cm in diameter and typically more than 75 ml or 5.2 cm) should be managed very carefully given the risk of adnexal torsion. In such cases, puncture possibly ultrasound-guided should be considered and allows molecular analysis of the cystic fluid for activating GNAS mutation.

Removal of exogenous exposure to sex steroids is obvious but the search for environmental exposure is often very difficult and requires careful investigation.

Benign Variants of Premature Sexual Maturation

Benign variants of premature sexual maturation should be followed clinically with reassurance to the parents. There is limited data on long term outcomes of individuals with these conditions and it has been suggested that premature pubarche is a risk factor for hyperandrogenism in adulthood.

Medications

There is no aetiological treatment for peripheral causes of precocious puberty and the rarity of the diseases renders evaluation of therapeutic strategies very difficult. In McCune-Albright syndrome and recurrent ovarian cysts, aromatase inhibitors and Selective oestrogen receptor modulators have been used to inhibit the production or action of oestrogens, respectively. These approaches are partly effective but no definitive strategy has emerged [42]. In familial male precocious puberty due to LH receptor activating mutations, ketoconazole, an inhibitor of androgen biosynthesis has been shown to be effective in the long term and the combination of anti-androgens and aromatase inhibitors has been proposed [43]. However, caution must be used with the use of ketoconazole given the risk of liver toxicity. Non classical and classical forms of congenital adrenal hyperplasia should be managed with glucocorticoids.

Conclusion

The main concern when examining a patient with premature sexual development should be the existence of a malignant or potentially threatening lesion, either intracranial, in the gonads, the adrenals, or elsewhere. However, these lesions are exceedingly rare and on a daily basis, the main difficulty is with the differentiation of progressive and non-progressive forms of precocious puberty and with the decision to treat, particularly for girls with an onset of puberty between the ages of 6 and 8 years. The psychological aspects of precocious puberty should also be evaluated during and after the treatment of these patients.

7.4

Transition in Endocrinology

Helena K. Gleeson and Rohana J. Wright

Introduction

Healthcare professionals are increasingly aware that the transition from childhood to adulthood requires special consideration, in terms of meeting the needs of young people with any long term condition, both through healthcare design and delivery and the need for a specific skill and behaviour set in order to do this effectively. Young people can be a forgotten group, not adequately considered in paediatric or adult service development strategies resulting in disrupted care. This phase of life is key, as it is when a young person develops their ideas about, and relationships with the healthcare system and their own health condition, thus setting the scene for future interactions.

Young people with endocrine conditions, whether onset is in early childhood or during adolescence, often require lifelong care, and therefore both paediatric and adult healthcare professionals require knowledge about:

1. Biopsychosocial development and how it can both affect and be affected by having an endocrine condition
2. Key aspects of adolescent health
3. Developmentally appropriate healthcare
4. Effective transition between paediatric and adult services
5. Endocrine specific care during adolescence and young adulthood

Adolescence and Young Adulthood

The WHO have defined 'adolescence' as the period from age 10 to 19 years, but have also described a 'young person' as being from age 10 to 24 years [1]. This supports the move from developmental psychologists to consider biopsychosocial development not only in adolescence but extending into the third decade, embracing the concept of 'emerging adulthood' [2]. Further supporting evidence for the extension into young adulthood is provided from neuroscience research into brain development.

Differential pace of brain development during adolescence and young adulthood has been proposed as providing an explanation for 'adolescent' behaviour, for example, exploratory risk-taking behaviours. The limbic regions develop earlier, the areas associated with emotion and reward, followed much later by the pre-frontal cortex, which enables planning, considers inhibition, and allows future thinking. The pre-frontal cortex is thought to continue developing into the mid-20s [3].

Biopsychosocial development is an interdependent process (Figure 7.4.1), and there are a number of factors, including cultural and socioeconomic, that may alter the rate of progression through adolescence and into young adulthood. Understanding

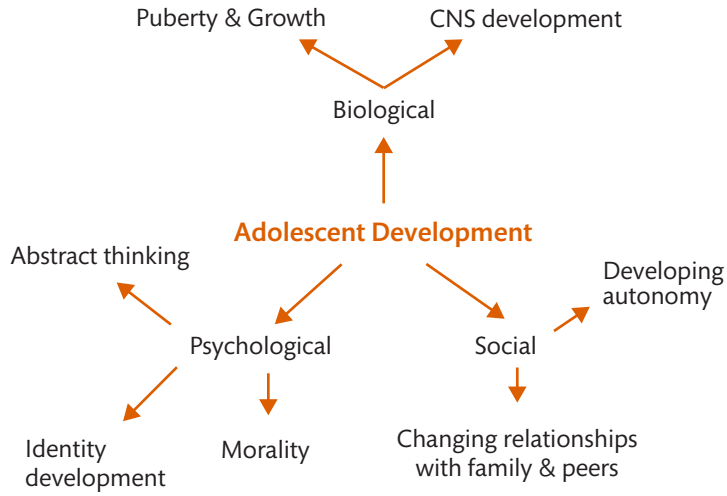

Figure 7.4.1 Biopsychosocial development of adolescence.

biopsychosocial development, (summarized in Table 7.4.1), and the potential complex interplay is invaluable for all clinical interactions between healthcare professionals and young people. The bidirectional relationship between 'normal' development and having an endocrine condition is significant.

Biological Development

Growth and puberty are covered in Chapter 7.1, but there are also changes in body composition beyond the achievement of adult height in late puberty with considerable sexual dimorphism [4–6].

Total body fat increases during puberty, with a steady increase in females and a slower increase in males due to the simultaneous rise in fat-free mass. This can be perceived as weight gain leading to impact on self-esteem and body image. Lean body mass (fat-free mass) increases to age 15 years in females but to age 18 years in males, with the maximal rate of change age between 12 and 15 years [7, 8]. The endocrine role of adipose tissue through release of adipocytokines during adolescence and young adulthood has potential implications for the development of future health problems such as cardiovascular disease, obesity, and diabetes; metabolic programming impacts on energy expenditure and insulin resistance [9–12].

Bone mineral content also increases, with 40% of bone density accrued during adolescence [13], with peak bone mass typically occurring in the early 20s in females and late 20s in males [14].

Muscle strength and mass increase through adolescence, most significantly in males due to the effect of androgens. This accrual peaks during the growth spurt in males and during menarche in females. By age 17 years, muscle mass is two-fold higher in males compared with females [15].

Other biological changes include:

- Blood pressure increases in puberty, more rapidly in males than females [16].
- Lipids -Total cholesterol and LDL cholesterol decrease in both males and females as puberty progresses; HDL is lower and triglycerides are higher in males by the end of puberty when compared to both males in earlier pubertal stages and females [17].
- Haemoglobin and haematocrit increase in males due to androgens, and can decrease in females due to menstruation [18].

Psychosocial Impact of Altered Biological Development

Pubertal Development

When compared to previous generations, girls now have menarche at a younger age [19]. Early pubertal maturation can have a detrimental impact on mental health [20]. Girls entering puberty at a younger age have been shown to have elevated rates of depression and these rates remain stable over the pubertal period. Earlier onset of puberty in girls is associated with earlier age of first sexual encounter, teenage pregnancy as well as the development of mood disorders [21–23].

Early-maturing males experience an initial benefit of entering puberty before their peers, conferring social benefits of increased muscle mass and older appearance. However over time rates of depression also increase in this group, potentially as a result of earlier introduction to risk taking behaviours, and association with older acquaintances [20].

Delayed or absent puberty can also have dramatic impact on psychosocial and emotional well-being [24–28]. Victimization and bullying have been reported. Young men diagnosed with congenital hypogonadotropic hypogonadism and Kallmann Syndrome have increased rates of anxiety and depression compared with their peer group [29–32]. Some young people become socially isolated as a result. Self-esteem and social outcomes do improve with the timely introduction of treatment at a physiologically appropriate age, as shown in both Kallmann syndrome and Turner syndrome [32, 33]. However, if the diagnosis is made late there can be ongoing sequelae for the young person, lasting into adult life. Psychological counselling is a key aspect of managing hypogonadism in adolescence.

Short Stature

Children and young people with short stature are reported to be at risk of social isolation, bullying and stigmatization, and tend to have low self-esteem and be underestimated by their parents, peers, and teachers [34, 35]. Parents also experience heightened anxiety and seem to have more awareness of potential impact on future functional limitations [36, 37], though levels of concern seem to be similar for families of children with other long-term conditions and may be more related to illness burden than height itself [38, 39].

Table 7.4.1 Biopsychosocial phases of adolescence

	Early 10–13 yrs	Mid 14–16 yrs	Late 17–19 yrs
Biological/ physical	**Girls** Breast bud and pubic hair development (Tanner stage II); initiation of growth spurt **Boys** Testicular enlargement; beginning of genital growth (Stage II)	**Girls** Mid to late puberty (Stage IV–V); completion of growth; menarche (Stage IV event); development of female body shape with fat deposition **Boys** Mid puberty (Stages III & IV); spermarche & nocturnal emissions; voice breaking; initiation of growth spurt (Stage III–IV)	**Boys** Completion of pubertal development (Stage V); continued androgenic effects on muscle bulk and body hair **Boys & Girls** Increase in bone mass
Psychological/ cognitive	Thinking remains concrete but with development of early moral concepts Progression of sexual identity development Sexual orientation Reassessment and restructuring of body image in face of rapid growth	Emergence of abstract thinking although ability to imagine future applies to others rather than self (self-seen as 'bullet-proof') Growing verbal abilities; adaptation to increasing educational demands conventional morality (identification of law with morality) Development of fervently held ideology (religious/political)	Complex abstract thinking Post-conventional morality (ability to recognise difference between law and morality) Increased impulse control Further completion of personal (and sexual) identity Further development or rejection of ideology and religion
Social	Realization of differences from parents Beginning of strong peer identification Early exploratory behaviours	Emotional separation from parents Strong peer group identification Exploratory/risk behaviours Heterosexual peer interests develop Early notions of vocational future	Development of social autonomy Development of intimate relationships Development of vocational capability

Psychosocial Development

Identity

The concept of 'self' evolves during adolescence, with the young person developing their own identity, and becoming autonomous in their thinking and acting. Part of this process is an evolving separation from the parents/main caregivers, with less reliance on their opinions and development of their own. Young people become more aware of how others see them, and more or less comfortable with who they are and what their life looks like from the outside. This includes the development of their sexual identity, along with moral/religious identity and academic/vocational identity. Self-esteem and self-efficacy form part of this process—the judgement or evaluation of one's ability and the belief in one's ability to achieve a particular task/goal. Where on the continuum of development an individual sits will hugely impact on their ability and confidence in managing their long-term condition, and this therefore needs to be taken into account during any clinical interactions. For example, the way a young person feels about their body image and how it is changing during adolescence will impact on their consultations; young people with long-term conditions have been shown to have lower self-esteem when it comes to body image than their counterparts without any underlying medical conditions [40, 41].

Thinking

The mode of thinking evolves during adolescence, with concrete thinking early in the process (rigid ideas with no sight of potential future effects of current actions), and the development of abstract thinking and logical thought process over time (the ability to link current actions with future consequences). It takes time for the 'bullet-proof' effect to progress to the complex abstract thinking needed to understand the long-term consequences on their future and their health of actions taken now. By late adolescence (age 17–20 years) young people are starting to understand these potential consequences, so the approach of healthcare professionals needs to adjust depending on the stage of development of a young person's thought processes.

Social Development

As young people develop biologically and psychologically, they are also adapting to a changing social environment. This involves changes in the way they interact with family, peers, and potential partners, with exposure to new behaviours and responsibilities. There can be significant cultural differences in how these changes evolve, depending on geography and ethnic background, with additional impact of socioeconomic status.

- **Relationships and support frameworks**

Throughout adolescence, there is an expected change in the interaction with parents/guardians, moving from a reliance on their support and guidance, to an active rejection of their input in favour of peer support. Ultimately there is re-acceptance of parental support in collaboration with peer support and the input of partners by late adolescence. With a long-term condition in the equation, the parental support relationship can be more complex: it is often relied upon, having been essential from childhood, potentially preventing young people from developing independence; for parents it can be hard to relinquish that control.

- **Exploratory and risk-taking behaviours**

During adolescence it is normal to explore behaviours that healthcare professionals consider risky. Substance use, including smoking, drugs, and alcohol, will commonly be tried for the first time during adolescence. Ninety-five percent of adult smokers have usually started by age 25 years [42], which indicates that health choices made during adolescence translate into longer term habits and adverse health outcomes [43]. The Key Data on Adolescence for 2017 [42] revealed that 5% of 15 year olds are regular smokers. Interestingly, the number of 15 year olds regularly using drugs has halved between 2001 and 2015, and only 9% of school pupils aged 11–15 years had consumed alcohol in the week preceding the survey, the lowest rate since the 1980s. This indicates that education and awareness raising in young people is having an impact. In consultations with young people with endocrine conditions, consideration should be given to whether these exploratory behaviours are occurring, potentially at a higher rate than in healthy peers [44], and that such behaviours may have more serious consequences for some young people, for example, childhood cancer survivors. There, therefore, needs to be a non-judgemental and open approach to discussing these issues. This is also a real opportunity to consider health promotion elements of consultations, as these behaviours often translate into adult life.

- Sexual and reproductive health

The average age of first sexual intercourse is 16 years of age, which falls in the middle of this adolescent development phase. There is therefore a duty to consider sexual health issues in consultations with young people in an endocrine clinic. Young people may have questions regarding sex and intimacy that they do not have the opportunity to discuss with other healthcare providers; indeed many young people will see the endocrine clinic as their main healthcare point of contact and will not attend their GP much, if at all. There is an opportunity to address safe sex, sexually transmitted infections (STIs) and contraception. Two thirds of new diagnoses with chlamydia happen in those under 25 years old. Teenage pregnancy remains a real issue, though rates have been consistently falling from the 1990s onwards, with the most recent reported under 18 pregnancy rate in 2015 in the UK being 20.8 per 1000 young women [42]. This remains higher than in other European countries. Some endocrine conditions may generate questions around ability to have sex, fertility, and whether there is a need for contraception—this needs to be openly addressed and questions should be welcomed.

- Education and vocation

Attainment of educational goals and progression to vocation are normal aspects of adolescent development. This can be affected by the presence of a long-term condition: attendance at school/college may be interrupted by health issues/hospital attendances. It has been shown that the presence of a long-term condition can lead to less educational attainment, less preparation for the move into the workplace, and less likelihood of achieving financial independence from parents [45, 46]. This is most marked in those with a significant disability, such as some survivors of childhood cancer [47].

- Concordance/adherence

Young people may not reliably take their medications, and if catastrophic consequences do not occur, it is difficult to convince young people to take their medications solely on the premise that bad things may happen. This relates most often to the concrete thinking of early adolescence, having yet to progress to abstract thought processes and an understanding of consequence. Other factors include lack of practice at looking after their own medications, differing priorities and psychological problems. This is a challenge in some endocrine disorders, the prime example being glucocorticoid insufficiency, where healthcare providers must ensure safety education highlights that glucocorticoid replacement is vital for a healthy life. Concordance, or the establishment of a therapeutic alliance between young person and healthcare provider, is the key to improving adherence with a long-term medication regimen for a long-term condition. The emphasis is on a shared approach to the condition and its treatment, rather than a judgemental, paternalistic approach, which is likely to be ineffective. Where there are cognitive impairments limiting adherence to treatment regimens (e.g. in some congenital/genetic disorders) or after brain radiotherapy, there needs to be collaboration with families and caregivers to develop practical solutions to the problem.

Common Physical Health Concerns in Young People

There are some common physical health concerns that present during adolescence. It is useful for healthcare professionals interacting with this age group to have an understanding of these, and where to signpost young people, as this may be the main focus for the young person in a consultation. Figure 7.4.2 illustrates common health concerns affecting young people [48].

- Skin

Acne is a problem for 85% of adolescents, with 10–20% affected by moderate to severe acne [49]. It usually begins with the onset of puberty. It can have significant psychosocial consequences for a young person, affecting their self-esteem and body image, and impacting on social interactions and interpersonal relationships. It can be treated either topically or systemically depending on severity. Endocrine disorders potentially aggravating acne during adolescence include PCOS and congenital adrenal hyperplasia due to increase in circulating androgens.

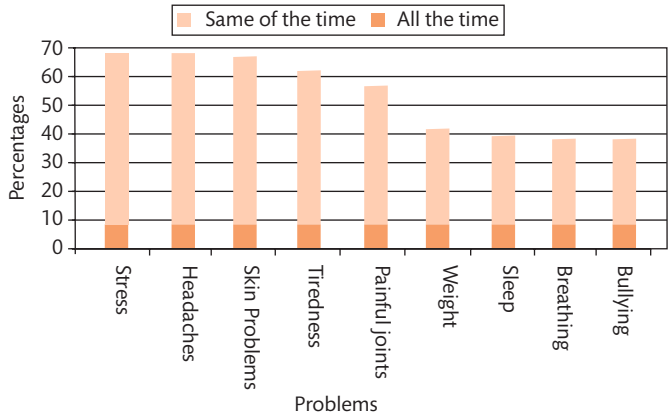

Figure 7.4.2 Self-reported health concerns among 13- to 15-year-olds.

- Sleep and fatigue

Sleep disorders can be both a cause of problems and the result of other issues in adolescence. The normal circadian rhythm slows during adolescence, meaning that young people are awake for longer, and it can be normal to be unable to sleep until after 11 p.m. [50]. Between 8 and 10 hours are needed per night for optimal functioning during adolescence, but many do not achieve this. It is also more likely that sleep patterns will vary day to day, which can disrupt sleep quality. Treatable sleep disorders can also occur, including insomnia, narcolepsy, sleep apnoea, and restless legs.

Fatigue is also a common problem in adolescence, and could be considered normal for many young people. It is defined as abnormal exhaustion after normal activities. There are increasing demands during adolescence as a result of physical changes, growth, increasing social and academic demands, all of which are compounded by reduced sleep time. Most young people will still manage to engage in usual activities despite experiencing fatigue. But for the minority this fatigue is significant and leads to reduced school attendance, impaired academic performance, reduced social interaction and impacts on relationships. When fatigue is persistent and impacting on function over a period of greater than 3 months, consideration should be given to investigation for underlying medical causes, psychological causes, and also the possibility of chronic fatigue syndrome. CFS is reported to occur in 0.2–0.6% of young people in the UK, a much higher rate than in the adult population [51]. CFS is the most common cause of school absence in the UK.

- Musculoskeletal issues and pain

A quarter of children are believed to suffer from recurrent or chronic pain, most commonly headache, back pain, or abdominal pain. The proportion affected is believed to increase during adolescence [52]. Sometimes these physical complaints can signify underlying psychological distress. Headache is reported in 20–25% of young people on at least a weekly basis [52]. Common causes are tension headache, migraine, ENT or dental causes, or dietary causes such as caffeine related. Back pain is common and nonspecific, often related to growth spurts and settling thereafter (e.g. Scheuermann's disease). Joint problems, sports injuries, and trauma are also common presentations.

- Breathing problems and asthma

A study of 12–14 year olds has shown that one third have experienced wheeze in the preceding year, with one-fifth having a diagnosis of asthma [53]. Most experience remission of symptoms by the end of puberty, but there is evidence that it is under-recognized during the teenage years.

- Overweight and underweight

One in five children aged 11–15 years is obese in England. It is now the commonest disorder in childhood and adolescence. Teenagers consume 8 times the recommended daily sugar allowance, and exercise levels are decreasing—by age 13–15 years, only 19% of boys and 7% of girls achieve 1 hour of exercise per day, and only 1 in 12 young people aged 11-18 years eat 5 portions of fruit and vegetables per day [42]. Some young endocrine clinic attenders have particular issues with appetite and weight gain, such as those with hypothalamic disorders. The sequelae of obesity in adolescence are multifactorial and include psychosocial issues, development of type 2 diabetes and increased cardiovascular risk, asthma, musculoskeletal problems, and liver disease.

At the opposite extreme, eating disorders including anorexia nervosa, bulimia nervosa, and binge eating can also present in adolescence. Factors influencing their development include biological, psychological, and cultural factors. Being underweight during adolescence can impact on normal endocrine development with poor pubertal progression or cessation of menses, poor growth, and poor bone development.

- Self-harm and mental health issues

75% of mental health issues start before 24 years of age, with 10% of young people experiencing a mental health disorder at any one time [54]. A quarter of young women aged 16–24 years exhibit symptoms of anxiety or depression [54]. There may be concurrent issues that point towards mental health problems, such as trouble at school, violence, and substance use. Long-term conditions increase the likelihood of mood disorder in young people as well as in adults, including endocrine conditions [55].

Consultations with Young People and Psychosocial Screening

To meet the needs of young people, as with patients of any age, the healthcare professional requires good communication skills. There are however some differences, which are important to emphasize. Confidentiality can be a concern for young people, particularly noted in older teenagers and young women [56]. It is important to explain the right to confidentiality including its limitations, rather than assuming it is understood. Encouragement of lone consulting for all or part of the consultation will also benefit the therapeutic alliance between healthcare professional and young person, hopefully increasing their confidence in negotiating consultations [57, 58]. To ensure that all aspects of a young person's life are covered, a psychosocial screen is useful, and one known as 'HEEADSSS' provides a useful framework (Table 7.4.2). It is important that the young person is the focus of the consultation, and while ideally this is done with the young person on their own, if accompanied the questions should be directed to them rather than their parents/caregivers [59, 60].

Developmentally Appropriate Healthcare

Due to the complexity of this period of life, health services must support the young person to engage with endocrine care; appropriate care in this age group is now called 'developmentally appropriate healthcare'. A recent review of the literature and a qualitative survey have identified the following themes that are required to deliver such care [61, 62]:

(i) Biopsychosocial development and holistic care
(ii) Acknowledgement of young people as a distinct group
(iii) Adjustment of care as the young person develops
(iv) Empowerment of the young person by prioritising health education and health promotion
(v) Interdisciplinary and interorganizational work.

Table 7.4.2 HEEADSSS communication framework

Theme	Relevance	Opportunity
Home	Identifying whether a young person feels happy and safe at home and has a supportive family who they can communicate with is a protective factor	Identifying safeguarding issues
Education & Employment	Young people with endocrine conditions may have lower educational and vocational attainment for any number of intrinsic and extrinsic reasons Identifying whether a young person is engaged with education or training and has a plan for employment when they leave is a protective factor	Assessing and addressing the impact of having an endocrine condition on education, training, and employment Assessing and addressing vocational readiness including aspiration of the young person; educational achievement; prior work experience; knowledge of resources, responsibilities, and rights; psychological aspects including self-esteem; expectations of the young person, their family, their teachers Addressing information needs of school, college, university, employment agencies and work to support the young person Discussing with the young person about disclosure to appropriate people about their condition to support education and vocation Offering neuropsychology for some young people, such as those treated for brain tumours, to guide them towards their strengths
Exercise & Eating	Young people with endocrine conditions are at risk of having or developing obesity which is associated with low self-esteem and potentially longer-term consequences such as diabetes, cardiovascular disease, reduced fertility, and sleep apnoea Young people who are childhood cancer survivors and have had treatment with the chemotherapy agent anthracyclines need advice about exercise such as weightlifting	Employing the 5As (Ask, Advise, Agree, Assist, Arrange) may support the young people becoming more active and eating more healthily
Activities (Including Peers)	Young people with an endocrine condition may have a disrupted peer network due to intrinsic or extrinsic factors Identifying young people with a supportive peer network and involvement in group activities is a protective factor	Enquiring about teasing and bullying may identify an area of risk and a young person in need of support Exploring potential for peer interaction through young person support groups, youth groups or with the assistance of a youth worker Enquiring about use of public transport and driving to support independence
Drugs (Smoking, Alcohol, Other Substances)	Young people with endocrine conditions are as likely as their healthy peers to explore the use of drugs Some young people with endocrine conditions are at risk of cardiovascular and/or respiratory disease, in particular childhood cancer survivors Young people on hydrocortisone or desmopressin who drink alcohol may increase their risk of adrenal crisis or hyponatraemia, respectively	Enquiring whether family or peers smoke, drink alcohol or use drugs is a recognized risk even if the young person denies use Employing the 5As (Ask, Advise, Agree, Assist, Arrange) may support the young people changing their drug use Educating young people on hydrocortisone or desmopressin about keeping themselves safe when drinking alcohol
Sexuality	Young people with endocrine conditions are as likely as their healthy peers to become sexually active in adolescence and be at risk of unwanted pregnancy or sexually transmitted infections Young people with endocrine conditions may have questions about sexuality, ability to have sex and fertility. Young people with PCOS on anti-androgens should be advised about avoiding pregnancy Young people with endocrine conditions caused by genetic disorders or associated with cardiac concerns should be advised about prepregnancy counselling	Identifying gender concerns Educating young people about sexual health and contraception and signposting to relevant services Discussing concerns about ability to have sex, in particular young people with disorders of sex development, and referring for further assessment if appropriate Discussing implications of their condition on fertility and referring for further assessment if appropriate Educating young people about the importance of pre-pregnancy genetic counselling and cardiac assessment and avoiding pregnancy in those on antiandrogens
Suicide, Depression, & Self-Image	Mental health issues are common in adolescence Protective factors include: having an adult to talk to when stressed, a peer support network and coping skills, as well as positive self-esteem and image	Asking them to rate their general happiness to encourage discussion Asking about self-harm and suicide Referring to appropriate services if required
Sleep	Sleep problems in adolescence are common and can be a sign of anxiety and depression	Enquiring about sleep and discussing sleep hygiene
Safety	Safety about driving alone or with friends Safety about internet use Safety about hydrocortisone and desmopressin in general and when away from home	Enquiring about safety with regards to driving and internet use Educating about medic alert jewellery, sick day rules, emergency hydrocortisone injection and keeping safe with diabetes insipidus Discussing with the young person about disclosure to appropriate people (friends, colleagues) about their condition and offering to provide them with education Empowering them to insist on optimal care in healthcare settings

This approach to care should be adopted by both children's and adult services. It is relevant not only to those undergoing transition and transfer to adult services but also for young people presenting for the first time to an endocrine service during adolescence and young adulthood. To assist healthcare organizations in provision of developmentally appropriate healthcare, a toolkit is available [63].

Training Healthcare Providers

Delivering developmentally appropriate healthcare requires trained, competent healthcare providers. Whilst this is logical, and is a feature of all of the national and international guidance available in this area, it is recognized that training in this area is suboptimal, and therefore presents a barrier to implementing optimal care. A survey of specialist trainees in Diabetes & Endocrinology in the UK revealed that they felt under-prepared to deal with young people in clinics, with 65% rating their training in adolescent and young adult health as minimal or non-existent (76% in endocrinology, 42% in diabetes) [64].

Transition and Transfer

Transition is defined as the purposeful, planned process that addresses the medical, psychosocial, and educational needs of adolescents and young adults with long term conditions, as they move from child-centred to adult-oriented healthcare systems [65]. This is not to be confused with transfer—which is the isolated event when the healthcare of a young person moves from services for children to services for adults.

The aims of transition are to:

- Provide high quality, coordinated, uninterrupted healthcare that is patient-centred, age and developmentally appropriate, culturally competent, flexible, responsive, and comprehensive with respect to all persons involved
- Promote skills in communication, decision-making, assertiveness and self-care, self-determination, and self-advocacy
- Enhance the young person's sense of control and interdependence
- Provide support for the parent(s)/guardian(s) of the young person during this process
- Maximize lifelong functioning and potential

There is a limited but emerging evidence base regarding transition of young people. A Cochrane review conducted in 2016 [66] revealed only four randomized controlled trials involving 238 participants. In the UK in 2016 NICE reviewed the evidence and published guidance on 'Transition from children's to adult services for young people using health or social care services' [67]; this makes recommendations on the overarching principles, how to plan and support transition and transfer, and on supporting infrastructure.

A recent trial [68] recruited 374 young people with long term conditions (diabetes, autistic spectrum disorder and cerebral palsy), retaining 274, with 149 crossing into adult services. The aims of the study were to address the needs and wishes of young people, to identify the features of care that were most effective and efficient, and to determine how transitional care should be designed, commissioned, and delivered. This trial found that, although the present guidance on the care of young people suggested a number of key requirements of a transition service, there were three factors that made a real impact on the young people: meeting the adult team before transfer, the development of self-efficacy/self-management skills, and being allowed to have parents/guardians involved if that suited them.

Due to the limited evidence base a Delphi study of international experts identified key elements that should be part of a transition program (**Box 7.4.1**) and what indicators could be used to assess its success (**Box 7.4.2**).

There is evidence, although limited, that transition in endocrinology could be improved. A single centre study identified that 25% of young people transferred from paediatric care were not seen within 12 months of transfer by adult services [69, 70]. In congenital adrenal hyperplasia, there is evidence that 50% of young people with CAH were lost to follow up during the transition period, and are not receiving specialist care despite the risks of long-term morbidity [61, 62]. One study found that patients with CAH who did transition successfully had a better quality of life [71]. In Turner syndrome, one survey of adult women with the condition found

Box 7.4.1 Key elements for successful transition: Delphi study

1. Co-ordination (timing of transfer, communication, and follow-up) between paediatric and adult healthcare professionals
2. Planning transition from an early age, possibly from the transition to high school aged approximately 12 years old (and at least 1 year before the planned date of transfer to adult services)
3. Setting the scene with young people and their families with regards to the aims for evolving self-management
4. Involving young people in the planning of transition—taking into account their thoughts and preferences
5. If developmentally appropriate, seeing the adolescent alone at least for part of the consultation (and talking about leading up to this in preparation)
6. Identifying an adult care provider willing to take on the young person before transfer
7. Tailoring the transition plan to the needs of the young person and family
8. Identifying someone within the team who will play the role of transition coordinator/named contact
9. Providing a written health summary and biopsychosocial profile summary to the young person and the adult care provider before transfer
10. Having a written transition protocol/plan that is available to young people, parents, and providers
11. Making sure that at least one appointment with the adult provider after transfer is fixed in anticipation
12. Ensuring healthcare professionals involved in these clinics have sufficient knowledge and skills in adolescent health
13. Parents and caregivers should be included in the process of transition
14. Keeping the primary care provider (GP, family doctor, nurse practitioner/advanced practice nurse) informed of the transition process
15. Putting in place mechanisms/resources to contact young people lost to follow-up
16. Discussing the differences between paediatric and adult care with the young person and their family
17. Discussing risk behaviours and healthy lifestyles and their influence on health

Box 7.4.2 Key indicators of successful transition: Delphi study

1. Young person not lost to follow-up
2. Attending scheduled visits in adult care (no missed consultations unless previously cancelled and rescheduled)
3. Young person building a trusting relationship with adult provider
4. Continuing attention to self-management
5. Young person's first visit in adult care no later than 3–6 months after transfer
6. Number of emergency department/unscheduled care visits for regular care in the past year (avoidable if routine medical care had been occurring)
7. Young person and family satisfaction with transfer of care
8. Maintenance/improvement of standard for disease control evaluation (such as glycosylated haemoglobin for diabetes).

that only 63.2% had regular follow-up and many were not on oestrogen replacement [72].

Young People with Endocrine Conditions Undergoing Transition

The approach to a young person with an endocrine condition depends on the condition and the timing of the presentation and includes the following aims:

- To ensure the young person who presented earlier in childhood has all the information previously shared with their parents about their diagnosis, previous investigations, and management
- To address the priorities of the young person presenting later in adolescence, particularly in respect of delayed puberty and short stature
- To revisit the diagnosis or degree of hormone deficiency/excess
- To discuss investigations and management with the young person regarding cardiometabolic, bone and reproductive health, as well as quality of life
- To raise awareness of maintaining safety for those on hydrocortisone and desmopressin and recognizing ill health and what to do and when to seek help
- To identify the level of endocrine care required in adult life and whether care can be provided by the family doctor, for example, in congenital hypothyroidism, or whether transfer to adult services are required

In addition, more generic approaches are also important:

- To encourage increasing independence in healthcare including organizing medication and prescriptions, arranging appointments at times suitable to them, coming in for part or all the consultation independently of their parents and contacting the hospital in between appointments to seek information and advice
- To address barriers to engagement with healthcare including adherence
- To discuss useful resources to get health information and support including patient support groups
- To address concerns about venepuncture or injections, particularly around transfer to adult services
- To highlight benefits and ways of disclosure about condition to friends, teachers, and employers
- Through psychosocial screening (see earlier) to address broader issues such as psychological, social, and educational/vocational issues, and health behaviours by identifying risk and protective factors
- To deliver health promotion, including discussion about sexual health and contraception

Ongoing Management of Congenital and Acquired Conditions Diagnosed in Childhood

Who Needs Re-Evaluation?

The completion of linear growth is an opportunity to review current endocrine status, and adequacy of endocrine replacement, and for some to revisit the diagnosis, and screen for health conditions more common in adult life. Agreement would be required between paediatric and adult endocrine teams and the young person and their carers where it is most appropriate for these evaluations to take place.

This is the case for:

- patients where the underlying diagnosis made in childhood was unclear, and establishing that the endocrine issues persist is important
- patients with hypopituitarism, particularly isolated hormone deficiencies which may recover, for example, growth hormone deficiency (see next) and hypogonadotropic hypogonadism (10–20% exhibit spontaneous recovery)
- patients at risk of evolving hypopituitarism: post radiotherapy and those with congenital hypopituitarism associated with structural abnormalities in the hypothalamic–pituitary area (e.g. ectopic posterior pituitary), midline brain, and optic nerve abnormalities and genetic defects (e.g. in the *GH-1* or *POU1F1* genes)
- patients with congenital adrenal hyperplasia; a short synacthen test to assess cortisol status may assist with those who are poorly compliant with glucocorticoids, by providing further information to support discussion with the young person, or in those with non-classical CAH as alternative management could be considered at this age
- patients who require assessment of reproductive health; for example, testicular ultrasound for testicular adrenal rest tumours in boys with CAH and assessment by gynaecology for some girls with CAH
- patients who require comprehensive health screening, for example, in young people with Turner syndrome (requirement for cardiovascular and hearing assessment) and in childhood cancer survivors (monitoring for non-endocrine late effects)

Who Needs to be Part of the Wider Multidisciplinary Team Involved in Transition in Endocrinology?

Involvement of the multidisciplinary team is important at this time; paediatric and adult endocrinologists and endocrine nurses need to liaise with each other. Young people should have access to the following people (dependent on the condition):

- Psychologists (although not always available within the service) can provide much needed support for all young people with endocrine conditions as they make the transition from childhood to adulthood
- Clinical geneticist should be a key member of the transition team from several perspectives; to provide information about those with a clear or potential genetic diagnosis that may have previously been shared with parents, to explain the potential implications of genetic mutations for future offspring (as in congenital adrenal hyperplasia)
- Urologist/gynaecologist is essential for many patients with a disorder of sex development (DSD) who may require a physical assessment and a discussion about sexual function and future pregnancy
- A fertility specialist is essential for those focussed on understanding more about options for fertility at this time, particularly if there may be opportunities for fertility preservation; for example in females with Turner syndrome with a menstrual cycle, female childhood cancer survivors at risk of premature ovarian insufficiency, males with Klinefelter syndrome, males with CAH who have testicular adrenal rest tumours
- A cardiologist is important for females with Turner syndrome and cancer survivors previously treated with anthracyclines or chest irradiation
- Neurorehabilitation specialists, neurologist and neurosurgeons for young people are required for those with a past history of a brain tumour who require ongoing surveillance or have neurological sequelae from the tumour or its treatment
- ENT/audiology are key for groups of young people with endocrine conditions associated with reduced hearing which in turn reduces quality of life; for example, Turner syndrome, Charge syndrome, and some childhood cancer survivors

The focus of care in late adolescence is related to quality of life, and cardiovascular, bone and reproductive health from the perspective of monitoring and optimizing hormone replacement. In adolescents after the achievement of adult height, there is a change in the management approach in some conditions from that in paediatrics to reflect adult practice, for example, the management of sex steroid deficiency or glucocorticoid replacement in CAH in adolescents who have completed puberty. However, adolescence and young adulthood is seen as a distinct treatment period for young people with growth hormone deficiency (GHD).

Childhood Onset Growth Hormone Deficiency in Adolescence and Young Adulthood

Following on from the established role of GH replacement in children with GHD starting in the 1960s and the availability of recombinant GH in the 1990s, the extension of indications for GH replacement in GHD were considered [73]. The term 'adult growth hormone deficiency syndrome' was used to describe the clinical entity that included decreased lean body mass and bone mineral density, increased visceral adiposity, abnormal lipid profile, decreased muscle strength and exercise endurance, diminished quality of life, and the potential for increased morbidity and mortality [74]. In addition, evidence from clinical trials showed that GH replacement improved aspects of the syndrome [75]. It was only logical that potentially a lifelong role for GH replacement should be explored in patients with childhood onset (CO) GHD on achieving adult height, to address developmental aspects described in CO GHD and/or metabolic aspects described in AO GHD [75].

One key study [76] compared body composition in 92 CO GHD patients with 35 age-matched untreated AO GHD patients (with the majority of both groups having other hormone deficits); the mean age of those with severe GHD was 21 years and they had been off GH replacement for a mean of 1.6 years. Compared with AO GHD, CO GHD patients were shorter and had a lower body mass index. Corrected for height, CO GHD compared with AO GHD patients had a lower bone mineral content (BMC), lean body mass (LBM) and fat mass (FM) [76]. The closer the CO GHD patients were to achieving their genetic target height, the higher the BMC and LBM (76). Therefore, there was a significant maturational deficit (16–20% less compared with AO GHD patients) in somatic development in CO GHD patients treated with GH replacement during childhood [76].

In 2003 there was a consensus meeting focussing on the management of patients treated with GH replacement for GHD during childhood [77]. Based on the available evidence at that time it was recommended that ongoing GH replacement should be offered to all adolescents at the end of growth who remain GHD. The main rationale for continuing GH replacement included optimizing body composition and peak bone mass with the potential outcome of reducing fractures in later life. With this 'new' indication came the challenge of defining the biochemical diagnosis of GHD in adolescence, reassessment strategy, the approach to initiation and monitoring of treatment.

Bone and Body Composition

Although there is a clear maturational deficit in both bone mass and lean body mass, there is little evidence that this low bone mass contributes to an increase in fractures. The evidence suggests an increased fracture risk in AO hypopituitarism, but is insufficient for isolated CO or AO GHD (reviewed in [78]). There is no evidence that isolated CO GHD or severe GH resistance (e.g. Laron syndrome) causes an increased fracture risk in children or adults. Only one study in GH-naive Russian adults with CO MPHD demonstrated an increase in non-traumatic fractures [79].

Overall, it is proposed that fracture risk is related to other hormone deficits with over/under replacement (e.g. sex steroid, glucocorticoids, or diabetes insipidus) or other non-endocrine factors rather than GHD.

One explanation for this is the skeleton has adapted both to relative short stature and low muscle mass. Using appropriate size-corrections, bone density is normal in children and adults with isolated GHD (reviewed in [78]). Cortical density, trabecular density and trabecular volume are normal when measured by peripheral quantitative computerized tomography (pQCT) and histomorphometry [80]. The only clear deficit affects cortical thickness (periosteal expansion). It has been proposed that untreated CO GHD in adolescence and young adulthood results in a reduction of muscle mass and force, which would ultimately have an impact on bone geometry, more specifically reducing cortical thickness, described as the mechanostat theory. In support of this theory, during

GH therapy muscle enlargement precedes and exceeds any gain in bone mass (reviewed in [78]).

After discontinuing GH replacement at adult height, several but not all studies have showed a significant reduced accrual of bone mass, decrease in lean mass (LM) (–8%) and increased fat mass (FM) (10–17%) in patients with CO GHD who were diagnosed with persistent GHD and had stopped GH replacement for at least 2 years (reviewed in [81]). In terms of muscle strength, previous studies have reported a lower maximum isotonic strength in young adults with CO GHD, as measured by hand grip force (reviewed in [81]).

Restarting GH replacement therapy resulted in a notable improvement in body composition, with LM increasing by 14% and FM being reduced by 7% over 2 years of therapy (reviewed in [81]). Some but not all studies also reported a positive effect on bone with increases in total body BMC and lumbar spine bone mineral density (BMD) after one or two years (reviewed in [81]).

Methods of assessing bone in these studies are key. A study using pQCT, which is uninfluenced by short stature, showed a reduction in cortical thickness after 6 months off GH replacement [82], while after 2 years on GH replacement a significant increase in cortical thickness was observed using digital X-ray radiogrammetry, another technique not influenced by short stature [83]. Assessment of bone quality, using more advanced non-invasive imaging tools, may provide a greater insight into the effects of GHD and GH replacement on bone [84].

In summary it is clear from the evidence that GH replacement in late adolescence and young adulthood increases LBM and reduces FM mass, and this in turn has a positive effect on bone geometry, although the benefit to long-term health and reduction in fractures has not been quantified.

Cardiovascular Risk

The potential that GH replacement may reduce cardiovascular morbidity and mortality in adults remains unproven and therefore an important area of research [85].

In adolescents and young adults with CO GHD some studies have reported an adverse lipid profile and also other indicators of increased cardiovascular risk at adult height despite conventional GH replacement [86–88], which deteriorates further on discontinuation [86–90] and improves on recommencement [87–89]. In contrast, some studies comparing discontinuation with continuation of GH replacement or recommencement have shown no difference in lipid profile changes or other indicators [86, 90–94]. In a database study, those patients with organic CO GHD that had been off GH for more than 2 years had a more adverse lipid profile with improvement in HDL cholesterol after 1 year on GH replacement [95].

Cardiac structure and function were assessed by echocardiography. At baseline, GHD subjects had a lower early-to-late mitral flow velocity ratio (E/A; marker of diastolic function) but a normal left ventricular (LV) mass index and ejection fraction compared with normal controls. Six months after GH replacement withdrawal, both LV mass index and E/A decreased, although remaining within the normal range. Six months after restarting GH replacement, cardiac parameters were brought back to the levels measured at study entry, with LV ejection fraction and E/A remaining lower than in normal controls [87]. Similar results were identified in older patients with CO GHD [96]. Two other studies have not identified any echocardiographic abnormalities [86, 92]. The clinical relevance of these cardiac changes is not clear. Reassuringly, continuation, discontinuation and recommencement of GH replacement have not been shown to have any effect on exercise capacity [92, 93].

Intima-media thickness (IMT) at the common carotid arteries has been reported to be both similar after 6 months off GH replacement [88] and increased after 3 years off GH replacement [94] in GHD patients compared with controls at baseline. Therefore, duration off GH replacement may be a factor.

Studies have demonstrated an increase in insulin sensitivity [88, 91, 97] with a reduction in fasting glucose [93] on discontinuation of GH replacement. Once GH replacement is restarted, insulin sensitivity decreases [88, 97], resulting in an increase in fasting glucose levels (93), but glucose tolerance was not impaired [86]. Importantly, there was no further deterioration in insulin sensitivity [86, 91] or fasting glucose with continued GH replacement [93].

In summary the results from studies of cardiovascular risk in adolescence are inconsistent; however there is some suggestion that with more prolonged discontinuation of GH replacement, there may be negative effects on cardiovascular risk, in particular lipid profile and intima media thickness, but only subtle effects on cardiac morphology and function Reassuringly, no clinically significant effects on insulin sensitivity or glucose homeostasis were observed.

Quality of Life

Quality of life is recognized as an area that improves with GH replacement in some adults with GHD, and is the main indication for treatment in some countries.

In the transition period, one study examined the effect of seamless continuation of GH replacement compared with discontinuation and found no effect on QoL at baseline or after 2 years off GH replacement [92]. In a study looking at recommencement of GH replacement, although QoL was significantly lower than in normal controls (females –0.4 vs. 1.2 SDS; males –0.7 vs. 1.1 SDS), no change in the overall score was identified with GH replacement despite significant improvement in individual parameters that were low at baseline, including sexual arousal and body shape [98]. No such effect on individual QoL parameters was confirmed by a similar study design [86]. However other studies have shown benefit. In one study of 22 subjects followed through 2 years discontinuation and 1 year recommencement of GH therapy, the number of psychological complaints and depression increased during the first 6 months of discontinuation, while anxiety decreased and QoL improved during the first 6 months that GH was recommenced [99]. Some differences were observed between those with MPHD and those with IGHD [99]. In a database study, a lower QoL was identified in those with organic GHD but not those with idiopathic GHD; the former group who had a higher BMI, had achieved less height gain and had been off GH for longer (more than 2 years). However, after 1 year on GH replacement, there was improvement in QoL in both organic and idiopathic GHD groups [95]. In a slightly older cohort of patients (25–29 year olds) with CO GHD having routine clinical care recorded in the KIMS database, QoL as measured by

adult growth hormone deficiency assessment (AGHDA) differed between different aetiologies but demonstrated similar levels of improvement with GH replacement [100]. It is possible that studies with less heterogeneous groups selected for poor QoL would show greater improvements in QoL with GH.

Using different measures of QoL in a study exploring discontinuation in 40 GHD adolescents and young adults, no changes were found in the Nottingham Health Profile and Psychological General Well-Being Index but differences did occur in the Mood Adjective Check List and visual analogue assessment [101]. QoL tools have not been specifically developed for this age group, and there is a pressing need to have an appropriate well-validated tool for these patients [102].

Retesting GH Status at Adult Height

Retesting is essential as patients diagnosed as GHD in childhood will not necessarily be GHD in late adolescence and young adulthood, in part because of the different GH stimulation cut offs applied in adolescence compared with paediatric practice and also with apparent recovery in significant numbers of GHD patients. This has been attributed to long-term exposure to sex steroids potentially augmenting pituitary size and GH secretion, transient GHD and incorrect diagnosis due to issues with biochemical testing [103].

Likelihood of Persistent Severe GHD

Information about the extent of hypopituitarism, structure of the hypothalamic pituitary area and the underlying aetiology allows retesting of GH status at end of growth to be stratified into those that do not need retesting (very high likelihood of persistent GHD) and those with a high and low likelihood of persistent GHD (Table 7.4.3).

Number of additional pituitary hormone deficits can predict likelihood of persistent GHD. Data from the adult population has identified that three or four additional pituitary hormone deficits has specificity of 96% and 99% respectively for diagnosing severe GHD [104], and this has been confirmed in the adolescent population [105]. In addition, evidence of severe GHD on testing in childhood increases the likelihood of persistent severe GHD in adolescence and young adulthood [106, 107].

The presence of structural abnormalities in the hypothalamic-pituitary area also predicts likelihood of ongoing GHD. The majority of patients diagnosed with GHD in childhood and with no structural pituitary abnormality on MRI will have adequate GH secretion when retested (66–85% depending on the test and cut-off used) [105, 108, 109–112]. The presence of structural abnormalities, such as an ectopic posterior pituitary (EPP), increases the likelihood of persistent GHD; 60% had persistent GHD out of a cohort of 18 with ectopic posterior pituitary [113]. The higher the location of the EPP in relation to the pituitary stalk, the more likely will be the persistence of GHD; in the majority of patients with persistent severe GHD (defined as GH peak <5 μg/L), the posterior pituitary was located at the median eminence (93%), whereas in around 80% of subjects with a GH peak of at least 5μg/L at reassessment, it was visible along the stalk [110].

The aetiology of CO GHD spans genetic and acquired causes and while proven genetic causes usually have a high likelihood of persistence [114], acquired causes are associated with more variation dependent on the insult. GHD is a frequent consequence in childhood cancer survivors treated for tumours in the hypothalamic–pituitary area [115] and in brain tumour and nasopharyngeal carcinoma survivors exposed to HP axis radiotherapy ≥30 Gy [116–118]. GHD can also be diagnosed in childhood following cranial radiotherapy for haematological malignancies exposed to lower doses of 18–24 Gy or doses used for haematopoietic stem cell transplantation. However, recovery is more likely in this group [119]. In an analysis of 73 patients who had received cranial irradiation and were diagnosed with GHD in childhood, those treated with higher doses, as used in the treatment of brain tumours, 61% had persistent severe GHD (peak GH <3 mcg/L) compared with 33% following cranial radiation or total body irradiation used in the treatment of haematological malignancies [106].

Traumatic brain injury may also result in GHD; the incidence of hypopituitarism is reported over the broad range of 10–60% [120–122]. Recovery is also variably reported. In one study, 23 patients aged 16 to 25 years were followed up at 3 and 12 months after the event; at 12 months hormone deficits persisted in 30%, consisting of mainly GH and gonadotropin deficiencies [120].

Retesting Strategy Based on Likelihood of Persistent Severe GHD

The first consensus on retesting for GHD [77] and subsequent guidelines [123, 124] have proposed strategies based on likelihood (Figure 7.4.3).

For those patients with panhypopituitarism (defined as three or more additional hormone deficiencies) retesting was optional and in these patients GH replacement can be continued seamlessly if the young person agrees. Those with known transcription factor or genetic mutations also did not require retesting [123].

Table 7.4.3 Factors increasing likelihood of persistent GHD (* indicates very high likelihood)

Higher likelihood	Lower likelihood
• Severe GHD (<3mcg/L) on testing in childhood • Three additional pituitary hormone deficits* • Abnormal pituitary MRI including ectopic posterior pituitary • Proven genetic cause for GHD* • Tumour in the hypothalamic-pituitary area • High-dose cranial irradiation (>30Gy)	• Peak GH during provocative testing during childhood >3 mcg/L • Isolated GHD with normal pituitary MRI • Low dose irradiation (<30 Gy) • Traumatic brain injury

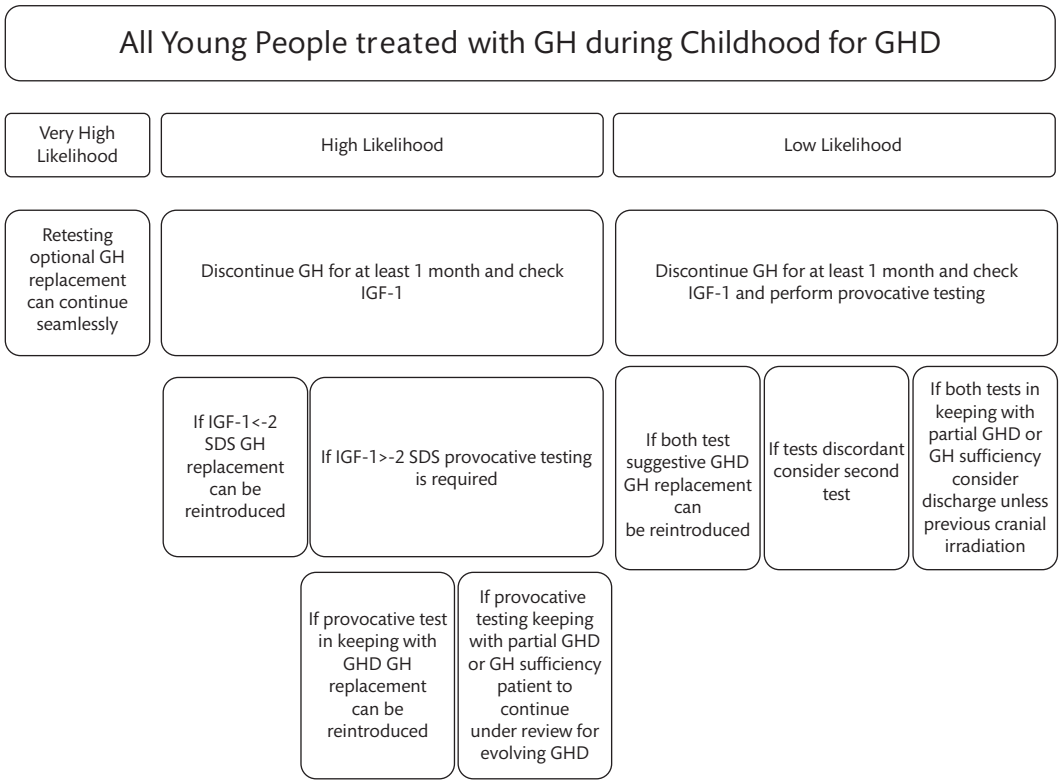

Figure 7.4.3 All young people treated with GH during childhood for GHD.

For those with a high likelihood of having persistent GHD, a measurement of serum IGF-1 concentration at least one month after finishing GH replacement should be done, progressing stimulation testing only if the IGF-1 is in the normal range. Patients with a low likelihood of persistent GHD, should have both serum IGF-1 estimation as well as a GH stimulation test.

Evidence Base for Retest Strategy

While an IGF-1level in general has low accuracy in diagnosing GHD, regardless of aetiology, an IGF-1 of less than –2SDS has a positive predictive value for severe GHD in adulthood of 96% [104]. This has been shown in studies in adolescents and young adults in the transition period with non-acquired GHD [125] and radiation-induced GHD [126].

If provocative testing is required only one provocative test is recommended by all the consensus statements in those with a high likelihood when IGF-1 is within the normal range, and in those with a low likelihood of persistent GHD [77, 123, 124]. However, guidelines from the Endocrine Society highlight that as idiopathic GHD in adults is very rare, more stringent criteria are proposed including the performance of two provocative tests, particularly if the IGF-1 is in the normal range [124].

The insulin tolerance test (ITT) has been validated for the diagnosis of persistent GHD in the transition period. There is a lack of agreement as to the peak GH cut-off in this age group, with all three consensus/guideline documents suggesting three different cut-off levels from the adult criterion of <3 mcg/L (124) to the evidence-based <6 mcg/L [123]. The latter was defined in a study of 26 patients (8 had isolated GHD and 18 had MPHD in childhood) which identified that a GH cut-off of 6.1 μg/L during an ITT had a sensitivity of 96% and specificity of 100% [127]. This was validated in a study of 79 patients divided by high and low likelihood of severe GHD, and found that a GH cut-off of 5.6 μg/L during an ITT had the highest accuracy for predicting persistent GHD with a sensitivity of 77%, specificity of 93%, and correct classification of 87% of patients [107]. More recently, a study looking at cut-offs in children and adolescents suggested that the optimal cut-off during an ITT was 5.1 μg/L, that during an arginine stimulation test was 6.5 μg/L, and that for clonidine was 6.8 μg/L [125]. The other test with supporting evidence in the transition period is the GH-releasing hormone (GHRH)—arginine test and a higher cut-off compared with adults (19 μg/L) had optimal sensitivity and specificity [128]. However, the GHRH-arginine test may be falsely normal in individuals with hypothalamic dysfunction. Although the ITT and GHRH-arginine test have been validated, GHRH is not always available and the ITT is contraindicated in some individuals and is not practical in many endocrine practices. The arginine test can be used but the response is dependent on BMI, so the arginine test should be limited to non-obese adolescents. Glucagon stimulation testing is a promising alternative for provocative testing in adults but has not been tested in the transition period.

Further Re-Evaluation of GH Status

Some groups may require further re-evaluation, regardless of the results of initial testing at the end of growth. Those at risk of evolving hypopituitarism, including GHD, are those treated with

radiotherapy [106] and patients with ectopic posterior pituitaries [110, 129]. In addition, patients with discordant results pose a particular challenge. For example, in one study 50% of patients (4 of 8) with IGHD and an ectopic posterior pituitary had discordant results with an adequate peak GH but with a low IGF-1 concentration [107]. Despite the normal GH peak, this cohort of patients should be monitored as they are at risk of development of severe GHD and evolving pituitary hormone deficiencies [110, 129].

Further evaluation using adult criteria around the time of assumed attainment of peak bone mass and attainment of full somatic development (~25 years) can be considered but is likely to be dependent on the severity of GHD and the local indication for ongoing GH replacement in adult life. Those with low likelihood of persistent GHD as described earlier, who retest as GHD at end of childhood, should be re-evaluated before a commitment is made to lifelong GH replacement as should those with discordant tests (normal IGF-1; GHD on provocative testing).

Growth Hormone Replacement in Adolescence and Young Adulthood

For those young people who test as being persistently GHD, there needs to be a discussion as to whether their preference is to continue GH replacement in the transition period with potential but unclear long-term benefits or have a holiday from daily injections, which may be preferable to young people for many reasons.

The optimal GH dose during the transition period is not clear. Studies have used GH doses that varied from 12.5 to 25 μg/kg/day (weight-based) to 200 μg/day (fixed dosing) [86, 98, 130, 131]. With respect to bone health and body composition, one study demonstrated no dose dependency [130, 131], whereas another found that a higher dose had a greater effect on spine BMD compared with a lower dose. Although similar effects were observed with LBM and FM at 6 months between the two doses, these were more likely to be sustained with the higher dose [86]. This study also demonstrated a greater improvement in LDL-C with the higher dose of GH replacement [86]. A dose effect in relation to quality of life has not been demonstrated [86, 98].

Some differences in dosing based on age have been recommended by The Endocrine Society Guidelines for Evaluation and Treatment of Adult Growth Hormone Deficiency [124]; patients <30 years of age may benefit from initial doses of 0.4–0.5 mg daily (as opposed to the initial doses of 0.2–0.3 mg daily for patients aged 30–60 years) and those transitioning from paediatric to adult replacement may need even higher doses. Females receiving oral (but not transdermal) oestrogen may need higher doses than other patients.

Doses should be titrated to normalize serum IGF-I concentrations for age and gender (0 to +2SDS). Despite these recommendations, a review of young people (aged 15–26 years) with childhood onset GHD on the KIMS database showed that their mean IGF-1 SD score was –1.36 (–1.83 SDS in females) after 1 year on a GH dose of 0.5 mg/day, suggesting inadequate dosing [132]. However, the relationship between IGF-1 level and biological endpoints is lacking [133]. As such, there is a lack of a biomarker for GH replacement in late adolescence and young adulthood [134].

Changes in body composition and bone mineral density are the most obvious candidates to be used as biomarkers and all the guideline documents recommend these parameters are assessed at baseline and during treatment. However, as previously described, there is little evidence of reduced bone mineral density, if correct methods are used such as volumetric BMD assessment or an adjustment to the areal BMD [78]. Finally, it is not clear how these measures would be used to alter management.

Other markers to assess could include cardiometabolic parameters including glucose homeostasis. These are most important to monitor in at risk groups such as adolescents and young adults with obesity or a family history of type 2 diabetes or at risk of diabetes or adverse lipid profile as a consequence of treatment, for example following total body irradiation or brain tumours. They are not required in all patients.

It is also recognized that adolescents may develop impaired quality of life and experience psychosocial problems related to GHD and/or the underlying chronic disease. There is a pressing need for validated instruments to assess QoL in this age group.

Holistic Approach to the Patient with Childhood Onset GHD

In keeping with the approach for all young people with long term conditions, it is important to focus on the wider aspects of growing up. Several studies in patients with childhood onset GHD compared with patients with AO GHD have identified reduced social outcomes including being less likely to live independently, living in partnership and having children, regardless of the underlying diagnosis [47]. Although some studies have shown similar educational and vocational outcomes to patients with AO GHD [47], others have shown lower educational level, lower income, higher risk of retirement compared with the general population and that this in turn impacts on mortality [135]. The endocrine team should routinely address these aspects with a view to offering support and encouraging independence as well as signposting.

Oestrogen Replacement in Adolescents

Girls with gonadotrophin deficiency or premature ovarian insufficiency (POI), including Turner Syndrome and some childhood cancer survivors, require oestrogen replacement throughout life. There are choices for the young person to consider, whether they are presenting in adolescence with delayed puberty or have completed pubertal induction and are considering their preferred oestrogen replacement in adult life. Guidelines for POI [136] and Turner syndrome [137] detailing the rationale for the most appropriate approach to oestrogen replacement have been published.

Girls with delayed puberty require an individualized approach to ensure that the priorities for achieving maturity or maximizing remaining growth are met. A shortened protocol for pubertal induction is generally successful, although available studies are too small to identify the reasons for unsatisfactory pubertal outcomes such as breast hypoplasia [138]. No data on long-term outcomes such as peak bone mass are available.

After pubertal induction, optimizing oestrogen replacement is important because oestrogen deficiency, particularly in the setting of POI, is associated with reduced life expectancy largely due to cardiovascular disease [136]. Oestrogen deficiency is also associated

with reduced bone mineral density (BMD) and an increased risk of fractures later in life [136, 137]. Despite lack of longitudinal outcome data, early initiation of oestrogen replacement is strongly recommended to control future risk of cardiovascular disease and optimize BMD; it should be continued at least until the average age of menopause. Lifestyle measures, such as regular weight-bearing exercise, avoiding smoking, maintaining a healthy body weight as well as adequate dietary calcium and vitamin D, are important.

Oestrogen prescribing for pubertal induction varies between countries and clinicians. After pubertal induction is complete, there is now a move towards offering young women with oestrogen deficiency physiological oestrogen replacement in the form of hormone replacement therapy (HRT) rather than the combined oral contraceptive pill, unless there are concerns about the possibility of spontaneous pregnancy. The reason for this move is based on HRT being more favourable for bone health and cardiovascular health with lower blood pressure, better renal function, and less activation of the renin angiotensin system [136].

Evidence for the optimal mode of oestrogen administration (oral or transdermal) is inconclusive. Transdermal oestradiol results in more physiological oestrogen concentrations and is preferred in young women with obesity, hypertension, migraines, and increased risk of venous thromboembolism [136]. Cyclical progestogen is required to maintain the health of the endometrium. Young women and their parents, particularly their mothers, should be reassured that concerns about the increased risk of breast cancer with HRT does not apply to this age group [136].

Altered sexual function and genitourinary symptoms may still occur despite adequate oestrogen replacement [136], and these should be discussed at their appointments. If these issues do occur, options such as increasing oestrogen dose as well as lubricants and local oestrogen can be considered. For some women with POI and reduced libido, the use of testosterone supplementation could be considered, although young women should be counselled about lack of data on long-term efficacy and safety. Duration of this therapy should potentially be restricted to 24 months.

Routinely annual evaluation should include smoking status, BMI and blood pressure; in some groups, such as those with Turner syndrome and some cohorts of survivors of childhood cancer, those with brain tumours and following bone marrow transplantation, this should also include a lipid profile and HbA1c. Assessment of bone mineral density (BMD) should be considered, particularly if other risk factors are present, and repeated at 5 years if evidence of osteoporosis has been found [136]. Appropriate adjustments to BMD should be made for short stature. A decrease in BMD should prompt review of oestrogen replacement and other potential factors.

Glucocorticoid Replacement in Adolescents with Congenital Adrenal Hyperplasia

Management of adolescents with congenital adrenal hyperplasia (CAH) presents challenges, but also offers opportunities to involve young people in making decisions about their management [139]. Control can deteriorate in adolescence due to physiological changes during puberty [140] and reduced adherence to medical therapy. Once linear growth is complete, there is a shift in focus of treatment to prevention of long-term adverse outcomes such as subfertility secondary to testicular adrenal rest tumours or menstrual irregularities, increased cardiovascular risk, and osteoporosis. These long-term adverse outcomes are in evidence during adolescence [141].

In adolescents with classical CAH, education about avoiding and recognizing signs and symptoms of adrenal crisis is key, as there is evidence that adrenal crises in CAH increase in frequency in young adulthood [142]. Although it is accepted that lifelong glucocorticoid therapy is required, the glucocorticoid regimen should be re-assessed after completion of growth and puberty, particularly in those struggling to achieve optimal control. While hydrocortisone is almost exclusively used in paediatrics for the management of CAH, studies from the UK and US demonstrate that two thirds of adults are on long-acting glucocorticoid preparations such as dexamethasone or prednisolone [143, 144]. There are no randomized controlled trials comparing these regimens, however a recent UK study did identify that increased adiposity, insulin resistance and use of prednisolone or dexamethasone are associated with impaired QoL in adults with CAH [145]. While hydrocortisone may be the optimal glucocorticoid, in some the priority will be simplifying the glucocorticoid regimen and changing to a long acting glucocorticoid once or twice daily as required. Long-acting hydrocortisone preparations are being trialled in patients with CAH [146]. Choice of long-acting glucocorticoid may depend on circumstances. In adolescent males with testicular adrenal rest tumours, short term dexamethasone may potentially preserve or restore fertility [147]. In females who are heterosexually active without adequate contraception, dexamethasone should be avoided because the placenta does not inactivate it. The exception to this would be when the young woman who is planning a pregnancy and has been assessed by a clinical geneticist as being at risk of having an affected child, when the pros and cons of dexamethasone should be discussed.

The overall aim is to use the lowest dose of glucocorticoid to normalize androstenedione concentrations (normalizing 17OHP concentrations will result in overtreatment). Long-acting glucocorticoid medications have reduced mineralocorticoid effects but monitoring plasma renin activity and blood pressure is always indicated. Fludrocortisone doses should be adjusted to maintain plasma renin activity within the normal range.

Patients with non-classic CAH represent a group less at risk of adrenal crisis and consequently may not need glucocorticoid therapy continuously lifelong. Guidelines suggest that patients should be given the option for discontinuing glucocorticoids [148]. Some authors have recommended weaning boys with non-classical CAH off hydrocortisone from mid puberty and girls 2–3 years after achieving menarche [149]. In patients diagnosed in late adolescence, glucocorticoid therapy might be indicated only at specific times. In females, glucocorticoids may be required to regularize periods to enhance fertility and reduce rate of miscarriage [149]; other options such as the use of the combined oral contraceptive pill and antiandrogens are available for other symptoms in those not seeking fertility [150]. Assessment of adrenal function is important as around a third will have subnormal cortisol levels during a short Synacthen test and, despite a lack of evidence in relation to the occurrence of adrenal crisis, the advice to cover sickness with hydrocortisone should be emphasized [151, 152]. Although data are lacking for long-term outcomes in non-classical CAH, follow up into adulthood is advised, particularly in females who may require management of hyperandrogenaemia or assistance with fertility.

Conclusion

Addressing the health needs of adolescents and young adults with long-term endocrine conditions requires developmentally appropriate healthcare with effective and safe transition and transfer to adult endocrine services. More evidence is required to inform how to deliver effective care to this age group. Paediatric and adult endocrinologists need to recognize the implications of having an endocrine condition on psychological and social development. They need the knowledge about common presentations of endocrine conditions and management during adolescence to allow appropriate counselling of patients about their choices and involve them in their care.

SECTION 8

Female Reproductive Endocrine Disorders

8.1

Normal Female Endocrinology and Ovarian Disorders

8.1.1 Neuroendocrinology of Reproduction

The Role of Hypothalamus and Pituitary

Christopher R. McCartney and John C. Marshall

Introduction

Female reproductive physiology is characterized by highly complex hypothalamic–pituitary–ovarian interactions that, when functioning properly, achieve ovarian follicular development; episodic presentation of ova for possible fertilization (ovulation); and physiological preparation for possible pregnancy (e.g. endometrial decidualization). Reproductive neuroendocrine systems coordinate cyclic ovarian function to accomplish these goals, and gonadotropin-releasing hormone (GnRH)-secreting neurons represent the final common pathway for hypothalamic control of reproduction.

Anatomy of the Reproductive Hypothalamic–Pituitary Axis

The hypothalamus resides at the base of the brain, constituting the floor and inferior-lateral walls of the third ventricle. The hypothalamus is involved with a wide variety of biological processes including growth and development, energy homeostasis, weight maintenance, responses to stress, and reproduction. With regard to reproduction, the cell bodies of some 1000–1500 GnRH-secreting neurons are diffusely located throughout the preoptic area and the infundibular nucleus (the arcuate nucleus in lower mammalian species) (**Figure 8.1.1.1**) [1]. Selective destruction of the arcuate nucleus in mature female monkeys leads to severe hypogonadotropic hypogonadism [2], suggesting that normal gonadotropin secretion is particularly dependent on the population of GnRH neurons residing in the infundibular (arcuate) nucleus.

GnRH neurons extend processes through the tuberoinfundibular tract to the median eminence at the base of the third ventricle. GnRH neuron fibres have been called 'dendrons' because, in mice, they demonstrate characteristics of both axons and dendrites, including functional synaptic inputs throughout the length of the fibre [3]. Bursts of GnRH neuronal firing result in the release of GnRH into an extensive capillary network located within the median eminence—the proximal portion of the hypophyseal portal system. GnRH release may also be influenced by interactions with other cell populations in the median eminence. For example, projections from tanycytes—specialized ependymal cells lining the third ventricle—can reduce GnRH release by enveloping and physically isolating GnRH nerve terminals [4].

The hypophyseal portal circulation represents the anatomical and functional connection between the median eminence and cells of the anterior pituitary. The superior hypophyseal artery feeds the capillary network within the median eminence. This network drains into sinusoids that coalesce to form the hypophyseal portal veins, which traverse the pituitary stalk and constitute the chief blood supply for the anterior pituitary.

The pituitary gland is located within a saddle-like structure of the sphenoid bone (the sella turcica), and it is connected to the base of the hypothalamus by the pituitary stalk. The anterior lobe (pars distalis) of the pituitary contains specialized cells (gonadotropes)

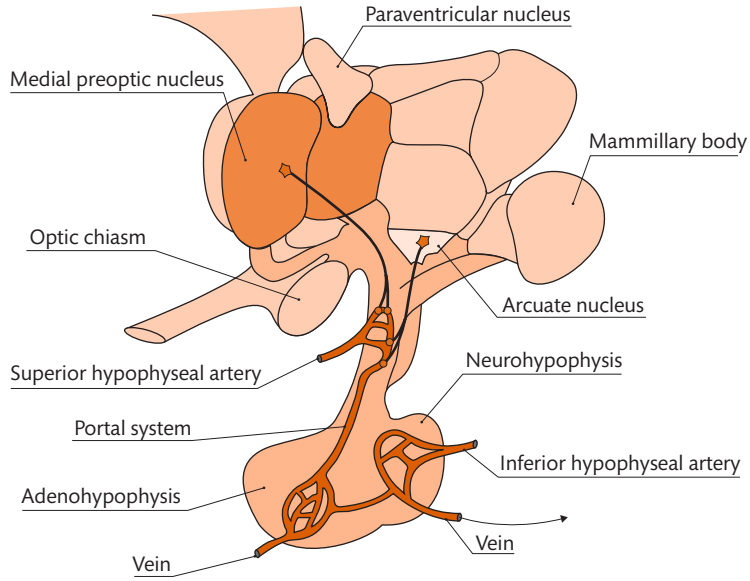

Figure 8.1.1.1 Anatomic foundations for GnRH neuron-gonadotrope interactions. GnRH neuron cell bodies reside in the infundibular nucleus (part of the mediobasal hypothalamus) and the preoptic area. GnRH neurons processes (dendrons) extend to the median eminence (also part of the mediobasal hypothalamus), where GnRH is released into the hypophyseal portal system. GnRH subsequently travels to the anterior pituitary where it interacts with gonadotrope cells.

that produce luteinizing hormone (LH) and follicle-stimulating hormone (FSH). GnRH binds to GnRH receptors on the cell surface of gonadotropes, initiating an intracellular cascade that results in the synthesis and secretion of LH and FSH. These gonadotropins are released directly into the systemic circulation and ultimately direct ovarian follicular development, cyclic ovulation, and cyclic changes of ovarian sex steroid production.

Embryological Origins of GnRH Neurons

During embryologic development, nascent GnRH neurons are first identified in the nasal (olfactory) placode [5]. Initial GnRH cell migration toward the hypothalamus is guided by olfactory/vomeronasal neuron axons projecting toward the olfactory bulb, with subsequent migration guided by neurons that project caudally into the forebrain (Figure 8.1.1.2). Once reaching the hypothalamus, GnRH cells extend processes to the median eminence and gain access to the hypophyseal portal system.

As olfactory neurons form a pathway to guide GnRH neuronal migration, appropriate GnRH cell migration is dependent on normal olfactory system development. This is exemplified by Kallmann syndrome, in which abnormal olfactory system development renders an inadequate guidance infrastructure for GnRH neurons. Accordingly, individuals with Kallmann syndrome have congenital hypogonadotropic hypogonadism in addition to anosmia (absent

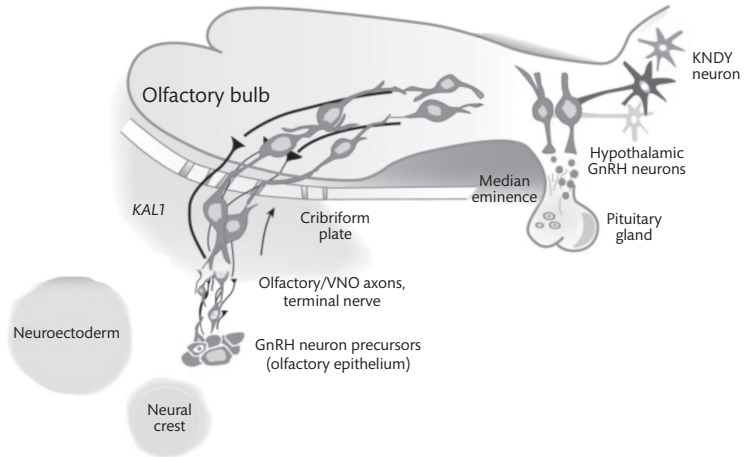

Figure 8.1.1.2 Schematic of embryological GnRH cell migration from the nasal epithelium to the hypothalamus, guided by olfactory/vomeronasal neurons.

sense of smell). Kallmann syndrome was first described in patients with deletion of the *ANOS1* (formerly *KAL1*) gene, which encodes a matrix glycoprotein important for fetal olfactory development. Human fetuses with X-linked Kallmann syndrome exhibit arrested migration of GnRH-immunoreactive cells along terminal nerve fascicles in the nasal mucosa or at the cribriform plate [6]. Numerous other genes related to fetal GnRH cell migration underlie forms of congenital hypogonadotropic hypogonadism with and without anosmia [5].

GnRH Secretion

GnRH-1 is a decapeptide encoded by the *GNRH1* gene on human chromosome 8 (8p11.2-p21) [7]. *GNRH1* produces a 92-amino acid precursor peptide (prepro-GnRH) with the following segments: a 23-amino acid signal sequence, GnRH, a 3-amino acid proteolytic processing site, and a 56-amino acid GnRH-associated peptide. Essentially all mammalian species demonstrate the same amino acid structure of GnRH-1: (pyro) Glu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH_2.

Although loosely affiliated from an anatomical perspective, GnRH neurons are highly integrated from a functional perspective. GnRH neurons exhibit extensive connections to other GnRH neurons and to other neuronal populations. GnRH neuronal activity is characterized by episodic and coordinated bursts of action potential firing, which presumably correlate to changes in GnRH release at the median eminence. Episodic firing rate activity—with periods of high and low firing rates—appears to be an intrinsic property of GnRH neurons, but firing patterns and rates are substantially influenced by complex afferent neuronal networks (*vide infra*).

GnRH is released into the hypophyseal portal system in episodic bursts (Figure 8.1.1.3) [8]. Intermittent GnRH presentation to gonadotropes is an absolute requirement for maintenance of gonadotropin synthesis and secretion: there are no known parallel or backup systems. In particular, intermittent GnRH stimulation increases or maintains GnRH receptors on gonadotropes—the 'self-priming' or 'autopriming' effect, which is partly mediated via GnRH receptor density on gonadotrope cells. Absent or inappropriate GnRH secretion in humans leads to pubertal failure, hypogonadotropic hypogonadism, and infertility, all of which can be reversed with pulsatile exogenous GnRH administration [9].

Gonadotropin responses to GnRH can decrease with higher GnRH pulse frequencies [10]. Continuous GnRH receptor stimulation markedly reduces gonadotropin synthesis and secretion (desensitization) (Figure 8.1.1.4) [11], which is partly a reflection of reduced GnRH receptor expression on gonadotropes (i.e. receptor downregulation). Desensitization can be achieved for therapeutic purposes with long-acting GnRH receptor agonists, which transiently increase gonadotropin release, but subsequently cause desensitization of gonadotropin secretion. Competitive GnRH receptor antagonists are also available: these peptides reversibly bind to, but do not stimulate, the GnRH receptor, reducing gonadotropins within 24 to 72 hours.

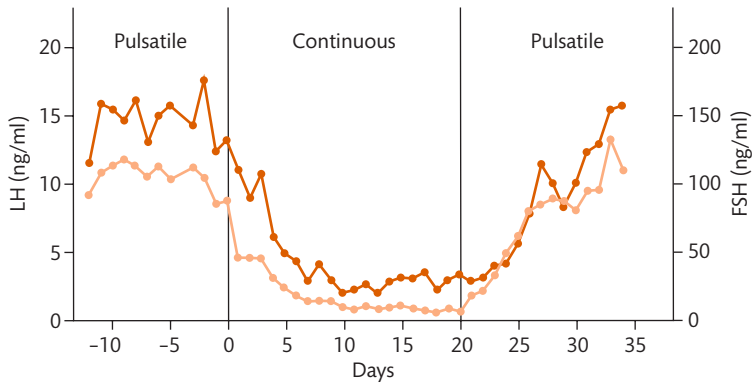

Figure 8.1.1.4 Impact of pulsatile vs. continuous GnRH administration in GnRH-deficient monkeys. These monkeys were gonadectomized (but sex steroid-replaced) and rendered GnRH deficient via radiofrequency ablation of the arcuate nucleus. Normal gonadotropin secretion is maintained with intermittent exogenous GnRH administration. However, continuous GnRH infusion markedly downregulates luteinizing hormone and follicle-stimulating hormone production.

Upstream Regulation of GnRH Neurons

The regulation of pulsatile GnRH release is highly complex. A number of upstream neuronal populations—along with their associated neurotransmitters and neuropeptides—substantially impact GnRH neuron activity and largely mediate ovarian feedback—largely via circulating sex steroid concentrations—in addition to mediating the influence of energy availability and stress. Relevant signalling compounds include dopamine, norepinephrine, glutamate, γ-aminobutyric acid (GABA), nitric oxide, kisspeptin, neurokinin B, and endogenous opiates.

Kisspeptin is a critical requirement for normal GnRH secretion [12, 13]. The human kisspeptin gene (*KISS1*) encodes a 154-amino acid precursor protein (kisspeptin 1–145); and proteolytic modification yields a number of bioactive kisspeptin fragments: kisspeptin-54, -14, -13, and -10. Functional native kisspeptin species contain the carboxy-terminal amino acids 112 to 121, which are important for receptor binding and function. Kisspeptin neurons form synaptic contacts with GnRH neurons, including at GnRH neuron terminals in the median eminence. Kisspeptin stimulates GnRH neurons via the kisspeptin receptor (KISSR; also known as the G-protein coupled receptor 54, or GPR54)—a seven transmembrane domain, G-protein-coupled receptor expressed by a majority of GnRH neurons. Persons with inactivating *KISS1R* or *KISS1* mutations exhibit pubertal failure and hypogonadotropic hypogonadism. Kisspeptin-related stimulation of LH release is blocked by GnRH antagonists, and pulsatile GnRH administration can fully restore reproductive function in patients with *KISS1R* mutations. These findings suggest that the effects of kisspeptin on LH release is mediated by GnRH. Of interest, the effects of kisspeptin on LH release appear to be influenced by several factors including menstrual cycle phase and hormonal milieu.

Rodents exhibit two distinct populations of kisspeptin neurons. Kisspeptin neurons in the arcuate nucleus (mediobasal hypothalamus) mediate the negative feedback effects of oestrogen on GnRH release; while kisspeptin neurons in the anteroventral periventricular nucleus (AVPV) of the preoptic area mediate the positive feedback effects of oestrogen on GnRH release (i.e. GnRH surge generation). Kisspeptin neurons are primarily located in the infundibular (arcuate) nucleus in humans and monkeys. It remains uncertain whether unique populations of kisspeptin neurons play similar respective roles in primates [14].

Neurokinin B (NKB) is a decapeptide encoded by the tachykinin 3 gene (*TAC3*) [12, 15]. NKB preferentially binds to and acts via the neurokinin 3 receptor (*NK3R*), encoded by the *TACR3* gene. The role of NKB in central reproductive function is complex. Homozygous loss-of-function *TAC3* or *TACR3* mutations cause pubertal failure and hypogonadotropic hypogonadism. Senktide, a selective NK3R agonist, can provoke LH release, and this effect is abolished by GnRH receptor antagonism. Of interest, a number of studies suggest that NKB primarily influences GnRH release via its effects on kisspeptin release. For example, kisspeptin neurons express *NK3R;* senktide increases kisspeptin neuronal activity; LH responses to senktide are absent or impaired in Kiss1R knockout mice, with Kiss1R antagonism, or after Kiss1R desensitization; and continuous kisspeptin infusion enhances LH secretion in patients with loss-of-function *TAC3* or *TACR3* mutations. NKB analogues may have therapeutic use in the future.

Endogenous opioid peptides (EOP)—including endorphins, enkephalins, and dynorphins—participate in numerous neuroendocrine functions. Endorphins (e.g. β-endorphin) are derived from proopiomelanocortin (POMC) and act primarily via μ (micro)-opioid receptors; while dynorphins are products of the precursor prodynorphin and act chiefly at κ (kappa)-opioid receptors (KOR). Although derived from different precursor proteins, active endorphins, enkephalins, and dynorphins contain a common sequence at the amino-terminal (Tyr-Gly-Gly-Phe-[Met or Leu]). Ample evidence suggests that sex steroid negative feedback on GnRH release is at least partly mediated by hypothalamic opiates. Hypophyseal blood concentrations of β-endorphin increase during the luteal phase in monkeys [16]; opiate receptor antagonists increase LH pulse frequency when administered to women in the luteal phase [17], and exogenous opiates (e.g. morphine) can cause hypogonadotropic hypogonadism. Recent animal studies suggest that dynorphin is an important mediator of GnRH pulse frequency suppression by progesterone [12, 13]. For example, progesterone receptors colocalize with arcuate nucleus dynorphin neurons; dynorphin-containing varicosities associate with GnRH neurons; progesterone treatment increases dynorphin A concentrations in the third ventricle cerebrospinal fluid; and delivery of κ-opioid receptor antagonists to the mediobasal hypothalamus reverses progesterone inhibition of LH pulse secretion.

Animal studies suggest that kisspeptin, NKB, and dynorphin are often coexpressed in single neurons [12]. Such KNDy ('candy') neurons (Kisspeptin, Neurokinin B, Dynorphin) are extensively interconnected and project to GnRH neurons, including GnRH neuron fibres within the median eminence. Although corresponding data in humans are limited, autopsy studies generally support the notion that kisspeptin and NKB colocalize in a portion of neurons in the infundibular nucleus [18]. Regardless, kisspeptin, NKB, and dynorphin—released from neurons that do or do not colocalize with the other peptides—substantially influence GnRH neuronal function in humans, and such neurons are likely a fundamental component of the GnRH pulse generator (vide infra).

RFamide-related peptides (RFRPs)—the mammalian orthologues of gonadotropin-inhibitory hormone (GnIH)—also appear to exert an important influence on central reproductive function [19]. RFRP-immunoreactive cells have been identified in human hypothalami, and RFRP-immunoreactive fibres approximate GnRH neurons. Animal studies suggest that RFRP-3 reduces GnRH neuronal firing rates, but an understanding of the roles of RFRPs in humans requires further study.

The GnRH Pulse Generator

The fundamental nature of pulsatile GnRH secretion—including the neuroanatomical components of the GnRH pulse generator and mechanisms underlying episodic GnRH release—remains unclear. The mediobasal hypothalamus, which contains both the infundibular (arcuate) nucleus and the median eminence, appears to contain all requisite components of the GnRH pulse generator. In monkeys and sheep, LH pulse initiation is temporally associated with discrete episodes of neuronal firing (multiple unit electrical activity) in the area of the mediobasal hypothalamus (**Figure 8.1.1.5**) [20, 21]; and in monkeys, experimental electrical stimulation of the

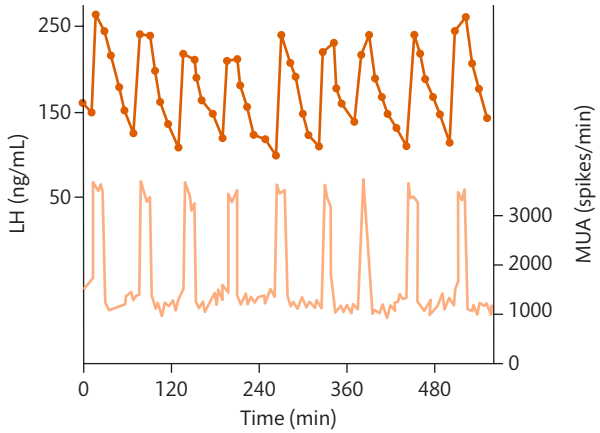

Figure 8.1.1.5 Temporal relationship between hypothalamic multiple unit activity (MUA) and pulses of luteinizing hormone (LH) in the peripheral circulation. These data were obtained from an ovariectomized monkey.

Adapted with permission from Knobil E. The electrophysiology of the GnRH pulse generator in the rhesus monkey. *J Steroid Biochem* 1989; 33:669–71. Copyright © 1989 Elsevier Ltd. (21).

mediobasal hypothalamus provokes GnRH release into the hypophyseal portal system [22]. Moreover, pulsatile LH secretion is maintained in monkeys after mediobasal hypothalamic isolation from the remainder of the brain; and isolated human mediobasal hypothalami release GnRH in a pulsatile fashion [23].

Numerous studies suggest that pulsatility is an intrinsic property of GnRH neurons; and coordination of GnRH release may reflect extensive interconnections among GnRH neurons. However, a number of observations suggest that kisspeptin, NKB, and dynorphin help to orchestrate coordinated GnRH neuronal activity [12, 24]. Although mechanisms remain unclear, some investigators have proposed a model whereby initial NKB release stimulates kisspeptin secretion, which initiates a GnRH pulse; and subsequent dynorphin release inhibits kisspeptin secretion, terminating the GnRH pulse. Although pulsatile GnRH release may occur in the absence of kisspeptin action (e.g. humans with KISSR mutations demonstrate low-amplitude LH pulses [25]), it seems clear that kisspeptin is mandatory for normal GnRH secretion.

Pituitary Gonadotropes

The anterior pituitary (adenohypophysis) is of ectodermal origin and forms during embryological development as an upward invagination of pharyngeal epithelium (Rathke pouch). Gonadotropes are specialized cells of the anterior pituitary that synthesize and secrete LH and FSH. GnRH binds to the GnRH type I receptor, a seven transmembrane G-protein-coupled receptor on the plasma membrane of gonadotropes: this activates a number of intracellular signalling cascades that enhance gonadotropin synthesis and secretion [26].

Each gonadotropin consists of α and β subunits, which dimerize. The biological specificity of LH and FSH relates to their unique β-subunits (the 121-amino acid LHβ and the 117-amino acid FSHβ, respectively). The α-subunit is common to LH, FSH, human chorionic gonadotropin (hCG), and thyrotropin. Gonadotropins also undergo variable post-translational modification—glycosylation in particular—which alters both bioactivity and elimination half-life.

Even though both LH and FSH are produced in a common cell type in response to GnRH stimulation, circulating LH and FSH concentrations vary differentially throughout ovulatory cycles. Numerous mechanisms underlie differential release of LH and FSH throughout the cycle [26]. For example, higher frequency GnRH pulses favour LH synthesis and secretion, while lower frequency GnRH pulses enhance FSH synthesis and secretion (**Figure 8.1.1.6**) [10]. In addition, inhibins and oestradiol selectively restrain FSH release during the mid- and late follicular phase and the luteal phase.

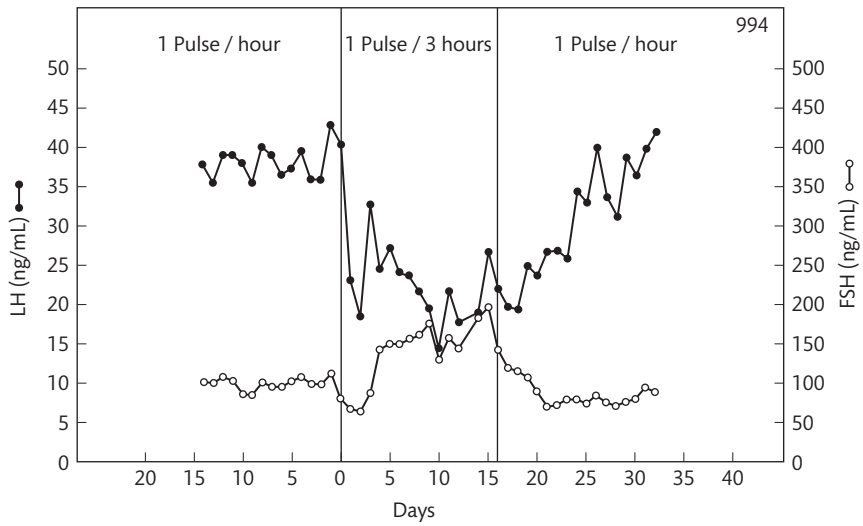

Figure 8.1.1.6 Impact of GnRH pulse frequency on LH and FSH secretion in GnRH-deficient monkeys. These monkeys were gonadectomized (but sex steroid-replaced) and rendered GnRH deficient via radiofrequency ablation of the arcuate nucleus. Normal gonadotropin secretion is maintained when exogenous GnRH was administered in a pulsatile fashion every hour. Decreasing the frequency of GnRH pulse administration to once every 3 hours was followed by a decrease in circulating LH but an increase in circulating FSH concentrations.

Patterns of GnRH and Gonadotropin Secretion in Women

The hypophyseal portal system is inaccessible in humans, so direct *in vivo* measurements of pulsatile GnRH secretion are unavailable. However, LH pulses identified in the peripheral circulation correspond on a one-to-one basis with GnRH pulses identified in the hypophyseal portal system in animals (Figure 8.1.1.3) [8]; thus, LH (or α-subunit) pulse frequency—as determined by frequent peripheral blood sampling—accurately reflects GnRH pulse frequency. While LH (GnRH) pulse frequency approximates one pulse every 60–90 minutes in the follicular phase, LH pulse frequency decreases to approximately one pulse every 3 to 8 hours during the luteal phase [27, 28]. In open loop conditions (e.g. surgical or natural menopause), LH pulse frequency approximates one pulse per hour [29]. Similarly, isolated human mediobasal hypothalami generate a GnRH pulse every 60 to 100 minutes [23]. Thus, a 'circhoral' (once per hour) pulse frequency may be a fundamental characteristic of the adult GnRH pulse generator, with changes reflecting the application or withdrawal of sex steroid (primarily progesterone) negative feedback. Since high and low GnRH pulse frequency preferentially favours LH and FSH secretion, respectively, cyclic changes in GnRH pulse frequency contribute to differential changes in LH and FSH concentrations across ovulatory cycles [30].

LH pulse amplitude can be modulated by changes of GnRH released per pulse, by changes of gonadotrope responses to GnRH stimulation, or both. LH pulse amplitude also varies inversely with the preceding LH interpulse interval [31]. LH pulse amplitude tends to decrease across the follicular phase as a result of oestradiol negative feedback. However, the very high oestradiol concentrations at midcycle provoke increased gonadotropin release (the midcycle gonadotropin surge). During the luteal phase, LH pulse amplitudes are variable, but generally approximately double the amplitudes observed in the follicular phase.

In normally cycling women, circulating FSH concentrations are highest in the early part of follicular phase, wane across the follicular phase, but increase again as part of the midcycle gonadotropin surge. FSH concentrations remain relatively low during the luteal phase, but increase again at the luteal-follicular transition. The longer half-life of FSH tends to mask pulsatile release.

Negative Feedback Regulation of GnRH and Gonadotropin Secretion

In normally cycling women, changes in circulating oestradiol concentrations reflect follicular development during the follicular phase and corpus luteum function during the luteal phase. In general, oestrogens restrain gonadotropin secretion; and oestrogen deficiency (e.g. natural or surgical menopause) leads to a marked increase in gonadotropin secretion. Oestrogen restraint at the hypothalamus primarily reflects reductions in GnRH pulse amplitude rather than pulse frequency. GnRH pulse amplitude, but not GnRH pulse frequency, are increased in postmenopausal women and in ovariectomized post-pubertal female monkeys, and this is reversed with oestrogen replacement [32]. Low-dose oestradiol administration does not substantively alter LH release in GnRH-deficient women treated with fixed-dose exogenous GnRH pulses [33].

Day-to-day changes in GnRH pulse frequency primarily reflect the imposition and removal of progesterone negative feedback. In the early luteal phase, the increase in progesterone secretion from the corpus luteum slows LH pulse frequency, and exogenous progesterone slows follicular phase LH pulse frequency [34]. This effect of progesterone requires the permissive presence of oestradiol [35, 36], likely through increased hypothalamic progesterone receptor expression [37]. In contrast, androgens appear to reduce hypothalamic progesterone receptor expression and, thus, antagonize progesterone's ability to inhibit GnRH pulse frequency [38, 39]. At the gonadotrope, progesterone augments pituitary gonadotropin responses to GnRH [40, 41].

Sex steroid feedback on GnRH secretion appears to be largely mediated by kisspeptin (KNDy) neurons (Figure 8.1.1.7) [13]. While GnRH neurons express few sex steroid receptors, kisspeptin and KNDy neurons colocalize with oestrogen, progesterone, and androgen receptors. Oestrogen or oestrogen plus progesterone reduces kisspeptin expression in the arcuate nucleus in monkeys, while kisspeptin expression in the infundibular (arcuate) nucleus is increased in sex steroid deficient monkeys and women. Similarly, postmenopausal women demonstrate fewer infundibular

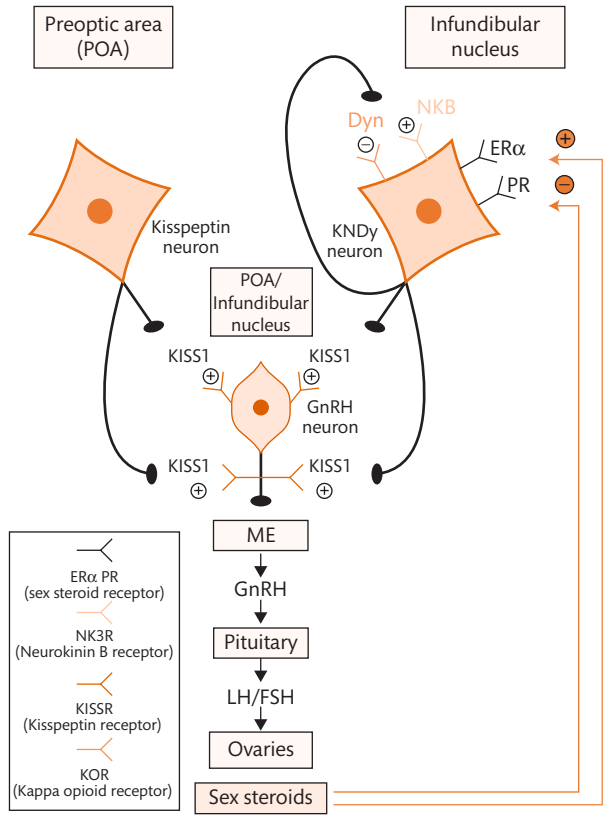

Figure 8.1.1.7 Model of kisspeptin and KNDy signalling to GnRH neurons. Kisspeptin (KISS1) stimulates GnRH neurons. KnDy neurons also release neurokinin B (NKB), which stimulates KISS1 release; and dynorphin (Dyn), which inhibits KISS1 release. ERα, oestrogen receptor alpha; KISS1, kisspeptin; ME, median eminence; POA, preoptic area; PR, progesterone receptor.

prodynorphin-expressing neurons compared to premenopausal women.

FSH secretion is also selectively impacted by inhibins, activins, and follistatin [42]. Inhibins are heterodimer peptides that selectively inhibit FSH release from pituitary gonadotropes and contribute to differential LH and FSH release across the menstrual cycle. Two inhibin isoforms contain identical α-subunits but different β-subunits (βA for inhibin A, βB for inhibin B). Inhibin B is primarily secreted by ovarian granulosa cells in response to FSH stimulation during the early follicular phase; while inhibin A is primarily secreted by the corpus luteum in response to LH stimulation during the luteal phase. Activins and follistatin are pituitary gonadotrope products that influence FSH secretion via autocrine-paracrine signalling. Activins stimulate production of FSH, while follistatin reduces FSH production by binding activin. Follistatin production varies as a function of GnRH pulse frequency and partly mediates the reduction in FSH production in response to high GnRH pulse frequencies.

Sex Steroid Positive Feedback and the Midcycle Gonadotropin Surge

In contrast to the effects of relatively low oestradiol levels, high oestradiol concentrations at midcycle provoke the midcycle gonadotropin surge, characterized by an approximately tenfold increase in LH and an approximately fourfold increase in FSH levels. While some studies suggest that oestradiol alone can produce normal gonadotropin surges, the modest preovulatory increase in circulating progesterone may coordinate the timing of the surge, increase the duration of the surge, and/or contribute to the midcycle increase in FSH release [43, 44].

Midcycle levels of sex steroids markedly increase gonadotrope responsiveness to GnRH stimulation [45, 46]. Although midcycle surge generation in women is critically dependent on continued GnRH stimulation and can be prevented with GnRH receptor antagonists [47], it remains unclear whether midcycle GnRH surges occur in women. A study involving incomplete GnRH receptor antagonism suggested that GnRH secretion does not increase at midcycle in women [48]. Moreover, pulsatile administration of constant-dose exogenous GnRH—or even reduced dose—produces gonadotropin surges in GnRH-deficient women [46]. Taken together, these findings suggest that sex steroid augmentation of pituitary gonadotropin release is sufficient for gonadotropin surge generation in women.

Physiological Influences on GnRH Secretion

Energy Availability

Biological processes require metabolic energy. In settings of restricted energy availability, maintenance of life-sustaining functions is prioritized. Pregnancy and lactation are metabolically expensive; and since reproduction is not critical for individual survival, it is metabolically gated. Inadequate energy availability suppresses reproductive function: this forms the basis for both nutritional infertility and functional hypothalamic amenorrhea (discussed in Chapter 8.8.2). The neurobiological mechanisms underlying the influence of nutritional status on the reproductive system remain poorly understood. However, inadequate energy availability culminates in impaired GnRH and gonadotropin secretion. The reproductive effects of reduced energy availability appear to be mediated by circulating factors (e.g. leptin and insulin) in addition to complex central neural pathways involving myriad neuropeptides (e.g. kisspeptin) and neurotransmitters [49].

Stress

A 'stressor' is a potential threat to homeostasis (e.g. injury, illness, reduced energy availability, situations that provoke psychological distress, etc.). Both marked acute stress and chronic stress can reduce reproductive function, and in some cases this can be viewed as an appropriate adaptive response. As examples, critical illness is typically characterized by a reversible hypogonadotropic hypogonadism [50]; and psychological stress can play a role in functional hypothalamic amenorrhea [51]. Stress-related impairment of reproductive function primarily relates to suppression of GnRH secretion. The reproductive effects of stress appear to be mediated by corticotropin-releasing hormone (CRH), arginine vasopressin (AVP), and cortisol, in addition to complex central neural pathways involving numerous neuropeptides (e.g. kisspeptin) and neurotransmitters [52].

Lactation

Lactation is often accompanied by amenorrhea and subfertility. In the setting of limited resources, lactational amenorrhea can be viewed as an important adaptation since short interbirth intervals could jeopardize infant well-being. In the setting of lactation, pulsatile GnRH release is slowed, rendering hypogonadotropic hypogonadism. Mechanisms remain unclear, but this in part reflects the very high metabolic cost of milk production and, thus, reduced energy availability for reproductive functions. Reduced GnRH secretion during lactation may partly reflect hyperprolactinemia, and neural mechanisms may also be important since the frequency and duration of suckling appears to impact contraceptive effectiveness.

Circadian Changes and Sleep

Both basal gonadotropin secretion and LH surges may exhibit circadian patterns, but the degree to which this pertains is species dependent. For example, LH surges in female rodents are temporally constrained to the late afternoon hours; but in female monkeys and women, LH surges do not appear to be confined to a specific time of day. Similarly, although women exhibit diurnal changes in gonadotropin secretion, recent studies suggest that LH and FSH secretion does not change markedly when accounting for sleep status, body position, activity level, light exposure, and nutritional cues [53].

Sleep can have a profound influence on pulsatile LH (and by inference GnRH) secretion in humans, and such changes may contribute to normal gonadotropin production across puberty and during the early follicular phase (EFP). Early puberty is characterized by a sleep-associated increase in LH pulse amplitude and frequency: this begins shortly after sleep onset and also occurs during daytime sleep [54]. During puberty, LH pulse initiation appears to be encouraged by slow wave sleep but discouraged by rapid eye movement (REM) sleep [55]. Sleep-related slowing of LH pulse frequency occurs in late pubertal girls and in women, most prominently during the EFP, but also in the late follicular phase. In women

studied during the EFP, LH pulse initiation is encouraged by brief awakenings but discouraged by REM sleep [56]. Naloxone appeared to prevent the sleep-associated decrease in LH pulse frequency in the EFP, suggesting that sleep-related slowing may be mediated by hypothalamic opioids [57].

8.1.2 Ovarian and Uterine Development from Fetal Life to Puberty

Terhi Piltonen and Juha Tapanainen

Sex Organ Development

The development of embryonic gonad towards gender specific phenotype is a sequential and complex process. In humans, fetal

organogenesis starts 4 weeks post conception and is completed by the gestational week (GW) 9. After this, a rapid growth will follow and the fetus will maturate for organ functions. The primordial germ cells can be identified in the wall of the yolk sac at GW 3 onwards. At this bipotential state the germ cells migrate into the dorsal mesentery of the hindgut in the urogenital ridges of undifferentiated gonads (Figure 8.1.2.1). The karyotype of the embryo (46,XX or 46,XY) and the presence of the sex determining region on the Y-chromosome (SRY) determines whether the gonads will develop into an ovary or testis. Female or male gonads can be distinguished as early as by the GW 8 [1, 2]. Furthermore, several other genes like SRY box-related gene 9 (SOX9), Wilms tumour gene 1 (WT1), EMX2, LIM1, and steroidogenic factor 1 (SF-1) in males and WNT-4, RSPO-1, FOXL-2, and DAX-1 in females, have also been identified coordinating the gonadal development [3, 4]. After the differentiation process, the gonadal hormones, mainly dihydrotestosterone converted from testosterone and anti-Müllerian hormone (AMH, Müllerian inhibiting substance, MIF), have significant role in the development of genitalia (Figure 8.1.2.1). The Müllerian ducts will develop as a female tubule system, the uterus and fallopian tubes, whereas the Wolffian ducts will become epididymis and ductus dereference. In the presence or in absence of testosterone the urogenital sinus will form as male or female external genitalia.

Embryological Development of the Ovarian Follicle Pool and the Transient Activation of the Ovaries

In females, after migration to gonadal ridges, the primordial germ cells start proliferating through mitosis into oogonial stem cells that enter meiosis at GW 22, arresting at the diplotene stage to become primary oocytes. Only part of the oogonia will undergo meiosis having potential to ovulate eventually after puberty while the rest of them will undergo apoptosis. The oocytes that have reached the diplotene stage start associating with clusters of somatic cells that form pre-granulosa cells, forming primordial follicles that reach the highest number of 7 million around mid-gestation (Figure 8.1.2.2). After the saturation point, the number of primordial follicles starts to decrease by means of apoptosis and only 2 million primordial follicles are left at the time of birth.

The levels of follicle stimulating hormone (FSH) and luteinizing hormone (LH) in fetal circulation peak at mid-gestation and decrease by the end of the third trimester [5, 6]. The meaning of this rise in gonadotrophins is not well known, however, it is thought that this enhanced gonadotrophin secretion results into occasional follicle development in the fetal ovary, supported by the concomitant follicular expression of AMH that can also be measured from

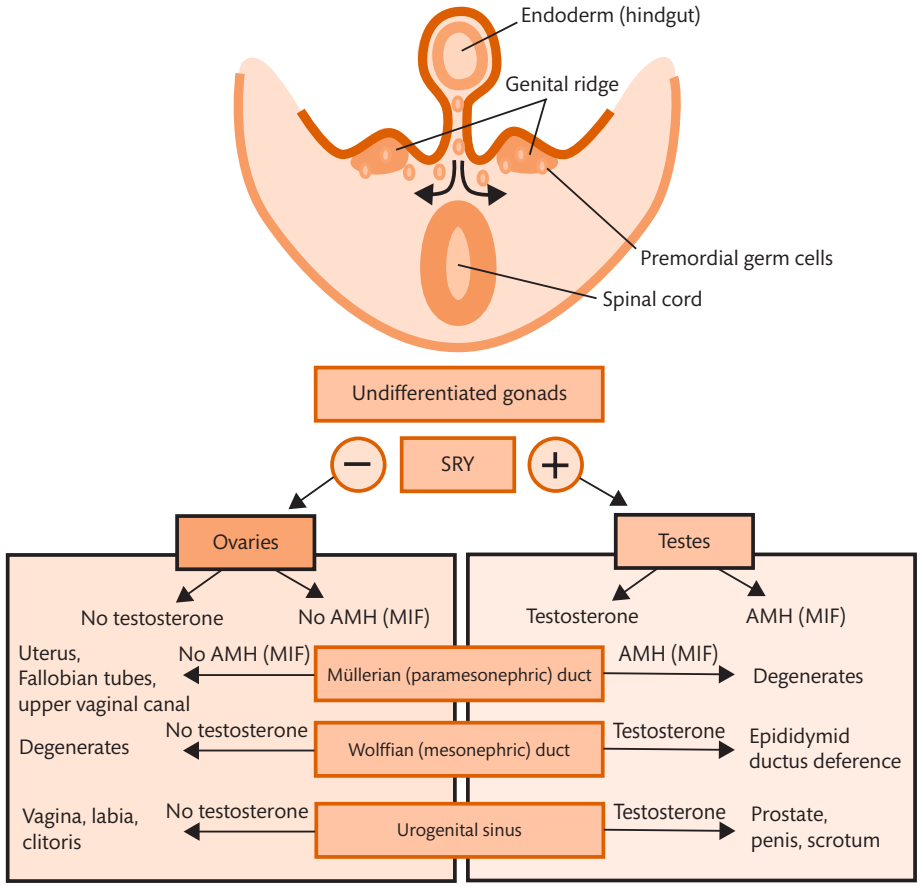

Figure 8.1.2.1 The sex organ development in human. At the bipotential state the germ cells migrate into the dorsal mesentery of the hindgut in the urogenital ridges. The karyotype of the embryo (46,XX or 46,XY) and the presence of the sex determining region on the Y-chromosome (SRY) determines whether the gonads will develop into an ovary or testis.

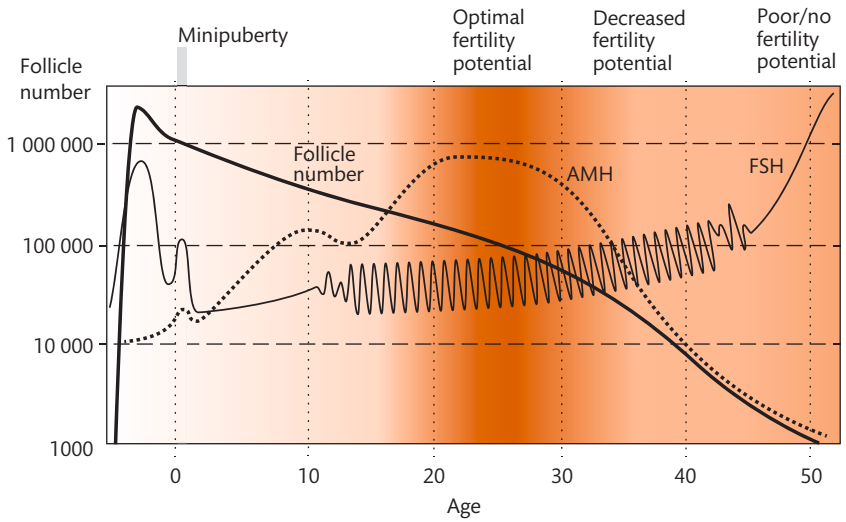

Figure 8.1.2.2 The number of ovarian follicles and the fluctuations in serum AMH and FSH levels throughout female reproductive life span. Primordial follicles reach the highest number of 7 million at gestational week 20. Through apoptosis the number of follicles decrease and only around 2 million are left at the time of birth. Thereafter, the follicle number decreases rapidly with 400 000 being present at the onset of the puberty. The follicle pool is diminished around age of 50 years leading into menopause.

the fetal circulation [7]. The levels of gonadotrophins decrease gradually towards the term of the pregnancy.

The withdrawal of placental steroids and thereby the lack of inhibitory feedback at birth induce a transient activation of hypothalamus–pituitary axis during the first months of infancy. This results into a short-term and transient release of gonadotrophins from the pituitary of the neonate, activating follicular development and proliferation of granulosa cells reflected by the rise in serum AMH levels. This phenomenon, known as minipuberty, is dependent on the fetal age at birth, prematurity delaying the onset [7–9]. After the postnatal ovarian activation, gonadotrophins and thereby sex steroid hormone and AMH levels decrease and remain low until puberty. The quiescent period ends before puberty as a consequence of maturation of the hypothalamus–pituitary–ovarian axis (Figure 8.1.2.2).

Initiation of the Puberty and Menstrual Cycles

Sensitization of the hypothalamus-pituitary-axis to ovarian steroid hormones and maturation of feedback mechanisms initiate the menstrual cycles (menarche) at puberty between the ages of 10 and 16, the mean age of the menarche being 12–13 years. During the uterine maturations, the tubal form of the uterus will change into a round adult shape under oestrogen influence and the endometrium will start proliferating. At this point, the ovarian follicle pool has further diminished beholding only around 400 000 follicles that will serve as oocyte reserve for ovulatory cycles during female reproductive life (Figure 8.1.2.2). After menarche, the menstrual cycles are irregular due to incomplete maturation of the hypothalamus–pituitary–ovarian axis, and it may take over 2 years for it to mature and the cycles to become regular. Eventually, approximately 400 follicles will ovulate during the reproductive life span. As the follicle pool diminishes, also the menstrual cycles become irregular. At menopause, around the age of 50 years, only a few hundred or possibly thousands of follicles are left as the follicle pool is exhausted.

8.1.3 Menstrual Cycle and Ovulation

Gurkan Bozdag, Baris Ata, and Engin Türkgeldi

Introduction

The vast majority of our knowledge about follicle development had been retrieved from animal studies conducted before the 1950s [1]. Although initial attempts to understand human folliculogenesis has begun with histologic examinations of ovaries derived from post-mortem examination or oophorectomy, recent imaging studies and endocrinologic assessments have made significant improvements throughout the process of understanding the whole human menstrual cycle and related folliculogenesis. Nowadays, we can appreciate the fact that each follicle is distinct and controlled by endocrine and diverse paracrine factors that will determine its own fate [2].

According to studies performed on early human fetus, follicular development begins as early as the fourth month of fetal life [3]. In the early life of female, oogonia initiates the first meiotic division and arrests in the dictyate stage to generate the primary oocytes and then is surrounded by somatic cells. At the end of 20 weeks of gestation, number of those follicles containing oocytes constitutes true ovarian follicular reserve and reproductive potential with an estimated number of 7 million. Of them, only 400 become a Graafian follicle and rest deplete during reproductive ages (see Chapter 8.1.2). The current chapter aims to summarize the journey of primordial follicles while aiming to reach the stage of dominant follicle and its corresponding endometrial changes.

Follicle Activation and Growth

In the context of follicle activation, it is noteworthy to mention that medical or surgical hypophysectomy has been shown to be associated with decreased ovarian weight and a significant reduction in the total number of developing follicles in animal studies [4]. On the contrary, induction of those rats with an amount of follicle stimulating hormone (FSH) yields an improvement in ovarian weight and initiates follicle development from preantral stage up to the antral stage. Although development to the antral stage is not solely dependent on FSH as shown in FSH-null mice [5], preantral follicles are responsive to FSH treatment [2]. Those findings suggest that FSH has a critical role for the regulation of preantral follicle growth accompanied by oocyte and granulosa cell derived paracrine factors [2]. From the view of clinical practice, it might be postulated that a prolonged stimulation of FSH, longer than 2 weeks might eventually induce follicle development from preantral stages.

Oocyte–Granulosa Cell Interaction

Under the subheading of '*granulosa cell derived*' paracrine factors, one should mention about C-type natriuretic peptide (CNP) as an autocrine/paracrine follicle-stimulating agent secreted during secondary and antral follicle stages in response to FSH stimulation [6]. It activates its receptor natriuretic peptide receptor-B or 2 as expressed in granulosa cells of secondary follicles and signal via the production of cGMP to evoke desensitization reflected by dephosphorylation in the kinase-homology domain [7]. Whereas stimulation of cGMP production induces follicle development from primary and early secondary to the late secondary stages, it inhibits meiotic resumption of the oocyte [8].

Other than CNP, a large group of diverse peptide/protein ligands derived by granulosa cells have been explored to modulate follicle growth [2]. Of those activins, anti-Müllerian hormone (AMH) and bone morphogenetic protein-6 (BMP-6) act throughout RSK receptors. AMH is a glycoprotein from TGF-β family that is secreted by granulosa cells within 2–5 mm antral stage follicles and decreases when the follicles begin their FSH-dependent cyclic recruitment process [9, 10]. The main action of AMH is avoiding transition from primordial follicle to primary follicle and hence inhibiting the FSH-dependent cyclical recruitment [9].

It appears that not only granulosa cells but also oocyte itself is an active member of folliculogenesis. R-spondin2 [11], growth differentiation factor-9 (GDF9) and bone morphogenetic protein-15 (BMP15) [12] have been shown to promote granulosa cell growth as '*oocyte-derived*' structures. A diminished level of R-spondin2 in primary and larger follicles was noticed to be associated with a failure in follicle development during late reproductive life and premature ovarian insufficiency [13]. Although they are lacking in primordial follicles, *in-vivo* administration of R-spondin agonist might stimulate the development of primary follicles to the antral stage in animal models [11]. GDF-9 is also an important local factor for the development of follicles beyond the primary stage and promotes androgen production from theca cells [14]. Similarly, BMP15 is another potent stimulator of granulosa cell proliferation and yields different actions among species.

Steroids and Gonadotropin Receptors

In addition to local peptide hormones, oestrogens, androgens, and progesterone play important role for the regulation of folliculogenesis via specific receptors. Whereas oestrogen receptor-alpha variants and theca cell-specific deletion of oestrogen receptor-alpha leads to premature ovarian failure [15], deletion of androgen receptors may yield subfertility [16]. Notably, local increment in the concentration of oestrogens induces follicle growth and contributes to the selection of dominant follicle. Dihydrotestosterone, as an androgen, increases FSH receptor expression and provokes oestrogen and progesterone biosynthesis [2]. On the contrary, high levels are associated with follicular atresia.

As might be clearly understood from the aforementioned studies, the full process for detecting the dominant follicle is highly

complicated. The total duration of time to reach a preovulatory stage takes around 85 days. Although FSH cannot control every step of folliculogenesis, without any circulating FSH, particularly follicles 2–5 mm in diameter undergo atresia. During the lifespan of a Graafian follicle, with parallel to the molecular mechanisms given here, the initial change is morphological alteration, as granulosa cells timely become more cuboidal. Nevertheless, for the activation of a primordial follicle, BMP acts as a promoter. Nerve growth factor, brain derived neurotropic factor, neutrophin-3 and 4/5 are various neurotrophins that may alter the early follicular development. After the first awakening of the primordial follicles, FSH receptors also arise in number [17]. The decline in previous luteal phase both in the process of steroidogenesis and production of inhibin A from granulosa cells, a significant rise in concentration of FSH becomes evident particularly during the mid-late luteal phase.

Two-Cell, Two-Gonadotropin System

The next step after the awakening of a primordial follicle is formation of multilayer of granulosa cells surrounding the oocyte to form the preantral follicle stage (Figure 8.1.3.1). While zona pellucida appears around the oocyte, the outer stroma modifies to theca cells. FSH receptors not only induce proliferation of granulosa cells but also act to induce the function of aromatase enzyme that converts androgens to oestrogens. Hence, local increase of oestrogen concentration steadily increases the number of FSH receptors on granulosa cells. Although low dose of androgens are essential as a precursor of aromatase activity and induction of the enzyme, high doses are associated with overproduction of 5-alpha androgens that in turn inhibit the enzyme activity and causes atresia.

As the layers of granulosa cells increase and fluid accumulation begins within a preantral follicle, the later stage of those follicles is designated as antral follicle. During this process, granulosa cells around the oocyte differ from the ones that cover the whole follicle with its functionality and called as cumulus oophorus. The content of the fluid within an antral follicle essentially consists of oestrogen and hence concentration of the steroids reflects the functional capacity of granulosa and theca cells within the context of two-cell, two-gonadotropin system. Insulin like growth factor-II produced in theca and granulosa cells also stimulate aromatase activity. One should also address that LH receptors are present only theca cells, and solely granulosa cells have FSH receptors. LH secretion is responsible for the production of androgens, namely androstenedione and testosterone which in turn metabolize to estrone and oestradiol with aromatase activity, respectively. Notably, inhibin induces and activin stimulates action of FSH, LH, and IGF-I. These findings might suggest that LH is also important for the late development of folliculogenesis and maturation. Nevertheless, within the context of selection of dominant follicle, a fall in FSH levels due to increased concentration of oestrogen decreases the aromatase activity and associated oestrogen synthesis. Impairment in granulosa cell will lead to a significant reduction in aromatase activity and cause more androgenic microenvironment and finally atresia. Briefly, containing the highest potency of aromatase activity and LH receptors with response to FSH appears to be the crucial factor for a given follicle in order to be attained as a dominant follicle in the later phase of the menstrual cycle [17].

Novel Pathways of Follicle Activation

One of the novel discovered pathways in the process of folliculogenesis appears to be '*Hippo signalling*' that is also essential for organ size control. As an incision is made to the ovary, G-actin within granulosa cells polymerize to F-actin and inhibits several negative growth regulators acting in a serine/threonine kinase cascade that ultimately phosphorylates and inactivates key transcriptional coactivators, Yes-associated protein and transcriptional co-activator with PDZ-binding motif [2]. These alterations induce expression of downstream CCN growth factors and BIRC apoptosis inhibitors that in turn activates dormant follicles.

Another molecular mechanism to induce dormant follicles appears to be related with '*PTEN-PI3K-AKT pathway*'. Stimulation of phosphatidylinositol-3-kinase (PI3K) yields AKT stimulation that subsequently suppresses FOXO3 actions in nucleus to promote primordial follicle growth. Meanwhile, PTEN gene encodes an enzyme that converts PIP3 to PIP2, thus damping the actions of PI3K. Oocyte-specific deletion of the PTEN gene leads to global activation

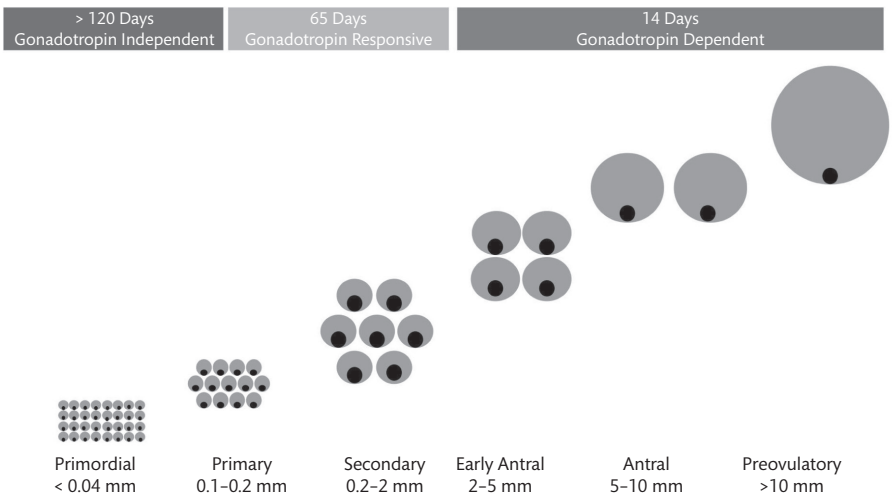

Figure 8.1.3.1 Phases and durations of follicular development.

of primordial follicles [18] whereas treatment with PTEN inhibitors promotes primordial follicle activation [19].

Early Follicular Phase

During early follicular phase, activin has a critical role with respect to an improvement in aromatase activity with parallel to FSH exposition and simultaneous inhibition of production of androgens. Activin has also a role in boosting the receptivity of FSH. According to imaging studies, recent theories of ovarian follicular recruitment proposed that there are two or more cohorts of antral follicles during the early phases of menstrual cycle (Figure 8.1.3.2). Of interest, whereas the dominant follicle develops from the final wave, other waves of cohorts do not produce an ovulatory follicle [1]. Those findings suggest that Graafian follicle selection might be observed more than once during natural menstrual cycles [20] rather than being once in the early follicular phase of the menstrual cycle, as mentioned earlier [21]. The competency of corpus luteum also seems to be similar in women with two versus three waves or in women with major versus minor waves preceding the ovulatory wave [22]. However, the appearance of second wave in the late luteal phase or early follicular phase, rather than in mid-luteal phase, facilitates the selection of a dominant follicle [20]. The functional status of dominant follicles that develop during anovulatory waves preceding the ovulatory wave in women is not fully understood; but available data suggest that dominant follicles of anovulatory waves may exhibit different physiologic characteristics than dominant follicles of ovulatory waves in women [1].

In the follicular phase, there are substantial changes in the endometrium with respect to increased levels of oestrogen and enhanced receptivity. All components of the endometrium including glandular structures, stromal cells, and vascular tissues present proliferation. Two-thirds of its upper part constitutes the functional layer, the remaining inner part makes up the basal layer. According to imaging studies, an average of 5 mm increase is observed in the thickness of endometrium. Ciliogenesis is also initiated 7/8th day of the cycle [17].

Mid-Late Follicular Phase

During mid-late follicular period, namely preovulatory phase, dominant follicle grows up with a rate of 1–4 mm per day and reaches to the maximal diameter of 30 mm. There is a steady increase in the aromatase activity and hence oestradiol levels but a contradictory decrease in fluidic AMH concentration. IGF-II continues to induce aromatase activity and oocyte-derived substances. GDF-9 and BMP-15 are involved in the process of follicle development and cumulus expansion [23]. There are also increased numbers of LH receptors, which will be used during ovulation, and time of triggering.

Ovulation

In a regular cycle of 28 days, ovulation occurs in mid-cycle, around the 14th day. In this short but defining period, two important events take place. First, the oocyte resumes meiosis and is released from the ovary along with a cumulus complex. Second, transition from follicular phase to luteal phase of the cycle is observed. The key step for both of these events is the mid-cycle LH surge.

Oestradiol rises constantly in the follicular period and reaches significant levels at the late follicular phase. Beyond a certain threshold, the inhibitory effect of oestradiol on GnRH is reversed and a positive feedback mechanism takes over. High oestradiol levels increase the sensitivity of the anterior hypophysis to GnRH, leading to increased secretion of LH and FSH, which in turn results in production of more oestradiol. An oestradiol level of around 200 pg/ml^{-1} for a minimum of 48 hours and some progesterone activity is required to induce this positive feedback mechanism [24]. Some researchers believe that increased inhibin A levels also play a role in the LH surge [25].

The rise in the serum progesterone levels contributes to the increased responsiveness of LH to GnRH. Progesterone is the dominant hormone in the luteal phase, however, studies show that progesterone starts to rise just prior to LH surge in ovulatory women. This elevation is believed to contribute to the increased sensitivity of LH to GnRH. While the rise in progesterone is relatively

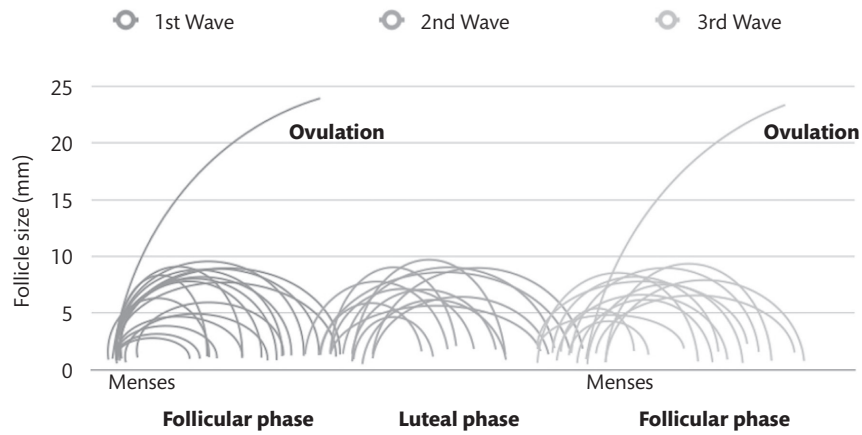

Figure 8.1.3.2 A schematic representation of a three-wave cycle. Each line represents growth and regression of a follicle.

small, it is essential for the LH surge. The surge is delayed or totally inhibited in patients receiving antiprogestin RU486 [26].

The positive feedback loop climaxes with the discharge of nearly all LH stored in the anterior hypophysis, causing 10- and 4-fold increase in LH and FSH levels, respectively [27]. The surge lasts about 40–48 hours, resulting in meiotic maturation and releasing of the cumulus-oocyte complex. During and after the LH surge, progesterone levels keep rising, whereas oestrogen levels show a significant and swift drop. This drop is what limits the LH surge, since progesterone alone cannot support the LH sensitivity to GnRH without oestradiol.

The LH surge blocks cGMP production in granulosa cells consequently decreases the cAMP levels in the oocyte and meiosis, which was arrested for years, resumes [28]. Then, second meiotic metaphase stage is completed, and first polar body is extruded. At this point, meiosis once more waits for completion, this time to be achieved with fertilization. One of the consequences of the LH surge is the initiation of a series of reactions that will lead to release of the cumulus-oocyte complex. The initial step is the expansion of the cumulus cells, also known as mucification. A group of epidermal growth factors (EGFs), namely amphiregulin, epiregulin, and betacellulin, cause secretion of glycoproteins from cumulus cells that result in the formation of an extracellular hyaluronan-rich matrix [29]. This results in the dispersion of the cumulus cells and significant expansion of the cumulus-oocyte complex [30]. Mucification is believed to be important in the release of the cumulus-oocyte complex from the ovary and its transport to the Fallopian tube.

Another event preceding the release of the oocyte-cumulus complex is the induction of prostaglandin production by the aforementioned progesterone rise prior to LH surge. The prostaglandins, produced by the follicle wall, stimulates the release of proteases that first thins and then perforates the apex of the follicle wall, an area known as macula pellucida. Thus, the cumulus-oocyte complex is released from the ovary along with 2–3 ml follicular fluid approximately 36 hours after the LH surge.

There appears to be no histologically significant change in the endometrium during ovulation; however, LH surge and ovulation are the key events that result in the transition from the proliferative phase to the secretory phase of the endometrium.

Luteal Phase and Menstruation

Unless pregnancy occurs, luteal phase begins with ovulation and lasts around 14 days. Mainly, it consists of two parts referred as luteinization and luteolysis.

Macroscopically, the ruptured follicle fills with fibrin clot and undergoes a series of changes. after ovulation. Theca and granulosa cells luteinize and form a cell complex with increased expression of LH receptors. Angiogenic and inflammatory changes contribute to this new formation as well [31]. The formation of corpus luteum now constitutes the principal unit in the ovary to support luteal phase.

Luteinization begins with ovulation and lasts about 7–9 days. During this period, corpus luteum is highly sensitive to LH. While LH pulses in this period are relatively less frequent compared to the preovulatory stage, they are still regular enough to induce significant production of progesterone and oestradiol [32]. Along with these two major hormones, 17-hydroxyprogesterone, estrone, inhibin A, and relaxin are also secreted from the corpus luteum and increase during luteinization.

If conception does not occur, luteolysis begins. This is marked with the regression of the corpus luteum and the gradual decline in progesterone and oestradiol levels. While a LH pulse occurs every 90–100 minutes in the follicular phase and almost every hour in the preovulatory period, their frequency drops to a pulse every 3–5 hours in the mid-luteal phase [33]. The most prominent mechanism behind the drop of pulse frequencies of LH and FSH in the luteal phase is the inhibitory effect of progesterone on the hypothalamus. It provokes production of an endogen opioid, β-endorphin, which reduces the secretion of GnRH, resulting in more sparse LH pulses as progesterone increases [34]. As these pulses get irregular and less frequent in the late luteal phase, the corpus luteum starts to degenerate and eventually undergoes apoptosis.

Two different pathways keep FSH levels low throughout the luteal phase. The first one is the inhibitory effect of increased oestradiol and inhibin A on FSH. The second is the reduction of GnRH pulses due to the increased production of β-endorphin by increased progesterone levels [35]. As the corpus luteum degenerates in the absence of human chorionic gonadotropin (hCG) or regular LH pulses, both of these pathways lose their inhibitory effect on FSH. Thus, towards the end of luteolysis, FSH starts to increase and the first step for initiating the recruitment of follicles in the next cycle is taken.

If conception occurs, luteolysis and apoptosis of the corpus luteum is avoided by hCG that is secreted by the fetal trophoblastic cells. LH and hCG share the same β-subunit, which allows hCG to act as an LH substitute by binding to LH receptors on the corpus luteum. hCG levels increase dramatically with the rapid growth of fetal trophoblastic cells as pregnancy advances, and this not only maintains but also increases the production of progesterone, oestradiol, and other ovarian steroids by the corpus luteum. This increased workload is visible as the size of the corpus luteum is doubled by the sixth gestational week due to hypertrophy of its cells [36]. Endometrial decidua is stabilized and supported by the progesterone secreted from the corpus luteum until the eighth gestational week. At this week, the placenta is developed enough to produce sufficient progesterone to support endometrium by itself, and gradually takes over this duty from the corpus luteum. This is known as the luteoplacental shift.

With regard to the luteal phase of the ovary, the secretory phase of the endometrium begins with the LH surge and ovulation. It can be divided into three periods, namely, early secretory, mid-secretory, and premenstrual phases.

In the early secretory phase, glycogen builds up in glandular epithelial cells, shifting the nuclei centrally. It is interesting to note that mitotic activity in the endometrium is observed almost exclusively in the first 3 days following ovulation [37].

Coiled arteries that can extend as endometrium thickens, known as spiral arteries, develop in the mid-secretory phase. Concomitantly, endometrial glands attain their peak activity and stroma takes an oedematous character. During this period, endometrium thickness may reach up to 8–10 mm as a maximum. In anticipation of a possible pregnancy, stromal cells proliferate around

blood vessels, natural killer cells accumulate around them, and a complex series of immunological, haematological, and metabolic changes take place in order to promote any possible implantation.

In the premenstrual phase, secretory activity is reduced due to decreased progesterone and oestrogen levels. The secretory endometrium cannot maintain itself and degrades. Inflammatory cells invade the endometrium as catabolic events that result in shrinkage of the endometrium follow. Finally, intermittent contraction of the arterioles in the endometrium results in local ischaemia and leads to shedding of the functional layer of the endometrium, manifesting itself as menstrual bleeding.

Evaluation of the Female Patient with Suspected Reproductive Endocrine Disorders

8.2.1 Clinical Evaluation of Patients with Suspected Reproductive Endocrine Disorders

Rachel Roberts, Steve Franks, and Channa Jayasena

Introduction

Female reproductive endocrine disorders are common, and can result in significant morbidity for women due to their impact on fertility, in addition to physical, psychological, and sexual consequences. It is therefore important that women with menstrual disorders are recognized, receive thorough clinical evaluation, and have access to appropriate services, to facilitate prompt diagnosis so that hormone levels are maintained and the potential health consequences on fertility, bone, and cardiovascular health are minimized. Women with reproductive endocrine disorders are most likely to present with either menstrual irregularity or infertility, or, more rarely, with a physical, psychological, or sexual consequence of the underlying condition such as acne, depression, or dyspareunia. In women of reproductive age who present with difficulty in conceiving following at least 12 months of regular unprotected intercourse thorough clinical evaluation is warranted [1]. Earlier assessment after six months may be appropriate in women over 35 years, or in those with a known history of oligo- or amenorrhea, known or suspected uterine, tubal, or peritoneal disease, or moderate to severe endometriosis. In cases of infertility it is essential that both partners are evaluated as 35% of infertile couples have combined male and female factor infertility [2]. It is also important to remember that multiple factors may impair fertility in an individual couple, which may be both male and female factor. Furthermore, because both partners are affected by decisions surrounding fertility investigation and treatment, it is optimal to see couples together in clinic. Fertility evaluation may also benefit women planning to conceive using sperm from a known or anonymous donor. A thorough history and physical examination is essential in the assessment of reproductive disorders. Clinical assessment may help to suggest the cause of reproductive disorders, and allow for more focused investigations and diagnostic evaluation. Diagnosis enables appropriate treatment to be sought, which is particularly important to minimize long-term health consequences and given the time-sensitive treatment goal of pregnancy, if desired.

History

A detailed history is arguably the most powerful diagnostic tool in determining the underlying cause of female reproductive disorders. A good history will enable the clinician to perform a relevant examination and to target investigations to confirm a likely diagnosis. The history is also important to identify women who have modifiable risk factors, such as disordered eating or excessive exercise. In women with infertility, it is necessary to establish the duration that a couple has been trying to conceive and to review the results of any previous evaluation and treatments. It is also necessary to enquire about childhood development; sexual development during puberty; menstrual history; sexual history; contraceptive history; previous obstetric history; illnesses and infections; surgeries; medications used; exposure to certain environmental agents and social and personal history. Table 8.2.1.1 summarizes some of the key clinical findings for different causes of female reproductive endocrine disorders.

Childhood and pubertal development: Determining a woman's childhood and adolescent development may reveal abnormalities in growth and/or pubertal development, which in turn may help to identify the underlying cause of menstrual disturbance. Patients may have experienced primary amenorrhea, most frequently caused by

Table 8.2.1.1 Common symptoms and signs of conditions causing infertility

	Symptoms	Signs
Hypothalamic amenorrhea	Oligo/amenorrhea Weight fluctuations Eating disorders Strict eating habits and dieting Stress History of excessive exercise Previous fractures (e.g. stress fracture) Dyspareunia Poor libido Substance abuse Family history of eating and reproductive disorders	Low BMI Lanugo Mottled, cool extremities Hypercarotenaemia Signs of self-harm Hypotension Bradycardia Atrophic breasts Atrophic vaginitis
Hyperprolactinaemia	Oligo/amenorrhea Headaches Galactorrhoea Poor libido Visual disturbance History of relevant medications e.g. antidepressants	Scotoma or bitemporal hemianopia Breast secretions
Hyperthyroidism	Oligo/amenorrhea Heat intolerance Weight loss Increased appetite Irritability Mood changes Tremor Eye complaints	Tremor Hyperkinesis Goitre, bruit Warm vasodilated peripheries Tachycardia or atrial fibrillation Eye signs incl. exophthalmos, lid lag, 'stare', ophthalmoplegia
Hypothyroidism	Menorrhagia Lethargy Depression Weight gain Cold intolerance Dry skin and or hair History of thyroid disease or surgery	Mental slowness Dry, thin hair Goitre Neck scars Hypertension Bradycardia Slow relaxing reflexes
PCOS	Oligo/amenorrhea Weight gain Acne Hirsutism Family history of PCOS	Raised BMI with central adiposity Hirsutism Acne Acanthosis nigricans Skin tags Hypertension
Obesity	Oligo/amenorrhea Weight fluctuations Eating disorders Eating behaviours and diet	High BMI Central adiposity Acanthosis nigricans Hypertension
Primary ovarian insufficiency	Oligo/amenorrhea Poor libido Dyspareunia Previous fractures (e.g. stress fracture) Hot flushes Urogenital symptoms (e.g. frequency) Family history of POI/early menopause History of radiation therapy or chemotherapy	Often no signs Atrophic vaginitis Signs of other autoimmune disease (e.g. goitre, vitiligo)
Turner's syndrome	Primary or secondary amenorrhea Pubertal delay Hearing loss	Short stature Webbed neck Shield chest with widely spaced nipples Cubitus valgus Low posterior hairline Short fourth and fifth metacarpals Hypertension Abnormality of cardiac examination (e.g. murmur)
Late-onset congenital adrenal hyperplasia (21-hydroxylase deficiency)	Oligo/amenorrhea History of precocious puberty Acne Hirsutism	Short stature Hirsutism Acne Androgenic alopecia Hypertension Clitoral hypertrophy

Table 8.2.1.1 *Continued*

	Symptoms	Signs
Androgen-secreting tumour	Hirsutism Acne Rapid onset of symptoms	Hirsutism Acne Androgenic alopecia Hypertension Clitoral hypertrophy Deepening of voice
XY karyotype-Androgen Insensitivity Syndrome	Primary amenorrhea Lower abdominal pain History of gonadal tumours	Tall stature Thin Clitoral hypertrophy Underdeveloped labia Blind vaginal pouch Normal breast development Underdeveloped pale nipples Absent/sparse pubic and axillary hair
XY karyotype-gonadal dysgenesis	Primary amenorrhea Lower abdominal pain History of gonadal tumours	Tall stature Thin Female external genitalia Underdeveloped breasts Narrow pelvis and hips Sparse pubic hair
Cushing's syndrome	Oligo/amenorrhea Weight gain Change in appearance Depression Poor libido Thin skin/easy bruising Acne Muscular weakness Polyuria/polydipsia History of fractures History of steroid use	High BMI/central adiposity Moon face Plethora Acne Hirsutism Thin skin Bruising Striae Buffalo hump (dorsal fat pad) Proximal myopathy Visual fields Hypertension
Acromegaly	Oligo/amenorrhea Headaches Change in appearance Vision changes	Skin changes—thickening, skin tags, hirsutism, hyperhidrosis Peripheral vision loss Enlarged jaw Frontal bossing Macroglossia Visual field defects

primary ovarian insufficiency (e.g. Turner's syndrome), congenital deficiency of gonadotrophin releasing hormone (GnRH) (see next) or, much more rarely, anatomical abnormalities such as Müllerian agenesis [3]. Delayed or absent pubertal development may be a manifestation of congenital hypogonadotropic hypogonadism, a group of heterogeneous disorders typically caused by GnRH deficiency [4] or may be attributable to intersex disorders [5].

Menstrual history: Women with reproductive endocrine disorders predominantly present with menstrual disturbance, and the most common cause of female infertility is ovulatory dysfunction [2]. It is important to establish the regularity and duration of menses. A history of regular and consistent menses is highly suggestive of normal ovulatory function. In most ovulatory women, menstrual cycles are regular and predictable, occurring, on average, every 25–35 days, and should have consistent flow and characteristics. Some degree of variation in menses is normal, however; a study of more than 1000 menstrual cycles found that 56% of women experienced variations in intermenstrual interval exceeding 5 days within 6 months and in 75% of women within 1 year [6]. Assessing for regular symptoms of premenstrual molimina (breast tenderness, ovulatory pain, bloating) is also useful in suggesting a patient is likely to be ovulating regularly [7]. Irregular and infrequent menstrual periods (oligomenorrhea) usually signals irregular ovulation, and is defined as fewer than six to eight menstrual periods per year. Although it does not make pregnancy impossible, it can reduce the opportunities to conceive and clearly has an impact on fertility. Absent menstrual periods (amenorrhea) signals an absence of ovulation resulting in infertility, and can be classified as either primary or, more commonly, secondary amenorrhea. There are multiple causes of oligo- and amenorrhea, many of which are shared, which a full history and examination can help to determine. It is also important to ascertain the duration of menstrual disturbance, as this can influence what investigations and management is appropriate.

Identifying the flow of a woman's menstrual periods and the presence of abnormal uterine bleeding is another essential component of a menstrual history, and is of particular importance in women presenting with infertility, who may have a purely gynaecological condition, rather than a reproductive endocrine disorder. Abnormal uterine bleeding including menorrhagia can be a symptom of uterine polyps or fibroids, hypothyroidism, cancer, or perimenopause. The presence of painful menstrual periods (dysmenorrhoea) can also help to identify conditions that may affect fertility, such as endometriosis, pelvic inflammatory disease, fibroids, and

adenomyosis. If these conditions are suspected, further assessment with gynaecological review is indicated.

Many women record the timing of their menstrual cycle and characteristics of menstrual bleeding, especially in those having menstrual irregularity or attempting conception. Traditionally a paper record or diary may be kept; however, several electronic software applications have been developed to assist women in tracking their menstrual cycles, which may be accessible on computers and smartphones for minimal or no cost. It may be useful to look at these during a clinic appointment to give an accurate overview of a woman's menstrual patterns. Some women may chart serial basal body temperature (BBT) to help track ovulation and monitor their menstrual cycles. BBT is usually measured first thing in the morning before getting out of bed and in ovulatory cycles is meant to show a biphasic pattern, with a woman's temperature rising after ovulation; whereas anovulatory cycles typically result in monophasic patterns. However, BBT is an unreliable method of ovulation detection as some ovulatory women do not have clear biphasic BBT patterns [8] and interpretation of the charts can be difficult and subject to wide interobserver variation [9]. Furthermore, several cohort studies that evaluated the use of BBT to time intercourse reported no improvement in the chance of natural conception [10, 11]. Women should therefore be advised that charting BBT is generally not recommended.

Sexual history: The sexual history of the couple is a sensitive, yet important, element of clinical evaluation of women with infertility. Frequency and timing of intercourse as well as sexual dysfunction should be explored, since infrequent or ineffective intercourse can be an explanation for infertility. Spontaneous pregnancy rates are reported to be highest during the two-to-six days immediately prior to ovulation [12, 13]. However, there are limitations to timing intercourse in couples with infertility: ovulation can be difficult to predict in women with irregular menses; furthermore, timed intercourse has been reported to be emotionally stressful for couples [14]. Therefore, couples that are concerned about their fertility should be advised that vaginal sexual intercourse every 2 to 3 days optimizes the chance of pregnancy [15]. Women should be specifically asked about pain during sexual intercourse (dyspareunia), as it is rarely self-reported by patients and often only revealed after direct questioning [16]. Dyspareunia may contribute to infertility either by reducing the frequency of coitus, or because the underlying aetiology negatively affects fertility. For example, superficial dyspareunia may be caused by vaginal atrophy, as seen in hypo-oestrogenic conditions such as GnRH deficiency, hypothalamic amenorrhea, or premature ovarian insufficiency, whereas deep dyspareunia may be related to endometriosis or pelvic inflammatory disease. The use of sexual lubricants should also be assessed. *In vitro* studies have shown that vaginal lubricants can have a detrimental effect on sperm motility [17, 18], although the evidence for this is mixed [19]. It is possible that vaginal lubricant use during intercourse may negatively impact conception rates, particularly when the male partner has reduced sperm quality. For this reason, it is generally advised that common vaginal lubricants are not used during sexual intercourse, in couples trying to conceive [20]. It is also important to discuss previous sexually transmitted infections, and their treatment, as well as the number of sexual partners; the number of which increases the incidence of undiagnosed sexually transmitted diseases. *Chlamydia trachomatis* and *Neisseria gonorrhoea* are both important causes in the development of pelvic inflammatory disease, salpingitis, and subsequent tubal infertility.

Contraceptive history: It is important to ascertain the use of any previous contraceptive methods and duration since ceasing contraception. Progesterone-only injectable contraceptives have been reported to cause amenorrhea lasting up to 1 year following cessation of therapy [21, 22]. There is no clear evidence to suggest that oral contraceptives, progesterone-only subdermal implants, copper intrauterine devices or the levonorgestrel intrauterine system cause a delay in return of menses or fertility [23]. The use of a copper intrauterine device for contraception has historically been linked to increased rates of pelvic inflammatory disease and subsequent tubal infertility [24]. However this link is controversial, with recent evidence showing no increased risk of tubal infertility in copper intrauterine device users [25]. Women should therefore be counselled that the potential risks of pelvic inflammatory disease or infertility among intrauterine device users is likely to be very low.

Endocrine history: Symptoms of oestrogen deficiency such as hot flushes, vaginal dryness, dyspareunia, poor libido, depression, loss of concentration, and urogenital symptoms, may represent primary ovarian insufficiency or hypothalamic amenorrhea. Young women have the highest risk of developing thyrotoxic disorders such as Graves' disease, so it is important to screen for features such as hyperphagia, heat intolerance, palpitations, diarrhoea, tremor, mood disturbance, and insomnia. Symptoms of hirsutism and acne are associated with hyperandrogenic states most often caused by polycystic ovarian syndrome; however, other hyperandrogenic disorders include ovarian or adrenal tumours (often rapid onset of symptoms), congenital adrenal hyperplasia, and Cushing's syndrome. While Cushing's syndrome and acromegaly can commonly cause menstrual disturbance and infertility [26, 27], they usually present with other classical symptoms, which may include weight gain, changes in facial appearance, bruising, acne, weakness, polyuria and polydipsia, headaches, mood changes, and changes in vision. Pituitary tumours may disrupt gonadal function, either because of mass effect, or because of the effects of hormonal secretion from the tumour [28]. Symptoms may include changes in vision, headaches, or change in sense of smell. In addition, symptoms of hormone excess may be present if the tumour is functioning. Surgical treatment or irradiation of pituitary tumours may also result in infertility from disruption of gonadotrophic cells or resulting hypopituitarism [29, 30]. Radiation therapy for non-pituitary brain tumours is also associated with a significant risk of hypothalamic-pituitary dysfunction, and subsequent infertility [31]. The development of hypogonadism following cranial radiotherapy is dose-related and therefore a specific history of radiotherapy treatment is necessary [32]. Galactorrhoea and decreased libido are signs of hyperprolactinaemia. A history of traumatic brain injury can be associated with altered GnRH function and hypothalamic amenorrhea [33]. Infections and infiltrative disorders such as sarcoidosis, haemachromatosis or, tuberculosis can damage the hypothalamus or pituitary resulting in disrupted menstruation and infertility [34–37]. Diabetes mellitus may cause menstrual irregularities, oligomenorrhoea or secondary amenorrhoea [38].

Other medical history: Chronic illness or ill-health *per se* may disrupt menstrual cycles, which can be associated with impaired female fertility. Chronic kidney disease and renal replacement therapy

are associated with hyperprolactinaemia [39], ovulatory dysfunction, amenorrhoea, and reduced fertility [40]. Malabsorptive diseases, such as coeliac disease or inflammatory bowel disease, can cause reproductive changes including delayed onset of menarche, amenorrhea, impaired fertility, and adverse pregnancy outcomes, possibly related to autoimmune-mediated mechanisms or nutritional deficiency. Infertility may be the initial clinical feature of coeliac disease in women who are otherwise asymptomatic from a gastrointestinal perspective [41]. Women with Turner's syndrome may have symptoms of hearing loss, or valvular heart disease. It is widely recognized that cytotoxic chemotherapy drugs and pelvic irradiation can result in premature ovarian failure; it is therefore essential to elicit a past history of any cancer and cancer treatment, including childhood cancer [42, 43].

Surgical history: A surgical history is also of importance when evaluating a woman with a potential reproductive disorder. A history of total or partial thyroidectomy may be associated with ongoing thyroid hormone dysfunction that can adversely affect fertility [44]. A history of fractures, particularly stress fractures, may point to women whose subfertility is caused by a condition resulting in oestrogen deficiency, such as hypothalamic amenorrhea or primary ovarian insufficiency. It is also important to note previous abdominal and pelvic surgery such as appendicectomy or ovarian cystectomy, which predispose to adhesion formation and increase the likelihood of tubal dysfunction. Unilateral oophorectomy does not generally cause reduced fertility in young women, since they have many primordial follicles per ovary; however, prior unilateral oophorectomy may impact fertility in older women as they may develop diminished ovarian reserve sooner than women with two ovaries [45].

Obstetric and gynaecological history: In addition to a thorough menstrual history, a full obstetric and gynaecological history should be assessed for events potentially associated with subsequent infertility or with an adverse outcome in a future pregnancy. If necessary, further clinical evaluation and investigation by a gynaecologist may be appropriate. Important points to discuss are a history of abnormal smears, colposcopy, cervical surgery (including cone biopsies) or endometrial or cervical malignancies, which may cause cervical stenosis, a history of pelvic inflammatory disease or endometriosis and previous pregnancies and their outcome including ectopic pregnancies and their treatment, miscarriages and their management, molar pregnancies, and termination of pregnancies. A history of significant peripartum haemorrhage in previous pregnancies, or insufficient postpartum breast milk production, is classical for Sheehan's syndrome, which is caused by hypoperfusion and subsequent ischaemic necrosis of the pituitary gland [46]. Genital tuberculosis is rare in countries with high mean income, but it should be carefully considered in women from other countries, where it may be a more common cause of female infertility [47]. Clinical symptoms of genital tuberculosis are varied, but include chronic lower abdominal or pelvic pain, vaginal bleeding, menstrual irregularity, general malaise, and infertility.

Personal and social history: Several aspects of personal and lifestyle history may contribute to reproductive disorders and profoundly affect fertility, including age, weight, diet, exercise, smoking, alcohol, illicit drug use and occupation. Personal and lifestyle history can also help to determine whether any modifiable risk factors are present, and if so, to provide appropriate advice and support. It is important to specifically enquire whether trends in body weight and eating patterns mirror changes in reproductive function such as menstrual disturbance. Women with obesity have an increased risk of ovulatory dysfunction when compared with women with lower body mass index, even after adjusting for menstrual irregularity [48]. Participating in a group programme involving exercise, dietary advice and support improves pregnancy rates more than weight loss alone [49]. Low body weight or recent weight loss may signify hypothalamic amenorrhoea. Women with hypothalamic amenorrhoea have a higher than normal risk of having a previous eating disorder (whether or not formerly diagnosed). Restoration of body weight and reduction in exercise intensity may be sufficient to restore menses and improve rates of conception in some patients with hypothalamic amenorrhoea [50]. It is crucial that the subgroup of women with anorexia nervosa or bulimia are detected and referred for specialist care including psychiatric evaluation. High intensity strenuous exercise can also lead to disrupted menstrual cycles or amenorrhea, so this is another important lifestyle factor to explore while taking a history [51]. There is substantial evidence that female smokers have reduced fertility [52], and there is also an association between passive smoking in women and delayed conception [53]. Furthermore, it is widely known that maternal smoking in pregnancy is associated with increased risks for the infant. Women should therefore be strongly advised against smoking, and referred to appropriate smoking cessation intervention groups. Furthermore, it is important to realize that conception planning represents an effective window of opportunity to support and motivate smoking cessation in women [54]. There is inconsistent evidence about the impact of drinking alcohol on female fertility. However, it is known that excessive alcohol consumption is harmful to a developing fetus, and current advice from the UK Chief Medical Officer is to abstain from alcohol consumption while trying to conceive and when pregnant [55]. Drugs of abuse such as cocaine and marijuana can negatively impact ovulation and tubal function [56, 57]. A specific enquiry about occupation may also reveal potential aetiological factors in female infertility. Shift work, intense physical workload and long working hours have all been associated with reduced fecundability and prolonged time to conception [58, 59]. Furthermore, chemical substances used in lamp, wood, shoe, rubber, and textile manufacturing have been reported to negatively impact female fertility, although further detailed research is required [60].

Psychiatric/Psychological history: The belief that psychological factors play a role in menstrual disturbance and infertility is long-standing. In the seventeenth century, Richard Morten described that psychiatric illness and infertility were two cardinal features of anorexia nervosa [61]. It is important for a clinician to explore potential stressors in females presenting with menstrual disturbance or infertility, such as work- or study-related stress, personal stress, in addition to psychiatric disorders such as anxiety and depression. Psychological stress or psychiatric symptoms may contribute to the cause of infertility; be the consequence of infertility; or both. There is evidence that preconception stress, as measured by salivary alpha-amylase, is associated with a longer time-to-pregnancy and an increased risk of infertility [62]. Psychological stress is a common cause of hypothalamic amenorrhea, resulting in infertility [63]. Furthermore, the recognition, evaluation, and treatment of infertility are stressful for most couples, with one study finding 40% of infertility patients fulfilling the diagnosis of a psychiatric disorder,

most commonly anxiety disorders and depressive disorders [64]. Stress can negatively impact the success of fertility treatment [65]; as well as contribute to the discontinuation of fertility treatment before pregnancy is achieved [66]. It has been found that psychosocial interventions for couples during infertility treatment, in particular cognitive behavioural therapy, may be effective both in reducing psychological distress and in improving clinical pregnancy rates [67]. It is therefore essential that any clinician evaluating a woman for reproductive disorders pays attention to their emotional and psychological health when thinking about the cause, as well as when planning potential fertility treatment.

Family history: In women without consanguineous parents, reproductive disorders rarely have an obvious, Mendelian inheritance. However, several factors relevant to female reproductive disorders and infertility may affect multiple family members, which is likely to represent a combination of genetic and environmental factors, such as pubertal disorders, eating disorders, functional hypothalamic amenorrhea, polycystic ovary syndrome, premature ovarian insufficiency, diabetes mellitus, and autoimmune thyroid disease.

Drug history: Various prescribed and over-the-counter drugs can adversely affect reproductive function, and therefore a detailed drug history is an important component of clinical evaluation. Drugs which interfere with the female reproductive system typically do so by one of three mechanisms; inhibiting GnRH release, inducing hyperprolactinaemia or causing hypophysitis, resulting in hypopituitarism. Opioids profoundly inhibit hypothalamic kisspeptin and GnRH secretion, leading to hypogonadotropic hypogonadism [68], and are an under-recognized cause of secondary amenorrhea [69]. Several psychotropic medications including neuroleptics, selective serotonin reuptake inhibitors (SSRIs) and clomipramine cause hyperprolactinaemia by inhibiting the tonic inhibition of hypothalamic dopamine on prolactin secretion [70–72]. Drugs for gastrointestinal conditions, such as the dopamine antagonists metoclopramide and domperidone [73, 74], and certain antihypertensives [75, 76] have also been associated with hyperprolactinaemia. Cytotoxic agents Ipilimumab and tremelimumab are human monoclonal antibodies, which target CTLA-4, and promote an immune-mediated response against cancer cells. However, they can also cause autoimmune reactions in other areas of the body, including the pituitary; leading to hypophysitis and hypopituitarism in 2.3% of patients [77].

Examination

A physical examination should be performed to assess for potential causes of reproductive disorders. Examination should include basic anthropometric measurements, general inspection, examination of the neck, eyes, cardiovascular, and respiratory systems, abdominal and pelvic palpation, examination of secondary sexual characteristics, and gynaecological examination.

Anthropometric measurement: Anthropometric measurements are a simple but powerful tool in the assessment of female reproductive disorders. Measurement of height is useful to determine women with short stature, which may be associated with Turner's syndrome (often combined with a stocky or square appearance) or growth hormone deficiency caused by hypothalamic or pituitary disease; or women with unusually tall stature, which can be associated with XY karyotype. Height and weight can also be used to calculate body mass index (BMI). Underweight women with BMI <18.5 kg/m^2 are more likely to have ovulatory dysfunction, hypothalamic amenorrhea, eating disorders, and hyperthyroidism. Women with obesity are at increased risk of ovulatory dysfunction, as well as polycystic ovary syndrome, hypothyroidism, or rarer endocrine diseases such as Cushing's disease. Waist circumference or waist-to-hip ratio is also helpful as it can identify women with central obesity (defined by a waist circumference of >88 cm in adolescent and adult women [78]) and is associated with insulin resistance and polycystic ovarian syndrome. High waist circumference can also be a sign of Cushing's disease. If available in the clinic, it is useful to measure body fat percentage, using the bioelectrical impedance method, as some women who exercise strenuously or maintain a restrictive diet can have an abnormally low body fat percentage, in spite of a normal BMI, which is in itself associated with ovulatory dysfunction and amenorrhea [79].

Inspection of skin: Close inspection of the skin is invaluable for gaining diagnostic clues to the aetiology of female reproductive endocrine disorders. Women with hypothalamic amenorrhea caused by weight loss, restrictive eating, or an eating disorder may be characteristically thin, with lanugo, mottled, cool extremities or yellow pigmentation (hypercarotenaemia) of the skin. There may be evidence of non-suicidal self-injury (for example skin cutting, picking, or burning with a lit cigarette), which is common in anorexia nervosa [80]. Hyperthyroidism may be associated with tremor, hyperkinesis, and warm vasodilated peripheries; whereas patients with hypothyroidism may display characteristic 'peaches and cream' complexion, dry thin hair, loss of eyebrows, cold peripheries, dry skin, and oedema. Conditions causing androgen excess, most commonly polycystic ovarian syndrome, or more rarely congenital adrenal hyperplasia, 5-alpha reductase deficiency, or androgen-secreting ovarian or adrenal tumours, can cause hirsutism, acne, and androgenic alopecia. Hirsutism is defined clinically as an abnormal amount of terminal hair growth that occurs in a male pattern in women [81] and is commonly graded by the modified Ferriman–Gallwey system where hair growth is rated from 0 (no growth of terminal hair) to 4 (extensive hair growth) in nine areas of the body. A total score of $\geq$ 6–8 is considered as hirsutism. However, the scale is limited by its subjective nature and because it does not take into account all areas of the body that can be affected by androgenic hair growth, for example, buttocks and sideburns. Furthermore, it requires a full-body examination, which some patients may consider invasive. Given these limitations some clinicians prefer to use 'patient-important hirsutism', which takes into consideration all symptoms of hirsutism that cause the patient distress, irrespective of the degree of physical findings [82]. Hirsutism must be distinguished from hypertrichosis, the generalized growth of excessive vellus hair, which can be congenital, caused by metabolic disorders, such as thyroid dysfunction, or a side effect of some medications (see Chapter 8.4.4, for details). Excessive acne vulgaris is another important cutaneous manifestation of hyperandrogenaemia, although there is no universally accepted, well-validated scale for reporting acne severity. Androgenic alopecia, or male-pattern baldness, is a less common symptom of hyperandrogenaemia, usually affecting the fronto-temporo-occipital scalp. Insulin resistant states, which can be found in obesity or polycystic ovarian syndrome,

can also be associated with skin changes including skin tags and acanthosis nigricans (thickened, hyperpigmented skin, predominantly of the flexures). Turner's syndrome, a cause of primary ovarian insufficiency, is associated with a characteristic phenotype including a short-webbed neck, 'shield' chest with widely spaced nipples, cubitus valgus, and Madelung deformity of the forearm and wrist. Characteristic facial features may also be present including epicanthal folds, downslanting palpebral fissures, low set ears, and micrognathia. Women with Cushing's syndrome typically have a moon face, plethora, acne, hirsutism, thin skin, bruising, striae, dorsal fat pad, frontal balding, skin pigmentation, and oedema. Acromegaly can cause changes in appearance including frontal bossing, enlarged jaw, macroglossia, thick greasy skin, spade-like hands and feet, tight rings, and oedema.

Eye examination: Examination of the eyes is useful to determine patients with menstrual dysfunction caused by Graves' disease or a pituitary tumour. Hyperthyroidism caused by Graves' disease can be accompanied by thyroid eye disease, signs of which include exophthalmos, tearing, conjunctival oedema, and periorbital oedema. Examination of eye movements may also reveal ophthalmoplegia. Impairment of vision in one or both eyes is a common consequence of suprasellar extension of a pituitary tumour. Classically this may cause a bitemporal hemianopia, although initially more subtle visual loss can be elicited, such as a scotoma on the bitemporal fields [83].

Neck examination: Inspection of the neck may reveal a transverse scar from total- or subtotal thyroidectomy, and palpation may reveal a goitre, thyroid nodules, or thyroid tenderness in cases of infertility associated with thyroid disease. Parotid gland swelling, or sialadenosis, is a common sign of bulimia nervosa [84].

Breast examination: Inspection of the breasts may reveal atrophic breasts in cases of hypo-oestrogenemia such as GnRH deficiency, hypothalamic amenorrhea, or primary ovarian insufficiency. Applying pressure in a clockwise manner around the areola may elicit nipple discharge [85], which may be present in about 25% of cases of premenopausal women with hyperprolactinemia [86].

Cardiovascular examination: Blood pressure and radial pulse rate are important basic measurements that should be taken during clinical assessment. Bradycardia and hypotension are associated with anorexia nervosa; tachycardia or atrial fibrillation, a full pulse and/or systolic hypertension with hyperthyroidism; bradycardia and/or hypertension with hypothyroidism; and hypertension with obesity, or hyperandrogenic conditions, such as polycystic ovary syndrome, congenital adrenal hyperplasia, or an androgen-secreting tumour. Women with primary ovarian insufficiency caused by Turner's syndrome may have hypertension, and/or a number of cardiac malformations, including aortic valve abnormalities, aortic arch abnormalities, atrial and ventricular septal defects, and pulmonary venous abnormalities [87]. The risk of aortic dissection or rupture increases dramatically in pregnancy, and is associated with a 2% risk of mortality [88]. It is therefore critical that women with Turner's syndrome planning pregnancy (usually through *in vitro* fertilization), have a full medical evaluation, with particular attention paid to the cardiovascular system, before fertility treatment is considered [89].

Pelvic and abdominal examination: Abdominal and pelvic palpation should be performed on all women presenting with menstrual dysfunction or infertility. A palpable mass may suggest uterine fibroids or an ovarian mass. Scars indicate previous surgery, which may be a consequence of gynaecological disease (e.g. previous surgical treatment for endometriosis), or may be a cause of infertility due to subsequent adhesion formation. Tenderness on pelvic palpation may suggest pelvic inflammatory disease, ovarian cysts, or endometriosis.

Gynaecological examination: Gynaecological examination should be performed by a clinician with appropriate experience. Patient consent should be requested before conducting a gynaecological examination, and a chaperone offered, regardless of whether the clinician performing the examination is a male or female [90]. Some women may experience substantial fear, embarrassment, or anxiety regarding gynaecological examinations, which can be related to previous pelvic examinations, or rarely due to previous traumatic experiences such as sexual abuse or assault [91]. Providing an explanation of each step of the procedure, having a considerate and sensitive approach to examination and, have both been found to improve patient experience during a vaginal examination [92]. Patients should always be given the opportunity to stop the examination at any point, and clinicians should be sensitive to signs of patient discomfort. The external genitalia should be examined first. Vulval and vaginal atrophy, thin reddened skin, and lack of lubrication are signs of oestrogen deficiency. Clitoral hypertrophy is a sign of virilization and can be associated with congenital adrenal hyperplasia, androgen-secreting ovarian or adrenal masses, or androgen insensitivity syndrome [93]. External genitalia should be examined for female genital mutilation, also known as female circumcision or female genital cutting, which is a common cultural practice in some parts of Africa and Asia, affecting more than 125 million females worldwide [94], and increasingly seen by clinicians throughout the world as a result of immigration. Female genital mutilation should be classified according to the World Health Organization, and clearly documented. Infertility is more common in women with female genital mutilation, and there is a positive association between the anatomical extent of female mutilation and infertility [95]. Furthermore, women with female genital mutilation are significantly more likely than those without female genital mutilation to have adverse obstetric outcomes, with greater risks associated with more extensive female genital mutilation [96]. Anatomical abnormalities of the vagina and cervix should be assessed, including an intact hymen, transverse vaginal septum, or Müllerian agenesis, especially in cases of primary amenorrhea. Speculum examination is appropriate to examine the vagina and cervix. Abnormal mucopurulent discharge may signify infection and should be further investigated. A bimanual examination can be performed to assess the uterus for size, shape, position, and mobility, and the adnexae for tenderness or masses. Uterine enlargement, irregularity, or lack of mobility are signs of a uterine anomaly, including fibroids, endometriosis, or pelvic adhesions. Tenderness or masses in the adnexae or recto-uterine pouch is consistent with chronic pelvic inflammatory disease, ovarian cysts, or endometriosis. Endometriosis may also cause palpable tender nodules in the posterior fornix, recto-uterine pouch, uterosacral ligaments, or rectovaginal septum [97].

Secondary sexual characteristics: If indicated by the history, clinical examination of secondary sexual characteristics should be performed, including pubic hair and breast development, as assessed by Tanner stages (Figure 8.2.1.1) [98]. Tanner stages rate sexual maturity for pubic hair and breast development in five stages, with stage one representing pre-puberty and stage five

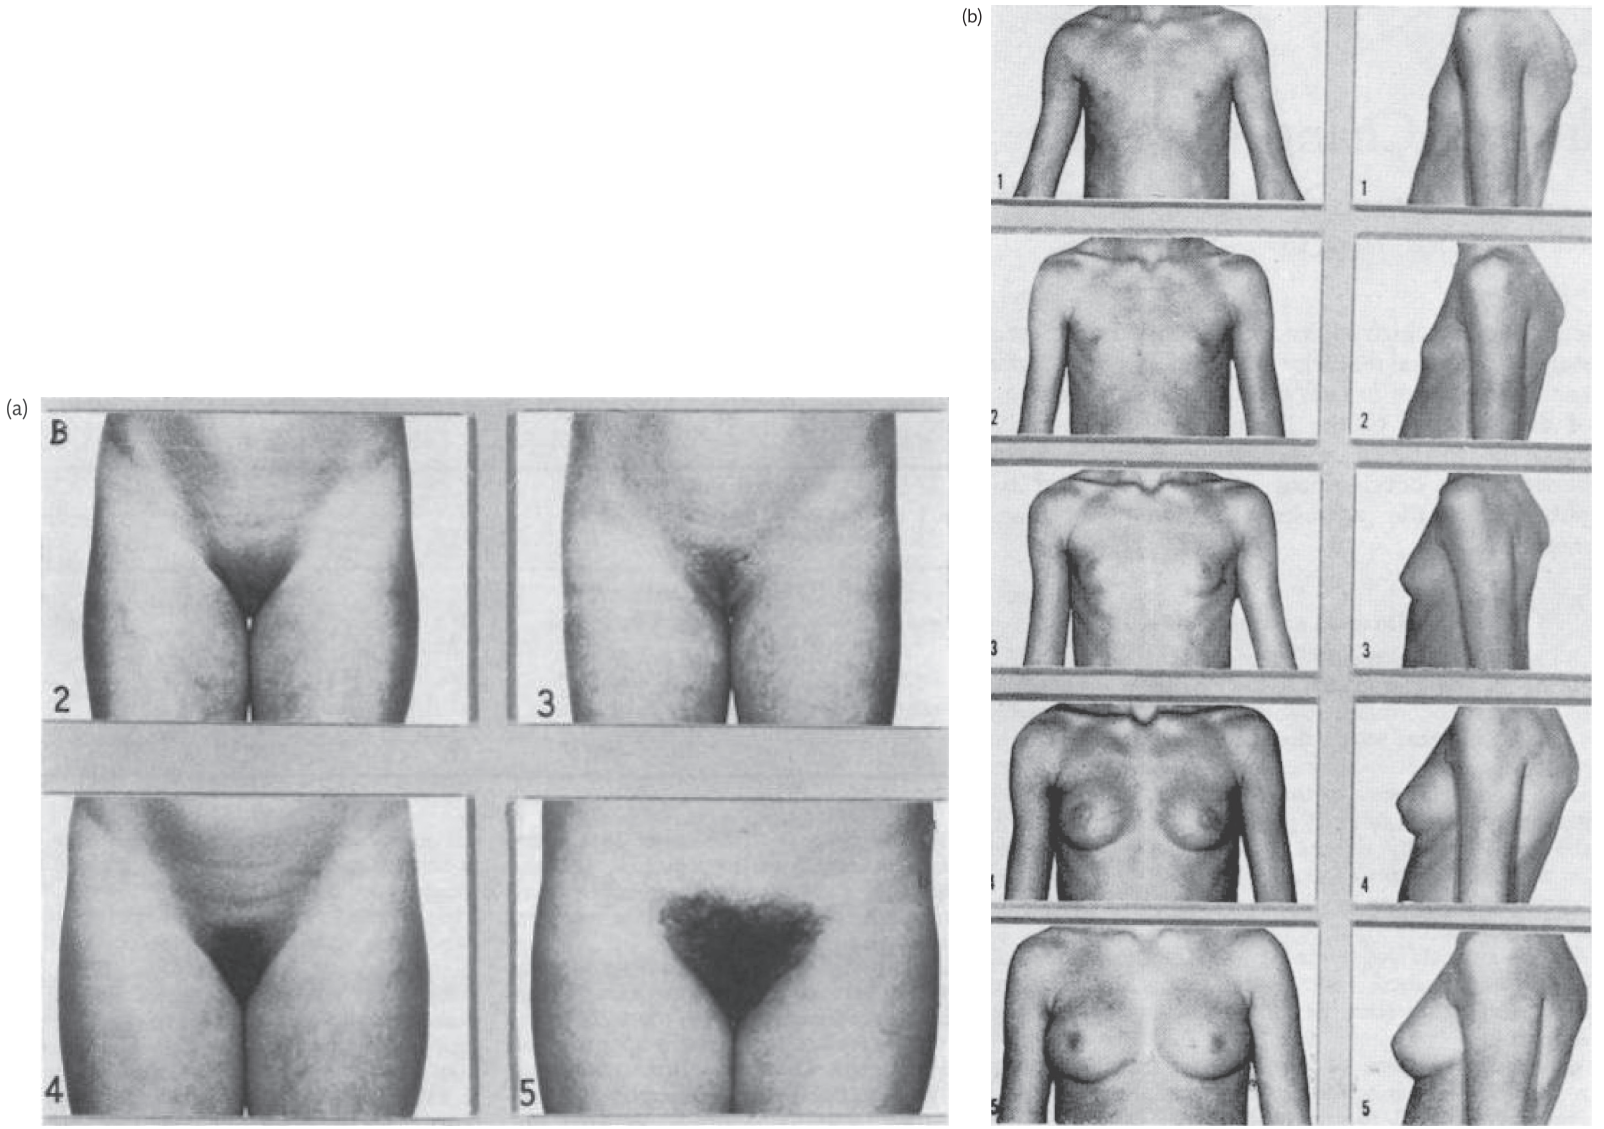

Figure 8.2.1.1 Tanner stages for rating sexual maturity. The secondary sexual developments of pubic hair and breast changes are assigned stages from 1 (pre-adolescent) to 5 (mature). Pubic hair development: Stage 1: Pre-adolescent; Stage 2: Sparse growth of long, slightly pigmented hair, straight, or curled along labia; Stage 3: Considerably darker, coarser, and more curled; Stage 4: Adult type but considerably smaller area; Stage 5: Adult in quantity and type. Breast development: Stage 1: Pre-adolescent; Stage 2: Breast bud stage; Stage 3: Further enlargement of breast and areola with no separation of their contours; Stage 4: Projection of the areola and papilla to form a secondary mound; Stage 5: Mature stage with projection of papilla only.

representing mature adult development. Incomplete pubertal development is usually associated with primary amenorrhea, and suggests oestrogen deficiency, which could be caused by hypothalamic or pituitary dysfunction, ovarian failure, and/or a chromosomal abnormality.

8.2.2 Laboratory Evaluation

Daniel Dumesic and Zain Al-Safi

Hormonal Evaluation

β-hCG

In cases of abnormal uterine bleeding (irregular, heavy or absent), it is important to rule out pregnancy. Measuring urine or serum β-hCG should be the initial laboratory evaluation in these women. Therefore, all patients with menstrual bleeding disorders should be tested for pregnancy.

Oestradiol, Progesterone, LH, and FSH

Measuring serum gonadotropins (FSH, LH) along with serum oestradiol and progesterone levels provides information to aid in the diagnosis of hypothalamic, pituitary, and ovarian causes of amenorrhea or oligomenorrhea. It can rule out causes such as ovarian insufficiency when elevated serum FSH and LH levels accompany low serum oestradiol (<20 pg/ml) and progesterone (<1 ng/ml) levels, indicating low or absent ovarian reserve.

Finding a transient elevation in serum FSH and LH levels with serum oestradiol levels <150 pg/ml and progesterone <2 ng/ml can indicate the midcycle ovulatory gonadotropin surge [1].

Compared to normal women, women with functional hypothalamic amenorrhea have a 53% reduction in LH pulse frequency but comparable LH pulse amplitude [2]. In these women, the diagnosis of functional hypothalamic amenorrhea is made after excluding other causes such as severe weight loss, excessive exercise resulting in low body fat, severe psychological stress, and physical wasting from severe systemic diseases (i.e. disseminated malignancies and pituitary or central nervous system lesions). Serum LH and FSH

levels are often normal; however, very low and often undetectable serum LH and FSH levels suggest organic hypothalamic amenorrhea due to genetic mutations affecting gonadotropin-releasing hormone (GnRH) production and function or central causes, such as pituitary, hypothalamic, or other brain tumours, and infiltrative lesions [1]. Patients with hypothalamic amenorrhea characteristically have a low level of serum oestradiol and low or low-to-normal levels of LH and FSH, whereas the gonadotropin response to GnRH stimulation can be preserved.

Serum oestradiol assessment can be limited by factors related to the assay used, such as poor sensitivity, variation among assays, and the fact that a measurement reflects a single time point [3].

Low serum oestradiol and progesterone (<1 ng/ml) levels are consistent with anovulation and may be seen in women with underlying polycystic ovary syndrome (PCOS). An elevated serum LH to FSH ratio previously has been reported in PCOS patients, but neither circulating levels of LH and FSH, nor the ratio of serum LH to FSH contribute significantly to the diagnosis of PCOS, particularly since LH secretion is pulsatile in nature and one-third of PCOS patients have normal circulating LH levels. Moreover, LH secretion and pulse amplitude are inversely related to body mass index (BMI) and percent body fat, suggesting that obesity in PCOS patients further modifies gonadotropin secretion [4].

Serum FSH and oestradiol checked on cycle days 2–4 can help to measure ovarian reserve. Serum FSH concentration starts to increase early in the menstrual cycle with diminished ovarian reserve and in reproductive ageing, but the assays have significant inter- and intracycle variability limiting their reliability [5].

Basal oestradiol alone should not be used to screen for diminished ovarian reserve. The test can aid to correctly interpret basal serum FSH value. With lower ovarian reserve as normally occurs with reproductive ageing, there is an early rise in serum oestradiol levels that can lower an otherwise elevated basal serum FSH concentration into the normal range

Anti-Müllerian hormone is another measure for ovarian reserve and is discussed later in this section.

Androgens (Testosterone, DHEAS)

Measuring serum testosterone is essential to identify hyperandrogenaemia as one of the criteria for diagnosing PCOS. Testosterone is produced either directly by the ovary or adrenal gland, or indirectly through metabolism of secreted androstenedione or DHEA (or its sulphate DHEAS) in peripheral tissues, such as fat and skin [6]. Approximately 50% of testosterone arises from peripheral conversion of androstenedione, whereas 25% is secreted by the ovaries and an additional 25% by the adrenal. LH is the stimulus for ovarian testosterone production.

High serum testosterone values in the adult-male range may indicate the presence of an androgenic tumour, while only a moderate increase of this androgen is a poor predictor of androgenic tumours. Androgen-producing ovarian tumours are uncommon, occurring only in about 1 in 500 hirsute women [7]. Ovarian tumours that produce androgens directly include Sertoli–Leydig cell tumours (androblastoma, arrhenoblastoma), granulosa-theca cell (stromal cell) tumours, and hilus cell tumours. Nevertheless, any large ovarian tumour (i.e. cystic teratomas, Brenner tumours, serous cystadenomas, and Krukenberg tumours) can produce androgens indirectly by causing hyperplasia of the surrounding normal stroma [8].

Several limitations exist, however, in measuring testosterone, which include lack of a standardized assay; poor sensitivity and accuracy in the female range; and variability based upon menstrual cycle phase, time of day, and feeding [9]. Avoiding interference by steroids of similar configuration requires extraction and separation of other circulating steroids chromatographically before subjecting the sample to immunoassay or mass spectrometry [9].

Serum total testosterone levels are above the upper normal limit in about 50% of women with PCOS by 1990 NIH criteria [10]. There is an overlap in total testosterone values between PCOS patients and normal women. When measured by liquid chromatography–mass spectrometry (LC-MS/MS), serum total testosterone levels that best distinguish PCOS from normal women are approximately 50 ng/dl in the general population (10% estimated PCOS prevalence) and 35 ng/dL in the clinical or referred, setting (70% estimated PCOS prevalence) [11].

Measuring free testosterone is recommended by the 2004 Rotterdam consensus to detect hyperandrogenism in PCOS women [12]. Free testosterone is more sensitive than total testosterone in assessing hyperandrogenaemia [13]. As a surrogate of free testosterone by equilibrium dialysis, the free androgen index (FAI) is calculated by measuring sex hormone binding globulin (SHBG) and total testosterone [14]. The FAI is elevated in about 54–89% of women with PCOS by 1990 NIH criteria [10, 15]. The FAI also is elevated in 30% of women with PCOS by Rotterdam criteria who have normal total testosterone levels, thereby identifying a subset of these PCOS women who should be considered as hyperandrogenic [15].

Serum levels of total testosterone in excess of 200 ng/dL are suspicious for an ovarian androgen-producing tumour. However, the best predictor of an androgen secreting neoplasm is virilization defined as male temporal balding, deepening of the voice, and enlargement of the clitoris, which occurs in 98% of such tumours, regardless of circulating testosterone levels [16].

The value of routinely measuring circulating androstenedione or DHEA as precursors of testosterone in hyperandrogenic women is more controversial. Serum androstenedione and total testosterone levels are elevated in 88% and 65% of PCOS women by Rotterdam criteria, respectively [17]. The combined use of total testosterone, androstenedione and FAI identifies hyperandrogenaemia in about 90% of PCOS patients [15].

Elevated serum DHEAS levels occur in 40–70% of hyperandrogenic women with PCOS [18]. Although increased in women with symptoms of androgen excess, only 16% of hyperandrogenic women have increased serum DHEAS in the presence of normal total and free testosterone levels [7]. Conversely, low serum DHEAS levels can occur in adolescents and young women with functional hypothalamic amenorrhea from anorexia nervosa, despite hypercortisolism and adequate adrenocorticotropic hormone (ACTH) [19, 20]. Measuring serum DHEAS, however, should be considered to rule out adrenal aetiologies [1]. In general, measurements of DHEAS are of lower yield unless indicated by clinical findings of severe hirsutism with high concentrations far exceeding the normal range (>6000 ng/dl), suggestive of an adrenal tumour [21].

17 α-Hydroxyprogesterone (17 OHP)

A basal serum 17-OHP level is useful to exclude late-onset congenital adrenal hyperplasia (CAH) due to 21-hydroxylase deficiency. It must be remembered, however, that an elevated basal serum 17-OHP level can also represent a normal finding in the luteal phase of the menstrual cycle [22], and can be repeated in the follicular phase of the menstrual cycle if necessary.

Random measurements of basal serum 17-OHP may be normal in mildly affected non-classic patients unless performed in the early morning (i.e. before 08.00 h) [23].

A morning serum 17 OHP level more than 200 ng/dL should prompt a measurement of serum cortisol and 17OHP at 30 to 60 minutes after ACTH administration (250 mcg intravenous or intramuscular). Post-ACTH 17OHP values in the 1000–10000 ng/dl range are typical of non-classic 21 hydroxylase enzyme deficiency [24–26]. If laboratory data are equivocal, genetic testing for mutations in the *CYP21A2* gene on DNA from peripheral blood cells is available.

Prolactin

A single measurement of serum prolactin level is usually adequate to document hyperprolactinemia. Prolactin secretion, however, is pulsatile and stress, as well as a number of physiological states such as sleep, and exercise can also mildly elevate prolactin levels. For these reasons, a test that shows a level of 25–40 ng/ml should be repeated before hyperprolactinemia is diagnosed [27]. When other causes of hyperprolactinemia have been ruled out (including medication intake) on the basis of history, physical examination, and assessment of thyroid and renal function, the diagnosis of a prolactinoma can be confirmed by gadolinium-enhanced magnetic resonance imaging (MRI) (see later in this section).

In general, serum prolactin levels are correlated with tumour size. Values between upper limits of normal and 100 ng/ml may be due to drugs or idiopathic causes, but can also be caused by microadenomas. Macroadenomas are typically associated with levels of over 250 ng/ml, and in some cases the level exceeds 1000 ng/ml [27, 28]. Care must be taken in interpreting a moderate elevation of the prolactin level (<100 ng/ml) in the presence of a macroadenoma, as this may be due to either compression of the pituitary stalk by the tumour or these values can be artificially low due to the 'hook effect'. The 'hook effect' occurs when a very high serum prolactin level saturates both the capture and signal antibodies used in immunoradiometric and chemiluminescent assays, preventing the binding of the two in a 'sandwich'. The artefact can be avoided by repeating the assay with serial serum dilution [29].

The degree of prolactin elevation correlates with the severity of hypogonadism. High prolactin levels greater than 100 ng/ml are associated with hypogonadism and low serum oestradiol levels, which result in amenorrhoea and vaginal dryness; while levels of 50 to 100 ng/ml can be associated with both oligomenorrhea and amenorrhea, and levels of 20 to 50 ng/ml can result in insufficient progesterone secretion and luteal phase shortening that may result in subfertility [30].

In PCOS, elevations in serum prolactin have been reported to occur and likely represent lactotrope stimulation by chronic oestrogen exposure [31, 32] rather than coexistence of a prolactinoma.

Growth Hormone

Growth hormone (GH) is secreted by the anterior pituitary somatotroph cells in a pulsatile fashion. Over 95% of patients with acromegaly harbour a GH secreting pituitary adenoma arising from somatotroph cells, leading to GH and insulin-like growth factor-1 (IGF-1) hypersecretion.

Patients with clinical features of acromegaly or with a pituitary mass require biochemical evaluation. Serum IGF-1 measurement is recommended as the initial screening as it is the best marker for integrated GH secretion [33]. A normal serum IGF-1 level effectively excludes the diagnosis of acromegaly. Hepatic and renal failure, hypothyroidism, malnutrition, severe infection, and poorly controlled diabetes mellitus may cause falsely elevated, normal, or low IGF-1 values [33]. Levels must be assessed in age-appropriate normal values with knowledge of the specific assay being used due to significant interassay variability [34].

Random measurements of GH are not useful due to the pulsatile nature of its secretion and the significant level variation throughout the day and in response to stimuli.

A dynamic test, such as an oral glucose tolerance test, is more specific and can be used to establish the diagnosis in those with elevated or equivocal IGF-1 levels. Normally GH should decrease to 1 ng/ml or less within 2 hours after ingestion of 75 g of glucose, and so a nadir serum GH level < 1 ng/ml excludes the diagnosis [35].

Anti-Müllerian Hormone (AMH)

AMH is a homodimeric disulphide-linked glycoprotein of the transforming growth factor-β (TGF-β) superfamily [36]. AMH level is lowest at birth and remains low during the prepubertal years; it then peaks during puberty and ultimately declines to undetectable levels at menopause [37, 38]. During ovarian follicle development, minimal AMH is produced by primordial follicles as was shown in immunohistochemistry studies in human ovarian tissue confirming the absence of AMH staining in primordial follicles [39]. The production of AMH increases in pre-antral and early antral follicles until a follicular diameter of 8 mm after which a sharp decline occurs [40]. It was demonstrated that 5–8 mm sized follicles contribute 60% of the circulating AMH. In contrast, granulosa cells of larger preovulatory follicles beyond 10 mm fail to produce AMH [40].

Anti-Müllerian hormone has been suggested as an ideal marker for assessing the remaining oocyte pool because it correlates with antral follicle counts (AFC), outcomes from ovarian stimulation, and the onset of menopause [41, 42]. AMH level can be an additional helpful assessment measure in women with PCOS [43], as it has been shown to correlate with polycystic ovaries. Serum AMH levels in women with PCOS are elevated 2- to 3-fold and are positively correlated with AFC and serum androgen levels [44, 45]. High serum AMH is specific but not sensitive to distinguish PCOS from asymptomatic women with polycystic ovaries [46].

Thyroid Hormone

The diagnosis of thyroid disease is easily made with modern immunoassays. Thyroid stimulating hormone (TSH) is the initial test to diagnose thyroid disease linked with reproductive dysfunction. An elevated serum TSH level greater than 10 mIU/L indicates hypothyroidism.

Clinical hypothyroidism is defined by both elevated serum TSH levels and reduced serum free T_4 concentrations, while subclinical hypothyroidism describes the mild or early changes when the TSH rises before the free T_4 falls below normal. The mild elevation in TSH compensates for the early decline in T_4 production by the thyroid.

During pregnancy, trimester-specific and lab-specific reference ranges should be used to determine the optimal serum TSH range and the diagnosis of clinical hypothyroidism [47].

Although not necessary for the diagnosis of hypothyroidism, additional tests of thyroperoxidase and antithyroglobulin antibodies may influence treatment decisions by establishing underlying Hashimoto thyroiditis.

Serum TSH measurement has the highest sensitivity and specificity of any single blood test used to evaluate suspected thyrotoxicosis and should be used as an initial screening test [48]. However, when thyrotoxicosis is strongly suspected, diagnostic accuracy improves when a serum TSH, free T_4, and total T_3 are assessed at the initial evaluation [49].

The diagnosis of thyrotoxicosis is clear with elevated free T_4 and low TSH levels. However, a low TSH level with a low or normal free T_4 level has several additional diagnoses to consider other than subclinical hyperthyroidism. Diagnosis of thyrotoxicosis during pregnancy should be made more cautiously than hypothyroidism, because the serum TSH level can be low in the first trimester due to hCG-mediated thyroid stimulation. Thyroid binding globulin is elevated during a normal pregnancy and so serum total T_4 would be increased accordingly. Serum free T_4 concentration can be measured instead and will be elevated in overt hyperthyroidism.

Cortisol

ACTH-dependent or independent endogenous Cushing syndrome may need to be ruled out in certain scenarios. Cushing's syndrome may arise from a cortisol-producing tumour of the adrenal gland or from an ACTH-producing pituitary adenoma (Cushing's disease). Cushing syndrome is a rare cause of androgen excess in women and may be mistaken for PCOS. Screening for Cushing syndrome is indicated if clinical signs of Cushing's syndrome are suspected, including obesity, increased fat over the face (moon faces), trunk, and cervico-dorsal as well as supraclavicular regions, hypertension, easy bruising from thinning of the skin, impaired glucose tolerance, muscle wasting of the upper legs and arms, osteoporosis, and purple abdominal striae. Other manifestations include hirsutism, acne, and irregular menses. Mental disturbances include excessive euphoria, irritability, insomnia, and depression. Depression may occur due to excess cortisol action on the CNS limbic system.

The initial screening tests for hypercortisolism (after ruling out exogenous glucocorticoid use) include: 24-hour urine free cortisol, overnight dexamethasone suppression test, or late-night salivary cortisol [50]. Both false-positive and false-negative results are common. Consequently, tests often must be repeated before a diagnosis can be made or excluded. Once hypercortisolism is confirmed, an ACTH measurement will determine if the disease is ACTH-dependent or ACTH-independent.

Patterns of hormonal changes with different endocrine disorders are summarized in Table 8.2.2.1.

Imaging Studies

Head Imaging

This can be performed with computed tomography (CT) or more commonly with brain MRI with gadolinium enhancement to provide better details. MRI is the single best imaging procedure for most sellar masses, and there is usually no need to perform any other imaging study. Specific appearance depends on the underlying aetiology:

Craniopharyngioma: Both CT and MRI can be helpful in diagnosing craniopharyngiomas. CT can show calcification that is characteristic of the adamantinomatous subtype, whereas MRI with gadolinium enhancement provides better structural analysis.

Rathke's cleft cyst: Most cysts are small and discovered incidentally by MRI. The MRI characteristics include a sellar and/or suprasellar, symmetrical, round, or ovoid mass that enhances on either T_1 or T_2-weighted images but does not concentrate gadolinium. MRI often shows a hypointense sellar lesion with rim enhancement and a hyperintense signal in the T_2-weighted images. Hyperintensity on T_1-weighted images and isointensity on T_2-weighted images

Table 8.2.2.1 Common causes of abnormal menstrual bleeding and accompanying laboratory patterns

	LH (IU/L)	FSH (IU/L)	LH/FSH	E2 (pg/mL)	P4 (ng/mL)	AMH (ng/mL)	PRL (ng/mL)	TSH (μU/mL)	T4 (μg/dL)	DHEA-S (μg/dL)	17 OHP (ng/dL)	T (ng/dL)
Functional hypothalamic anovulation	<10	<10	~1	<50	<1	>1	Low nl	Low nl	Low nl	nl	nl	Low nl
Ovarian insufficiency menopause	>15	>15	FSH>LH	<50	<1	<0.5	nl	nl or ↑	nl or ↓	nl	nl	Low nl
PCOS	<15	<10	LH>FSH	<50	<1	nl or ↑	High nl	nl	nl	High nl	nl	High nl or slight ↑
Non-classical CAH	<15	<10	LH>FSH	<50	≤1	nl	nl	nl	nl	High nl	↑	↑
Hyperprolactinemia	<10	<10	LH<FSH	<50	<1	nl	↑	nl or ↑	nl	nl or slight ↑	nl	nl

Abbreviations: 17OHP, 17-hydroxyprogesterone; nl, normal; P4, progesterone; PRL, prolactin; T, testosterone.

suggests that mucoid material is present in the cyst; hyperintensity in both T_1- and T_2-weighted images suggests the presence of blood.

Sarcoidosis: Lesions can appear as subdural plaques or infundibular plaques, infiltrating masses, or as multiple nodules on MRI studies.

Langerhans cell histiocytosis: Findings on MRI are abnormal in most patients with Langerhans cell histiocytosis and endocrinopathy. Most common abnormalities on MRI include the loss of the posterior pituitary bright spot on T1-weighted images and infundibular enlargement. Other less common radiological abnormalities include a thickened infundibular stalk, a partially or completely empty sella, and lesions in the hypothalamus [51].

Prolactinoma: Head MRI should be performed in a patient with any degree of hyperprolactinemia to identify a mass lesion in the hypothalamic–pituitary region, unless the patient is taking a medication known to cause hyperprolactinemia. MRI may show either a micro (<1 cm) or macro (>1 cm) adenoma. Most microadenomas have lower signal intensity than the normal bright pituitary gland on T1-weighted images, and they usually do not distort the architecture of the gland. A convex outline of the pituitary gland or deviation of the pituitary stalk can also be detected [52].

The enhancement of macroprolactinomas with gadolinium is quite variable. These macroprolactinomas may distort the architecture of the gland with the inferior portion, as they also tend to invade the cavernous sinus and erode the bony floor [52].

If a mass lesion is found in the sellar region, secretion of other pituitary hormones should also be evaluated. A pituitary adenoma can cause hypersecretion of other pituitary hormones, but any sellar mass can cause hyposecretion of one or more pituitary hormones.

Pituitary apoplexy: Pituitary apoplexy can be confirmed by MRI in essentially all cases, while CT may not show this disorder in 54% to 79% of patients [53]. However, because vascular emergencies are more common than pituitary apoplexy, head CT is often the first procedure performed to evaluate the symptoms that are common to both conditions.

Sheehan's syndrome: In the early stage of Sheehan syndrome, MRI shows an enlarged pituitary; in later stages, an empty sella can be present [54], with the typical finding of intrasellar cerebrospinal fluid (CSF) filling in continuity with overlying subarachnoid spaces, and residual pituitary gland with a semi-lunate morphology flattened against the sellar floor [55].

Lymphocytic hypophysitis: MRI often shows an enlarged pituitary mimicking an adenoma, sometimes with suprasellar extension and occasionally with thickening of the infundibulum. In rare cases, an empty sella is present [56].

Functional hypothalamic amenorrhoea: If there are no clear indications or other explanations for the amenorrhea (an eating disorder such as anorexia nervosa or history of excessive exercise, or weight loss), brain MRI should be considered [1]. Empty sella syndrome can also be present as an underlying diagnosis [57]. A history of significant head trauma should raise suspicion of pituitary stalk damage and associated pituitary hormone deficiencies [1].

Ovarian Imaging

In 2003, a polycystic ovary was defined at a consensus conference in Rotterdam, Netherlands as having 12 or more follicles per ovary, measuring 2–9 mm in diameter irrespective of location, or an ovarian volume of greater than 10 cm^3 [12]. With newer equipment and advanced technology, however, the precision of counting follicles has improved. A recent task force report recommends that the threshold for polycystic ovary morphology based on follicle count should be increased to greater than 25 follicles per ovary to avoid overinterpretation of polycystic ovary morphology and misdiagnosis of PCOS [58]. This new recommendation warrants further investigation and may need to be adjusted by patient age.

While the sonographic evidence of polycystic ovaries in the presence of clinical or biochemical hyperandrogenism and/or oligoanovulation is regarded as confirmatory for PCOS, polycystic ovary morphology can occur in normal ovulatory women without a history of hyperandrogenism [59]. Moreover, the polycystic ovary should not be confused with ultrasound appearance of an ovary containing multiple small antral follicles in women recovering from hypogonadotropic hypogonadism. Therefore, the implication of a multifollicular ovary or polycystic ovary should be considered within the clinical setting. Few cysts are seen in severe hyperthecosis and the ovaries appear more solid [60].

Pelvic ultrasound (US) may be helpful to rule out structural causes for abnormal uterine bleeding such as fibroids or polyps, but currently, there are not enough data to support measuring endometrial thickness to evaluate premenopausal women with abnormal uterine bleeding. On the other hand, thin endometrium (less than 4 mm) can be seen in women with hypoestrogenic causes of amenorrhea.

When clinically indicated and supported by severe androgen excess, e.g. testosterone levels exceeding 200 ng/dl, a pelvic ultrasound is warranted to rule out ovarian virilizing tumours. In addition, some granulosa cell tumours produce oestrogen and may present with symptoms of unopposed oestrogen, depending on their age of presentation.

Virilizing tumours of the ovary are most commonly solid, non-calcified, and unassociated with ascites [61]. Steroid cell tumours, Leydig tumours, and Sertoli–Leydig cell tumours are characteristic virilizing neoplasms. Leydig cell tumours are usually small tumours (mean size 2.4 cm) that may be difficult to depict via different imaging methods, and are reportedly isoechoic to the uterus by sonography and hypoattenuating by CT [62].

Sertoli–Leydig cell tumours (mixed sex cord-stromal tumours) have a non-specific appearance. On US, these tumours usually present either as a distinct hypoechoic mass or a heterogeneous mass that is primarily solid with multiple cystic spaces. Small virilizing Sertoli–Leydig cell tumours may be easily detected using colour Doppler US rather than transvaginal US alone [62, 63].

Granulosa cell tumours are typically unilateral masses (average size, 12 cm) [62]. Although granulosa cell tumours are the most common oestrogen-producing tumours, a small subset is androgenic [62, 63]. Women typically present with hyperoestrogenicity, including abnormal uterine bleeding [62, 63].

Variability in appearance depends in part on tumour type, with Sertoli–Leydig tumours mostly solid and virilizing granulosa cell tumours more cystic [61].

Ultrasound is typically sufficient for the evaluation of adnexal masses, but MRI may be used if further characterization of an adnexal mass is needed. If metastatic disease is expected and preoperative evaluation is attempted, CT, MRI, or positron emission tomography (PET) may be needed.

Adrenal Imaging

DHEAS levels exceeding 6000–7000 ng/dl (or testosterone levels >200 ng/dl) may be associated with an androgen-producing tumour of the adrenal gland [21]. Imaging studies of the adrenal glands may be considered to locate the lesion.

Although CT remains the primary adrenal imaging procedure [64], MRI has advantages in certain clinical situations to characterize local invasion from adrenal carcinoma without exposure to ionizing radiation.

The maximum diameter of the adrenal mass is predictive of malignancy. Most adrenal adenomas are less than 4 cm in diameter. In contrast, most adrenal carcinomas are greater than 4 cm in diameter when discovered [65].

Bone Density Imaging

After 6 months of amenorrhea, clinicians should consider a baseline bone density evaluation in any adolescent or woman with functional hypothalamic amenorrhea [1].

Dual energy X-ray absorptiometry (DXA) is the most commonly used densitometric technique for adolescents and adults throughout the world because of its speed, precision, safety, low cost, and widespread availability [1]. Z-score should be used in adolescents or premenopausal women (as opposed to T-score in postmenopausal women) as recommended by the International Society for Clinical Densitometry. A Z-score of –2.0 or lower is defined as 'below the expected range for age', and a Z-score above –2.0 is 'within the expected range for age' [66]. The Z-score compares the bone density measure to age-, sex-, and race-matched controls.

The goal of bone densitometry is to identify individuals with low bone mass who are at increased risk for skeletal fragility, and to guide and monitor treatment [67]. Baseline bone mineral density at –2.0 or less at any skeletal site has the greatest risk for fractures, and in these patients, clinicians should attentively monitor nutritional intake and a patient's skeletal status [67].

The spine (a trabecular-rich site) is the most common site of low bone density in adolescents and young women with amenorrhea and also predicts fracture risk; it is therefore an important site to monitor [68–71]. In older adolescents (above age 15 years) and women with functional hypothalamic amenorrhea, measuring hip bone density gives information about weight-bearing cortical bone and can be useful to monitor bone density longitudinally [67].

In one study of 130 young females with anorexia nervosa (mean age 24 years), more than 90% had osteopenia and nearly 40% met World Health Organization (WHO) criteria for osteoporosis (T-score ≤ 2.5) [72].

Patients with primary ovarian insufficiency on average have 2–3% lower bone mineral density at L1–L4, femoral neck, and total hip. More than 1-year delay in the diagnosis of oestrogen deficiency is a risk factor for reduced bone mineral density below the expected range for age (Z-score < -2) [73].

Thyroid Imaging

Radioactive iodine scans are not necessary to make the diagnosis of hyperthyroidism but are most useful for distinguishing Graves' disease from toxic adenoma, thyroiditis, and factitious disorder. Usually, clinical factors often obviate the need for diagnostic scans, especially since radioactive iodine scans are contraindicated during pregnancy.

In pregnancy, breastfeeding, or women trying to conceive, ultrasonography with Doppler blood flow may be useful for distinguishing Graves' disease from thyroiditis. The need for experienced technicians and radiologists, however, limits the ability to recommend the general use of ultrasonography for this purpose [47].

Other Tests

These tests may be indicated when encountering a diagnosis of hypergonadotropic hypogonadism related to spontaneous primary ovarian insufficiency (i.e. non-iatrogenic). Insulin resistance testing is also listed to be considered when a diagnosis of PCOS is encountered.

Karyotype

Turner syndrome occurs in 1 in 2500–3000 girls and young women [74]. Approximately 50% of patients have a monosomy X with complete loss of one X chromosome (45,X) [75], while the rest may have a mosaic chromosomal complement of 45, X. Therefore, once the diagnosis of primary ovarian insufficiency is established, a karyotype with 30 cells counted is recommended to identify women who have primary ovarian insufficiency related to abnormal karyotype [76].

Fragile X Testing

Premutation in the FMR1 gene (expansion of CGG trinucleotide repeats to 55–200 repeats) can lead to increased risk of primary ovarian insufficiency [77]. FMR1 premutation is found in 14% of patients with familial primary ovarian insufficiency and the prevalence is about 2% in sporadic cases [78]. Testing for FMR1 premutation is helpful to rule out fragile X associated primary ovarian failure and is indicated in these situations.

Autoimmune Testing

Autoimmune primary ovarian insufficiency is associated with multiple endocrine disorders (i.e. hypothyroidism, adrenal insufficiency, hypoparathyroidism, diabetes mellitus, hypophysitis) and non-endocrine abnormalities (chronic candidiasis, idiopathic thrombocytopaenic purpura, vitiligo, alopecia, autoimmune haemolytic anaemia, pernicious anaemia, systemic lupus erythematosus, rheumatoid arthritis, Crohn's disease, Sjögren's syndrome, primary biliary cirrhosis, and chronic active hepatitis) [79–81].

Testing for associated autoimmune conditions in women diagnosed with primary ovarian insufficiency is important to identify the mechanism of the disease (autoimmune lymphocytic oophoritis) [82], and to treat or monitor patients who have these other autoimmune disorders (i.e. polyglandular autoimmune endocrinopathies). These tests include checking for the presence of adrenal autoantibodies by either 21-hydroxylase (CYP21) immunoprecipitation or indirect immunofluorescence [76].

Measurement of serum thyroid autoantibodies is reasonable as thyroid autoimmune disease, most commonly Hashimoto's thyroiditis, is present in 14–27% of women at initial diagnosis [76, 83, 84].

Testing for diabetes with fasting/postprandial glucose or haemoglobin A1c appears justified in those patients with normal karyotype and spontaneous primary ovarian insufficiency [83].

Box 8.2.2.1 Tests for patients with confirmed ovarian insufficiency

Karyotype
Fragile X testing
Adrenal autoantibodies
Thyroid autoantibodies
Testing for diabetes
Testing for pernicious anaemia
Serum calcium
Vitamin D levels
Bone density scan

Other tests to rule out associated autoimmune disorders may be considered, including complete blood count, chemistry panel levels to rule out pernicious anaemia, and hypoparathyroidism, respectively.

These tests that can be ordered in patients with primary ovarian insufficiency are listed in Box 8.2.2.1.

Insulin Resistance Testing

About 60–95% of women with PCOS have insulin resistance [85], as do most women with simple obesity. Therefore, ascertainment of metabolic dysfunction is warranted, particularly in these high-risk individuals. Determining insulin resistance in the presence of euglycemia is limited by the lack of a highly sensitive test that is practical for population-based clinical use [86–88]. Nevertheless, an oral glucose tolerance test is simple and is the best screening measure for detecting glucose intolerance or diabetes, particularly in PCOS women who often have normal fasting glucose levels [89].

Haemoglobin A1C was a strong predictor of the development of glucose-defined diabetes during the Diabetes Prevention Program [90] and its follow-up [91]. Hence, it is reasonable to consider an A1C range of 5.7–6.4% as identifying individuals with prediabetes. Prediabetes should not be viewed as a clinical entity in its own right but rather as an increased risk for diabetes and cardiovascular disease [92]. Similar to those with impaired fasting glucose and/or impaired glucose tolerance, individuals with A1C of 5.7–6.4% should be informed of their increased risk for diabetes and cardiovascular risk and counselled about effective strategies to lower their risks [92]. Haemoglobin A1C of 6.5% or greater can be used as a diagnostic test for diabetes, as suggested by the current guidelines from the American Diabetes Association [92].

The efficacy of interventions for primary prevention of type 2 diabetes [93, 94] has primarily been demonstrated among individuals who have impaired glucose tolerance with or without elevated fasting glucose, not for individuals with isolated impaired fasting glucose or for those with prediabetes defined by A1C criteria.

From a cardiovascular risk perspective, a 2-hour 75-gram oral glucose tolerance test (Table 8.2.2.2), along with a fasting lipid panel (with target levels based on cardiovascular disease risk factors) [95, 96]) should be performed in obese individuals or in lean PCOS women with advanced age (40 years), personal history of gestational diabetes, family history of type 2 diabetes, or other cardiovascular disease risk factors (i.e. smoking, hypertension, etc) [97].

Women with normal glucose tolerance and lipid levels can be rescreened every 2 years or sooner if additional risk factors are identified, while those with impaired glucose tolerance should be screened annually to rule out developing type 2 diabetes [98].

Table 8.2.2.2 Two-hour glucose tolerance test values (values in mg/dl)

	Fasting	2 hour
Normal	<100	<140
Impaired fasting glucose	100–125*	
Impaired glucose tolerance		140–199
Diabetes	≥126	≥200

* It should be noted that the World Health Organization (WHO) and numerous other diabetes organizations define the impaired fasting hyperglycaemia (IFG) cut-off at 110 mg/dl.

8.3

Female Reproductive Endocrinology

8.3.1 Disorders of Gonadotropin Secretion

Sarah L. Berga

Introduction

Folliculogenesis and ovulation require appropriate gonadotropin-releasing hormone (GnRH) input to drive appropriate pituitary secretion of LH and FSH. Ovarian dysfunction either causes or is caused by altered GnRH drive. The myriad of factors that modulate GnRH drive convey information about (1) developmental stage; (2) ovarian function and reserve, including stage of folliculogenesis; (3) energy balance, body composition, and metabolism; (4) circadian and circannual position; (5) stress and emotional states; and (6) cognitive assessments. When hypoestrogenism results from diminished or absent follicle pool, maximal GnRH-LH pulsatility ensues and reflects insensitivity to oestradiol negative feedback [1]. Polycystic ovary syndrome may be viewed as masculinization of the GnRH 'pulse generator' that results in an increase in LH pulse frequency and amplitude accompanied by a decrease in FSH that leads to chronic anovulation and thecal-stromal ovarian hyperstimulation [2]. GnRH-LH drive that is chronically too slow to support full folliculogenesis results in hypothalamic hypogonadism that reflects increased sensitivity to estradiol negative feedback.

Clinically, reduced GnRH drive results in a spectrum of ovarian compromise, ranging from luteal insufficiency to chronic anovulation and a variety of menstrual patterns such as amenorrhoea, polymenorrhoea, menorrhagia, and oligomenorrhoea (Figures 8.3.1.1 to 8.3.1.4). Rarely, there is an organic or congenital cause for reduced GnRH drive, such as brain tumours, coeliac disease, or migration of an insufficient number of GnRH neurons from the olfactory placode into the hypothalamus during fetal development [3].

Typically, the cause of hypothalamic hypogonadism is functional, that is, due to the endocrine consequences of psychological or behavioural variables. Anorexia nervosa provides the most dramatic example, but most women who develop functional hypothalamic hypogonadism (FHH) or functional hypothalamic anovulation and amenorrhea (FHA) do not meet diagnostic criteria for syndromal eating or psychiatric disorders. The nomenclature used to describe FHH reflects behavioural antecedents and also includes exercise amenorrhoea, stress-induced anovulation, functional hypothalamic chronic anovulation, and hypothalamic hypoestrogenism. Reifenstein [4] first introduced the term 'psychogenic amenorrhoea'. Despite the multiplicity of names, the pathogenesis of anovulation is similar. Typically FHH presents as secondary amenorrhoea. The diagnosis requires exclusion of organic causes. The term 'functional' also implies that amelioration of causal behavioural factors will restore ovulatory ovarian function. Support for the concept that the proximate cause of the anovulation in FHA is insufficient GnRH drive was initially provided by showing that administration of exogenous pulsatile GnRH restored folliculogenesis [5–7]. The reduction in GnRH pulsatility manifests in the circulation and can be detected as a reduction in LH pulsatility [8].

Appropriate treatment depends on understanding the psychoneuroendocrinology of FHH. The primary cause of anovulation in FHH is insufficient GnRH drive that reflects altered brain modulation of hypothalamic function in response to perceived or actual psychogenic and metabolic stressors. As shown in Figure 8.3.1.1, FHH is more than diminished GnRH drive and comprises a constellation of neuroendocrine secretory adaptations including obligatory activation of the hypothalamic–pituitary–adrenal (HPA) axis that aligns reproduction with circumstance [8]. Not surprisingly, reduced HPA activation precedes recovery of ovarian function [9, 10]. Appropriate treatment of FHA requires recognizing the critical role GnRH drive for ovarian function and the role of behavioural factors in activating the HPA axis.

Regulation of the GnRH Pulse Generator

The GnRH pulse generator refers to the collective functioning of GnRH neurons residing in the mediobasal hypothalamus that

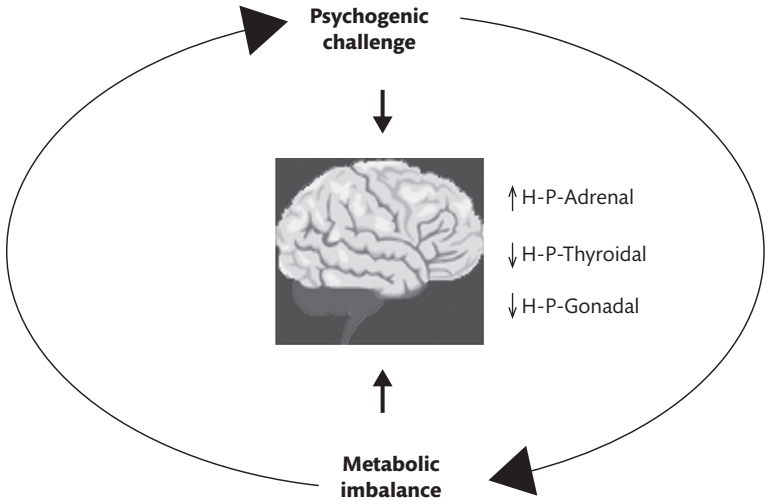

Figure 8.3.1.1 In stress-induced anovulation/functional hypothalamic amenorrhoea, energetic imbalance, and psychosocial challenge synergistically amplify the independent impact of the other upon neuroendocrine outputs to thereby suppress the hypothalamic–pituitary–ovarian (HPO) and hypothalamic–pituitary–thyroidal (HPT) axes, while concomitantly activating the hypothalamic–pituitary–adrenal (HPA) axis.

secrete GnRH into the portal vasculature and thereby regulate LH and FSH release from pituitary gonadotrophs (Figure 8.3.1.2). GnRH neurons are endogenously pulsatile. However, for the bolus of GnRH to be sufficient to trigger gonadotropins release, a group of GnRH neurons must secrete synchronously. Bolus size reflects the cohort size of GnRH-to-GnRH synapses or appositions. The GnRH pulse generator is active during fetal life and then is suppressed by central processes that cause enhanced negative feedback sensitivity to oestradiol until the onset of puberty. HPA activation increases the sensitivity of GnRH to oestradiol inhibition [11]. Figure 8.3.1.3 illustrates a hypothetical scheme to explain how different pulse frequencies might result from varying the size of the GnRH cohort that synchronously releases GnRH pulses into the portal circulation to drive the pituitary release of LH and FSH (Figures 8.3.1.5 and 8.3.1.6).

Figure 8.3.1.7 illustrates the proximate neuromodulatory cascade that alters GnRH function [12]. Behavioural activation of the HPA axis reduces GnRH drive and results in FHH. Hypercortisolaemia, as reflected by increased urinary free cortisol and elevated cerebrospinal fluid levels of cortisol [13], has been demonstrated in amenorrhoeic athletes and non-athletes [8, 10, 14, 15]. Acute nutritional deprivation activates the HPA axis and reduces LH pulsatility [16]. Given the energetic expense of reproduction, it is not surprising that metabolic factors gate reproductive function. Psychosocial influences, including external stressors and attitudes, heighten behavioural reactivity [17–19] and alter the

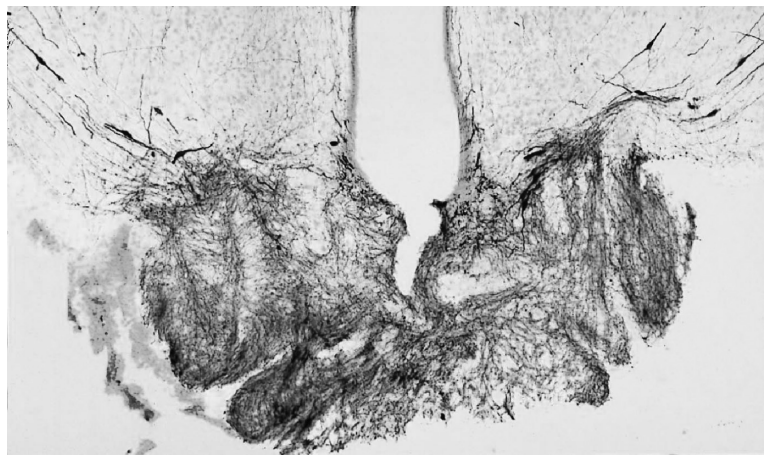

Figure 8.3.1.2 Neuroanatomical photomicrograph of gonadotrophin-releasing hormone pulse generator. Shown is the hypothalamic region from a rhesus monkey. Median eminence and adjacent basal hypothalamus are stained for gonadotrophin-releasing hormone in brown and counterstained with a methyl-grey Nissl stain. Gonadotrophin-releasing hormone neurons are visible at the border of the median eminence, within the median eminence, and within the hypothalamus. The dense accumulation of gonadotrophin-releasing hormone axons occurs where gonadotrophin-releasing hormone axons converge upon the portal loops that carry the gonadotrophin-releasing hormone to the pituitary.

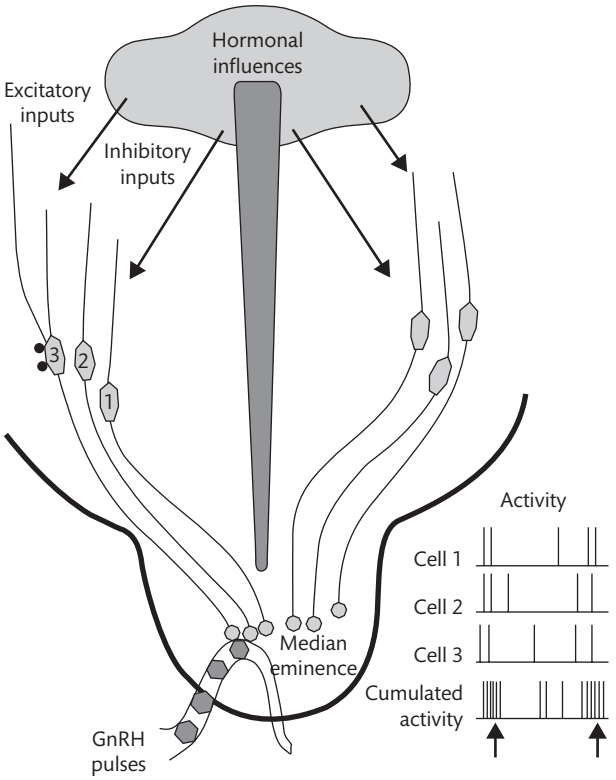

Figure 8.3.1.3 Diagram of the gonadotropin-releasing hormone pulse generator and its modulation. The gonadotrophin-releasing hormone pulse generator and mechanisms of its control are illustrated. The hypothetical activity of three gonadotrophin-releasing hormone neurons is shown in the lower right. When the activity of the neurons is summed at the level of the median eminence, bursts of activity that result in pulses of gonadotrophin-releasing hormone (short arrows) are produced. Some of the factors that influence the firing or release of gonadotrophin-releasing hormone are also illustrated. The gonadotrophin-releasing hormone neurons shown in this figure receive input from other gonadotrophin-releasing hormone neurons, both dendritic (in the form of bridges) and axonal (indicated by the terminal from the unlabelled neuron to cell 3). These cells also receive extrinsic excitatory and inhibitory inputs from neurons in various regions of the brain whose activity, in turn, is greatly modified by gonadal steroids and nutritional signals. In addition, pulse generator activity can be affected by changes in glial investment of gonadotrophin-releasing hormone soma and terminals that influence cohort size. Glia also can reversibly isolate gonadotrophin-releasing hormone cells from extrinsic influences or prevent gonadotrophin-releasing hormone from gaining easy access to the portal vasculature.

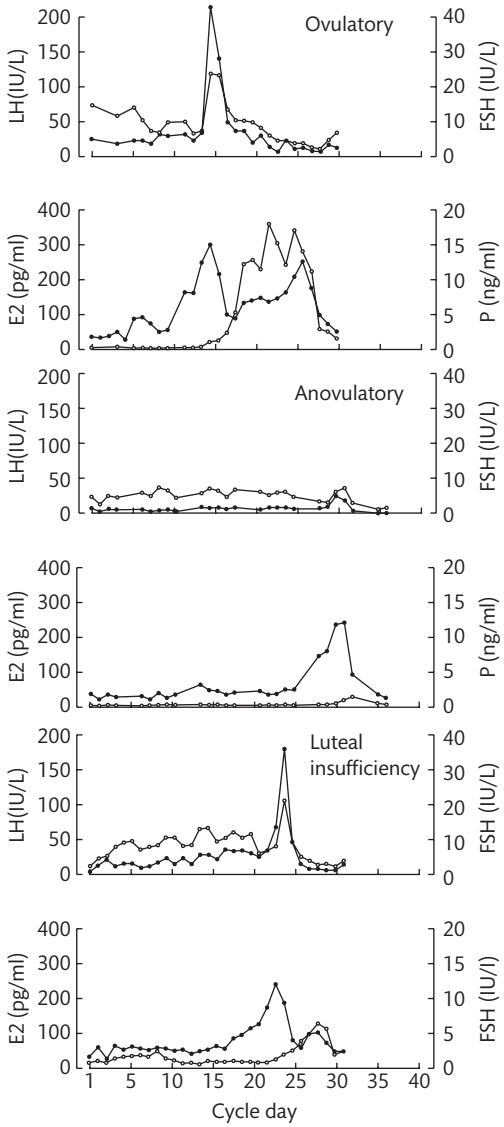

Figure 8.3.1.4 Graph of three types of menstrual cycles: ovulatory, anovulatory, and luteal insufficiency. Blood samples were taken daily or nearly daily across a menstrual interval (from the first day of vaginal bleeding of one cycle to the first day of bleeding of the next cycle) in three women between ages 20–30 years who reported regularly regular menstrual cycles. The top panels for each menstrual cycle type show the gonadotrophins, luteinizing hormone (closed circles) and FSH (open circles). The bottom panels show oestradiol (closed circles) and progesterone levels (open circles). In the ovulatory cycle (top two panels), FSH was highest in the early follicular phase and the luteinizing hormone surge occurred as expected at midcycle. There was the expected preovulatory exponential rise in oestradiol and roughly 14 days of progesterone secretion above 1 ng/ml after the midcycle surge. In the anovulatory cycle (middle two panels), gonadotrophin levels were relatively low, indicating that the cause of the anovulation was not follicular depletion. Late in the cycle, there was an elevation and decline in oestradiol unaccompanied by any significant progesterone secretion. The decline in oestradiol triggered withdrawal bleeding, leading to anovulatory cycling. In the cycle labelled luteal insufficiency (bottom two panels), there was a luteinizing hormone surge, but it occurred around day 22 and progesterone secretion occurred for only 6 days. None of these cycles were clinically distinguishable from the other and all women assumed that they were having normal menstrual cycles although the hormone levels reveal that they were not.

neuroendocrine cascade that modulates GnRH drive [20, 21]. Endocrine-disrupting chemicals, such as bisphenol A and some polychlorinated biphenyls, may sensitize GnRH and kisspeptin neuroregulatory cascades to stressors by modulating GnRH gene transcription and/or by acting as oestrogen agonists or antagonists [22]. Behavioural modifications that reduce cortisol levels reversed the associated neuroendocrine cascade and restored ovulation in women with FHA [23, 24].

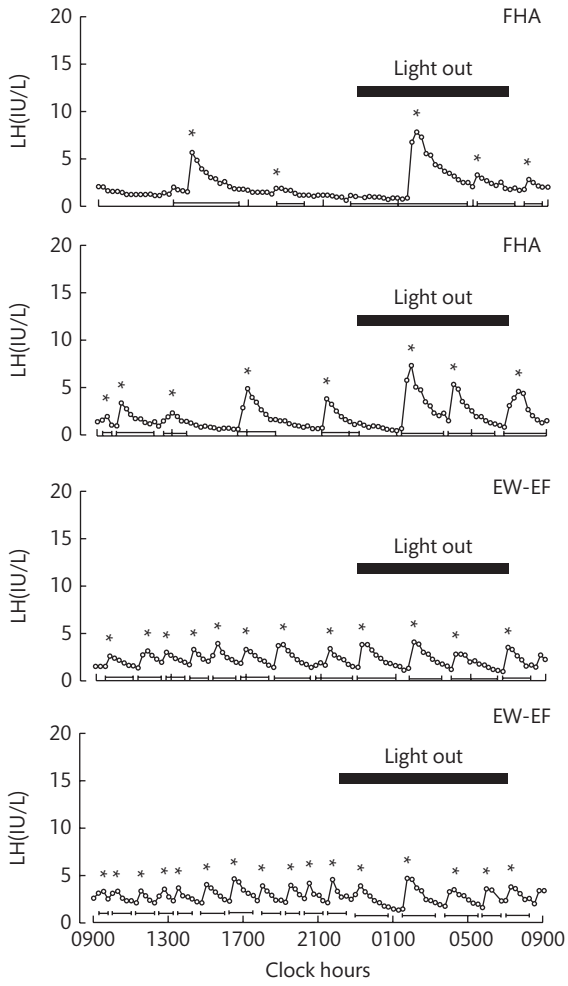

Figure 8.3.1.5 Luteinizing hormone pulse patterns in two women with FHA are shown in the top two panels and in two eumenorrheic, ovulatory women who were studied in the early follicular (EF) phase in the bottom two panels. Luteinizing hormone pulse patterns are the best *in vivo* surrogate for assessing gonadotrophin-releasing hormone activity in humans. To assess luteinizing hormone pulsatility in conditions in which slower frequencies are anticipated, one generally obtains blood samples from a forearm vein at 15-min intervals for 24 h. Computer-driven algorithms are then used to resolve the string of luteinizing hormone determinations into pulses so that frequency and amplitude can be computed. The eumenorrheic women regularly display regular luteinizing hormone pulses of even amplitude whereas the women with FHA display irregular luteinizing hormone pulses with an overall slower frequency and variable amplitude. In general, women with FHA have luteinizing hormone pulse frequency that is roughly half of that observed in eumenorrheic women. The expected nocturnal slowing is seen in the eumenorrheic women whereas some augmentation of luteinizing hormone is seen in women with FHA, a pattern that is somewhat similar to that seen in puberty.

As shown in Figure 8.6.1.7, kisspeptin is the G protein–coupled receptor ligand for its receptor, GPR54. Kisspeptin–GPR54 signalling plays a critical role in the initiation of GnRH secretion during puberty. Kisspeptin/neurokinin B/dynorphin (KNDy) neurons within the arcuate nucleus secrete kisspeptin, which stimulates GnRH neurons [25]. KNDy neurons integrate other neuromodulatory signalling systems linked to reduced GnRH pulsatility [26]. Stressors, regardless of type, activate the HPA axis and elicit a constellation of neuroendocrine alterations, including hypothalamic hypothyroidism that conserves and diverts energetic expenditure [8, 10]. Metabolic signals such as leptin regulate KNDy neurons via a GABAergic mechanism [12]. In monkey models, administration of a CRH antagonist, astressin reversed the impact of social stress upon central GABA-a binding in prefrontal cortex and altered responsivity to ghrelin [27–29].

Mechanisms implicated in the regulation of GnRH pulsatility include glial interposition into the synaptic cleft to reduce appositions and effective GnRH cohort size [30] and multiple neuromodulatory factors including corticotropin-releasing hormone, endogenous opioids, neuropeptide Y, leptin, γ-aminobutyric acid (GABA) and ghrelin [12, 29, 31]. In monkeys, challenge paradigms have included restraint stress, exercise, nutritional restriction, injection of insulin, endotoxin [32], and social instability; stressors are synergistic [20]. However, monkey studies do not reveal why humans initiate deleterious coping strategies or persistently engage in stressful behaviours. The response to some stressors, such as endotoxin, is blunted by sex steroids [32], while the response to restraint is heightened if the ovaries are present [15]. Further, some individuals are more sensitive to the same stressor than others [20, 21, 33, 34]. The neuroendocrine and endocrine responses to exercise were exaggerated in men whose cortisol levels did not suppress when given dexamethasone when compared with the responses in men whose cortisol levels did suppress [35]. In women with FHA, a 20-minute exercise challenge not only provoked a drop in glucose that was not seen in eumenorrheic women but also elicited a proportionally larger rise in cortisol [36]. In contrast, in lactational amenorrhoea, stress responses to challenge are blunted [37]. Reactivity to challenge may be mediated in part by the serotonergic system [33], particularly variants in the serotonin transporter [11, 34]. Overall, the impact of stressors is species-specific, context-dependent, and idiosyncratic.

Although the hypothalamus synthesizes and secretes specific releasing hormones that govern the synthesis and secretion of specific pituitary hormones, it nonetheless functions as an integrated unit to coordinate the endocrine responses to internal and external signals. Because of these complex interdependent relationships, it is simplistic to view FHA as an isolated disturbance in GnRH drive (Figure 8.3.1.1).

Recognition of Functional Hypothalamic Anovulation

The diagnosis of functional hypothalamic anovulation entails excluding all other causes of amenorrhoea and anovulation. Reduced GnRH drive manifests as FSH>LH with low oestradiol (<60 pg/ml) and progesterone concentrations (<1 ng/ml). A thorough search for organic causes must be conducted. While focal neurological signs would be certain to raise suspicion of a central organic cause, conditions such as adult-onset hydrocephalus [38] may be accompanied by dizziness or vague symptoms, rather than lateralizing symptoms. In most instances, if suspected, organic causes can be confirmed by magnetic resonance imaging (MRI). Conditions such as coeliac disease (gluten enteropathy) and irritable bowel syndrome that result in nutritional insufficiency should be excluded as well.

The epidemiology of FHA is not well described. In addition to individual factors, there appears to be a dose–response relationship

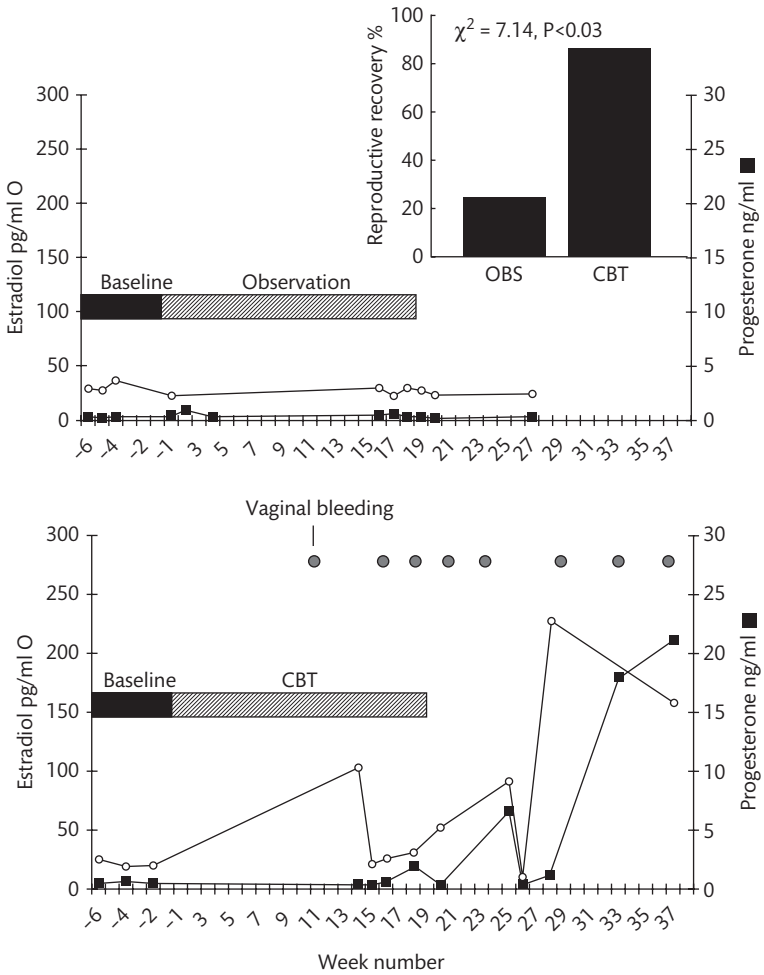

Figure 8.3.1.6 Serum oestradiol (o) and progesterone (■) levels and vaginal bleeding (•) in a woman with functional hypothalamic amenorrhoea (FHA) who was observed and did not recover (top panel) compared with a woman with FHA who was treated with cognitive behaviour therapy (CBT) and recovered (lower panel). The inset depicts the proportion of women with FHA who had evidence of ovarian recovery following randomization to observation (OBS, n = 8; o) or CBT (n = 8; ■).

between the type and severity of stress and the proportion of individuals who develop amenorrhoea [39]. To what extent more subtle forms of anovulation and luteal insufficiency are due to intermittent or mild reductions in GnRH drive is difficult to ascertain in general clinical practice because the manifestations may be clinically subtle or occult [40]. Oligoasthenospermia may sometimes be the male analogue of functional hypothalamic anovulation. The behavioural causes of FHH may differ in men and women, but this is an area that has received minimal investigative attention [41]. A combined metabolic and psychogenic stressor, a war drill, acutely and reversibly raised cortisol levels while suppressing testosterone and gonadotropin levels in men [42]. Short-term fasting studies suggest that the GnRH pulse generator of men may be more sensitive to metabolic challenge than that of women [43]. Available evidence suggests that extreme forms of hypothalamic hypogonadism, such as anorexia nervosa or bulimia affect 3% of women [44], that FHA unrelated to an eating disorder affects roughly 5% of college-aged women [39], that recreational running is associated with a roughly 55% prevalence of cycles that are anovulatory or display luteal insufficiency [40], and that men are susceptible to functional reductions in GnRH drive without obvious clinical manifestations [41, 42].

Pathogenesis of Functional Hypothalamic Anovulation

The final common aetiological pathway to functional hypothalamic anovulation is reduced GnRH drive that manifests in the circulation as a reduction in LH pulse frequency [8]. Several studies have documented that the LH pulse frequency of amenorrhoeic women with FHA is about half that of women in the follicular phase [8]. (**Figure 8.3.1.5**). Pulsatile administration of GnRH resulted in ovulation and conception in women with FHA [5–7]. For folliculogenesis to result in ovulation, however, GnRH drive must remain above and below critical thresholds for approximately 12–14 days. Presumably, intermittent or lesser reductions in GnRH pulse frequency lead to poor follicular development with subsequent luteal insufficiency.

FHA is more than an isolated interruption of the hypothalamic–pituitary–ovarian axis. A constellation of neuroendocrine secretory aberrations has been demonstrated [8]. While cortisol levels are higher in FHA than in eumenorrheic women, the diurnal pattern remains intact [8, 10]. In both eumenorrheic and amenorrhoeic women, cortisol secretion peaks nocturnally. Among women with anovulation, increased cortisol secretion appears to be specific to FHA [10]. Ovarian function is not necessary for GnRH drive to be suppressed by stress. FSH levels in postmenopausal women admitted to the intensive care unit continue to decline after the peak in cortisol levels demonstrating a lag between recovery of the hypothalamic–pituitary–adrenal and resumption of GnRH drive [45]. Elevated cortisol levels have been observed in women with depression and anorexia nervosa but not bulimia [46]. In women athletes, only those with amenorrhoea displayed elevated cortisol levels and reduced luteinizing hormone pulse frequency [47]. Interestingly, women with FHA did not meet criteria for depression [17–19]. The development of anovulation sufficient to cause amenorrhoea may require greater or more sustained HPA axis activation than generally seen in depression and bulimia. Since energy deficits enhance HPA activation, the extent of energy insufficiency may explain differential rates of FHA in women with depression and bulimia [20].

Cortisol *per se* is not likely to be the cause of reduced GnRH pulse frequency in FHA. Acute, exogenous, high-dose administration of cortisol (over 300% of physiological) did not reduce GnRH drive [48]. Hydrocortisone infusions given to mimic moderate (136% increase) and severe (197% increase) stress had no acute impact on gonadotropin secretion [49]. In FHA, the increase in cortisol is in the range of 20–30%. In underweight anorectics, the increase was in the range of 150%, but after short-term weight recovery, the increase was about 70% of the control group [46]. Typically, weight restoration alone is insufficient to restore menses, despite reduced cortisol levels. Since the increased cortisol secretion observed in women with FHA and anorexia nervosa is lower than the levels needed to independently suppress gonadotropin secretion, other factors must play a causal role. Of note, the decline in LH caused by insulin-induced hypoglycaemia in rhesus monkeys was comparable in monkeys pretreated with metyrapone to block cortisol synthesis and those who were not treated [50]. Similarly, an intravenous infusion of corticotropin-releasing hormone caused a decrease in gonadotropin in monkeys with and without adrenalectomy [51]. While these observations do not obviate a role for cortisol as an indicator of stress, they do suggest that neural concomitants of the stress signal or concomitant metabolic signals, rather than cortisol *per se*, cause stress-induced suppression of GnRH pulsatility. While an increase in cerebrospinal corticotropin-releasing hormone has been detected in women with anorexia nervosa [46], women with FHA do not have a detectable increase in cerebrospinal corticotropin-releasing hormone [52] despite an increase in cerebrospinal fluid (CSF) cortisol concentrations [13]. The lack of suppression of CSF CRH in the presence of increased CSF cortisol indicated resistance to feedback inhibition of hypothalamic CRH release by cortisol and suggests that mechanisms other than CRH and cortisol mediate the stress-induced suppression of GnRH [13].

Cortisol is a hormone with profound metabolic actions and increased secretion produces metabolic mobilization, including inhibition of gluconeogenesis. Cortisol also dampens thyroid-stimulating hormone (TSH) release and causes 'sick euthyroid syndrome', presumably as a means of conserving or diverting energy expenditure. As noted earlier, studies have suggested that increased HPA drive predisposes to further endocrine reactivity in response to the subsequent metabolic challenge of exercise [36]. The converse may also hold. Prior metabolic alterations may predispose to neuroendocrine reactivity in the face of psychogenic challenge [20, 21]. We found that women with FHA showed reduced levels of thyronine and thyroxine despite similar TSH patterns [8]. During recovery from FHA, TSH increased dramatically following a reduction in cortisol levels were reduced [10, 24]. These data indicate that the recovery begins with a decrease in CRH followed by recovery of GnRH and TRH drive.

In a monkey model, metabolic challenge sensitized the hypothalamic–pituitary–ovarian (HPO) axis to the effects of subsequent social stress [20]. Monkeys with the greatest sensitivity to stress had differential serotonergic tone [33] and higher baseline heart rates. Administration of a CRH antagonist reversed the inhibition of LH pulsatility induced by the administration of a potent orexigenic signal, ghrelin [29]. In women, caloric deprivation sufficient to slow LH pulsatility in eumenorrhoeic women dropped circulating glucose

and increased circulating cortisol levels, indicating that metabolic stress activates the HPA axis [16]. Women with FHA responded to a graded exercise challenge with a small drop in circulating glucose while eumenorrheic women showed a rise in glucose during exercise [36]. Simultaneously, exercise provoked a larger rise in cortisol in amenorrhoeic as compared to eumenorrhoeic women [36]. These data indicate that the impact of exercise is state dependent. While exercise is often performed to reduce psychological stress, at an endocrine level, it may amplify the stress cascade and heighten stress reactivity. Thus, the management of stress needs to be contextual. Psychogenic solutions need to be found for psychosocial dilemmas and exercise is not a substitute for good mental hygiene.

Role of Behavioural Variables

Behaviours linked to the development of FHH include exercise [40, 47], weight loss [53, 54], affective [17–19, 54], and eating disorders [44], various personality characteristics [17–19, 55], drug use [54], and a number of external and intrapsychic stresses [17–19, 39, 54, 55]. Given individual variation in metabolism, autonomic tone, habitus, aptitudes, and psychological valences, what is stressful to one may be more or less so to another. It is likely that any given stressor, when the 'dose' is large enough, can activate the central neural pathways leading to reduced GnRH drive [39]. Typically, women with FHA report multiple, seemingly minor, stressors, such as a combination of job or school pressures, poor eating habits, and relatively increased energy expenditure through activity or exercise rather than a solitary stressor [17–19]. Others report overeating or 'emotional eating' and weight gain as indicators of stress but the correlation between overeating and FHH has not been well established. Our studies indicated that women with FHA differed from eumenorrheic women and women with other causes of anovulation and amenorrhea psychologically. In particular, women with FHA displayed unrealistic expectations and attitudes such as perfectionism and high need for social approval that are likely to impair coping responses [17–19]. Although women with FHA do not typically meet criteria for an eating disorder, they display attitudes and behaviours similar to women with eating disorders. One is a drive for thinness and disordered eating. The bottom line is that attitudes and expectations engender a panoply of behaviours, such as aberrant food intake and excessive exercise, that independently and synergistically activate the HPA axis and elicit a constellation of neuroendocrine adaptations including reduced GnRH drive.

To test the hypothesis that changing attitudes would reduce stress and restore ovarian function, we randomized women with FHA to cognitive behaviour therapy (CBT) or observation for 20 weeks. CBT consisted of 16 sessions that focused on attitudes rather than behaviours and provided general guidance but not explicit requirements about nutrition and exercise. The goal of CBT was to improve problem-solving strategies and coping mechanisms, to foster realistic expectations of self and others, and to help the individual develop strategies for dealing with specific and common stressors [23]. Of those randomized initially to CBT, 87% recovered ovarian function while only 25% of those randomized to observation recovered ovarian function (**Figure 8.3.1.6**). Recovery of ovarian function was accompanied by decreased nocturnal cortisol [24], increased leptin and TSH independent of weight gain, and an improvement in attitudes.

Taken together, available data indicate that behaviours or expectations that activate to the HPA axis suppress ovarian and thyroidal function. Generally, a mix of multiple, seemingly minor, psychogenic, and metabolic stressors appears to be more deleterious to reproductive function than a solitary stressor.

Treatment Considerations

Recovery from FHA is expedited by identifying attitudinal antecedents that fuel stress sensitivity. Society might admire the achievements made possible by unbridled ambition, but the endocrine system rewards moderation. Conflicted aspirations may seem mundane to the clinician, but to the individual facing such decisions, having to choose among goals may be perceived as life-defining and potentially life-threatening. Certain behaviours, such as exercise and dieting, may provide a sense of autonomy and control, but ironically, these behaviours also serve as metabolic challenges that sensitize the endocrine system to ongoing or subsequent psychogenic stress and vice versa. Thus, addressing behaviours and attitudes that fuel FHA is likely to foster neuroendocrine recovery and resumption of ovulation while institution of dieting and exercise regimens are likely to sustain FHA and hypercortisolism.

Long-term health complications of FHH/FHA include osteopenia/osteoporosis and infertility. A key goal is to restore menstrual cycles. Kisspeptin has been investigated as a possible modality [56]. Likewise, subcutaneous daily recombinant leptin has been investigated as a treatment option for FHA but its use only restored ovulatory function in less than half of the 8 women treated [57]. In contrast, CBT not only fostered recovery of ovarian function, but also reduced hypercortisolaemia and increased in leptin and TSH [24].

Ovulation induction is often undertaken for women with FHA who desire fertility. Unfortunately, use of clomiphene, a selective oestrogen receptor modulator, or letrozole, an aromatase inhibitor, may not increase FSH sufficiently to foster folliculogenesis to the point of ovulation because of increased sensitivity to oestrogen negative feedback [11]. Indeed, the absence of increased FSH levels in women with FHA despite low oestradiol levels indicates increased sensitivity to oestrogen negative feedback. Women with FHA rarely report hot flashes even in the face of profound hypoestrogenism; the presence of hot flashes in a woman with presumed FHH should engender a thorough search for an organic aetiology. Other options for ovulation induction include exogenous pulsatile administration of GnRH and exogenous administration of gonadotropins [5]. Should ovulation induction be undertaken? Women with FHA who are underweight during pregnancy have an increased risk of intrauterine growth restriction and preterm delivery [58]. Children born to mothers with subclinical hypothyroidism (30% lower maternal thyroxine) had a mean full-scale intelligence quotient 7 points lower than the control population [59]. Women with FHA display varying decrements in thyroxine compared to control populations [8, 44], but our data indicated a 25% decrement in women with FHA in the absence of low weight [8]. During the first trimester, the mother is the sole source of thyroxine for the fetus, and in the second trimester, she is the predominant source. Ovulation induction in the presence of metabolic mobilization, such as that which accompanies FHA, may carry as yet unspecified risks for the child's neuropsychological development [60]. Women with FHA may also display compromised

parenting skills. A woman who is stressed to the point of developing anovulation is unlikely to cope well with the additional stress of a newborn. Thus, ovulation induction in a woman with FHA carries risks such as intrauterine growth restriction, preterm delivery, and poor neuropsychological development in the offspring. The preferred course of action would be to foster recovery through behavioural and cognitive alterations that spur neuroendocrine recovery including resumption of ovulatory function before resorting to ovulation induction or assisted reproduction. Recognizing that stress has profound effects on reproductive physiology provides a lens for understanding the social determinants of health [61].

A common rationale for instituting hormone replacement or contraceptive therapies is prevention of osteoporosis. While hormonal contraception or exogenous hormone replacement is unlikely to cause harm, it may also provide few benefits [9]. Hormone replacement strategies are unlikely to promote bone accretion in the face of metabolic imbalance including hypercortisolism. In particular, excess cortisol reduces osteoblast activity and impairs bone formation. Sex steroid therapy will not ameliorate ongoing metabolic compromise. Indeed, women with FHH/FHA may be catabolic rather than anabolic. When eumetabolic, oestrogens inhibit bone resorption but androgens are needed to stimulate bone formation. Both androgens and oestrogens are low in FHA. Further, cortisol interferes with oestrogen action [62]. Women with anorexia nervosa have lower bone mass than women with FHA, but both have lower bone mass than age-matched eumenorrhoeic women [63]. Women with anorexia nervosa do not build bone in response to exogenous sex steroid administration because of concurrent nutritional deficits and ongoing metabolic compromise including hypercortisolaemia [63]. While sex steroids and bisphosphonates primarily retard bone resorption, women with anorexia nervosa, and FHA already have reduced bone formation, so it is not clear that the use of either will significantly improve bone accretion [9]. Further, bisphosphonates get incorporated into the maternal skeleton and are mobilized during pregnancy and thus carry the additional hazard of being potentially teratogenic. Resumption of menses is associated with bone accretion, but bone density remains below expected values, indicating that it may not be possible to fully recover 'lost bone'. Delayed menarche in young ballet dancers was associated with higher rates of scoliosis, as well as fracture [64]. In one small study of amenorrhoeic athletes, oral contraceptive use led to a small gain in bone over placebo, while cyclic progestin exposure led to greater bone loss than placebo [65].

The characteristic hypothalamic alterations induced by challenge only become problematic when challenge elicits a chronic, rather than acute, response. The long-term consequences of persistent HPA activation have been studied in animal models and hippocampal neuronal loss has been documented. The multiple health consequences of chronic stress in humans are impressive [66]. Persistent stress in elderly women (manifested as an elevated urinary free cortisol) was associated with cognitive decline across time, while stress reduction led to cognitive improvement [67]. Both perceived stress and chronicity of stress were significantly associated with advanced cellular ageing as evidenced by lower telomerase activity and shorter telomere length in healthy premenopausal women [68]. Hormone therapy *per se* is unlikely to be harmful, but more than hormone administration is needed. The stress process needs to be dampened.

Although psychopharmacological approaches have not been studied in FHA, they should be considered. Benzodiazepines are contraindicated during pregnancy, so their use would carry the greatest risk were conception to occur during pharmacological intervention. Antidepressants may reduce HPA activation, but it is not clear that their use will address associated metabolic imbalances that would be problematic were conception to occur. Naltrexone has been employed with variable success [69]. The optimal treatment is to reduce stress and restore metabolic balance so that the hypothalamus recovers and gonadal function resumes. An integral goal of treatment is to help women identify sources of psychogenic and metabolic stress, and to provide emotional support, while coping mechanisms other than dieting or exercise are learned. Non-pharmacological therapies, such as stress management, relaxation training, and psychoeducation empower individuals by fostering self-care and competency. In this regard, non-pharmacological therapies have the potential to produce long-term mental and physical health benefits extending beyond resumption of ovulatory function.

FHA is theoretically reversible, but few studies have documented the course of recovery or the likelihood. Hirvonen found that 72% recovered in 6 years [70]. One report showed that 9 of 16 women with FHA who underwent ovulation induction and conceived became eumenorrhoeic postpartum [71]. Roughly half of women with anorexia nervosa or bulimia have a full recovery [44]. To avoid disappointment and unrealistic expectations, patients should be counselled that reproductive recovery may not immediately ensue following lifestyle alterations.

Summary

The development of FHH/FHA demonstrates that attitudes, moods, and behaviours alter neuroendocrine function. Although a link between brain states and gonadal function has long been hypothesized, only recently have we been able to specify some of the mechanisms mediating this relationship. In the psychoneuroendocrinologic context, health depends on achieving psychological harmony through realistic expectations of self and others and metabolic harmony through balanced diet and energy expenditure. Although reduction in or avoidance of some stresses may be possible, the complete elimination of frustrations and demands is in itself unrealistic. Thus, the development of awareness and the institution of appropriate coping patterns are instrumental to maintaining health, including reproductive health. The burden of reducing and managing stress should not fall exclusively to the individual, but should also be a societal goal. While the medical profession participates in defining and understanding the role of stress in disease, it is by no means the only profession or social institution with an obligation to ameliorate this health burden.

8.3.2 Hyperprolactinaemia

Julian Davis and Agnieszka Święcicka

Prolactin Biology

Prolactin is a polypeptide hormone, named from its well-known effects to promote lactation. It is essential for successful reproduction in man and mammals, although it is known to have a wide variety of non-reproductive effects whose clinical significance remains uncertain. Prolactin is secreted by lactotrophic cells of anterior pituitary gland, but many other sites of production have been identified, including the endometrium, immune cells including T-lymphocytes, and skin [1–4]. Circulating prolactin is generally assumed to derive mainly from pituitary secretion, and extrapituitary production is thought to exert mainly local paracrine effects within tissues. The clinical condition of hyperprolactinaemia is almost always attributable to abnormal pituitary prolactin secretion and ectopic neoplastic causes of hyperprolactinaemia are extremely rare.

Lactotrophic cells constitute a large proportion (25–40%) of the endocrine cell types in the pituitary, though their numbers and size can vary during and after pregnancy [5]. This indicates a significant degree of plasticity in pituitary structure that may be important in the susceptibility of the pituitary to the frequent formation of microadenomas [6].

Unlike other pituitary hormones, pituitary prolactin secretion is under predominantly inhibitory control from the hypothalamus, and transection of the pituitary stalk results in sustained hyperprolactinaemia. The prolactin inhibitory factor was identified as dopamine, secreted by tubero-infundibular neurons, which acts on D2 receptors on lactotrophic cells to reduce prolactin synthesis and secretion [4, 7]. A series of other hypothalamic hormones may act as stimuli to prolactin secretion, including TRH, VIP, galanin, and fibroblast growth factor [4]. However the main physiological mechanism for pulses of prolactin secretion is thought to be the episodic interruption of dopamine inhibition.

The reproductive effects of prolactin are found at all levels of the hypothalamo-pituitary-gonadal axis, with effects on the frequency of gonadotropin-releasing hormone (GnRH) pulses, inhibition of the secretion of gonadotrophins, and suppression of luteolysis [8]. These multiple levels of suppression of gonadal function mean that the hyperprolactinaemia that normally occurs during breastfeeding effectively suppresses fertility [9].

A variety of non-reproductive effects of prolactin have been documented which are of less clear significance in man. The prolactin receptor (PRLR) is found in many peripheral tissues, and studies of prolactin and PRLR knockout mice have clearly confirmed not only the reproductive effects of prolactin, but also effects on maternal behaviour, adipose tissue depots, bone mineralization, and immune response [10, 11].

Hyperprolactinaemia

Hyperprolactinaemia, reflecting sustained overproduction from the pituitary, is relatively common in the population [12]. The causes are listed in **Box 8.3.2.1**. The commonest cause is the use of drugs that have dopamine D2 receptor antagonist activity, including antipsychotic agents such as phenothiazines, although some newer agents have little effect [13]. Pregnancy and lactation are the commonest

Box 8.3.2.1 Causes of hyperprolactinaemia

- Pregnancy and lactation
- Acute stress
- Medication
  - Metoclopramide
  - Domperidone
  - Sulpiride
  - Phenothiazines
  - Haloperidol
  - Selective serotonin reuptake inhibitors
  - Methyldopa
- Chest wall and nipple stimulation
  - Herpes zoster
  - Burns
  - Nipple stimulation, piercings
- Pituitary-hypothalamic disease
  - Non-tumoural (idiopathic) hyperprolactinaemia
  - Prolactinoma—microprolactinoma, macroprolactinoma
  - Disconnection hyperprolactinaemia
    - Hypothalamic tumour
    - Granuloma
    - Craniopharyngioma
    - Meningioma
    - Trauma
  - Acromegaly: mixed mammosomatotroph adenoma
- Associated endocrine conditions
  - Hypothyroidism
  - Polycystic ovary syndrome
- Miscellaneous conditions
  - Renal failure
  - Cirrhosis

physiological causes, and short-term acute stress, such as the anxiety provoked by blood sampling, is also a frequent cause of transient rises in serum prolactin that may be misinterpreted in clinical practice and necessitate a second confirmatory blood sample.

Pathological pituitary causes of hyperprolactinaemia may reflect a functioning pituitary prolactinoma, a prolactin-secreting microadenoma or macroadenoma, but in many cases no adenoma is detectable on scanning, in which case the condition is termed idiopathic or non-tumoural hyperprolactinaemia. Anatomical disturbance in the suprasellar region may cause effective functional disconnection of the anterior pituitary gland from the inhibitory effects of dopamine: the resulting 'stalk disconnection' hyperprolactinaemia may lead to diagnostic confusion between functioning prolactinomas and non-functioning pituitary adenomas or other non-pituitary lesions, which usually require different management.

Prolactin hypersecretion can coexist with various conditions. Prolactin is frequently cosecreted with growth hormone by mammosomatotroph cells, and mixed GH-prolactin-secreting tumours can present clinically as either acromegaly or hyperprolactinaemia. Thus the evaluation of hyperprolactinaemic patients should consider the possibility of acromegaly. Hyperprolactinaemia complicates the presentation of polycystic ovarian syndrome in up to 30% of patients [14], though the mechanism and nature of the association remain uncertain. Other miscellaneous recognized causes of hyperprolactinaemia include hypothyroidism, nipple, or chest wall stimulation (including herpes zoster, burns, nipple piercings), chronic renal failure, and cirrhosis.

Presentation

The typical clinical features that suggest hyperprolactinaemia are those of galactorrhoea and oligo-/amenorrhoea. Galactorrhoea is frequent though not universal, and may be unilateral or bilateral, and is explained by the direct effects of prolactin in the breast, to promote milk protein synthesis, and ductal epithelial cell proliferation. Oligomenorrhoea is due to suppression of the hypothalamic–pituitary–ovarian axis, though some women may develop irregular anovulatory menstrual bleeding. Prolonged hypogonadism due to hyperprolactinaemia may lead to osteopaenia [15].

Weight gain has been reported in hyperprolactinaemic women [16], which improves with dopamine agonist treatment, but whose mechanism is still not well understood. Insulin resistance has also been described in hyperprolactinaemic women [17].

Although prolactin receptors are widespread and prolactin has been described to have a series of effects on immune tissues, there appear to be no clinically significant abnormalities in immune function or autoimmune disease in patients with hyperprolactinaemia, although prolactin deficiency in severe hypopituitarism may have adverse effects [18, 19].

Investigation

Prolactin Measurement

Serum prolactin levels are readily measured by most clinical biochemistry laboratories, and most immunoassays generate results that are expressed in terms of a WHO international standard that comprises 23kD monomeric prolactin, and expressed in mU/L or ng/ml [20]. Prolactin levels should be measured on more than one occasion, and persistent unexplained hyperprolactinaemia requires evaluation. It should be remembered that pregnancy is a well-known physiological cause of hyperprolactinaemia, and the possibility should be considered before embarking on further investigation of a woman with amenorrhoea and hyperprolactinaemia.

Serum prolactin levels rise at night during sleep, but this is rarely a problem in routine clinical practice, and blood samples therefore do not need to be timed. The reference range for serum prolactin varies slightly according to age and gender, with slightly higher levels seen in premenopausal women. Dopamine antagonist drugs can markedly raise prolactin levels to several times the upper limit of the normal range, and in patients on prolactin-raising medication a judgement needs to be made as to whether further investigation is necessary or not.

In patients with pituitary adenomas the degree of prolactin elevation is generally roughly proportional to the size of the adenoma, with microprolactinomas (<10 mm tumour diameter) usually associated with prolactin levels below 8000 mU/L, and macroprolactinomas usually giving levels above 10 000mU/L. Patients with large pituitary adenomas and only slight prolactin elevation may have non-functioning pituitary tumours causing stalk disconnection hyperprolactinaemia.

Pitfalls in Prolactin Assays: Hook Effect and Macroprolactinaemia

Some prolactin assays are susceptible to a 'high dose hook effect', whereby extreme elevation of prolactin in the sample saturates both the capture and the detection antibodies in an immunometric sandwich assay resulting in gross under-reading of the sample concentration. If such an effect is suspected in a patient with clinical features of a large macroprolactinoma but only marginal hyperprolactinaemia, the blood sample should be re-analysed after dilution to overcome this hook effect.

The other important issue affecting serum prolactin assays is the frequent occurrence of macroprolactinaemia, in up to 10% of the population. Prolactin normally circulates as monomeric protein, but it is also found in a dimeric form and in high molecular weight complexes (>100kD), formed of prolactin-immunoglobulin complexes ('big-big prolactin', or 'macroprolactin') [21]. Some patient samples contain large amounts of macroprolactin, a condition termed macroprolactinaemia, though the complexes are thought to have limited bioactivity. Macroprolactinaemia is found in a proportion of patients with hyperprolactinaemia, so its presence cannot be taken to exclude genuine pituitary disease. On the other hand, the incidental finding of artefactually raised prolactin in a patient with no features of pituitary disease can lead to fruitless or misleading investigation, and therefore most laboratories now screen for the presence of macroprolactin complexes using polyethylene glycol precipitation [20].

Other Biochemical Investigation

Patients with genuine unexplained and persistent hyperprolactinaemia should be considered for investigation of pituitary function, including assessment of the pituitary gonadal axis (serum oestradiol, LH, and FSH measurement, and assessment of ovulation). Thyroid function should be tested as hyperprolactinaemia

can be a feature of hypothyroidism. The possibility of acromegaly should be considered, with assessment of GH and IGF-1 levels. Polycystic ovary syndrome should also be considered, and biochemical evaluation could include measurement of androgen levels. In patients with pituitary disease the adequacy of pituitary-adrenal function should be tested, by measurement of 9am plasma cortisol or a short tetracosactrin test (see Box 8.3.2.2).

Pituitary Imaging and Other Tests

Persistent hyperprolactinaemia may be due to pituitary or hypothalamic mass lesions, as outlined previously, and these should be evaluated by pituitary imaging (see online Figure 8.3.2.1). The main purpose of imaging is to exclude a large mass lesion that threatens adjacent structures: small pituitary microadenomas are common incidental findings in the normal population, and they may require no action at all. In most centres MR scanning is the investigation of choice. CT scanning is a good alternative but often less satisfactory for imaging of adjacent structures such as the optic chiasm and cavernous sinus. Although some patients find the machines less claustrophobic than MR scanners, CT involves a significant X-ray dose, and repeated scanning of the orbits should be avoided to minimize risk of cataract. In patients where a pituitary or hypothalamic mass lesion is detected, visual fields should be assessed formally by manual or computerized perimetry.

Treatment

Microprolactinomas and Non-Tumoural Hyperprolactinaemia

Patients with hyperprolactinaemia may require treatment for various reasons, including restoration of ovulatory function, maintenance of adequate oestrogenization, suppression of galactorrhoea, or reduction in size of a mass lesion. Some patients may not require treatment at all, for example patients who have no significant mass lesion and no galactorrhoea, and with adequate oestrogen status. The main current treatment option is dopamine agonist therapy, and this will be considered first, followed by the other available options. Treatment is mainly directed at the hormonal disturbance, and patients with small pituitary microprolactinomas are often treated in the same way as patients with non-tumoural hyperprolactinaemia.

Box 8.3.2.2 Investigation of hyperprolactinaemia

- Exclusion of pregnancy, review of medication
- Biochemical testing
  - Serum prolactin (two occasions)
    - Screen for macroprolactinaemia if appropriate
  - Thyroid function testing
  - Pituitary function testing
    - Gonadal function: oestradiol, LH, FSH
    - Screening for acromegaly: GH levels, IGF-1
    - Adrenal function: 9.00 a.m. cortisol, stimulation testing if appropriate
  - Screening for polycystic ovary syndrome if appropriate (serum androgens)
- Visual field testing
- Pituitary imaging: MR or CT scanning

The issues for patients with macroprolactinomas are slightly different, and these will be considered separately.

Dopamine Agonists

Pituitary prolactin synthesis and secretion are suppressed by dopamine, and ergot-derived dopamine D2 receptor agonists have become the standard treatment for hyperprolactinaemia since their introduction in the 1970s [22, 23]. The drugs in current use are all orally active and include bromocriptine, the first drug of this class to be used, and cabergoline; quinagolide is a non-ergot dopamine agonist, with similar effects at the D2 receptor, but slightly different side effects. A series of other ergoline derivatives have been used including pergolide and lisuride, but are not in routine use at present. Bromocriptine and quinagolide are usually given daily, whereas cabergoline is given once or twice weekly.

Prolactin levels fall rapidly, within hours of first administration, and the effect of treatment can be judged biochemically within days or weeks. Prolactin levels typically normalize within 12–24 months of dopamine agonist therapy in up to 95% of patients with microprolactinoma, whereas restoration of normal ovulatory function occurs in approximately 82% of females; recovery of gonadal function is less common in male patients [23, 24]. Resistance to dopamine agonists is uncommon, and treatment is more often constrained by side effects, which are outlined next. Thus women with anovulatory infertility due to hyperprolactinaemia can rapidly and effectively be rendered fertile with simple oral treatment, and ovulation may occur before the resumption of a first period after long spells or amenorrhoea. Patients should therefore be warned to take contraceptive precautions if pregnancy is not sought immediately.

Cabergoline is usually recommended as the drug of choice in hyperprolactinaemia because of its higher efficacy in normalizing prolactin levels, as well as a higher frequency of pituitary tumour shrinkage [25]. The greater efficacy of cabergoline may be explained by the higher affinity for dopamine receptor binding sites as well as potentially superior drug compliance, owing to lower incidence of unpleasant side effects compared to bromocriptine [25]. Although no clinical trials have directly compared the mass-reducing effects of different dopamine agonists, collective evidence suggests that bromocriptine decreases pituitary tumour size by approximately 50% in two-thirds of patients, compared with a 90% decrease with cabergoline [25].

All dopamine agonist drugs have potential side effects of nausea, postural hypotension, headache, and nasal stuffiness, but these are more pronounced with bromocriptine and these side effects are relatively unusual with quinagolide and cabergoline. Patients should be warned about the risk of developing mood disturbances or impulse control disorders such as pathological gambling, hypersexuality, and/or uncontrollable spending which have previously been reported in patients taking dopamine agonists. Psychotic depression is occasionally seen with all of these drugs, which should be avoided in patients with a psychotic predisposition.

Cabergoline and pergolide are used in higher doses in the treatment of Parkinson's disease, and high cumulative doses of ergot-derived drugs have been found to be associated with the development of a fibrotic cardiac valvulopathy in these patients, possibly due to their action at the 5-HT2B serotonin receptor [26]. The doses used for hyperprolactinaemia are generally 5–10 times lower than in Parkinson's disease, but caution

and echocardiographic monitoring have been advised for pituitary patients, although almost all studies so far reported have shown no excess of valvulopathy in pituitary patients treated with low cumulative doses [27, 28]. This caution does not apply to quinagolide, as a non-ergot derivative.

Oestrogen Replacement

In patients in whom galactorrhoea and tumour bulk are not a problem, and the only issue is oestrogen deficiency due to anovulation, it may be possible to avoid the use dopamine agonists by simply replacing oestrogen. This should be considered in premenopausal anovulatory women to avoid symptoms of oestrogen deficiency and bone mineral loss, if dopamine agonists are not considered necessary or cause excessive side effects. The effect of oral oestrogen therapy on the growth of microadenomas has not been examined in a randomized controlled fashion. However, patients treated with oral contraceptives and oestrogen/progesterone replacement for 2 years have not shown an increase in tumour size [29, 30].

Ovulation Induction Without PRL Suppression

In most patients dopamine agonists are highly effective in restoring normal ovulatory function and fertility. However, some patients prove to be genuinely resistant to high doses of dopamine agonists, or have intolerable side effects, and for these women it may be necessary to use exogenous gonadotrophin therapy to induce ovulation.

Observation Alone

In postmenopausal patients, oestrogen replacement therapy can be considered if necessary for control of symptoms and for maintenance of bone mineral density. As for premenopausal women, pituitary size and serum prolactin levels should be monitored, as pituitary adenoma growth may otherwise progress without symptoms.

In both pre and postmenopausal patients it may be possible to withhold any treatment. Thus, if cyclical ovarian function and endogenous oestrogen levels are preserved despite moderate hyperprolactinaemia, or in an asymptomatic postmenopausal woman, there may be no indication for any treatment at all. In such cases, annual checks of serum prolactin level should be continued, and pituitary MR scanning should be carried out if prolactin levels progressively rise.

Surgery and Radiotherapy

Surgery is rarely indicated for microprolactinomas, and success rates have been disappointingly low even in highly specialist centres [31]. This does however depend on the surgical expertise available, and selective microadenomectomy may be worth considering in patients who are resistant to or develop troublesome side effects on dopamine agonist treatment. Radiotherapy is almost never indicated—most of these patients have otherwise normal pituitary function, and stand to develop hypopituitarism as a long-term consequence of pituitary irradiation.

Long-Term Follow-Up

Patients with microadenomas or idiopathic hyperprolactinaemia who achieve normal serum prolactin concentrations on dopamine agonist therapy should continue the treatment for at least one year. After that, an attempt to reduce the dose of dopamine agonist can be made, ensuring prolactin remains within normal range. If the prolactin levels continue to remain normal for two or more years and no adenoma is seen on magnetic resonance imaging, discontinuation of the drug can be considered.

If the drug is discontinued, prolactin should be measured initially every three months and annually thereafter. The risk of recurrence of hyperprolactinaemia appears to be highest in the first 12 months after cessation of the therapy, and ranges from 26% to 69% [32, 33]. In the event of recurrence of hyperprolactinaemia, a magnetic resonance imaging of the pituitary should be performed and dopamine agonist therapy resumed at the dose which previously resulted in normoprolactinaemia and shrinkage of the pituitary lesion.

Macroprolactinomas

Pituitary prolactinomas larger than 10 mm in diameter may present not only with anovulation, but also with mass effects of headache and visual field loss due to optic nerve compression, and with features of hypopituitarism. Most of these patients can be successfully treated with dopamine agonists, but there are some specific issues to be considered. In such patients the diagnosis should be reviewed at the start of treatment, as it includes not only prolactinoma, but also acromegaly, and non-functioning adenoma.

Dopamine Agonists

Dopaminergic drugs have proved highly effective even with very large prolactinomas, and both reduce prolactin levels and shrink adenomas in 85–90% of cases [22]. Tumour shrinkage is generally rapid, and is usually sufficient to remove pressure on the optic chiasm and allow recovery visual field loss within days. Most tumour shrinkage occurs within the first few weeks of therapy, but it may continue for months or even years. The mechanism is not fully understood but is likely to involve apoptosis of tumorous lactotroph cells.

Prolactin levels should be measured regularly, and dopamine agonist dose increased, as necessary, until normoprolactinaemia is achieved.

A magnetic resonance imaging should be repeated in 6 to 12 months after commencing the therapy to determine if the size of the adenoma has decreased.

A small number of patients will demonstrate resistance to dopamine agonists, defined as either failure to achieve normoprolactinaemia on maximum tolerated dose

and/or absence of tumour shrinkage by at least 50%. Most patients will achieve normal prolactin level with 0.25–3 mg of cabergoline weekly. Treatment-resistant patients are often managed with much higher doses of cabergoline, which carries a higher risk of cardiac valvular abnormalities, as previously observed in patients with Parkinson's disease taking at least 3 mg of cabergoline daily. Interval echocardiography might be required in this group of patients to assess for the development of valvular abnormalities.

Surgery and Radiotherapy

Surgery is rarely used even for large prolactinomas, because the majority respond so well to dopamine agonist drugs, and because it is extremely difficult to achieve a long-term cure with larger tumours with extrasellar extension of tumour tissue. However, it may have a role in debulking large tumours that have failed to show useful

shrinkage with drug therapy, in order to decompress and protect the optic chiasm.

Radiotherapy is rarely used alone, and has long-term adverse effects of hypopituitarism and increased risk of cerebrovascular disease, and risk-benefit analysis needs to be undertaken for individual patients. It does have a role in selected patients with macroprolactinoma to reduce the risk of tumour regrowth after debulking surgery, although hyperprolactinaemia tends to persist for many years, possibly due to radiation damage to hypothalamic dopaminergic neurons.

Even large tumours may shrink to disappearance, as judged by MR scanning, and long-term remission is seen in up to 50–60% of cases, which should prompt trial withdrawal of dopamine agonists in most patients who achieve sustained tumour shrinkage. However, in these patients, cautious follow-up with interval MR scanning is mandatory, as these tumours have displayed their potential for substantial growth.

Patients with hyperprolactinaemia and pituitary macroadenomas may have either large prolactinomas or non-functioning macroadenomas that are causing stalk disconnection hyperprolactinaemia. In general, prolactin levels exceed 10 000 mU/L (500 ng/ml) in most patients with macroadenomas composed of lactotrophic cells, whereas non-functioning tumours cause disconnection hyperprolactinaemia that rarely exceeds 5000 mU/L (20 ng/ml) [22]. The response to dopamine agonists may be useful in discriminating the true diagnosis before resorting to pituitary surgery. Although serum prolactin levels are suppressed by dopamine agonist therapy regardless of the nature of the tumour, substantial shrinkage of a macroadenoma suggests that it is in fact a prolactinoma, whereas non-functioning adenomas usually show little or no change in size.

Withdrawal of Treatment

In the case of a stable clinical picture, normoprolactinaemia and marked decrease in the size of macroadenoma, the dopamine agonist therapy can be decreased gradually to lowest dose necessary to maintain normal prolactin levels.

Discontinuation can be considered in those patients whose serum prolactin concentrations have been normal for more than two years, and whose adenoma can no longer be visualized by MRI [25, 34]. If the drug is discontinued, prolactin concentration and the size of the adenoma by MRI must be monitored.

Management of Pregnancy

In anovulatory hyperprolactinaemic patients, an important objective of therapy is the resumption of ovulatory cycles and pregnancy. However, oestrogen is a potential stimulus to pituitary lactotroph proliferation, and the very high oestrogen levels seen during normal pregnancy can result in clinically significant enlargement of a prolactinoma. Pregnancy is associated with significant pituitary enlargement in normal subjects, attributed mainly to proliferation of lactotroph cells, but in patients with prolactinoma there is a risk of substantial increase in tumour volume, sufficient to threaten the optic nerve.

In most patients, pregnancy is achieved by treatment of hyperprolactinaemia with dopamine agonists. Bromocriptine has been used for this purpose for over 30 years, and the accumulated evidence suggests that is it safe to use in pregnancy [35]. Similarly, cabergoline use in this setting does not appear to be associated with excess risk of miscarriage or congenital malformation [36]. However, it is probably advisable to limit exposure of any of these agents as far as possible, and all dopamine agonists of course would impair or prevent lactation and breastfeeding postpartum. In general, therefore, it is prudent to stop dopamine agonist agents as soon as pregnancy is confirmed, but patients should be warned of the small risk of adenoma enlargement once the restraint of dopaminergic treatment has been removed.

The actual risk of clinically important pituitary enlargement has been addressed by important meta-analyses and guidelines that help advise patients about pregnancy management [37, 38]. Women with microprolactinomas have a low risk (1–2%) of tumour enlargement during pregnancy, and dopamine agonists should be stopped when pregnancy is confirmed. Patients should be warned to report symptoms of pituitary expansion, including headache or visual impairment. Prolactin measurements can be made during pregnancy, but are highly variable between individuals and of limited value in guiding management. Women with macroprolactinomas have a higher risk of clinically significant or symptomatic tumour enlargement, approximately 20–30%. These patients can therefore be offered a choice of continuation of dopamine agonists throughout pregnancy, or stopping the drug with close monitoring of symptoms and visual fields until delivery. If a patient develops severe headaches and/or visual field abnormalities, a pituitary MR scan can be performed to evaluate the tumour mass, and if there is a significant threat to the optic chiasm, a dopamine agonist can be restarted or pituitary surgery considered. Prolactinoma debulking before pregnancy may reduce the risk, but carries its own risks and is probably not justifiable for these patients.

Women whose micro- or macroadenoma remained stable during pregnancy should not be discouraged from breastfeeding, and re-initiation of dopamine agonist can be delayed until breastfeeding is complete. However, women who experienced symptoms and signs in keeping with enlargement of lactotroph adenoma during or after pregnancy should not breastfeed and dopamine agonist therapy should promptly be initiated. A substantial (40–60%) proportion of women display features of disease remission after pregnancy obviating the need for treatment with dopamine agonist [39, 40].

8.3.3 Premenstrual Syndrome

Deepthi Lavu, Radha Indusekhar, and Shaughn O'Brien

Introduction

Premenstrual disorders (PMD) are psychoneuroendocrine disorders which affect millions of women and their families all over the world. These disorders are characterized by cyclical recurrence of psychological, physical, and/or behavioural symptoms experienced in the luteal phase of the menstrual cycle and relieved soon after the onset of menstruation. They have a negative effect on the personal, social, and occupational lives of affected women leading to a reduced quality of life during their reproductive years. Premenstrual syndrome (PMS) affects 30–40% of women worldwide and 3–8% experience a severe form of PMS called premenstrual dysphoric disorder (PMDD).

The absence of objective tests and poor reliability relating to retrospective symptoms complicate diagnosis and efficient treatment. Until the recent publication of the International Society for Premenstrual Disorders (ISPMD) classification, there was a lack of consensus internationally among authoritative bodies regarding the classification, diagnosis, and management of these disorders [1]. The ISPMD classification now enables diagnostic accuracy and guides management of PMD. This chapter will review the classification, aetiology, symptoms, diagnosis, and management options recommended for treating PMD (PMS and PMDD).

Prevalence and Morbidity

The difference in PMD classification and symptom interpretation, prior to the ISPMD consensus, resulted in several studies providing a wide estimate of the prevalence of PMD [2]. The extent of impact of PMD is under-recognized by both the medical and non-medical community. It is considered that as many as 80–89% of women suffer from physiological premenstrual symptoms. Approximately 40% suffer from PMS and 3–8% have extreme symptoms with a diagnosis of PMDD. Symptoms occur during reproductive life and are absent before menarche, during pregnancy, and post-menopause. PMD are experienced cyclically over most ovulatory cycles and spontaneous remission is rare. Withdrawal of effective treatment usually results in symptom resurgence after a few cycles.

Women with PMDD are estimated to be incapacitated for 3.8 years of their reproductive life [3]. Morbidity results from the symptom severity experienced, including cyclical symptom recurrence, symptom duration, and the interference caused relating to daily functioning and productivity. This includes interpersonal relationships, work, and social life. PMDD is a chronic medical condition with an economic impact relating to loss of work productivity, which exceeds the medical costs involved in management [4].

Classification of PMD

Although PMD are widely prevalent and have a major impact on millions of women worldwide, until recently there was no international agreement among authoritative bodies on their classification. The ISPMD classification of PMD was formulated based on existing systems in use for defining and categorizing the disorders. This included the World Health Organization's *International Classification of Diseases (ICD)* 10th edition, the American College of Obstetricians and Gynecologists (ACOG) definitions, the Royal College of Obstetricians and Gynaecologists (RCOG) definition and the American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders, fourth edition (DSM-IV) criteria. According to the ISPMD, PMD can be classified into Core and Variant PMD based on strict clinical diagnostic criteria [1].

Core Premenstrual Disorders

The key characteristic is the timing of the symptom occurrence. It must involve all or part of the two premenstrual weeks and must resolve during or shortly after menstruation with a clear symptom free interval before ovulation. Although there is no need to establish ovulation for diagnosing core PMD, the elimination of ovulation results in a reduction or absence of symptoms. See **Figure 8.3.3.1** and **Box 8.3.3.1**.

Core PMD were defined as PMS and PMDD. A distinction can be made between the definitions of PMD suggested by authoritative bodies to determine the ones which meet core PMD criteria and those which do not. See **Table 8.3.3.1**.

Variant Premenstrual Disorders

Symptoms in this group do not meet the criteria for core PMD. They are further classified into four types:

Premenstrual Exacerbation

There is increased severity of symptoms of an underlying medical or psychiatric disorder in the luteal phase of the menstrual cycle. For example, diabetes, asthma, depression, migraine, etc. may exhibit premenstrual exacerbation. Symptoms reduce following menstruation, but are not absent. See **Figure 8.3.3.2**.

Non-Ovulatory Premenstrual Disorders

Unspecified non-ovulatory ovarian activity is incriminated in causing symptoms in a small proportion of women. This area is

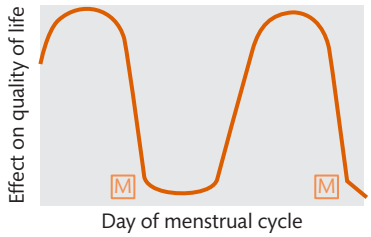

Figure 8.3.3.1 Core premenstrual disorder.

Box 8.3.3.1 Characteristics of symptoms in core PMD

1. Occur in ovulatory cycles
2. The type and number of symptoms are not specified—they may be somatic and/or psychological
3. Absent after menstruation and before ovulation (symptom free week in follicular phase)
4. Must recur in luteal phase
5. Must be prospectively rated for a minimum of two cycles
6. Must cause significant impairment to normal daily functioning, interfere with work, school, or interpersonal relationships or cause significant distress

poorly understood due to lack of robust evidence. Follicular activity in the ovary is hypothesized in symptom causation.

Progestogen-Induced Premenstrual Disorders

Symptoms are iatrogenic and arise due to use of exogenous progestogens such as cyclical hormone replacement therapy or combined oral contraception. Continuous administration of progestogens such as progestogen only contraception including a levonorgestrel intrauterine system (LNG-IUS) can cause PMD like side effects in women sensitive to progestogens but these would not be classified as core or variant PMD as there is no cyclicity. See Figure 8.3.3.3.

Premenstrual Disorders Without Menstruation

Symptoms are reported in some women who have medical or surgical amenorrhoea secondary to procedures such as hysterectomy with conservation of ovaries, endometrial ablation, or when using the LNG-IUS. These are due to an intact ovarian cycle. See Figure 8.3.3.4.

Symptoms

There are more than 200 reported symptoms. These encompass emotional, physical, behavioural, and cognitive domains (see Table 8.3.3.2). Probably, 80–95% of women experience some degree of premenstrual symptoms as a result of ovulation. These are called moliminal symptoms. The minimal severity of these

Table 8.3.3.1 Distinction between PMD definitions

PMS	PMDD
The negative impact of symptoms on daily functioning and severity of distress differentiates PMS from physiological premenstrual symptoms. Definitions which meet criteria for core PMD RCOG ACOG Definitions which do not meet core PMD criteria ICD-10	The diagnosis of PMDD is focused on psychological symptoms and lays emphasis on the number, character, and severity of symptoms. Definitions which meet criteria for core PMD DSM-5

Table 8.3.3.2 Characteristic symptoms of PMD

Physical	Emotional	Behavioural/ Cognitive
Breast tenderness or pain Abdominal swelling or bloating Headaches Acne Fatigue Weight gain Swelling of extremities Musculoskeletal pains or arthralgia	Mood swings Irritability Anger Loss of control Lack of interest in usual activities Loneliness Anxiety Depression Hopelessness Suicidal ideation or attempts	Change in appetite and food cravings Sleep disturbances Restlessness Social withdrawal Poor concentration Confusion

symptoms differentiates them from PMS, as they do not interfere with daily functioning of the individual. When symptoms are very severe, women might fulfil the criteria for premenstrual dysphoric disorder (PMDD). Often symptoms are similar to those experienced in other medical or psychiatric conditions. Their premenstrual timing and cyclical recurrence help differentiate PMD from other conditions. Complexity in diagnosis often arises when there is premenstrual exacerbation of an underlying medical or psychiatric condition, and one should be cautious when ruling out PMD in women suffering from chronic medical or psychiatric conditions.

Measurement of Symptoms

The ISPMD recommends two months of prospective rating of daily symptoms to enable accurate diagnosis. Studies have found retrospective recall of symptoms to be unreliable and bias in reporting can be due to the phenomenon of 'menstrual magnification' where any symptom exacerbated premenstrually is attributed to PMDs [5].

A variety of methods to quantify premenstrual symptoms is available with none universally preferable. Paper based methods include Calendar of Premenstrual Experiences, the Premenstrual Assessment Form, the Prospective Record of the Impact and Severity of Menstruation, Daily Record of Severity of Problems charts (DRSP) [6–9]. DRSP (Figure 8.3.3.5) is recommended by the RCOG as reliable and easy to use, but they are also noted to delay diagnosis and are reported to be inconvenient when completing and analysing symptoms hence are rarely used by clinicians [10]. Some clinicians use the premenstrual symptoms screening tool (PSST) to avoid unnecessary data collection when the diagnosis of PMS is unlikely [11]. Electronic methods of symptom quantification acceptable to women are being explored to overcome the limitations of using paper charts to aid diagnosis. One of the earlier methods was the Menstrual Symptometrics Device which quantified menstrual blood loss and premenstrual symptoms [12]. The Carolina Premenstrual Assessment Scoring System is a more recent computerized system developed to provide an electronic diagnosis of PMD [13, 14]. The latest advance in this area include an easy to use, commercially available mobile phone app, PreMentricS, which is currently being validated for use as a clinicians' aid to diagnosis (Figure 8.3.3.6).

Diagnosis

Establishing a diagnosis of PMD is complex as there are no objective tests available for this purpose. Clinical review should include a detailed review of medical, psychological, and psychiatric history, life stressors, substance abuse, and domestic violence. As a diagnosis of PMD is one of exclusion, physical examination is recommended including a breast and pelvic examination as dictated by the symptoms. Prospective symptom recording for 2 months prior to making a diagnosis is recommended [1, 10]. The benefits of prospective symptom charting include facilitation of diagnosis, providing a sense of symptom control for women by enabling a visualization of change in symptoms based on lifestyle modifications. and treatment tailoring. An accurate diagnosis supports the use of the most effective management strategies for PMD.

Differential Diagnosis

Due to the range of symptoms experienced, a number of medical, psychiatric, and psychological conditions can mimic PMD and vice versa (see Table 8.3.3.3).

Many of the aforementioned conditions exhibit premenstrual exacerbation of symptoms which can often complicate diagnosis and lead to ineffective treatments (see Table 8.3.3.4). Diligence in diagnosing and treating these conditions is essential for optimal symptom management.

Risk Factors and Comorbidity

Studies on twins have established a clear genetic influence in PMD [15]. Black women are noted to experience significantly less PMS and PMDD symptoms compared to Caucasian women [16]. Lifestyle risk factors for PMD include higher perceived stress levels, cigarette smoking, raised body mass index, earlier age of menarche, and greater alcohol or caffeine consumption. Recent evidence suggests that antiepileptic medication affects premenstrual symptoms experienced by women with epilepsy [17]. Studies have found an association between PMD and developing hypertension later in life [18].

Mood and anxiety disorders peak in the reproductive age group in women and are highly likely to be comorbidities with PMD [19]. Major depressive disorders are the most prevalent psychiatric disorder in women with PMD [20]. The relationship between bipolar disorder and PMD is less clear. Women with PMD have higher rates of obsessive-compulsive disorders and a quarter of women with PMD are affected by panic and anxiety disorders. Premenstrual exacerbation of schizophrenia has also been reported [21].

Pathophysiology

The definitive cause of PMD is unknown. There is no evidence to back hormonal imbalance as the cause. As there are no recorded differences in the hormonal levels, including thyroid stimulating hormone, oestrogen, progesterone, gonadotrophins, and adrenocorticotropic hormones, in women with PMD, and those without, there are no laboratory investigations to help diagnosis.

PMS appears to be triggered by ovulation as it is absent in anovulatory cycles. Progesterone released by the corpus luteum is implicated in symptom causation. It is hypothesized that the degree of sensitivity in the central nervous system (CNS) to the effects of hormones (especially progesterone) influences the severity of premenstrual symptoms experienced. A study where exogenous progestogen caused recurrence of symptoms in women with severe PMD post hysterectomy and bilateral salpingo-oophorectomy demonstrated the sensitivity of those women to the effects of progestogen. Women with PMD do not have the characteristic biological markers seen in depression [22]. They respond to antidepressant medication within days, while in women with depression and anxiety disorders, may require weeks of treatment before symptom

DAILY RECORD OF SEVERITY OF PROBLEMS

Please print and use as many sheets as you need for at least two FULL months of ratings.

Name or Initials _____

Month/Year _____

Each evening note the degree to which you experienced each of the problems listed below. Put an "x" in the box which corresponds to the severity: 1 - not at all, 2 - minimal, 3 - mild, 4 - moderate, 5 - severe, 6 - extreme.

		1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25	26	27	28	29	30	31

Figure 8.3.3.5 Daily Record of Severity of Problems chart for prospective recording of symptoms.

response. Several neurotransmitters have been implicated in the causation of progesterone hypersensitivity including GABA, serotonin, allopregnanolone, dopamine, endorphins, acetylcholine, cholecystokinin, and norepinephrine.

Serotonin

Serotonin has systemic hormone like effects influencing mood, behaviour, sexual function, appetite, and the immune system. Low serotonin levels cause panic, anxiety, irritability, and mood disturbances. Conditions characterized by depletion of serotonin such as a tryptophan poor diet result in symptoms similar to PMD. Antidepressants (selective serotonin reuptake inhibitors (SSRIs) and serotonin norepinephrine reuptake inhibitors (SNRIs)) which enhance synaptic serotonin levels, provide relief from symptoms in women with PMDs in contrast to medications which increase norepinephrine or dopamine.

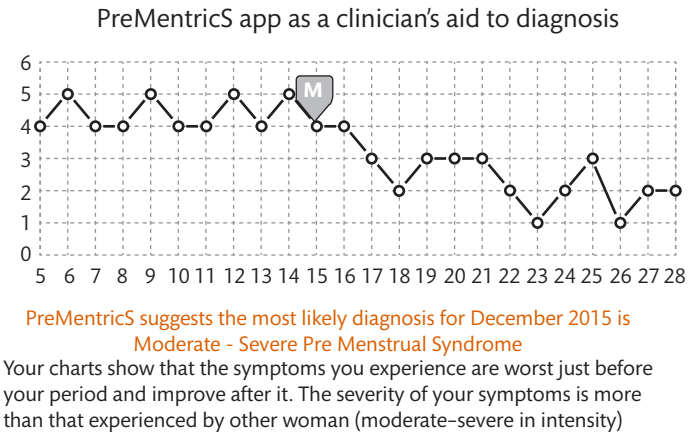

Figure 8.3.3.6 PreMentricS smartphone app allows daily recording of symptoms and graphically represents symptom scores to aid clinicians diagnosing premenstrual disorders.

Table 8.3.3.3 Differential diagnosis of PMD

Symptoms experienced	Disorders to exclude	Features differentiating symptoms from PMD
Headaches	Migraine	Timing of symptoms and absence of symptom free interval preovulation.
Abdominal bloating	Irritable bowel syndrome	Timing of symptoms and absence of symptom free interval preovulation.
Pelvic or abdominal pain	Chronic pelvic pain Endometriosis	Positive findings on clinical examination and investigations. Timing of symptoms helps exclude PMD diagnosis in women with chronic pelvic pain.
Fatigue	Chronic fatigue syndrome Anaemia Fibromyalgia Hypothyroidism	Absence of cyclical symptom recurrence. Clinical examination and laboratory investigations will yield positive results.
Breast symptoms	Fibrocystic breast disease Breast cancer	Clinical examination and radiological findings.
Emotional symptoms	Depression Anxiety disorders Substance abuse Post-traumatic stress disorder Psychosis	No pure cyclical symptoms Absence of asymptomatic phase pre ovulation. Past psychiatric history and failure to establish occurrence of symptoms in the luteal phase of the cycle should prompt psychiatric evaluation.
Combination of symptoms: Headaches, breast tenderness, sleep disturbances, hot flushes	Perimenopause	Lack of luteal timing. Elevated follicle stimulating hormone in perimenopause is of limited value.

Table 8.3.3.4 Disorders with premenstrual exacerbation

Somatic	Psychological
Endometriosis, adenomyosis, dysmenorrhoea Side effects of medications (especially hormonal contraception) Perimenopausal symptoms Migraines Anaemia Autoimmune disorders (e.g. systemic lupus erythematosis, multiple sclerosis) Hypothyroidism Fibromyalgia, chronic fatigue syndrome Breast disorders: fibrocystic, breast cancer, galactorrhoea Eating disorders	Major depressive disorder Bipolar disorder Anxiety disorders Seasonal affective disorder Personality disorders Substance abuse Stress Domestic violence

Allopregnanolone and GABA

Allopregnanolone, a neuroactive steroid, is a metabolite of progesterone which has been studied widely in relation to PMD. Allopregnanolone affects GABA, a major inhibitory neurotransmitter system in the CNS (see Figure 8.3.3.7). Of the different types of GABA receptors, GABA $_A$ receptor carries out the basic inhibitory control mechanism which is essential to the functioning of the CNS and regulation of mood and behaviour. This receptor is the site of action of allopregnanolone, alcohol, anticonvulsants, benzodiazepines, and barbiturates [23]. It is hypothesized that alteration of the GABA $_A$ receptor isoform is responsible for symptoms of PMD by causing decreased neurosteroid sensitivity and CNS excitability [23]. This is based on a study which used saccadic eye velocity as a proxy for central GABAergic tone and showed decreased responsiveness to pregnanolone and benzodiazepines in the luteal phase in women with PMS. SSRI treatments increase the GABA concentration in the occipital cortex of the brain hence providing evidence of a link between the serotonergic and GABAergic neurotransmitter systems.

Ovarian Steroids

The positive impact of ovulation suppressing treatments on premenstrual symptoms in women with PMD provides evidence of the involvement of ovarian steroids, oestrogen, and progesterone, in symptom development. Ovulation suppression using combined oral contraception has had varied results with symptoms being experienced all throughout the cycle in some women. Although still unclear, the mechanism of symptom development in relation to ovarian steroids is hypothesized on the fluctuations in the presence of the sex hormones and effects of the oestradiol on the renin angiotensin system and sensitivity of the CNS to the circulating (endogenous and exogenous) progestogens. Unlike other endocrine abnormalities where there are differences in the levels of the related hormones (such as thyroid hormones in thyroid disorders), studies have not found any difference in the levels of ovarian hormones in women with PMD compared to asymptomatic women, which strengthens the hypothesis suggesting that the differences lie in the sensitivity of women to these hormones.

Treatment of PMD

The key to effective management of PMD lies in accuracy of the diagnosis. A diagnosis based on two months of prospective symptom recording is recommended prior to initiating treatment for these disorders. In case of discrepancy in diagnosis between two months of symptom recording, further months recording is recommended. Once diagnosis is established, management should be individualized and the woman should be involved in the decision-making process as this leads to better understanding of the condition by the woman and greater treatment compliance. Contraceptive needs should be discussed in every case and a multidisciplinary team approach, involving the family physician, gynaecologist, psychiatrist/psychologist, should be the ideal although this is rarely possible. Severe PMD which involves suicidal ideation should involve urgent consultation with a psychiatrist.

The most logical way of treating PMD involves the elimination of ovulation and ovarian steroid activity. Alternatively, as serotonin depletion is hypothesized in symptom causation, medications which increase the serotonergic functioning can be used. Dietary and environmental interventions reduce sensitivity of the neuroendocrine system. Pilot studies investigating the use of the GABA$_A$ receptor modulating steroid, sepranolone, in treating symptoms have shown initial positive results [24].

During the time of completion of the prospective symptom charts it may be prudent to initiate treatment by giving advice regarding lifestyle changes. Although there is no symptom-based classification for PMD, in situations where there is one dominant symptom, symptom-based treatment is likely to be most effective. In general, treatment options for PMD can be divided into those which involve suppression of ovulation and those which do not. See Figure 8.3.3.8.

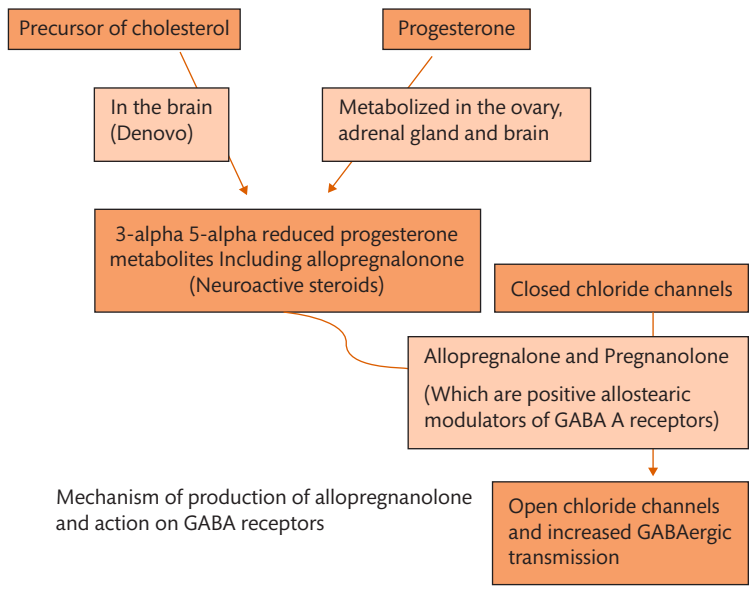

Figure 8.3.3.7 Mechanism of production of allopregnanolone and action on GABA receptors.

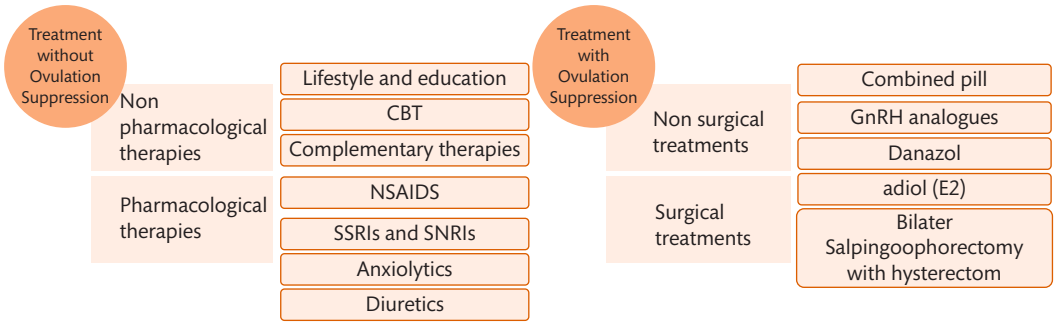

Figure 8.3.3.8 Management options for treating premenstrual disorders.

Treatments Without Ovulation Suppression

The strongest evidence for efficacy of non-pharmacological therapies include calcium, chasteberry, and cognitive behaviour therapy (CBT).

Lifestyle and Education

There are no randomized control trials (RCTs) to support the reported decrease in premenstrual symptoms with regular aerobic exercise. It is believed that relief in symptoms is due to the release of endorphins [25]. Education regarding the condition to allow satisfactory lifestyle modifications including reducing stress levels, incorporating exercise and weight loss have been suggested as an initial intervention in women presenting with PMD symptoms.

Dietary and Nutritional Supplements

Very few of the many dietary recommendations have been scientifically explored. Calcium supplementation has the strongest evidence of benefit among the nutritional supplements explored. Dosage of 1200 mg/day of calcium carbonate can be used for this purpose. 100 mg of vitamin B_6 daily has been shown to be slightly superior to placebo. Caution is recommended when increasing the dose of vitamin B_6 as it may precipitate peripheral neuropathy and it should be discontinued if any tingling or numbness is experienced in the extremities. Chasteberry (*Vitex agnus castus*) has shown encouraging results when dealing with emotional and physical PMD.

Cognitive Behavioural Therapy

This treatment can be initiated when prospective symptom recording is being carried out and its efficacy is thought to stem from improved coping strategies and modification of irrational thinking [25]. Recent studies have indicated some benefit of couples CBT compared to one-to-one therapy [26]. CBT in combination with SSRIs was found to have longer maintenance of treatment effect compared to SSRI alone.

NSAIDS

Useful for pain management, but not effective in the presence of emotional or behavioural symptoms.

Anxiolytics

Anxiolytics such as benzodiazepines may be of use in women with predominant anxiety/irritability symptoms. However, there is poor evidence to support their use in PMD and concerns regarding drug dependence have suggested usage restricted to the luteal phase of the menstrual cycle. Buspirone, a 5HT1A partial agonist, is an alternative as it has low dependence and has shown some efficacy in treating PMD.

Selective Serotonin Reuptake Inhibitors (SSRIs) and Serotonin Norepinephrine Reuptake Inhibitors (SNRIs)

There is strong evidence of symptomatic benefit with the use of SSRIs for PMD. It is important to rule out bipolar disorder prior to prescribing this class of medication as they may trigger a manic episode if used without a mood stabilizer. As the onset of action is short for SSRIs when used for PMD, their use can be limited to the luteal phase of the cycle, with efficacy similar to continuous daily dosing of SSRIs as demonstrated in recent Cochrane review [27]. Dosage of use is recommended to be similar to that used in the treatment of depression: fluoxetine 20–40 mg/day; sertraline 50–150 mg/day; paroxetine 10–20 mg or 12.5–25 mg of paroxetine continuous release (paroxetine CR) per day; and citalopram 10–20 mg/day. Most of the side effects of SSRIs are transient and include nausea, insomnia, headache, fatigue, diarrhoea, dizziness, and decreased libido or delayed orgasm. Although most of these disappear with continued use, the effects on sexual dysfunction reduce only after discontinuation of treatment, which can be a cause of discontinuation of treatment. The overall response to SSRIs is 50–60% and low response usually triggers the use of an alternative SSRI [25].

Diuretics

Spironolactone, an aldosterone receptor antagonist, may be useful in the management of women with mastalgia and severe bloating [28].

Complementary and Alternative Medicine

A number of other modalities which have had positive initial results but should only be offered in the context of a clinical trial are: acupuncture, Qi therapy, relaxation, reflexology, massage, krill oil, lavender oil, Chinese herbs, and transmagnetic stimulation.

Treatment by Suppression of Ovulation

These treatments are not recommended for women who wish to conceive as they involve the suppression of ovulation.

Combines Oral Contraception (COC)

The 'pill' is the most commonly used contraceptive method worldwide. As the COC prevents ovulation, it eliminates the luteal phase of the cycle. In spite of this, traditional COCs have not shown efficacy in the treatment of PMD. This is related to sensitivity of women

to the progestogen component of the pill leading to PMS-like side effects.

RCTs have shown that newer oral contraceptives, containing ethinyl oestradiol (20 μg) and drospirenone (3 mg) in a 24/4 regimen are effective in treating women with PMD. Drospirenone is an antiandrogenic progestogen. It is derived from 17-α-spironolactone and has antimineralocorticoid properties. A shorter hormone free interval in the 24/4 regimen maintains sufficient sex steroid hormone levels to prevent follicular development and supresses ovarian steroid synthesis. This regimen is approved by the United States Food and Drug Administration (FDA) for use in the treatment of PMDD. Most clinicians use this pill continuously (omitting the four placebo tablets), but there is no supportive research for this strategy.

Gonadotrophin-Releasing Hormone (GnRH) Analogues

GnRH agonists down-regulate gonadotrophin release, hence suppressing ovarian function and the production of ovarian steroids. This reduces oestrogen and progesterone to postmenopausal levels. This treatment provides relief to women with PMD symptoms, but use is restricted by the cost and hypo-oestrogenic side effects. Add-back therapy with oestradiol and progestogen, although reducing the short-term vasomotor side effects and long term adverse effects (vaginal atrophy, increased cardiovascular risk, bone demineralization and potentially osteoporosis), may cause resurgence of PMS-like symptoms. A recent review found that add-back therapy does not decrease the efficacy of GnRH analogue treatment [29]. Various types of add-back therapies, including tibolone, have been attempted, but none was found to be superior. Treatment with GnRH analogues is reserved for situations where other approaches have failed. It is a useful way of predicting efficacy of hysterectomy and bilateral oophorectomy in women contemplating surgery as a treatment option for severe PMD. It can also be used to determine whether severe symptoms are related to PMDD or another comorbidity. GnRH antagonists have the advantage of being orally active and avoid the agonist 'flare', but there are no published studies.

Danazol

Danazol is an androgen analogue which inhibits gonadotrophins at high levels. Danazol has, in the past, been effective in treating PMD, but is rarely used due to its masculinizing side effects. There is a risk of virilization of a female fetus should pregnancy occur while taking it, necessitating use of reliable long acting contraception.

Oestradiol (E2)

Transdermal oestradiol (200 μg) effectively inhibits ovulation. No published studies support the use of oral oestrogens for this purpose. To prevent endometrial hyperplasia and irregular bleeding secondary to unopposed oestrogen, addition of a progestogen is recommended. This has been given in the form of 2.5 mg of norethisterone or 100 mg of oral micronized progesterone for the first 7–10 days of each calendar month or as an intrauterine system with 52 mg levonorgestrel in its core. The short duration of progestogen is to prevent the recurrence of symptoms in women already sensitive to progestogens. An intrauterine system may be an effective alternative treatment option in women as there is (usually but not always) minimal systemic absorption after the initial few months; it also provides effective contraception.

Tibolone

This is a synthetic steroid with oestrogenic, progestogenic, and androgenic properties. There is some evidence that 2.5 mg tibolone may be effective in treating PMS [30]. Further trials are necessary before recommending it as a treatment option.

Surgery

This treatment option involves bilateral oophorectomy with hysterectomy and may be contemplated in women over 35 years of age, whose family is complete, suffering from severe symptoms or where hysterectomy is indicated for other comorbidities. Careful selection of cases is necessary as it involves major surgery. GnRH administration to confirm the efficacy of the planned surgery is advised [10]. Hormone replacement therapy is then recommended at least up to the age of menopause. Unopposed oestrogen can be used in women where hysterectomy has been performed. In women who have had bilateral oophorectomy with conservation of the uterus, a progestogen is required for endometrial protection when oestrogen replacement therapy is prescribed. This can reintroduce symptoms of PMS and therefore is not a recommended surgical option for treating PMD.

Summary

Premenstrual syndrome affects millions of women all over the world with up to 3–8% of women suffering from a very severe form called PMDD. PMD occur during a woman's reproductive years causing significant impairment in relationships, productivity, and quality of life. The aetiology is unknown. This in combination with the absence of objective diagnostic tests complicate diagnosis and treatment. Prospective symptom quantification is required to make a diagnosis. Lifestyle modifications, CBT, and calcium can be initiated in the diagnostic phase. Once diagnosed, a personalized case-based approach is recommended for managing this complex condition. Treatments involving COC, GnRH analogues with add-back hormone therapy, for example, oestradiol patches along with progestin can be attempted in young women where ovulation suppression is acceptable. Luteal phase SSRIs are recommended for those not wanting hormonal therapies. In very severe conditions surgical options involving bilateral oophorectomy and hysterectomy can be considered. The ICD-11 was released recently in 2018 and this, unlike the previous version, recognises the category of PMDD [31].

Polycystic Ovary Syndrome and Other Androgen Excess Disorders

8.4.1 Polycystic Ovary Syndrome

Definitions, Phenotypes, Prevalence, and Genetics

Sezcan Mumusoglu and Bulent Okan Yildiz

Introduction

Polycystic ovary syndrome was first reported in 1935 by Stein and Leventhal in seven cases, with large stiff ovaries, amenorrhoea, and infertility. Five of the patients were hirsute and one had acne. Wedge resection resulted in two pregnancies and regular cycles in remaining [1]. As an heterogenous disorder, the definition of PCOS remains still controversial. Nevertheless, available international guidelines emphasize that androgen excess, ovulatory dysfunction and polycystic ovaries are the main features of the syndrome [2].

Clinical Features Defining Polycystic Ovary Syndrome

PCOS is not a disease, but a syndrome; therefore, it reflects various potential aetiologies with diverse clinical presentations. The principal clinical features of PCOS are hyperandrogenism (HA), ovulatory dysfunction (OD) and polycystic ovarian morphology (PCOM). A recent meta-analysis of 24 studies on PCOS prevalence from all around the globe including Europe, United States (US), Asia, and Australia, revealed that overall reported prevalence (95% CI) of hirsutism, biochemical HA, OD, and PCOM in population were 13% (8–20%), 11% (8–15%), 15% (12–18%), and 28% (22–35%), respectively [3].

Androgen Excess (Hyperandrogenism)

Androgen excess is detectable either by clinical exam or biochemical analysis. Hirsutism is the main diagnostic criterion of clinical HA whereas acne and androgenic alopecia are among other skin manifestations. Androgen excess presented by elevated serum androgen levels is referred as hyperandrogenaemia or biochemical HA. Most of the women with PCOS, but not all, have both clinical and biochemical evidence of HA [4].

Hirsutism is defined as excess growth of body or facial terminal hair in females, in a male-like pattern and assessed by using a modified Ferriman–Gallwey (mFG) scoring system in which nine areas of the body (the upper lip, chin, chest, upper and lower abdomen, thighs, upper and lower back, and upper arms) are scored from 0 to 4 by the observer [5]. Hirsutism is usually defined by a total mFG score of ≥4–6 depending on ethnicity. Hirsutism is present in up to 80% of patients with HA. The rates of hirsutism would show variation depending on geographical region and ethnicity and it is important to use a population-specific cut-off level. Standardized visual scales [6] should be preferred when assessing hirsutism with acknowledging that self-treatment is common and can limit clinical assessment [2]. Approximately 70% of women with hirsutism have PCOS [7].

Other uncommon and less specific markers of clinical HA are acne and alopecia. A meta-analysis of pooled data on studies of PCOS prevalence reported that the prevalence of acne and alopecia are 16% (95% CI, 8–26%) and 2% (95% CI, 0–5%) in adult women, respectively [3]. Approximately 40% of women complaining of severe acne have a risk of having PCOS, whereas only 18% of women with androgenic alopecia were found to have PCOS [8]. On the other hand, acne or alopecia alone are not commonly associated with and should not be considered as a sign of clinical HA [7].

Assessment of biochemical HA in clinical practice is most useful in establishing the diagnosis of PCOS and/or phenotype where clinical signs of HA, particularly hirsutism is unclear or absent [2]. Biochemical HA could not be reliably assessed in women on hormonal contraception and drug withdrawal is required for at least three months. The use of calculated free or bioavailable testosterone or free androgen index (FAI) is recommended for evaluation of

biochemical HA. FAI is calculated as the ratio of total testosterone (tT) divided by sex hormone binding globulin (SHBG) and multiplied by hundred (FAI = TT × 100/SHBG). Direct measurement of tT by chemiluminescence or radioluminescence immunoassays without extraction/chromatography is not generally recommended for children or women including PCOS due to low precision, sensitivity, and specificity of these assays. Commercially available assays for direct measurement of free testosterone (fT) are not reliable and should not be used in assessment of biochemical HA [9]. Most reliable results could be obtained by properly validated extraction/chromatography immunoassays or liquid chromatography-mass spectrometry (LC-MS). Measurement of androstenedione (A4) and dehydroepiandrosterone sulphate (DHEAS) might provide limited information if total or free testosterone are not elevated. Normal values of androgens should be determined from healthy non-hirsute, eumenorrheic women, or by a cluster analysis of a large sample of general population. At least 70% of PCOS patients presenting to the clinics show biochemical HA when high-quality assays are used [10]. We have previously reported in a population study that 76% of unselected women with PCOS had biochemical and/or clinical HA [11].

Ovulatory Dysfunction

Ovulatory dysfunction presents with menstrual irregularities (<21 or >35 days) often characterized by oligomenorrhoea, due to infrequent or absent ovulation. Oligomenorrhea is defined as menstrual cycle length >35 days or having <8 menstrual cycles in a year whereas amenorrhea is the absence of menstruation for three or more consecutive months. PCOS is the most common cause of oligo-anovulation. Among women with oligo-anovulation, ~70% will have a diagnosis of PCOS [12], while ~80% of the women with PCOS have oligo-amenorrhea [10].

Most women with PCOS have a history of menstrual irregularities starting from puberty or primary amenorrhea, whereas, some may have regular cycles at the beginning and subsequently develop irregular menstruation in association with weight gain [13]. Weight loss in those obese PCOS patients usually leads to a recovery of menstrual cycles [14]. Additionally, many women with PCOS tend to have more regular cycles by ageing [15], probably due to follicle loss through the process of ovarian ageing or a decrease in androgen levels by ageing [16].

Regular menses indicate ovulatory cycles in almost every woman in the general population [17]. On the other hand, having regular cycles might not be confirm regular ovulation particularly in women with HA [18]. A study revealed that 40% of 132 hirsute women claiming 'regular cycles' had actually OD and this entity is known as 'subclinical-OD' [10]. Accordingly, in patients with hirsutism or PCOM who have apparently regular menstrual cycles, luteal phase (days 21–24 of the cycle) progesterone levels need to be measured and a progesterone level ≥5 ng/ml should be used as a proof of ovulation.

Polycystic Ovaries

Polycystic ovarian morphology on ultrasound is the most common feature of PCOS affecting up to 1 in 3 adult women in the population (22–35% in prevalence studies) [3]. Introduction of the high frequency ultrasound into clinical use, in1990s, enabled observation of the histologic findings of polycystic ovaries non-invasively. Initially, presence of ≥10 antral follicles in each ovary between 2 to 8 mm in diameter with peripheral location and relatively increased amount of stroma on ultrasound had been defined as PCOM, without any threshold for ovarian volume [19]. In 2003, presence of PCOM was included in the set of diagnostic criteria known as Rotterdam criteria and presence of ≥12 antral follicles in either ovary between 2 to 9 mm in diameter and/or increased ovarian volume (>10 ml; calculated by the formula 0.5× length × width × thickness) was described as ultrasound criteria for PCOM [20]. It was recommended to use transvaginal rather than transabdominal ultrasound [10].

A recent meta-analysis including 12 population-based PCOS prevalence studies [3] reported that the lowest prevalence of PCOM (11%) was obtained from a study conducted with 5 MHz probe [21], whereas, the highest prevalence (53%) was observed in a study with 5–9 MHz ultrasound probe [8]. It appears that the ultrasound technology and frequency of the transducer effect definition of PCOM, the selected threshold for antral follicle count (AFC), the application of ovarian volume and the precise diagnosis of PCOM. Accordingly, 2018 international evidence-based guideline for the assessment and management of PCOS recommends the use of ≥20 antral follicles and/or an ovarian volume ≥10 ml on either ovary as a threshold for PCOM when an endovaginal ultrasound transducer with a frequency bandwidth that includes 8 MHz is used [2]. If using older technology or transabdominal ultrasound, the threshold for PCOM could be an ovarian volume ≥10 ml on either ovary due to difficulty or reliability of assessing follicle number with these approaches [2]. Considering the decrease of ovarian volume and AFC with ageing, age-specific cut-off values are needed to define PCOM.

It is noteworthy to mention that PCOM has a low predictive value for the diagnosis of PCOS in that only one out of four adult women with PCOM would eventually be diagnosed with PCOS [3]. On the other hand, pooled analysis of 13 studies including 3361 women with a diagnosis of PCOS revealed that ~75% of the women with PCOS have PCOM on ultrasound with using both above-mentioned sets of ultrasound criteria [10].

Anti-Müllerian Hormone (AMH), a polypeptide secreted only by granulosa cells of the pre-antral and antral follicles, has been proposed as an alternative surrogate marker for the detection of PCOM due to limitations and challenges of the ultrasound in the diagnosis of PCOS. Even though AMH levels are higher in women with PCOS than healthy women and correlate with AFC on ultrasound, the available assays show significant heterogeneity and lack standardization. Therefore, routine use of AMH as part of laboratory evaluation in PCOS is not yet recommended by current guidelines [2, 22].

Diagnostic Criteria of Polycystic Ovary Syndrome

Diagnostic criteria of PCOS in adult women are not necessarily applicable in adolescents. Some normal features of puberty including irregular cycles, ovulatory dysfunction, multicystic ovaries, and acne could be identical with features of PCOS. In this context, sets of diagnostic criteria for adults and adolescents have been reviewed separately (Table 8.4.1.1).

Table 8.4.1.1 Sets of diagnostic criteria for polycystic ovary syndrome in adults and adolescents

Features of PCOS	In adults			In adolescents	
	NIH 1990	Rotterdam* 2004	Androgen Excess Society 2006	ICPE 2017#	International PCOS Network* 2018

Ovulatory dysfunction (OD)	✓[a]	±	±	✓[b]	✓[d]
Polycystic ovarian morphology (PCOM)	–	±	±	±[c]	–[e]
Diagnosis statement	HA and OD are indispensable features	Any 2 out of 3 features (HA, OD, PCOM) is sufficient	HA is a must and it should be accompanied by any one out of OD and PCOM or both	HA and OD are indispensable features	HA and OD are indispensable

NIH, National Institutes of Health; ICPE, International Consortium of Pediatric Endocrinology.

* Recommended sets of diagnostic criteria by the "*The international evidence-based guideline for the assessment and management of PCOS*" in 2008. # Severe cystic acne is suggested as optional criteria used in concert with indispensable criteria.

✓ A must criteria for diagnosis; ± It may present or not (optional); – Not identified or suggested features in diagnostic set.

[a] detected by only menstrual irregularities

[b] should persist 2 years beyond menarche

[c] PCOM used in concert with the required criteria, and defined as ovarian volume>10 cm^3

[d] reassessment is advised 8 years postmenarche

[e] should not be used <8 years after menarche

Diagnostic Criteria of Polycystic Ovary Syndrome in Adults

For the diagnosis of PCOS in adults, different groups have proposed three different sets of diagnostic criteria in the last three decades (Table 8.4.1.1) [20, 23]. The common prerequisite in all three sets is that the mimicking disorders should be ruled out before making the diagnosis of PCOS.

In 1990, an expert meeting sponsored by National Institutes of Health (NIH) produced the first set of diagnostic criteria [24]. As a result of a survey of participants, after the exclusion of mimicking disorders including non-classical congenital adrenal hyperplasia (NCAH), thyroid dysfunction, and hyperprolactinemia, the presence of clinical and/or biochemical HA and presence of menstrual irregularities was proposed as indispensable features of PCOS for diagnosis (Table 8.4.1.1). Majority suggested that detection of PCOM by ultrasound was not essential for the diagnosis even though it was in the list of possible diagnostic criteria [24].

In 2003, European Society for Human Reproduction and Embryology/American Society for Reproductive Medicine (ESHRE/ASRM) sponsored consensus workshop was held in Rotterdam and the second set of diagnostic criteria was proposed [20]. In addition to NIH criteria, PCOM on ultrasound was accepted as a diagnostic feature. Presence of any 2 out of 3 following features was sufficient for the diagnosis of PCOS: (i) clinical and/or biochemical HA; (ii) OD; and (iii) PCOM (Table 8.4.1.1). Rotterdam criteria expanded the definition of PCOS by adding new phenotypes to the NIH criteria (Figure 8.4.1.1).

In 2006, the Androgen Excess & PCOS Society (AE-PCOS) published a task force report on diagnosis of PCOS [23]. The conclusion was that PCOS is a mainly hyperandrogenic disorder and the presence of clinical and/or biochemical HA is indispensable. The second criterion in addition to HA could be OD or PCOM (Table 8.4.1.1). Hence, the AE-PCOS criteria were a compromise between NIH and Rotterdam criteria excluding the new non-hyperandrogenic phenotypes proposed by Rotterdam [23].

There are many similarities between each proposed set of diagnostic criteria. However, the following differences and limitations are worth discussing: (i) the original NIH criteria defines menstrual dysfunction by <6 menses per year, it fails to include the women with regular menses and 'subclinical-OD', whereas the Rotterdam

NIH 1990

AE-PCOS 2006

	Phenotype A	Phenotype B	Phenotype C	Phenotype D
Androgen excess (Clinical and/or biochemical-HA)	✓	✓	✓	–
Ovulatory dysfunction (OD)	✓	✓	–	✓
Polycystic ovaries (PCO)	✓	–	✓	✓
Distributions of PCOS phenotypes (%)	40–45		~35	~20

Figure 8.4.1.1 Phenotypes of polycystic ovary syndrome according to diagnostic criteria sets.

and AE-PCOS criteria do not; (ii) in Rotterdam and AE-PCOS criteria the diagnosis depends on the use of a reliable method and cut-off to describe PCOM; (iii) neither Rotterdam nor AE-PCOS criteria described how hypothalamic amenorrhea with PCOM will be differentiated from PCOS; (iv) using different sets of diagnostic criteria decreases the comparability of PCOS research worldwide and causes confusion in clinical practice.

In 2012, NIH Evidence-based Methodology Workshop on PCOS was convened and announced the following recommendations [25]; (i) assigning a new name which reflects the complex metabolic, hypothalamic, pituitary, ovarian, and adrenal interactions that characterize the syndrome, however, no specific name was suggested; (ii) using the broad, inclusionary diagnostic criteria of Rotterdam which includes the 'classic NIH' and the Androgen Excess and PCOS Society criteria, however with specifically identifying each subphenotype in research and clinical initiatives: phenotype A: HA + OD + PCO; phenotype B: HA + OD; phenotype C: HA + PCO; and phenotype D: OD + PCO (Figure 8.4.1.1); and (iii) improving the methods and criteria used to assess androgen excess and OD.

The guidelines and position statement papers published after the NIH workshop all support the use of broader Rotterdam criteria for the diagnosis of PCOS with explicit reporting of the specific phenotypes [2, 26, 27].

Diagnostic Criteria of Polycystic Ovary Syndrome in Adolescents

In pubertal transition after menarche, 85% and 59% of menstrual cycles are anovulatory in the first and third years, respectively [26]. Therefore, OD has not been considered as a sign of PCOS until it persists 2 years beyond menarche [28]. Similarly, PCOM is a very common finding among adolescents even by abdominal ultrasound when the Rotterdam criteria are applied [26]. However, after 2 years from menarche the thresholds for increased ovarian size in adolescents becomes similar of those for adults [29]. Therefore, using ovarian volume is a better option than using AFC for defining PCOM in adolescents [29]. With regard to definition of HA in adolescents, mFG scores are not affected by age and tT and fT levels 1 to 2 years after menarche are generally comparable with those in adults [30]. Therefore, documented persistent HA could be diagnostic feature in adolescents. Overall, evidence suggests that assessment and diagnosis of PCOS in adolescents, particularly before the age of 18 years may cause overdiagnosis of the syndrome [31].

In the last few years, four sets of diagnostic criteria have been proposed for PCOS in adolescents: First, in 2012, the Amsterdam ESHRE/ASRM-sponsored 3rd PCOS Consensus Workshop Group recommended to observe all three features (HA, OD, and PCO) for the diagnosis of PCOS but only in adolescents who are at least 2 years postmenarche and/or those with primary amenorrhea by the age of 16 years before diagnosis, after exclusion of related disorders [7]. Second, in 2013, Endocrine Society suggested that diagnosis should be based on clinical and/or biochemical HA in the presence of persistent oligomenorrhea after exclusion of other pathologies. However, Endocrine Society recommended against the use of PCO appearance to make diagnosis in adolescent [26]. Third, in 2017, International Consortium of Pediatric Endocrinology (ICPE) recommended that for the appropriate diagnosis of adolescent PCOS clinical and/or biochemical HA and menstrual irregularities 2 years beyond menarche are required after exclusion of related disorders. According to ICPE guideline PCO on ultrasound and severe cystic acne are optional features of PCOS and recommended to be used in concert with HA and menstrual irregularities to diagnose PCOS in adolescents (Table 8.4.1.1) [32]. Lastly, in 2018, 'The international evidence-based guideline for the assessment and management of PCOS' recommended both oligo-anovulation and HA as required criteria, however, suggested against use of PCO on ultrasound <8 years after menarche [2]. The guidelines also suggest that in adolescents with a feature of PCOS who do not meet diagnostic criteria an increased risk could be considered planning reassessment at or before full reproductive maturity after 8 years postmenarche (Table 8.4.1.1) [2].

Differential Diagnosis of Polycystic Ovary Syndrome and Exclusion of Mimicking Disorders

All mimicking and similar disorders should be excluded before making the diagnosis of PCOS. Thyroid dysfunction and hyperprolactinemia could mimic PCOS causing OD and should be excluded by measuring thyroid stimulating hormone and prolactin, respectively. These two disorders are relatively rare in PCOS. Accompanying thyroid dysfunction in 7563 PCOS patients was reported to be 1.15% whereas prevalence of hyperprolactinemia was 2.8% in women with PCOS [10].

In patients with HA, non-classical congenital adrenal hyperplasia (NCAH) should be excluded. NCAH is an autosomal recessive disease characterized with the deficiency of 21-hydroxylase. Depending on ethnicity, the prevalence of NCAH ranges between 1% and 10% in patients with HA [33]. The clinical presentation of NCAH is identical with the classical features of PCOS; including OD, clinical- and biochemical HA, and PCOM ~40% of the patients [34]. Basal morning 17-hydroxyprogesterone (17-HP) is measured in the early follicular phase for the diagnosis of 21-OH-deficient NCAH. A cut-off value >2 ng/ml detects NCAH with 90% sensitivity. Patients with a screening level greater than 2 ng/ml should undergo an acute adrenocorticotropic hormone (ACTH) stimulation test.

Other rare disorders such as adrenal or ovarian androgen-secreting neoplasms, Cushing's syndrome, acromegaly, disorders of severe insulin resistance including hyperandrogenic insulin-resistant acanthosis nigricans (HAIR-AN) and lipodystrophy should be excluded by appropriate tests in case of clinical suspicion.

Phenotypes of Polycystic Ovary Syndrome

PCOS presents with various phenotypes. The NIH 2012 evidence-based methodology PCOS workshop recommends the use of broader ESHRE/ASRM diagnostic criteria, with explicit reporting of specific phenotypes in all research studies and clinical care [25]. In 2009; an AE-PCOS Task Force recommended using nine subphenotypes considering the four features of OD, clinical HA, biochemical HA, and PCOM [10]. Later, in 2012, NIH Evidence-based Methodology

Workshop on PCOS recommended to use phenotypic approach with four subphenotypes in order to maximize the homogeneity and comparability in research and clinical initiatives NIH as just stated [25] (Figure 8.4.1.1). This approach was also endorsed by the 2018 international evidence-based guideline for the assessment and management of PCOS [2].

Phenotype A and B (Classic PCOS)

About 15–20% of women with PCOS will have phenotype A (HA + OD + PCO) whereas 30–35% will show phenotype B (HA + OD) (Figure 8.4.1.1). Women with classic PCOS appear to be more hirsute and obese, show a more irregular menstrual pattern and more likely to have insulin resistance, dyslipidaemia, hepatic steatosis with an increased risk for metabolic syndrome compared to ovulatory or non-hyperandrogenic phenotypes (C and D) [31, 35].

Phenotype C (Ovulatory PCOS)

Phenotype C (HA + PCOM) or ovulatory PCOS seem to affect ~35% of the women with PCOS in unselected population studies of the syndrome (Figure 8.4.1.1) [31]. Hirsutism scores, androgen and lipid levels, and risk of metabolic syndrome of women with phenotype C are in between classic PCOS and phenotype D [36].

Phenotype D (Non-Hyperandrogenic PCOS)

Phenotype D or non-hyperandrogenic PCOS is the least prevalent phenotype comprising ~15–20% of the women with PCOS. These patients have normal androgen levels and the mildest degree of metabolic dysfunction including insulin resistance and (Figure 8.4.1.1) [31]. Patients with phenotype D who have increased body mass index (BMI) might be more insulin-resistant compared to healthy women even though at a level lower than classic PCOS [37].

Referral Bias in Phenotypes of PCOS

Most of the available data linking PCOS with endocrine and metabolic dysfunction and long-term comorbidities are derived from studies where included patients are those referred to the clinics for medical care. It should be kept in mind that there are significant differences between clinical versus unselected populations of PCOS patients. Patients presenting to the clinics have more severe phenotypes, more severe clinical and biochemical HA and higher BMI compared to patients identified in unselected populations reflecting significant referral bias [38].

Prevalence of Polycystic Ovary Syndrome

There are substantial discrepancies between the results of the epidemiological studies investigating the prevalence of PCOS. For example, reported prevalence with Rotterdam criteria is between the range of 2–21% [3]. The variation might be due to differences of selected study populations (referral bias) [38], limitations within the sampling and protocols applied, and a lack of standardized definitions for the features of PCOS. The effects of race and ethnicity, particularly, on the clinical presentation of androgen excess and enhancement in the ultrasound technology over time for visibility of AFC might also contribute to the inconsistencies between prevalence studies.

Recently, we have reported a systematic review and meta-analysis of 24 studies on prevalence of PCOS from all around the globe including Europe, US, Asia, and Australia [3]. Since there was significant heterogeneity among the studies, we have also generated an appraisal tool, which showed that available studies had low to moderate methodological quality. The PCOS prevalence (95% CI) according to the diagnostic criteria of NIH, Rotterdam and AE-PCOS Society were 6% (5–8%, n = 18 trials), 10% (8–13%, n = 15 trials) and 10% (7–13%, n = 10 trials), respectively. Higher prevalence rates with Rotterdam and AE-PCOS Society criteria compared to NIH are due to expansion of definition with inclusion of more phenotypes in addition to classic PCOS defined by NIH criteria (Figure 8.4.1.2) [3].

Genetics of Polycystic Ovary Syndrome

It has long been recognized that PCOS clusters in families and that both genetic and environmental factors contribute to the development of the syndrome [39]. A twin study on heritability of PCOS from The Dutch Twin Register database estimated about 70% influence of genetic factors on the pathogenesis of PCOS [40]. Recently, genome-wide association studies (GWAS) have supported the idea that PCOS has an oligogenic/polygenic inheritance similar to type 2 diabetes and cardiovascular disease [41]. However, clarifying the type of inheritance is difficult due to incomplete penetrance and epigenetic modifications with contributions of environmental effects [39].

Several studies have examined association of PCOS with more than 100 candidate genes involved in gonadotropin secretion and action, androgen biosynthesis, and action, folliculogenesis, insulin action, and diabetes, metabolism, and inflammation [42, 43]. These studies have limitations including small sample size, not well-matched cases and controls and lack of replication [39, 44]. In this context, GWAS studies provided a new insight and a more comprehensive approach to identify the genetic basis of PCOS [45–50]. The mapped genes, genotype-phenotype associated genes, pathway associated genes, and functional genes elucidated by GWAS studies in Han Chinese and European ancestry are shown in Table 8.4.1.2. Although there are substantial ethnic differences, cross-ethnic meta-analysis of genetic variants for PCOS revealed that 12 of 17 genetic variants mapping to the Chinese PCOS loci, including *YAP1, RAB5B/SUOX, LHCGR, THADA, DENND1A, FSHR, c9orf3, SUMO1P1*, similar effect size and identical direction in PCOS patients from Northern European ancestry, indicating a common genetic risk profile for PCOS across populations and supports the hypothesis that PCOS is an ancient disorder that may have persisted for more than 50 000 years [51, 52].

Despite major advances in the field of PCOS genetics, identified susceptibility loci in GWAS studies so far appear to contribute less than 10% of the heritability of the disorder. In the future, identification of rare variants and functional gene networks by next generation sequencing along with epigenetic studies might further increase our understanding of the pathophysiology of the syndrome [53].

Table 8.4.1.2 Genetic studies and identified genes in PCOS patients

Types of study	Asian ancestry	European ancestry
Associated gene polymorphisms with PCOS in case-control genetic studies [39, 44]	GnRHR, FSHR, FTO, IR, IRS	StAR, GnRHR, FTO, IR, IRS, VDR, PPAR-γ, IL-1β/ IL-1Ra
Mapped genes in GWAS studies [51]	*YAP1*, *RAB5B*, and *SUOX*, *LHCGR*, *THADA*, *DENND1A*, *FSHR*, *C9orf3*, *SUMO1P1/ZNF217*, *HMGA2*, *TOX3*, *INSR*	*YAP1*, *RAB5B*, *LHCGR*, *THADA*, *DENND1A*, *FSHR*, *c9orf3*, *SUMO1P1*, *GATA4–NEIL2*, *KCNA4–FSHB*, *ERBB4*, *ERBB2*, *ERBB2*, *RAD50*, *KRR1*
Genotype-phenotype associated studies [43]	*THADA*, *DENND1A*—associated with endocrine and metabolic disturbances and polycystic ovaries *LHCGR* and *INSR*—associated with anovulation *C9orf3*—associated with all classical PCOS features	*DENND1A*—associated with androgen excess and anovulation *FSHR*—associated with lower levels of FSH *RAB5B*—associated with glucose metabolism dysfunction
Pathway analysis studies using a data set obtained from GWAS studies [42, 45–52]	*INS*, *GNAQ*, *PLCB3*, *STXBP1*, *SMC3*, *PLCB2*, and *PLCZ1*—associated with oocyte meiosis and the regulation of insulin secretion	*LHCGR*, *FSHR*, *THADA*, *DENND1A*, *YAP1*, *RAB5B*, and *SUOX*—associated with alteration of gonadotropin secretion. *GATA4*—associated with gonadal development and transcription of steroidogenic genes. NEIL2—associated with DNA repair. FDFT1-associated with cholesterol-biosynthesis pathway
Functional studies elucidated by GWAS [45–52]	*LHCGR* and *INSR*- genetic variants of might have changed the expression level via modification on methylation	NA

GWAS, genome-wide association studies; FSH, follicle-stimulating hormone; GnRHR, gonadotropin-releasing hormone receptor; FSHR, follicle-stimulating hormone receptor; FTO, fat mass and obesity associated gene; IR, insulin receptor; IRS, insulin receptor substrate; VDR, vitamin D receptor; MTHFR, methylenetetrahydrofolate reductase; PPAR-γ, peroxisome proliferator-activated receptor gamma; IL-1β/ IL-1Ra, interleukin-1beta/IL-1 receptor antagonist; DENND1A, DENN/MADD domain-containing 1 A; NEIL2, endonuclease 8-like 2; GATA4, zinc-finger transcription factor; FDFT1, farnesyl-diphosphate farnesyltransferase; NA, not available.

Criteria	Phenotype A	Phenotype B	Phenotype C	Phenotype D
Hyperandrogenism	Present	Present	Present	Absent
Anovulation	Present	Present	Absent	Present
PCO	Present	Absent	Present	Present

According to the Rotterdam consensus criteria, the diagnosis of PCOS can be established by presence of 2 out of 3 criteria listed in the 1st column (1). Hence, there are 4 possible phenotypes of PCOS based on the various combinations of these criteria (1). Phenotypes A and B fulfil the NIH criteria and are associated with the greatest degree of insulin resistance and metabolic dysfunction (6).

8.4.2 Polycystic Ovary Syndrome

Reproductive Aspects

R. Jeffrey Chang

Introduction

The characteristic features of polycystic ovary syndrome (PCOS) are irregular menstrual bleeding, hirsutism, and distinctive ovarian morphology. Menstrual irregularity is due to chronic anovulation whereas excess hair growth results from androgen overproduction by the ovaries. The ovaries as demonstrated by ultrasonography are slightly enlarged and contain increased number of small follicles compared to that of normal ovaries. This appearance gives rise to the term polycystic ovary and the syndrome by which it is known. Despite this distinctive appearance, the morphogenesis of the polycystic ovary is unknown. While PCOS also is associated with metabolic dysfunction this section will focus on the reproductive aspects of the disorder.

Clinical Features

Menstrual Irregularity

Menstrual dysfunction characterized by irregular or absent bleeding is extremely common in PCOS. Generally, women with this disorder have never assumed regular menstrual cyclicity. At late puberty, the onset of menstrual function is commonly associated with irregular bleeding episodes that may persist for several years before assuming a cyclical monthly pattern. During this time, young adolescent women are anovulatory and bleeding may be infrequent or absent. The duration of menstrual irregularity may be variable. As a result, suspicion of PCOS in early adolescence based solely on menstrual bleeding is unreliable. However, clinical expediency may warrant an evaluation for menstrual irregularity after 2 years. Despite the preponderance of anovulation in this condition, a small percentage of hirsute women with PCOS may exhibit normal ovulatory function with monthly menstrual bleeding. The mechanism for maintaining regular ovulatory cycles is unknown.

As women with PCOS enter late reproductive life, a resumption of ovulation and normal menstrual cyclicity may ensue for unknown reasons. These individuals have a smaller cohort of follicles, elevated levels of follicle-stimulating hormone (FSH), and reduced serum

androgens compared to age-matched anovulatory PCOS women. The reasons for this transformation in some PCOS women are unclear.

Hirsutism

Excessive hair growth usually appears on the face, chin, and lower abdomen in a male pubic hair pattern. Hirsutism may also include hair on the extremities, abdominal flank, and back. More severe cases include the appearance of hair on the chest. A rapid onset of hair growth is important as this may reflect an androgen-producing neoplasm. Virilization is uncommon in women with PCOS. While the amount of hirsutism has been correlated to serum androgen concentrations, variation among individuals may exist due to ethnic differences. Thus, determination of androgen excess is based on clinical and biochemical evidence. The primary source of androgen overproduction is the ovary. In approximately 30–50% of individuals, serum adrenal androgens are elevated.

Excessive hair growth based on activity of the androgen receptor (AR) in PCOS women has been studied with inconsistent results. The AR gene encodes variable length CAG repeat polymorphism in the X chromosome; notably, length of the CAG repeat, and AR activity are inversely correlated. While shorter CAG repeat number has been associated with PCOS women compared to normal controls, it is unclear whether AR activity accounts for the inconsistent relationship between hirsutism and serum androgen levels in some ethnic populations of PCOS women.

Obesity, which is common in women with PCOS, may contribute to hirsutism by virtue of lowered sex-hormone-binding globulin (SHBG). Reduction in SHBG is directly correlated to obesity, thus giving rise to increased free testosterone levels. In particular, obese women with acanthosis nigricans are highly likely to have insulin resistance with compensatory hyperinsulinemia, which is known to suppress SHBG and contribute to excess ovarian androgen production.

The Polycystic Ovary

In women with PCOS the ovaries are slightly enlarged and contain a 2–3-fold increase in the numbers of growing pre-antral and small antral follicles compared with those of normal ovaries. The accumulation of small follicles of approximately 2–5 mm size appears to result from arrested growth at the mid-antral stage of development (Figure 8.4.2.1). Currently, the polycystic ovary (PCO) is defined as more than 12 follicles per ovary or an ovarian volume over 10 ml as demonstrated ultrasonographically [1]. Whether the greater follicle number is due to an increased rate of entry into the growing pool or a decreased rate of follicle atresia has not been established. It has been suggested that anti-Müllerian hormone (AMH) may be involved. AMH is produced by granulosa cells (GCs) of growing pre-antral and small antral follicles and negatively regulates follicle maturation. Its expression in growing pre-antral follicles of PCOS ovaries is decreased compared to that of normal ovaries, which may, in part, contribute to a greater number of small follicles [2]. While AMH levels in women with PCOS are elevated 2–3-fold compared to that of normal women, this increase probably reflects an increased number of growing pre-antral and small antral follicles in women with this disorder.

Another factor that may contribute to PCO morphology is androgen excess. It has been described that hyperandrogenic women with congenital adrenal hyperplasia or androgen-producing ovarian tumours display PCO. In addition, PCO are found in male-to-female transsexuals treated with long-term androgen. Notably, administration of high-dose testosterone to non-human primates increased ovarian size and follicle number, suggesting that PCO may be a consequence of increased local androgen production [3]. Recent studies have demonstrated that androgens decrease the expression of AMH and AMH receptor mRNA [4]. This suggests that an effect of androgen on the ovarian follicle population also may involve suppression of AMH.

Infertility

The leading cause of anovulatory infertility in women is PCOS as approximately 80% demonstrate irregular menstrual cycles. It

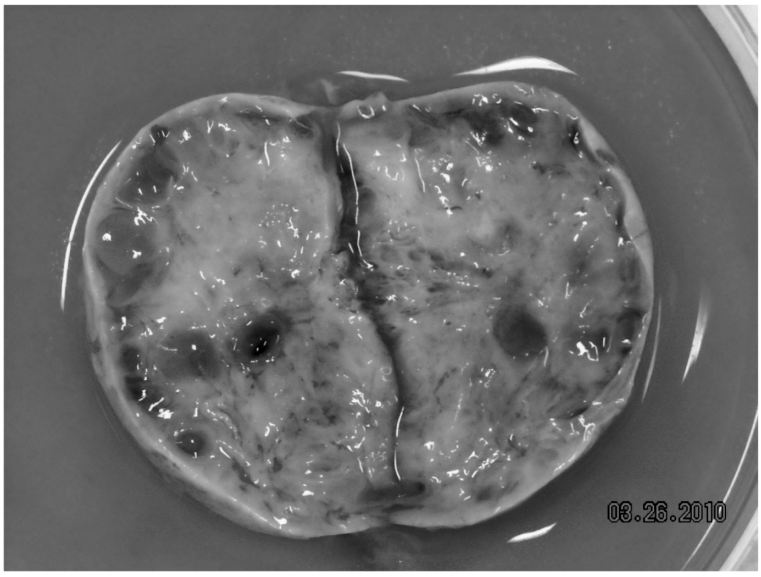

Figure 8.4.2.1 A cut section of a polycystic ovary. Note the peripheral distribution of small follicles within the ovarian cortex and the prominent central stroma. The ovary is encased by a thickened outer capsule.

is noteworthy that the presence of regular menstrual cycles does not preclude anovulation as demonstrated in 16% of women with PCOS as defined by hyperandrogenism and oligo-anovulation [5]. Obesity in a majority of PCOS women also may contribute to infertility. While the mechanism underlying ovulatory dysfunction in obese PCOS women is unclear, the interaction of PCOS and obesity likely serves to disrupt ovulation [6]. This may underlie restored ovulation in many obese PCOS women who sustain weight loss as opposed to PCOS individuals without obesity that fail to ovulation following weight loss.

In normal weight PCOS women, increased luteinizing hormone (LH) secretion and hyperandrogenaemia seem to impact follicle development, with insulin also enhancing gonadotropin actions on ovarian steroidogenesis and GC differentiation. By comparison, in obese women with PCOS the presence of metabolic disruption, including abnormal glucose-insulin homeostasis and adipogenic dysfunction, may be more important than LH in altering follicle development and oocyte maturation.

Altered Reproductive Physiology

The basis for the failure of ovulation in women with PCOS has not been clearly established. Despite evidence incriminating alteration of hypothalamic–pituitary–ovarian interaction, neither the inciting event nor dominant disruptor responsible for the reproductive phenotype has been defined. Inappropriate gonadotropin secretion, excess ovarian androgen production, arrested follicle development, and distinctive ovarian morphology have been well described and conceptualized into numerous pathophysiological schema (Figure 8.4.2.2). However, the underlying basis for PCOS remains to be established.

Inappropriate Gonadotropin Secretion

Women with PCOS exhibit increased LH secretion as shown by greater pulse frequency and amplitude, higher mean serum concentrations, and greater response to gonadotropin-releasing hormone (GnRH) compared to that of normal women [7]. As LH secretion reflects hypothalamic GnRH activity, it is assumed that activity of the hypothalamic GnRH pulse generator is increased. Conversely, increased activity of GnRH delivery favours the expression of LHβ gene expression [8]. In addition, excess androgen production may dictate LH pulse frequency in this disorder. Administration of progesterone and oestrogen to women with PCOS failed to slow LH pulse frequency whereas in normal women a significant reduction in the pulsatile LH secretion was noted. However, when women with PCOS were pretreated with an androgen-blocking agent before oestrogen and progesterone treatment, normal LH pulse release was subsequently restored [9].

In contrast, FSH secretion in women with PCOS is decreased compared to that observed in normal women. The mechanism for decreased FSH secretion in PCOS has not been fully determined, although negative feedback by chronic oestrogen secretion has been suggested. Alternatively, reduced serum FSH levels may result from increased activity of the GnRH pulse generator, which favours LHβ gene expression at the expense of the FSHβ gene [8].

Whether hyperinsulinemia influences inappropriate gonadotropin secretion in PCOS is not clear. In contrast to studies performed in rodents that suggest insulin may enhance LH response to GnRH, an effect of insulin in PCOS women has not been able to show consistent alterations in LH secretion or LH release following GnRH stimulation [10, 11]. Recently, it has been shown that AMH may influence GnRH secretion. *In vitro* studies of rat hypothalamic tissue have demonstrated that exposure to AMH was associated with an increase of GnRH neuronal activity [12]. This finding was supported *in vivo* by an injection of AMH into the lateral ventricle of female mice that produced a rapid increase of serum LH. Because serum AMH is elevated in women with PCOS, these results suggest that AMH may influence inappropriate gonadotropin secretion in this disorder.

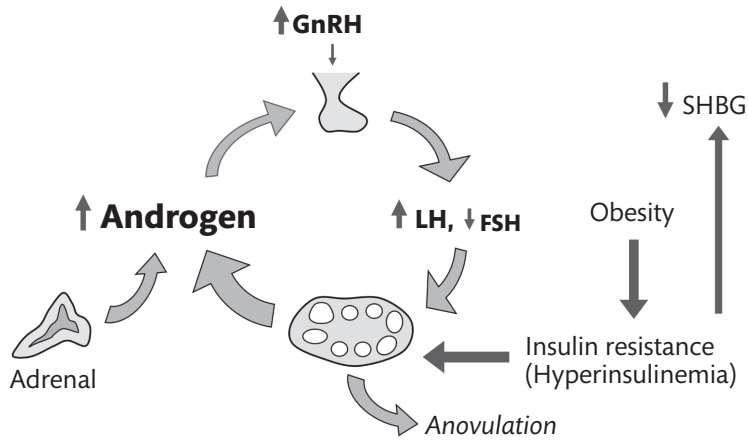

Figure 8.4.2.2 Proposed pathophysiology of polycystic ovary syndrome (PCOS). Increased hypothalamic GnRH activity drives pituitary LH hypersecretion that stimulates excess theca androgen production. Conversely, FSH secretion is decreased, which contributes, at least in part, to impaired follicle growth. Hyperandrogenaemia may inhibit steroid negative feedback on GnRH activity. Androgen excess in PCOS also is associated with increased visceral fat that contributes to insulin resistance, leading to hyperinsulinemia and dyslipidaemia. Altered metabolic function may disrupt ovarian folliculogenesis and increase theca cell androgen production. Hyperinsulinaemia lowers hepatic sex-hormone-binding globulin (SHBG) that results in an increase of bioactive testosterone in the circulation.

Disordered Follicle Function

Inadequate FSH Secretion

It is well established that women with PCOS exhibit reduced serum FSH levels. The relative lack of FSH has been incriminated as a cause for anovulation in PCOS women as ovulation may be achieved with the administration of FSH. The relative suppression of FSH secretion may be the result of increased activity of hypothalamic GnRH in women with PCOS as described previously. Alternatively, reduction of circulating FSH may also arise from the negative feedback of chronic oestrogen secretion characteristic of this disorder. However, GCs of PCOS women exhibit increased FSH binding and are readily responsive to FSH *in vitro* and *in vivo* [13]. This raises the issue of whether other factors within the microenvironment of the ovary exist to hinder follicle maturation.

Anti-Müllerian Hormone

Because AMH inhibits aromatase and circulating AMH levels are elevated in women with PCOS, excessive local production of this protein, combined with reduced FSH secretion, could set the stage for follicle arrest and decreased oestradiol (E_2) production by the ovary. This is consistent with *in vitro* studies showing that GCs incubated for 48 hours in the presence of FSH exhibited reduced AMH production [14]. In addition, during controlled ovarian hyperstimulation, serum AMH levels declined with length of treatment. However, these observations may also be explained by the decrease in AMH production seen in the final stages of follicle development in normal ovaries. The possible role of AMH in follicle arrest in PCOS is uncertain as endogenous factors that regulate this protein are currently unknown.

Premature Luteinization

It has been shown *in vitro* that GCs obtained from small PCOS follicles produced more progesterone following LH stimulation than that observed in GC from larger sized normal follicles [15]. These results suggested that PCOS GCs acquire LH receptors at an earlier stage of development and, subsequently, undergo luteinization prematurely. Consistent with this notion LH receptor mRNA expression has been shown to be greater in PCOS GCs compared to GCs from normal follicles [16]. Because LH secretion is increased in PCOS, this proposed mechanism may be a prelude to terminal differentiation and arrested follicle development.

It is unclear how small antral follicles in PCOS might gain early acquisition of LH receptors. It is known that FSH induces LH receptor content in cultured GCs. However, in women with PCOS, FSH secretion is reduced. Insulin may amplify FSH-induced LH receptor in GCs although inhibition of LH receptors by insulin has also been reported [17]. Moreover, androgen has been shown to inhibit FSH-induced LH receptor expression in cultured rat GCs [18]. Despite these findings, insulin and LH were shown to act synergistically in stimulating steroid production in GCs from PCOS follicles [19]. These results suggest that increased hyperinsulinemia in women with PCOS promotes LH action on GCs, and by extension, contributes to follicle atresia and eventual arrest.

Growth and Differentiation Factor-9

Studies have demonstrated that the most pronounced increase of growing follicles in PCOS occurs at the primary stage [20, 21]. This suggests that developmental transition from the primary to secondary stage may be slower in PCOS. A potential mechanism for restricted early follicle growth was reported by Filho *et al.* [22]. In women with PCOS the expression of growth differentiation factor-9 (GDF-9), an oocyte-specific member of the TGF-β family known to play a critical role in folliculogenesis, was decreased compared to that observed in normal oocytes at all developmental stages. Only 8–12% of oocytes of primary follicles in PCOS contained signal for GDF-9 compared to 96% noted in normal controls. In addition, the signal, when present in more advanced follicles, was weaker than corresponding normal follicles. In mice, adequate amounts of GDF-9 are required for growth beyond the primary follicle as female GDF-9 knock-out mice are infertile with a complete block in folliculogenesis at the primary stage [23]. Together, these results suggest that defects in follicle growth in PCOS may begin at the earliest stages of folliculogenesis.

Granulosa Cell Function

Despite chronic anovulation, isolated PCOS granulosa cells appear to be extremely sensitive to FSH compared to normal GCs. Clinically, FSH-stimulated E_2 responses have been shown to be greater in women with PCOS compared to those observed in normal women [24]. The heightened oestrogen response to FSH is consistent with ovarian hyper-responsiveness to gonadotropin stimulation commonly encountered in this disorder. In these clinical studies, FSH-induced rises of E_2 levels within three hours of administration, which suggests that any aromatase inhibition, previously suspected in PCOS, is relatively mild.

It is unknown whether PCOS granulosa cell are more sensitive to FSH primarily or secondarily due to intraovarian or extraovarian factors. Previously, it has been demonstrated that GCs obtained from unstimulated follicles of PCOS women have greater FSH binding of compared to GCs from normal ovaries [13]. Thus, increased FSH receptor expression in PCOS GCs may account for increased ovarian responsiveness to FSH.

Early *in vitro* studies have shown that androgens may enhance FSH-induced aromatase activity and thus, possible involvement of the FSH receptor. Subsequent studies in non-human primates revealed that testosterone treatment induced increases of FSH receptor mRNA expression, which likely contributed to greater ovarian size and increased follicle number observed in these animals [25]. Collectively, these findings suggest that androgen excess is responsible, at least in part, for enhanced GC responsiveness to FSH.

Insulin is another consideration that might impact GC function. *In vitro* studies have shown that PCOS GCs exhibit extreme sensitivity to insulin whether in the presence or absence of gonadotropin stimulation [19]. Thus, insulin may act as a 'co-gonadotropin' within the ovary. In PCOS women treated with an insulin-lowering drug, thiazolidinedione, GC responsiveness to FSH during insulin infusion was significantly increased compared with that observed prior to treatment [26]. These findings suggested that the GC in women with PCOS may be insulin resistant.

Theca Cell Function

Androgen excess appears to be the result of an inherent defect of theca cell (TC) steroidogenesis in women with PCOS. The enzyme cytochrome P450 c17A1 (CYP17) catalyses two distinct activities, 17α-hydroxylase and 17,20 lyase, that are essential to the production of ovarian androgens. Studies have indicated greater activities of 17α-hydroxylase, 17,20 lyase, and 3β-hydroxysteroid dehydrogenase in PCOS TCs than those observed in TCs from normal women, which likely form the basis for androgen overproduction in PCOS [27]. These results are commensurate with clinical studies, in which PCOS exhibited increased responsiveness of 17-hydroxyprogesterone to gonadotropin stimulation compared with normal women and has led to the concept of dysregulated expression of the CYP17A [28]. In addition, in PCOS women enhanced hCG-stimulated 17-hydroxyprogesterone production persisted despite suppression of endogenous gonadotropins by GnRH agonist. Together, these findings support the concept of a primary abnormality of TC steroid production.

Within the TC androgen production is driven by LH secretion, which activates CYP17A. It has been shown in TCs that LH stimulated androgen production is dose-related. These results are consistent with the positive correlation between elevated serum LH levels and circulating testosterone concentrations in women with PCOS. Moreover, in PCOS women treated with sex steroids or GnRH agonists, elevated LH levels are reduced or eliminated with a corresponding reduction in circulating androgen levels and hair growth [29]. Summarily, increased secretion of LH, combined with a highly responsive TC, is an essential component of androgen overproduction in PCOS.

In PCOS other factors may contribute to androgen excess, the most notable of which is insulin. Receptors for insulin, insulin-like growth factors I and II have been demonstrated in theca tissue from both normal and PCOS women. In addition, *in vitro* studies of TCs from normal women have shown that these growth factors may independently stimulate androgen production as well as enhance androgen responses to LH [30].

Consistent with *in vitro* studies, insulin-induced hyperandrogenaemia has been reported in women with PCOS following prolonged insulin infusion over 16 hours [31]. During the administration of insulin changes in gonadotropin levels were not observed. These findings coincide with studies that have shown reduced hyperinsulinemia and associated decreases of serum androgens without corresponding changes of LH in women with PCOS treated with insulin-lowering drugs.

Treatment

Hirsutism

The primary therapeutic approach to excessive hair growth is reduction of ovarian androgen production by suppression of ovarian steroidogenesis. Combination oral contraceptives containing combination oestrogen-progestin readily decrease circulating androgen levels and effectively slow the rate of hair growth. However, the range of response may be variable largely due to the severity of hirsutism at the time of treatment. Oral contraceptive therapy inhibits serum gonadotropin levels leading to a decrease of ovarian androgen production. In addition, the oestrogen component increases SHBG leading to a reduction of bioactive testosterone, whereas progestin serves to increase the metabolic clearance rate of testosterone as well as compete for 5α-reductase and the AR.

In adolescent PCOS with androgen excess, a proposed alternative to oral contraceptives includes a combination of low-dose pioglitazone–flutamide–metformin [32]. This therapy was as effective as ethinyl oestradiol-cyproterone acetate in reducing hyperandrogenaemia and also improved metabolic dysfunction and reduced markers of cardiovascular risk.

Antiandrogenic agents, either alone or more commonly in combination with oral contraceptives, may be considered in the treatment of hirsutism. Spironolactone is an aldosterone antagonist that competes for testosterone binding sites to lower the clinical effects of androgen excess. In addition, spironolactone appears to interfere with cytochrome P450 to inhibit steroid enzyme action and decrease androgen production. Considering its antiandrogenic activity, pregnancy should be avoided in individuals using spironolactone. Because this medication may decrease the action of aldosterone, serum potassium levels may increase and therefore should be monitored.

Other antiandrogens shown to have therapeutic benefit include flutamide and finasteride. Flutamide competes for the AR whereas finasteride inhibits 5α-reductase. Flutamide is not approved by the United States Food and Drug Administration for the treatment of hirsutism due to a reported increased risk for hepatic toxicity particularly in individuals that are obese. Because of its antiandrogenic effects, flutamide should be avoided during pregnancy.

Menstrual Irregularity

In PCOS women with irregular bleeding, the primary treatment option is combination oral contraceptives. In the majority of cases, regular withdrawal bleeding will result. In individuals who are unable to tolerate combination oral contraceptives, administration of progestin only containing oral contraception or intermittent progestin alone may decrease or eliminate bleeding. Long-acting progestational agents should be considered carefully due to the enduring effect after administration. Alternatively, an intrauterine device containing progestin also may be used. An additional benefit of progestin therapy is the reduced risk of endometrial cancer.

Insulin-Lowering Drugs

Insulin-lowering drugs improve insulin sensitivity in PCOS women with insulin resistance. Metformin, a biguanide, increases insulin sensitivity in the liver to reduce gluconeogenesis and hyperinsulinemia. Administration of metformin to women with PCOS decreases androgen levels, increases rates of spontaneous ovulation, and enhances ovulatory responses to clomiphene. However, in cases of severe obesity metformin has been shown to be considerably less effective. In addition, evidence for metformin ameliorating excessive hair growth is lacking. Side effects of metformin include gastrointestinal symptoms, which are dose-related and tend to resolve after several weeks. A rare adverse effect of metformin therapy is lactic acidosis, which may occur in individuals with systemic and debilitating diseases.

Infertility

Medical Treatment

In anovulatory women with PCOS that are overweight or obese, diet and lifestyle intervention are highly recommended as first-line therapy. Reduction in weight by 5–10% may successfully restore ovulation and fertility. When pharmacological therapy is required, clomiphene citrate has been considered first-line therapy for ovulation induction in PCOS women due to its ability to inhibit oestrogen negative feedback and induce an increase in FSH secretion. Recent studies have demonstrated that letrozole, an aromatase inhibitor, may also be considered as another first-line therapy for ovulation induction in PCOS women. Letrozole diminishes hypothalamic oestrogen negative feedback and is thought to transiently increase FSH release without depleting oestrogen receptors. Both clomiphene and letrozole appear to have equivalent efficacy with respect of successful ovulation induction and pregnancy rates. Another alternative therapy is metformin that reduces circulating insulin and androgen levels, inhibits hepatic glucose production, decreases intestinal glucose uptake, and increases peripheral insulin sensitivity. If monotherapy with these agents is not successful, then metformin and clomiphene citrate may be combined in an effort to improve ovulation and pregnancy rates before proceeding to low-dose gonadotropin therapy or laparoscopic ovarian drilling.

In the absence of ovulation, induction using the aforementioned drugs would warrant use of low-dose gonadotropin therapy. Because women with PCOS are prone to excessive follicle responsiveness to gonadotropin administration and potential ovarian hyperstimulation, caution must be exercised when using these preparations. The goal is to create a transient increase in FSH above a threshold dose for selecting a limited number of developing follicles. Use of exogenous gonadotropins is associated with increased risks for multiple pregnancy and severe ovarian hyperstimulation syndrome.

Surgical Approach

In the original description of PCOS in 1935, several women that had undergone wedge resection resumed ovulation. Over the past several decades therapeutic wedge resection has gained in popularity as electrocautery of the ovarian capsule during laparoscopy (i.e. laparoscopic ovarian drilling) induced high rates of ovulation and pregnancy [33]. Moreover, spontaneous ovulation appeared to persist following the procedure, although the duration was highly variable [34]. Laparoscopic ovarian drilling (LOD) is best suited for anovulatory women with PCOS who are resistant to clomiphene citrate or letrozole treatment. Disadvantages of this surgical method include surgical complications, adhesion formation, and premature menopause, particularly when large numbers of punctures are used, although, long-term surveillance of PCOS women undergoing LOD has been reassuring.

In vitro fertilization (IVF) is indicated for PCOS women who have associated infertility conditions, including tubal damage, severe endometriosis, and male factor infertility, or who require preimplantation genetic testing. In addition, IVF also is a reasonable option for PCOS women who fail clomiphene therapy, are older or at increased risk of multiple birth from gonadotropin therapy because the multiple birth rate can be reduced by transferring one embryo at a time.

8.4.3 Polycystic Ovary Syndrome

Metabolic Aspects

David A. Ehrmann and Susan Sam

Introduction

Polycystic ovary syndrome (PCOS) is a common endocrinopathy among reproductive age women associated with reproductive features related to disordered gonadotropin release and increased androgen production leading to anovulation, infertility, and clinical hyperandrogenism Figure 8.4.3.1. The most commonly used and

accepted criteria for diagnosis is based on the 2003 Rotterdam consensus that has been endorsed internationally [1]. The definitions, phenotypes, and prevalence of PCOS is covered in Chapter 8.4.1.

In the 1980s, a series of studies clearly established that PCOS is associated with a significant reduction in peripheral insulin sensitivity that is independent of adiposity [2–5]. Furthermore, obesity is common among women with PCOS especially in the United States and exacerbates insulin resistance associated with the disorder. The combination of both intrinsic and obesity-related insulin resistance places women with PCOS at high risk for other metabolic complications such as type 2 diabetes (DM2), metabolic syndrome, and possibly cardiovascular disease. Although the reproductive features of the disorder may improve with age, the associated metabolic abnormalities may actually worsen. Furthermore, the risk for insulin resistance varies according to the phenotype of PCOS identified by the Rotterdam criteria. Women who present with all three criteria for PCOS (phenotype A) or those who fulfil the NIH criteria (phenotype B) exhibit the greatest degree of insulin resistance [6]. This chapter will explore the pathophysiology of aberrant insulin action in women with PCOS and discuss the long-term metabolic complications and treatment strategies.

Pathophysiology of Insulin Resistance in PCOS

Insulin resistance is a common feature of PCOS that is independent of body weight and is the underlying cause for the heightened metabolic risk [2–5]. Non-obese women with PCOS have the same degree of insulin resistance as obese reproductively normal women and obese women with PCOS are more insulin resistant compared to reproductively normal women of the same body mass index (BMI) [3, 7]. Insulin resistance in PCOS is characterized by reduced sensitivity and responsiveness to insulin-mediated glucose utilization primarily in the skeletal muscle and adipose tissue even among non-obese women [3, 7, 8]. The cellular mechanisms for insulin resistance in PCOS have not been fully characterized. Studies on subcutaneous adipocytes of women with PCOS have revealed impaired insulin sensitivity [7, 9–11] and reduced glucose transport [7–9] related to lower expression of the insulin-sensitive glucose transporter, GLUT-4 [12, 13]. This defect is present even among non-obese women with this condition [7] although the finding has not been confirmed in all studies [8]. Additionally, subcutaneous adipocytes from women with PCOS display reduced insulin sensitivity to the antilipolytic effect of insulin [10]. These appear to be post-receptor defects since no reduction in insulin receptor number or alteration in insulin binding have been identified [7, 9, 11].

A predisposition to accumulate fat in central depots independent of BMI has been reported in PCOS especially in non-obese women [14–17] and predisposes to insulin resistance although this finding has not been demonstrated in overweight or obese women with this condition [18]. The predisposition to abdominal adiposity maybe related to chronic hyperandrogenism. Administration of a weak anabolic androgen to postmenopausal women over 9 months increases visceral fat [19]. Female to male transsexuals have an increase in visceral fat following administration of androgens [20]. Some, but not all, short-term interventions designed to lower androgen levels or block androgen action in women with PCOS demonstrate improved insulin sensitivity [21–25]. These findings have not been universal especially among obese women although inadequate sample size has been a limitation [26–31]. A reduction in adipose tissue expression of adiponectin associated with lower circulating levels of this adipokine has been demonstrated even among

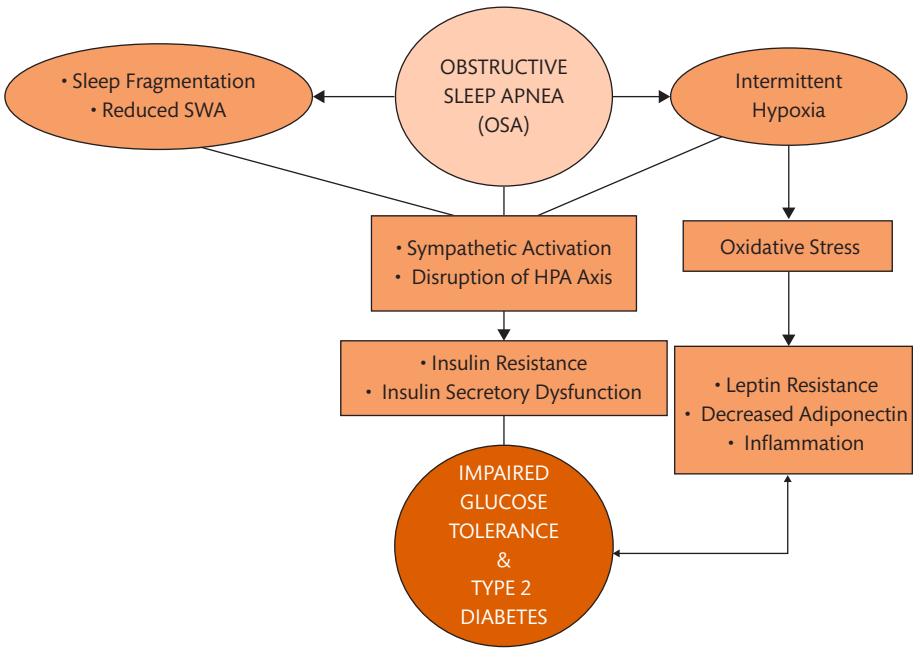

Figure 8.4.3.1 Women with PCOS display disordered gonadotropin release that favours increased luteinizing hormone (LH) compared to follicle-stimulating hormone (FSH) resulting in overproduction of testosterone with defects in follicular development. Insulin resistance is an intrinsic abnormality in PCOS and further contributes to ovarian androgen production as well as reduction in SHBG leading to higher levels of bioavailable testosterone.

non-obese women with PCOS [17, 32, 33]. In addition to reduced insulin action, women with PCOS have evidence for inadequate insulin secretion related to β-cell dysfunction placing them at heightened risk for DM2 [34].

Hyperinsulinemia resulting from insulin resistance promotes ovarian and adrenal androgen overproduction. *In vitro*, theca cells from women with PCOS overproduce androgens in response to insulin [4]. Treatment of women with PCOS with agents that lower insulin levels decreases both ovarian and adrenal androgens [35]. Hyperinsulinemia increases the availability of bioactive androgens such as bioavailable testosterone through its suppressive effect on circulating sex hormone-binding globulin (SHBG) [36]. Hence, insulin resistance and hyperinsulinemia adversely impact hyperandrogenism and reproductive complications of PCOS as well as contribute to development of metabolic consequences.

Additionally, there is heterogeneity in insulin resistance among the various phenotypes of PCOS according to the Rotterdam criteria. Insulin resistance and metabolic dysfunction is largely confined to women who present with the classical form of PCOS consisting of oligomenorrhea and hyperandrogenism especially in combination with polycystic ovaries [6].

Type 2 Diabetes Mellitus

Women with PCOS are at increased risk for glucose intolerance related to the intrinsic insulin resistance present in many women and worsened by the high prevalence of obesity. Furthermore, women with PCOS demonstrate pancreatic β-cell dysfunction and inadequate insulin secretion for the degree of insulin resistance [34]. About 30–40% of obese reproductive-aged PCOS women have been found to have impaired glucose tolerance (IGT), and about 10% have frank type 2 DM based on a 2-hour glucose level >200 mg/dl [37].

In a meta-analysis of 40 studies that examined the relationship between PCOS and glucose intolerance, a diagnosis of PCOS was associated with an odds ratio of 3.26 (95% CI: 2.17–4.90) for IGT and 2.87 (95% CI:1.445.72) for DM2 [38]. However, the risk varied according to ethnicity and geographic location. Asian women had a fivefold increase, followed by women in the Americas (fourfold increase) and women in Europe (threefold increase) [38]. Furthermore, women with PCOS are at increased risk of conversion from normal to IGT or from IGT to DM2 over time. The overall conversion rate from normal glucose tolerance to glucose intolerance over time is in the range of 2–5% per year [14, 39]. However, the risk is higher among obese women approaching 5–15% within 3 years [40].

Dyslipidaemia

Studies have demonstrated a number of lipid abnormalities in women with PCOS including elevated low-density lipoprotein (LDL) cholesterol and triglyceride levels compared to control women of the same age, BMI, and ethnicity [41, 42]. Smaller studies have also revealed lower high-density lipoprotein (HDL) cholesterol in PCOS compared to matched control women [43]. Women with PCOS have an atherogenic lipoprotein profile even if non-obese [44]. Current guidelines recommend a screening lipid profile on all women with PCOS [45].

Metabolic Syndrome

The diagnosis of metabolic syndrome is often based on ATP III criteria. These criteria include a waist circumference above 88 cm in women, HDL cholesterol less than 50 mg/dl, triglyceride above 150 mg/dl, hypertension defined as BP above 130/85 and impaired fasting glucose equal or greater than 100 mg/dl [46]. The presence of three of these criteria will establish the diagnosis of metabolic syndrome which is a strong predictor for cardiovascular disease.

The risk for metabolic syndrome is increased among women with PCOS. A meta-analysis of 16 studies comparing the prevalence of metabolic syndrome in women with and without PCOS, demonstrates an OR 3.01 (CI 2.06, 4.41); however, there is significant statistical heterogeneity [47]. After PCOS and control women are matched for BMI, the statistical heterogeneity was resolved, yet women with PCOS still had a greater prevalence of metabolic syndrome OR 2.2 (CI 1.36, 3.56). Additional subgroup analyses that included only lean women (BMI <25 kg/m^2) indicated a significant increase in risk for metabolic syndrome in PCOS with OR 3.00 (CI 1.30, 6.93) [47]. These data clearly indicate that the prevalence of metabolic syndrome is increased in PCOS women independent of obesity.

Non-Alcoholic Fatty Liver

Non-alcoholic fatty liver disease (NAFLD) is a hepatic complication that is strongly associated with insulin resistance and is the second most common indication for liver transplantation in the United States. A number of small cohort and cross-sectional studies indicate that the risk for NAFLD is increased among women with PCOS. in addition, a recent systematic review and meta-analysis [48] as well as a large retrospective analysis [49] show that the odds ratio for NAFLD is ~2.5 (95% CI 2.19–2.95) [48] and 2.23 (95% CI 1.86–2.66), respectively [49]. The increase in risk appears to be related to androgen excess in the current studies.

The current guidelines recommend that women with PCOS with metabolic risk factors may be screened using serum markers of liver dysfunction. If serum markers are elevated, non-invasive quantification of fibrosis by ultrasound and liver biopsy may be considered [45].

Cardiovascular Disease

Women with PCOS tend to have multiple risk factors for cardiovascular disease such as dyslipidaemia, DM2, abdominal adiposity, and metabolic syndrome. A number of studies reveal an increased prevalence of surrogates for cardiovascular disease such as increased carotid intima media thickness [50, 51] and coronary artery calcification [52, 53]. Yet at this time, conclusive evidence for increased cardiovascular disease morbidity and mortality among women with PCOS is lacking. A number of older studies did not find the prevalence of non-fatal or fatal cardiovascular disease to be increased although risk for non-fatal cerebrovascular disease was higher [54, 55].

In more recent studies, such as a substudy of the Women's Ischemia Evaluation Study (WISE), multivessel coronary disease was observed in 35% of women with PCOS compared to 25% of women without PCOS and the risk for stroke was also increased [43, 56]. Accordingly, a consensus statement by the Androgen

Excess and Polycystic Ovary Syndrome Society considers women with PCOS who are obese with a history of cigarette smoking, hypertension, glucose intolerance and subclinical vascular disease to be at risk and those with metabolic syndrome/DM2 to be at high risk for development of cardiovascular disease [43].

Sleep Apnoea

Women with PCOS have an increased prevalence of obstructive sleep apnoea (OSA) that may even exceed those in men [57, 58]. Both obesity and hyperandrogenism have been proposed to account for the high prevalence of OSA in PCOS [59, 60]. However, it appears that the increased risk may be independent of these two risk factors; the risk has been shown to be increased by nine times even after adjusting for BMI compared to control women [60, 61]. Furthermore, in women with PCOS the presence of OSA was associated with 2-fold higher fasting insulin levels and other surrogate measures of insulin resistance (Figure 8.4.3.2) [62]. The current guidelines for clinical management of women with PCOS suggest screening overweight/obese adolescents and women with PCOS for symptoms suggestive of OSA, and when identified, obtaining a definitive diagnosis using polysomnography. If OSA is diagnosed, patients should be referred for institution of appropriate treatment [45].

Gynaecological Cancers

Women with PCOS have many risk factors for endometrial cancer such as chronic anovulation with unopposed endometrial stimulation by oestrogen, central adiposity, and type 2 diabetes. A meta-analysis assessing the association between PCOS and endometrial cancer found an increased risk of developing endometrial cancer in PCOS (RR = 2.7; 95% CI, 1.0–7.29) [63]. Similar results were confirmed by a subsequent systematic review that revealed a threefold increased risk for this complication [64]. There are currently no data supporting routine screening with pelvic ultrasound or endometrial biopsy in asymptomatic women for endometrial cancer and such practices are not routinely recommended by the guidelines [45].

Evaluation of Women with PCOS for Metabolic Abnormalities

Evaluation should cover the multiple metabolic abnormalities discussed here which could be present in women with PCOS. The risk factors for metabolic complications are not uniform among women with PCOS [6]. Women who display all three diagnostic criteria for PCOS by Rotterdam consisting of menstrual irregularity, hyperandrogenism and polycystic ovaries or those who fulfil the NIH criteria consisting of menstrual irregularity and hyperandrogenism have been shown to manifest the greatest degree of insulin resistance and are at the highest risk for metabolic abnormalities [6]. Furthermore, the risk for metabolic abnormalities is modified by the presence of obesity, OSA, and family history of DM2 and cardiovascular disease. Hence, obtaining a comprehensive history that includes a detailed assessment of menstrual cycles, weight, and lifestyle factors such as smoking in addition to family history of PCOS, diabetes, and cardiovascular disease is essential. It is also important to assess for obesity including abdominal obesity and hypertension to further stratify metabolic risk.

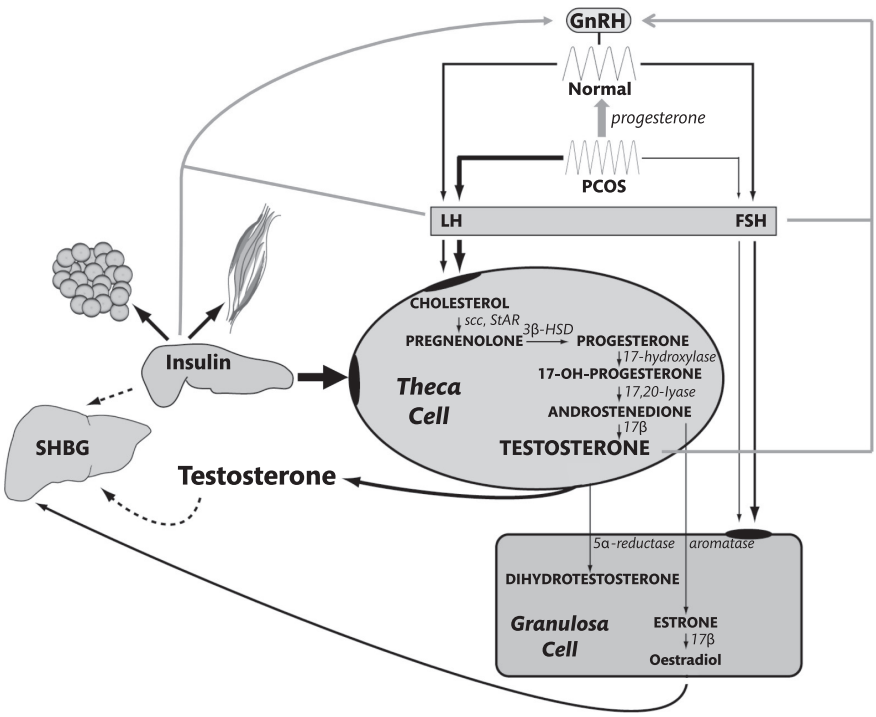

Figure 8.4.3.2 Obstructive sleep apnoea contributes to development of glucose intolerance and type 2 diabetes by activation of sympathetic pathways related to fragmented sleep and intermittent hypoxia. These defects predispose to insulin resistance, inflammation, and insulin secretory defects that eventually lead to development of glucose intolerance.

Due to the high prevalence of abnormal glucose tolerance in PCOS, screening for prediabetes and DM2 is indicated. The current guidelines recommend use of an oral glucose tolerance test with a 75-g oral glucose load to screen for IGT or DM2 [45, 65]. Haemoglobin A1c may have poor sensitivity in detecting IGT and women with PCOS have been shown to have 2-hour glucose values above 200 mg/dl on a 75-g oral glucose load consistent with DM2 despite normal fasting glucose [66]. Studies have also demonstrated increased risk of conversion to glucose intolerance over time in women with PCOS [67] although the rate of overall conversion among all women with PCOS may not be higher than 2% per year [39]. The risk for conversion from normal to IGT and from IGT to DM2 is high among obese women with PCOS, reportedly 5 to 15% within 3 years [40]. Because of the higher risk of conversion to IGT and DM2 in PCOS, most current guidelines recommend periodic screening although an interval screening period has not been clearly established [45, 65]. The risk for abnormal glucose tolerance is higher in women with PCOS with a family history of DM2 especially if obese so an individualized approach to screening for glucose tolerance is essential. Screening for metabolic abnormalities should not include fasting insulin levels since fasting insulin levels lack adequate accuracy and sensitivity [45] and are not useful in the diagnosis or management of PCOS or its metabolic sequelae. Specifically, there is no threshold value that defines insulin resistance that is independent of obesity. Any woman with PCOS who is overweight or obese should be presumed to be insulin resistant.

Women with PCOS should undergo screening with a fasting lipid profile due to a higher prevalence of dyslipidaemia [45, 65]. The guidelines do not provide specific recommendations regarding how often the screening should be repeated. Clinical judgement incorporating factors such as presence of dyslipidaemia at baseline, obesity, DM2, tobacco use, and personal or family history of cardiovascular disease are important considerations in this regard.

Due to a heightened risk for OSA especially among obese women with PCOS, screening for symptoms of this disorder is essential and supported by guidelines [45]. If women report symptoms suggestive of OSA, they should undergo a polysomnograph to obtain a definitive diagnosis followed by treatment [45].

Approach to Long-Term Treatment of Women with PCOS

The best long-term therapy for women with PCOS is a matter of debate, and often deduced from diabetes or cardiovascular prevention trials in similar populations, because such studies do not exist for women with PCOS. An individualized approach to each patient depending on symptoms and long-term risk is advised.

Lifestyle Modification

Lifestyle intervention resulting in weight loss is the principal treatment of metabolic dysfunction in obese women with PCOS and additionally often results in improvements in menstrual irregularity and even fertility. Even a small reduction in body weight by as little as 5% has been shown to improve ovulation in women with PCOS [68]. There is a paucity of data in regard to the 'optimal' diet for the management of obesity in women with PCOS. In a systematic review of dietary studies in PCOS, weight loss improved the presentation of PCOS regardless of dietary composition [69]. Subtle differences were detected among the diets with greater reduction in insulin resistance and improved quality of life with a low-glycaemic index diet, greater weight loss for a monounsaturated fat-enriched diet and greater improvements in depression and self-esteem for a high protein diet [69].

Exercise improves insulin resistance and reduces cardiovascular risk in women with PCOS if performed for at least 30 minutes per day for 5 days per week. However, exercise without concomitant caloric reduction is unlikely to induce weight loss in women with PCOS [70].

Bariatric Surgery

Bariatric surgery is increasingly utilized in morbidly obese patients as a first line obesity therapy [71]. The current recommendations are to utilize bariatric surgery in patients with a BMI greater than 40 kg/m^2 or with a BMI greater than 35 kg/m^2, and serious medical comorbidities [71]. Bariatric surgery should be considered in women with PCOS who fulfil the general criteria based on BMI and comorbidities. A meta-analysis of 13 studies of 2130 women of whom 45.6% had PCOS, demonstrated that bariatric surgery and subsequent weight loss results in significant improvements in menstrual irregularity from 56.2% to 7.7%, hirsutism from 67% to 32%, and infertility from 18.2% to 4.3% [72].

Metformin

In the 1990s, metformin was shown to ameliorate hyperandrogenism in both obese and non-obese women with PCOS [35]. Metformin lowers testosterone levels by approximately 20–25% in women with PCOS [35]. This effect may be more pronounced among non-obese women with PCOS. There is significant variability in the clinical response to metformin treatment in women with PCOS including in its ability to reduce testosterone and insulin levels, regulate menses and improve body weight and composition [73].

Current guidelines for management of PCOS recommend metformin treatment for women with IGT or type 2 diabetes who do not respond to lifestyle modification [45]. The impact of metformin on weight loss and body composition has been examined in a number of observational and randomized clinical trials but the results have been conflicting. A meta-analysis of 16 randomized clinical trials of 630 participants treated with metformin for 6 months at an average daily dose of 1500 mg reported no evidence of an effect on BMI and only a marginal reduction of waist:hip ratio [74]. However, there may be evidence for a beneficial effect of metformin on BMI and abdominal obesity when added to lifestyle modification. In a meta-analysis published in 2015, comparing nine randomized clinical trials (n = 493 participants) of metformin plus lifestyle vs. lifestyle alone, metformin plus lifestyle was more effective in reducing BMI [49]. Metformin may also have a favourable impact on body composition by reducing abdominal fat, although larger well-designed randomized studies are necessary to establish a clear benefit [75].

GLP-1 Agonists

Glucagon-like peptide-1 analogues have proven effective in reducing body weight among obese and overweight individuals without diabetes [76–78]. Small studies have also demonstrated effectiveness in this regard in women with PCOS [79]. Additional small studies have shown that the combination of these agents and metformin is more effective in inducing weight loss in women with PCOS [80–82]. In addition to lowering body weight, these agents on their own or in combination to metformin have been shown to reduce testosterone levels and may have additional metabolic benefits [82, 83]. Larger randomized clinical studies of longer duration are warranted to examine the potential benefits of these agents in women with PCOS.

Combination Oral Contraceptives

Combination oral contraceptives are commonly used as first-lined treatment for menstrual abnormalities, hirsutism, and acne in women with PCOS. Oral contraceptives suppress gonadotropin release with subsequent reduction in ovarian androgen secretion and stimulate SHBG production from the liver, thus reducing free testosterone level. Oral contraceptives are associated with a significant reduction in risk for endometrial cancer [84]. The choice for 'best' oral contraceptives for women with PCOS is unknown. A low dose formulation including ethinyl oestradiol and progestin is recommended. There are often adverse effects on insulin sensitivity that may be dose and drug dependent [85]. Oral contraceptives may also be associated with a significant elevation in circulating triglycerides, as well as in HDL levels, although these do not appear to progress over time. However, there is no evidence that risk for cardiovascular disease is increased with oral contraceptive use in PCOS although appropriate risk stratification is necessary in each individual case based on patient's personal cardiometabolic risk profile at baseline [86].

Conclusion

Insulin resistance, obesity, dyslipidaemia, and type 2 diabetes are common among women with PCOS. Management of these women should include an evaluation for metabolic risk at baseline and close follow-up especially for those who are identified at higher risk. Treatment tends to be symptom-based and should be individualized.

8.4.4 Polycystic Ovary Syndrome

Hirsutism

Duarte Pignatelli, Ricardo Azziz, and Bulent Okan Yildiz

Physiology and Pathophysiology of Hair Growth

Androgen Metabolism in Women

Androgens are 19 carbon (C19) steroids, synthesized from the steroid substrate pregnenolone, which is itself derived from cholesterol. Androgens are produced by both the ovary and the adrenal cortex. They may also be derived from the conversion of precursor steroids by the liver and some peripheral tissues including the skin and adipose tissue. The main circulating androgens in women include testosterone, and its 5α -reduced metabolite dihydrotestosterone (DHT), androstenedione (A4), dehydroepiandrosterone (DHEA) and its metabolite dehydroepiandrosterone sulphate (DHEAS). Recently the importance of 11-oxygenated androgens such as 11-ketotestosterone (11-KT) and 11-ketoDHT (11-KDHT) has been recognized as these are also potent agonists of the human androgen receptor [1–3]. Further study is required, however, to determine the clinical utility of 11-KT and 11-KDHT in the evaluation of androgen excess disorders in women. See Figure 8.4.4.1.

Only free androgens are able to interact with androgen receptors on target tissues. Thus, the biological action of testosterone and DHT is significantly influenced by the circulating SHBG level. Even without a change in total hormone concentrations, a decrease in SHBG will result in increased free fractions of testosterone and DHT, increasing androgenic action. Conversely, higher SHBG levels will result in decreased free fractions, and a decreased androgenic action. SHBG levels are inversely correlated with androgen and insulin levels, whereas oestrogens increase circulating SHBG concentrations. SHBG also influences the clearance of androgens from the circulation.

Androgen production and clearance are influenced by various physiological states. Obesity, particularly the abdominal type, increases the formation of testosterone from A4, and decrease SHBG levels resulting in increased circulating free androgens. Additionally, because androgens are fat soluble, excess adipose tissue serves as an extravascular pool for androgens. The number of androgens metabolized to oestrogens by adipose tissue aromatase are also enhanced in obesity.

Normative ranges for androgens also differ depending on age. Circulating levels of A4, total and free testosterone, and, DHEA/DHEAS, decline with age, beginning in the mid/late 30s. It is well established that normal menopausal androgen levels are lower than those produced in the reproductive years.

Normal Hair Physiology

Hair covers the vast majority of the body, sparing only the lips, palms of the hands, and the soles of the feet. There are about 5 million hair follicles on a human, of which 1 million on the head. Almost all hair follicles are present at birth and no additional follicles arise thereafter, although the size of the follicles may change over time.

A hair follicle is present in conjunction with a sebaceous gland and an erector pili muscle, forming the pilosebaceous unit (PSU) (Figure 8.4.4.2). The physiology of hair growth is covered elsewhere [4].

Structurally, there are three types of hair. Lanugo is soft hair covering the surface of the fetus, which is shed sometime in late gestation or early postpartum. Vellus hair is soft, fine, non-pigmented, or containing little pigment, generally measuring less than 2 mm in length, and covering apparently hairless areas of the body. Terminal hair is long, coarse, thick, pigmented, and contains a central core of compacted keratinocytes (i.e. medullated), which vellus hairs do not have. Terminal hairs are found primarily on the upper and lower limbs, the scalp, the face, the upper and lower back, the chest, abdomen, and in the axillary and pubic areas. This type of hair shows significant regional morphological differences (i.e. longer in some sites, more pigmented in others, etc.) due to genetically determined differences in the follicles. Nonsexual terminal hair presents in the scalp, eyebrows, and eyelashes [5].

Race and ethnicity influence the body hair type and distribution. The number of hair follicles per unit skin area and the rate of hair growth vary among ethnic groups. For example, Asians have less dense hair than Blacks, who in turn have less dense hair than Whites. However, men and women within the same race or ethnic group have similar follicle numbers and the visible differences between them are related to the type of hair arising from these follicles (i.e. terminal versus vellus hairs).

Hair follicles undergo cyclic changes and there are three phases of the hair follicle growth cycle (Figure 8.4.4.3). Anagen is the active growing phase of hair. During this phase, keratinocytes are dividing extensively with downwards progression of the dermal papilla. Anagen is followed by the transitional catagen phase in which the hair stops growing and the hair bud shrinks forming a club end,

and finally by a resting, or telogen phase, after which the hair sheds [5]. Although in many animals the growth cycles of all hair follicles are in synchrony, in humans, the growth phases of different hair follicles are not synchronous and, for that reason, hairs appear to be continuously growing. The length of hair cycle phases varies significantly in different parts of the human body. Scalp follicles have the longest anagen phase, which may last 2–6 years. They have a catagen phase of 1–3 weeks and a telogen phase of up to 3 months. Normally, 80–85% of scalp hairs are in anagen. The anagen phase of body hairs may as short as 3–6 months (e.g. forearms or legs) or as long as 2–3 years (e.g. on scalp).

Development and growth of hair follicles are regulated by hormonal factors. Growth and thyroid hormones stimulate a generalized increase in hair growth. Both hypo- and hyperthyroidism are, however, associated with hair loss. Pregnancy temporarily increases the number of hair follicles in anagen, of which many enter catagen or telogen postpartum resulting in diffuse hair loss. Oestrogens oppose the effects of androgens, by increasing SHBG levels and reducing free androgens rather than showing a direct effect on hair follicles [5].

Effects of Androgens on Hair Follicle

Androgens are the principal hormonal regulators of type and distribution of body and facial hairs. In hair follicles, circulating testosterone is metabolized by 5α-reductase to the more potent DHT. Both hormones (and to a limited extent, A4, and DHEA) bind to the androgen receptor. Androgen actions on the PSU, include: (1) increased sebum production; (2) the differentiation of the hair follicle from vellus to terminal hairs (in sensitive areas of the body), or vice-versa (in scalp); and (3) the prolongation of the anagen phase resulting in longer thicker hairs. See Figure 8.4.4.4.

The growth and differentiation of hair follicles in response to androgens varies greatly in different body areas, in association with the local content of AR, 5α-reductase, l-ornithine decarboxylase (ODC), 17β-hydroxysteroid dehydrogenase, and other enzymes.

Three types of skin areas concerning sensitivity to androgens are generally considered (Table 8.4.4.1), although we should note that there is wide variability in skin responsiveness across the body and face.

Some skin areas are relatively independent of the effect of androgens and are defined as *non-sexual skin areas*. Alternatively, other skin areas (e.g. lower pubic triangle and the axilla) are quite sensitive to androgens, and hair follicles are readily terminalized even in the presence of relatively low levels of circulating androgens. These skin areas begin to develop terminal hair in early puberty, when only minimal increases in adrenal androgens are observed, and are termed as *ambosexual skin areas*. Finally, other areas of the skin respond to androgens, but only to significantly higher levels. These areas are defined as *sexual skin areas* [6, 7]. In women, the presence of increased terminal hairs in sexual skin areas, in a male-like pattern, is considered pathological and is termed hirsutism.

Androgens, particularly in excess, may transform vellus into terminal hairs in androgen-sensitive areas in an irreversible manner (i.e. terminalization). Paradoxically, in certain areas androgens may transform terminal hairs into vellus hairs (i.e. miniaturization), as is observed in male-pattern balding. The process of transformation (i.e. terminalization or miniaturization), occurs progressively over many hair growth cycles, requiring months to years of androgen exposure. Interruption of the process sufficiently early (e.g. through use of antiandrogens in case of vellus hair terminalization) can reverse the observed effects.

Epidemiology of Hirsutism

The prevalence of hirsutism will depend on the method used to determine its presence, the definition used for hirsutism, and the population under investigation. Although objective methods are available for the assessment of hair growth including photographic evaluations and microscopic measurements, they are not suitable for widespread clinical use due to a significant degree of complexity and high cost. Alternatively, various methods, based on visual assessment of hair type and growth, have been proposed to evaluate patients suspected of having hirsutism [8].

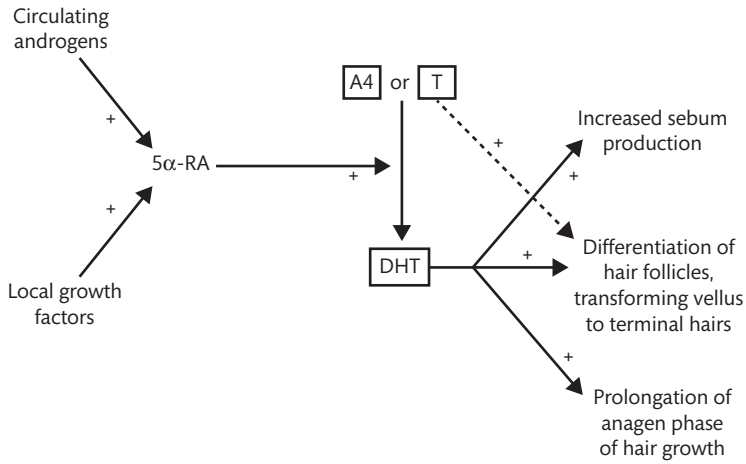

Figure 8.4.4.4 Effects of androgens at the pilosebaceous unit.

A4, Androstenedione; T, testosterone; DHT, Dihydrotestosterone. 5A-RA, 5a-reductase.

Table 8.4.4.1 Hair type and localization in relation to sensitivity to androgens

Hair type	Skin area	Androgen sensitivity
Nonsexual hair	Eyelashes, eyebrows, and lateral and occipital aspects of the scalp	Relatively independent of the effects of androgens
Ambosexual hair	Lower pubic triangle, the axilla, and the forearm and lower leg	Sensitive to low levels of androgens
Sexual hair	Upper lip, chin, and neck, cheek and sideburn areas, chest, upper and lower abdomen, upper and lower back, thighs, and upper arms	Sensitive to high levels of androgens

The most commonly used method of scoring body and facial terminal hair growth, for defining the presence of hirsutism, is based on a modification of the method originally described by Ferriman and Gallwey in 1961 [9, 10]. The modified Ferriman–Gallwey (mFG) visual assessment method scores the presence of hair growth between 0 (absence of terminal hairs) and 4 (extensive terminal hair growth) at nine different body sites (Figure 8.4.4.5) [8, 10]. However, we should note that this system is semi-quantitative at best, and subject to interobserver variability and there is also a lack of consensus on what score defines hirsutism [10]. See Figure 8.4.4.6.

To determine the prevalence of hirsutism in the general population some large studies have been done [11–14]. Overall, 7.5% of the population could be defined as being hirsute by an mFG scores ≥8. However, when using cluster analysis to define what the 'natural' cut-off should be, the investigators observed that a score of 3 or more, defined a population that complained of being hirsute more frequently (70% vs. 15% below this score) and who used some form of treatment for unwanted hair [11]. Consequently, it is likely that the mFG score defining 'hirsutism' should be lower than what is generally used clinically today. More studies on defining 'hirsutism' are needed.

The degree of body hair growth, may be affected by ethnicity and race. While the degree of facial and body terminal hair growth appears to be similar in Black and White women, at least in the United States [11], it is highly unlikely that Asian women have similar degrees of hair growth. Furthermore, while there may be significant differences in the degree of hirsutism between ethnic groups, it is less clear that there are significant differences in the cut-off values used to define hirsutism between populations.

Other Signs of Androgen Excess

Acne

Acne is a common disorder of the PSU. It occurs in adolescence, and may persist into adulthood. Acne presents most commonly on the face, neck, chest, shoulders, and back. Androgens stimulate sebocyte proliferation, cause the sebaceous glands to enlarge and produce more sebum. In women whose acne is severe, or associated with hirsutism or irregular menstrual periods, hyperandrogenism should be considered [15].

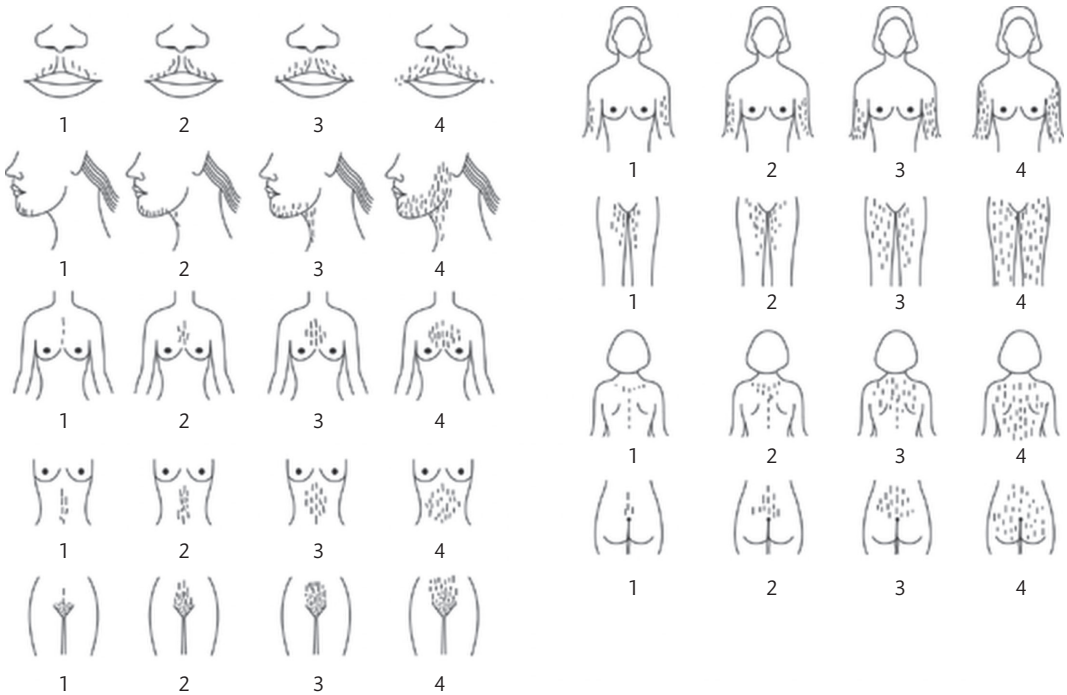

Figure 8.4.4.5 Modified Ferriman–Gallwey (mFG) hirsutism scoring system. Each of the nine body areas is rated from 0 (absence of terminal hairs) to 4 (extensive terminal hair growth), and the numbers in each area are added for a total score. A mFG score ≥6–8 generally defines hirsutism.

Androgenic Alopecia

The term 'alopecia' refers to loss of scalp hair. Androgenic alopecia is sometimes referred to as 'androgenetic' alopecia on the presumption of an underlying, yet to be determined genetic factor. In the presence of androgens, anagen phase of sensitive scalp hairs is shortened, and hair follicles shrink or become miniaturized. With successive anagen cycles, the follicles become smaller and shorter, and non-pigmented vellus hairs replace the thick pigmented terminal hairs.

Androgenic alopecia is a form of alopecia in women (female-pattern hair loss or FPHL), generally characterized by diffuse loss of hair in the sagittal (top) part of the scalp [16]. In severe forms of hyperandrogenism, hair loss in women may be similar to that of men ('male-pattern balding'), with frontal, sagittal and eventually occipital hair loss.

While most of the women with FPHL have normal endocrine function, and regular ovulatory cycles, it is not uncommon for androgenic alopecia to be accompanied by other androgenic skin manifestations, such as hirsutism and acne in the same patient. The prevalence of hyperandrogenaemia is higher when FPHL presents in association with other signs of androgen excess, such as hirsutism and menstrual dysfunction [17].

Virilization

Virilization is a relatively uncommon clinical finding, and its presence is usually associated with markedly elevated levels of circulating androgens and significant pathology. Depending on the duration of the underlying pathology, virilization is characterized by male-pattern balding, clitoromegaly, and severe hirsutism. It may also be accompanied by signs of masculinization including deepening of the voice, increased muscle mass, and loss of typical female fat deposition, including decreased breast size. Women with virilization are nearly always amenorrhoeic [18]. The presence of an androgen-secreting neoplasm (ovarian or adrenal) should always be suspected in any woman who develops signs of virilization, particularly if the onset is sudden with a rapid progression, although there may be other rare causes.

Differential Diagnosis of Hirsutism

The causes of hirsutism are summarized in Box 8.4.4.1. Over 80% of hirsute patients will have PCOS, with a small percentage of patients having idiopathic hirsutism, and other rare disorders including non-classic congenital adrenal hyperplasia (NCAH), the hyperandrogenism-insulin resistance-acanthosis nigricans (HAIRAN) syndrome, and androgen-secreting neoplasms [14, 19].

Cushing's syndrome, acromegaly, thyroid dysfunction, and hyperprolactinaemia may be associated with hirsutism, but patients usually present with other clinical features common to these disorders.

Polycystic Ovary Syndrome

PCOS is a common disorder characterized by androgen excess, ovulatory dysfunction, and polycystic ovaries [19, 20]. PCOS affects 5–15% of women of reproductive age and over 80% of hirsute women. There are currently three sets of criteria for diagnosing PCOS [21–24], although the 2003 Rotterdam classification system is the broadest and most widely used. This defines PCOS by the presence of as least two of the following three criteria: (1) oligo- and/or anovulation, (2) clinical/biochemical hyperandrogenism, (3) polycystic ovaries on ultrasonography, and exclusion of other related disorders [22, 23].

The aetiology(s) and genetic basis of the syndrome remain largely unknown. Patients with PCOS have several interrelated characteristics including dysregulated ovarian and adrenal steroidogenesis, altered gonadotropin dynamics, chronic anovulation, polycystic ovaries, and insulin resistance [20]. It is noteworthy that insulin resistance and hyperinsulinaemia are dominant features of PCOS both in obese and lean patients, and over 80% of patients with PCOS demonstrate varying degrees of insulin resistance [25]. Insulin directly enhances LH-stimulated androgen secretion from the ovarian theca cells. Increased insulin levels also decrease the synthesis of SHBG by the liver and reduce circulating SHBG levels, thus resulting in higher concentrations of free androgens.

  - Acromegaly[b]
  - Thyroid dysfunction
  - Hyperprolactinemia
- Other causes
  - Drugs
  - Chronic skin irritation

[a] Hirsutism in a patient with normal ovarian function (normo-ovulation), no polycystic ovaries, and normal circulating androgen levels.
[b] If clinical findings are highly suggestive of these very rare disorders, further testing may be needed.

Additionally, PCOS is associated with increased risk of type 2 diabetes, dyslipidaemia, cardiovascular disease (CVD), and endometrial carcinoma [19].

Current treatment regimens are directed at reducing hirsutism, menstrual cycle regulation, and at times achieving pregnancy. In addition, improvement of insulin sensitivity, weight control, and prevention of long-term health consequences are also important therapeutic goals.

Idiopathic Hirsutism

Hirsute patients with normal ovarian function and morphology (i.e. regular ovulation, and no polycystic ovaries on ultrasound), along with normal androgen levels, in the absence of features that suggest other specific identifiable causes of hirsutism, are diagnosed as having idiopathic hirsutism (IH).

It must be said that routine androgen assays may not be suitable to detect mild to moderate hyperandrogenaemia in women (see next). Furthermore, available evidence suggest that up to 40% of hirsute women who claim to have 'regular menses' actually demonstrate oligo-ovulation and so, a percentage of these women should be diagnosed as having PCOS [26].

In some patients with idiopathic hirsutism the activity of 5α-reductase in the hair follicle, which converts testosterone to the more potent androgen DHT, appears to be increased. Increased numbers of ARs or the presence of polymorphisms in the AR gene that result in an increased receptor activity may also be the basis for the disorder in other patients.

Prevalences of idiopathic hirsutism of up to 17% of hirsute women have been reported [6, 27]. However, it is important to note that with the use of the more expansive Rotterdam criteria for PCOS, the prevalence of IH is nowadays significantly lower.

Overall, the aetiology and epidemiology of idiopathic hirsutism remains unclear, although the prevalence is decreasing as the definition of PCOS broadens and the quality of the clinical and laboratory evaluation improves.

Non-Classic Congenital Adrenal Hyperplasia (NCAH)

Between 1% and 10% of patients with hirsutism have NCAH. The most common form is adrenocortical 21-hydroxylase (21-OH) deficiency. In this autosomal recessive disorder, the steroid precursors for 21-OH, particularly 17α-hydroxyprogesterone (17-HP) and A4, accumulate and are secreted in excess. Hyperandrogenic symptoms most commonly appear in the peri- or postpubertal period, but may be absent (i.e. cryptic) even in the presence of elevated circulating androgen levels. In addition to hirsutism, other features may include oligo-ovulation, and polycystic ovaries. Some children may present with premature pubarche. Clinically, it is difficult to distinguish these patients from patients with PCOS [28]. Biochemically, the levels 17-OHP are elevated while the adrenal androgen DHEAS is not higher than that of other hyperandrogenic women [29].

Hyperandrogenic-Insulin Resistant-Acanthosis Nigricans (HAIRAN) Syndrome

Patients with the HAIRAN syndrome present with marked acanthosis nigricans (a velvety thickening and hyperpigmentation of the skin found on intertriginous areas, reflecting hyperinsulinemia) and significant degrees of hyperandrogenism [30]. Normal or low

luteinizing hormone levels accompany increased androgen levels. The clinical distinction between HAIRAN and PCOS is not always clear. Nevertheless, HAIRAN syndrome can be diagnosed in patients with hyperandrogenism and acanthosis, by the presence of severe insulin resistance and hyperinsulinemia, generally determined as fasting basal circulating insulin levels higher than 80 μU/ml and/or 500 μU/ml during an oral glucose challenge. The ovaries are enlarged and hyperthecotic with proliferating islands of luteinized theca cells in the ovarian stroma, and tend to be less cystic than the typical polycystic ovary.

Androgen-Secreting Tumours

Androgen-secreting tumours, whether ovarian or adrenal, are relatively rare. The clinical onset of these tumours is usually sudden and may rapidly lead to virilization and masculinization. Other systemic symptoms, such as weight loss and anorexia might also be observed in patients with carcinomas. Ovarian neoplasms are usually not malignant, and include Sertoli–Leydig cell tumours and lipoid cell tumours. They are usually palpable on pelvic exam and/or are associated with unilateral ovarian enlargement on imaging. Androgen-secreting tumours of the adrenal are often carcinomas. Androgen-secreting adrenocortical carcinomas are frequently associated with Cushingoid features.

The clinical presentation is generally the most sensitive indicator of an androgen-producing tumour. Biochemical suppression or stimulation tests are not recommended for the diagnosis of androgen-secreting tumours as these tests can be misleading. Likewise, basal levels of androgens vary widely in patients with these tumours. In patients suspected of suffering from an adrenal or ovarian androgen-producing tumour, imaging studies and ovarian and/or adrenal venous sampling may be of value in identifying the neoplasm [18].

Drugs

A number of non-androgenic drugs, such as phenytoin, cyclosporine, and diazoxide might result in generalized growth of body and facial hair, leading to vellus hypertrichosis. Alternatively, the use or abuse of androgenic/anabolic drugs, such as danazol and methyltestosterone, may produce hirsutism in addition to amenorrhoea and liver dysfunction.

Clinical Evaluation of Hirsutism

A thorough history and a focused physical examination are essential for the evaluation of the patient with hirsutism. It is firstly important to clinically distinguish between hirsutism and hypertrichosis in order to determine the necessary subsequent evaluation and management. Hypertrichosis is characterized by increased vellus hair growth and is not caused by androgen excess [31]. Nevertheless, some of the patients with hyperandrogenism will have excess growth of both terminal and vellus hairs.

History

In a patient with suspected hyperandrogenism, the use of androgenic/anabolic drugs or skin irritants use should be excluded. Onset and progression of hirsutism or signs of virilization should be determined. Peripubertal onset of hirsutism with slow progression is more consistent with non-neoplastic disorders, such as PCOS. Alternatively, rapid progression of hair growth with signs of virilization in a previously asymptomatic woman should raise suspicion of an androgen-secreting neoplasm.

A detailed history of the onset (menarche) and subsequent development of the patient's menstrual pattern should be obtained. Menstrual irregularities may accompany hirsutism, although some hirsute women can have regular cycles (eumenorrhea) or even normal ovulatory function. A history of galactorrhoea or symptoms of thyroid dysfunction should also be sought. Finally, a detailed family history for endocrine, metabolic, cardiovascular, neoplastic, and reproductive disorders should be obtained.

Physical Examination

Firstly, the physical exam should focus on determining whether features of hyperandrogenism are truly present. Hyperandrogenism in women may present as hirsutism, acne, androgenic alopecia, or virilization. The type, pattern, and extent of excessive hair growth should be established and preferably scored by using the mFG method.

Finally, in addition to evidence of hyperandrogenism, signs of other endocrine disorders should be sought for, including acanthosis nigricans, the presence and body distribution of obesity, Cushingoid features, and facial features suggestive of acromegaly.

Laboratory Evaluation

In patients with hirsutism, measurement of total and free testosterone, and possibly DHEAS and A4, may assist in detecting underlying hyperandrogenaemia. Patients with androgen-secreting neoplasms have very high levels of androgens.

Total testosterone should be measured with a high-quality immunoassay after sample extraction and chromatography, or preferably mass spectrometry. Currently available, direct assays for the measurement of free testosterone are not reliable to be used in hirsute women [32]. Free testosterone should be measured, based on the total testosterone level, using equilibrium dialysis, competitive binding, or ammonium sulphate precipitation, or estimated from the ratio of total testosterone and SHBG (i.e. the free androgen index or FAI). Overall, free testosterone is more sensitive for the detection of hyperandrogenaemia than is total testosterone alone. The measurement of A4 or DHEAS increases the proportion of women detected as hyperandrogenaemic modestly.

Recently a new class of androgens (11-oxy-c19 steroids) have been reported to potentially play a role in androgen excess, including 11-KT, and 11-KDHT, which may become clinically useful in the future [1–3].

The initial evaluation of a hirsute woman should also include the measurement of a morning follicular phase 17-HP level to exclude NCAH. If the 17-HP level is between 2 and 10 ng/ml an acute adrenocorticotropic hormone (ACTH) stimulation test should be performed for the diagnosis of NCAH. The diagnosis of 21-OH-deficient NCAH is made biochemically if the basal or the stimulated levels are greater than 10 ng/ml or 15 ng/ml.

Prolactin and thyroid stimulating hormone (TSH) levels should also be checked if menstrual dysfunction or galactorrhoea or signs of thyroid dysfunction are present.

In the evaluation for PCOS, it is important to determine whether they have ovulatory dysfunction and polycystic ovaries. Many

women with hirsutism present with ovulatory and/or menstrual dysfunction. However, in up to 40% of hirsute patients with apparent regular menstruation, anovulation may still be present [26]. Consequently, in hirsute women with apparently regular menses, ovulatory function should be confirmed by obtaining a luteal phase progesterone level, best between 22 to 24 days after the start of menstruation. Progesterone levels lower than 3–5 ng/ml in a eumenorrhoeic patient are consistent with anovulation. Additionally, all hirsute patients should undergo pelvic ultrasonography to determine whether they have polycystic ovaries. Patients diagnosed with PCOS should also assess glucose intolerance and cardiometabolic risk factors.

Treatment of Hirsutism

A combination of pharmacological therapies and cosmetic amelioration is recommended for the treatment of hirsutism. If the underlying cause is one of the rare disorders previously discussed, therapies for these disorders should be undertaken.

The primary aim of the treatment of hirsutism is to stop the development of new terminal hairs. Hormonal therapy may also decrease the growth rate, diameter, and pigmentation of terminal hairs that are already present. Patients should be informed that the effect of treatment will probably only be observed after at least 6 months and the achievement of optimal results will require 12–24 months of therapy.

Any terminal hairs remaining after medical therapy must be destroyed mechanically.

Current treatment of hirsutism may consist of: (1) suppression of androgen production; (2) blockade of peripheral androgen action; and (3) mechanical and cosmetic means of hair removal.

Suppression of Androgen Production

Suppression of ovarian androgen secretion can be accomplished using combination hormonal contraceptives. Long-acting gonadotropin-releasing hormone (GnRH) analogues and insulin sensitizers are currently not indicated in the routine treatment of hirsutism in most women [33]. Likewise, suppression of adrenal androgen secretion can be achieved using various glucocorticoids, although the effect on hair growth is minimal at best, not to mention the significant negative impact of these medications on metabolic status.

Combination (oestrogen-progestin) oral contraceptive pills (OCPs) have been a mainstay for the treatment of hirsutism [33]. Oral contraceptives suppress the pituitary secretion of luteinizing hormone and lead to a decrease in ovarian androgen production. The oestrogenic fraction in OCPs increases the levels of SHBG which, in turn, results in a decrease in the free testosterone fraction. The progestin in the pill can compete for 5α-reductase and the AR. Combined oral contraceptives have also been shown to modestly decrease adrenal androgen production by a yet unclear mechanism, possibly due to decreasing ACTH levels.

Most OCPs contain ethinyl oestradiol as the oestrogenic fraction. Progestins in the oral contraceptives vary in their androgenic potential and some may actually decrease SHBG levels. Norethindrone, norgestrel, and levonorgestrel are known to have some intrinsic androgenic activity. Alternatively, the third-generation progestins norgestimate and desogestrel are non-androgenic and have the advantage of less metabolic side effects, including minimal impact on glucose, insulin, and lipids. There are a number of combined oral contraceptives containing antiandrogenic progestins. Of those, the ethinyl oestradiol and cyproterone acetate combination has been the most widely used in hirsutism. See Box 8.4.4.2.

Blockade of Peripheral Androgen Action

Agents that suppress androgen production (see earlier) when used alone usually have modest effect on hair growth, and in most hirsute patients, peripheral androgen blockers need to be added for an adequate treatment response [34]. These include AR blockers (spironolactone, cyproterone acetate, or flutamide) and 5α-reductase inhibitors (finasteride or dutasteride). All these agents are similarly efficacious and the main difference rests in their side effects profile. All have teratogenic potential, inducing feminization of a male fetus, and therefore should be used with effective contraception. The addition of combination contraceptives to peripheral androgen blockers provides protection against the risk of unwanted pregnancy, reduces the risk of irregular menstrual bleeding, and suppresses androgen levels by a different mechanism, thus improving their efficacy.

Spironolactone

Spironolactone is a potent antimineralocorticoid and mild diuretic. It is an effective therapy for hirsutism by competing with androgens for the AR, 5α-reductase, and SHBG. It also inhibits at least partially the activity of some of the ovarian and adrenal enzymes involved in androgen biosynthesis. Doses of 50–200 mg/day are generally used for the treatment of hirsutism. Side effects include menstrual irregularity, dyspepsia, nausea, polyuria, nocturia, hypotension, and headaches. If the dose is increased from 25 mg/day in a progressive fashion to the dose desired, patients tend to develop less side effects. Menstrual irregularity may be avoided if spironolactone is given in conjunction with an OCP.

Cyproterone Acetate

Cyproterone acetate is an antiandrogenic progestin effective in treatment of hirsutism and acne. It acts mainly by competitively binding with the AR. In mild to moderate cases, cyproterone acetate in a dose of 2 mg/day combined with ethinyl oestradiol generally

Box 8.4.4.2 Pharmacological treatment of hirsutism[a]

- Suppression of ovarian or adrenal androgen production
  - Combined contraceptive pills
  - Long-acting gonadotropin-releasing hormone (GnRH) analogues
  - Insulin sensitizers
  - Glucocorticoids
- Blockade of peripheral androgen receptor action
  - Cyproterone acetate
  - Spironolactone
  - Flutamide
- Blockade of 5α-reductase activity[b]
  - Finasteride/Dutasteride
  - Combination therapy

[a] At least 6 months of treatment is needed for an observable clinical response.
[b] Minimizing the conversion of testosterone to dihydrotestosterone

improves the symptoms. However, in more significant hirsutism, higher doses of cyproterone acetate may be required (up to 100 mg/day) for significant improvement. Side effects include mood changes, loss of libido, and weight gain.

Flutamide

Flutamide is an AR blocker, initially used as adjuvant treatment for prostate cancer. It is as effective as spironolactone in the treatment of hirsutism in doses of 125–500 mg/day, but with significantly less side effects, with the exception of the rare occurrence (3/10 000 users) of dose-dependent severe hepatotoxicity including the possibility of death. Careful monitoring of liver function tests is required due to the potential hepatotoxicity. Some authors completely recommend against the use of flutamide for hirsutism, considering its risk of potentially fatal hepatotoxicity [33].

Finasteride/Dutasteride

Finasteride is a competitive inhibitor of type 2 5α-reductase and is used for the treatment of benign prostatic hyperplasia. Although type 1 is the predominant isoform of 5α-reductase found in the PSU, finasteride 5 mg daily has been found to be useful for the treatment of hirsutism. Alternatively, dutasteride targets the type 1 isoform of 5a-reductase and may prove to have even higher efficacy, but so far there were no randomized controlled clinical trials with this drug.

Mechanical Means of Hair Removal

Pharmacological agents should be combined with appropriate mechanical/cosmetic treatments for optimal results in hirsute patients. Shaving, bleaching, or chemical depilation may be useful to temporarily ameliorate unwanted hair. Shaving does not affect the rate or duration of the anagen phase or diameter of the hair. Thus, patients can be reassured that shaving does not lead to a worsening of hirsutism. However, shaving can lead to a blunt hair end, which would give the false impression of thicker hair.

Plucking or waxing are not very much recommended because they cause discomfort and may lead to folliculitis with the subsequent development of in-grown hair. Furthermore, excessive or indiscriminate use of any depilating agent can result in chronic skin irritation.

Efluornithine is a topical irreversible inhibitor of l-ornithine decarboxylase (ODC), an enzyme which catalyses follicular polyamine synthesis necessary for hair growth. Efluornithine hydrochloride, marketed in a 13.9% cream, has been found to reduce unwanted facial hair in women. Efluornithine does not remove the hair, but rather reduces the rate of hair growth. Adverse effects are usually mild and include dry skin and itching.

Electrolysis, recently most often replaced by laser epilation, can be used to achieve a more permanent destruction of unwanted hairs, although long-term efficacy of these therapies is not well established. Electrolysis may still have an important role in women with blond or white hair in which laser epilation is not so effective. Repeated sessions of electrolysis can result in 20–50% permanent hair loss, which may last for months to years [35], significantly longer even than laser epilation.

Laser epilation, a selective photothermolysis technique, is also available for the treatment of hirsutism. A recent meta-analysis of the available randomized controlled trials involving 444 subjects reported that laser epilation results in about a 50% hair reduction that is maintained at least for up to 6 months after the final treatment [36]. Laser epilation appears to be more effective for hirsute women with dark hair and light skin. Side effects, including scarring and discoloration, might be observed after either electrolysis or laser epilation.

Emotional Support/Therapy

Hirsute women usually have high levels of emotional distress and some patients will have significant psychological morbidity including anxiety and depression [19]. Thus, education and psychological support are key elements of the overall therapeutic approach. Diagnosis, treatment alternatives, and expectations should be discussed in detail. Patients need to participate in shared decision-making regarding the treatment choice that best addresses their concerns. Observable decreases in unwanted hair with therapy help reduce their emotional burden. Nevertheless, professional psychological counselling may be needed in some patients.

Key Points

- Hirsutism is a common and significant health problem in women, with a negative impact on their quality of life.
- Hirsutism often signals an underlying androgen excess disorder, most commonly PCOS.
- A thorough evaluation in a hirsute woman should include a detailed clinical history and physical examination, a diagnostic work-up comprising a focused hormonal profile and a pelvic ultrasound.
- The first-line pharmacological treatment is oral contraceptives and/or antiandrogens, accompanied by mechanical/cosmetic hair removal as needed.

Female Hypogonadism in Pre- and Post-Menopause

8.5.1 Female Hypogonadism

Premature Ovarian Insufficiency

Ephia Yasmin and Gerard S. Conway

Introduction

The ovary is a unique organ in the body in that is has a defined lifespan of approximately 50 years. The life expectancy of the ovary is determined by germ-cell number which is a balance between germ-cell multiplication *in utero* and factors affecting programmed cell death throughout life. The peak germ-cell number occurs at six months gestation with >700 000 eggs. Current understanding of ovarian reserve suggests that once this maximum number of oocytes has been achieved, the ability to the make new oocytes is lost and the total number gradually declines. New research questions whether oogonial stem cells can be activated to make new oocytes [1]. It is estimated that nearly 50% of germ cells have been destroyed by the age of menarche, and by the onset of menopause, only a few thousand remain. Throughout life therefore, germ-cell apoptosis takes place at a rate of approximately 25–150 lost per day. The decline in oocytes is roughly parallel with a fall in the concentration of anti-Müllerian hormone (AMH) in the circulation from about the age of 30 [2]. Only a small fraction of oocytes are accounted for by ovulation; about 500 in all. As the number of germ cell falls, a critical point is reached when periods stop with subsequent reduction in circulating oestrogen, and to a lesser extent, testosterone concentrations.

The menopause is defined by the last menstrual period and occurs at an average age of 50.7 years in the Western world [3]. Premature ovarian insufficiency (POI) is defined as amenorrhoea with raised FSH (>25 IU) on two occasions and low oestradiol before the age of 40 years [4]. POI occurs in approximately 1% of females and becomes increasingly rare in younger age groups. For instance, in presence of normal karyotype, 1:1000 of women at 30 has POI, 1:10 000 at 20 and 1:100 000 of women will present with gonadal failure and primary amenorrhoea (**Figure 8.5.1.1**). The prevalence of POF varies by ethnicity with women of oriental origin having a lower risk and African Americans a higher risk compared to Caucasian Americans [5]. In terms of the mode of presentation, POI is the aetiology of 10–28% of cases with primary amenorrhoea and about 10% of those with secondary amenorrhoea [6, 7].

The term premature ovarian insufficiency is preferred to earlier alternative, premature ovarian failure, because it is an all-encompassing term that accounts for the variable course and occasional remission [7]. The term hypogonadotropic hypogonadism is also used to emphasize ovarian origin whereby the raised concentrations on luteinizing hormone (LH) and FSH contrast from low gonadotrophins in hypothalamic or pituitary causes of hypogonadism. Gonadal dysgenesis refers to hypogonadotropic hypogonadism with a known genetic cause such as an abnormal 46,XY or 45,X karyotype and implies that ovarian development was halted at an early stage of embryonic development. In the case of Turner syndrome it

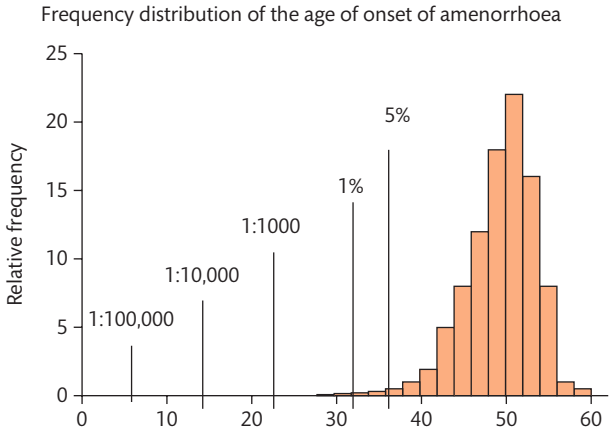

Figure 8.5.1.1 A schematic of the distribution of the age of onset of amenorrhoea according to the life span of the ovary. Data amalgamated from a variety of sources for the purposes of illustration.

is thought that early ovarian development is usually normal but that the chromosome anomaly leads to rapid germ-cell apoptosis [8].

The Menopause

Menopause describes the end of natural reproductive life when menstruation has been absent for at least 1 year. The process can be abrupt but in many women, symptoms precede amenorrhoea by months or even years. The age of menopause varies between 45 and 60 years and may have a familial link [9]. The interval between periods usually shortens as the menopause approaches from an average of 28 days often to 21 days. The diagnosis of menopause may not be obvious in women taking hormone treatments for period control or who have had a hysterectomy. In addition, non-specific symptoms such as joint and muscle stiffness, reduction of cognitive function and concentration, or simply low mood can occur in the absence of classical symptoms. Oestrogen deficiency should be considered as a possibility for anyone experiencing new onset of symptoms after the age of 40. The diagnosis of menopause is mainly based on history and, for the majority of women, no diagnostic test is required. A measurement of FSH can be unreliable as it may not correlate with symptoms of the premenopause.

The majority of women experience some symptoms of the menopause which often gradually diminish over several years [10]. In a proportion of women, disabling symptoms can be lifelong requiring indefinite treatment with hormone replacement therapy (HRT). Treatment of the menopause is individualized and includes information, counselling, lifestyle, hormone-based treatments, and treatments to improve sexual function. A discussion regarding the spectrum of symptoms that are associated with oestrogen deficiency can be reassuring and will ensure that no hidden symptom is left untreated. Symptoms relating to change of mood, libido, sexual function, and urogenital dysfunction should be elicited in history taking.

The risks and benefits of HRT require discussion as this treatment is not essential and non-pharmaceutical alternatives are available. Reports arising from the Women's Health Initiative (WHI) that highlighted the risks of HRT between 2002 and 2004 resulted in a decline in the use of HRT [11]. Subsequent assessments, however, have shown that the risks of HRT may have been overestimated. In addition, the risk of stroke can be reduced by the use of transdermal oestrogen instead of oral oestrogen that formed the basis of most of the early HRT studies.

Premature Ovarian Insufficiency

Clinical Evaluation and Diagnosis of POI

The clinical presentation of POI varies depending on the age of presentation [12, 13]. In very early onset in adolescence POI leads to pubertal delay and primary amenorrhoea. After menarche, the presentation is with symptoms of oestrogen deficiency and secondary amenorrhoea or as part of a work-up for irregular periods or infertility. In addition, POI can be part of clinical syndromes that can be genetic, such as Turner syndrome, or autoimmune endocrinopathies.

The formal diagnosis of POI is based on the presentation of amenorrhoea with finding of elevated serum FSH concentrations (FSH >25 IU/L) on at least two occasions separated by 4 weeks [4]. The requirement for two samples takes into account the fact that ovarian function can fluctuate and raised FSH can be a transient phenomenon. In addition, because the diagnosis has such severe implications, certainty of the diagnosis is required. While it is the usual expectation that the condition will be permanent, some women follow an unpredictable course of relapse and remission particularly in the first year after diagnosis [14]. There is a commonly quoted pregnancy rate of approximately 1–5% in women with POI and it is therefore important to inform women with POI of this phenomenon and advise use of contraception when appropriate. Because of this background fertility, case reports of effective treatment of POI must be viewed with caution. Fluctuating ovarian function probably accounts for many cases which are labelled 'resistant ovary syndrome'. It is now understood that ovarian biopsy is not predictive of remission and should no longer be included as part of the work up of POI [4]. Anti-Müllerian hormone has found a place as a diagnostic marker of low ovarian reserve but once the FSH concentration is raised, AMH offers little additional information [15].

A careful family history can identify other affected female members in as many as 30% of cases [16] and in this situation more genetic screening is indicated and genetic counselling for relatives may be appropriate. A karyotype should be performed in anyone with a positive family history because small chromosome deletions can be inherited. Fragile X (Fra-X) premutation analysis should be offered to all women with POI because of its value in detecting a new pedigree for the prevention of fragile X syndrome [17, 18].

Oestrogen receptors are widely distributed throughout the body and the effects of oestrogen deficiency are diverse. While the classical symptoms of hot flushes, sleep disturbance, and vagina dryness are obvious, subtle changes in mood and musculoskeletal pain may go unrecognized as part of this symptom spectrum. A careful history listing any change in wellbeing, no matter how minor, that coincides or precedes amenorrhoea will provide a useful guide to optimizing HRT.

The major medical issues for health surveillance in women with POI revolve around the quality of life and bone protection offered by HRT. Oestrogen deficiency is a risk for osteoporosis and DXA scans should be performed at intervals to assist in the correct dosing of HRT. Fertility is often a concern for women with POI. A discussion on options for reproduction include use of donated oocytes and adoption. Prepregnancy counselling should include health issues such as risk of aortic root dissection in Turner syndrome.

Psychological and emotional support to deal with impact of diagnosis on their health and relationships should form part of the multiprofessional care in POI. Long-term follow-up is essential to monitor HRT and to consider emerging associated autoimmune pathology.

Aetiology of POI

Ovarian insufficiency is the final outcome many pathogenic mechanisms. Table 8.5.1.1 shows the main categories of pathogenic mechanisms that lead to ovarian insufficiency. Despite diagnostic advances, particularly in the identification of genetic associations, the cause of POI remains unknown in the majority of cases [13].

Genetic Causes of POI

A genetic aetiology for POI is suggested not only by a positive family history but also if there are features of an associated syndrome. Cytogenetic chromosome anomalies occur in about 2% of cases with the majority involving the X chromosome.

Table 8.5.1.1 Summary of pathogenic mechanisms causing premature ovarian insufficiency

Chromosome anomalies	Chromosomal defects cause both abnormal ovarian development and accelerated apoptosis. Turner syndrome is the most common causing and females with Downs Syndrome have later onset POI.
Single gene defects	Many single gene defects have been described but in total they account for only a small minority of cases of POI. Mutations are commonly in genes vital for ovarian development or function. The most common gene defect is the Fra-X permutation.
Autoimmune	Autoimmune ovarian damage is usually presumed because of the association with other organ specific autoimmune conditions. Thyroid and adrenal autoimmunity is common. Ovarian autoantibodies are rarely positive.
Metabolic	In galactosaemia, abnormal metabolites are thought to mediate ovarian damage.
Iatrogenic	Ovarian damage following pelvic surgery and radiotherapy of chemotherapy during treatment of cancer.
Environmental factors	Viral infections and toxins such as pesticides are presumed. Smoking results in younger age of natural menopause.

X chromosome defects and Turner's syndrome: Defects of the X chromosome associated with POI include complete or partial deletion of monosomy X (Turner syndrome), trisomy X or X-autosome translocations. In the case of Turner syndrome variants, there is a great deal of variability in severity of the condition and this corresponds approximately with genotype and the amount of X chromosome disruption. Ovarian histology can vary from streak ovaries to those with well-preserved structure and follicles. Those with monosomy X (45X) tend to be the most severely affected while those with partial deletions of the X chromosome or mosaic 45X/46XX karyotype often lack the typical phenotypic features of the syndrome but may present with only with ovarian insufficiency and secondary amenorrhoea. Among women with Turner syndrome, the prevalence of ovarian failure is between 80% and 90% with most experiencing primary amenorrhoea and complete pubertal delay.

X chromosome deletions appear to segregate in two specific regions: POI1 at Xq26-qter and POI2 Xq13.3--Xq21.1 [19]. There are various proposed mechanisms by which X chromosome defects causes POI. Genes responsible for germ-cell development located along the critical region may be interrupted although break point genes that determine ovarian function have not been convincingly identified. It seems most likely that structural rearrangements of the X chromosome do not affect single genes but rather disrupt normal pairing at meiosis leading to meiotic arrest and subsequent atresia. It must also be noted however that some X chromosome break points are not associated with POI [19].

Single gene defects causing POI: A growing number of genes have been linked to ovarian insufficiency although the strength of evidence linking each anomaly with POI is variable [20, 21]. The most clinically useful genetic association is that between carriers of the Fra-X premutation and ovarian failure. Fra-X premutations occur in 3% of women with sporadic POI and 15% of those with the familial form and this genetic test is the only one advised in the United Kingdom as part of routine work up of POI [22]. In general, the phenotype of this subgroup of women with POI is indistinguishable from others although a minority are reported to a progressive intention tremor. The pathway by which Fra-X premutations damage ovarian function is unclear as this type of expansion of exon 1 of the gene is not thought to effect protein transcription even though the protein is expressed within the ovary.

Autoimmune Causes of POI

Autoimmune mechanisms may be involved in pathogenesis of up to 30% of cases of POI [23, 24]. POI has been reported to be associated with various endocrine (thyroid, adrenal, hypoparathyroidism, diabetes mellitus, and hypophysitis) and non-endocrine (chronic candidiasis, idiopathic thrombocytopenic purpura, vitiligo, alopecia, autoimmune haemolytic anaemia, pernicious anaemia, SLE, rheumatoid arthritis, Crohn's disease, Sjogren's syndrome, myasthenia gravis, primary biliary cirrhosis, and chronic active hepatitis) autoimmune disorders [25]. In many cases non-ovarian autoimmune involvement exists only at subclinical level [24]. POI may be part of the autoimmune polyglandular syndromes (APS) when accompanied by other autoimmune endocrinopathies. POI is more common with APS types I and III than with APS type II. The single most common autoimmune association is with hypothyroidism which occurs in 10% of women with POI.

Various pathways of autoimmune ovarian damage have been described but a reliable ovarian specific autoimmune marker is still lacking. Several putative pathogenic autoantibodies have been explored [26]. Antiovarian antibodies detected by routine *immunofluorescence* have been reported in several studies of women with POI but their specificity and pathogenic roles are questionable. The incidence of antiovarian antibodies in POI in different studies has been reported to vary from 4% to 69% [27]. Other candidate autoantibodies include those directed against steroidogenic enzymes (such as 3ß-hydroxysteroid dehydrogenase), gonadotropins, and their receptors, the corpus luteum, zona pellucida, and oocyte. None of these, however, have been validated as a diagnostic marker of autoimmune ovarian failure. Therefore, in the clinical work up of POI, screening for an autoimmune aetiology is usually only possible by seeking coexisting autoimmune diseases.

Women with idiopathic POI show an increased number of activated T cells in peripheral blood. Similar findings have been described in other autoimmune endocrinopathies, such as recent onset Graves' disease, type 1 diabetes mellitus, and Addison's disease. However, postmenopausal women also show raised numbers of activated peripheral T cells and oestrogen substitution has been shown to lower the number of activated peripheral T cells in women with POI. Therefore, it is difficult to be certain whether the raised numbers of activated blood T cells is the cause or the result of ovarian failure in this situation [25].

POI Resulting from Cancer Treatments

As the number of survivors of childhood cancer increases across the world, so iatrogenic POI becomes a greater proportion of women with this condition. Both chemotherapy, alkylating agents in particular, and radiotherapy used in the treatment of cancer or benign diseases are damaging to the ovary [28, 29]. The return of ovarian

function after cancer treatment is commonly observed although difficult to predict. For women estimated to be high risk of POI, oophorectomy or oocyte harvesting for cryopreservation may be considered [30].

Miscellaneous Causes of POI

Viral oophoritis is a possible occult aetiology that could theoretically account for the many cases of idiopathic POI. There is, however, little direct evidence of viral ovarian damage beyond case reports such as mumps oophoritis [31]. Cigarette smoking in known to be associated with earlier age of natural menopause but whether environmental effects are sufficiently strong to cause POI is unlikely. The available data regarding effects of endocrine disruptors, heavy metals, solvents, pesticides, plastics, and industrial chemicals on female reproduction is equivocal [32].

Hormone Replacement Therapy

Physiological replacement of ovarian steroid hormones until the age of normal menopause at 50, is generally accepted as routine for women with POI. However, there is little risk/benefit data for this young population. The principle of HRT use in young women differs only slightly from that in older women with the main treatment goal being optimal quality of life. Young women may require a higher oestrogen dose than that used in an older age group. Also, expectations for sexual function can be higher commonly requiring consideration for vaginal oestrogen and androgen replacement. An HRT regimen should be based on the individual preferences of each patient who should be encouraged to undertake a trial and error approach through the wide variety of product available.

Management of oestrogen replacement for young women presenting with primary amenorrhoea requires liaison with paediatric endocrinologists with experience in the induction of puberty in order to optimize breast and uterine development. For instance, a popular strategy is to maximize the time between the introduction of oestrogen and starting progesterone withdrawal bleeds is thought to benefit breast development. Conversely, the common practice of starting a low dose combined oral contraceptive in this circumstance may not offer the best outcome of uterine development.

Among **oral oestrogen** choices, oestradiol esters and 17β-oestradiol provide the mainstay of treatments [33]. Conjugated equine oestrogens are used less frequently than in the past because of a greater risk of hypertension and thrombosis compared to oestradiol [34, 35]. Some young women with POI find the **combined oral contraceptive pills** (COCP) pills a more acceptable option for oestrogen replacement but careful assessment of the pill free week is advised. The pill free week amounts to three months of oestrogen deficiency each year which may coincide with symptoms of oestrogen deficiency or bone loss. In choosing a type of COCP those with lower dose ethinylestradiol and second generation progestins have the lowest risk to thrombosis [36]. **Transdermal oestrogen** avoids first-pass liver metabolism involves non-invasive self-administration and attainment of therapeutic hormone levels with low daily doses [37]. This route of oestrogen administration also appears to be associated with a lower risk of thrombo-embolism. **Subcutaneous oestrogen** replacement involves placement of 25–50 mg oestradiol pellets usually in the lower abdomen or buttocks in a minor office procedure that is not currently available in some countries including the United Kingdom. **Topical vaginal oestrogen** may be used as an adjunct to systemic oestrogen. Creams, pessaries, tablets and vaginal ring appear to be equally effective for control of symptoms [38].

Once the choice of oestrogen has been made, separate consideration can be given to the **progestin** in women with an intact uterus. Progestins vary from the more potent such as norethisterone to the weaker such as dydrogesterone. Trial and error will allow the user to find the most suitable progesterone preparation. The route may be oral, transdermal, vaginal, or uterine. With the **oral** and **transdermal** routes there is a choice between continuous or sequential (for 10–14 days each month) delivery. Sequential regimen ensures monthly menstrual bleed. Continuous regimen avoids menstrual flow but break through bleeding may be more common in young women compared to an older age group in whom there is greater uterine atrophy. **Uterine delivery** with the levonorgestrel intrauterine device (Mirena) has the advantage of avoiding the adverse effects of oral progestins highlighted in the studies of older women [39].

Androgen replacement is useful in some instances when fatigue and loss of libido persist despite optimized oestrogen replacement [40] Transdermal testosterone administration and dehydroepiandrosterone treatment are two of the options for androgen replacement in these women. However, testosterone preparations are generally not licensed for use in females and most preparations available in the market are for use in men. Out of licence use in the female with involve using a significantly lower dose of testosterone.

Fertility Options for Women with POI

Different fertility options will be appropriate for each individual with POI. It is important that discussions on this topic from a professional with experience in the field, is made available not only soon after diagnosis but at intervals throughout follow-up as the technology and opportunities in this field are continually developing.

Spontaneous Fertility in POI

Women with POI have a 5–10% chance of spontaneous conception at some time after diagnosis as in some cases hormone levels and disease activity fluctuate and return to biochemical normality; this is often transient and the likelihood of recovery of ovulation is not possible to predict. Pregnancy loss in those who conceive is reported at 20%, which is similar to that of the normal population. Several medical therapies have been tried to induce ovulation in women with POI; however, in a systematic review all were reported to be equally ineffective [16]. In particular, glucocorticoids have been considered for those with autoimmune markers and although promising in early case reports, a controlled trial failed to show benefit [41].

Ovum Donation

Assisted conception with donated oocytes has been used to achieve pregnancy in women with POI for over 20 years and remains the only realistic fertility treatment for the majority of women with established POI [42]. The availability of donated oocytes varies from

country to country and this option is not acceptable in certain cultures. Embryos are developed with the using donated eggs fertilized with partner's sperm. The best embryo is chosen for transfer with the recipient having been prepared with oral or transdermal oestrogen. Because of the lack of a corpus luteum, progesterone support is required which can be administered orally, vaginally, or in injectable form.

Embryo Cryopreservation

Cryopreservation of embryos is a long-established technique as part of *in vitro* fertilization (IVF) but it will apply to only a small number of women with normal ovarian function who can anticipate imminent ovarian failure but have sufficient time to allow for controlled ovarian hyperstimulation(28). This circumstance might arise in some cases of malignancy or in someone who is known to be at risk of ovarian failure such as those with X chromosome anomalies or Fra-X premutation who may wish to delay starting a family for some years. Donor sperm could be used for those without a partner.

Oocyte Cryopreservation

Cryopreservation of oocytes has become popular since the advent of vitrification which improved the freezing process for such a large cell. Vitrification involves rapid cooling in high concentrations of penetrating cryoprotectants which avoids formation of intracellular ice and resulting damage during cooling and warming. Oocyte cryopreservation also requires controlled ovarian stimulation but in contrast to preservation of embryos, no sperm is required. In practice, this option is only applicable to women with normal ovarian function and old enough for oocyte harvesting. The success rate for achieving pregnancy is likely to be lower than for embryo cryopreservation because oocyte survival and subsequent fertilization is impaired. This option has been used for women with Turner syndrome who retain some ovarian function [43] but so far the overall fertility outcome is not known for this subgroup compared to the more common application in women diagnosed with cancer.

Ovarian Tissue Cryopreservation

The use of ovarian tissue cryopreservation for later use has been explored in young women undergoing anticancer treatment. Cryopreservation of ovarian cortex or strips of ovarian cortical tissue has resulted the birth of over 100 children [44]. This procedure has the advantage of not requiring sperm and being appropriate for prepubescent girls accepting that a laparoscopy is required. The cryopreserved tissue can be re-implanted into the pelvis with ovulation and pregnancy occurring spontaneously or after IVF. Re-implanted ovarian tissue has the added advantage of providing endogenous oestrogen but will be subject to the same mechanism causing POI primarily.

Psychology

The diagnosis of POI is distressing and a life experience with high levels of depression and low levels of self-esteem with negative effects on sexuality in affected women. Many women with POI report moderate to severe stress at the time of diagnosis and are unsatisfied with the amount of information provided by their clinician. Therefore, access to a clinical psychologist is recommended. Often several visits will be required for detailed information on aetiology and fertility options to be retained. Regular specialist follow-up is recommended so that women have access to accurate fertility information and so that the need for psychology support can be reassessed at intervals. Often crises arise some years after the original diagnosis, for instance, when a near relative or peer achieves a pregnancy.

Box 8.5.1.1 An overview of the management of POI

Education and counselling

- Return of ovarian function May occur in 5 – 10% of women with POI but it is not possible to predict when and if this may happen with precision.
- Adoption and oocyte donation are the only realistic options for fertility although cryopreservation ovarian tissue it is possible for those at risk of developing POI.
- Access to follow-up counselling is important as issues return with life events such as a close friend all family member becoming pregnant.

Investigations

- Thyroid function tests, vitamin B_{12}, and ferritin because of associated autoimmune conditions.
- Autoantibody screen including thyroid and adrenal antibodies.
- Karyotype for early onset POI and genetic screen for FRAXA premutation.
- Pelvic ultrasound and ovarian biopsy are not recommended.

Treatment

- Oestrogen and progesterone replacement is usually indicated an individualized.
- Education is required regarding risks and benefits of oestrogen preparations—oral, transdermal, and vaginal.
- Inform on media coverage of the use of HRT in postmenopausal women that are not relevant to young women.
- Consider vaginal oestrogen and testosterone supplements.
- Psychosexual and fertility counselling.

Conclusions

Premature ovarian failure is a complex condition that requires specialist services. The diagnostic work-up is aimed at determined the aetiology where possible and is followed by a screen for syndromic conditions. Oestrogen replacement and fertility options need to be reassessed at intervals and clinicians have to be vigilant for psychological sequelae (see Box 8.5.1.1).

8.5.2 Female Hypogonadism

Endocrinology of the Menopause and Hormone Replacement Therapy

Stavroula A. Paschou, Panagiotis Anagnostis, and Dimitrios G. Goulis

Introduction

Menopause marks the permanent cessation of menstruation and the transition to the non-reproductive stage of a woman's life. The alteration in the hormonal milieu during menopause is the result of a decline in the ovarian reserve and varies significantly among individuals, affected by both genetic and environmental factors. A complex and challenging pattern of clinical and metabolic consequences is associated with the transition to menopause. The purpose of this chapter is to provide current knowledge regarding the definition of menopause and the different stages preceding and following the final menstrual period, the physiology of the endocrine changes occurring during the menopausal transition, the clinical manifestations, diagnosis, and differential diagnoses, as well as the pros and cons of its medical management.

Definitions

The term 'menopause' is used to describe the post-reproductive period in a woman's life, after completion of 12 months of amenorrhea or immediately after bilateral oophorectomy. The mean age of natural menopause is 50–52 years. In cases in which the menopause is recorded before the age of 45 years, the term 'early menopause' (EM) is used [1, 2]. EM has been recorded in 10% of postmenopausal women, while in 1% of cases, menopausal age has been reported before the age of 40 years. In the latter situation, the term 'premature ovarian insufficiency' (POI) is used. The prevalence of POI in women younger than 30 years of age is 0.1% [1–3]. 'Perimenopause' refers to the period during which a woman experiences variable menstrual cycle changes and symptoms attributed to different degrees of decline in ovarian reserve [4].

To describe the transition through the different stages of reproductive age during the years preceding or following the menopause, the Stages of Reproductive Aging Workshop (STRAW) system has been developed [4]. Its initial form was proposed in 2001 and its update in 2011, the latter known as STRAW + 10. It is considered as the standard staging system that describes the transition to menopause in a detailed way since it discriminates the onset of late reproductive life and early menopausal transition. It also provides a more detailed classification of postmenopausal status [4]. The STRAW system is based not only on the woman's symptomatology and menstrual pattern but also on the alterations in serum concentrations of specific endocrine markers of ovarian ageing, such as inhibin B and anti-Müllerian hormone (AMH) [4].

According to the STRAW classification system, the menopausal transition is divided into two stages, Stage –2 ('early menopausal transition'), which is designated by a persistent difference of seven or more days in the length of consecutive menstrual cycles. Stage –2 is also characterized by elevated follicular stimulating hormone (FSH) with low AMH and inhibin B concentrations, as well as, low antral follicle count (AFC). Decreased AMH, inhibin B and AFC with a shorter cycle duration (without any change in menstruation pattern and normal FSH concentrations) are the first signs observed in the Stage –3, which marks the late period of reproductive age [4]. Stage –1 ('late menopausal transition') is characterized by persistent elevation in FSH (more than 25 IU/L) concentrations, associated also with high oestradiol (E2) concentrations. AFC, AMH, and inhibin B concentrations are low. The first vasomotor symptoms may occur during this stage. The early postmenopausal Stage follows and is divided into Stages +1a (referring to the first 12 months and marking the end of perimenopause), +1b (covering the next 12 months) and Stage +1c, lasting for 3–6 years. During the Stage +1c, FSH concentrations stabilize, whereas AMH and inhibin B concentrations and AFC are extremely low [4]. In general, AMH and AFC seem to be superior to FSH as markers of ovarian ageing not only because they herald the late reproductive stages and transition to perimenopause, but also because they are not affected by menstrual cycle phase [4].

It must be underlined that the STRAW criteria are not applicable to women with polycystic ovarian syndrome (PCOS), hypothalamic amenorrhoea, and chronic illnesses, such as human immunodeficiency virus (HIV) infection. They cannot also be used in cases of chemotherapy-associated menopause (after administration of alkylating agents) or treatment with tamoxifen. Furthermore, in cases of hysterectomy or endometrial ablation, it is recommended to use the STRAW criteria only on the basis of endocrine biomarkers rather than on menstrual pattern, after at least three months postoperatively [4]. The lack of standardized assays and the variability for biomarkers, such as inhibin B and AMH, constitute another limitation of the STRAW classification system [4].

Endocrine Physiology

Transition to menopause is the result of the coalescence of an acceleration of follicle loss and a decline in the functional quality of oocytes. The reduction in ovarian reserve is indicated by the decrease in AFC, total non-growing follicle and primordial follicle pool [5]. The nerve growth factor (NGF) pool numbers, approximately seven million at birth, reaches the number of 300 000 at the onset of puberty and declines at 12% and 3% of the initial number at the age of 30 and 40 years, respectively. Non-growing follicles finally decrease

to less than 1000 at the age of natural menopause (50–52 years) [5]. During the late stages of reproductive life, a gradual decrease in the number of follicles entering the growth phase (from 45 during the age of 25–30 years to six during the age of 38–45 years). During perimenopause, 20% of cycles with a duration of less than 40 days and 80% of those with a duration of more than 40 days are anovulatory [5, 6].

The acceleration of follicle depletion is the result of an early rise in FSH concentrations, due to abnormal gonadotrophin-releasing hormone (GnRH) pattern. The latter is the consequence of dysregulation of the GnRH pulse generator in the hypothalamus, due to the progressive loss of control from brain centres [6]. FSH is also elevated due to the loss of negative feedback by inhibin B, whose concentrations decrease as the non-growing follicle pool declines with age. The sustained FSH elevation during late perimenopause and early postmenopausal period is responsible for the increase in cycle length variability [5, 6]. In parallel with FSH, E2 concentrations increase during the early follicular phase of the menstrual cycle, especially during early perimenopause, as a result of accelerated follicular growth. The primary circulating oestrogen during menopause is estrone, which is mainly produced through the peripheral conversion of the adrenal steroid hormone Δ_4-androstenedione by the enzyme aromatase, in adipose tissue. Only 5% of estrone is converted to E_2 via the enzyme 17β-hydroxysteroid dehydrogenase (17β-HSD). A decline in progesterone is observed during the mid-cycle and luteal phase with advancing reproductive age [5, 6].

Inhibins A and B are members of the transforming growth factor-β (TGF-β) superfamily and secreted by the granulosa cells of ovarian follicles. Their primary role is the inhibition of gonadotrophins, mainly FSH. Inhibin A is produced by the dominant follicle and the corpus luteum (during the luteal phase), whereas inhibin B is secreted by the granulosa cells of the antral follicles, being the principal regulator of the FSH concentrations during the follicular phase. During menopausal transition, inhibin B and AMH concentrations start to decrease along with AFC, as a result of the shrinkage of the follicle cohort [5, 6]. AMH is also a member of the TGF-β superfamily peptides, secreted by granulosa cells of late preantral and small antral follicles, and exerts an inhibitory effect on the primordial to primary follicle transition. AMH concentrations, reflect the reserve of follicle cohort and constitute a reliable tool for predicting the age of menopause [7]. Genetic predisposition and environmental factors, such as smoking, diet, physical activity, and socioeconomic status affect the time of transition to menopause, explaining in part the variability in the age of menopause [4–6].

Clinical Picture

The earliest and most prevalent symptom of a woman entering the menopause is a disordered pattern of menstruation, specifically an alteration in cycle length by more than seven to more than 60 days [1–4]. As just mentioned, the former is the characteristic pattern of the 'early menopausal transition' (Stage −2), whereas the latter is defined as the 'late menopausal transition' (Stage −1), lasting 1–3 years until the menopause [4]. Except for the menstrual irregularities, a variability in menopause-related symptoms exists during these stages, associated with the fluctuations in oestrogen concentrations [4].

Many tools have been developed to assess the severity of menopausal symptoms. One of the most widely used is the Greene Scale, which is a self-report questionnaire, consisting of 21 items, which measure physical and psychological symptoms (four options, from 0, corresponding to 'not at all', to 3, corresponding to 'extremely'). These items cover vasomotor symptoms (two items, range 0–6), anxiety (six items, range 0–18), depression (five items, range 0–15), somatic symptoms (seven items, range 0–21) and sexuality (one item, 0–3). The whole score ranges from 0 to 63 [8].

Vasomotor symptoms (VMS) are the predominant menopause-related clinical manifestations and include hot flushes, palpitations, night sweating, disturbed sleep pattern, and fatigue. VMS last 7.4 years on average, as shown by large epidemiological studies, such as the Study of Women's Health Across the Nation (SWAN). More specifically, VMS last for a median period of 4.5 years following the menopause. The total duration of VMS depends on the time of onset, being longer in cases of its initial appearance during the premenopausal or early perimenopausal period (11.8 years on average) and shorter in women who were postmenopausal at the onset of VMS (median duration 3.4 years). The race and the age at onset seem to affect the duration of VMS since it is the longest in African-American women (median duration 10.1 years) and women younger than 45 years. Low educational level and higher depressive symptomatology are also associated with a longer duration [9]. Hot flushes appear as a sudden sensation of heat located at the face and upper chest, which lasts for 2–4 min. They may be aggravated by stress and anxiety, spicy food, or alcohol. VMS can rarely occur in older ages (more than 65 years) and may be associated with increased risk of cardiovascular disease (CVD). The neuroregulators kisspeptin, neurokinin B, and dynorphin, along with disorders in the thermoregulatory system, are implicated in the pathogenesis of VMS [1].

Another category of menopausal symptomatology involves the neuromuscular system, including headaches, loss of memory, dizziness, breathing difficulties, diffuse muscle and joint pain, and numbness. Skin dryness may also be present. Transition to menopause is also associated with a variety of psychogenic symptomatology, including irritability, mood swings, anxiety, depression, poor concentration, general loss of interest and decreased libido [1, 2]. Finally, genitourinary symptomatology, mainly present during the late postmenopausal stage [4], includes vaginal dryness, dyspareunia, vaginitis, dysuria, and recurrent urinary tract infections [1].

The decline in oestrogen concentrations is associated with long-term consequences, such as dysregulation in glucose and lipid metabolism, creating an atherogenic lipid profile [increase in total cholesterol, low-density lipoprotein cholesterol (LDL-C) and triglycerides, and decrease in high-density lipoprotein cholesterol (HDL-C) concentrations] [10], body fat redistribution (central adiposity), increase in systolic and diastolic blood pressure, and loss of bone mass [11, 12]. These metabolic disturbances predispose to an increased risk of CVD, type 2 diabetes mellitus (T2DM), osteoporosis, and fractures, especially in the case of coexistence with environmental and genetic factors [12]. Postmenopausal women with EM or POI seem to be at a 1.5 to 2-fold increased risk of CVD and T2DM [13].

Diagnosis

In women with an intact uterus, the diagnosis of menopause is retrospective, based on clinical criteria and established after completion of 12 months of amenorrhea. The diagnosis is more straightforward when cessation of menses occurs at an average age of 50–52 years, in the absence of surgery or medication. Further investigation, including inhibin B, AMH, FSH, and E2, does not confer any benefit in the diagnosis and management, except for cases seeking fertility [1]. A hormonal investigation, including FSH and serum E2 assessment, is recommended in cases of hysterectomy without bilateral oophorectomy. In these cases, persistently elevated FSH with low E2 concentrations (less than 20 pg/ml) support the diagnosis [1].

A potentially postmenopausal woman should be asked about the presence and duration of the symptoms mentioned earlier and the extent to which these affect her quality of life. The pattern of menstruation (cyclicity and length of menses), the age of menarche and the number (if any) of established pregnancies (including both live births and abortions) should be recorded. The medical history should include investigation for chronic diseases (such as T2DM, hypertension, and CVD events), surgical operations, fractures, current and past medications, smoking habits, alcohol use, and allergies.

The physical examination should accompany the medical history and include body mass index (BMI) assessment (calculated in kg/m^2), waist and hip circumference, blood pressure, and heart rate. The clinician should also search for signs associated with specific medical conditions, such as polycystic ovary syndrome (PCOS). The latter may augment the risk for T2DM and, potentially, CVD. Signs, such as acanthosis nigricans, hirsutism, alopecia, and acne, should be searched for and recorded. A physical and sonographic gynaecological examination is needed to exclude anatomical causes of menstrual disturbances and uterine disorders.

A hormonal investigation is necessary only in cases in which a definite diagnosis cannot be made by the medical history and physical examination, especially in women younger than 45 years. In such cases, a combination of increased FSH with decreased E_2 concentrations is confirmatory. Oligomenorrhoea or amenorrhoea for at least four months and FSH concentrations >25 IU/l on two occasions, at least 4–6 weeks apart, establish the diagnosis of EM or POI [2, 14]. In all cases of non-iatrogenic POI, obtaining a karyotype and testing for Y-chromosomal material (if positive, a gonadectomy should be performed) and FMR1 (fragile X mental retardation 1) gene mutations are recommended [14]. Test for autosomal gene mutations should be considered only in cases of suspicion of a specific syndrome (e.g. epicanthus inversus syndrome). In case of POI of unknown aetiology or an indication of autoimmunity, further investigation should include assessment of antithyroid and antiadrenal autoantibodies followed by thyroid stimulating hormone (TSH) and Synacthen test in case of positivity, respectively [14], as well as, testing for autoimmune polyendocrine syndromes [3]. In cases of iatrogenic menopause due to chemotherapy or radiotherapy, clinicians should take into consideration that a resumption in gonadal function may occur even 12 months after intervention [1].

Other causes of menstrual disturbances, such as hyperprolactinaemia, thyroid dysfunction and PCOS should be excluded. A hormonal profile should include assessment of TSH, prolactin, luteinizing hormone (LH), total testosterone and sex hormone binding globulin (SHBG) concentrations [3]. In case that more rare situations are suspected (non-classical adrenal hyperplasia, ovarian hyperthecosis, androgen-secreting tumours, Cushing's syndrome, acromegaly), laboratory investigation should include baseline concentrations of the involved hormones or the respective dynamic tests, as suggested by international guidelines to confirm or exclude the diagnosis [15].

Further examination could include mammography and bone mineral density (BMD) assessment, with dual-energy X-ray absorptiometry (DXA), ideally in both lumbar spine and femoral neck. Repeated DXA scans at 1–2-year intervals in cases of osteoporosis or osteopenia with increased fracture risk should be obtained [1, 2].

Differential Diagnosis

The differential diagnosis should include causes that mimic menopausal (mainly vasomotor) symptomatology, such as thyrotoxicosis, carcinoid syndrome, pheochromocytoma, acromegaly, mastocytosis, renal or medullary thyroid carcinoma, pancreatic islet cell tumours or lymphomas, which may also manifest with flushing, palpitations, and/or sweating. Therefore, assessment of TSH, urinary or serum metanephrines, urinary 5-hydroxyindoleacetic acid (5-HIAA), serum tryptase, insulin-like growth factor-1 (IGF-1) and calcitonin concentrations, as well as, an abdominal ultrasound may be considered in cases of ambiguous diagnosis. Furthermore, medications [such as opioids and their withdrawal, selective serotonin reuptake inhibitors (SSRIs), nicotinic acid, calcium channel blockers (CCBs)], dietary factors (such as alcohol, spicy food, and food additives) and chronic infections should be excluded [1].

Special consideration should be given to women with hysterectomy without bilateral oophorectomy. In such cases and in the presence of vasomotor symptomatology, assessment of pituitary-gonadal axis, with measurement of FSH and serum E_2, as well as prolactin and TSH, will elucidate the aetiology of menstrual disturbances. This assessment is also suggested in cases of a pre-existing history of irregular cycles, in which the pattern of menstruation cannot contribute to the diagnosis of menopause. Women on oral contraceptive pills (OCPs) constitute a challenging case. In these, withdrawal of the OCP and hormonal assessment on day 3–5 of a spontaneous menstrual cycle may unmask potential menopausal transition.

It is of utmost importance to differentiate postmenopausal pattern of menstruation from other causes of abnormal uterine bleeding, such as coagulopathies, fibroids, polyps, adenomyosis, endometrial carcinoma, and endometrial intraepithelial neoplasia. In these cases, transvaginal ultrasonography is a useful diagnostic tool. When the diagnosis is obscure, further evaluation with hysteroscopy, plus dilation and curettage, is recommended [16]. In contrast, menopause-associated uterine bleeding is the result of the unopposed effect of E_2 due to anovulation, causing significant proliferation and thickening of the endometrium [17].

Medical Management

Hormone Replacement Therapy

Hormone replacement therapy (HRT) is the treatment of choice for women with menopausal symptoms and urogenital atrophy.

Additionally, HRT is indicated for the treatment of osteoporosis and prevention of fracture, but only for women who present climacteric symptoms. There has been some concern about possible adverse effects of HRT regarding increased risk of breast cancer, especially with the use of prolonged combined therapy with certain progestins, and venous thromboembolism (VTE), especially with the use of oral oestrogens. In general, however, the benefits of HRT outweigh these risks, particularly for women under 60 years of age or for those who are in menopause for less than ten years. HRT is the most effective treatment for menopausal symptoms, while many of the regimens given systematically, and all of the local applications are effective in treating vaginal atrophy, vaginal dryness, bruising, dyspareunia, and pruritus. HRT can also positively affect mood disorders and sleep disturbances. Furthermore, it exerts beneficial effects on bone metabolism, as standard dose regimens reduce the incidence of fragility fractures, while low or very low dose regimens improve bone density and bone turnover markers. HRT has been associated with improvement of cardiometabolic risk factors too and, when given in women younger than 60 years of age or women who are in menopause for less than ten years, protects them against CVD. The use of HRT has also been associated with a decrease in the risk of colon and rectal cancer, while there is some evidence for a reduction in risk of Alzheimer's disease [18–20].

HRT Regimens

Women after hysterectomy should receive formulations with oestrogens only, while for women with intact uterus progestogen needs to be added, to counteract the possible harmful effects of oestrogen on the endometrium. A combination of conjugated oestrogen and bazedoxifene has been introduced in Europe for use in women with an intact uterus that have contra-indications or are intolerant in progestogens. Alternatively, tibolone is a synthetic steroid with oestrogenic, androgenic and progestogenic activities and can be used in women with and without hysterectomy [21–24]. Table 8.5.2.1 presents the available types of oestrogen formulations according to the route of administration.

Table 8.5.2.1 Oestrogenic formulations of HRT and route of administration

Oral medications	
• 17β-E_2 • Steroidized oestrogens • Tibolone • Conjugated equine oestrogens • Oestrogen-progestogen combinations • Conjugated oestrogen/bazedoxifene	Once per day
Patches	
• 17β-E_2 • 17β-E_2/norethisterone	Twice per week
Gel	
• 17β-E_2	Once per day
Vaginal applications	
• 17β-E_2 • Estriol	Tablets or creams daily for 15–20 days, then 1–2 per week

17β-E_2:17β-oestradiol.

The dosage should be personalized according to the therapeutic goals, the age of woman, and the years after menopause. In Table 8.5.2.2, a classification of oestrogen dosages and indications is presented.

The progestogens used in HRT are distinguished in natural human progesterone and synthetic forms. Among the most common used progestogens are microsomal progesterone, norethindrone acetate (NETA), dydrogesterone, drospirenone, and medroxyprogesterone acetate. Concerning the mode of administration, oral progestogens are administered once or twice daily constantly, resulting in amenorrhea, or periodically, 12–14 days per month, resulting in regular monthly bleeding. Transdermal progestogens (norethisterone) are administered twice per week in a continuous manner, leading to amenorrhea, or in a cyclical manner, for 14 days per month, leading to regular monthly bleeding. Vaginal progesterone can be used once a day before bedtime in a continuous way leading to amenorrhea, or in a periodical manner, 12–14 days per month, leading to regular monthly bleeding. An intrauterine device that releases levonorgestrel can also be used. This device remains active for 3–5 years and provides contraception during perimenopause, while it can be used in combination with oestrogens as proper HRT. In the case that libido is not restored after adequate replacement, low-dose testosterone therapy may be effective. Even if virilizing effects with low-dose and proper follow-up are rare, the long-term effects of testosterone treatment in women, particularly regarding breast cancer risk, are not known [18, 25–27]. In Table 8.5.2.3, the recommended dosages of progestogens according to oestrogens doses are presented.

Follow-Up of Women on HRT

Initial monitoring of women receiving HRT should be performed 2–3 months after the introduction of treatment to evaluate the efficacy and possible adverse effects. Persistence of menopausal symptoms usually requires an increase of oestrogen dose. Women on HRT often complain of unexpected vaginal bleeding, breast tenderness, flatulence, fluid retention, headaches, and mood changes. Symptoms are more common in women with prolonged time in menopause but tend to decline over the time of treatment. In that case, treatment modifications can include a decrease in the dose of oestrogens, change of the type of progestogen or change of the route of administration. When the woman is satisfied by HRT, follow-up and monitoring should be performed on an annual basis. Then, the cost-to-benefit ratio should be assessed, while the dose of oestrogens should be redefined. The duration of treatment depends on the patient characteristics and preferences, the individualized cost-to-benefit analysis and the oestrogens dose used [27–29].

HRT and CVD

HRT has been associated with a favourable effect on the cardiometabolic profile by improving serum lipids concentrations, body fat composition, glucose metabolism, insulin resistance and vascular function [17, 30]. However, primary and secondary analyses of the Women's Health Initiative (WHI) study have shown that the exact effects of HRT on CVD risk largely depend on the age of the women. Younger menopausal women aged 50–59 years or women who are within the first ten years after menopause present, in general, lower risk of CVD when on HRT, while initiation of HRT at an older age (more than 60 years of age or more than

Table 8.5.2.2 Dosages and indications of oestrogens

Dosage	Indication	Oral oestrogens	Transdermal 17β-E_2	Tibolone
Standard dose	Premature ovarian insufficiency	17β-E_2 2–4 mg or CEE 0.625–1.25 mg	50–100 µg	-
	Perimenopause	17β-E_2 2 mg or CEE 0.625 mg	50 µg	-
	Menopause: poor response at a low dose	17β-E_2 2 mg or CEE 0.625 mg	50 µg	2.5 mg
Low dose	Perimenopause	17β-E_2 1 mg or CEE 0.300–0.450 mg	25–37 µg	-
	Menopause	17β-E_2 1 mg or CEE 0.300–0.450 mg	25–37 µg	2.5 mg
Ultra-low-dose	Menopause: starting dose or maintenance dose after initial control of symptoms at low dosage	17β-E_2 0.25–0.5 mg	14 µg	1.25 mg

17β-E_2, 17β-oestradiol; CEE, conjugated equine oestrogens.

10 years after the menopause) can increase the CVD risk. The findings of two additional landmark studies, Kronos Early Estrogen Prevention Study (KEEPS) and Early versus Late Intervention Trial with Estradiol (ELITE) trial, support the notion of a 'window of opportunity', demonstrating a cardioprotective activity of HRT, if they are initiated close to the time of menopause, when women still present good vessel health and low prevalence of atherosclerosis. Therefore, all postmenopausal women should be individually assessed for CVD, in order a decision for HRT initiation to be taken [18, 28–32]. Table 8.5.2.4 presents a template of individualization of HRT according to CVD risk.

HRT and Venous Thromboembolism

Treatment with standard oral oestrogen doses, either as monotherapy or in combination with progestogen, has been associated with the development of VTE [31–32]. Large epidemiological studies have shown that the risk of VTE does not increase with administration of transdermal oestrogens in contrast to the administration of oral regimens. Smaller doses of oral oestrogens may have less adverse effects. The addition of a progestogen increased the risk for VTE significantly, but this risk is highly associated with the type of progestogen. Natural progesterone appears to have a favourable profile, while derivatives of norpregnane and medroxyprogesterone acetate have been associated with an increased risk for VTE. The absolute risk for VTE is small in the age group of 5–60 years of age. However, the presence of one or more additional risk factors can increase it. Healthcare providers should clinically assess the risk for VTE in each patient individually, before initiation of HRT. Genetic screening for thrombogenic mutations is not recommended for all women, but individuals in high risk due to personal or family history of thromboembolic events may profit from such an approach. Among other thrombogenic mutations, prothrombin and Factor V Leiden mutations have been associated with a higher risk for VTE [27, 33–34]. Recommendations regarding the individualization of HRT according to the risk for VTE are presented in Box 8.5.2.1.

HRT and Breast Cancer

Combined HRT with oestrogen and progestogen has been associated with a small increase in breast cancer risk in middle-aged women. This risk is mainly attributed to the effects of progestogen, as oestrogen monotherapy for seven years in the WHI study did not increase the risk of breast cancer. Major epidemiological studies have provided evidence that natural progesterone and dydrogesterone present a more favourable safety profile concerning breast cancer. Furthermore, cyclical HRT may have a more favourable risk profile compared to continuous combined regimens, probably due to the lower cumulative exposure of the breast cells to the progestogen. From a clinical point of view, a detailed history can help in identifying women at high risk for breast cancer [17, 24, 26, 29, 31]. Nevertheless, these women represent the minority and, therefore, HRT can be safely administered in the majority of postmenopausal women after evaluation for breast cancer risk factors (Box 8.5.2.2).

Non-Hormonal Treatment of Menopausal Symptoms

Alternative Drug Therapies

Non-hormonal treatment options can be used for the treatment of hot flashes for women who are not good candidates for HRT. Clonidine, selective serotonin, and norepinephrine reuptake

Table 8.5.2.3 Dosages of progestogens according to oestrogens doses

Oestrogen dose	Natural progesterone	Dydrogesterone	Norethisterone	Drospirenone
Standard dose	200 mg	10–20 mg	*Per os* 1–5 mg *Transdermal* 0.25 mg	–
Low dose	100 mg	5–10 mg	*Per os* 0.5 mg *Transdermal* 0.125 mg	2 mg
Ultra-low-dose	50 mg	2.5–5 mg	*Per os* 0.25 mg *Transdermal* 0.063 mg	1 mg

Table 8.5.2.4 Individualization of HRT according to CVD risk

High CVD risk	
• >60 years old • >10 years in menopause • Long-term uncontrolled T2DM • Clinically evident CVD	No HRT
Intermediate CVD risk	
• 5–10 years in menopause • Dyslipidaemia • Central obesity • Smoking • Hypertension • T2DM	Transdermal HRT
Low CVD risk	
• Peri- or recently postmenopausal • None of the above factors present	Any HRT

HRT, hormone replacement treatment; CVD, cardiovascular disease, T2DM, type 2 diabetes mellitus.

inhibitors (SNRIs) and SSRIs can be effective for the treatment of vasomotor symptoms. Clonidine presents alpha-2 agonist properties and has been associated with a decrease in hot flushes after an average time of three months, obtaining approval for this indication in some countries. Among SSRIs, paroxetine has been shown to be most effective for the vasomotor symptoms. Venlafaxine and desvenlafaxine are the most commonly administered SNRIs in women who cannot take HRT. Gabapentin also has beneficial effects, but adverse effects, such as severe drowsiness, can limit its use in everyday clinical practice [26, 35].

Non-Pharmaceutical Alternative Therapies

Although topical low-dose oestrogen therapy is the treatment of choice for the symptoms of urogenital atrophy, an alternative approach is the use of non-hormonal products that hydrate the vaginal tissues. Long-acting vaginal moisturizers are a confirmed first-line treatment for women with complications of vaginal atrophy. The treatment is usually given as a daily application booster for 2 to 3 weeks and then as maintenance treatment with one to two applications per week. Dyspareunia usually requires additional application of water-based lubricants, silicone, or oils before sexual contact in combination with the regular application of long-acting vaginal moisturizers [36–37].

Phytoestrogens are substances produced by plants with a chemical structure similar to that of human E_2. The four main categories include coumestans, prenylflavonoids, isoflavones, and lignans. Phytoestrogens can interact with both types of oestrogen receptors, type α and β. The effectiveness of the individual substances depends on their intestinal absorption and metabolism, the affinity to oestrogen receptors and their oestrogenic activity. The evidence is indicative of beneficial properties resulting from the administration of phytoestrogens, but further research is needed. Studies evaluating the effect of phytoestrogens have shown some benefit concerning the frequency of hot flashes and the degree of vaginal dryness, but the effect was inferior to that resulting from HRT. Therefore, phytoestrogens represent an alternative suggestion for women, who do not wish or cannot take HRT for menopausal symptoms [35–37].

Meditation, cognitive behavioural therapy, relaxation techniques, and controlled breathing, acupuncture, and homoeopathy have also been used to treat postmenopausal symptoms. Data regarding the efficacy and safety of these approaches are sparse so that no evidence-based recommendations can be made [18, 35].

Lifestyle Changes

Many consequences of the menopause can be positively affected by lifestyle changes, such as optimal diet, increasing physical activity, giving up smoking, and decreasing alcohol consumption. Weight loss should be achieved through specific clinical nutrition recommendations, such as consumption of mono- and polyunsaturated fat rather than saturated forms, reduction in the total amount of carbohydrates and preference to those deriving from fruits and whole grains, as well as an increase of protein intake deriving from fish, poultry, or skimmed dairy products. Smoking represents an important risk factor for many diseases associated with menopause and ageing, such as CVD, osteoporosis, and cancer, while adversely affects the effectiveness of osteoporosis treatment. Therefore, smoking discontinuation should be an

- High density in mammography

HRT individualization
- Use of oestrogen in dose inversely proportional to age
- Natural progesterone or dydrogesterone
- Cyclical mode of administration
- Annual cost-to-benefit analysis and dose adjustment

essential part of routine clinical consultation of women in menopause. Physical exercise can prevent weight gain and decreased muscle mass, improve bone quality, decrease T2DM, and CVD incidence and improve psychological status. Postmenopausal women should be encouraged for regular aerobic physical activity, spending at least 150 min per week of average exercise intensity or at least 75 min per week of high-intensity exercise. Anaerobic activities targeting and strengthening major muscle groups should also be performed at least twice per week. Menopausal women who cannot achieve the aforementioned recommendations for exercise should be advised to be as active as possible, according to their abilities [18, 38].

Postmenopausal Osteoporosis Treatment

The recommended calcium and vitamin D daily intake in women older than 50 years with risk of fracture is 1000–1200 mg and 600–800 IU, respectively. Calcium and vitamin D sufficiency improves bone quality and mineralization, prevents the development of secondary hyperparathyroidism, and regulates bone turnover. Furthermore, the maximum efficacy of antiosteoporotic treatment is only achieved in cases of adequate calcium and vitamin D intake. Therefore, women in menopause should be encouraged to consume dairy products or other calcium-rich foods. Alternatively, dietary supplements should be recommended. Vitamin D supplementation therapy should be adjusted at doses which will achieve 25-hydroxyvitamin D [25(OH)D)] concentrations of at least 30 ng/ml. If osteoporotic fracture or osteoporosis is present or the risk for fracture, as assessed by the FRAX score, is increased, antiosteoporotic treatment should be added according to international guidelines. Selective oestrogen receptor modulators (SERMs, raloxifene, and bazedoxifene), bisphosphonates, denosumab, and teriparatide are the currently approved agents for the treatment of postmenopausal osteoporosis [39].

Contraception in Perimenopause and Late Parenthood

Women experiencing perimenopausal menstrual cycle disorders tend to believe that they are no longer fertile and often stop the use of contraception. However, the annual pregnancy probability for women aged 40–44 years is approximately 30% and for women aged 45–49 years is approximately 10%. Indeed, sporadic ovulation may occur even in women with non-regular vaginal bleeding. Therefore, in women who are at risk of an unwanted pregnancy, contraception should stop only two years after the last menstrual episode, if they are less than 50 years, and one year after the last menstrual episode, if they are older than 50 years. The criteria for the appropriate use of contraceptives in women over 40 years of age are set according to their underlying health condition. All currently available contraceptive methods can be given as choices to women older than 45 years, but physicians should weigh the decision depending on the age-related CVD risk, smoking status, or other complications. Women older than 40 years without particular CVD risk factors can take safely hormonal contraception. With regard to oral contraceptives, formulations with second-generation progestogens should be preferred, as these have a better profile regarding VTE. Especially in the perimenopausal population, oral administration of contraceptives is associated with non-specific benefits, such as the restoration of menstrual cycle, the treatment of bleeding problems and menopausal symptoms, the reduction of risk of ovarian and endometrial cancer, as well as bone loss prevention. In women with CVD risk factors, such as obesity, dyslipidaemia, smoking, hypertension, or T2DM, the use of contraceptives should be weighed against the potential CVD risk; in most cases, they should be avoided [40].

In case of desire for late parenthood, the perimenopausal woman should be advised that advanced age is associated not only with infertility but also with pregnancy complications and may have an impact on the long-term health of the offspring. Appropriate hormonal assessment and therapeutic approach can assist in the management of infertility. An experienced multidisciplinary team is needed in the case of such a pregnancy [41].

Conclusions

Menopause represents the end of reproductive life in women and is associated with a substantial decrease in endogenous oestrogen production. These hormonal changes have various metabolic, bone, CVD, and psychological effects. HRT is the treatment of choice for women with menopausal symptoms and urogenital atrophy. In general, the benefits of HRT outweigh possible risks, such as breast cancer and VTE risk, particularly for women under 60 years of age or for those who are in menopause for up to 10 years. Postmenopausal women should also be managed with lifestyle interventions, including diet, exercise, smoking cessation, and decrease in alcohol consumption, with a particular focus on bone and cardiovascular health. Alternative drug or non-pharmaceutical therapies may contribute to the alleviation of postmenopausal symptoms. The ultimate goal of the healthcare providers should be an integrated plan for the postmenopausal woman, bearing in mind that most women will spend more than one-third of their lifespan in menopausal status.

8.6

Female Infertility

8.6.1 Female Infertility and Assisted Reproduction

Adam H. Balen and Susie Jacob

Introduction

Infertility is common. It has recently been suggested that approximately 9% of couples are involuntarily childless although the exact number inevitably depends on how the complaint is defined [1]. Medical definitions of infertility tend to emphasize the immediate problem brought to the consultation, reflecting the typically short-term interaction of many doctors, particularly specialists, with their patients. Most accepted definitions therefore involve the number of months prior to the consultation during which the couple has been exposed to the chance of a pregnancy. When the lifetime experience of a couple's attempt to raise a family is considered, a quite different picture emerges: at least a quarter of all couples experience unexpected delays in achieving their desired family size [2, 3], although only a half may seek treatment [3].

The single most important determinant of a couple's fertility is the age of the female partner. For women up to and including the age of 25 the cumulative conception rate is 60% at 6 months and 85% at a year. For couples where the female partner is 35 years of age or older, the conception rates are 60% at a year and 85% at 2 years. Women are born with a finite complement of eggs, which do not undergo further cell division until just after fertilization. Thus, an oocyte ovulated today is pretty well the same age as the woman from whose ovary it came. Even DNA, the most stable molecule in biology, is not completely invulnerable to the passage of years; this impact of age on oocytes is consistent with its effect on the risk of congenital abnormalities, well known in many cases to increase with maternal age.

When one refers to a patient as being 'infertile' one is referring to a slow rate of conception—infertility is rarely absolute; indeed some prefer the expression 'subfertility'. If, despite a regular menstrual cycle and a normal sex life, pregnancy has not occurred by 12 months, most authorities would accept that that couple has a fertility problem and would offer investigation and treatment. If there is a history of a menstrual disturbance, pelvic inflammatory disease, or in the male partner an attack of orchitis or a history of cryptorchidism, investigation should begin sooner rather than later.

A more difficult problem is defining infertility in the couple with an older female partner. In one way, one might consider delaying investigation because it takes longer for a woman of 35 years and older to achieve a particular conception rate. On the other hand, the slope of the line relating the risk of childlessness to age gets much steeper as one approaches the age of 40. Furthermore, the prospects of achieving a pregnancy with treatment is parallel to this curve. There is therefore little time to lose and we are more active in advising investigation and treatment. There seems little point in waiting beyond a year and in many women (particularly those with some diagnostic clue in their history) we recommend initiating investigation after 6 months of unprotected intercourse.

A review published in 2007 has examined the collective prevalence of infertility from 25 population surveys (of 172 413 women) from around the world [1] there was a wide range of infertility rates from 3.5% to 16.7% in developed countries and 6.9% to 9.3% in less developed countries, with a median overall prevalence of 9%, which equates to over 70 million women worldwide. Overall approximately 56% (range 27–76%), that is 40 million couples seek medical care although only an estimated 22% receive care [1]. In 1993 and 1995 two surveys in England of 2377 and 728 women reported prevalence rates of 26.4% and 17.3%, respectively, of whom 50–61% sought assistance [4, 5].

According to the UK Government Statistical Services there is a steadily rising proportion of women in the UK who have never had a child. The mean age of mothers at childbirth fell from 28.7 years for women born in 1920 to a low of 26.0 years for women born in the mid-1940s (**Figure 8.6.1.1**) [6]. Women born in the 1940s had the lowest average age at childbirth contributing to the 1960s 'baby boom', when family size was also larger [7].

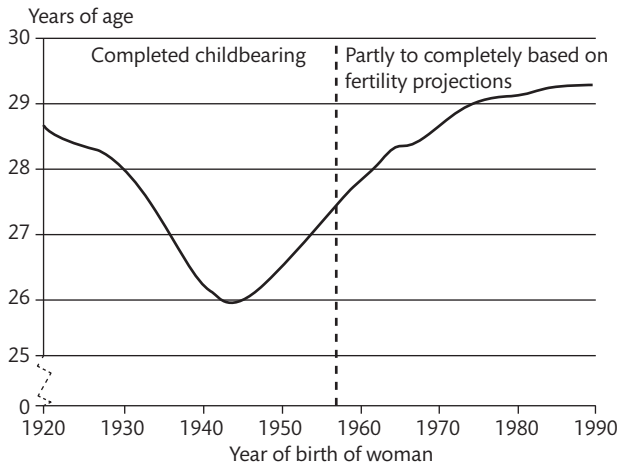

Figure 8.6.1.1 The mean age of UK mothers at first childbirth.

The proportion of childless women reaching the end of their childbearing years continues to rise. The most recent data [8] for those born in 1971, found that 18% are childless by 45 years compared with 11% for those born in 1944 who are presumed to be their mothers' cohort [8]. The average family size for the 1971 cohort is 1.9 children, the lowest level recorded. A trend to later childbearing continues, shown by those who are childless by the age of 30 years; 48% of those born in 1986 are childless at their 30th birthday compared with 44% born in 1971. The secular change in delayed childbirth relates to a number of factors, including contraceptive usage, the desire for a career, rising rates of sexually transmitted infections and the decline in fertility with age.

Obesity

Obesity is a common problem among women of reproductive years, with 56% of women in the UK being either overweight or obese. Obesity has a negative impact on spontaneous conception, miscarriage, pregnancy and the long-term health of both mother and child due to both an increased rate of congenital anomalies and the possibility of metabolic disease in later life. Obesity also has a negative impact on male fertility. Women who are obese respond less well to drugs that are used for ovarian stimulation for the treatment of both anovulation and assisted conception, although this does not always equate with a reduction in ongoing pregnancy rates. Furthermore, obesity may affect the safety of procedures, for example the ability to see ovaries on ultrasound scan or the provision of safe anaesthesia for laparoscopy or oocyte retrieval. Obesity also has a major impact during pregnancy and at delivery.

A normal body mass index (BMI) is considered to be 19–24.9 kg/m^2, although some would consider the lower limit of normal to be 20 kg/m^2. Being underweight leads to hypothalamic amenorrhoea and increases risk to pregnancy if conception does occur. Overweight is defined as a BMI of ≥25 kg/m^2 (World Health Organization (WHO) definitions) with 'pre-obese' being 25.0–29.9 kg/m^2, moderate obesity (class I) 30.0–34.9 kg/m^2, severe obesity (class II) 35.0–39.9 kg/m^2, and very severe ('morbid') obesity (class III) ≥ 40 kg/m^2.

Miscarriage rates appear to be increased with increasing maternal weight [9]. In those who conceive spontaneously there is an increased risk of miscarriage in those who are moderately overweight (BMI 25–27.9 kg/m^2). This has also been demonstrated in those who conceive by IVF [10] or who are recipients of donated oocytes. Pregnancy carries significant risks for those who are obese with increased rates of congenital anomalies (neural tube (OR 3.5), omphalocele (OR 3.3) and cardiac defects (OR 2.0)), miscarriage, gestational diabetes, hypertension, and problems during delivery [11]. The risks of congenital anomalies appear real, although there are also technical difficulties in assessing the fetus by ultrasound because adipose tissue attenuates the signal. Pregnancy itself exacerbates any underlying insulin resistance and as a result women with PCOS and/or obesity have an increased risk of gestational diabetes.

Obesity is associated with an increased risk to the mother during pregnancy. Risks include increased incidence of hypertension, pre-eclampsia, gestational diabetes, and thromboembolic disorders as well an increased caesarean section rate. Obesity contributes significantly to the risk of maternal mortality [9]. Macrosomia, admission to neonatal intensive care, birth defects, stillbirth, and perinatal death are all increased in the infants of women who are obese.

Polycystic ovary syndrome (PCOS) affects 20–25% of women and the prevalence appears to be rising because of the current epidemic of obesity [12]. PCOS accounts for 90–95% of women who attend infertility clinics with anovulation. At least 40% of women with PCOS are obese and they are more insulin resistant than weight-matched individuals with normal ovaries. Increasing abdominal obesity is correlated with reduced menstrual frequency and fertility together with greater insulin resistance. Several studies have shown that weight loss in women with PCOS improves the endocrine profile, menstrual cyclicity, rate of ovulation, and likelihood of a healthy pregnancy. Even a modest loss of 5–10% of total body weight can achieve a 30% reduction of central fat, an improvement in insulin sensitivity and restore ovulation. Lifestyle modification is clearly a key component for the improvement of reproductive function for overweight, anovulatory women with PCOS [9].

Weight loss should therefore be encouraged prior to ovulation induction treatments, such as clomiphene citrate or gonadotropin therapy, both to improve the likelihood of ovulation and enhance ovarian response. Monitoring treatment is also harder in the obese as visualization of the ovaries is more difficult which raises the risk of multiple ovulation and multiple pregnancy. National guidelines in the UK for the management of overweight women with PCOS advise weight loss, preferably to a BMI of <30 kg/m^2 prior to commencing drugs for ovarian stimulation [9]. The British Fertility Society suggests that ideally women should not commence assisted conception treatments until they have reduced their BMI to less than 35 kg/m^2, but if time is on their side (e.g. under the age of 35 years with normal ovarian reserve, they should aim for a BMI of less than 30 kg/m^2) [9].

Investigating Infertility

Fertility investigations should normally be instigated as soon as the couple seeks help. Even if they have been trying for less than a year, it is worthwhile asking some general questions to ensure that major problems, such as irregularities of the menstrual cycle, a history of pelvic surgery or orchidopexy have not been ignored. If the couple's medical history is normal the expected cumulative chance of conception over a period of time should be explained and investigations deferred until they have been trying for a year. When the

female partner is aged 35 years or older, monthly fecundity is significantly reduced but we do not believe that investigations should be delayed proportionately because of the concomitant age-related decline in the success of treatment.

Once the decision has been taken to investigate a couple it should be possible to perform the basic screening tests within 2–3 months and provide them with a management plan, which may involve reassurance, more detailed investigations, or treatment. A pragmatic approach should be taken. Infertility is rarely absolute and treatment options may be discussed to enhance a couple's fertility even in the absence of a clear diagnosis.

General Investigations

The fertility clinic should be used for general health screening and preconception counselling. Particular attention should be paid to body weight, blood pressure, urinalysis, cervical cytology, and rubella immunity. Some clinics ascertain hepatitis B, C, and HIV status before offering assisted conception—this has become routine practice in the UK because of the putative risk of viral contamination of cryopreserved embryos via liquid nitrogen.

It is important to perform a general physical examination and a pelvic examination should be performed. Endometriosis is suggested by the presence of nodules in the vagina, thickening of the posterior fornix, tenderness, and fixity of the pelvic organs. If the examination is painful one should be alerted to the possibility of pelvic pathology and include a laparoscopy early in the course of investigations. Adnexal masses should be investigated by ultrasound in the first instance.

Chlamydia Screening

A controversial subject is the routine swabbing of the cervix for *Chlamydia trachomatis*. Chlamydial DNA has been recovered from 50% of women with tubal infertility compared with approximately 12% in pregnant women or women with non-tubal infertility. Chlamydia infection is the commonest cause of tubal infertility in developed countries and is the commonest sexually transmitted pathogen in the UK. It is thought that at least 1 in 20 women in the UK between the ages of 18–25 years may have undiagnosed infection. *Chlamydia trachomatis* causes urethritis and epididymitis in men and cervicitis, salpingitis, and endometritis in women, although symptoms can be mild and non-specific. The high efficacy of 'self-swabbing' to test for chlamydia and gonorrhoea infections, has been proven when used in conjunction with reliable nucleic acid amplification techniques, which can negate the need for repeated vaginal examinations [13]. Chlamydia serology provides evidence of past infection and is a routine screening test in some clinics. The presence of chlamydial antibodies correctly predicts tubal damage in 90% of cases, of whom over half have no history of pelvic inflammatory disease. We advise the use of chlamydia screening to help identify patients whose tubal status should be tested early in the investigative process. There is evidence, however, that screening tests may be negative in the presence of infection in the upper genital tract and so there is rationale for prophylactic antibiotics prior to any procedure that involves instrumentation of the cervix (doxycycline or azithromycin).

Diagnosis of Anovulatory Infertility

Determining the cause of anovulatory infertility is the key to treatment as correction of the cause will result in cumulative conception rates that mimic those expected for normal women of the same age. It is first necessary to ascertain whether ovulation is occurring. Patients with anovulatory infertility will have oligomenorrhea or amenorrhea and a low luteal phase progesterone. A progesterone concentration of greater than 30 nmol/L suggests ovulation but it can be difficult to know when to take the blood if the patient has an erratic cycle—and impossible if she is amenorrhoeic. If the progesterone is 15–30 nmol/L the timing may have been incorrect. It is then necessary to check the timing of the blood test to subsequent menstruation and repeat the test in the following cycle (sometimes two progesterone measurements in the same cycle are helpful). The optimal way to assess ovulation in women with irregular cycles is by a combination of serial ultrasound scans and serum endocrine measurements (follicle stimulating hormone (FSH) and luteinizing hormone (LH) in the follicular phase and progesterone in the luteal phase).

The optimal frequency of intercourse is every 2–3 days in the follicular phase of the cycle and, if possible, daily for 2–3 days at the predicted time of ovulation. Abstinence until the 'day of ovulation' can be detrimental to sperm function. It is therefore important to advise couples about the frequency of intercourse and try to diffuse the tensions that often result from timed intercourse 'to order'.

The timing of sexual intercourse in relation to ovulation has a strong influence on the chance of conception. The precise number of fertile days in a woman's menstrual cycle is uncertain. A recent study [14] demonstrated that the probability of conception was 10% when intercourse occurred 5 days before ovulation and 33% when it took place on the day of ovulation. The fertile period appears to last 6 days and ends on the day of ovulation. The rapid decline in the probability of conception after this time is due either to a short survival time of the oocyte or a swift change in the nature of the cervical mucus. If commercially available kits for detecting the mid-cycle surge of LH in the urine are used to focus a couple to have intercourse on the day of the LH surge and the following day, they may be missing 3 or 4 fertile days prior to this and reducing their chance of conception. With respect to the precise timing of the 'fertile window' in the menstrual cycle, this occurs between days 10 and 17 in only about 30% of women [14].

The luteal phase of the cycle normally lasts for between 10 and 17 days and the concept of 'luteal phase deficiency' (LPD) is controversial. Probably the most convincing argument against the phenomenon of LPD is the failure of luteal support—with either progesterone or hCG—to improve pregnancy rates in spontaneous pregnancies. Endometrial biopsy has been used to assess the quality of ovulation further by equating histological changes with serum progesterone levels. Histological dating is, however, an unreliable indicator of the endometrial response to hormonal stimulation and is open to considerable biological variability and observer error. We do not recommend endometrial biopsy for determining whether the patient has ovulated.

Endocrine Profile

A baseline endocrine profile is optimally performed during the first 3 days of the cycle. It is essential to be aware of the normal reference range for the assay in the laboratory in which it is being performed. Reference ranges vary from laboratory to laboratory and can be quite different if different types of assay are used, for example, radioimmunoassays and immunoradiometric assays give

very different results for gonadotrophin measurements. There are a variety of recent advances in assay technology including chemiluminescence assays and mass spectrometry. It is therefore important to have knowledge of normal ranges for the assays used by your laboratory and also to ensure that they are appropriately calibrated for your 'normal' population.

Standard tests include a baseline measurement of FSH, LH, and oestradiol, thyroid function and in those with menstrual irregularity or amenorrhoea, prolactin, and testosterone. In women with evidence of hyperandrogenism or PCOS a more detailed assessment of androgen profile and metabolic screen may be indicated.

Ovarian Reserve Tests

It is natural for a woman to wish to have an idea of her potential fertility. A measurement of serum FSH concentration taken during days 1–3 of menstruation has been the traditionally used test of 'ovarian reserve'—a term that refers both to the number of oocytes within the ovary and their fertility potential (see Table 8.6.1.1). Ovarian reserve, or the number of releasable oocytes, declines with ovarian age, which does not always equate with the age of the woman. An elevated FSH level indicates reduced ovarian reserve and, generally, if greater than 10 IU/L on more than one occasion, the ovaries are unlikely to be ovulating regularly and will also be resistant to exogenous stimulation. When the serum concentration of FSH is above 15 IU/L the chance of ovarian activity is slim and levels greater than 25 IU/L are suggestive of the menopause or premature ovarian insufficiency. Even if ovulation is occurring in the presence of an elevated serum FSH concentration the fertility potential of the oocyte within the follicle is significantly impaired and in the unlikely event of fertilization taking place, there is an increased likelihood of a chromosomally abnormal embryo developing, and consequent risk of miscarriage and fetal chromosomal abnormality.

Additional measurements can be made in order to increase the positive predictive value of FSH, including an assessment of ovarian volume and the number of visible antral follicles on ultrasound scan, serum inhibin B and anti-Müllerian hormone (AMH) [15]. It has even been suggested that these tests may help determine a woman's future fertility over forthcoming years—although the evidence for longer term predictions has been disappointing [16]. There is debate about the widespread use of ovarian reserve testing outside of the context of planning infertility treatment. More clinics now offer the opportunity to have a fertility 'check' which includes a review of ovarian reserve. These may be counterproductive if the aim is to plan motherhood as may falsely reassure women about their own fertility leading to delays in attempting to conceive [17].

Table 8.6.1.1 Gonadotrophin hormonal profile and potential diagnosis

FSH	LH	Oestradiol	Diagnosis
Normal	Elevated	Usually normal	PCOS
Normal	Low	Low	Weight-related amenorrhoea
Low	Low	Low	Hypogonadotropic hypogonadism, functional or organic
Elevated	Elevated	Low	If oligo-/amenorrhoeic: ovarian failure
Elevated	Elevated	High	If mid-cycle, think of mid-cycle surge

The number of **antral follicles** in the ovary, as assessed by pelvic ultrasound (see on) has been reported as the best single predictor of poor ovarian response to stimulation for IVF [18]. Indeed it is the number of small antral follicles, 2–6 mm in diameter, that declines significantly with age, while there is little change in the larger follicles of 7–10 mm, which is still below the size at which growing follicles have been recruited.

Anti-Müllerian hormone (AMH) is a dimeric glycoprotein and member of the transforming growth factor-β (TGF-β) superfamily, which is best known as a product of the testes during fetal development that suppresses the development of Müllerian structures. AMH is also produced by the granulosa cells of preantral and antral follicles and appears to be a more stable predictor of the ovarian follicle pool than FSH, as it does not fluctuate through the menstrual cycle. For many fertility clinics, AMH has superseded the traditionally used FSH level in measuring ovarian reserve and planning ovarian stimulation [19]. Indeed it has been reported that higher AMH concentrations are associated with increased numbers of mature oocytes, embryos, and clinical pregnancies during IVF treatment [20]. Assays for AMH are now available for routine use despite a problematic history with assay stability [21]. AMH has also been proposed as a biochemical marker for the presence of polycystic ovaries, with high AMH concentrations being characteristic although a consensus has not been agreed. A recent series from our clinic found cut-off values of xxx and xxx for the presence of polycystic ovaries and the polycystic ovary syndrome, respectively.

Chromosomal Analysis

It is sensible to study the chromosomes of women with infertility and any dysmorphic features, and those with premature ovarian insufficiency (POI). Routine chromosomal analysis for those with recurrent miscarriage is not recommended as the chance of finding an abnormality is slim. If there is a congenital abnormality within the offspring, unbalanced chromosomal abnormalities in the family or a detected translocation in pregnancy tissue, chromosomal analysis may be prudent [22]. Men with severe oligospermia (<1 million/ml) should also have an endocrine profile and a chromosomal analysis.

Autoantibodies

Women with premature ovarian failure sometimes have ovarian autoantibodies or signs of other autoimmune disease (thyroid, pernicious anaemia, diabetes mellitus, SLE). The presence of autoantibodies alerts one to the risk that these conditions may become manifest in the future.

Antiphospholipid Syndrome

Women with recurrent miscarriage might have elevated levels of lupus anticoagulant, anticardiolipin antibodies and β2 glycoprotein I antibodies; and may benefit from an acquired thrombophilia screen [22].

Pelvic Ultrasound

An ultrasound assessment of ovarian volume and antral follicle count in the early follicular phase has been used as a predictor for ovarian response prior to IVF treatment, with small volume ovaries indicating

reduced ovarian reserve. We recognize in the ovary three distinct morphological appearances: normal, polycystic, and multicystic. Multicystic ovaries are characteristically observed in pubertal girls and women recovering from weight loss-related amenorrhea. These multicystic (or multifollicular) ovaries are normal in size or slightly enlarged and contain six or more cysts that are 4–10 mm in diameter; in contrast to women with polycystic ovaries (PCO), the stroma is not increased. The multicystic ovary appears to develop as a consequence of reduced hypothalamic secretion of gonadotrophin-releasing hormone (GnRH) which results in subnormal stimulation of the ovaries by the gonadotrophins. Polycystic ovaries are a separate entity and have a distinct response to induction of ovulation and ovarian stimulation for *in vitro* fertilization (IVF). Polycystic ovaries may be present in women who are non-hirsute and who have regular menstrual cycles. It is important to differentiate between PCO and PCOS. The former describes the morphological appearance of the ovary whereas the latter term is only appropriate when PCO are found in association with a menstrual disturbance (amenorrhea or, more commonly, oligomenorrhea) and/or the complications of hyperandrogenization (seborrhoea, acne and hirsutism) [23]. Polycystic Ovary Syndrome is also associated with endocrinological abnormalities and in particular with elevated serum concentrations of androgens (testosterone, androstenedione), LH, prolactin, and oestrogens. As with the clinical picture, these changes are variable and patients with PCOS may have normal endocrine concentrations.

With the advent of high-resolution ultrasound, identification of polycystic ovaries is simple and the polycystic ovary should have at least one of the following: either 12 or more follicles measuring 2–9 mm in diameter or increased ovarian volume (>10 cm^3) [24].

Besides making a careful assessment of ovarian morphology, it is necessary to perform a baseline ultrasound scan of the ovaries before commencing ovarian stimulation in order to detect the presence of ovarian cysts, which may be a physiological remnant of ovulation or representative of ovarian pathology. An endometrioma has the characteristic hazy, echodense appearance of blood in a cyst. Dermoid cysts are sometimes seen in women of reproductive age and may be difficult to distinguish from endometriomas, as both may be bilateral with a hazy, homogeneously echodense appearance of lipid matter in dermoids and blood in endometriomas. All but obviously simple cysts should be treated with caution as ovarian malignancy may occur in young women. Therapeutic stimulation of the ovaries should not be performed until complex ovarian cysts have resolved, either spontaneously or surgically.

The baseline ultrasound scan also permits inspection of the other pelvic structures and might reveal the presence of hydrosalpinges, fibroids, or congenital developmental anomalies of the uterus. Endometrial changes can be seen clearly using pelvic ultrasound. The endometrial thickness in the early follicular phase is 4–6 mm, by the time of ovulation it is about 8–10 mm and in the mid-luteal phase it reaches 14 mm. It has been suggested that there is a reduced chance of pregnancy if the triple line appearance is absent or if the preovulatory endometrial thickness is less than 7 mm [25].

Assessment of Tubal Patency and the Uterine Cavity

Hysterosalpingography

Tubal infertility is diagnosed in between 15% and 50% of couples presenting with subfertility. X-ray hysterosalpingography (HSG) provides a delineation of both the uterine cavity and the fallopian tubes. An HSG is the simplest preliminary test for the delineation of the uterine cavity and fallopian tubes and has few complications. An HSG is performed if there are no pointers in the history to an increased risk of tubal disease, for example pelvic infection, peritonitis, pelvic pain.

Hysterosalpingo-Contrast-Sonography (HyCoSy) and Saline Infusion Sonohysterography (SIS)

Similar to the HSG, a HyCoSy and SIS can be carried out relatively easily in an outpatient setting. Saline with/without the addition of a foam, can be used to outline both the uterine cavity and passage of fluid through the fallopian tubes during an ultrasound assessment. There is no risk of radiation exposure unlike with the HSG. This technique should be carried out when there are no tubal disease risk factors. An additional benefit is the concurrent assessment of uterine and ovarian morphology.

Laparoscopy and Hysteroscopy

Hysteroscopy permits assessment of the uterine cavity at the same time as laparoscopic assessment of the pelvic contents. Congenital anomalies of uterine development occur in about 4% of women; although rarely affecting fertility they may sometimes predispose to an increased risk of second trimester miscarriage. It is our practice to consent all patients undergoing diagnostic laparoscopy for treatment of mild endometriosis or adhesiolysis, which should not prolong the procedure by more than 15–20 minutes. There is evidence that even mild endometriosis may adversely affect fertility and so ablation, with diathermy or laser, can be performed during the initial diagnostic procedure. Fine periovarian and peritubular adhesions can often be broken down at the time of the initial laparoscopy. The presence of hydrosalpinges warrants salpingectomy to improve the chance of success in subsequent IVF treatment.

Investigating the Male

The general examination should include an assessment of BMI, blood pressure, secondary sexual characteristics, the abdomen, and genitalia. Some chest diseases are associated with infertility (congenital absence of the vas, spermatic duct obstruction) and might be elicited at the time of the examination. An absent or deficient sense of smell in patients with hypogonadotropic hypogonadism gives the diagnosis of Kallmann's syndrome.

Men with androgen deficiency of prepubertal origin will have a high-pitched voice, small soft testes, and a small penis, lack of adult hair, and decreased muscle mass. They are often tall with a large arm span that exceeds their height. If hypogonadism develops after puberty the skin becomes fine, body hair and beard growth diminish. There may be gynaecomastia, as in Klinefelter's syndrome. Gynaecomastia may also occur with hyperthyroidism, liver disease, oestrogen, or hCG-producing tumours or with some drugs (most notably antiandrogens such as cimetidine, spironolactone, digitalis). Transient gynaecomastia is normal during puberty. Other signs of endocrine disease (Cushing's syndrome, thyroid disease, pituitary tumour) should also become evident on the general examination. A full neurological examination is required when there are problems with sexual function.

Congenital deformities of the penis or hypo-/epispadias may cause problems with semen deposition. Testicular size should be

assessed using an orchidometer and is normal if over 15 ml. Small testes that are soft are usually associated with gonadotrophin deficiency, as in hypopituitarism or Kallmann's syndrome. Small testes that are firm (implying fibrosis) are usually associated with severe and permanent destruction of germinal epithelium (as in Klinefelter's syndrome) and androgenization may be normal. Testicular masses or asymmetry warrant further investigation by ultrasound in the first instance.

The Semen Analysis

The specimen of semen should be produced by masturbation into a clean, dry container and delivered to the laboratory within 30 minutes of its production. There should have been a period of abstinence of 3 days. A fixed period of abstinence not only improves the standardization of the test but more than 5 days abstinence is associated with a decrease in motility despite an increase in sperm number. There are large swings in semen parameters in healthy, fertile sperm donors and so the results of a single semen analysis should be viewed with caution and repeated on two or more occasions, 3 months apart. Sperm production by the testis takes 10–12 weeks and so an abnormal semen specimen is a reflection of testicular function 3 months previously. See **Table 8.6.1.2**.

Defining 'normal' sperm parameters has been a historically difficult subject due to the lack of consensus on who makes up a 'normal' population. Recognized globally, the WHO has provided standardized measurements adopted by many laboratories. The most recent edition [26], has attempted to address previous concerns regarding levels falling well within a fertile range; this has led to a reduction in the three main parameters (count, motility, morphology). The male populations used have proven fertility within a relationship with time to pregnancy ≤12 months [27]. The chance of natural conception falls significantly when the sperm concentration is less than 5×10^6/ml. When the total count is low there is often a corresponding reduction in motility. It has been suggested that sperm morphology is one of the better prognosticators for fertility [28]. Immotility can be caused by infection, superoxide production by leukocytes, antisperm antibodies, or defects in the microtubules and dynein arms of the sperm tail.

Sperm function can be impaired by lipid peroxidation in the sperm plasma membrane. Oxidative stress correlates with reduced motility and a decreased capacity for oocyte fusion. Reactive oxygen species (ROS) initiate lipid peroxidation and are produced either within the dysfunctional spermatozoa or by leukocytes. Seminal plasma contains a rich concentration of antioxidants and removal of sperm from seminal plasma during preparative procedures for assisted conception can expose the sperm to damaging ROS. A matter of some concern is the notion that ROS are well-known mutagens and sperm-derived genetic damage to embryos might occur through chromosomal breakage (while oocyte-derived damage occurs through chromosomal rearrangement) [29]. It has been suggested that spermatozoa that have been exposed to ROS are at increased risk of carrying chromosomal breakages. Measurements of DNA fragmentation, are one suggested method to assess spermatozoa integrity and have been related to recurrent pregnancy loss, although are not recommended for routine screening [30].

Table 8.6.1.2 Normal semen parameters (WHO, 2010)

Volume	≥ 1.5 ml
pH	≥ 7.2
Sperm concentration	≥ 15 x 10^6/ml
Total sperm count	≥ 39 x 10^6/ejaculate
Total Motility (progressive + non-progressive)	40%
Progressive motility	32%
Vitality (live spermatozoa)	58%
Morphology (normal forms)	4%
Peroxidase-positive leukocytes	<1.0 x 10^6/ml
MAR test (motile spermatozoa with bound particles)	<50%
Immunobead test (motile spermatozoa with bound beads)	<50%
Seminal zinc	≥ 2.4 µmol/ejaculate
Seminal fructose	≥ 13 µmol/ejaculate
Seminal neutral glucosidase	≥ 20 mU/ejaculate

Management of Tubal Infertility

In vitro fertilization has revolutionized many forms of fertility therapy, yet the question of IVF versus tubal surgery for mild to moderate tubal disease is still debated. Successful tubal surgery can provide a permanent cure, with the possibility of more than one pregnancy and can be performed laparoscopically

The techniques employed in tubal surgery are of paramount importance and require adequate training, whether performed at laparotomy or laparoscopy. Open tubal surgery is optimally performed using an operating microscope. While some surgeons advocate the continued use of open microsurgery, the laparoscopic approach has gained favour in recent years. One study compared the outcome of microsurgical and laparoscopic adhesiolysis and found no statistically significant difference in cumulative conception rates, which were a little over 40% after 12 months [31]. Peritubal adhesions interfere with ovum pick-up and tubal transport, while periovarian adhesions may inhibit ovulation. When the tubes are patent and the ovaries freely mobile, adhesiolysis will result in good cumulative conception rates (60% in 24 months), although at second-look laparoscopy there is often a recurrence of the adhesions to some degree. Dense adhesions carry a worse prognosis than fine, filmy adhesions.

The mainstay of salpingostomy is the fashioning of a small ostium at the tip of the tube, with eversion of the tubal mucosa so that the reconstructed fimbriae are positioned to allow the ostium free movement over the ovary. Raw areas and linear incisions in the tube will heal over and should be avoided. The best cases to treat are those in which the tubes have thin walls, normal mucosa, and no periovarian adhesions, although when the distal end of the tube is blocked there are usually periovarian and peritubular adhesions. Large hydrosalpinges, greater than 1.5 cm in diameter, carry a worse prognosis and are often excised.

Cornual occlusion due to infection (salpingitis isthmica nodosa, pelvic inflammatory disease, tuberculosis) is often associated with microscopic damage along the length of the tube and so there is a worse prognosis and greater risk of ectopic pregnancy than after reversal of sterilization. Reversal of sterilization leads to the best results, not only because the patient is of proven fertility, but also

because damage is to a very small portion of the tube. Pregnancy rates are between 60% and 80%, with ectopic pregnancy rates usually less than 5%.

Women with moderate to severe tubal infertility are optimally treated with IVF. If they have a history of repeated ectopic pregnancy there is a case for performing a sterilization prior to IVF, as there is nothing more traumatic than developing a further ectopic pregnancy after the stresses of an IVF treatment cycle. The overall rate of ectopic pregnancy after IVF is 5% (i.e. higher than normal) because uterine transfer of the pre-embryo(s) does not ensure that it will remain in the uterine cavity.

There is good evidence to suggest that the presence of hydrosalpinges affects the outcome of IVF by having an effect on the endometrial environment, possibly through the passage of toxic fluid into the uterine cavity, which disrupts implantation. If the tubes are completely blocked and there are large hydrosalpinges there is a case for surgical intervention. A large prospective randomized controlled trial evaluated salpingectomy versus no intervention. Despite no significant difference in the pregnancy rate between the salpingectomy group (36.6%) and the non-intervention group (23.9%), the live birth rates were increased (28.6% vs. 16.3%, $P = 0.045$) [32]. The differences were more significant in the presence of bilateral hydrosalpinges and particularly so with ultrasound visible hydrosalpinges (clinical pregnancy rate 45.7% vs. 22.5%, $p = 0.029$, live birth rate 40% vs. 17.5%, $P = 0.038$). More recently, it has been suggested that tubal occlusion may offer an alternative to salpingectomy with equal results. This is particularly useful for cases where significant adhesions or pelvic pathology may make salpingectomy a more difficult procedure. A recent Cochrane review evaluates any surgical intervention for those with hydrosalpinges prior to IVF and concludes that both occlusion and salpingectomy increase the clinical pregnancy rate, with no significant advantage over either one [33]. Salpingectomy can usually be performed laparoscopically and care should be taken not to compromise ovarian blood supply. Interest in hysteroscopic tubal occlusion prior to IVF has waned due to inferior success rates and increased risk of miscarriage [34].

Fibroids and Myomectomy

Fibroids are common with increasing incidence with age. Prevalence has been reported as low as 3% in Swedish Caucasian women aged 25–32 years and 8% in those aged 33–40 [35]. While rates have been reported as high as 70% in white Americans and 80% in African Americans age 50 years [36]. Imaging and initial assessment of fibroids is by ultrasonography but magnetic resonance imaging (MRI) can be extremely helpful in further delineating the position of multiple fibroids and distinguishing fibroids from adenomyoma. Classification of fibroids is by their position, with serosal fibroids being of least significance to fertility, there is then increasing significance of the presence of subserosal fibroids (in which >50% projects out of the serosal surface), intramural fibroids, and submucous fibroids, which in turn may be pedunculated into the cavity of the uterus (type 0), sessile with intramural extension of either ≤50% (type I) or ≥50% (type II). It is thought that fibroids are most likely to affect fertility if they either distort the endometrial cavity or have an intramural component of >4 cm.

Fibroids are often removed indiscriminately and myomectomy can result in extensive pelvic adhesion formation and damage to the integrity of the uterine cavity. The debate continues as to how many fibroids should be removed and from what location. There is increasing evidence that intramural fibroids affect implantation, even when there is no deformation of the uterine cavity. A meta-analysis of 17 studies concluded that all fibroids may affect fertility, with a greater influence on delivery than pregnancy rates [37]. The most recent review from the American Society for Reproductive Medicine, concludes that there is insufficient evidence that the presence of myomas reduce the likelihood of achieving pregnancy, however, myomectomy for cavity distorting myomas (open, laparoscopically or hysteroscopic) improves pregnancy rates and reduces the chance of miscarriage [38]. Myomectomy is a major procedure with potential risks to the integrity and viability of the uterus. Preoperative treatment with a gonadotropin-releasing hormone agonist for 6–8 weeks will cause significant shrinkage of the fibroids and reduce vascularity and blood loss during surgery

Less invasive procedures than operative myomectomy are being evaluated for the management of fibroids, including uterine artery embolization and MRI-guided laser coagulative necrosis or high intensity focused ultrasound for the destruction of fibroids. The place of these techniques in the management of infertility is still being evaluated. Furthermore, while uterine artery embolization has become popular in the management of fibroids it is not recommended for those who wish to preserve fertility because of the potential adverse effect on both uterine and ovarian blood supply.

Endometriosis

Endometriosis can cause pelvic pain and infertility. Treatment is best achieved with surgery without delaying the chance of conception by hormonal therapies that are contraceptive. Careful laparoscopic assessment of the pelvis reveals signs of endometriosis in up to 18% of women with proven fertility [39]. While a number of theories have been proposed for the pathogenesis of endometriosis, that of retrograde menstruation is the most popular and plausible. Retrograde menstruation is common, being seen in 75–90% of women who have had laparoscopies performed at the time of menstruation. Menstrual blood does not always contain endometrial cells and the factors that influence implantation of ectopic endometrium are uncertain, for the prevalence of endometriosis has been estimated as 1–20%, not 75–90%. Women with endometriosis appear to have altered immune function, which may permit implantation of regurgitated endometrium. Abnormalities of cellular adhesion molecules, including the integrins and extracellular matrix proteins, are also thought to play a role in pathogenesis. The detection of endometriosis in women being investigated for subfertility is thought to reflect their lack of conception and exposure to frequent menstruation rather than being a cause of the infertility. Indeed, the likelihood of finding evidence of endometriosis in women who attend for sterilization is increased in proportion to the interval since the birth of their last child.

Women with symptomatic endometriosis may have a genetic disposition to endometrial implantation on the peritoneum and a further disposition to an inflammatory response to the cyclical changes that occur in the ectopic endometrium. As is well known, the degree of endometriosis does not correlate with symptomatology: pelvic pain, dyspareunia, and dysmenorrhoea. It is not possible, moreover, to predict which patients will develop progressive disease with resultant pelvic adhesions and ovarian cysts.

It is easy to envisage how severe endometriosis can affect fertility by distorting pelvic anatomy, with adhesions that smother the ovaries and tubes and with endometriotic ovarian cysts. Furthermore, the prevalence of endometriosis in infertile women is as high as 20–68% [40]. There is debate about the extent to which endometriosis affects fertility in the absence of pelvic deformity. It has been suggested that the peritoneal environment is altered, with an increased concentration of macrophages which impede sperm motility, phagocytose spermatozoa, and interfere both with oocyte pick-up by the fallopian tube and with fertilization.

The management of endometriosis depends upon the wishes of the patient, specifically whether her predominant complaint is pain or infertility. If fertility is required but pain is also a problem then management has usually been with analgesics, either alone or combined with surgical treatment. Non-steroidal anti-inflammatory drugs (NSAIDs) are regularly used although their effectiveness is questionable. There is some evidence that NSAIDs inhibit the process of ovulation through their antiprostaglandin action but endometriotic pain usually occurs at the time of menstruation rather than mid-cycle and so these drugs should be safe in women wishing to conceive.

Laparoscopy is the mainstay of the classification of endometriosis and the best known system of classification is that of the American Fertility Society (AFS, now American Society of Reproductive Medicine, ASRM). in which the appearance of the disease, the degree of adhesions, and obliteration of the pouch of Douglas provide a score. It has been suggested that the AFS classification is limited by its inability to provide an indication of the activity of the disease and has no predictive value with respect to either pain or subfertility. Surgical therapy for the treatment of endometriosis can be performed at the time of the diagnostic laparoscopy, although only if the diagnosis has been suspected and the patient has been given appropriate information and consent.

There is little to choose between the medical therapies (e.g. progestogens, GnRH agonists, danazol or the combined oral contraceptive pill) with respect to subsequent fertility and a body of evidence that indicates no benefit when compared with expectant management. These have been collected together in a systematic review [41, 42] in which 23 trials involving 3043 women were included. The odds ratio for pregnancy following ovulation suppression versus placebo or no treatment for all women randomized was 0.79 (95% CI 0.54–1.14), $P = 0.21$ and 0.80 (95% CI 0.51–1.24), $P = 0.32$, respectively for subfertile couples only despite the use of a variety of suppression agents. This absence of demonstrable efficacy, together with the fact that the treatments are contraceptive, means that medical therapies are inadvisable for women who wish to conceive.

There is now convincing evidence that laparoscopic treatment of mild to moderate endometriosis is superior to diagnostic laparoscopy alone for both ongoing pain management and clinical pregnancy rate. Laparoscopic treatment provides improved pain scores at 6 and 12 months, respectively (odds ratio (OR) 6.58, 95% CI 3.31–13.10, 3 randomized controlled trials (RCTs), 171 participants, and OR 10.00, 95% CI 3.21–31.17, 1 RCT, 69 participants). Excision or ablation of endometriosis yields a higher live birth rate or ongoing pregnancy rate past 20 weeks when compared with diagnostic laparoscopy alone (OR 1.94, 95% CI 1.20–3.16, $P = 0.007$, 2 RCTs, 382 participants, moderate-quality evidence) [43].

In considering surgery for endometriosis a distinction should be made between ovarian endometriomata and deeply infiltrating endometriosis (i.e. endometriosis that penetrates more than 5 mm below the peritoneal surface). Cystic ovarian endometriosis tends to be associated with adhesions, while deep infiltrating endometriosis is not and is often found in the pouch of Douglas, on the uterosacral ligaments, and in the uterovesical fold. Sometimes the lesions can be very deep yet have only a small visible surface area. MRI can be helpful in localizing the lesions and guiding the surgery.

There is some evidence that excisional surgery for endometriomata of greater than 3 cm in size provides for a more favourable outcome than simple drainage and ablation [43, 44]. A systematic review reported that laparoscopic excision of the cyst wall of the endometrioma was associated with a reduced rate of recurrence of the endometrioma (OR 0.41 95% CI 0.18–0.93), reduced requirement for further surgery (OR 0.21 95% CI 0.05–0.79), reduced recurrence rate of the symptoms of dysmenorrhoea (OR 0.15 95% CI 0.06–0.38), dyspareunia OR 0.08 95% CI 0.01–0.51), and non-menstrual pelvic pain (OR 0.10 95% CI 0.02–0.56). It was also associated with a subsequent increased rate of spontaneous pregnancy in women who had documented prior subfertility (OR 5.21 CI 2.04–13.29) [45]. While surgery for endometriomata may improve outcomes, care must be taken to retain normal ovarian tissue to prevent further depletion of the ovarian reserve.

Laparoscopic surgery should only be performed by appropriately trained and skilled surgeons as endometriosis taxes the skill of the surgeon more than any other disease in the pelvis. It may be necessary to resect affected bowel or bladder and the help of a colorectal surgeon or a urologist may be required. Great care is required when operating near the ureter and ureteric stenting may be helpful. Large lesions often require laparotomy although such major surgery is usually reserved for patients with severe pain who have completed their family rather than for those with infertility, in whom GnRH agonist therapy combined with IVF is usually more appropriate.

Aggressive treatment of deeply infiltrating endometriosis and cystic ovarian endometriosis is associated with cumulative pregnancy rates of up to 60% over 12 months, after which IVF will probably provide a greater chance of conception than a second-look procedure. Severe endometriosis may reduce the success of IVF therapy, by impairing the rates of fertilization and implantation. It is commonplace to suppress active endometriosis with a GnRH agonist for 2–3 months prior to IVF, particularly if pituitary desensitization is part of the IVF treatment protocol [42].

Adenomyosis, a benign condition where endometrial glands and stroma are found within the myometrium, may impact on fertility. Theories to this effect include altered uterine contractility, impaired uterotubal transport and reduced sperm function secondary to high uterine cavity nitric oxide levels [46]. A detrimental effect on IVF outcomes is recognized with a reduction in implantation and increased early pregnancy loss. A 41% reduction in live birth rate for those with adenomyosis following an embryo transfer has been shown (OR 0.59, 95% CI 0.42–0.82) [46]. Diffuse adenomyosis appears to be a worse prognostic feature than focal adenomyosis, which is more amenable to surgical excision. Pre-IVF treatment with a GnRH agonist appears to be beneficial and is certainly less invasive then surgical options.

Anovulatory Infertility, PCOS, and Ovulation Induction

These subjects are dealt with in Section 8.4, 'Polycystic Ovary Syndrome and Other Androgen Excess Disorders'.

Unexplained Infertility

One can consider two approaches to the diagnosis and management of unexplained infertility. The first is strictly scientific, with a quest for and exclusion of each known cause of infertility before the label 'unexplained infertility' can be given. The second approach is a pragmatic one based upon a management-oriented policy, whereby treatment is commenced after the common obstacles to fertility have been excluded. The treatment of unexplained infertility essentially aims to boost fertility, usually by a combination of superovulation and close apposition of sperm and egg(s).

Studies of populations of patients with infertility indicate that approximately 10–25% have unexplained infertility, 20–30% ovulatory dysfunction, 20–35% tubal damage, 10–50% sperm dysfunction, 5–10% endometriosis, and 5% coital dysfunction. A degree of subfertility is found in both partners in 30–50% of couples, as usually a couple's subfertility is a relative rather than an absolute barrier to conception. Unexplained infertility has been defined as the inability to conceive after 1 year in the absence of any abnormalities. Between 40% and 65% of couples given this label will conceive spontaneously over the following 3 years and it has been suggested that treatment should be deferred until the couple has been trying to conceive for at least 3 years, as before this time therapy does not confer any benefit over the natural chance of conception [47, 48]. It appears that the most important prognostic factors are the duration of infertility and the age of the female partner.

A number of approaches have been employed in the management of unexplained infertility. Therapy should aim to boost the monthly pregnancy rate above the natural rate of 1.5–3% that is expected for couples who have been trying to conceive for over a year.

It used to be thought that clomiphene enhanced fertility by correcting a subtle defect in ovarian function—either follicular development or luteal phase defect. A recent three arm randomized controlled trial in couples with infertility for over 2 years, confirmed ovulation, patent fallopian tubes, and motile sperm randomized 580 women to expectant management (n = 193), oral clomiphene citrate (n = 194), or unstimulated intrauterine insemination (n = 193) for 6 months [49]. Live birth rates were 32/193 (17%), 26/192 (14%), and 43/191 (23%), respectively. Compared with expectant management, the odds ratio for a live birth was 0.79 (95% CI 0.45–1.38) after clomiphene citrate and 1.46 (0.88 to 2.43) after unstimulated intrauterine insemination. Despite no benefit with respect to live birth rates, more women randomized to clomiphene citrate (159/170, 94%) and unstimulated intrauterine insemination (155/162, 96%) found the process of treatment acceptable than those randomized to expectant management (123/153, 80%) ($P = 0.001$ and $P < 0.001$, respectively). A subsequent review also concluded that clomiphene citrate was no more effective than no treatment or placebo for live birth (odds ratio (OR) 0.79, 95% CI 0.45–1.38; $P = 0.41$) [50]. The addition of clomiphene also increased the risk of multiple pregnancy

Although it is reasonable to assume that the combination of gonadotropins to induce superovulation, with the release of two or three oocytes, with insemination of a prepared sample sperm into the uterine cavity should boost fertility, this appears to be unfounded. A meta-analysis of 14 RCTs including 1867 women with unexplained infertility found no conclusive evidence of benefit in cumulative live birth rate when compared with timed intercourse, both with and without ovarian stimulation [51]. A recent trial questions this indifference, evaluating stimulated intrauterine insemination (IUI) against expectant management. An increased live birth rate was seen with IUI (risk ratio (RR) 3.41, 95% CI 1.71–6.79; $P = 0.0003$) [52].

IVF confers the advantages of being able to study fertilization and the selection of good quality pre-embryos for transfer into the uterus. The Cochrane database [53] reports a higher live birth rate per woman with IVF compared with expectant management (OR 22 95% CI 2.56–189.4, 1 RCT, 51 women, very low-quality evidence) or unstimulated IUI (OR 2.47, (%% CI 1.19–5.12, 2 RCTs, 156 women, low-quality evidence). For those women who had no pretreatment with either IUI or ovarian stimulation, there was no conclusive evidence of a difference in live birth rates with IVF. The overall paucity of evidence means firm conclusions as to the benefit of IVF cannot yet be made in unexplained infertility. Overall it seems sensible to progress to IVF in couples with unexplained infertility after 2 years of regular unprotected intercourse.

In Vitro Fertilization (IVF)

Assisted conception techniques involve the laboratory preparation of gametes, artificially bringing them closer together and hence enhancing fertility by either bypassing an absolute obstruction to fertilization or boosting fecundity above that expected without treatment. Assisted conception is indicated if the prognosis for tubal surgery is considered too poor or if conception has failed to occur within 12 months of tubal surgery. IVF is indicated for moderate to severe endometriotic disease if conception has failed to occur within 12 months of ablative laparoscopic surgery. When there is severe sperm dysfunction and sperm preparation provides an inadequate specimen for superovulation intrauterine insemination or if conception has failed to occur after 3–4 cycles of superovulation/IUI, IVF should be offered. Micromanipulation techniques (i.e. intracytoplasmic sperm injection (ICSI)) may be required to achieve fertilization if there is severe male factor infertility.

Prior to assisted conception treatment, in addition to baseline infertility investigations, it is usual for most clinics to test couples for HIV, hepatitis B, and hepatitis C, in order to avoid iatrogenic transmission from one partner to the other and also to protect laboratory staff who are handling bodily fluids. Furthermore, cryopreserved gametes and embryos have the potential—albeit unproven—of cross-contamination through liquid nitrogen.

For a couple to undergo IVF, the female partner should have functioning ovaries and a normal uterus and the male partner at least one sperm per ejaculate. However, the lack of ovarian function can be bypassed with oocyte donation, the absence of sperm can be bypassed with sperm donation, and the absence of a uterus by IVF surrogacy. Sometimes both sperm and oocytes, or surplus embryos

from another couple, are donated so that the resultant child has inherited no genetic material from either parent. Such parents have in reality 'adopted' the embryos but do, of course, gain from the experience of pregnancy and childbirth.

IVF is sometimes embarked upon before all other treatment modalities have been exhausted and while we do not advocate unnecessary delay, particularly in older patients, the notion that IVF is the high-tech modern answer to every couple's subfertility is erroneous. The stresses placed upon a couple by IVF (and other assisted conception procedures) are immense and the treatment has risks and complications (e.g. ovarian hyperstimulation syndrome (OHSS) and multiple pregnancy).

Regimens for IVF

IVF therapy has become increasingly simplified in recent years. The use of gonadotropin-releasing hormone (GnRH) agonists and antagonists with gonadotropins has resulted in greater ease of planning the superovulation stimulation. When GnRH agonists or antagonists are used the oocyte retrieval can be precisely timed to occur 34–38 hours after the administration of hCG. The latter acts as a surrogate for the normal mid-cycle LH surge and causes resumption of meiosis within the oocytes and their preparation for fertilization. Furthermore, there is good evidence that the oocytes do not become over-mature within follicles that are considered to be ready for collection and so the administration of hCG can be delayed to avoid oocyte collection at weekends. Most large clinics, however, provide flexibility with a 6- or 7-day service.

A disadvantage of the use of GnRH agonists in a classic 'long protocol' is the 2 weeks or more lead-in to the therapy during which pituitary desensitization ('downregulation') is achieved before stimulation with gonadotropins can be commenced. Pituitary desensitization is assessed by a combination of endometrial shedding and low serum concentrations of oestradiol (ultrasound confirmation of a thin endometrium and quiescent ovaries is adequate without recourse to biochemistry).

The GnRH agonists can be administered intranasally, subcutaneously, or intramuscularly (by depot in some instances). The shorter acting preparations can be used to induce a flare response, being commenced on day 1 of the cycle, with gonadotropin stimulation starting the following day. The agonist is then either continued through to the day of hCG administration or given for 3 days only. The flare response can be utilized in those patients who have had a poor response in the past in order to try to maximize the response to stimulation—this it does to varying degrees.

The advent of the third-generation GnRH antagonists enables us to dispense with pituitary desensitization and commence ovarian stimulation on day 2, with the daily administration of an antagonist on day 6 of stimulation or once the leading follicle(s) has reached a diameter of 14 mm (usually day 6 or 7). Although it appears that success rates are better when commenced on day 6 rather than using a flexible protocol [54]. The GnRH antagonist acts immediately to inhibit pituitary secretion of FSH and LH, without the flare effect of agonists or the need for 10–14 days' desensitization. An endogenous LH surge can be prevented, thereby allowing oocyte retrieval at the desired time. GnRH antagonist cycles are certainly much shorter and more convenient for patients than the 'long protocol' and many clinics are now increasingly using them.

Initial studies found pregnancy rates were lower when using the antagonist protocol. A recent review, however concluded that there is a similar probability of livebirth when either GnRH agonists or antagonists are used (OR 1.02, 95% CI 0.85–1.23; 12 RCTs n = 2303, moderate-quality evidence) [55] with no difference in miscarriage rates (OR 1.03, 95% CI 0.82–1.29 34 RCTs, n = 7082, moderate-quality evidence). The advantage of the antagonist protocol is a reduction in incidence of OHSS (OR 0.61, 95% CI 0.51–0.72; 36 RCTs, n = 7944, moderate-quality evidence). The pharmacokinetics of the antagonist protocol allows use of a GnRH agonist to initiate oocyte maturation, rather than human chorionic gonadotrophin (hCG), further reducing the risk of OHSS due to the agonists' shorter half-life. Using a GnRH agonist as a trigger was initially found to be detrimental to the pregnancy rate [56] (OR 0.47, 95% CI 0.31–0.70; five RCTs, 532 women, moderate-quality evidence) but with intensive luteal phase support, using a combination of oestradiol, progestogen, and hCG, similar pregnancy rates to hCG are now reported [57].

Gonadotropin Therapy

Gonadotropin therapy for the stimulation of superovulation can be with either human menopausal gonadotropins (hMG), which contain urinary-derived FSH and LH in differing proportions depending on the preparation, or with urinary-derived FSH alone; or with recombinant-FSH (rFSH). The advent of the recombinantly derived gonadotropins has broadened the scope of therapeutic agents and resulted in a potentially unlimited supply.

Most RCTs comparing gonadotrophin preparations have evaluated efficacy in terms of number of oocytes retrieved, focusing on ovarian response and potency rather than on treatment outcome. Only very few RCTs have been powered to compare gonadotrophin preparations with respect to ongoing pregnancy rates, and none have been powered for live birth rate which is the outcome of interest to couples seeking infertility treatment. Live birth rate can however be appropriately addressed by meta-analysis. A recent meta-analysis of RCTs compared rFSH to all other gonadotrophins, irrespective of downregulation protocol used, and did not find any statistically significant difference in live birth rate (OR 0.97, 95% CI 0.87–1.08, 28 RCTs, 7339 couples) [58]. If urinary gonadotrophins were considered separately, there were significantly fewer live births after rFSH than HMG (OR 0.84, 95% CI 0.72–0.99), 11 RCTs, n = 3197). There were no significant differences between hMG and rFSH with respect to miscarriage rate or multiple pregnancy. The authors conclude that any differences between urinary gonadotrophins were unlikely to be clinically significant and therefore choice of gonadotrophin should depend on availability and cost. In ovulation induction, similar pregnancy outcomes between urinary-derived gonadotrophins and rFSH have also been documented [59].

Oocyte Retrieval

The preovulatory hCG 'trigger' is usually administered when the leading follicle is at least 17–18 mm in diameter and there are at least three follicles greater than 17 mm. Ultrasound-guided oocyte retrieval is usually performed under light sedation plus analgesia; combinations of benzodiazepines, midazolam, and opiates are given intravenously or intramuscularly, with appropriate monitoring during and after the procedure. Administration of a local anaesthetic (1% lidocaine (lignocaine)) into the vaginal fornices is of

additional benefit. The procedure should be pain free. The patient is awake or lightly sedated and may be shown the oocytes on a closed-circuit video monitor attached to the embryologist's microscope. Oocyte retrieval should take about 20 minutes.

After oocyte retrieval, the semen is washed and prepared. Insemination is usually performed 1–6 hours after oocyte retrieval with 50–200 000 motile spermatozoa being placed with each oocyte; 16–18 hours later the oocytes are examined to ensure that correct fertilization has occurred, as defined by the presence of two pronuclei. Multiple pronuclei indicate polyspermic fertilization or digyny (i.e. failure to extrude the second polar body) and are not suitable for transfer.

Embryo Transfer

Embryo transfer was traditionally performed 2–3 days after oocyte collection (at the 4–8 cell stage). There has been a recent shift in favour of extended culture to the blastocyst stage (day 5 of embryo development). Improved clinical pregnancy rates (OR 1.30, 95% CI 1.14–1.47; 27 RCTs, 4031 women, moderate-quality evidence) and live birth rates (OR 1.48, 95% CI 1.2–1.82; 13 RCTs, 1630 women, low-quality evidence) are seen when compared with fresh cleavage stage transfers [60]. This equates to 29% of women achieving a live birth after fresh cleavage stage but 32–42% following blastocyst transfer. Arguments favouring blastocyst transfer include: avoidance of premature exposure of embryos to the highly oestrogenized uterine environment; reduced uterine pulsatility; and improved implantation as the most viable embryos reach blastocyst stage. Lower embryo freezing rates (OR 0.48, 95% CI 0.4–0.57; 14 RCTs, 2292 women) and higher failure to transfer cycles (OR 2.50, 95% CI 1.76–3.55; 17 RCTs, 2577 women) are seen at the blastocyst stage. Limited evidence suggests no difference in cumulative pregnancy rates following fresh and frozen embryo transfer cycles after a single oocyte retrieval between blastocyst and cleavage stage embryos. An RCT to compare day 5 transfer of a single blastocyst with transfer of a single cleavage embryo on day 3 had to be terminated early after a prespecified interim analysis found a higher rate of pregnancy and delivery in the blastocyst group (32.0% vs. 21.6%, RR 1.48 95% CI 1.04–2.11) [61].

Number of Embryos for Transfer

One major problem that has arisen from the growth of assisted conception treatment in a competitive environment is the dramatic rise in multiple births. Triplets and greater have been prevented by legislation introduced by the Human Fertilisation and Embryology Authority (HFEA) in the UK in 2002 limiting the number of embryos transferred to two for women under 40, as there is no evidence that the transfer of three significantly increases the chance of pregnancy and recommends the transfer of no more than 3 in women over the age of 40. In the UK, over the last 10 years, there has been a strong drive towards elective single embryo transfer (eSET). This has led to a significant reduction in multiple birth from 28% of all IVF treatment cycles in 1991 to 11% in 2016 [62]. American data, supports elective single embryo transfer with no significant impact on cumulative live birth rate. Good prognostic features include maternal age <38 years, surplus good quality embryos for cryopreservation and a previous live birth from IVF [63]. Evidence suggests that by adopting a SET policy and cryopreserving the spare embryos for subsequent replacement if the initial cycle should fail, the live birth rate is not significantly different to that following a double embryo transfer and multiple pregnancy rates can be reduced to 5% [64, 65]. Furthermore, there is a significant cost benefit with respect to maternity and paediatric care [64, 65].

Time lapse imaging (TLI) is now regularly used to help select the best embryo to transfer. There is some evidence that TLI improves clinical outcomes due to increased knowledge about the embryos' development and the closed incubation system. A recent retrospective review of TLI reported an improved live birth rate with TLI (TLI 36.8 versus standard culture 33.9%, adjusted odds ratio 1.28, 95% CI 1.05–1.57). A reduction in preterm birth and low birth weight has also been reported [66].

Luteal Phase After IVF

The embryo transfer procedure usually takes 5–10 minutes. The procedure should be performed under ultrasound guidance rather than using the 'clinical touch' method, as this results in significant increase in ongoing pregnancy (OR 1.51 95% CI 1.31–1.74) and livebirth rates (OR 1.78 95% CI 1.19–2.67) [66]. After embryo transfer the patient can go about her normal daily activities. Indeed, inactivity is best avoided as the 2 weeks up to the pregnancy test are hard for couples to cope with as they are no longer attending the clinic for regular scans and monitoring. It is usual to provide luteal support until the results of the pregnancy test are known and this itself can delay the onset of menstruation and give the couple false hope. Luteal support can be provided by either hCG or parenteral or vaginal progesterone. The administration of hCG should be avoided if there is any risk of OHSS as it will continue to stimulate the ovaries, while exogenous progesterone will of course replace the secretion of the corpora lutea. Many clinics have now stopped giving hCG because OHSS is not always easy to predict.

Pregnancy Rates After IVF

A clinical pregnancy is defined as the ultrasound visualization of a gestational sac. Biochemical pregnancies are so named if hCG is present in the serum (in the absence of exogenously administered hCG for luteal support) yet bleeding occurs before a gestational sac is seen on ultrasound. It is a sensible convention not to include biochemical pregnancies in treatment results and care must be taken when comparing the results of different clinics or studies to ensure that the same definitions of pregnancy have been used.

Modifications to the treatment process, from superovulation strategies to create a larger cohort of mature oocytes, through to the advances in culture technology to allow embryos to thrive in the laboratory have led to a steady increase in live birth rates over the last 20 years with the overall live birth rate per cycle in the UK greater than 25% per cycle. Approximately 68 000 assisted conception treatments are performed annually in the UK, resulting in approximately 1% of all births. There are huge variations in both provision and outcomes of assisted conception treatments around Europe (and the globe).

The chance of a pregnancy following a single cycle of IVF is now approximately 30–40% in the larger units. With the eSET policy supported in the UK, the chance of multiple pregnancy is now 11%, with the majority being twin pregnancies. The miscarriage rate is about 20% and the chance of an ectopic pregnancy is approximately 5%.

The pregnancy rates achieved by IVF equate favourably with those expected for a couple without infertility when adjusted for the age of the female partner. Cumulative conception and live birth rates, calculated by life table analysis, provide the best form of comparison between treatments, although they do not take into consideration couples who drop out of treatment because they are perceived as having a poor chance or because they cannot cope with the stresses of the therapy. The major factors that determine the chance of an ongoing pregnancy are the age of the woman, with rates declining over the age of 35, increasing duration of infertility, parity, and the number of oocytes collected. Not surprisingly, couples who have achieved a pregnancy are more likely to do so if they try again.

Most IVF cycles fail after embryo transfer, and so research has focused on trying to identify which are the correct embryo/s to transfer. Non-invasive ways to assess embryo health have focused on embryo metabolism, and in particular their amino acid profile [67, 68]. Metabolically quiet embryos seem to have more developmental potential than those with a high amino acid turn over. Although these methods have appeared promising, there continues to be limited evidence of any benefit when metabolomic testing is implemented [69].

A high proportion of embryos are karyotypically abnormal, with this increasing substantially with progressing age. Preimplantation genetic screening (PGS) of those patients at highest risk of aneuploidy has been considered; initial outcomes were disappointing [70], but with changes in technique these are improving. Trophectoderm biopsy is currently favoured, for those embryos reaching the blastocyst stage. Use of next generation screening (NGS) rather than array comparative genomic hybridization (aCGH) is providing promise with improved implantation rates (NGS 71.6% vs. aCGH 64.6%) and live birth rates (NGS 62% vs. aCGH 54.4%). These improvements are in part due to the ability of NGS to detect mosaic embryos and those with partial aneuploidies or triploidy [71].

Micromanipulation of Gametes for Severe Male Factor Infertility

Standard IVF requires the presence of more than 500 000 motile sperm in the total ejaculate. In cases where the sperm count is lower, fertilization can be assisted by a variety of micromanipulation techniques, such as ICSI—the injection of a single spermatozoon directly into the cytoplasm (ooplasm) of the oocyte, which has revolutionized the management of male infertility and has provided the possibility of a pregnancy for men who previously would have required their partners to undergo donor insemination.

ICSI can be used not only for men with profound oligozoospermia or asthenoteratozoospermia but also for those with obstructive azoospermia, after microsurgical or direct aspiration of sperm from either the epididymis or the testis. Fertilization rates with ICSI are in the region of 60%, irrespective of the origin of the sperm, providing 90% of couples with an embryo transfer and chance of a pregnancy. Pregnancy rates after ICSI are the same as after IVF.

There is some evidence for an increased rate of strand breakages in the DNA of sperm from men with subfertility, some of whom have cystic fibrosis or are carriers of cystic fibrosis mutations or other recessive gene anomalies. Furthermore, the stage at which genomic imprinting takes place is not known and there is a suggestion that genes may be modified in the epididymis—in other words, distal to the site of aspirated testicular sperm. The data on children born to date as a result of micromanipulation techniques are reassuring with respect to major congenital abnormalities but there is an increased rate of sex chromosome anomalies.

Cryopreservation of Gametes and Embryos

Cryopreservation of sperm and oocytes may offer the preservation of fertility for those about to undergo potentially sterilizing therapy for cancer. The introduction of vitrification as a freezing technique has revolutionized the clinical outcome of oocyte freezing. Clinical pregnancy rates equivalent to fresh embryo transfers have been reported [72]. With this improvement in outcome, there has been a steady rise in those wishing to freeze their oocytes for 'social reasons', and in doing so delaying starting a family. This approach should be taken with caution as too many choose to freeze oocytes at an age when fertility is already in significant decline. It is also possible to cryopreserve ovarian tissue followed by reimplantation or *in vitro* culture of follicles to provide a chance of viable oocytes for women who are about to undergo chemo/radiotherapy or have an oophorectomy.

Embryo survival is in the region of 70% and if individual blastomeres are damaged, as each is pluripotent, there appears to be no harmful effect on the developing fetus. Thawed embryos are transferred time-accordingly to stage of freezing after ovulation in carefully monitored natural cycles or after the commencement of progesterone therapy in artificial cycles in which pretreatment has been performed, with a GnRH analogue and then with oral oestradiol which is administered until the endometrium has developed adequately. There is no apparent difference in clinical outcome between natural or hormonal replacement cycles [73]. With vitrification technology yielding superior clinical outcomes over older slow freeze techniques, there has been a move by some clinics to consider frozen embryo transfer cycles for all, foregoing any initial fresh embryo transfer. There appears to be little difference in clinical outcome between fresh or frozen transfer cycles when cumulative livebirth rates are considered [74]; although as would be expected there will be a delay to pregnancy for some women.

Cryopreservation has enabled sperm donation to be an achievable option for those men who are found to be azoospermic and for whom surgical sperm retrieval is unsuccessful. It is also a valuable necessity for those in same—sex female relationships or those wishing to embark on motherhood as a single parent. Similarly, oocyte donation has become more accessible with cryopreservation, although for many who require donor eggs, they are often donated 'fresh' allowing fertilization and embryo cryopreservation where possible.

Preimplantation Genetic Testing

The ability for couples with a known genetic condition or balanced translocation, to have unaffected children, or at most be carriers of the condition, has been made possible by the development of preimplantation genetic testing (PGT, formerly "diagnosis" (PGD)). Cystic fibrosis or Huntingdon's chorea are examples of conditions that can be prevented being passed on to offspring. When the genetic mutation and surrounding genetic region are known for the affected

person, individualized genetic probes can be developed to test material from developing embryos. Trophectoderm biopsy from a blastocyst is now favoured (as with PGS), with most clinics freezing embryos until the embryos' genetic identity is known. If there are unaffected or carrier embryos, these can then be transferred in a subsequent frozen transfer cycle. For this to have a chance of success, there should be a reasonable ovarian reserve and adequate sperm numbers to provide a group of potential viable embryos that can reach blastocyst and withstand a biopsy and freezing. Alternatively, women can choose to have antenatal screening or testing to establish if their pregnancy is affected.

Surrogacy

IVF surrogacy is an option for women with ovaries but without a uterus, either because of a congenital absence (e.g. Rokitansky syndrome) or after hysterectomy (e.g. after severe obstetric haemorrhage or cervical carcinoma), or for women for whom a pregnancy would be a medical risk (e.g. severe heart or lung disease). Sperm must be frozen and quarantined for 6 months to reduce the risk of infection with HIV. A standard IVF regimen is used and the surrogate host prepared for a frozen embryo replacement cycle. Egg collection can sometimes be difficult if the ovaries are situated high in the abdomen, in which case a transabdominal approach may be required.

Straight surrogacy is another option, less commonly performed within clinics, in which the surrogate host donates her own oocytes either to be inseminated *in vitro*, in a standard IVF protocol, or *in vivo*, in an IUI protocol. There are strict regulations concerning surrogacy arrangements and few clinics offer this treatment because of ethical concerns and the complexities of the arrangements. Key components of a successful programme are an experienced counsellor and the selection of properly motivated surrogates who are fully informed of all of the IVF processes, their risks, and complications.

Ovarian Hyperstimulation Syndrome

The OHSS is a consequence of superovulation therapy for assisted conception procedures. This potentially fatal condition is avoidable by the judicious use of gonadotropins and careful monitoring of stimulation regimens. Women who are at particular risk of developing the syndrome include those who have polycystic ovaries and those who are young (under 30 years).

The pathophysiological hallmark of the OHSS is a sudden increase of vascular permeability which results in the development of a massive extravascular exudate. This exudate accumulates primarily in the peritoneal cavity, causing a protein rich ascites. Loss of *fluid* into the 'third' space causes a profound fall in intravascular volume, haemoconcentration, and suppression of urine formation. Loss of *protein* into the third space causes a fall in plasma oncotic pressure which results in further loss of intravascular fluid. Secondary hyperaldosteronism occurs and may cause hyponatraemia.

The syndrome is graded according to severity. Mild ovarian hyperstimulation is characterized by fluid accumulation, as evidenced by weight gain, abdominal distension, and discomfort. Ultrasound examination shows enlarged ovaries with a mean diameter greater than 5 cm but less than 8 cm. Grade 2 (moderate) ovarian hyperstimulation is associated with the development of nausea and vomiting. The ovarian enlargement and abdominal distension are greater, with ovarian diameter 8–12 cm, and cause more discomfort and dyspnoea. Ascites can be detected by ultrasound.

Grade 3 (severe) OHSS is a life-threatening condition in which there is clinical evidence of contraction of the intravascular volume (subnormal central venous pressure with reduced cardiac output), severe expansion of the third space (tense ascites, pleural, and pericardial effusions, all of which compromise the circulation and breathing), severe haemoconcentration, and the development of hepatorenal failure. In addition to the circulatory crisis these patients are at risk from intravascular thrombosis. Deaths have been recorded in women with grade 3 OHSS, caused usually by cerebrovascular thrombosis, renal failure, or cardiac tamponade resulting from pericardial effusion. Some authors have classified the most severe group as 'Critical OHSS', when the haematocrit is >55%, oliguria/anuria, thromboembolism, and acute adult respiratory distress syndrome (ARDS).

Risk Factors for OHSS

OHSS generally only occurs after overstimulated ovaries have been exposed to human chorionic gonadotropin (hCG). The condition therefore results most commonly when sensitive ovaries are exposed to gonadotropin preparations that contain FSH and then to hCG. The finding that severe OHSS is often associated with pregnancy is probably related to the persistence of hCG in this situation. Even when the ovaries have been severely overstimulated, OHSS can usually be prevented by avoiding exposure of the ovaries to hCG and/or LH. Thus in the context of a woman undergoing a cycle of ovarian stimulation while donating oocytes, hyperstimulation is likely to be a self-limiting situation as a pregnancy, by definition, will not occur.

In IVF the rate of OHSS varies in published series from 1% to 10%, being highest in those combining gonadotropin stimulation with treatment with a GnRH analogue. Severe cases occur in 0.25–8% of IVF cycles with mild cases occurring in up to 33% of cases [75]. A distinction has been made between early and late OHSS, with those presenting early (that is, 3–7 days after hCG administration) having significantly higher serum oestradiol concentrations and more follicles than those presenting late (12–17 days after hCG). Those presenting early usually have a self-limiting condition of relatively short duration while those presenting late are more likely to be pregnant and have a severe and more prolonged form of the syndrome, due to persistent stimulation of the ovaries by hCG from the placenta.

The greatest cause of morbidity and potential mortality in OHSS is from thromboembolism. When considering the pathophysiology of the OHSS it is easy to appreciate the potential risk of deep venous thrombosis (DVT) and thromboembolic events. Not only is there a hypercoagulable state but also the combination of enlarged ovaries and ascites leads to reduced venous return from the lower limbs, which combined with immobility places the patient at risk of DVT. Venous thrombosis in the lower limb most often resolves without long-term sequelae, unless pulmonary embolism occurs, which may be fatal. Upper limb venous thrombosis may lead to disabling long-term disability, with persistent discomfort, cramp, weakness, and cold hands. Cerebral thrombosis may resolve completely

or lead to various forms of long-term disability. The prevalence of thrombophilia may be increased in women with severe OHSS and prophylactic screening for thrombophilia has been advocated in those who have experienced severe OHSS [76].

Management of the OHSS

It goes without saying that prevention is the key and this can be achieved by using mild stimulation regimens, particularly in those at increased risk (young women and those with polycystic ovaries). The antagonist protocol is recommended for those at high risk of OHSS due to the lower incidence of OHSS, in part due to a shorter duration of gonadotrophin stimulation. Use of the GnRH antagonist then allows the GnRH agonist to be used as a 'trigger' in place of hCG, utilizing the natural LH within the women's system and further reducing the risk of OHSS. Other options for those with a high follicle count (>20–25 follicles) include: withhold hCG and not perform the oocyte retrieval or collect the oocytes and cryopreserve all embryos, as by not transferring an embryo the potential for severe late OHSS is avoided. For those at high risk of OHSS, Dopamine agonists such as Cabergoline can be used shortly after hCG administration to reduce the likelihood of moderate-severe OHSS and ovarian volume with no detriment to clinical pregnancy rates. Mild ovarian hyperstimulation is common and is managed expectantly, its importance being that it should alert both patient and doctor to the risk of a more severe condition developing, particularly if a pregnancy occurs. The patient should be encouraged to weigh herself daily and take plenty of oral fluids. A marked increase in weight (more than 5 kg) with the development of abdominal distension, nausea, and vomiting indicate the onset of grade 2 hyperstimulation and the need for hospital review. In non-conception cycles, moderate ovarian hyperstimulation can be expected to resolve with the development of menstruation, although the ovarian cysts may persist for a month or more.

Patients with grade 2 hyperstimulation need reassurance and explanation, together with rest. Oral fluids are encouraged although vomiting may make an intravenous infusion necessary. If hospitalized, TED stockings are advised to reduce the risk of deep vein thrombosis. Adequate analgesia is required. Preferred drugs are paracetamol, with or without codeine, and pethidine for very severe pain.

The development of clinically detectable and usually painful ascites, together with a deterioration in respiration, circulation and renal function indicates the development of severe grade 3 hyperstimulation and may require admission to an intensive care unit. The intravascular volume should be monitored by measurements of central venous pressure, renal function by meticulous attention to input and urine output and haemoconcentration by measurement of haematocrit, whose level reflects intravascular volume depletion and blood viscosity. A haematocrit of over 45% is a serious warning sign and a measurement greater than 55% signals a life-threatening situation. There may be a striking leucocytosis, the WBC count rising up to 40 000/ml. Measurement of body weight, serum urea, creatinine, and electrolytes, together with serum albumin and liver function tests and periodic assessments of the coagulation profile are mandatory.

Infusion of colloid (e.g. human albumen or 6% hydoxyethyl starch (HES)) is required to maintain intravascular volume, as indicated by restoration of a normal central venous pressure and improved haematocrit. It can be implemented on a day case basis if the clinic has capacity for careful patient monitoring. Crystalloid (normal saline usually) is administered for rehydration, although with careful monitoring of fluid balance. Prophylactic low molecular weight heparin should be given to prevent thromboembolism and as the risk continues up to the end of the first trimester of pregnancy there is an argument to continue heparin until that time [77].

A further concern is the development of hyponatraemia, secondary to antidiuretic hormone hypersecretion. If urine output remains suppressed despite restoration of central venous pressure and rehydration, abdominal paracentesis, under ultrasound guidance, should be undertaken. The indications for this procedure are therefore the need for symptomatic relief of a tense ascites, oliguria, rising serum creatinine, falling creatinine clearance, and haemoconcentration unresponsive to medical therapy. Severe oliguria or renal failure persisting despite these measures usually necessitate dialysis.

Paracentesis of hydrothorax should be considered for relief of dyspnoea. Cardiac tamponade from pericardial effusion may prove fatal if not rapidly relieved. Careful cardiology assessment together with cardiac ultrasound should therefore feature in the management of these patients. One must be aware of the possibility of re-accumulation of fluid in any of these cavities.

OHSS is a condition that should be taken extremely seriously because of the physical and emotional distress that it can cause and the thromboembolic risks. The triennial confidential enquiry into maternal deaths and morbidity in the UK reports on the numbers and causes of maternal mortality [78]. The report for 2003–2005, entitled *Saving Mothers' Lives,* had for the first time recorded deaths related to OHSS. In the triennium 2003–2005 there were four deaths out of approximately 119 641 IVF stimulation cycles, a mortality rate of 1:30 000. While problems with appropriate follow-up and expert care were identified in the management of these patients, it goes without saying that there is no acceptable rate of mortality as a result of fertility treatment. Reassuringly, the most recent report entitled *Saving Lives, Improving Mothers' Care* does not attribute any deaths directly to OHSS although there were 6 women (3%) who died between 2013 and 2015 who had achieved a pregnancy through assisted reproductive techniques [79].

8.6.2 Female Infertility

Fertility Preservation

Kutluk Oktay and Enes Taylan

Introduction

Treatments with antineoplastic agents and ionizing radiation have been successfully used in the management of a broad range of diseases including neoplastic diseases to various autoimmune and haematological disorders. With the remarkable advancements in modern treatment regiments, the survival rates have significantly improved in paediatric and reproductive age females. However, as the number of patients cured of the disease has increased the number of women facing infertility and early menopause after such treatments has also dramatically risen [1, 2].

Human ovarian reserve consists of a limited number of primordial germ cells numbers of which are determined *in utero*. Those germ cells possess the capacity to produce mature oocytes that can fertilize with sperm and provide offspring throughout the reproductive lifespan. However, treatment regimens, especially ones that include a high dose of alkylating agent and/or pelvic ionizing radiation, can irreversibly deplete ovarian reserve impairing reproductive capacity and shortening the fertile lifespan [3, 4]. In the last few decades, the number of females confronting these challenging issues has larger grown, hence, the necessity of fertility preservation has become more evident. Reproductive medicine specialists in collaboration with scientists from several other scientific disciplines have developed and introduced multiple options for preserving reproductive potential in women under the risk of gonadal failure or ovarian insufficiency (OI).

In this chapter, we will briefly describe the mechanisms of and risk factors for OI and then provide an overview of currently available options for fertility preservation in women.

Ovarian Reserve and Mechanisms of Ovarian Insufficiency

Contrary to continuous testicular germ cell regeneration in males, ovarian germ cell development, and proliferation process in females is limited to earlier intrauterine life. At birth, usually, the human ovary hosts approximately one million primordial germ cells surrounded by a single layer of squamous granulosa cells, and only 300 000–500 000 of those primordial follicles reach pubertal age. The large number of primordial follicles are lost due to an apoptotic process. This remaining pool of primordial follicles serves as the ovarian reserve throughout the reproductive years of a woman and nearly exhausts at menopause [5]. Primordial follicles initiate growth from intrauterine life, and their growth initiation is not dependent on pubertal status. By the age of 37 years, the number of primordial follicles in the ovarian reserve decreases to about 25 000 and the reserve depletes at the time of menopause. Recently, researchers reported the presence of mitotically active cells with stem cell characteristics in the adult ovary that can produce oocytes. However, their role in folliculogenesis and the follicle reserve is still unclear and needs to be further investigated [6, 7].

The Impact of Gonadotoxic Treatments on Ovarian Reserve

With the advancements in modern chemoradiation therapies and surgical practice, a growing group of patients with ovarian insufficiency has emerged. While modern cancer treatments can target cancer cells, in tandem high doses of chemotherapy and pelvic radiotherapy can irreversibly destruct ovarian follicles by causing DNA damage and induce massive germ cell apoptosis [3, 8].

Modern chemotherapeutic agents can have a spectrum of ovarian toxicity, depending on the class of the agent, patient age at the time of treatment, and the cumulative dose [4]. We have shown that the most gonadotoxic agents are those that mainly cause DNA double-strand breaks (DBSs) in oocytes [3]. DNA repair mechanisms can maintain genomic integrity in oocytes under normal circumstances. However, at the level of severe DNA damage due to genotoxic agents, those repair mechanisms remain insufficient and lead to apoptotic death of the oocyte [3]. Among all chemotherapeutic agents, the most gonadotoxic drugs are the members of the alkylating category such as cyclophosphamide [9]. Because these drugs are non-cell-cycle specific chemical compounds they can target and damage dormant primordial follicles that constitute ovarian reserve.

Although menstruation is a poor surrogate for ovarian reserve and fertility, using menstruation as an outcome in women with breast cancer who underwent chemotherapy researchers were able to demonstrate the negative impact of alkylating agents on ovarian function. For example, Gadduci *et al.* reported that after treatment with CMF protocol (cyclophosphamide + methotrexate + 5-fluorouracil) 20–70% of women younger than age 40 experienced

amenorrhea [10]. When CMF protocol was compared to the AC protocol (doxorubicin + cyclophosphamide), significantly lower rates of amenorrhea (69% vs. 34%, respectively) have been reported with the AC protocol [11]. This result is most likely associated with a lower cumulative dose of cyclophosphamide administered in the AC regimen. However, combination of a taxane agent (paclitaxel) with AC (AC-T) did not significantly increase the risk of amenorrhea compared with standard AC regimen [12].

Patient age at the time of chemotherapy is another critical factor that determines the nature of the ovarian response to the insult of the gonadotoxic agent. In women with breast cancer, the incidence of chemotherapy-induced amenorrhea was reported as 15–40% under the age of 30. However, this incidence dramatically increases to 49–100% for women older than 40 years of age [13]. This is because gonadotoxic chemotherapy regimens result in the loss of approximately 10 years' worth of ovarian reserve [14] and it is more likely to push older women towards the menopausal state as they have lower reserve compared to younger women. However, regardless of age, females of all ages including children are expected to experience early menopause after exposure to gonadotoxic chemotherapy agents. Therefore, fertility preservation and completion of the family building as early as possible is critical regardless of the age at chemotherapy exposure in most instances [15].

The Impact of BRCA Mutations on Ovarian Reserve

Mutations in *BRCA1* and *BRCA2* genes are well-known due to their association with the increased risk for multiple hereditary malignancies such as breast and ovarian cancers. *BRCA* genes are members of the ataxia-telangiectasia-mutated (ATM)-mediated DNA damage signalling pathway and are essential for DNA double-strand break (DSB) repair [16]. Moreover, in several studies, we followed by others showed that *BRCA*1 and *2* mutations are associated with diminished ovarian reserve [8, 17, 18]. In our recent report of controlled ovarian stimulation in women with breast cancer by using aromatase inhibitors for fertility preservation, we observed significantly lower ovarian response rates in *BRCA* mutation carries particularly, among those with *BRCA1* mutations [19]. In another study, *BRCA* mutation carrier women were found to experience menopause 3–4 years earlier than healthy controls [20]. Recently, we showed that in ovaries from both mouse and human with BRCA1 mutation the ovarian reserve was significantly reduced due to the increased age-related accumulation of DNA DBSs in primordial follicle oocytes. Additionally, we showed that affected women with *BRCA1* mutations had lower serum anti-Müllerian hormone (AMH) levels compared to controls [8]. In another very recent study, examining ovaries obtained from unaffected *BRCA* mutation carriers and age-matched organ donor cadavers, we provided direct evidence of diminished ovarian reserve and accelerated primordial follicle loss in both women with *BRCA1* and *2* mutations [21].

Based on the current evidence from animal and clinical studies, it appears that the ovarian reserve may be lower in women with BRCA mutations, and as we have shown recently, are more prone to chemotherapy-induced loss of ovarian reserve [22]. Hence, women with BRCA mutation should be informed about the possibility of higher risk of chemo-induced infertility and available fertility preservation options as well.

Table 8.6.2.1 Indications for fertility preservation in reproductive-age women

Benign conditions	Malignant conditions
• Benign ovarian diseases (endometrioma, benign ovarian tumours, etc.) • Haematological and autoimmune diseases that require chemotherapy or HSCT (SLE, sickle cell anaemia, rheumatoid arthritis, severe combined immunodeficiency syndrome, etc.) • Genetic conditions that can cause ovarian insufficiency *(BRCA 1* and *2* mutations, *FMR1* premutation, Mosaic Turner syndrome, etc.) • Conditions that can cause autoimmune oophoritis and ovarian insufficiency (polyglandular autoimmune syndrome type 1 and 2, SLE, pernicious anaemia, myasthenia gravis, viral infections, etc.) • Genetic conditions that can require prophylactic oophorectomy *(BRCA 1* and *2* mutations, *p53* mutation)	• Breast cancer • Hodgkin lymphoma • Non-Hodgkin lymphoma • Endometrial cancer • Uterine sarcomas • Cervical cancer • Ovarian cancer • Rhabdomyosarcoma • Tumours that require pelvic radiotherapy *(colorectal cancers, bladder cancer, cervical cancer, pelvic bone tumours, etc.)*

The Importance of Timely Referral and Intervention

As previously mentioned, OI can be caused by several intrinsic and external factors, and the rate of progression may vary from days to years depending on the underlying reason. Therefore, with early diagnosis patients can be given a chance to preserve their reproductive potential before complete loss of ovarian reserve. Accordingly, guidelines by the American Society of Clinical Oncology (ASCO) and the American Society of Reproductive Medicine (ASRM) for fertility preservation in cancer patients strongly recommend that physicians should inform their patients about the potentially harmful effects of the planned treatments on fertility before the initiation of it and promptly refer patients to reproductive specialist to discuss the risk of ovarian damage and currently available fertility preservation options [23, 24] (Table 8.6.2.1).

In a recent study, we have shown that in breast cancer patients, especially before breast surgery, early referral yields to retrieval of a more significant number of oocytes and embryos being cryopreserved for future fertility and reduced delay to the initiation of chemotherapy [25]. However, surveys evaluating the awareness of physicians regarding the fertility preservation reported that less than half of the oncologists in the United States always or often refer their cancer patients with fertility-related questions to fertility preservation specialist [26]. Fertility and ovarian endocrine health are important components of quality of life [27]. Hence, providing timely and accurate information about available fertility and ovarian preservation options for women of reproductive age with the risk of OI is critical before complete loss of the limited and irreplaceable ovarian reserve.

Current Options for Fertility Preservation

Embryo Cryopreservation

Embryo cryopreservation is a well-established fertility preservation option and currently offers the best chance of livebirth comparing to other fertility preservation options. However, embryo cryopreservation requires a partner or use of donor sperm. In one study, Frozen embryo transfer resulted in a clinical pregnancy rate of 60%, and around 34% live birth in infertility patients with mean age of 35.1 ± 4.03, which is comparable to that of fresh embryo transfer success rates [28]. In women with breast cancer with the mean age of 35.8 ± 4.1, we reported a live birth rate of 45%, which appeared to be superior to those undergoing frozen embryo transfer for infertility [29]. With the utilization of preimplantation genetic screening, the live birth rates can increase up to 77% per embryo transfer in women with average age of 36.7 [28–43] after transfer of euploid frozen-thawed embryos [30].

Oocyte Cryopreservation

For post-pubertal girls and women who do not have a partner or wish to use donor sperm due to legal, ethical or religious considerations, cryopreservation of mature oocytes is an established fertility preservation option. An adequate number of oocytes can be collected following approximately 10–12 days of controlled ovarian hyperstimulation treatment, and mature oocytes can be successfully cryopreserved using a vitrification method. With increasing experience and further advances in cryopreservation methods, fertilization, and pregnancy success rates for frozen-thawed oocytes have approached to those with fresh oocytes in young patients, though success rates with frozen embryos may still be better [31]. We have performed an individual patient data meta-analysis where we calculated age-based success rates for women undergoing egg freezing. Based on this publication we created an online success rate estimator [32]. This estimator can be found at this website link (http://www.fertilitypreservation.org/contents/probability-calculator) and may be useful for counselling patients on egg freezing.

Immature oocytes can also be obtained from patients who cannot undergo ovarian stimulation due to lack of time and even at the time of ovarian tissue harvesting for fertility preservation. Those oocytes can be successfully matured through *in vitro* maturation (IVM) procedure and subsequently cryopreserved. Performing IVM for immature oocytes before cryopreservation rather than post-thaw also results in significantly higher maturation and survival rates [33]. Recently, livebirths following the use of IVM in patients with infertility has been reported; however, it is still an experimental fertility preservation method limited to a number of fertility centres [34].

Controlled Ovarian Hyperstimulation Protocols for Women with Oestradiol-Sensitive Cancer

Controlled ovarian hyperstimulation (COH) can provide development and collection of a considerable number of oocytes in a single treatment cycle and yield multiple embryos for fertility preservation. On the other hand, the growth of numerous follicles at the same time results in elevated circulating oestradiol levels, which is considered unsafe in patients with oestradiol-sensitive cancers. For those patients, we have developed safer ovarian stimulation protocols using tamoxifen and aromatase inhibitors such as letrozole. These medications possess a dual pharmacological effect of stimulating ovarian follicle development and reducing serum oestradiol level concurrently. Use of tamoxifen alone for ovulation induction or in combination with low dose gonadotropins yielded significantly higher numbers of mature oocyte and embryo compared to natural cycle IVF [35, 36].

Likewise, letrozole in combination with gonadotropins can produce comparable outcomes to conventional COH while providing significantly lower oestradiol levels and decreased gonadotropin requirements [37]. We further showed that the letrozole-gonadotropin protocol in breast cancer patients was not associated with an increase in recurrence after short- and mid-term follow-up [38, 39]. Hence, these protocols can be safely utilized for fertility preservation in patients with oestradiol-sensitive tumours.

As COH typically requires 10–12 days of treatment, the delay in the initiation of adjuvant or neoadjuvant chemotherapy is may be of concern. However, studies in breast cancer have shown that initiation of chemotherapy can be delayed up to 12 weeks after breast surgery without any adverse effect on survival and recurrence rates [40, 41].

Random-Start Controlled Ovarian Hyperstimulation

Controlled ovarian stimulation for oocyte/embryo cryopreservation is traditionally initiated after menses at the beginning of the follicular phase. However, this approach may require 2–4 weeks to start ovarian stimulation depending on the patients' menstrual cycle phase at the time of the presentation and cause up to 6 weeks of delay in the initiation of cancer treatments. Recently, studies have shown that there are multiple major follicle recruitment waves during a normal menstrual cycle [42]. Based on this ovarian biological fact, we introduced an ovarian stimulation approach which we named 'random-start ovarian stimulation' [43]. Our and others' studies have shown that ovarian stimulation can be initiated any time during the menstrual cycle, without reducing the yield of oocytes and embryos [43, 44]. Random-start COH offers an effective strategy for emergency fertility preservation by eliminating the long delays for cancer treatments.

Ovarian Tissue Cryopreservation and Transplantation

Oocyte and embryo cryopreservation are currently considered as established methods of fertility preservation by the American Society of Clinical Oncology (ASCO) and the American Society of Reproductive Medicine (ASRM). However, these methods usually require on average 10–12 days of COH treatment to obtain mature oocytes. Women who do not have sufficient time for ovarian stimulation cannot benefit from these options. Moreover, controlled ovarian stimulation is not an appropriate strategy for prepubertal girls. In that instance, the only available approach other than immature oocyte retrieval and *in vitro* maturation is ovarian tissue harvesting and cryopreservation for future transplantation [45].

Cryopreservation of ovarian tissue before the initiation of gonadotoxic treatments enables preservation of a large number of primordial follicles embedded in ovarian cortex. This procedure can be done at any age and at any time of the menstrual cycle without the need for ovarian stimulation [46]. Typically, one ovary is harvested via a simple laparoscopic outpatient procedure. The cortical tissue is then separated from stroma and cut into small pieces and cryopreserved using cryoprotectants and slow freezing methods

[47]. Even though there are some encouraging data on ovarian vitrification, the clinical experience is very limited. When the patient is cured of her disease and desires having a child, the tissues are thawed and autotransplanted via minimally invasive surgical approaches including robotic technology [48, 49]. While the primary purpose of ovarian tissue cryopreservation and transplantation is restoring fertility, this approach has also been used for restoration of endocrine function, potentially resolving menopausal symptoms, and improving the quality of life [50].

Although ovarian tissue cryopreservation and subsequent autotransplantation has previously been considered an experimental fertility preservation method, there have been more than 130 live births with 37.7% of live birth rate after ovarian transplantation since the first case reported by our group [51–54]. As a result of improving success rates, a number of countries and the American Society of Reproductive Medicine in the United States have removed ovarian tissue freezing from experimental category [55].

Despite the concern of reintroducing malignant cells along with ovarian tissue in patients with a history of cancer, studies showed no evidence of cancerous cells in cryopreserved ovarian tissues from non-metastatic breast cancer patients and those with bone and soft tissue tumours [56]. However, in haematological malignancies there is the possibility of the presence of malignant cells in cryopreserved ovarian tissue. Even though clinical significance of this is unknown, patients should be informed about the potential risks, and the ovarian tissue should be carefully examined for malignant cells before proceeding with transplantation [57]. Furthermore, in the instance of leukaemias, the initial induction chemotherapy is generally non-gonadotoxic and does not require fertility preservation. However, fertility preservation is required before these patients receive high dose alkylating agents with or without total body irradiation to precondition before haematopoietic stem cell transplantation. At that point however, the patient is typically in remission and there are no circulating cancer cells. In fact, xenografting studies showed that, leukaemia cells are not present or transmitted via transplantation from ovarian tissue samples obtained from patients who are in remission [58]. Hence in general, the risk of reseeding of cancer cells and causing a relapse by ovarian autotransplantation is low, limited to few case scenarios, and currently theoretical.

The Use of Gonadotropin-Releasing Hormone (GnRH) Analogues for Ovarian Protection

Recently, few randomized studies in women with breast cancer suggested a beneficial effect of gonadotropin-releasing hormone analogues (GnRHa) against chemotherapy-induced damage [59, 60]. However, those studies were marred by numerous issues including the use of unreliable markers such as menstrual status, lack of placebo or blinding, and lack of correction for the difference in desire to conceive between study and control groups [61, 62]. Because irregular or even regular menstrual periods can be observed in patients with occult OI, menstrual status cannot be accepted as a surrogate for ovarian reserve. Currently, the most reliable ovarian reserve marker is AMH, and when it was used with serum follicle-stimulating hormone (FSH) level for defining ovarian failure, studies showed no benefit from GnRHa treatment in cancer patients [63, 64]. Among the several concerns raised against this hypothesis, the major concern is that primordial follicles that constitute the ovarian reserve are quiescent and do not express receptors for gonadotropins or GnRH analogues [65]. Therefore, manipulation of serum gonadotropin or GnRH levels has no plausible direct or indirect effect on primordial follicles [66]. Another critical concern is that gonadotoxic drugs such as cyclophosphamide induce primordial follicle death by causing DNA DBSs in oocytes in a non-cell cycle-dependent fashion; hence there is no mechanism for ovarian suppression by GnRHa to prevent chemotherapy-induced DNA damage in oocytes [2, 3, 8]. Moreover, gonadal suppression using GnRHa induces a hormonal state similar to the prepubertal stage, and if ovarian suppression were to be protective, children of prepubertal age would be resistant to gonadotoxic effects of chemotherapy. However, thousands of female children experience endocrine issues and gonadal failure following treatments with chemotherapeutic agents [2]. Based on these facts, the use of GnRHa for the prevention of ovaries from chemotherapy

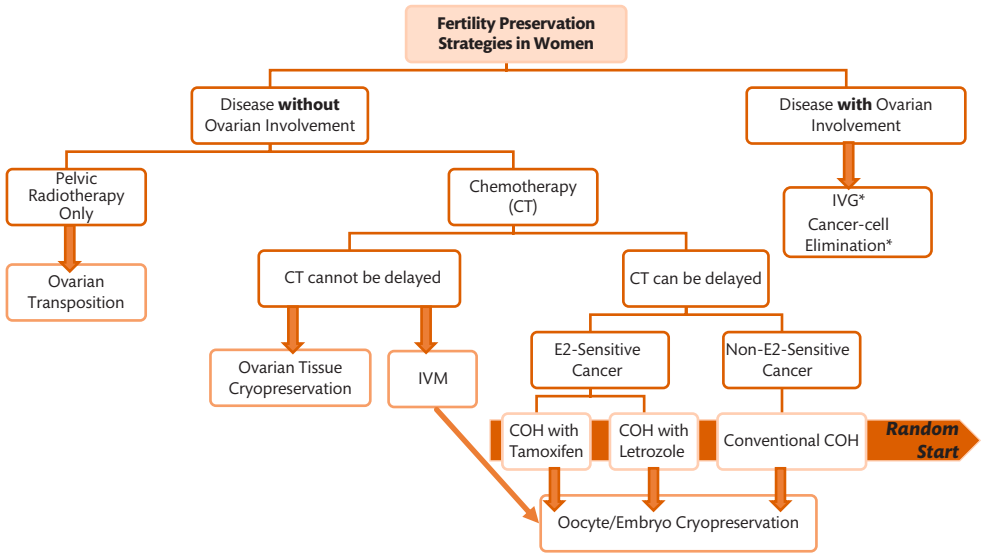

Figure 8.6.2.1 Fertility preservation strategies in women under the risk of ovarian insufficiency. Symbol (*) represents currently theoretical and experimental methods based on animal data. COH, controlled ovarian stimulation; E2, oestradiol; IVG, *in vitro* growth; IVM, *in vitro* maturation.

damage is still controversial and should not be recommended as an effective method of fertility preservation.

Conclusion

Fertility preservation is a rapidly developing field with an increasing pace of advancements in understanding ovarian physiology and cryobiology, and new surgical techniques using minimally invasive approaches. It is becoming a crucial part of cancer survivorship and an essential aspect of comprehensive women's healthcare [67]. Fortunately, there are several non-experimental treatment options including embryo, oocyte, and ovarian tissue cryopreservation, and other emerging ones such oocyte *in vitro* maturation [55, 68–70] (see Figure 8.6.2.1). In order to maximize the benefits from these available options and improve the quality of life, timely referral to fertility preservation counselling should be an integral part of the medical care of reproductive age women.

8.7

Hormonal Contraception

8.7.1 Hormonal Contraception

Jennifer Chin and Bliss Kaneshiro

Introduction

The first widely used hormonal contraceptive, the birth control pill, became available in the 1960s. Hormonal contraception revolutionized the way society views reproduction, sexuality, and the link between the two. For the first time in history, women with access to the birth control pill could determine when and if they had children. This ability to separate sex from childbearing led to the sexual revolution and brought reproductive rights into focus. The ability to plan pregnancy is now regarded as one of the most importance public health successes of the 20th century. Family planning services more than triple the savings of public funding spent on care for pregnant mothers and newborns [1].

Hormonal contraception has two main categories: combined hormonal contraceptive methods which contain both oestrogen and progestin, and progestin-only methods. With both categories, progestin creates the main contraceptive effect, while the oestrogen mainly helps with bleeding regulation through stabilization of the endometrial lining [2]. Combined hormonal contraceptives are available as an oral pill, an injectable, a vaginal ring, and a transdermal patch. Progestin-only methods are available as an oral pill, an injectable, a subdermal implant, and an intrauterine device (IUD).

All methods have a low risk profile, especially when compared to the health risks of pregnancy. The World Health Organization (WHO) developed criteria that clinicians can use to assess the appropriateness of different methods for patients with specific medical conditions. The WHO Medical Eligibility Criteria assigns contraceptive methods a score ranging from one to four depending on a patient's medical condition: 1 means no restrictions on use of the method; 2 means advantages generally outweigh the risks; 3 means the risks generally outweigh the benefits; and 4 means the risk is unacceptable and another method should be used. This system is based on an extensive review of the medical literature and, when evidence is lacking, expert opinion [3]. Throughout this chapter, efficacy will be explained as typical-use failure rate. Researchers have derived typical-use failure rates from data exploring how most women take the prescribed method and have calculated the risk of pregnancy based upon those patterns. Providers should use typical-use rates, rather than perfect-use rates, which assumes a woman takes a contraceptive method with perfect compliance, when counselling patients regarding efficacy.

Many methods have non-contraceptive benefits. These include the treatment of endometriosis, adenomyosis, dysmenorrhoea, abnormal uterine bleeding, and acne. Specific methods also can reduce the risk of certain cancers. These benefits will be described in detail throughout the chapter.

Progestin-Only Methods

Progestin-only methods do not contain oestrogen and thus do not incur the thromboembolic risks associated with oestrogen. These methods have few absolute contraindications and are generally safe for most women including those with comorbidities. Additionally, both the subdermal implant and the IUD are among the most effective types of hormonal contraception. Because little needs to be done beyond insertion for a woman to be compliant with an IUD or implant, the typical-use failure rate of 0.1% approaches the perfect-use failure rate [4].

Intrauterine Devices

IUDs are now the most widely used type of long acting reversible contraception worldwide [4]. Current IUDs are safe and have few contraindications as shown in **Box 8.7.1.1**. Though we focus our discussion on levonorgestrel IUDs, copper IUDs are also highly effective at pregnancy prevention and are an ideal option for women seeking emergency contraception and those unable to take exogenous oestrogen or progestin.

Levonorgestrel IUDs vary in the amount of levonorgestrel released daily and in size of the device. All have a T-frame though some of the newer levonorgestrel IUDs boast flexibility in the size of the arms of the IUD. Levonorgestrel IUDs work by thickening the cervical mucus making it impenetrable to sperm [5]. Approximately 50–75% of women continue to ovulate [6]. The primary mechanism of action of the levonorgestrel IUD does not involve interrupting implantation after fertilization has occurred [7].

The progestational effect results in less frequent and lighter menses. After the first three to six months of use, most women experience light periods or amenorrhea. Levonorgestrel IUDs are 99.9% effective at pregnancy prevention and have a 1-year continuation rate of 81% [8]. Return to fertility after removal is immediate [9]. The 52-mg levonorgestrel IUD is currently marketed for use up to 5 years, though recent studies suggest efficacy up to 7 years [10]. The 52-mg levonorgestrel IUD initially releases 19.5 mg of levonorgestrel which declines to approximately 10 mcg/day after 5 years [11, 12]. The 13.5-mg levonorgestrel IUD is smaller than the 52-mg levonorgestrel IUD (28 mm × 30 mm vs. 32 mm × 32 mm) and provides contraception for up to 3 years. It initially releases 14 mcg of levonorgestrel per day which declines to 5 mcg/day at 3 years [11]. The 19.5-mg levonorgestrel IUD is effective for up to five years and measures 28 mm × 30 mm. It initially releases 17.5 mcg/day which declines to 7.4 mcg/day at 3 years [11]. The devices with a lower levonorgestrel content do not result in amenorrhea as commonly as the 52-mg levonorgestrel IUD.

The IUDs have an excellent safety profile. At the time of insertion, the risk of perforation is less than 1% [13]. It is a common misconception that IUDs cause pelvic inflammatory disease (PID) and ectopic pregnancy. Patients are not at increased risk of PID outside of the first 20 days of insertion, and even within this time frame, the risk is less than 1% [14, 15]. Antibiotics are not indicated at the time of IUD insertion [15]. Screening for sexually transmitted infections (STI) prior to IUD placement has not been shown to be of benefit [16]. Even if a woman ultimately screens positive for chlamydia or gonorrhoea, the risk of upper genital infection with IUD insertion is low with absolute risk of 0–5% for those with an STI and 0–2% for those without [17]. In symptomatic women, testing and treatment should occur prior to IUD insertion.

If a woman is diagnosed with PID with an IUD in situ, patients may opt to start treatment with the IUD in place and proceed with removal only if they do not clinically improve after 48 to 72 hours [16]. In terms of ectopic pregnancy, IUDs decrease the risk of both intrauterine and ectopic pregnancy; however, if a pregnancy does occur with the IUD in place, it is more likely to be an ectopic pregnancy.

The postpartum period is an excellent time to address long-acting reversible contraceptives (LARC) methods. IUDs can be inserted anytime postpartum; however, certain times incur more risks of expulsion than others. Providers should discuss and offer to interested patients immediate post-placental placement of IUDs during antenatal visits [18]. Although the expulsion rate is higher with immediate post-placental placement compared to placement at six weeks postpartum (10–27% vs. 3%), studies have shown that the cost:benefit ratio favours post-placental placement, especially in instances where postpartum follow-up may be difficult. Continuation rates with post-placental placement are as high as 85% after 12 months [19]. Two separate studies found an increased risk of perforation with post-placental IUD placement in breastfeeding women and in women who delivered at or less than 36 weeks of gestation [3].

Historically, clinicians preferred to insert the IUD at the start of menses so they could be assured the patient was not pregnant. Insertion was thought to be easier at the time of menses, though no studies have demonstrated that this is the case. More recent studies show a higher rate of expulsion with insertion at the time of menses [20]. Current recommendations state IUDs can be inserted as long as a clinician is reasonably certain a woman is not pregnant [21].

After IUD insertion, women do not need a routine follow-up visit; however, they should be advised to return at any time to discuss side effects or different methods if they are dissatisfied. At routine gynaecologic visits, providers can check IUD strings and women can palpate their own IUD strings periodically if they desire. Failure to visualize or palpate strings could be a sign of expulsion or perforation, though most of the time, the IUD will be in the uterus with the strings pulled into the cervix. Pelvic ultrasound can determine intrauterine IUD placement when strings cannot be identified. If the IUD is not visualized on ultrasound, and a patient does not recall expulsion, an abdominal X-ray can be used to determine if a perforation has occurred.

Satisfaction with the IUD requires proper counselling about the bleeding profile after insertion. Irregular spotting and bleeding are common in the first 3 to 6 months after insertion. Approximately 40% of women become amenorrhoeic after placement of the 52-mg levonorgestrel IUD [22, 23] and providers should counsel women that amenorrhea while using a hormonal IUD is common and not harmful.

Box 8.7.1.1 WHO medical eligibility criteria contraindications to levonorgestrel IUD insertion (category 4 or risk is unacceptable)

- Pregnancy
- Puerperal sepsis
- Immediate post-septic abortion
- Gestational trophoblastic disease (persistently elevated beta hCG levels or malignant disease)
- Cervical cancer (do not place IUD but may continue use if already in)
- Endometrial cancer (do not place IUD but may continue use if already in)
- Current breast cancer
- Uterine fibroids with distortion of the uterine cavity
- Distorted uterine cavity that is incompatible with IUD insertion
- Current infection (once treated, no longer a contraindication)
- Pelvic tuberculosis

Data from World Health Organization. Medical Eligibility Criteria for Contraceptive Use. Fifth Edition, 2015. Available at http://www.who.int/reproductivehealth/publications/family_planning/MEC-5/en/ Retrieved 15 May 2018.

The IUD offers many non-contraceptive benefits in addition to being a highly effective contraceptive. Because most women will experience lighter bleeding and some will experience amenorrhea, it is an effective treatment for dysmenorrhoea due to endometriosis and heavy bleeding due to adenomyosis [24–27]. Due to its progestational effect on the endometrium, it has been described as a treatment for endometrial hyperplasia and for endometrial protection in the setting of tamoxifen use or postmenopausal oestrogen therapy [28–30].

Implants

The first widely utilized contraceptive implant was a levonorgestrel implant comprised of six separate silicone capsules, each containing 36 mg of levonorgestrel. It was effective for up to seven years in normal weight women. Removal could be difficult because of the number of capsules and it was phased out of production by 2008 and replaced by a two-rod levonorgestrel implant that is used in many parts of the world today. The two rods are 43 mm long, contain a total of 75 mg of levonorgestrel, and provide contraception for up to five years.

A single 4 cm rod containing 68 mg of etonogestrel, the active metabolite of desogestrel, is also available. The etonogestrel implant is marketed for use up to 3 years; however, more recent studies have shown efficacy for up to 5 years [31]. The contraceptive implant does not increase the risk of osteopenia, osteoporosis, or fracture [32, 33].

Contraceptive implants are highly effective with a 1-year typical-use failure rate of 0.09% for the etonogestrel implant and 0.1% for the levonorgestrel implant [34]. After 2 years, 82% of women will continue to use this method [35]. The implant effectively prevents ovulation, though it also thickens cervical mucus and thins the endometrium [4]. Return to fertility with discontinuation is rapid with 90% of women ovulating within 3 weeks after removal [34].

Providers should counsel patients that a common side effect is irregular, unpredictable bleeding, which, unlike the IUD, generally does not improve over time. Though bleeding is rarely heavy, it is unpredictable which can lead to dissatisfaction [36].

Older versions of this implant could not be visualized on X-ray though the most current version of the etonogestrel implant is impregnated with barium sulphate. Providers can now use computed tomography, ultrasound, X-ray, or magnetic resonance imaging to visualize non-palpable implants. When the implant is not easily palpated, ultrasound guidance can be used to assist with removal. Consult with a surgeon familiar with the anatomy of the arm is also helpful.

Injectable Contraception

Injectable medroxyprogesterone (DMPA) was first used in 1967 and consists of a 150 mg intramuscular dose of medroxyprogesterone that is administered every 12 weeks. A 104 mg subcutaneous dose is also available. DMPA provides contraception by inhibiting ovulation, while also thickening the cervical mucus and thinning the endometrium. After 1 year of use, 50% of women will develop amenorrhea and 80% develop amenorrhea within 5 years [35]. Though many women experience unscheduled bleeding with early injections, the frequency and duration of unscheduled bleeding decreases with continued use. Supplemental oestrogen, cyclooxygenase-2 inhibitors, or mifepristone have been used to treat unscheduled bleeding with DMPA though expectant management is most commonly used [37, 38]. DMPA has a 10-year continuation rate of 23% and typical-use failure rate of 6% in the first year [35]. Compared to other methods, return to fertility with DMPA is not immediate. The average time to the resumption of normal cycles is 6 to 8 months for patients. For the subcutaneous formulation, the return to fertility is a median of 7 months with 97% of patients returning to baseline fertility after 1 year [39].

Clinicians can start patients on DMPA at any time they are reasonably certain a patient is not pregnant. However, if a patient has a negative urine pregnancy test on the day of the visit but does not meet the criteria to ensure she is not pregnant, clinicians can administer DMPA with counselling regarding the possibility of a very early pregnancy and a delay in the diagnosis of pregnancy. No studies demonstrate teratogenicity of DMPA [40]. The only absolute contraindications to DMPA are known current pregnancy and breast cancer.

Concerns about temporary decreases in bone mineral density should not limit the use or duration of use of DMPA. Inhibition of gonadotropins causes a reversible decline in bone mineral density by 3–6% after 2 years of use. However, studies have shown that this loss does not continue after two years of use and is similar to the loss experienced during breastfeeding or the postpartum period. A year after discontinuation of DMPA, previous bone mineral densities are the same as non-users [41]. Providers should carefully weigh these potential risks against the negative consequences of an unintended pregnancy and should not limit use or duration of use [42]. Patients already prone to low bone density, including heavy smokers, patients with anorexia, amenorrhoeic athletes, or chronic steroid users, should use DMPA with caution. Providers should counsel all patients using DMPA on appropriate calcium intake, regular exercise, and smoking cessation. Routine monitoring of bone mineral density is not required.

Providers and patients also worry about the weight gain associated with DMPA use. Studies have had conflicting results as to whether DMPA truly causes weight gain. One randomized trial did not note significant weight gain with DMPA use [43]. Observational studies have reported overweight and obese adolescents gain more weight when using this method than when using no contraceptives or oral contraceptive pills [44–47].

DMPA has many unique non-contraceptive benefits. Unlike combined hormonal contraceptives, DMPA is unaffected by concomitant antiseizure medications and raises the seizure threshold [48]. In patients with sickle cell anaemia, DMPA stabilizes the red cell membrane and significantly decreases menstrual blood loss [49]. Due to the high rate of amenorrhea, DMPA is also effective for achieving amenorrhea and in treating conditions such as heavy menses, dysmenorrhoea, endometriosis, and ovarian cyst formation [50, 51].

Progestin-Only Pill

For patients who desire a birth control pill but are unable to take oestrogen, progestin-only pills, consisting of 0.35 mg of norethindrone

taken daily, are a good option. Typical-use failure rates are 9%, which is higher than other progestin-only methods [9]. The main mechanism of action is thickening of cervical mucus, so sperm do not pass into the uterus. Progestin-only pills also decrease tubal motility and thin the endometrial lining. Thickening of the cervical mucus happens approximately two to four hours after the pill is taken and lasts for about 22 hours. Patients need to take the pill at the same time every day. Taking a pill more than 3 hours late results in decreased efficacy and women should use a backup method for 48 hours [35]. Return to fertility is rapid due to the short-term effects of the progestin-only pill. Sixty per cent (60%) of women continue to ovulate while taking the progestin-only pill and 40–50% retain normal menstrual cycles. A new pill containing 4 mg of drospirenone works by inhibiting ovulation.

Absolute contraindications include breast cancer and known pregnancy though inadvertent administration during pregnancy does not result in teratogenicity. The progestin-only pill has diminished efficacy in those taking rifampin, phenytoin, carbamazepine, barbiturates, primidone, topiramate, oxcarbazepine, and St. John's Wort as these medications increase hormone metabolism [35].

Combined Hormonal Contraception

The first oral contraceptive pill was developed in 1957 for menstrual disorders and contained 150 mcg of mestranol and 9.85 mg of norethynodrel. In 1960, this hormonal combination became available to women for contraception. Over time, the oestrogen dose in pills has decreased and new progestin and oestrogen formulations have been developed. Combined hormonal contraception is now available as a pill, patch, ring, or injection.

All combined hormonal contraceptives work primarily by inhibiting ovulation. They also thicken the cervical mucus and thin the endometrium. The typical-use failure rate is approximately 9% [9]. Return to fertility is rapid with most women ovulating one to two weeks after discontinuing combined hormonal contraceptives. Combined hormonal contraceptives can provide multiple non-contraceptive benefits including reduced bleeding, decreased pain from dysmenorrhoea or endometriosis, regulating anovulatory cycles and improvement in acne.

The risks of combined hormonal contraceptives are associated with the thrombotic effects of the oestrogen component of the pill. The first reported thrombotic event associated with oral contraceptive pill use occurred in 1961 in a patient taking a 150 mcg mestranol pill for endometriosis. Newer formulations of oral contraceptive pills today have much lower oestrogen dose and thus the risk for thromboembolic events has greatly decreased. Overall, the risk is 2–3 per 10 000, lower than the risk of thromboembolism during pregnancy of 6 per 10 000. Absolute contraindications are listed in **Box 8.7.1.2**. Relative contraindications include women who smoke and are less than 35 years old, chronic hypertension that is adequately controlled with medication or with blood pressures<160/100, diabetes mellitus without vascular disease, connective tissue disorders, migraines without aura, and gallbladder disease [3].

Oral Contraceptive Pills

Combined hormonal oral contraceptive pills are easy to initiate, are safe and effective, and have many non-contraceptive benefits [52].

Box 8.7.1.2 WHO medical eligibility criteria contraindications to combined hormonal contraception (category 4)

- Less than 6 weeks postpartum in breastfeeding women
- Less than 21 days postpartum in women with risk factors for Venous Thromboembolism
- Smoking and age 35 or older
- Multiple risk factors for cardiovascular disease (e.g. older age, smoking, diabetes, hypertension, known dyslipidaemias)
- Systolic ≥160 or diastolic ≥100 mmHg
- Hypertension with vascular disease
- History of or acute deep venous thrombosis or pulmonary embolism
- Major surgery with prolonged immobilization
- Known thrombogenic mutations
- Current and history of ischaemic heart disease
- Stroke
- Complicated valvular heart disease
- Positive antiphospholipid antibodies
- Migraine with aura
- Migraine without aura, 35 years of age or older (may continue but should not initiate)
- Current breast cancer
- Diabetes with nephropathy, retinopathy, neuropathy, or any vascular disease or diabetes of 20 years' duration or more
- Liver disease including acute viral hepatitis, severe decompensated cirrhosis, hepatocellular adenoma, malignant hepatoma

Data from World Health Organization. Medical Eligibility Criteria for Contraceptive Use. Fifth Edition, 2015. Available at http://www.who.int/reproductivehealth/publications/family_planning/MECguidelinePart-2.pdf. Retrieved 15 May 2018.

Because of these qualities, they are one of the most commonly used contraceptive methods [4]. Traditionally, providers told women to start taking their pills on the next Sunday after their next menstrual period. Quick start, where a woman starts the pill the day she receives it and uses a backup method for the first seven days is an easy way to initiate the oral contraceptive pill. Quick start ensures that patients do not delay initiating a contraceptive method and does not increase the risk of breakthrough bleeding as compared to the other start methods [35]. Although oral contraceptive pills are easy to initiate and prescribe, women must remember to take the pill regularly [53]. The WHO has published guidelines on how to manage missed oral contraceptive pills as shown in **Box 8.7.1.3**.

Commonly prescribed low dose pills contain 20–35 mcg of ethinyl oestradiol and a progestin. Studies have shown similar efficacy, side effects, and safety profiles between these oestrogen doses [35]. Epidemiologic studies have classified generations of oral contraceptive pills based on their amount of oestrogen and the type of progestin used. First generation pills contain 50 mcg or more of ethinyl oestradiol and are not commonly used anymore. Second generation pills contain either levonorgestrel, norgestimate, or other types of norethindrone. Third generation pills contain desogestrel or gestodene. Fourth generation pills contain drospirenone. When the third and fourth generation pills were introduced, there was initially concern for a higher risk of thromboembolic events. However, prospective cohort studies reveal a similar risk for thrombotic events with different pills suggesting the findings in case–control studies, which suggested an elevated risk, were likely due to prescribing biases [54–56].

Most oral contraceptive pills contain 21 days of hormone and seven days of placebo; women have a week of bleeding related to hormonal withdrawal. Newer pills shorten this placebo time to

Box 8.7.1.3 Missed combined oral contraceptive pills

30–35 μg ethinyl oestradiol pills: Missed 1–2 hormonal pills or starts a pack 1–2 days late

20 μg ethinyl oestradiol pills: Missed 1 active pill or starts a pack 1 day late

- Take hormonal pill as soon as possible an continue taking one pill a day (will take 2 pills on the day she realizes she has missed a pill)
- Continue taking one pill a day
- No need for back up contraception

30–35 μg ethinyl oestradiol pills: Missed 3 or more hormonal pills or starts a pack 3 or more days late

20 μg ethinyl oestradiol pills: Missed 2 active pills or starts a pack 2 or more days late

- Take active pill as soon as possible
- Continue taking one pill a day
- Use back up contraception until she has taken hormonal pills for 7 days in a row
- If pills are missed in the 1st week, consider emergency contraception
- If pills are missed in the 3rd week, take active pills in current pack and start the next pill pack instead of taking inactive pills

Data from World Health Organization. Selected Practice Recommendations for Contraceptive Use. Second edition, 2015. Available at http://apps.who.int/iris/bitstream/handle/10665/252267/9789241565400-eng.pdf?sequence=1. Retrieved 15 May 2018.

three to four days resulting in a shorter, lighter period. A shorter placebo week results in lower contraceptive failures due to a lower risk of follicular development and subsequent ovulation [53]. Formulations have varied the amount of hormone throughout the cycle to mimic the fluctuations in hormone levels during a regular menstrual cycle. Both biphasic and triphasic patterns exist, but neither have shown any difference in efficacy or side effect profile.

Having a monthly withdrawal bleed while on hormonal contraceptives does not have a biological benefit. For patients who prefer not to bleed monthly or are taking oral contraceptives for heavy menses, anaemia, dysmenorrhoea, premenstrual syndrome, endometriosis, or menstrual migraines, continuous or extended dosing is a good option [35]. In extended dosing, women take hormonally active pills for several months without taking the placebo pills thereby postponing a hormonal withdrawal bleed. With continuous dosing, women take hormonally active pills indefinitely. With continuous and extended administration, women may experience more breakthrough bleeding and spotting which will improve over time. After discontinuation, women will return to the same pattern of menses they experienced prior to initiating the contraception.

Contraceptive Patch

The contraceptive patch is formulated as a transdermal patch that is worn for one week at a time for three weeks and then removed for a hormone free week to permit a withdrawal bleed. Each 4.5 cm square patch delivers 20 mg of ethinyl oestradiol and 150 mcg of norelgestromin daily. The patch can be applied on the lower abdomen, buttocks, upper outer arm, or upper torso (except for the breasts). The patch provides contraceptive effect for up to nine days though women are instructed to change the patch every seven days. Efficacy is similar to oral contraceptive pills, though studies suggest a higher failure rate in women weighing over 90 kg. Side effects unique to the patch include partial detachment of the patch, complete detachment, skin irritation, and pigment changes under the site of the patch [57]. When compared to oral contraceptive pills, women on the patch are more likely to experience nausea, breast discomfort, and headaches [35]. These side effects are more pronounced when women use the patch in a continuous fashion [58–61].

Contraceptive Ring

Contraceptive rings are placed in the vagina where oestrogen and progestin are absorbed through the vaginal mucosa. Different contraceptive rings provide anywhere from 1 week to 1 year of contraception [4]. The etonogestrel vaginal ring is a flexible ethylene vinyl acetate copolymer that releases 15 mcg of ethinyl oestradiol and 120 mcg of etonogestrel daily. It is 5.4 cm in diameter and 4 mm in thickness. The ring provides adequate contraceptive hormone for up to 5 weeks though women are instructed to leave the ring in place for 3 weeks and then remove it for 1 week to allow for a withdrawal bleed. While it is not recommended that patients remove the ring regularly, they can do so for up to 3 hours with no decrease in efficacy.

In contrast to the pill and the patch, the ring releases relatively low constant levels of hormone and thus results in fewer oestrogen-related side effects and breakthrough bleeding. While the ring may cause more discharge, vaginal flora and cervical cytology are not affected [62]. Women should dispose of their ring in a sealed plastic bag in order to minimize hormone leakage into the environment.

Combined Hormonal Contraceptive Injection

Although not widely utilized outside of Asia and Latin America, a monthly combined hormonal contraceptive injection is available. The injection contains 25 mg of medroxyprogesterone acetate and 5 mg of oestradiol or 150 mg of dihydroxyprogesterone acetophenide and 10 mg of oestradiol enanthate. In comparison to DMPA, patients have a quicker return to fertility and have less irregular bleeding. An automatic device for self-administration is available which may improve compliance by eliminating the need for monthly follow-up [63].

Emergency Contraception

Providers should counsel all patients about emergency contraception, when it is needed, and how it can be obtained. Although not a hormonal contraceptive, the most effective emergency contraceptive is the copper IUD. Trained providers can insert the copper IUD for up to five days after unprotected intercourse and it has the added benefit of providing long-term contraception.

Levonorgestrel emergency contraception consists of one dose of 1.5 mg dose of levonorgestrel which delays or inhibits ovulation [64, 65]. This method can be taken within 120 hours of unprotected intercourse, though efficacy is higher the sooner it is taken. Ulipristal acetate, a selective progestin receptor modulator, has higher efficacy in pregnancy prevention upto 120 hours after unprotected

intercourse. Ulipristal acetate is also more effective in overweight and obese women and is thus the preferred method over levonorgestrel emergency contraception for women with a body mass index (BMI) over 25. Because ulipristal acetate is a progestin receptor modulator, it may reduce the efficacy of other hormonal contraceptives and thus women should use either abstinence or a non-hormonal method of contraception for the first seven days after using ulipristal acetate [35].

Cancer Risk Reduction

One of the unanticipated results of long-term hormonal contraceptive use has been its role in cancer risk reduction. The type of long-term studies that can demonstrate a reduction in cancer have only been done with the combined oral contraceptive pills though similar effects are suspected with the contraceptive patch and the ring.

Combined hormonal contraceptives significantly decrease the risk of ovarian cancer. This is most likely due to a reduction in ovulation which decreases the inflammatory and reparative process that normally occurs during each cycle. DMPA has not been shown to provide the same effect although it also prevents ovulation [66]. Even among women who use combined oral contraceptives for as little as 3 to 6 months, a reduction in ovarian cancer protection was noted up to 20 years after discontinuation [67]. In patients who use oral contraceptive pills for less than 10 years, their risk of ovarian cancer is reduced by 40% and this reduction is doubled if used for more than 10 years [68–71]. This is particularly helpful for women with a strong family history of ovarian cancer, and studies have shown that for these women, the use of oral contraceptive pills can reduce their risk to that of the general population [72].

Because all hormonal contraceptives thin the endometrial lining and prevent cyclical growth and shedding, they all decrease the risk of endometrial cancer [73, 74]. After using combined hormonal contraceptives for four years, the incidence of endometrial cancer is reduced by 56% and further drops by 72% after 12 years [75–77]. For DMPA, the risk is reduced by 80% and extends for 8 years after discontinuing DMPA [78].

Facilitating Contraceptive Use

The goal of contraceptive counselling is to provide women with education about contraceptive options so that they can select a method that best fits their individual needs and desires for childbearing. Though effectiveness is an important aspect of each method, it may not be the most important contraceptive characteristic for a particular woman. Providers should respect a woman's reproductive desires which include the option of not using or discontinuing a contraceptive method.

Providers should ensure that all women have access to safe, appropriate, hormonal contraception if they desire it. Removing barriers to contraception includes using quick start and providing methods, including IUDs and implants, on the same days as contraceptive counselling. Overcoming systemic barriers including increasing health insurance coverage for all women and training an adequate number of clinicians skilled in contraceptive counselling is also important.

The WHO has created guidelines as to what is required of a clinician before initiating different methods of contraception. For the hormonal contraceptives, with the exception of IUDs, a pelvic exam is not necessary [3]. While it is advised that all women receive proper health maintenance and cancer screening, contraceptives should not be withheld or delayed if women do not wish to participate in cancer screening or other testing [79–85].

Providing women with a complete picture of contraceptive benefits, side effects, and risks provides them with realistic expectations and increases satisfaction. In particular, women should understand anticipated changes to the menstrual cycle with hormonal contraceptives. Patient-centred care allows a woman to be fully invested in her contraceptive method.

Summary

Since the advent of the first oral contraceptive pill, science, healthcare professionals, and society have made great strides in expanding the hormonal contraceptives available to women. Women can now choose between many different contraceptive formulations and routes of administration. Hormone dosages have greatly decreased. Side effect profiles have diminished. Women have the ability to choose the contraceptive method that fits their needs. Hormonal contraception has helped women and families safely prevent unwanted pregnancies. An unintentional advantage has been to offer many non-contraceptive benefits.

Hormonal contraception has proven to be one of the greatest inventions of this century. However, this advancement is often limited to women living in areas with more healthcare resources. Women around the world deserve the right to choose if and when they wish to become pregnant. Fertility has always been associated with the female body. All currently available methods of hormonal contraception require that women incur the risks and side effects of birth control. Development of a reversible male contraceptive would expand the options available to couples wishing to plan their families. We need to continue to strive, expand, and develop until every woman and man have the ability to determine their reproductive future.

Exogenous Factors and Female Reproductive Health

8.8.1 Exogenous Factors and Female Reproductive Health

Common Extragonadal Endocrinopathies Affecting Reproduction

Alessandra Gambineri and Daniela Ibarra-Gasparini

Introduction

Female infertility is estimated to affect between 8 and 15% of reproductive-aged couples worldwide. It is defined as the failure to establish a clinical pregnancy after 12 months of regular and unprotected sexual intercourse in women younger than 35 and after 6 months in women over the age of 35 [1]. In a World Health Organization (WHO) study of 8500 infertile couples, female infertility was reported in 37% of cases, male infertility in 8% of cases, and both male and female infertilities in 35% of cases [2]. Different causes may be behind female fertility, but ovulatory disorders account for more than a quarter of cases. Other causes of female infertility are endometriosis (15%), pelvic adhesions (11%), tubal blockage (11%), other tubal abnormalities (11%), and hyperprolactinemia (7%). Ovulatory disorders are more frequent in women with absent or irregular menses, whereas they are unusual in women who report monthly menses. Given that many conditions are potentially associated with ovulatory dysfunctions, the WHO classified anovulation into three main groups summarized in Box 8.8.1.1; hyperprolactinemia is recognized as an additional aetiology. Advanced age plays a triggering role in aggravating female infertility [3]. One study performed in 2004 on European women found that fertility peaks in the early and mid 20s; thereafter, there is a gradual fertility decline, and at age 40, a woman has only 3% of her ovarian reserve [4].

Box 8.8.1.1 World Health Organization (WHO) classification of anovulation

WHO class 1: Hypogonadotropic hypogonadal anovulation
These women have low or low-normal circulating levels of gonadotropins and low serum oestradiol concentrations due to decreased hypothalamic secretion of the gonadotropin-releasing hormone (GnRH), or pituitary unresponsiveness to GnRH, or decreased pituitary secretion of gonadotropins.

WHO class 2: Normogonadotropic normo-oestrogenic anovulation
These women have normal circulating levels of gonadotropins and of oestradiol. However, FSH secretion during the follicular phase of the menstrual cycle is subnormal. This group includes women with polycystic ovary syndrome (PCOS).

WHO class 3: Hypergonadotropic hypoestrogenic anovulation
These women have high circulating levels of gonadotropins and low serum oestradiol concentrations. The primary causes are premature ovarian failure and ovarian resistance to gonadotropins.

Hyperprolactinaemic anovulation
The anovulation is due to the inhibitory effect of prolactin on gonadotropin secretion. These women usually have normal circulating levels of gonadotropins and low serum oestradiol concentrations.

The Complex Hormonal Regulation of Folliculogenesis and Ovarian Steroidogenesis

The female reproductive function is influenced by the ovarian life span. The ovary is a metabolically active organ and acts as a germ cell reservoir. It consists of approximately 0.3 million primordial follicles that contain diplotene-arrested oocytes which represent the ovarian basic functional units. Folliculogenesis is a complex mechanism leading to the development of a mature follicle and ovulation. Each follicle has its own unique fate which is controlled by many endocrine and paracrine factors that support the passage from the first stage of follicle development, including the activation

of a primordial follicle that develops into primary and secondary follicles (preantral follicles and small antral follicles), through to the final stage of follicle development. This is where the small antral follicle develops into the antral follicle or Graafian follicle under the stimulatory control of pituitary gonadotropins.

In women of reproductive age, Graafian follicles are the major source of the cyclic secretion of ovarian oestrogens. In response to the preovulatory gonadotropin surge during each reproductive cycle, the dominant Graafian follicle ovulates to release a mature oocyte for fertilization, whereas the remaining theca cells (TCs) and granulosa cells (GCs) undergo transformation to become the corpus luteum that contributes to the circulating progesterone source. The production of steroid hormones by the ovarian cells is essential for supporting each stage of folliculogenesis; steroidogenesis is therefore a prerequisite for successful reproduction. Although the follicle-stimulating hormone (FSH) and luteinizing hormone (LH) are the primary regulators of folliculogenesis and of ovarian steroidogenesis, other hormones such as the thyroid hormones (THs), growth hormone (GH), prolactin (PRL), glucocorticoids and androgens participate in the regulation of follicular development and modulate the production of ovarian steroids (**Figure 8.8.1.1 and 8.8.1.2**).

THs receptors, triiodothyronine (T_3) and thyroxine (T_4) are present in the follicular fluid, whereas thyroid-stimulating hormone (TSH) receptors, THs transporters, and THs receptors are expressed in the ovary at the various developmental stages of the follicle. Studies in rats have demonstrated that T_3 amplifies proliferative FSH action at the GCs of the preantral follicle, stimulating its transition to the small antral follicle. In addition, T3 inhibits GCs apoptosis, through the activation of the phosphatidylinositol 3-kinase (PI3K)/protein kinase B (Akt) pathway, which is the pathway involved in the FSH-induced regulation of GCs survival [5]. Accordingly, THs administration in hypothyroid rats has been demonstrated to improve the maturation of ovarian follicles, increasing the number of healthy large antral follicles and ovulatory oocytes synergistically with gonadotropins [6]. Studies in humans are scarce. One *in vitro* study performed on fresh ovarian tissues form fertile women did not find an effect of T_4 or TSH administration on the follicle development [7], however other studies have demonstrated that THs induce oestradiol and progesterone ovarian synthesis acting directly at GCs. In particular, T_4 amplifies gonadotropins action on luteinization and progesterone secretion [8], whereas T_3 amplifies FSH stimulatory action on cytochrome P450 lanosterol 14α-demethylase (CYP51) expression. The latter is a key enzyme involved in sterol and steroid biosynthesis, expressed in oocytes and GCs of primordial follicles and of growing follicles [5].

Other studies have supported the role of GH in modulating folliculogenesis as well as ovarian steroidogenesis in humans. These actions may reflect the direct autocrine and paracrine actions of GH in the ovary or may be mediated by the Insulin Growth Factor (IGF)-1, whose hepatic production is induced by GH, since both GH- and IGF1-receptors have been found in the human ovaries. In addition, the GH releasing hormone (GHRH) and GHRH-receptors have been found in the ovary, thus supporting the presence of an ovarian regulation of GH synthesis by GH secretagogues in addition to the traditional hypothalamic–pituitary–regulatory axis. There is increasing evidence that GH plays an important role in controlling both follicular development and atresia. In particular, GH directly stimulates both the gonadotropin independent and the gonadotropin dependent phases of the follicle growth, acting at the level of small, preantral, and antral follicles. It has also been suggested that GH enhances follicular survival and cell proliferation by potentiating LH action at the ovary. Accordingly, GH deficiency is associated with a decrease in LH-receptors in the ovaries. GH also plays a role in follicle selection and in stimulating the development of the dominant follicle by enhancing nuclear and cytoplasmic oocyte maturation, by increasing the sensitivity of the follicle to gonadotrophins and by reducing the incidence of apoptosis of preovulatory ovarian follicles. In addition, GH facilitates ovulation by increasing tissue plasminogen activator synthesis, which plays an important role in the rupture of the ovarian capsule. GH also has

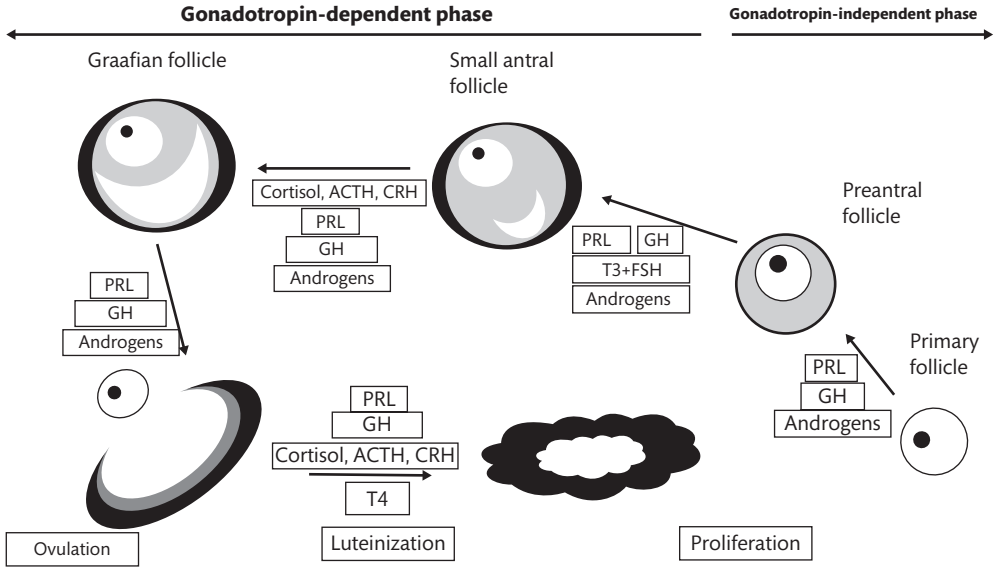

Figure 8.8.1.1 The complex hormonal regulation of folliculogenesis. Hormones of pituitary and/or ovarian origin bind their receptors on thecal cells (black), granulosa cells (grey) and luteal cells, and promote gametogenesis, thus inducing the development of primary follicles into preantral, antral, and mature antral (Graafian) follicles and taking part in ovulation and luteinization. ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; FSH, follicular stimulating hormone; GH, growth hormone; PRL, prolactin; T_3, triiodothyronine; T_4, thyroxine.

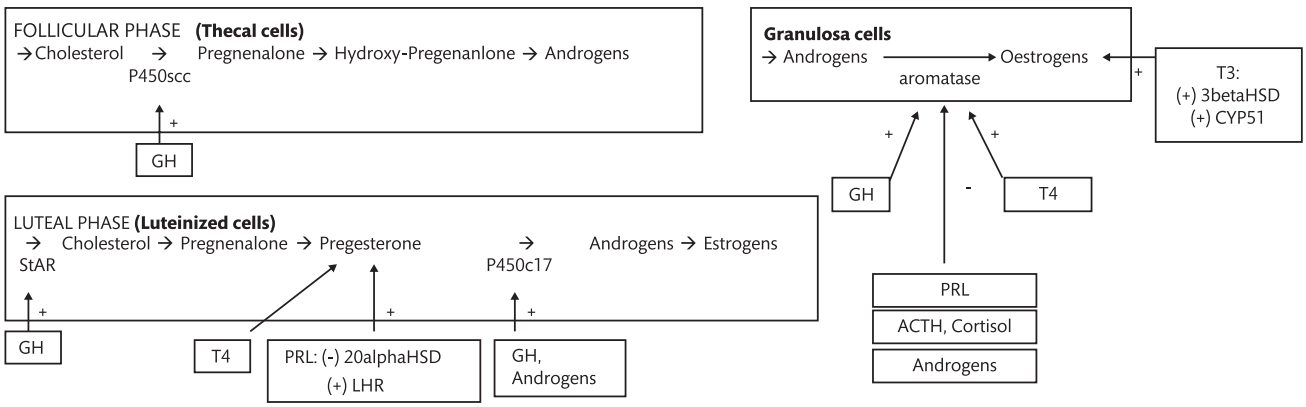

Figure 8.8.1.2 The complex hormonal regulation of ovarian steroidogenesis. Both thecal and granulosa cells are required for the production of oestrogens during the follicular phase. Following ovulation, granulosa cells become luteinized and acquire the ability to synthesize and secrete both oestrogen and progesterone. (+) indicates a stimulatory role; (–) indicates an inhibitory role. GH, Growth hormone; T_3, triiodothyronine; T_4, thyroxine; PRL, prolactin; ACTH, adrenocorticotropic hormone; FSH, follicular stimulating hormone; LHR, luteinizing hormone receptor; 20alphaHSD, 20 alpha hydroxyl-steroid dehydrogenase; StAR, steroidogenic acute regulatory protein; P450scc, cytochrome P450 side-chain cleavage; P450c17, 17alpha-hydroxylase; 3betaHSD, 3beta-Hydroxysteroid dehydrogenase; CYP51, cytochrome P450 lanosterol 14α-demethylase.

a stimulatory impact on local Aquaporin 1 (AQP1) synthesis. The amount of AQP1 at the level of the GCs and TCs membrane regulates cellular permeability to water, whereas its amount at the level of the cytoplasm regulates the intracellular action of steroid hormones, thus influencing the formation of human follicular antrum, the growth of follicles, and finally folliculogenesis [9]. GH regulates steroidogenesis in the GCs and TCs of the follicle through the stimulation of the activity of several steroidogenic enzymes, such as steroidogenic acute regulatory protein (StAR), cytochrome P450 side-chain cleavage (P450scc), 17alpha-hydroxylase (P450c17), aromatase, and 3beta-hydroxysteroid dehydrogenase (3betaHSD). This thus increases both oestrogen and progesterone synthesis and secretion during the follicular or luteal phase of the menstrual cycle [10].

Prolactin (PRL) is primarily known for its role in breast development and lactation, however it is also involved in the regulation of a wide variety of other physiological functions, including reproduction. In the ovary, PRL acts synergistically with gonadotropins to stimulate follicular development through interaction with the PRL receptor (R), a member of the cytokine superfamily. There are several isoforms of PRL-R, above all the long (long-R) and the short (short-R) isoforms, which are identical in their extracellular domains but differ in the lengths and sequences of their cytoplasmic tail [11]. This difference leads to different signalling properties and, therefore, to different biological actions. Although the long-R is the most expressed isoform of PRL-R in the ovary, coexpression of both long-R and short-R isoforms is necessary for the regular development of ovarian follicles [12]. Long-R shows an intrinsic thyrosine kinase activity. Acting through the long-R, PRL activates many kinases associated with the cytoplasmic domain, including Janus kinase 2 (Jak2), MAP kinase, and PI3K [11]. JaK2 phosphorylates several cellular proteins such as a family of transcription factors termed signal transducers and activators of transcription (Stats) which translocate into the nucleus. Here they regulate gene expression by inducing several PRL-responsive genes involved in cell proliferation and differentiation. Short-R is not thyrosine phosphorylated [13], thus showing different actions from long-R. The overactivation of short-R, which follows an excess in PRL circulating levels, leads to the dephosphorylation of a dual specific phosphatase-uridine diphosphate (D-UDP1), which in turn deactivates MAP kinase leading to an ovarian defect [14]. Short-R also down-regulates forkhead box O-3 (FOXO3) and galactose-1-phosphate uridyltransferase (GALT), two genes involved in normal ovarian development [11]. Therefore, to guarantee a normal ovulatory process, short-R should not be overactivated. Accordingly, female mice with only the short-R display an important ovarian defect and infertility. PRL also influences follicle development through a stimulatory impact on AQP1 [9]. In rodents, PRL also shows a luteotropic effect due to the ovarian upregulation of LH receptor expression [15] and repression of 20 alpha hydroxyl-steroid-dehydrogenase (20-alpha-HSD), both resulting in the upregulation of ovarian progesterone secretion which is fundamental for a correct implantation [16]. When PRL is in excess, however, the inhibitory effect of PRL prevails over aromatase activity, thus leading to low ovarian oestrogen production [11]. In addition, PRL inhibits gonadotropin-releasing hormone (GnRH) secretion and the LH pituitary response to GnRH stimulation, thus reducing LH pulse amplitude and frequency with a consequent inhibition in ovarian function. The PRL inhibitory effect on GnRH release is not direct but is mediated through the inhibitory effect of PRL on kisspeptin [17], which is the most important stimulator of GnRH secretion. Accordingly, kisspeptin administration in hyperprolactinaemic anovulation restores gonadotropin secretion and ovulation [18].

Glucocorticoids are also significantly involved in ovulation. Glucocorticoids, in fact, act as anti-inflammatory agents in the ovary to promote healing and repair after ovulation and restore ovarian function under stress conditions by inhibiting oxidative stress [19]. In addition, both glucocorticoids as well as the adrenocorticotropic hormone (ACTH) and corticotropin-releasing hormone (CRH) stimulate follicular development [20], but inhibit oestradiol and progesterone production in the ovary [19–22]. In addition, endogenous glucocorticoids released in response to perceived stress are protective against gonadotropin secretion, by inhibiting prostaglandin synthesis in the brain, thereby maintaining LH secretion regardless of the nature of the stressor [23]. However, an excess of glucocorticoid secretion or exogenous glucocorticoid administration may lead to an inhibition of GnRH pulsatility, and a decrease in gonadotropin responsiveness and release from the pituitary [24], as

demonstrated by a reduction of about 60% in the peak of LH in response to intravenous GnRH after prednisolone administration [22]. Glucocorticoids in excess also impair LH action at the ovary thereby reducing the ovarian LH-receptor level [19]. Similar results have been observed in the presence of ACTH excess [25]. Studies in mice have demonstrated an increased number of atretic antral follicles with a decrease in corpora lutea (CLs) and a consequent impairment in follicular development in stressed mice which show high cortisol levels [19]. In human studies, stressed-induced hypercortisolism increased the level of reactive oxygen species (ROS) beyond the physiological range, resulting in cell cycle arrest and apoptosis in follicular oocytes, reducing fertilization and pregnancy rates [26].

Finally, androgens also play an important role in regulating folliculogenesis. Androgen receptors (ARs) are expressed in GCs, TCs, and stromal cells of follicles at all the maturity levels. The highest expression level of ARs is in the GCs of preantral and small antral follicles, while their expression gradually decreases when follicles enter the preovulation stage. Androgens, particularly testosterone, promote preantral follicle growth, through the activation of the PI3K/Akt/FOXO3 pathway [27] and the modulation of the expression of key ovarian growth factors, such as growth differentiation factor-9 (GDF9). They also accelerate the development of primary into antral follicles and inhibit follicular atresia in mammals, by enhancing the expression of an antiapoptotic microRNA (miR-125b) [28]. The mitogenic properties of androgens may be due in part to the activation of glucose transporter type 4 (GLUT4) signalling and the consequent increased ovarian glucose metabolism [29]. In addition, androgens may up-regulate FSH-Receptor levels in a transcription independent manner, thus sensitizing preantral follicles towards FSH actions [30]. The activity of some steroidogenic enzymes located in the TCs has also been demonstrated to be increased by androgens. In particular, GDF-9, which is induced by androgens, stimulates P450c17 expression and inhibits aromatase activity leading to an androgen-rich environment [30]. Androgens also induce the expression of the vascular endothelial growth factor (VEGF), which is important for vascularization of the ovarian follicle and the corpus luteum [27].

The Hormonal Regulation of the Uterus Decidualization and of Implantation

THs, GH, PRL, glucocorticoids, and androgens act also at the uterine level, stimulating decidualization, and favouring implantation.

THs stimulate the production of progesterone from GCs, which is responsible for building up the endometrial lining for optimal implantation. They also up-regulate the leukaemia inhibitory factor (LIF) which is involved in embryo implantation and increase the expression of various adhesion molecules in early placental extravillous trophoblasts such as metalloproteinases-2 and -3 (MMP-2, MMP-3), fetal fibronectin, and integrin, thus promoting the invasion process.

Also, PRL and GH exert paracrine and autocrine actions at the level of the uterus finally regulating reproduction and are also synthesized locally. PRL is synthesized by the human endometrium around day 23 of the normal menstrual cycle primarily under the control of progesterone and oestradiol [11]. PRL decidual production rapidly increases soon after implantation in order to maintain pregnancy, since it inhibits detrimental factors such as interleukin-6 (IL-6) and 20-alpha-HSD, by linking to both long and short isoforms of PRL-R [31].

GH stimulates mitogenesis and promotes uterine proliferation and endometrial cell growth through the upregulation of oestradiol receptors and the stimulation of the uterine production of IGF-binding proteins (IGFBPs) and prostaglandins [10]. Through its mitogenic activity, GH increases the placental size, thus stimulating fetal growth and inducing the production of placental lactogens, oestradiol, and progesterone, thus supporting pregnancy and the maternal metabolism to induce nutrient repartitioning for fetal development. GH has a stimulatory effect on AQP1 which is localized in the uterus, thus stimulating uterine imbibition and facilitating embryo implantation [9].

Glucocorticoids inhibit oestradiol-stimulated uterine growth. In fact, the administration of dexamethasone in rats has been found to attenuate the uterine weight gain induced by oestradiol, through a reduction in intracellular oestrogen receptor concentrations or by glucocorticoid receptor-mediated inhibition of the c-fos/c-jun transcription factor. The latter is used in the signal transduction pathways of many growth factors and is directly or indirectly stimulated by oestrogens. CRH, expressed in human decidualized endometrial stroma, seems to stimulate the process of decidualization synergistically with progesterone [22]. In addition, during the luteal phase of the menstrual cycle, it is secreted into the lumen of the uterus, where it participates in the inflammatory phenomena of blastocyst implantation and, later in the menstruation cycle [32]. CRH also seems to stimulate the production of the blood supply to the fetus by activating the nitric oxide synthase of placental vessels [22]. Finally, placental CRH stimulates cortisol secretion during the latter part of pregnancy, and thus is responsible for the maternal hypercortisolism of pregnancy [22].

In the endometrium, testosterone induces collagen type 1 expression and VEGF, thus finally regulating neoangiogenesis which is important for implantation. However, high levels of progesterone and/or 17-OH progesterone during the preovulatory phase of the menstrual cycle have been associated with inadequate endometrial maturation and impaired embryo implantation [33].

In summary, the ovaries and the uterus are under the control of many hormones and an excess or defect of these hormones may account for infertility, thus complicating the diagnosis of reproductive disorders.

Extragonadal Endocrinopathies Affecting Reproduction

Thyroid Diseases

Among the extraovarian causes of infertility, the most frequent endocrine diseases are those affecting the thyroid gland.

THs disorders in terms of both an excess or defect and thyroid-peroxidase autoantibody (TPO-Ab) or thyroglobulin autoantibody (Tg-Ab) production alterations are associated with a disturbance in folliculogenesis, fertilization, and embryogenesis, as well as with some pregnancy complications.

Hypothyroidism

Hypothyroidism has mainly been associated with menstrual irregularities and anovulation, although there are some data that describe a link between hypothyroidism and many pregnancy complications.

The prevalence of menstrual irregularities is 23% among hypothyroid females, compared to 8% in euthyroid females [34]. More recent reports describe a lower prevalence of menstrual abnormalities among hypothyroid females, which may be attributed to earlier detection and treatment of hypothyroidism compared to the past [2].

Few studies describe the association between hypothyroidism and low fertility rates both in animals [35] and in humans where high serum TSH levels would seem to be a predictor of fertilization failure in women undergoing *in vitro* fertilization [36]. Hypothyroidism is also associated with early and late obstetric complications, namely miscarriage, preterm birth, placental abruption, fetal death, postpartum haemorrhage, respiratory distress syndrome, and impaired neurological development during childhood [37].

There may also be a link between low fertility rate and subclinical hypothyroidism which is defined as serum TSH levels over 4.5 mIU/L with normal T_4 and T_3 circulating levels [37]. In addition, some studies have described an association between subclinical hypothyroidism and reduced pregnancy outcome [37, 38] which improves after T_4 supplementation [39]. Accordingly, the 2017 American Thyroid Association (ATA) guidelines suggest considering treatment with T_4 with TSH levels above 4 mIU/L [40].

The link between hypothyroidism and infertility is related to three main factors: (i) a decrease in folliculogenesis (see previous section); (ii) a decrease in the sex hormone binding globulin (SHBG) synthesis and secretion by the liver, with a consequent increased peripheral bioavailability of oestrogens and, particularly, of androgens; and (iii) to an increased pituitary PRL secretion stimulated by TRH [2]. Reduced fertility in hypothyroid patients is also due to the peripheral insulin resistance and to the consequent hyperinsulinaemia that frequently follows hypothyroidism [37].

Altered Thyroid Autoimmunity with or Without Hypothyroidism

The most frequent form of autoimmune thyroid disorder is that sustained by TPO-Ab and/or Tg-Ab which may or may not be associated with hypothyroidism. The impact on fertility seems to be different among the forms with or without hypothyroidism [41]. In fact, although many studies have reported an increased prevalence of thyroid autoimmunity in women attending infertility centres [42], most studies suggest that pregnancy rates and pregnancy outcomes are negatively influenced only if thyroid antibodies are associated with hypothyroidism [38, 43]. However, some studies have reported a decreased pregnancy rate [44] and an increased miscarriage rate and obstetric complications also with normal TSH levels [45].

Although TPO-Ab has been found in the follicular fluid of women with autoimmune thyroid disorders [44], there are no data demonstrating a direct negative impact of TPO-Ab on folliculogenesis, nor on fertilization, implantation, or embryogenesis, although some authors have suggested the role of inflammation induced by autoimmunity in reducing oocyte quality. In any case, the 2017 ATA guidelines suggest considering treatment with T_4 with TSH levels above 2.5 mIU/L if there is a positivity for TPO-Ab [40].

Hyperthyroidism

Hyperthyroidism has been associated with a 5.8% infertility rate [46], which seems to be higher in the presence of autoimmune hyperthyroidism [41].

Menstrual irregularities are present in 8–60% of patients affected by hyperthyroidism and include oligomenorrhea or amenorrhea, hypermenorrhoea, and even anovulation [34, 37]. Hyperthyroidism in pregnancy is associated with an elevated prevalence of miscarriage, stillbirth, preterm birth, and intrauterine growth restriction. In addition, hyperthyroid pregnant females may develop preeclampsia or placental abruption [37].

Whether the negative impact of hyperthyroidism on fertility is entirely attributable to the direct action of THs on the ovaries and uterus (see previous section) or whether other mechanisms are involved is unknown. Indeed, thyrotoxicosis is associated with increased circulating levels of SHBG [47], with a consequent decreased peripheral bioavailability of oestrogens and, particularly, of androgens. An increased production rate of testosterone and androstenedione in hyperthyroid females has also been described [48], as well as an altered GnRH-induced LH secretion with a consequent significantly higher LH level in both the follicular and luteal phase of the menstrual cycle, thus contributing to anovulation [41].

Diseases of the Hypothalamic–Pituitary Axis

Several diseases affecting the hypothalamic–pituitary axis may impact on reproductive function, through a reduction in the GnRH drive to the pituitary and/or a reduction of FSH and LH input to the ovary with a consequent insufficient folliculogenesis and ovarian function.

Clinically variable menstrual cycle alterations, including oligomenorrhoea, amenorrhoea, or polymenorrhoea may be detected.

In rare cases, the reduction in GnRH drive may be due to gene mutations such as the fibroblast growth factor receptor 1 (FGFR1), prokineticin receptor 2 (PROKR2) and GnRH-receptor, to congenital GnRH deficiency due to the migration of an insufficient number of GnRH neurons from the olfactory placode into the hypothalamus during fetal development (Kallmann's syndrome) or to hypothalamic lesions [49]. More frequently it may be functional. Similarly, pituitary causes can be congenital or acquired. Congenital causes are alterations in genes involved in pituitary embryogenesis such as Homeobox protein prophet of PIT-1 (PROP-1) and Homeobox expressed in embryonic stem (ES) cells 1 (HESX1) [50]. Acquired causes are pituitary adenomas or other pituitary tumours, empty sella syndrome, trauma, or radiation of the pituitary area, sarcoidosis, lymphocytic hypophysitis (autoimmune diseases), and ischaemic alterations such as Sheehan's syndrome [50]. Hyperprolactinemia is the most frequent cause of infertility due to hypothalamic–pituitary axis dysfunction and may be due to organic or functional causes.

Pituitary Adenomas

Pituitary adenomas may be associated with infertility due to hypogonadotropic hypogonadism. There are three main underlying mechanisms: (i) hormonal hypersecretion (PRL, GH or cortisol); (ii) pathological interruption of hypothalamic–pituitary dopaminergic pathways (i.e. pituitary stalk compression), with consequent hyperprolactinemia; and (iii) the destruction or compression of

gonadotroph cells as a mass effect. Pituitary hormonal hyper- and hyposecretion also influence pregnancy outcomes [51]. However, with the improvement in clinical and surgical treatment, women harbouring pituitary adenomas can still become pregnant and give birth.

Hyperprolactinaemia

A number of physiological states including pregnancy, breast-feeding, stress, lack of exercise, and sleep can cause an increase in PRL. Non-physiological hyperprolactinemia may be due to pituitary lactotroph adenomas (prolactinomas), which account for approximately 40% of all pituitary tumours, pharmacological stimulation of PRL pituitary secretion, such as D2 antagonists administration, pathological interruption of hypothalamic–pituitary dopaminergic pathways (pituitary stalk compression), hypothyroidism or renal disorders, and, sometimes, due to unknown reasons (the idiopathic form). Regardless of aetiology, hyperprolactinemia may clinically manifest with galactorrhoea, menstrual abnormalities, hypogonadism, and infertility, which is found in approximately 10% of the patients affected, or it may remain asymptomatic [52]. In addition, women often note a decrease in libido and dyspareunia due to oestrogen deficiency [53].

Infertility in hyperprolactinemia is due both to the direct impact of PRL on folliculogenesis and to a PRL-induced hypogonadotropic hypogonadism, since PRL reduces GnRH secretion (see previous section). When pulsatile GnRH is administered in hyperprolactinaemic patients, ovulatory cycles and fertility may be restored [2].

Acromegaly

Acromegaly is a chronic disorder caused by GH hypersecretion which affects fertility in approximately 50% of females. Infertility in acromegalic patients is principally due to anovulation mainly for pituitary reasons, such as the destruction or compression of gonadotroph cells by the GH-secreting adenoma or hyperprolactinemia derived from tumour cosecretion or the stalk effect (pituitary stalk compression). Anovulation in acromegaly may also be due to polycystic ovary syndrome (PCOS) which derives from the direct effect of excessive GH/IGF-I secretion on the ovaries and/or from insulin resistance secondary to GH excess [53]. In fact, hyperinsulinemia, which is compensatory to insulin resistance, stimulates androgen production by TCs and reduces SHBG hepatic synthesis thus increasing the peripheral bioavailability of androgens. In acromegaly, however, infertility is also due to the increased prevalence of spontaneous abortion [54] and to pregnancy complications, such as gestational diabetes and hypertension [51, 55].

Cushing's Disease

The term Cushing's syndrome (CS) identifies a group of diseases caused by a chronic excess of glucocorticoids, and the term Cushing's disease identifies the forms of CS that are ACTH dependent. Menstrual irregularities and chronic anovulation are common in women with CS, affecting up to 80% of these patients and who clinically manifest with oligomenorrhea, amenorrhea, or polymenorrhoea. As a consequence, infertility is frequent in females affected by CS.

The mechanisms responsible for chronic anovulation in CS are still not completely clear, although high circulating levels of cortisol inhibits GnRH and gonadotropin release, thus resulting in hypogonadotropic hypogonadism [24]. In addition, high cortisol levels reduce the ovarian LH-receptor expression thus impairing LH action at the ovary, (19) thus contributing to anovulatory infertility [19, 26] (for more details, see previous section). The adrenal hyperandrogenism that accompanies all the forms of CS also plays a role in infertility [25].

Hypopituitarism

Hypopituitarism is defined by the decreased secretion of one or more of the hormones normally produced by the pituitary gland. The signs and symptoms of hypopituitarism vary depending on which hormone is lacking, with infertility always present when FSH and LH secretion are affected. A low serum oestradiol concentration with equally low LH and FSH circulating levels is the diagnostic key of gonadotropin deficiency. Hypoandrogenism is also a typical feature of the pituitary diseases affecting ACTH and gonadotropin secretion, with a consequent defect in the follicle maturation which stops growing at the small follicle stage. The consequence is a phenotype of low functional ovarian reserve, characterized by low oestradiol and anti-Müllerian hormone (AMH) levels due to declining GCs mass. The deficit in TSH and GH production contributes to hypogonadism and to anovulation through their impact on folliculogenesis and steroidogenesis as described in the previous section, although fertility is always not compromised in the isolated deficiency of the GH axis. In fact, a high proportion of GH-deficient women have normal menstrual cycles and conceive normally [10]. However, a deficiency in GH is frequently associated with intrauterine growth retardation. In addition, GH administration in hypopituitaric patients with both gonadotropin and GH deficiency significantly reduces the dosage and duration of the gonadotropin treatment required for ovulation induction and for a positive fertility outcome [50].

Diseases of the Adrenal Gland

Infertility in diseases of the adrenal gland may arise from hypercortisolism as well as from a glucocorticoid deficiency [19, 26]. There are two main adrenal causes of glucocorticoid deficiency; Addison's disease and congenital adrenal hyperplasia.

Addison's Disease

Addison's disease or primary adrenal insufficiency is characterized by a deficiency in cortisol, aldosterone, and androgen adrenal synthesis and secretion, usually caused by an autoimmune reaction towards the adrenal cortex. Data on the impact of Addison's disease on fertility and pregnancy outcomes are scarce. Recently, however, many studies have demonstrated reduced fertility in these patients [27] with a concomitant reduction in parity and an increased risk of unfavourable pregnancy outcomes such as caesarean section and preterm delivery, although an adequate glucocorticoid treatment generally improves pregnancy outcomes [56].

The underlying causes of reduced fertility in Addison's disease still need to be clearly defined, however many other factors are potentially involved than just a deficit in glucocorticoids. Excess glucocorticoid therapy has been suggested, together with the possible coexistence of other autoimmune diseases affecting fertility, such as autoimmune thyroid disease or premature ovarian failure

(POF), which has been found in 7% of women with Addison's disease [57], and also, interestingly, adrenal hypoandrogenism. A defect in adrenal androgens, in particular, seems to play a central role in fertility impairment and in the increase in spontaneous abortions observed in females affected by Addison's disease.

In fact, low testosterone results in poor follicle maturation and in the arrest of follicles at the small follicle growth stages. The consequence is a typical phenotype characterized by low oestradiol and high FSH levels, low testosterone and dehydroepiandrosterone (DHEA) and DHEA sulphate (DHEAS) levels, but high AMH levels, which are sometimes erroneously diagnosed as a premature ovarian insufficiency (POI). These cases, however, are not POI and should be diagnosed and specifically treated.

Since DHEA and DHEAS are exclusively produced by the adrenal and, therefore, reflect adrenal androgen production in the zona reticularis, the measurement of DHEA and DHEAS circulating levels could help clinicians in diagnosing these forms [58] which are surprisingly common in tertiary fertility centres but often go unrecognized [59]. A correct diagnosis is detrimental for the prognosis of these forms since androgen supplementation can improve ovarian function [60]. DHEA supplementation in such patients in fact improves both spontaneous fertility and *in vitro* fertilization (IVF) cycle outcomes [59].

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) due to 21-hydroxylase deficiency is a common autosomal recessive disorder due to mutations in the *CYP21A2* gene. Irregular menses are common in females with CAH, with amenorrhea being more frequent in patients with salt wasting (SW) and simple virilizing (SV) forms compared to non-classical (NCAH) forms [61]. In a recent report, pregnancy and delivery rates were significantly lower in 62 women with CAH (aged 18–63) with respect to controls, despite fertility treatments. These cases were also influenced by the severity of the genotype with a more severe negative impact on fertility outcomes observed in SW and the less severe impact observed in the NCAH forms [62].

The reduction in pregnancy and birth rates described in CAH can be attributed to several factors. It may be due to decreased sexual activity due to genital anomalies and to the consequences of genital surgery; psychological factors (i.e. homosexuality) and single status; together with the secondary PCOS phenotype, as a consequence of the hyperandrogenic state. Inappropriate therapy is also implicated in the infertility of CAH which has been observed both if corticosteroid supplementation is insufficient and if there is a glucocorticoid overtreatment for the mechanisms described in previous section.

When glucocorticoid supplementation is insufficient, androgen overproduction from the adrenal suppresses normal follicular development inducing follicular atresia and suppresses gonadotropin secretion from the pituitary, thus leading to anovulation and infertility. In addition, elevated progesterone concentrations that characterize CAH due to 21-hydroxylase deficiency interfere with the quality of the cervical mucus [2, 33]. Conversely, with glucocorticoid overtreatment, the development of obesity and insulin resistance can contribute to decrease fertility in females affected by CAH. Accordingly, when CAH patients are adequately treated, they have good fertility outcomes and pregnancies are usually spontaneous. Thus, an optimized glucocorticoid therapy regimen is important in CAH women also to guarantee adequate fertility [62].

8.8.2 Exogenous Factors and Female Reproductive Health

Nutrition and Reproduction

Siew Lim, Aya Mousa, Soulmaz Shorakae, and Lisa Moran

Introduction

Reproductive function is closely related to nutritional status. Undernutrition and overnutrition as reflected in body weight and body composition significantly impact fertility and reproductive outcomes. In addition, maternal micronutrient status in the periconception, pregnancy, and lactation period also influences the development of the offspring.

Undernutrition

The proportion of women of reproductive age that are underweight has decreased globally in the last few decades. Currently, the prevalence of maternal underweight is under 10% in all developed and developing regions except in South Asia and Africa.

Undernutrition and Ovulation

Undernutrition reduces fertility. A European multicentre study found that having BMI under 20 kg/m² is associated with delayed conception, defined as time to pregnancy exceeding 9.5 months of unprotected intercourse. Similarly, the Nurses' Health Study II found that 12% of ovulatory infertility in the US may be due to underweight (BMI<20 kg/m²) [1]. A 10–15% reduction in body weight from ideal body weight could result in amenorrhea. This may explain the higher prevalence of amenorrhea among anorexia nervosa patients, athletes, or dancers with very low body mass.

Undernutrition and Pregnancy Outcomes

In addition to reducing fecundity, undernutrition may also adversely affect pregnancy outcomes. A recent meta-analysis of 265 760 women reported that low prepregnancy BMI (<18.5) is associated with increased risk of miscarriage (relative risk 1.08, 95% CI 1.05–1.11) [2]. Maternal underweight is also associated with preterm births (BMI< 16: relative risk 1.54, 95% CI 1.40–1.68; BMI 17–18.49: relative risk 1.17, 95% CI 1.14–1.21) and small-for-gestational-age (SGA) birth (adjusted odds ratio 1.36, 95% CI 1.25–1.49). Achieving less than the recommended gestational weight gain further exacerbates these risks.

Undernutrition and Fertility Treatment Outcomes

A recent study in the US (n = 402 742 transfers) reported that underweight women had a significant decreased chance of intrauterine pregnancy (adjusted risk ratio [aRR] 0.97; 95% CI, confidence interval 0.96–0.99) and live birth (aRR 0.95; 95% CI, 0.93–0.98) per transfer [3]. As with naturally conceived pregnancies, maternal underweight is also associated with increased risk of low birthweight and preterm birth among cycles resulting in singleton pregnancies [3].

Overnutrition

More than half of all adults are overweight or obese in Western countries such as Australia and US. Overweight is defined as having BMI between 25 and 29.9 kg/m², while obese is defined as having BMI of 30 kg/m² and above. The prevalence of obesity has also increased dramatically in developing countries. The global epidemic of obesity is likely to be due to changes in dietary patterns towards greater consumption of energy-dense food and decreased physical activities associated with work, home, transport, or leisure. Obesity contributes significantly to the development of chronic diseases

such as diabetes, cardiovascular diseases, certain types of cancers (e.g. endometrial, ovary, cervix, and postmenopausal breast cancer) and reproductive disorders.

Obesity and Fertility

Overweight or obesity reduces fecundity in men and women. Twenty-five percent of ovulatory infertility in the US could be attributable to overweight or obesity (BMI $\geq$ 25 kg/m^2) [1]. Maternal overweight or obesity increases time to pregnancy regardless of age, cycle regularity, partners BMI, physical activity, smoking, parity, alcohol, and intercourse frequency. Body weight or body composition changes during the pubertal period may have an important impact on the development of the reproductive system. The onset of obesity during adolescence is associated with increased menstrual irregularities and ovulatory disorders. Weight gain or obesity in young adulthood also increases the risk of infertility in men and women. Obesity in men also increases the risk of infertility (OR 1.66, 95% CI 1.53–1.79) [4].

Obesity and Fertility Treatment Outcomes

Not only does obesity affect natural fertility, it may also compromise the success of assisted reproductive technology. Women who were overweight or obese had lower clinical pregnancy (RR 0.87, 95% CI 0.80–0.96), live birth (RR 0.80, 95% CI 0.71–0.90) and higher miscarriage (RR 1.43, 95% CI 1.22–1.67) following IVF treatment compared to normal weight women [5] Male obesity also contribute to decreased chances of live birth from assisted reproductive technologies (OR 0.65, 95% CI 0.44–0.97) [4].

Obesity and Pregnancy Outcomes

There is an increasing number of pregnant women who are obese. Obesity increases the risk of complications during pregnancy and delivery. Obese women are at higher risk of early miscarriage, pre-eclampsia, pregnancy-induced hypertension, gestational diabetes, caesarean delivery, and postpartum haemorrhage [6]. Higher maternal body weight also confers additional risks to the infants, including increased risk of being large for gestational age, having macrosomia, being stillborn, or being admitted to a neonatal intensive care unit [7]. These risks are further exacerbated by excessive gestational weight gain [8].

Polycystic Ovary Syndrome (PCOS)

PCOS is one of the most common endocrine conditions affecting up to 20% of women of reproductive age (see Chapter 8.4.1 for definition, diagnosis, and prevalence). Women with PCOS are more likely to be overweight (RR 1.95, 95% CI 1.52–2.50), obese (RR 2.77, 95% CI 1.88–4.10) or centrally obese (1.73, 95% CI 1.31–2.30) compared to women without PCOS [9].

Women with PCOS may be at greater risk of adverse pregnancy outcomes, including increased risk of gestational diabetes, pregnancy-induced hypertension, pre-eclampsia, preterm birth, and admission of infants to a neonatal intensive unit [10]. When fertility treatment is sought, women with PCOS may have a higher rate of cycle cancellation and longer duration of stimulation but the pregnancy and live birth rates are comparable to normal healthy women [11]. See online only Tables 8.8.2.1 and 8.8.2.2.

Box 8.8.2.1 The effect of insulin on androgen production

- Pituitary
  - Increases sensitivity to GnRH
- Ovaries
  - Increases the activity of 17,20 lyase
  - Increases the activity of 3β-hydroxysteroid dehydrogenase and aromatase in the granulosa cells
  - Increases LH receptors
  - Promotes ovarian growth and cyst formation
- Liver
  - Inhibits sex hormone binding globulin (SHBG) production

Obesity, Hyperinsulinaemia, Hyperandrogenaemia

Obesity is likely to promote hyperandrogenism and PCOS via hyperinsulinaemia, a compensatory response to insulin resistance. An increase in insulin level usually causes a concomitant increase in testosterone or androstenedione levels. The mechanisms underlying the relationship between hyperinsulinaemia and hyperandrogenism are summarized in Box 8.8.2.1 (Also see online only Table 8.8.2.3).

Treatment and Prognosis

Lifestyle Modification and Fertility

Weight loss through energy restriction, with or without exercise, improves reproductive function in overweight or obese women. In women with PCOS, about half of them had significant improvements in menstrual cyclicity or ovulation following weight loss through lifestyle modification. Among those who have lost at least 5% of their body weight, up to 80% experienced improvements in reproductive function. Improvements in reproductive hormones have been observed shortly after energy restriction (2 weeks) before weight loss occurs. This is consistent with the current understanding of reproductive function being influenced by energy balance instead of adiposity. In a Cochrane review, lifestyle modification reduced body weight, body mass index and free androgen index [12].

Diet and Fertility

A number of dietary factors have been associated with ovulatory infertility. In a prospective cohort study involving 18 555 pre-menopausal women, increasing consumption of vegetable as opposed to animal protein, choosing low glycaemic index carbohydrates and choosing unsaturated fatty acids (monounsaturated or polyunsaturated as opposed to transfats) were associated with reduced ovulatory infertility [13]. Research on dietary patterns found that greater adherence to a Mediterranean diet is associated with a higher likelihood of achieving pregnancy, clinical pregnancy, and live birth. Further research is warranted examining the effects of these dietary factors in intervention trials.

Evidence relating to supplements is more mixed. Consumption of iron supplements, other sources of non-heme iron, or multivitamins (particularly B vitamins and folic acid intake) is associated with decreased risk of ovulatory infertility in a prospective cohort study of 18 555 premenopausal women [14]. However, a Cochrane review of randomized controlled trials of antioxidant supplementation in women reported no benefits for increasing pregnancy or live birth rate. The high variability of interventions assessed makes it difficult to draw strong conclusions from the current evidence and further studies are needed.

Metformin and Fertility

Metformin has been used in women with PCOS, with effects on reducing the pulse amplitude of luteinizing hormone (LH) secretion, and on granulosa cell steroidogenesis and oocyte maturation. Metformin is also considered a safe option, with similar efficacy to insulin, for management of gestational diabetes during pregnancy with no increased risk of major birth defects [15]. It is given orally in doses of 1500 to 2000 mg in divided daily doses. A recent Cochrane review demonstrated that metformin use in women with PCOS compared to placebo may improve live birth rates, rates of clinical pregnancy, ovulation, and menstrual frequency although with increased gastrointestinal side effects. There was no clear evidence of an increase in miscarriage rates with metformin use. While metformin combined with clomiphene citrate had no clear benefit over clomiphene alone for live birth rates, it however resulted in higher rates of clinical pregnancy and ovulation. It is currently recommended that metformin could be used in women with PCOS at high metabolic risk including those with impaired glucose tolerance and in addition to clomiphene citrate for induction of ovulation in women with PCOS who are resistant to clomiphene citrate.

Bariatric Surgery and Fertility

Bariatric surgery is increasingly recognized as a treatment for morbid obesity (BMI >35 kg/m^2) in women of reproductive age who have failed other treatments including lifestyle modification. Current guidelines suggest that bariatric surgery be considered for patients with a BMI above 40 kg/m^2 or BMI above 35 kg/m^2 in the presence of obesity-related comorbidities, with PCOS considered to be one of those by some experts.

Bariatric surgery may improve menstrual cyclicity and ovulation through weight loss. A recent systematic review and meta-analysis reported 58% (22–92%) of infertile women become pregnant after bariatric interventions (weighted mean difference for successful pregnancy 0.580 (95%CI 0.539, 0.621)). A lower likelihood of gestational diabetes, hypertension and macrosomia are reported in pregnancies following bariatric surgery [16], however, it is notable that those pregnancies pose surgical, medical, and obstetric challenges including nutritional deficiencies, potential surgical complications, and difficulties with the diagnosis of gestational diabetes. It is generally recommended to avoid pregnancy within the first 12–24 months post bariatric surgery to allow for achievement of the full therapeutic benefit of the procedure and stabilization of the nutritional state and to reduce the risk of intrauterine growth retardation. To avoid nutritional deficiencies, it is advisable to optimize the nutritional status of women prior to and following bariatric surgery. Extra care must be taken to appropriately distinguish and treat other potential surgical and non-surgical complications of previous bariatric surgery during pregnancy.

Dietary Intakes and Pregnancy Outcome

Besides body weight and energy status, maternal dietary intakes before conception and during pregnancy can affect pregnancy outcomes. The following section summarizes the effect of various macronutrients and micronutrients on pregnancy outcomes.

Energy

During pregnancy, energy intakes are reported to range from 7710 to 9260 kJ/day, with relatively higher levels in the Americas and the Eastern Mediterranean than in Southeast Asia, the Western Pacific, and Africa. In a meta-analysis of three trials (n = 384), energy restriction during pregnancy in women with high BMI or with excess gestational weight gain resulted in reduced gestational weight gain [17]. However, it also reduced birthweight, with two of the three trials reporting adverse effects on birthweight. No improvements in pregnancy-induced hypertension or preeclampsia (gestational hypertension with proteinuria) were found. There is a lack of evidence to advise on energy restriction during pregnancy, however, prevention of excessive gestational weight gain in high-risk women (e.g. overweight and obese women, women at high risk of gestational diabetes) through diet and exercise is associated with reduced risk of infant macrosomia and infant respiratory distress syndrome.

Protein

In developed countries, pregnant women report consuming 14.7% to 16.1% of total energy from protein, which is adequate based on current recommendations. In a Cochrane review of 12 trials (n = 6705), balanced energy/protein supplementation (<25% energy from protein) increased birthweight and reduced the risk of stillbirth and SGA infants, but had no effect on gestational weight gain [18]. On the other hand, high protein supplementation (≥25% energy from protein) resulted in a significantly increased risk of SGA, with no effect on stillbirth, neonatal death, preterm birth, birthweight, or gestational weight gain (one trial, n = 505 African American women with a history of low birthweight infants) [18, 19]. Isocaloric protein supplementation (replacing other macronutrients with protein without changing the overall energy intake) had no effect on birthweight or gestational weight gain (two trials, n = 184) [18]. It is unclear whether high protein intake results in a subconscious reduction in overall energy intake, as is usually seen in high protein *ad libitum* weight loss trials. Current evidence supports balanced energy-protein supplementation (<25% energy from protein) to increase birth weight in those at risk of having SGA infants but further evidence is needed on the safety of high protein diet or supplement use during pregnancy.

Glycaemic Index, Glycaemic Load, and Fibre

The glycaemic index (GI) is a measure of the effect of dietary carbohydrate intake on blood glucose levels. High GI foods

cause a greater increase in blood glucose level within 2 hours of consumption. In a 2010 systematic review, two trials (n = 74) reported that low GI diets in healthy pregnancies reduced the risk of large-for-gestational-age (LGA) infants; however, an increased risk of SGA was reported in one epidemiological study of 1082 pregnancies [20]. In pregnancies complicated by gestational diabetes mellitus, benefits of a low GI diet have been consistently reported, including a reduced need for insulin to maintain optimal glucose management [20].

Prepregnancy dietary glycaemic load (GL) and fibre intake may also affect the risk of gestational diabetes as well as preeclampsia. In the Nurses Health Study II (n = 13 110), higher dietary GL was associated with greater risk of gestational diabetes. Conversely, a 10 g/day increment in total dietary fibre in prepregnancy was associated with a 26% reduced risk of developing gestational diabetes, with each 5 g/day increment in fibre from cereals or fruit reducing the risk by 23% or 26%, respectively [21]. Total dietary fibre has also been associated with improved lipid profiles and reduced risk of preeclampsia. Based on current evidence, low GI, low GL, and/or high fibre diets could be recommended preconceptionally to women at risk of gestational diabetes, pre-eclampsia, or having LGA infants.

Fatty Acids

Marine foods and fish oil supplements (mainly omega-3 supplements) are rich sources of *n*-3 long-chain polyunsaturated fatty acids such as docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA). DHA is proposed to influence the neural and visual development of infants, while EPA may reduce the synthesis of thromboxane A2 from arachidonic acid, which in turn may influence the risk of preeclampsia and timing to parturition. A recent review (54 trials, n >15 000) found that omega-3 supplementation during pregnancy reduced early preterm birth (<34 weeks' gestation) but increased the rate of prolonged pregnancies (>42 weeks' gestation) [22]. Other meta-analyses found no effect of omega-3 supplements on recurrent preterm birth or recurrent intrauterine growth restriction [23, 24]. In summary, evidence regarding the benefits of supplementation with *n*-3 fatty acids has been mixed, and further studies are needed before these supplements can be recommended for use in pregnancy to prevent hypertensive disorders or preterm birth, or to improve fetal outcomes.

Micronutrients

The requirements for most micronutrients rise during pregnancy. While some of these could be met by the increased absorption which occurs during pregnancy, certain populations may be at risk of developing micronutrient deficiency. Deficiency in one or more micronutrients could have long-term consequences for both the mother and the offspring.

Folate

Folate is present in various fruits and green leafy vegetables. Folate is essential for DNA and RNA synthesis, amino acid metabolism, and formate oxidation, and is considered an antioxidant as it removes oxidizing free radicals [25]. Folate is particularly important during phases of rapid cell division and tissue growth such as during embryonic and fetal periods. Circulating folate concentrations usually decrease during pregnancy in women not supplemented with folic acid (the synthetic form of folate). This is likely due to increased folate demand resulting from fetal and uteroplacental organ development, increased blood volume, increased folate catabolism or clearance, decreased folate absorption, or hormonal influences during pregnancy. Women from developing countries, particularly in areas with a high prevalence of malaria or sickle cell disease, are at high risk of folate inadequacy during pregnancy. Low levels of maternal folic acid can elevate serum homocysteine concentrations and increase the risk of fetal abnormalities.

Periconceptional supplementation with folic acid three months before and early in pregnancy can reduce the risk of neural tube defects by almost 75%. This protective effect is smaller in obese women compared to non-obese women. Evidence regarding whether folic acid prevents other fetal complications is less clear. In a 2015 Cochrane review (five trials, n = 7391), folic acid supplements prevented neural tube defects but had no effects on miscarriage, or other birth defects including cleft palate, cleft lip, or congenital heart defects [25].

The recommended daily folate requirement is 400 µg for women of reproductive age, 600 µg for pregnant women, and 500 µg for lactating women. From 12 weeks prior to conception until at least 12 weeks' gestation, all women should be supplemented with 400 µg/day of folic acid to reduce the risk of having a baby with a neural tube defect. A dose of 2.8 mg/week (or 5 mg intermittently) is or poor lifestyle habits including inadequate diet, smoking and alcohol consumption. To achieve optimal outcomes, women supplementing with folic acid should be advised to also maintain a folate-rich diet.

Vitamin A

Vitamin A is a fat-soluble vitamin present in carrots, sweet potatoes, eggs and dairy, and green leafy vegetables such as kale. The main physiological functions of vitamin A include vision, reproduction, growth, immunity, and cell proliferation. Deficiency is assessed by either a history of night blindness or serum or plasma retinol concentrations less than 0.70 µmol/L (subclinical vitamin A deficiency). Globally, the estimated prevalence of night blindness in pregnant women is 7.8% (9.8 million women), while 15.3% (19.1 million women) have deficient serum retinol concentrations. Maternal night blindness has been associated with low birthweight infants and infant mortality. However, a meta-analysis of 19 trials and over 310 000 women found that taking vitamin A supplements during pregnancy reduced risk of maternal anaemia, maternal infection, and maternal night blindness, but did not prevent maternal, perinatal, or newborn deaths, stillbirth, preterm birth, low birthweight, or anaemia in the newborn [26]. Excess retinol, the active form of vitamin A, could have teratogenic effects, hence the upper limit for vitamin A supplements is 10 000 IU per day (3000 µg retinol) and the non-toxic form (B-carotene) is preferred during pregnancy. Overall, due to the potential risk of toxicity, vitamin A supplementation should only be initiated after careful assessment of a woman's current intake. In most developed countries where hypovitaminosis A is rare, there is no need for supplementation.

Vitamin B_1 (Thiamine), Vitamin B_2 (Riboflavin), Vitamin B_3 (Niacin), Vitamin B_6 (Pyridoxine)

Vitamin B_1 (thiamine), vitamin B_2 (riboflavin), vitamin B_3 (niacin), and vitamin B_6 (pyridoxine) are involved in energy production and the metabolism of protein, fat, and carbohydrates. Greater energy and protein requirements during pregnancy increase the requirement for these vitamins. Thiamine deficiency could impair fetal brain development due to the role of thiamine-dependent enzymes in lipid and nucleotide synthesis in the brain. Deficiency in riboflavin has been associated with low birth weight, preeclampsia, and congenital heart defects; however, evidence regarding the use of riboflavin supplements to prevent these outcomes has been inconsistent. Periconceptional intakes of thiamine, niacin, and pyridoxine have been associated with lower risk of orofacial cleft, but causality has not been established due to the paucity of randomized trials testing these vitamins. In a systematic review of four trials (n = 1646), supplementation with pyridoxine did not prevent eclampsia or preeclampsia, and there was insufficient data to assess its effects on other maternal or neonatal outcomes. In summary, the effects of supplementing these vitamins during pregnancy remain unknown.

Vitamin B_{12} (Cyanocobalamin)

Vitamin B_{12} is vital for cellular growth, differentiation, and development [25]. Together with folate, vitamin B_{12} is responsible for the conversion of homocysteine to methionine, a process which is important for the methylation of DNA, proteins, neurotransmitters, and phospholipids. Because vitamin B_{12} is mainly derived from animal sources, those with restricted meat intake are at higher risk of deficiency. Global estimates suggest that vitamin B_{12} insufficiency is prevalent in 25% of pregnancies, ranging between 21%, 19%, and 29% in the first, second, and third trimesters, respectively. Women in the Indian subcontinent and the Eastern Mediterranean have high rates of vitamin B_{12} insufficiency.

Low vitamin B_{12} concentrations are associated with high plasma homocysteine levels, which have been implicated in various adverse pregnancy outcomes including placental abruption, stillbirths, low birthweight, and preterm deliveries. A meta-analysis of 18 longitudinal studies including individual patient data (11 216 observations) found that vitamin B_{12} deficiency (<148 pmol/L) was associated with an increased risk of low birthweight infants and preterm birth [27]. Similar to folate, low maternal vitamin B_{12} levels have also been associated with increased risk of neural tube defects and spina bifida. The effects of vitamin B_{12} supplementation during pregnancy are currently unknown and given the risks associated with B_{12} deficiency, further investigation by means of randomized controlled trials is warranted.

Vitamin C and E

Vitamin C (ascorbic acid) and vitamin E (tocopherols/tocotrienols) are important antioxidants which inhibit free radical formation, and vitamin C is additionally involved in collagen synthesis and iron and folate metabolism. Increased oxidative stress by free radicals has been implicated in the pathogenesis of preeclampsia and premature rupture of membranes (PROM), prompting interest into whether antioxidants such as vitamins C and E may protect against these conditions. In two separate Cochrane reviews, vitamin C (n = 29 trials, n = 24 300) and vitamin E (21 trials, n = 22 129), alone, or in combination with other supplements, were associated with a decreased risk of placental abruption, but an increased risk of self-reported abdominal pain [26, 27]. Vitamin C also resulted in a small increase in gestational age at birth and, when supplemented alone, reduced the risk of preterm and term PROM. Conversely, supplementation of vitamins C and E together, or vitamin E alone, increased the risk of term PROM [28, 29]. No other benefits or harms were reported for either vitamin. Overall, current evidence does not support the use of vitamins C or E for improving maternal or perinatal outcomes, and further research is needed to elucidate their roles in placental abruption and PROM.

Vitamin D

Vitamin D is a fat-soluble hormone with a well-established role in calcium metabolism and bone homeostasis. Vitamin D is synthesized by the skin upon exposure to sunlight and it can also be obtained from dietary sources such as oily fish or fortified dairy products, or from supplements in the form of ergocalciferol (vitamin D_2) or cholecalciferol (vitamin D_3). Vitamin D deficiency is determined by measuring its major circulating form, 25-hydroxyvitamin D (25(OH)D), where levels less than 75, 50, and 25 nmol/L are considered insufficient, deficient, and severely deficient, respectively. In developed countries, poor vitamin D status may result from low intake of fortified foods, highly pigmented skin, and minimal sunlight exposure due to long hours spent indoors and the use of sunscreen and protective clothing to prevent skin cancer. Global reports suggest that 40–98% of pregnant women are vitamin D-deficient, of which 15–84% are severely deficient.

Vitamin D deficiency is a known risk factor for rickets in infants and osteomalacia in adults. A meta-analysis of 15 trials (n = 2833) found that vitamin D supplements during pregnancy may reduce the risk of preeclampsia, low birthweight, and preterm birth. However, when vitamin D and calcium were combined, the risk of preterm birth was increased [30]. Limitations in the available studies and lack of reporting on adverse events were also noted. Hence, while preventing and treating vitamin D deficiency is important to maintain optimal maternal and fetal bone health, there is limited evidence to support the use of vitamin D supplements for other pregnancy outcomes.

Calcium

Calcium is an essential nutrient for various biological functions including skeletal development, muscle contraction, and enzyme and hormone homeostasis. Calcium absorption increases in pregnancy and a dietary intake of 1200 mg daily is recommended. Inadequate calcium intake during pregnancy can have adverse effects on both mother (osteopenia, paraesthesia, tremor, tetanus, muscle cramping) and fetus (delayed growth, low birthweight, poor fetal mineralization). However, trials evaluating the effect of calcium supplementation on maternal bone mineral density and fetal bone mineralization have been inconclusive.

Reduced calcium intake has also been implicated in the development of hypertension in pregnancy. A 2013 report by the World

Health Organization (WHO) combined two Cochrane reviews (21 trials; n >90 000) and found that calcium supplementation reduced the risk of preeclampsia by 52%, irrespective of baseline risk of hypertension or calcium intake status. The protective effect was greater in women at higher risk of hypertension and/or with lower calcium intakes (less than 900 mg daily). Modest reductions in preterm birth were also reported in women who received 1500–2000 g of elemental calcium daily compared to lower intakes; however, the quality of evidence was poor for this outcome [31]. Supplementation with 1.5–2.0 g/day of elemental calcium for prevention of preeclampsia has been recommended by the WHO for all pregnant women where dietary calcium intake is low, but particularly among those at higher risk of hypertension [31].

Iodine

Iodine is a non-metallic trace element essential for the synthesis of thyroid hormones. Dietary sources of iodine include kelp, seafood, and plants from iodine-rich soil, although the main source of iodine is via fortified salt. Nearly two-thirds of the populations in Western and Central Europe live in regions of mild to severe iodine deficiency, with those in mountainous and flooded areas being at increased risk. Iodine deficiency is the most common cause of preventable mental deficits globally, manifesting in a spectrum of iodine deficiency disorders (IDDs). These IDDs range from mild intellectual blunting to endemic cretinism (permanently and severely stunted physical and mental development). Other IDDs include maternal and fetal goitre and hypothyroidism, increased pregnancy loss, and infant mortality.

Given that the fetus depends on maternal iodine to synthesize its own thyroid hormones, even marginal iodine deficiency and hypothyroidism in pregnancy can influence the physical and mental development of the fetus. In a systematic review of 11 trials (n >2900), women receiving iodine supplements were 68% less likely to experience the adverse effect of postpartum hyperthyroidism and 15 times more likely to experience nausea and vomiting during pregnancy. A non-significant 34% reduction in perinatal mortality was also observed [32]. WHO recommends a daily intake of 250 μg during pregnancy and breastfeeding and periconceptional iodine supplementation should be considered for women at high risk of iodine deficiency. With the currently available evidence, the benefits and harms of iodine supplementation before, during, or after pregnancy remain unclear.

Iron

Meat, fish, legumes, green leafy vegetables, and iron-fortified cereals are the main dietary sources of iron. The most important role of iron is oxygen transport, although it is also involved in growth, reproduction, and healing. Pregnancy increases the risk of maternal anaemia, specifically iron-deficiency anaemia, due to an increased demand for maternal iron to support maternal and fetal needs. Global estimates suggest that 38.2% of pregnant women are anaemic, with the highest prevalence in South Asia (48.7%) and Africa (46.3%). Iron-deficiency anaemia contributes to 20% of post-birth maternal deaths in Asia and Africa.

Meeting the increased iron requirements during pregnancy is difficult from food sources alone, even with the increased iron absorption which occurs in the second and third trimesters. In a meta-analysis of 44 trials (n = 43 274), iron supplementation reduced the risk of maternal anaemia and iron deficiency in pregnancy. There was also some indication for improved birthweight and risk of preterm birth; however, the evidence for these outcomes was less clear [33]. As iron stores at conception are strong predictors of maternal iron status and risk of anaemia in later pregnancy, iron supplementation may have its greatest benefit if started at conception or in early pregnancy. Adequate iron status during pregnancy can also prevent postpartum anaemia, which is associated with postpartum depression. However, these benefits are weighed against a potential dose–response relationship with adverse events such as constipation, nausea, vomiting, and diarrhoea. Routine iron supplementation of pregnant women is recommended in some countries such as the US and France, but not in others such as the UK and Australia, which instead recommend screening pregnant women for anaemia and treating those with iron-deficiency anaemia (IDA). In countries where there is a high risk of IDA and screening is inadequate, daily supplementation of 60 mg during pregnancy is recommended by the WHO. Intermittent supplementation regimens should also be considered as they are as effective as daily supplementation but with fewer side effects.

Zinc

Zinc is present in meat and seafood. It is a cofactor in over 80 metalloenzymes with a ubiquitous role in biological functions including DNA transcription, protein synthesis, cellular division, wound healing, neurological function, immunity, folate utilization, and vision. Zinc also has antioxidant properties. It binds the sulphydryl groups in proteins and displaces iron or copper while preventing them from binding to lipids, proteins, and DNA. Zinc status is determined by measuring plasma or serum zinc levels, zinc-dependent enzyme levels, or 24-hour urinary zinc excretion. Cut-offs for defining zinc deficiency differ by age, sex, and time of day of sampling, making it difficult to establish global zinc deficiency status. Based on dietary data, however, it is estimated that 17% of the global population is at risk of zinc deficiency. Strict vegetarians and those with chronic diseases or infections are at increased risk. In two meta-analyses, zinc supplementation during pregnancy reduced the incidence of preterm birth by 14% but had no effects on neonatal mortality, birthweight, or preeclampsia [34, 35]. The effect of zinc on preterm birth was observed primarily in women from low-income settings, and thus may have been amplified by the poor overall nutritional status of these women. Altogether, the evidence shows limited benefits of zinc supplementation during pregnancy. Improving overall nutrition, particularly in women from low-income settings, is likely a more prudent approach for improving pregnancy outcomes than with zinc supplements alone.

Alcohol and Caffeine

Globally, it is estimated that 5–10% of pregnancies are at risk of alcohol-related birth defects. In addition to the known impact of alcohol abuse on fetal alcohol syndrome, regular alcohol intake (at least once a week) or high alcohol consumption (more than 14 units a week or more than 3 units a day) increase the risk of

first-trimester miscarriage and SGA infants. The effect of moderate or occasional alcohol consumption on pregnancy outcomes is less clear. Two systematic reviews reported that prenatal alcohol exposure was associated with poorer child cognition, behaviour, and mental development, irrespective of the level of alcohol consumed [36, 37]. In contrast, two other systematic reviews concluded that there was no convincing evidence of adverse effects from low to moderate prenatal alcohol exposure. Inconsistencies and weaknesses in the evidence, including lack of adjustment for sociodemographic confounders, preclude the ability to determine safe levels of drinking during pregnancy. As such, it is advisable that women avoid alcohol intake during pregnancy.

Evidence regarding the effects of caffeine on pregnancy outcomes has been inconsistent. Maternal caffeine intake appears to have no effect on cardiovascular malformations, oral clefts, or early miscarriage. Some prospective cohort studies have reported that high caffeine intake (>200 mg/day) increases the risk of miscarriage after adjusting for several confounders, while others found no relationship between caffeine consumption and miscarriage, growth restriction, low birthweight, or preterm delivery. Current evidence is insufficient to confirm or refute the benefits of caffeine avoidance in pregnancy. Until safety limits are established, women with high daily caffeine intake (>200 mg) should be advised to minimize caffeine intake during pregnancy.

Nutrition and Reproduction in Men

Compared to the literature in women, there is relatively limited information on nutrition and reproduction in men. Obesity is a risk factor for infertility in males, as it is in females. A dose–response relationship between BMI and infertility in men has been reported, and a high BMI has been associated with lower sperm count, density, and motility; reduced testosterone and testosterone/oestrogen ratio; and a greater number of sperm cells with chromatic damage measured using DNA fragmentation index. Paternal obesity may also

Table 8.8.2.4 Dietary recommendations for optimal reproductive outcomes

Energy	• There is lack of evidence to advise on energy restriction during pregnancy. Prevention of excessive gestational weight gain in high-risk women (e.g. overweight and obese women, women at high risk of gestational diabetes) is associated with reduced risk of infant macrosomia and infant respiratory distress syndrome.
Protein	• Balanced energy/protein intake (<25% energy from protein) may increase birthweight and reduce the risk of SGA infants and stillbirth, particularly in women at high risk of nutritional inadequacy • Isocaloric or high protein intake (>25% energy from protein) may increase the risk of SGA infants.
Glycaemic index (GI), glycaemic load (GL) and dietary fibre	• Low GI diets during pregnancy can reduce the risk of LGA infants and improve glycaemic control in gestational diabetes • Low GL and high fibre diets before pregnancy may prevent the development of gestational diabetes, and high fibre diets may also reduce the risk of preeclampsia
N-3 polyunsaturated fatty acids	• Insufficient evidence to support the use of fatty acid supplements to improve maternal or fetal outcomes.
Folate	• Supplementation is recommended for women from 12 weeks prior to conception until at least 12 weeks' gestation during preconception (400 µg) to prevent neural tube defects • Women supplementing with folic acid should be advised to also maintain a folate-rich diet.
Vitamin A	• Supplementation, preferably with β-carotene, should only be initiated in women with deficiency after careful assessment of current vitamin A intake. Excess retinol intakes may have teratogenic effects.
B vitamins (B_1, B_2, B_3, B_6, and B_{12})	• Deficiency may increase the risk of adverse pregnancy outcomes, but effects of supplementation are unknown.
Vitamin C and E	• Evidence for supplementation in pregnancy is inconclusive due to reports of both benefits and harms in relation to placental abruption and premature rupture of membranes.
Vitamin D	• Supplementation in women with inadequate vitamin D status may help maintain optimal maternal bone health and prevent poor bone mineralization in the fetus.
Calcium	• Supplementation of 1.5–2.0 g elemental calcium/ day is recommended by the WHO in women with low calcium intakes (<900 mg/day) and/or women at high risk of gestational hypertension to prevent preeclampsia and promote fetal bone mineralization.
Iodine	• The WHO recommends a daily intake of 250 µg during pregnancy and breastfeeding and periconceptional iodine supplementation should only be considered for women at high risk of iodine deficiency • The current evidence on the benefits and harms of iodine supplementation before, during, or after pregnancy is unclear.
Iron	• Pregnant women should be screened and treated for iron-deficiency anaemia • Daily supplementation of 30–60 mg from early pregnancy is recommended where screening is inadequate.
Zinc	• Some evidence of benefit in preventing preterm birth in low-income settings; however, the evidence is insufficient to support routine supplementation.
Alcohol and Caffeine	• Safety of low to moderate intake cannot be established from current evidence. Women are advised to limit or avoid alcohol and minimize caffeine consumption during pregnancy.

Abbreviations: GI/GL, glycaemic index/load; SGA/LGA, small/large for gestational age.

have adverse effects on the reproductive health of the offspring, leading to further amplification of subfertility.

Despite limited studies in this field, recent systematic reviews have revealed a number of trends linking nutrition with male reproductive health. First, higher sperm quality has been associated with diets which are low in saturated and transfatty acids and high in omega-3 fatty acids, folate, zinc, β-carotene, and vitamins D, E, and C. Second, healthy dietary patterns characterized by higher intakes of seafood, poultry, whole grains, fruits and vegetables, and low-fat dairy have been associated with higher sperm quality, whereas diets rich in processed meat, soy, potatoes, full-fat dairy, coffee, alcohol, sweets, and sugary drinks have shown the opposite relationship. Third, a Cochrane review of 34 trials (n = 2786 couples) reported that semen quality and clinical pregnancy rates were improved by antioxidant supplementation [36]. However, heterogeneity in study populations and regimens, and the expansive definition of antioxidants makes it difficult to ascertain which specific antioxidants, and at which doses, were responsible for these effects. Last, moderate intake of caffeine and alcohol do not appear to have a meaningful impact on semen quality or fecundability. However, further well-designed studies are needed to confirm these effects and to establish which patterns, level, and duration of alcohol or caffeine consumption may affect male reproductive health. See Table 8.8.2.4 and [39].

8.8.3 Exogenous Factors and Female Reproductive Health

Environment and Reproduction

Evanthia Diamanti-Kandarakis and Eleni A. Kandaraki

Overview of Female Reproduction and Environment

Female reproductive system is one of the most delicate systems of the human body. Under the orchestrating signals of hypothalamus, each component of the activated axis of hypothalamus–pituitary–ovary has to cointeract harmonically, in order to create the optimal hormonal milieu for its proper function.

Increased global industrial activity has exposed humans to a wide variety of modern chemical substances. In fact, we live in a world in which chemicals are an integral part of our everyday life. These exogenous insults can perturb hormonal balance of female body and threaten reproductive health and ultimately reproductive capacity.

Endocrine-Disrupting Chemicals (EDCs)

Definition and Mechanism of Action of EDCs

EDCs or endocrine disruptors are 'exogenous chemicals, or mixture of chemicals that interfere with any aspect of hormone action, leading to adverse effects in an intact organism or its progeny or (sub)populations'. Humans are continuously exposed to EDCs in daily life via multiple ways of contact [1].

Currently, nearly 800 chemicals are known or suspected to play a negative role in hormonal disruption, and this list is rapidly growing. EDCs are a heterogeneous group of molecules with the high potential to interact directly with hormone receptors (e.g. oestrogen, androgen, thyroid) as agonists or antagonists, triggering different molecular pathways. Some EDCs can also interfere with proteins involved in the transport of hormones, such as sex hormone–binding globulin (SHBG), and thus disrupt the delivery of endogenous hormones to target cells. Their molecular structure usually consists of a phenol group and may possess halogen group substitution by chlorine and bromine. Therefore, they can easily mimic steroid hormones and 'interfere with the synthesis, secretion, transport, metabolism, binding action, or elimination of natural blood-borne hormones that are present in the body and are responsible for homeostasis, reproduction and developmental process' (definition of the US Environmental Protection Agency, EPA). These effects, depending on exposure dose and timing, give rise to alternative phenotypes, which may lead to increased disease susceptibility (Table 8.8.3.1).

The molecular structure and lipophilic properties of some EDCs may promote their bioaccumulation in the adipose tissue of animals and humans. EDCs have been detected also in biological fluids such as sera, urine, amniotic fluid, and breast milk. Some EDCs persist in the body for a long time, such as persistent organic pollutants (POPs), and some (e.g. pesticides) are quickly metabolized and cleared from the organism, although chronic exposure can lead to bioaccumulation [1].

The affinity of the hormone receptors for the EDCs is usually much lower than for natural ligands. For example, the affinity of the classical oestrogen receptors (ER), ER-a, and ER-b, for one of the most commonly used EDCs, bisphenol A (BPA) is 1000–10 000-fold lower than for 17b-estradiol (E2). However, EDCs can act in several tissues, even in low doses, also below the level

Table 8.8.3.1 Classification and physiological effects of common EDCs

Substance categories	Name	Source/Uses	Effects
Bisphenols	Bisphenol A, Bisphenol F	Polycarbonate plastics, epoxy resins, plastic toys, and bottles, lining of food cans	Oestrogenic, obesogenic, Neurological effects, adverse thyroid hormone action, reproductive and developmental effects
Non-steroidal synthetic oestrogen	Diethylstilboestrol (DES)	Pharmaceutical	Transplacental carcinogen, teratogen
Plasticizers	Phthalates (DEHP, BBP, DBP, DPP, DPrP)	Contaminated food, PVC plastics and flooring, personal care products, medical devices and tubing	Carcinogen, liver damage, reproductive and developmental effects, asthma, obesogen
Organochloride	Polychlorinated biphenyl (PCBs)	Contaminated air and food, skin contact with old electrical equipment	Carcinogen, chloracne, stomach and liver damage, reproductive and nervous system effects and thyroid injury
Dioxins and dibenzofurans	2,3,7,8-TCDD, 2,3,7,8-p-TCDD, 2,3,7,8-PCDF, 2,3,4,7,8-PeCDF, 1,2,3,7,8 (9)-PeCDF	Arise as unwanted by-products from certain incineration and industrial chemical process	Antioestrogenic properties
Phyto-oestrogens	Isoflavones, coumestrol, Lignans, and stilbens	Synthesized in plants	Oestrogenic properties

of exposure at which no adverse effects in organism have been observed by toxicologists.

Timing of EDC exposure during lifespan is another crucial parameter for the severity of their biological effects. Firstly, embryonic development, organogenesis, and tissue differentiation *in utero* is a critical developmental window, during which any environmental perturbation can lead to structural and functional changes that can profoundly deflect the developmental trajectory, often leading to lifelong phenotypic changes. Childhood and puberty are also considered periods of rapid change in an endocrine-dependent manner and are recognized as sensitive periods. In other words, the younger organisms are more susceptible to EDCs' action.

Timing of exposure to EDCs is highlighted as such an important factor, due to the unique ability of EDCs to cause epigenetic changes. Epigenetics are defined as changes in gene expression that occur without changes in DNA sequence. Several possible mechanisms of epigenetics exist, including methylation of cytosine residues on DNA, post-translational modification of histones, and altered microRNA expression. These changes alter gene expression and lead to transient or persistent changes in gene transcription [2].

Epigenetic changes can be transmitted through mitosis and/or meiosis. Thus, an altered epigenome, after EDC exposure, will transfer to the subsequent generations by germline in the process called 'epigenetic transgenerational inheritance' [3]. When the F_o generation female is exposed to EDCs during her pregnancy, the fetus and the germline of the fetus of F_1 generation including the cells in the gonads of the F_1 fetus, which will become F_2 generation, are directly exposed to these chemicals too [3, 4].

This transgenerational component of EDC's effects has become really obvious in 'the diethylstilboestrol catastrophe'. Diethylstilboestrol (DES), a potent synthetic non-steroidal oestrogen, is one of the first studied endocrine disruptors. It was prescribed to pregnant women from the 1940s to 1975 to prevent miscarriage and other complications. Its use was discontinued when a subset of exposed daughters presented with early-onset vaginal clear-cell adenocarcinoma, with a 40-fold increase in risk compared to unexposed individuals. The prevalence of neoplasia caused by DES in exposed population is estimated to be 0.1%, but this is much lower than the prevalence of subfertility and infertility occurred in DES intrauterine exposed population which is estimated to be >90%, occurring in both sons and daughters. What's more, new data suggest that increased disease risk persists even in their grandchildren a potential epigenetic effect [1, 5, 6].

There has been extensive evidence from experimental studies showing that exposure to endocrine disruptors has a negative impact on ovarian physiology leading to morphological and functional alterations of the female reproductive system [7, 8]. In fact, environmental pollutants are shown to interfere with several aspects of follicle growth and ovarian steroid hormone production by modifying the expression and/or activity of regulatory enzymes or by altering hormone receptor binding and action. Furthermore, early exposure to EDCs has also been experimentally linked to reproductive tract malformations, earlier pubertal timing, alterations of the hypothalamic–pituitary–ovarian axis, disorders of ovulation, fertility, and fecundity [7].

EDCs Affect Early Gonadal Development

Early gonadal development begins with the primordial germ cells originating in the proximal epiblast, far from the testes or ovaries. At this stage of development, the gonadal ridges are still bipotential, and they remain so until gestational week 7 in humans [1]. The expression of the Y chromosome-specific gene (*Sry)* in XY gonadal ridges triggers the differentiation of the gonadal ridges into testes, whereas, in the absence of a Y chromosome, the XX gonadal ridges differentiate into ovaries. The differentiation of testes and ovaries is chiefly under genetic control and involves several morphogenetic pathways.

Recent data suggest that these early stages of folliculogenesis are vulnerable to exogenous perturbations [7]. For example, intrauterine exposure to the analgesic and antipyretic drug, acetaminophen, reduced the number of germ cells in female mouse fetuses, due to disrupted proliferation of the primordial germ cells.

Furthermore, continuous exposure of female mice to paracetamol until birth resulted in a reduction in ovarian follicle reserves and total number of follicles, which led to subfertility.

The industrial chemical BPA, which is widely reported to have oestrogenic and other endocrine-disrupting properties, also interferes with gonadal development. In mouse embryonic stem cells, exposure to BPA results in the downregulation of the testis-promoting genes *Sox9* and *Fgf9* and in the upregulation of the ovary-promoting genes *Wnt4* and *Foxl2* during differentiation, suggesting that exposure to BPA favours ovary differentiation4,. Acting in a similar way, tamoxifen, an oestrogen receptor (ER)-modulator used in breast cancer therapy, promotes ectopic upregulation of Sox9 and downregulation of Foxl2 in the XX gonads. Ultimately, disrupting the balance between these opposing factors can lead to sex-reversal phenotypes and cause reprogramming of the cell types in adulthood, which, in turn, will adversely affect the germ cell population, future oocyte reservoir, and reproductive lifespan, leading to infertility. Notably, *FOXL2* mutations in humans cause premature ovarian insufficiency [9, 10].

Another process of early gonadal development that is susceptible to exogenous effects is meiotic division. In females, meiosis begins during fetal life and arrests in prophase I until puberty. Disruption of germ cells at this stage can have long-lasting consequences for reproductive health parameters due to reduction in the number of oocytes. For example, gestational exposure to BPA [7], through its estrogenic effects, can disrupt meiotic division in mice and monkeys, via altered the expression of genes that control meiosis (*Stra8, Dazl, Nobox*). Furthermore, *in vitro* studies indicate that BPA impaired meiotic progression in cultured human fetal oocytes, increased levels of recombination (MLH1 foci), and induced epigenetic changes that may contribute to chromosome congression failure. Analogous data exist in literature for endocrine disruptor di(2-ethylhexyl) phthalate (DEHP) and paracetamol [1].

EDCs Affect Follicular Assembly and Folliculogenesis

Follicle assembly is crucial for establishing the primordial follicle pool. The assembly or formation of the primordial follicles requires individual oocytes to segregate and associate with squamous (i.e. precursor) granulosa cells. Nests of associated oocytes undergo random apoptosis of individual oocytes to derive isolated oocytes that then associate with precursor squamous granulosa cells [1]. In humans, the timing of primordial follicle assembly is very different from that of rodents, with follicle assembly occurring during mid-gestation stage. The mechanisms that control follicular assembly remain unclear. Evidence suggests that, in mouse fetuses, high levels of maternal oestradiol and progesterone inhibit follicle assembly and that a reduction in the levels of steroid hormone around the time of birth initiates the process. Furthermore, the human fetal ovary expresses steroidogenesis enzymes and steroid hormone receptors, particularly ERβ, during the second trimester, which enables oestrogenic, progestogenic, and androgenic signalling to occur.

These data indicate that oestrogen has an important role in follicle assembly but also highlights the potential susceptibility to disruption by oestrogenic compounds. Thus, several chemicals including BPA and DEHP can interfere with this process, possibly by disrupting apoptotic-signalling pathways. For example, oral exposure of pregnant mice to BPA results in an increased percentage of oocytes in germ cell nests, an increase in the total number of oocytes per ovary section and a decrease in the number of primordial follicles in offspring. Similarly, subcutaneous exposure of neonatal mice to the phyto-oestrogen, genistein, inhibits the breakdown of the germ cell nest and disrupts primordial follicle assembly. Taken together, these studies support the view that many EDCs can have capacity to disrupt follicle assembly, potentially affecting both the quantity and quality of follicles later in life [4, 5, 9].

After follicle assembly and the formation of primordial follicle pool, the first wave of follicular recruitment and folliculogenesis is initiated. Following exposure to BPA from 1 to 14 days postpartum, 30-day-old lambs had reduced ovary weight, fewer primordial follicles, more transitional and primary follicles, but a stable total number of oocytes compared with lambs that were not exposed to BPA. In proportion a decrease in the number of primordial follicles, concomitant with an increase in the number of secondary and antral follicles, has been observed in 15-day-old mice after exposure to DEHP from 7 to 14 days postpartum. Thus, EDCs can accelerate the rate of follicular recruitment, leading to adverse consequences later in life, such as a shorter reproductive lifespan due to a reduced number of primordial follicles [4].

EDCs Affect Steroidogenesis

EDCs also have the potential to interfere with ovarian steroidogenesis. In rat theca-interstitial and granulosa cell cultures, BPA significantly increases testosterone and progesterone levels by increasing the expression of several key cytochrome p450 steroidogenic enzymes, such as 17-a hydroxylase and cholesterol side chain cleavage enzyme, respectively. There is a hypothesis that BPA stimulates ovarian theca-interstitial cells to elevated androgens synthesis and also inhibits testosterone catabolism, thereby leading to elevated androgen levels. In fact, human studies have confirmed this positive correlation between serum BPA level and elevated androgen levels, such as total and free testosterone, androstenedione, and dehydroepiandrosterone (DHEA), in women with polycystic ovary syndrome (PCOS) [10].

Similar data exist for various EDCs. For example, exposure to the organochlorine pesticides were associated with a slower drop in the oestradiol ratio and progesterone metabolites after ovulation in women, with decreased progesterone levels and a shorter luteal phase in women, findings that were in accordance with inhibited production of oestradiol, testosterone, androstenedione, and progesterone in isolated mouse antral follicles [6].

EDCs Metabolic Disruption Combined with Female Reproductive Deregulation

After the initial observation that obesity affects unfavourably fertility and fecundability, it is now widely accepted that the metabolic profile of a woman stigmatizes her reproductive function, starting from *in utero* fetal development and offspring programming. In addition to that, there is considerable experimental evidence linking EDCs with metabolic alterations through deregulation of normal lipid and glucose homeostasis. Importantly, the world's modern epidemics—obesity and diabetes—are believed to be partly related

to the increasing presence of such substances including the intra and extrauterine environment of developing organisms. The so-called **obesogens** are environmental chemicals presumed to favour obesity development through inappropriate regulation of energy and lipid metabolism. Many of their effects are mediated through the peroxisome proliferator-activated receptor-γ (PPAR-γ) who acts as a regulator of adipocyte differentiation [1].

Interestingly, an environmental chemical may alter concomitantly reproductive as well as metabolic pathways. BPA is a characteristic example of such interaction as it has been incriminated for multiple reproductive abnormalities as well as metabolic ones. Remarkably, epidemiological evidence link BPA detected in urine with cardiovascular disease, type 2 diabetes, and liver enzyme abnormalities in a representative sample of adult US population, while data are suggestive that BPA is also elevated in obese women with fertility problems. Animal models of prenatal and perinatal BPA exposure demonstrate a disruption of weight control mechanisms leading to increased adipose storage in early postnatal and adult life in addition to impair follicular maturation process, ovarian steroidogenesis, oestrous cyclicity, ovulation, and ultimately fertility [4, 9].

EDCs Exposure and Reproductive Health

Taking all these aforementioned together, experimental data suggest that EDCs have the potency/potential to disrupt the reproductive function, targeting at multiple stages directly and indirectly at the level of the ovary, affecting follicle maturation and ovarian steroid hormone production [4]. Scientific community has introduced the term '**ovarian dysgenesis syndrome**' to describe schematically this disruption. Ovarian dysgenesis syndrome is defined as early alterations in ovarian structure or function that cause an impairment of reproductive parameters in adulthood. This compromised reproductive development or function constitutes an underlying pathophysiological mechanism for a group of related female reproductive diseases and disorders, such as reduced fertility, PCOS, premature ovarian insufficiency, and reproductive-site cancers (Figure 8.8.3.1).

Firstly, there is no doubt that a significant decrease in total fertility rates, measured as live births per woman, has been observed during the past few years in modern, industrialized countries all over the world [8]. This decrement has a multifactorial aetiology and can be partly explained by changing attitudes towards family planning, as well as by socioeconomic changes that took place in contemporary societies. However, we cannot argue the fact that our chemically burdened environment has contributed to the increase in women reporting difficulties with conceiving and maintaining a pregnancy [6].

Infertility: Although any causal relationship between EDC exposure and infertility has not been established yet, indirect evidence supporting this interaction are ample. The widespread medical use of assisted reproductive techniques in the modern era has contributed to this direction. Various studies of women undergoing *in vitro* fertilization (IVF) have documented the close association between EDC exposure levels and increased odds of implantation failure, higher risk of miscarriage, poor embryo quality, and decreased pregnancy and live birth rates. Furthermore, even when pregnancy is achieved, preterm birth, decreased gestational age at birth, decreased birth weight, and decreased body length can be observed in EDC exposed women [6, 11].

Polycystic ovary syndrome: PCOS is a multifactorial endocrinopathy of unknown aetiology affecting approximately 5–10% of women in the reproductive age spectrum. Cardinal features of the syndrome are reproductive and metabolic aberrations central to which is abnormal gonadotropin secretion, disrupted ovarian follicular maturation, and steroid hormones secretion as well as disturbed insulin action leading to insulin resistance and compensatory hyperinsulinemia. The role of the environment in

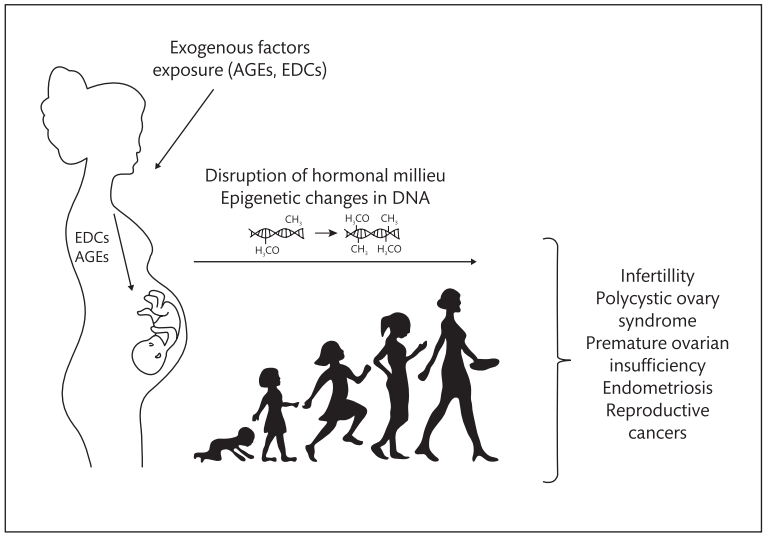

Figure 8.8.3.1 *In utero* exposure to exogenous factors (EDCs, AGEs) significantly affects multiple stages of early gonadal development. Via altering hormonal milieu and inducing epigenetic changes in DNA, endocrine disruptors have a negative impact on ovarian physiology leading to morphological and functional alterations of the female reproductive system. Ultimately, this compromised reproductive development/function constitutes an underlying pathophysiological mechanism for a group of related female reproductive diseases and disorders during adulthood, such as reduced fertility, polycystic ovary syndrome, premature ovarian insufficiency, and reproductive-site cancers.

PCOS pathogenesis has recently expanded to include EDCs, due to their potency to interfere with all hormone-sensitivity systems [11, 12].

The first study supporting the hypothesis that EDCs are actively implicated in the aetiology of PCOS was made by Fernandez *et al.* [7]. In this study, the effects of early life BPA exposure on reproductive parameters in a rat animal model, were investigated. When female rats were neonatally exposed to BPA, they exhibited a PCOS-like syndrome characterized by biochemical hyperandrogenaemia, anovulation, infertility, polycystic ovarian morphology, and increased gonadotropin-releasing hormone (GnRH) pulse frequency when they reached adulthood [7]. Human data have come to support this hypothesis. In a large study of 71 PCOS and 100 healthy women stratified by body mass index (BMI), it was showed that BPA levels are higher in PCOS women compared to controls, independently of body weight as both lean and overweight PCOS individuals had elevated BPA levels compared to normal ovulating non-hyperandrogenaemic women of matched body weight. Except for BPA, several studies have explored the higher serum concentration of other EDCs in PCOS patients: perfluorooctanoate, perfluorooctane sulfonate, polychlorinated biphenyls (PCBs), organochlorine pesticides, and polycyclic aromatic hydrocarbons [9].

Premature ovarian insufficiency: Premature ovarian insufficiency (POI) is a medical and biological diagnosis that affects young women, altering their quality of life and their fertility. In most cases, its aetiology remains undetermined, reflecting the fact that ovarian reserve can be perturbed by multifactorial, combining factors that are genetic, infectious, metabolic, as well as environmental. Given the multiple effects of EDCs in gonadal development and folliculogenesis, it is reasonable to assume that EDCs can be catalytic in POI pathogenesis. Human data to support this hypothesis are limited but illuminating. Epidemiological studies have shown that women with higher levels of phthalates and pesticides had an earlier mean age at menopause. Furthermore, DES *in utero* exposure was associated with an increased lifetime risk of early menopause in women, while increased urinary concentrations of BPA was positively associated with markers of oxidative stress and inflammation in women, suggesting BPA exposure promotes oxidative stress and inflammation, two key mechanisms of cellular senescence and ageing [1].

Endometriosis: Endometriosis affects up to 10% of women of childbearing age, causing infertility in about half of those women. EDCs have recently been implicated in the development or exacerbation of endometriosis. Women exposed to DES *in utero* may have an 80% higher risk of endometriosis than unexposed women. Furthermore, significantly higher levels of BPA, phthalates and PCB were found both in serum and peritoneal fluid of women with endometriosis, promoting chronic inflammation and triggering the stimulation of endometrial cells derived from retrograde menstruation [4, 8].

Reproductive cancers: Incidences of breast, endometrial, and ovarian cancers are increasing, and it is suspected that EDCs and other environmental factors may contribute to this increase. EDCs may act at many levels to disrupt female reproductive tissue development and to make tissue more vulnerable to a subsequent hit of an environmental chemical or hormonal insult. Several epidemiological studies have revealed an increased risk of reproductive cancer in association with EDC exposure. Occupational exposure to dioxins increased endometrial cancer risk in female workers, while women previously exposed to chlorotriazine herbicides showed a significant 2.7-fold increased risk for ovarian neoplasms [8, 11, 13].

Human Exposure Levels

Although the data about direct adverse health effects after human exposure to EDCs are still limited, abundant evidence from *in vitro* and animal studies, as well as from wildlife observations, are sufficiently alarming that several professional organizations have issued statements about a call to action. However, there is still a crucial question that has to be addressed; how experimental data can be applied in humans and whether the same chemicals can cause similar effects in humans at doses that are relevant to real-life exposure.

Several biomonitoring studies, undertaken by International Authorities are trying to estimate daily human EDCs exposure levels and establish safety margins, below which human exposure can be considered safe. Although there is chronic exposure to EDCs through inhalation and skin contact, the major route of human exposure is ingestion of food and water (e.g. meat, fish, dairy products, and vegetables), which can be contaminated with various pollutants. Indeed, plastic packaging of food, which commonly contains BPA, is now established as one of the most important daily sources of EDCs. The European Food Safety Authority has estimated that mean and high dietary exposure levels are 0.1 μg/kg and 0.4 μg/kg of bodyweight per day of BPA, respectively. Since animal studies have indicated that BPA affects ovary development at doses of ~20 μg/kg of bodyweight per day, there is a no-effect level below ~20 μg/kg of bodyweight per day in animals. When these data are applied to human risk assessment, a 100-fold difference (safety margin) between no-effect levels in animal studies human exposure levels is generally required, in order for human exposure to be considered safe. Thus, persons with high exposure levels to BPA can really be at risk for its adverse reproductive effects.

Finally, another parameter that needs to be highlighted is that humans at the same time are continuously exposed to numerous chemicals, including EDCs. Given the fact that most experimental studies typically study the effect of a single chemical under a certain period of time, it may be possible that synergistic action of various EDCs, for a longer period of time, can lead to even more deleterious consequences. Although some studies focusing on chemical mixtures have been carried out so far, there is still paucity of knowledge on how to interpret EDCs complex dose–response curves due to their overlapping additive/synergistic effects.

Nutrition: Oxidative Stress and Heat-Processed Food, Acting as Environmental Factors, Disrupting Female Ovarian Function

The function of female reproductive axis is closely linked to type and amount of nutritional intake. The impact of the quality of nutrition on female reproduction is expressed via the type of food

toxins and the oxidative stress produced from nutritional status. Westernized type of diets based on animal-derived food products are an important source of exogenous food toxins, glycotoxins (advanced glycosylated end products—AGEs) [4, 13, 14], which have been shown to interfere with ovarian function in experimental animals and in humans. Therefore, a diet containing high amounts of heat-processed food, especially with high sugar content may significantly increase the amount of these glycotoxins. Additionally, nutritional production of oxidative molecules is a critical regulator of intraovarian environment and subsequently folliculogenesis. A plethora of studies have been conducted so far in order to explore the putative role of oxidative stress in fertility. The majority of them involve women undergoing assisted reproductive techniques (ART), where various systemic and increased levels follicular fluid markers of oxidative stress were correlated with lower ovarian response, poorer embryo quality, decreased fertilization and pregnancy rates [11, 14]. Therefore, oxidative stress postprandially could be a potent, underlying mechanism of various reproductive abnormalities, including ovarian ageing, endometriosis, PCOS, and unexplained infertility. AGEs are important regulators of postprandial oxidative stress, initiating a clustering of molecular changes in several signalling pathways, including ovarian tissues. AGEs are known to induce effects within the body by two separate routes: receptor-independent or receptor—dependent [11, 12]. They can act intracellularly, by crosslinking with proteins, directly altering their structure and therefore their properties and function, or circulate and act on cell surface receptors such as the receptor for AGEs (RAGEs), which act as signal transduction receptors triggering activation of proinflammatory conditions and oxidative stress. AGEs once bonded to their multiligand receptor for advanced glycation end products (RAGE), initiate multiple downstream signalling cascades, such as nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB), protein kinase C (PKC) and mitogen-activated protein kinase (MAPK) pathways. NF-κB activates nicotinamide adenine dinucleotide phosphate (NADPH) oxidase and promotes reactive oxygen species (ROS) production and a sustained inflammatory response that exacerbates further oxidative stress [12, 14]. In fact, AGE-RAGE system seems also to be actively involved in ovarian function. Furthermore, AGEs can also interfere in the glucose homeostasis of granulosa cells, lead to reduced glucose uptake, and disrupt normal follicular growth. Human data, regarding the action of dietary AGEs in female reproductive system, mainly originate from women with PCOS. Specifically, AGEs were found to be distinctively elevated in the serum of women with PCOS, independent of the presence of obesity and insulin resistance. Experimental animal and human studies have underpinned the detrimental effects of dietary AGEs in reproductive and metabolic function of PCOS [14, 15]. In female high-AGE fed mice increased deposition of AGEs and RAGE in theca and granulosa cells was observed, altering the ovarian milieu. In addition, high-AGE diet, in synergy with androgen excess, was shown to downregulate glyoxalase-1 in the ovary, a protective enzyme against glycation, promoting AGE accumulation and ovarian dysfunction. Subsequently, AGE accumulation in the microenvironment of ovary has detrimental effects in the reproductive function [11, 12]. Through downregulating signalling cascades and enzymatic activity, there is no doubt that AGEs contribute significantly to follicular arrest, anovulation, and ovarian dysfunction in PCOS [16]. Analogous findings exist for AGEs, with increased concentration of them both in the follicular fluid and in serum of women undergoing IVF to be negatively correlated with follicular growth, fertilization, and embryonic development. On the other hand, sRAGE, the decoy scavenger of AGEs, via binding and inactivating circulating and follicular fluid AGEs, might be able to serve as a useful biological marker of the follicular environment. In women undergoing IVF it was shown that higher follicular fluid sRAGE levels were accompanied by increased number of oocytes retrieved. Altogether, the literature to date indicates that AGEs have a negative impact on reproductive outcome in women undergoing ART [16].

Summary

In conclusion, acute or chronic exposure to EDCs and AGEs through each stage of life cycle has the potential to alter the structure as well as the functional or hormonal homeostasis in female reproductive system. Extensive data from different scientific models, collected in recent years, have confirmed the increased concern on their negative role. Concomitantly, potentiating further the scientific efforts to explore efficient ways of avoiding their harmful effects on every system and especially on the female reproduction.

Endocrine Disorders of Pregnancy

9.1

General Considerations Relating to Thyroid Disease in Pregnancy

Peter N. Taylor, L.D.K.E. Premawardhana, and John H. Lazarus

Introduction

Thyroid hormone is essential for maintaining a pregnancy and ensuring fetal development [1]. Thyroid disorders are common in women of childbearing age and as pregnancy has a substantial impact on the hypothalamic–pituitary–thyroid axis, abnormal thyroid function is frequently encountered in antenatal clinics. It is also well established that overt thyroid disease is associated with adverse obstetric and offspring neuro-developmental outcomes [1, 2]. There is now growing concern that more marginal degrees of thyroid dysfunction particularly subclinical hypothyroidism (elevated TSH and normal fT_4 concentration) and isolated hypothyroxinaemia (normal TSH and low fT_4) are also associated with fetal loss, prematurity, and impaired offspring cognitive function [3–5]. In some studies, maternal thyroid autoimmunity has also been identified as a potential risk for fetal loss [1] even in euthyroid women. Correction of overt hypothyroidism and hyperthyroidism dramatically reduces the risk of major adverse obstetric outcomes including fetal loss and premature birth.

There has been a dramatic increase in our understanding of both thyroid physiology and immunology in pregnancy as well as the importance of more personalized thyroid hormone reference-ranges and the potential for adverse outcomes with even borderline thyroid function abnormalities. Equally, we now realize other factors including thyroid autoimmunity, hCG levels and iodine status play a role. Iodine is essential for thyroid hormone production. Iodine deficiency is also common and pregnant women and children at greatest risk of being iodine deficient. Iodine deficiency is associated with adverse profound pregnancy and obstetric outcomes. Endocrine disruptors may also interact with iodine status thereby influencing thyroid status and pregnancy outcomes.

Interpretation of Thyroid Function Tests During Pregnancy

The profound physiological changes that occur during pregnancy have substantial consequences for the thyroid axis and in the assessment of thyroid function. It is clear there is a significant overlap between the signs and symptoms of the hypermetabolic state typical of normal euthyroid pregnant women, and those due to thyroid dysfunction. Taken together, the diagnosis of thyroid disease during pregnancy can be challenging and the availability of reliable accurate tests for gestational thyroid function is critical. Unfortunately, the notable underlying physiological changes which occur during pregnancy also create challenges in laboratory assessments of thyroid function. The substantial but reversible changes in thyroid function which occur in pregnancy are summarized in **Table 9.1.1** and **Figure 9.1.1**.

Abnormal thyroid function is best defined using pregnancy-specific reference ranges. calculated in a population of pregnant women free of major factors that interfere with thyroid function. These factors include pre-existing thyroid disease and autoimmunity, iodine deficiency, or high hCG states (twin pregnancy or following IVF) [1]. Excluding thyroid autoimmunity can substantially lower the upper limit of the TSH threshold. The most recent American Thyroid Association guidelines advocate the use of pregnancy specific and population-based reference ranges [6]. Additionally, calls have been made for more personalized reference ranges based on ethnicity [7] BMI parity, and fetal sex [8].

Traditionally, TSH was the mainstay of assessing thyroid status in pregnancy, however there is increasing evidence of important obstetric and offspring outcomes with fT_4 status [1, 9]. Furthermore, fT_4 levels are needed to distinguish between subclinical and overt thyroid disease. fT_4 immunoassays which are commonly used may

Table 9.1.1 Physiological changes that influence thyroid function in pregnancy

Physiological change	Effect on thyroid function test	Key point for clinicians
↑ Thyroxine-binding globulin	↑ Serum total T_3 and T_4 concentration	Total thyroid hormone concentrations may be misleading; rely on free thyroid hormone concentrations
Secretion of human chorionic gonadotrophin	↑ Free T_4 and ↓ TSH	High human chorionic gonadotrophin levels may result in gestational thyrotoxicosis. This usually only requires symptomatic treatment but needs to be distinguished from pathological thyroid disease
↑ Iodine clearance	↓ Hormone production in iodine-deficient areas	Need to be mindful of iodine deficiency and ensure optimal intake ideally from before conception
↑ Plasma volume	↑ T_3 and T_4 pool size	
Increased type 3 5-deiodinase (inner ring deiodination) activity from the placental	↑ T_3 and T_4 degradation	Increasing thyroid demand in pregnancy
Thyroid enlargement (in some women)	Increased thyroglobulin	Be aware that a small goitre is common in pregnancy, but may be a sign of low thyroid function so merits thyroid function testing

be less accurate in the third trimester due to alterations in thyroid hormone binding proteins. Fortunately, results are more accurate in the first trimester which has greater influence on obstetric and offspring outcomes.

Overall, there is a transient rise in free T_4 in the first trimester due to the relatively high circulating human chorionic gonadotropin (hCG) concentration which stimulates the thyroid to produce thyroid hormone. This is followed by a decrease of free T_4 in the second and third trimester. In iodine-deficient areas (including marginal iodine deficiency seen in many European countries), pregnant woman may become significantly hypothyroxinaemic with preferential triiodothyronine (T_3) secretion. The thyroidal 'stress' is also evidenced by a rise in the median thyroid-stimulating hormone (TSH) and serum thyroglobulin levels. A summary of TSH fT_4 and hCG concentration during pregnancy are shown in Figure 9.1.1.

Thyroid Hormone Supply to the Fetus

The fetal thyroid begins concentrating iodine at 10–12 weeks' gestation and is under the control of fetal pituitary TSH at approximately 20 weeks' gestation. Maternal thyroid function is therefore critically important in the first trimester as thyroid hormone is crucial for the development of many organs including the brain. Maternal circulating T_4 crosses the placenta to the fetus at all stages of pregnancy by incompletely understood mechanisms but involving both the type 2 and type 3 deiodinase enzymes, which are both significantly expressed in the placenta. Type 3 deiodinase (D_3), which degrades thyroid hormones [10], is also expressed in pregnant uterus, placenta, and fetal and neonatal tissues, and may act as a 'gatekeeper' to prevent too much thyroid hormone transport. Type 2 deiodinase, also located in the uterus and other parts of the genital tract, degrades T_4 in the fetus to provide T_3 for tissue growth and differentiation, and may have a role in fetal implantation. Genetic association studies have also indicated that variation in the deiodinases are associated with maternal pregnancy outcomes, particularly pre-eclampsia [11].

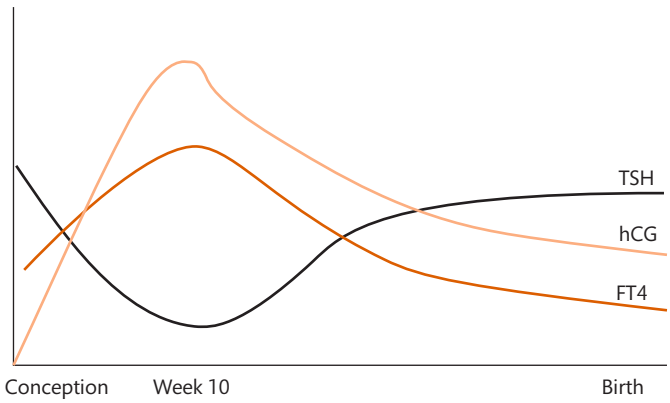

Figure 9.1.1 TSH, fT_4, and hCG levels over pregnancy.

Pregnancy and the Immune System

Human immune regulation involves homeostasis between T helper 1 (Th1) and T helper 2 (Th2) activity, with Th1 cells driving cellular immunity and Th2 cells humoral immunity [2]. In pregnancy, there is a bias towards a Th2 lymphocyte response evidenced by the fetal/placental unit producing Th2 cytokines, which inhibit Th1. Th1 cytokines are potentially harmful to the fetus, for example interferon-α, which is a known abortifacient.

Pregnancy also has a significant effect on the immune system in order to maintain the fetal–maternal allograft and prevent rejection. The trophoblast does not express the classic major histocompatibility complex (MHC) class Ia or II which are needed to present antigenic peptides to cytotoxic cells and T helper cells, respectively. Instead HLA-G, a non-classic MHC Ib molecule, is expressed which may be a ligand for the natural killer (NK) cell receptor thereby protecting the fetus from NK cell damage; it may also activate CD8 T cells that may have a suppressor function. Human trophoblasts also express abundant Fas ligand, thereby contributing to the immune privilege by mediating apoptosis of activated Fas-expressing lymphocytes of maternal origin.

Pregnancy and Thyroid Peroxidase Antibodies

Anti-thyroid peroxidase antibodies (TPOAbs) are found in around 10% of otherwise normal pregnant women when measured at the end of the first trimester. They are a marker of thyroid autoimmunity and the main risk factor for thyroid dysfunction in pregnancy and

in the postpartum period. Women who are TPOAb positive have higher TSH concentrations, lower T4 concentrations and a higher risk of thyroid dysfunction during pregnancy than women who are TPOAb negative [1]. Even in euthyroid women TPOAb positivity is associated with premature delivery and fetal loss [4, 12]. One randomized controlled trial has shown that levothyroxine administration reduced the risk of fetal loss and premature delivery in euthyroid TPOAb-positive women [13]. A later study failed to replicate the benefits for fetal loss but did find a reduction in pre-term delivery [14].

Worse pregnancy outcomes are seen in TPO antibody-positive women, especially those with higher TSH [15]. Recent data suggests that TPOAb positive women do not mount a thyroidal response to hCG [8]; this may, in part, explain the observed worse obstetric outcomes in TPOAb positive women as well as the interactive effect of TPO antibodies with higher levels of TSH. However, the benefits of treating with levothyroxine are unclear. An open label randomized trial in Chinese women with normal thyroid function and TPOAb positivity who were undergoing IVF found that levothyroxine did not reduce miscarriage rates or increase live birth rates [16]. The TABLET trial [17], a large double-blind, placebo-controlled trial also found no benefit from levothyroxine treatment on live birth rates in women with TPOAb positivity and a history of previous miscarriage or infertility. Furthermore, this trial [17] found no benefit of levothyroxine treatment on pregnancy loss, preterm birth, or neonatal outcomes. Nevertheless, it is still important to consider whether there is a synergistic effect of thyroid autoimmunity with borderline low thyroid dysfunction and whether results might have been different in the general population. Therefore, these trials, although elegant, do not address whether universal thyroid screening in pregnancy should be undertaken and trials here are still needed.

Effects of Iodine Status and Nutrition

It has long been established that iodine is essential for thyroid hormone synthesis [18]. Iodine deficiency is also common throughout the world with pregnant women and children at greatest risk of deficiency. Iodine deficiency during pregnancy is associated with maternal goitre due to the imbalance between the intake and increased requirements for iodine during gestation and results eventually in a reduced circulating maternal thyroxine (T_4) concentration. This gestational goitrogenesis is preventable by iodine supplementation [19], not only in areas of severe iodine deficiency, but also has been observed in areas of mild to moderate deficiency [20].

In addition to effects on thyroid growth, iodine deficiency is also associated with adverse obstetric outcomes including fetal loss, profound intellectual disability (cretinism), and goitre. The effects of iodine deficiency are most profound in areas of severe deficiency, but mild to moderate iodine deficiency may have adverse consequences at the population level. Even mild to moderate iodine deficiency in pregnant women is associated with adverse maternal effects including goitre [21] and lower IQ in offspring [22]. Although a recent trial did not show benefit of iodine supplementation on child neurocognition during pregnancy in areas of mild iodine deficiency [23] further studies are required, especially in areas of moderate iodine deficiency.

Table 9.1.2 Iodine status in pregnancy by urine iodine concentration

Median urinary iodine concentration (mcg/L)	Iodine status
Pregnant women	
<150	Insufficient iodine status
150–249	Satisfactory iodine status
250–499	Above required intake
≥500	Excessive iodine status

However, assessment of iodine status, particularly at the individual level is challenging and at present median urinary iodine concentration is used to determine the iodine status of a population. Alternative methods for assessing iodine status such as thyroglobulin levels are also being evaluated. Often there is an increase in urinary iodine in the first trimester compared to non-pregnant women, but where the population has a high median iodine concentration this difference may not occur. Urinary iodine excretion in pregnancy is maximal in the first trimester followed by a decline in the second and third trimesters.

The recommended daily iodine intake in pregnancy has been increased to 250 mcg/day which implies a urinary iodine excretion of 150–250 mcg/day as being adequate [24, 25] (Table 9.1.2). However, despite decades of advocacy, this is not always achieved even in developed parts of the world.

Iodine supplementation is essential to provide iodine sufficiency. This is usually undertaken using iodized salt. This vehicle has been chosen as salt is regularly added to meals during cooking and is used in staple foods such as bread and commercial ready meals. Universal salt iodization has been shown to be extremely effective in reducing iodine deficiency. In keeping with other food fortification initiatives, universal salt iodization programs require national legislation as regional or voluntary programs usually fail to succeed. In the last 30 years, there has been mandatory salt iodization in many countries particularly in the developing world. Iodine fortification of all food-grade salt is now mandated in ~120 countries [26]. While effective iodine supplementation can increase the risk of thyrotoxicosis in older individuals and thyroid autoimmunity in younger people, however, this is far less than the benefits of ensuring iodine sufficiency in pregnant women and children [18].

Screening for Thyroid Dysfunction in Pregnancy

Whether or not to initiate universal thyroid screening is a key debate in thyroidology [3]. Thyroid disorders represent a key easily modifiable risk factor for adverse maternal and offspring outcomes [1] and are common in women of childbearing age [27]. These factors have raised the possibility that universal thyroid screening may be desirable in pregnancy [28]. Some countries including Spain China and Poland are undertaking universal screening although the latest American Thyroid Association guidance discusses screening, but makes no decision for or against universal screening [6]. It is however accepted that targeted screening should be performed in those women at high risk for thyroid disease [6, 29] (Box 9.1.1).

Box 9.1.1 Women at high risk of thyroid disease during pregnancy

- Women with a history of thyroid disease (including hyperthyroidism, hypothyroidism, and post-partum thyroiditis) or thyroid surgery
- Women with a goitre
- Women with symptoms or signs suggestive of hypothyroidism or hyperthyroidism
- Women with a family history of thyroid disease
- Women known to be positive for thyroid antibodies
- Women with type 1 diabetes or other autoimmune disorders
- Women with a history of infertility, miscarriage, or preterm delivery
- Women with a history of head or neck irradiation

However, this targeted approach would miss approximately one third of women with significant thyroid dysfunction [30]. This approach has been further called into question as universal thyroid screening is pregnancy appears to very cost-effective; screening solely for overt hypothyroidism also had a cost-effectiveness ratio of $6776/QALY (quality adjusted life-year) [31] which is favourable compared to gestational diabetes mellitus screening ($12 078/QALY) and is well below the $50 000/QALY figure used in the United States as a criterion for screening decisions. This work also indicated universal screening appears to be more cost-effective than targeted screening.

Universal screening for thyroid dysfunction in pregnancy also meets the majority of the essential ten criteria for screening as recommended by Wilson and Junger [32]. Even if only overt thyroid disease is considered, it is still an important health problem (criteria 1). It is a common problem in pregnancy, overt hypothyroidism occurs in approximately 0.2–0.6% of pregnancies [33, 34] while overt hyperthyroidism, occurs with a frequency of about 0.2% [2]. Subclinical hypothyroidism occurs in 2–3% of pregnancies [1, 6] and isolated hypothyroxinaemia, may vary between 1% and 10% in iodine-replete populations [35] depending on the cut-off for the reference ranges used

Treatments for thyroid dysfunction are well established and acceptable to patients (criteria 2) with facilities for diagnosis readily available (criteria 3). In particular, levothyroxine is a safe treatment for hypothyroidism and we have over 50 years' experience with it [36]. The diagnosis of thyroid disease and treatment provision can also be easily be managed in outpatient clinics. Thyroid disease, particularly hypothyroidism, is frequently asymptomatic (criteria 4). In particular, subclinical hypothyroidism may represent an early disease state of hypothyroidism. In pregnancy, about 25% of women with subclinical hypothyroidism will have persistent TSH elevation following delivery [37].

Thyroid function testing relies on a simple blood test which is both suitable and acceptable (criteria 5 and 6) and these simple non-invasive tests are relatively inexpensive and available in modern laboratories. These blood tests can also be readily incorporated into routine blood tests which need to be done in early pregnancy. However, although pre-pregnancy screening would be likely to give the best outcomes, this is usually not practical. The natural history of thyroid disease is well understood (criteria 7) it is also cost effective (see earlier) (criteria 9) and the nature of screening in pregnancy means it will be a continuing process (criteria 10). Taken together these factors make a compelling case for universal thyroid in screening in pregnancy.

Only criteria 8, 'there should be an agreed policy on whom to treat as patients', is not satisfied. Whilst all relevant endocrine and obstetric societal guidelines endorse treatment of overt thyroid disease, it is the management of subclinical hypothyroidism and isolated hypothyroxinaemia which is less clear. It is also likely that there is an interaction with thyroid autoimmunity. Here the ATA guidance [6] is helpful which recommends to consider treatment with levothyroxine at TSH levels 4.0–10 mU/L if antibody negative and consider treatment at TSH levels 2.5–4 mU/L if antibody positive. Clinicians should definitely treat if TSH > 4.0 mU/L and antibody positive or TSH >10 mU/L [6] this provides much needed flexibility for clinicians although guidance is generally less clear.

An additional concern is that treatment with levothyroxine may not be free from consequences although widely regarded to be safe. Data from the Generation-R project [9] did show an inverse U shape with maternal fT_4 levels and offspring IQ. Thus, overtreatment may result in negating the benefits of supplementation with levothyroxine with the potential for a deleterious effect on offspring IQ. Preliminary data from the CATS II study also showed adverse outcomes in women who were over-treated with levothyroxine on offspring behaviour. While observational data [38] identified that SCH during pregnancy is associated with multiple adverse maternal and neonatal outcomes, the value of levothyroxine therapy in preventing these adverse outcomes remains uncertain. It is also worth highlighting that current management of thyroid hormone replacement in women established on levothyroxine prior to pregnancy is suboptimal with poorer control associated with increased odds of fetal loss [39].

The ultimate aim of screening for maternal thyroid disease in pregnancy is to optimize feto-maternal outcomes. Thus, therapeutic intervention when indicated should be implemented as early as possible in the course of fetal development. This will still need addressing with trials of universal screening and treating for low thyroid function in **early** (<10 weeks) gestation with key obstetric outcomes such as fetal loss, birthweight and gestational age evaluated as short term outcomes and with longer follow-up required for childhood neurological development outcomes. Until clearer evidence of benefit from treating marginal thyroid dysfunction is available from further randomized controlled trials in early pregnancy this controversy will continue.

A pragmatic approach may be to measure TSH and then reflex FT4 and TPOAb if TSH is outside of the relevant reference range. This will be challenging, but can with careful planning can be integrated into routine community health services. Preconception health examinations including thyroid hormone measurement have been managed successfully in rural parts of China [40]. A recent analysis of 184 611 pregnant participants in this programme has demonstrated an association between higher preconception TSH concentrations and risks of miscarriages and pre-term loss, highlighting key opportunities exist for modifying pregnancy outcomes with effective and timely preconception care [41].

A number of practical considerations will also need to be addressed before a universal thyroid screening program could be considered. There is a clear need for population specific and gestational age specific reference ranges in addition to a consensus regarding treatment thresholds and treatment targets. Furthermore, there will need to be enhancement in the skills in interpreting thyroid function tests in pregnancy by both endocrinologists and obstetricians.

Management of Thyroid Disorders Before Assisted and Spontaneous Pregnancies

Kris Poppe, Flora Veltri, and David Unuane

Introduction

Thyroid disorders are frequent in women of reproductive age, as shown in a recent survey in Spain in an area without iodine deficiency. Here, the prevalence of subclinical hypothyroidism (SCH) was 4–6%, hyperthyroidism 1% and thyroid autoimmunity (TAI) 10% [1]. Furthermore, the prevalence of TAI seems to be higher in women with particular causes of infertility such as polycystic ovary syndrome (PCOS) and idiopathic infertility compared to that in fertile women or with other causes of infertility [2]. Severe thyroid dysfunction may lead to irregular periods and infertility through direct and indirect interactions with the reproductive system. Although restoring normal thyroid function often results in a regular menstrual pattern and/or a normalized reproductive hormonal profile, it is not always followed by pregnancy. Indeed, in case of male infertility, endometriosis, tubal obstruction or PCOS, surgery and/or assisted reproductive technology (ART) may be necessary. Prior to the in-vitro part of ART treatment, an ovarian stimulation procedure (OH) is necessary. The latter is characterized by high oestradiol (E2) levels, adding additional strain on the thyroid gland during pregnancy. Especially in women with TAI this may be a supplementary reason to optimize thyroid function before pregnancy in order to obtain good quality embryos, and to avoid the progression from subclinical to overt hypothyroidism during pregnancy [3].

Before pregnancy, hypothyroid patients treated with levothyroxine (LT4) are advised to have a serum TSH level of less than 2.5 mIU/L, both in the case of assisted and spontaneous pregnancies. Women with Graves' disease desiring pregnancy should be advised of the increased risk of maternal and fetal complications as well as of possible side effects associated with antithyroid drugs (ATD). If necessary, contraception must be proposed and pregnancy postponed until euthyroidism is reached and confirmed [3].

With the exception of women planning ART or those known to have TAI, at present there are no recommendations regarding universal screening for thyroid function in the preconception phase. However, many physicians determine thyroid function parameters and antibody levels in general check-ups before pregnancy (sometimes upon request of the women/couple). Against this background, recommendations on how to manage fortuitous findings are useful [3, 4].

Thyroid (Dys)function and Female (In)fertility

Interaction Between Thyroid and Gonadal Function

The prevalence of hypothyroidism in women of reproductive age varies between 0.2% and 0.4% and is predominantly related to TAI [1, 2]. Moreover, the prevalence of TAI seems to be elevated in young women facing fertility problems, with thyroglobulin autoantibodies (Tg-abs) and thyroid peroxidase autoantibodies (TPO-abs) being reported in up to 25% of women affected by recurrent miscarriages [5, 6]. Thyroid hormones (TH) may influence fertility aspects in a direct or indirect manner. TSH and its receptor, as well as thyroid hormone receptors (TR-α1 and TR-β1) have been located in ovarian surface epithelium and in oocytes of primordial, primary, and secondary follicles. Therefore, they appear to play a role in the regulation of ovarian function [7]. Indirect mechanisms linking thyroid hormone to fertility issues may involve altering gonadotropin releasing hormone (GnRH) and prolactin secretion as well as changes in sex hormone binding globulin (SHBG) levels and coagulation factors [2]. Since TH influence the hormonal environment of the ovarian follicle and are essential in the signalling during implantation and early pregnancy, (mild) thyroid failure is plausible cause of infertility.

Thyroid Dysfunction and Reproduction

Subclinical and Overt Hyperthyroidism

Due to limited data the precise impact of hyperthyroidism on fertility is not well established.

However, in overtly hyperthyroid women, menstrual irregularities haven been reported in up to 65% compared to 17 % in healthy controls [8]. More recent reports have pointed towards a lower prevalence of menstrual abnormalities of about 22% compared to 8 % in healthy controls [2]. In hyperthyroidism, the most common abnormality was hypomenorrhea followed by polymenorrhagia, oligomenorrhea and hypermenorrhoea. Nevertheless, despite thyrotoxicosis being linked to reduced fertility, studies including endometrial biopsies have demonstrated that most hyperthyroid women seem to remain ovulatory [9].

Subclinical and Overt Hypothyroidism

There are inconsistent reports on the association between SCH and infertility, largely caused by different cut-offs used in various studies to define the condition. In general, despite a slight increase in the mean TSH concentration in infertile women, the incidence of SCH is comparable to that in the general population [5, 10]. Among these women affected by infertility, TSH levels were highest in those with ovulatory dysfunction.

As for hyperthyroidism, limited data are available on the prevalence of infertility in women with overt hypothyroidism. Nonetheless, some evidence suggests an association of overt hypothyroidism and an increased risk of infertility. Indeed, hypothyroidism may lead to a number of menstrual disturbances in women of fertile age. There may be changes in cycle length as well as the volume of menstrual bleeding secondary to breakthrough bleeding following anovulation and/or disturbances in haemostatic factors. The prevalence of menstrual abnormalities (especially oligomenorrhea) has been reported in 25–60% of hypothyroid women compared to 10% in euthyroid women [2].

Thyroid Autoimmunity

The prevalence of TAI varies considerably with ethnicity but is generally estimated around 10% [1, 11]. A higher prevalence of TAI has been reported in women affected by fertility problems [2, 5]. The underlying causal mechanisms that may account for any possible negative impact of TAI on fertility also remain unclear. On the one hand it has been proposed that the presence of TAI reflects a general immune imbalance possibly leading to implantation failure. Another explanation could be that thyroid antibodies are directly causative whereby the presence of thyroid antibodies could have an unfavourable effect on oocyte and embryo quality. Indeed, it has been hypothesized that thyroid antibodies may pass the 'follicle-blood' barrier during maturation of a secondary follicle. Cytotoxicity of these antibodies could then damage the maturing oocyte and eventually reduce oocyte quality and fertilization potential [12]. On the other hand, a positive TAI status increases the risk of developing (subclinical) hypothyroidism. Women with TAI are at increased risk of developing (sub)clinical hypothyroidism after ovarian hyperstimulation and during pregnancy [1, 2, 11].

General Considerations Relating to Fertility

Infertility is defined as the inability to conceive by a sexually active, couple not using contraception over a 12-month period for women <35 years and after 6 months for women >35 years. Infertility is a common condition and about 10–15% of all couples will experience difficulties to conceive (primary infertility) or to conceive the number of children they want (secondary infertility) [10, 13]. Subfertility is sometimes distinguished from infertility, where the latter is a synonym of sterility, defined as the absolute inability to conceive (absence of sperm, premature menopause, or complete tubal obstruction). According to the World Health Organization (WHO) task force on diagnosis and treatment of infertility, medical conditions contributing to infertility in developed countries were associated with female related infertility in 37 %, male infertility in 8% and both male and female infertility in 35% of the cases. Here, the most frequent causes of female infertility were: ovulatory disorders (25%), endometriosis (15%), pelvic adhesions (12%), tubal blockage (11%), other tubal abnormalities (11%), and hyperprolactinemia (7%) [13].

Infertility Causes Associated with Thyroid Disorders

In the case of idiopathic infertility, a higher prevalence of TAI has been reported when compared with fertile women [14, 15]. Additionally, an increased prevalence of TAI in women with polycystic ovary syndrome (PCOS) has been described. Possible underlying mechanisms may be polymorphisms of the PCOS-related gene for fibrillin 3 influencing the activity of TGF-β, a key regulator of immune tolerance. Together with lower TGF-β, low vitamin D levels and the high oestrogen-to-progesterone ratio these factors may contribute to autoimmunity [2, 16]. There are inconsistent reports with respect to women with endometriosis (by some considered as an autoimmune disease as such) having an increased prevalence of TAI, although this is not confirmed in other studies [5, 17].

Thyroid Disorders and Assisted Reproduction

Assisted Reproductive Technology (ART)/Ovarian Hyperstimulation (OH)

Once thyroid function is normal(ized) and lifestyle modifications and fertility counselling have not resulted in pregnancy, ART treatment can be proposed. Based on the fertility work up, different treatment strategies can be put forward. A first line treatment is intrauterine insemination (IUI), often used in couples with unexplained subfertility, cervical factor subfertility and male subfertility. If not successful, *in vitro* fertilization (IVF) or intracytoplasmic sperm injection (ICSI) represents alternatives, especially in cases of male infertility. IUI is sometimes preceded by a stimulation procedure with oral clomiphene citrate (an antioestrogenic drug), or injections of gonadotrophins in order to optimize egg maturation and ovulation prediction. IVF/ICSI is always preceded by an intense two-step hormonal treatment. In a first step the natural cycle is suppressed to prevent premature luteinization. To achieve this, two different protocols can be used either with prolonged administration of gonadotropin-releasing hormone (GnRH) agonists (analogues) desensitizing the pituitary gland, or GnRH antagonists instantly blocking the pituitary gland. In a second step, OH takes place with hormones that mimic effects of FSH (and LH). Gonadotropin preparations (human menopausal

gonadotropin (hMG) or recombinant FSH trigger the development of several follicles simultaneously, and the administration is done under hormonal and ultrasound control, to avoid overstimulation. Finally, the ovulation is triggered with a hCG-injection [18]. During natural cycles, E2 levels rise up to 121 pg/ml in the periovulatory phase (compared with 55 pg/ml in the early follicular phase). This, however, does not usually lead to changes in serum TSH levels [19]. Likewise, treatment with clomiphene citrate (CC) leads to increases of E2 levels of up to 1200 pg/ml, without impact on thyroid function [20]. After OH with gonadotropins however, E2 levels increase to supraphysiologic levels of 2700 pg/ml usually only seen in the late second or third trimester of pregnancy. These high E2 levels may lead to a strain on the thyroid gland through several mechanisms. First, by an E2-mediated increase in thyroxin-binding globulin (TBG) causing a drop in free thyroxine (fT_4) concentration. Second, by a direct central action of E2 on the release of thyrotropin-releasing hormone (TRH). A third mechanism maybe an E2-related immunomodulation favouring the occurrence of TAI. Finally, recombinant FSH may act directly as one of the triggers responsible for the serum TSH increase [21].

The impact of OH on thyroid function may be diverse, ranging from no impact to an isolated increase in serum TSH or even to decreased serum fT_4 levels [3, 21]. This variability can be explained by the type of the pituitary downregulating drugs (GnRH agonists versus antagonists) used, different stimulation protocols implemented, the duration of TSH measurement follow-up after OH, and whether or not the presence of TAI was determined. Significantly increased serum TSH levels are more commonly described in women treated with GnRH antagonists compared to women treated with GnRH agonists. Overall, TSH values were >4 mIU/L in 41% of the women, of whom 89% were treated with an antagonist and 11% with an agonist. Increased TSH levels were independent from E2 levels and may be due to the presence of GnRH-receptors in thyrotrope cells of the adenohypophysis [22]. Although based on limited evidence, the latest guidelines propose to consider a serum TSH target of <2.5 mIU/L in the case of TAI positivity and/or in women already being treated with LT4 prior to OH /ART [3]. When TAI is present, thyroid function adaptation to OH is attenuated compared with that in women without TAI. Changes in thyroid function usually last until the first trimester of pregnancy, compared to an only temporary impact of several weeks in women without TAI [23].

A common complication of OH is the ovarian hyperstimulation syndrome (OHSS) which occurs in 20–30% of ART cycles. It is characterized by very high E2 levels (>5000 pg/ml) and has been associated with the development of severe hypothyroidism in TAI positive women [24, 25]. Women with hypothyroidism treated with LT4 (for pre-existing hypothyroidism) should increase their dosage before OH to anticipate the increased demands. Indeed, in a study by Busnelli *et al.*, the authors showed that 80% of hypothyroid women pregnant after OH and with TAI had to increase their dosage of LT4, within the first 7 weeks of pregnancy compared to 40% in those without TAI [26]. The degree of increase in serum TSH after OH during early pregnancy also depends on the prestimulation TSH level [27]. Another explanation for the different results relating to the impact of OH on thyroid function is the follow-up period after OH, as changes in TSH usually take at least 2 weeks to occur [28]. Therefore, it is recommended to determine thyroid function before and 1–2 weeks after OH [3].

Pregnancy Outcome Data

At present, the exact impact of preconceptional thyroid (dys)function and/or TAI on outcomes after ART is still subject of debate. In general, there seems to be no difference in terms of implantation, pregnancy, and delivery rates between women with preconception serum TSH levels between 2.5–5.0 mIU/L and <2.5 mIU/L [2, 10]. Little evidence exists on pregnancy outcomes in women with a preconception TSH level >4.0 mIU/L and without TAI [29]. More coherent study results are available on the impact of TAI, showing similar implantation rates, but more first trimester miscarriages compared with women without TAI [2, 3, 14]. A cause-effect relationship remains to be proven, and therefore, several hypotheses might explain this finding of which the most important ones are the higher mean ages in women with TAI, the higher risk to develop SCH during pregnancy, the higher prevalence of concomitant antibodies (e.g. anticardiolipin), the presence of impaired immune mechanisms (e.g. in the Treg cells), and an attenuated TSH response to high hCG levels during the first trimester of pregnancy [2, 30–32]. Finally, the concomitant presence of both a higher serum TSH and TAI seems to lead to lower live birth rates compared with the presence of either factor alone [33]. In a recent meta-analysis, including infertile women with and without TAI that were treated only with ICSI and did not receive LT4, miscarriage rates were comparable between both study groups. The systematic use of ICSI in case of TAI may therefore become a standard/additional treatment if these findings are confirmed in future studies [34].

Evidence and Recommendations on the Treatment of Thyroid Disorders Before ART

In a meta-analysis in TPO-ab positive women (in a large majority with a serum TSH >4.0 mIU/L) and undergoing ART, the effects of pre-ART LT4 treatment showed that it did not ameliorate clinical pregnancy rates, but increased live birth rates (RR 2.76) [35]. Evidence relating to the impact of LT4 therapy in euthyroid women with TPO-abs is limited to two retrospective and one prospective study [36]. In none of them, LT4 treatment improved pregnancy outcomes, but several criticisms to these studies are summarized in a recent paper [37]. One of the weak points in these studies is that the diagnosis of TAI is based often on the presence of TPO-abs only [34, 37]. However, positivity for Tg-abs alone was more frequent in infertile women compared with that of TPO-abs. The presence of Tg abs was associated with higher serum TSH levels and with higher miscarriage rates [38, 39]. Therefore, not testing for Tg-abs may lead to misdiagnosis of AIT, resulting in misinterpretation of findings and mismanagement of women before and during pregnancy [3, 40].

Insufficient evidence exists thus to determine whether LT4 therapy improves pregnancy outcomes following ART in euthyroid women with TPO-abs (TSH <4.0 mIU/L). However, administration of 25–50 mcg of LT4 may be considered given its potential benefits in comparison to its minimal risk, and the prevention to progressing to hypothyroidism once pregnancy is achieved. Alternatively, a 'wait and see' option may be preferred, and LT4 treatment can be started

when TSH >4 mIU/ L after OH or during early pregnancy [3, 10]. Women with SCH (typically TSH >4.0 mIU/L or above the upper limit of the local reference range) and overt hypothyroidism undergoing an ART treatment should be treated with LT4, and aiming a TSH level <2.5 mU/L before starting an OH procedure.

In women who achieve pregnancy following OH, TSH elevations should be treated according to the recommendations for pregnant women, and when no pregnancy is achieved, but mild TSH elevations were present, serum TSH measurements should be repeated after 2–4 weeks because they will probably normalize, especially when no TAI is present [3].

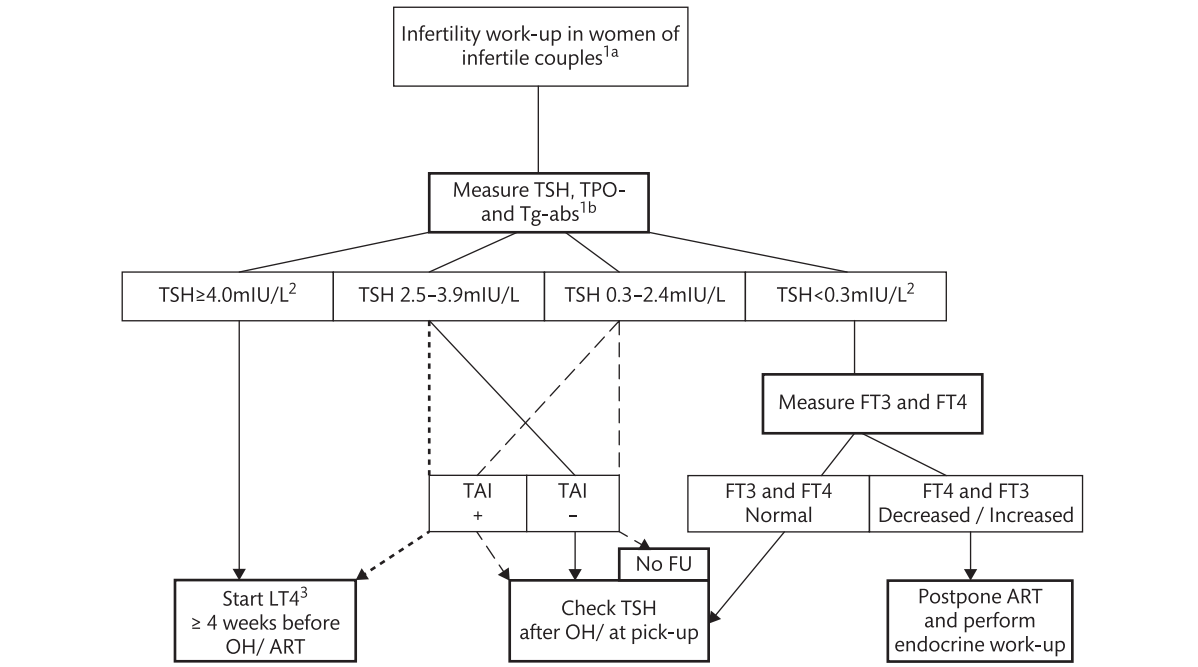
Of note, guidelines also point out that steroid treatment before ART is not beneficial and is not recommended in women with TPO-abs [3].

In Figure 9.2.1, an algorithm is proposed to screen and manage women of infertile couples.

Management of Thyroid Disorders Before Spontaneous Pregnancy

Hypothyroidism Before Pregnancy

The major physiologic thyroid change during pregnancy is that the total body T_4 pool must increase by approximately 40–50% to maintain a euthyroid state [2, 3, 30]. In healthy pregnant women, placental hCG is the major stimulus of maternal TH production, especially during the first trimester of pregnancy. However, in women with a history of thyroid disorders (post radioiodine, after thyroidectomy and/or inadequately treated with LT4), serum hCG will not stimulate the thyroid enough and (subclinical) hypothyroidism might occur during pregnancy. Increased demand in TH and/or LT4 takes place as early as 4–6 weeks of pregnancy. These requirements continue through 16–20 weeks of pregnancy, to stabilize thereafter until delivery. Treated women with hypothyroidism should be advised to contact their physician immediately upon a confirmed or suspected pregnancy, increase their dose of LT4 by 20–40% (by taking two additional tablets of their weekly LT4 dose) and undergo prompt testing and evaluation [41]. In case of de-novo overt hypothyroidism, women should receive full replacement doses of LT4 (1.6 mcg/kg/day). The importance and safety of LT4 treatment should be discussed with the patient to assure compliance [42]. Since T3 is degraded in the placenta, women treated with liothyronine or desiccated thyroid preparations should be switched to LT4 monotherapy [3, 4]. Because most women will be taking antenatal vitamin supplements (containing iron, calcium, and magnesium), they should be advised to leave a 4-hour gap between ingesting pregnancy supplements and T_4 replacement, to avoid LT4 malabsorption. Although based on limited evidence, traditionally, it is still recommended that hypothyroid women treated with LT4 should aim for a preconception serum TSH levels <2.5 mU/L, which is also the proposed threshold during pregnancy [3, 4, 42].



[1]when a choice has to be made for economical reasons [1a]measure only in case of ovarian causes or idiopathic infertility [1b]measure only TPO-abs
[2]or above / below the institutional cut-off
[3]dose depending on baseline TSH level and woman's body weight when ≥4.0mIU/L, and start 25 mcg when TSH 2.5–3.9 mIU/L; target a serum TSH level <2.5 mIU/L

Hyperthyroidism (Graves' Disease) Before Pregnancy

Graves' disease (GD) should be distinguished from gestational transient thyrotoxicosis (GTT) which is self-limiting requiring supportive treatment only but not antithyroid drugs (ATD) [3]. In women with GTT the typical features of GD (raised TSH-receptor antibodies (TRAbs), concentration goitre, family history and exophthalmos) are absent. In women with de-novo GD seeking pregnancy, three therapeutic options should be discussed: ATD, surgery and radioiodine therapy (RAI). The choice will depend on the preference of the patient, history of the disease, presence of a goitre, presence of high levels of TRAbs, and the timescale in which the couple hopes to conceive [43].

With regard to ATD, patients should be informed about the increased risk of birth defects associated with the use of either propylthiouracil (PTU) such as renal tract and head and neck anomalies or methimazole (MMI), including aplasia cutis, choanal atresia, trachea-oesophageal fistula, and dysmorphic facial features [44, 45]. However, the possibility of stopping ATD during the critical period of pregnancy (weeks 6–10) should be discussed. Finally, the preference for PTU before and during the first trimester of pregnancy, ATD titration (avoiding block-replace therapy), and the use of the lowest dose of ATD as possible should be highlighted. Concerning RAI therapy, the possible TRAbs increase after RAI therapy which may remain elevated for several years and the potentially long latency period before reaching euthyroidism should be mentioned [46]. The latter often leads to a delay in pregnancy (a minimum of 6 months and possibly longer) until a stable euthyroid state has been reached (with or without LT4 treatment). A pregnancy test should precede RAI therapy to exclude pregnancy. Thyroidectomy, may be indicated in case of contraindications/refusal of the two other therapeutic options, in case of relapse of GD and/or the presence of a large goitre or persistence of high maternal TRAbs (>3× upper reference for the assay) [43, 47]. After surgery, biochemical euthyroidism together with decreasing TRAbs should be confirmed before efforts to conceive commence.

Women already treated with ATD for GD should postpone pregnancy until a euthyroid state is reached, which should be verified by thyroid function in the normal reference range on two occasions over a period of at least 2 months and on stable therapeutic regimen. The use of contraception should be discussed, and pregnancy should be postponed if TRABs remain high and/or there is inadequate control of the hyperthyroidism. According to recent data, MMI should be switched to an equivalent PTU dose, at least 3 months before pregnancy to decrease the risk of congenital malformations due to MMI [45]. Women should be instructed to confirm pregnancy as soon as possible and contact their treating physician.

Screening in Daily Practice

There is insufficient evidence to recommend for or against universal screening for abnormal thyroid function preconception, with the exception of women with infertility, planning ART, a history of pregnancy loss, preterm delivery, or those known to have raised TPO-abs. Furthermore, it is unclear if only screening for thyroid dysfunction is recommended [3, 10]. Screening for TPO-abs may be of interest and indicated for several reasons. The prevalence of TPO-abs is around 10–15% in the general population and may identify women at risk for developing hypothyroidism during gestation or after OH, and be a predictive marker for the development of post-partum thyroiditis [3]. Furthermore, women with PCOS and idiopathic infertility are known to have a high prevalence of raised TPO-abs [5]. However, despite this rational basis, there are currently no data in terms of pregnancy outcomes that support such an approach. Nonetheless it is crucial that potential pregnancy wish is discussed with women undergoing treatment for hypo- or hyperthyroidism,

Thyroid Disease During Pregnancy

Tim I.M. Korevaar and Robin P. Peeters

Introduction

Adequate thyroid hormone (TH) availability is essential for a normal pregnancy and fetal development. During early pregnancy, an increase in maternal TH regulates the increased metabolic demand associated with pregnancy and ensures TH availability for the fetus which predominantly depends on the supply of maternal TH. As a consequence, untreated maternal hypothyroidism during pregnancy is associated with an increased risk of adverse pregnancy as well as child outcomes [1]. Although thyroid function is frequently assessed before and during pregnancy, accurate clinical assessment, and interpretation of maternal (and fetal) thyroid function during pregnancy is complicated by the maternal-placental-fetal interaction. Given this complexity, it remains difficult how and when to evaluate for thyroid dysfunction, as well as if and how to treat (mild) thyroid disease during pregnancy. This chapter discusses current insights on physiology, diagnosis, risk of adverse outcomes, and treatment options.

Thyroid Physiology

Pregnancy has clear effects on thyroid physiology. The maternal supply of TH to the fetus, an increase in thyroxine-binding globulin (TBG) concentrations under the influence of high maternal oestrogens, an increase in iodine clearance, and the degradation of TH by placental type 3 deiodinase (D3) all require increased TH production to ensure adequate TH availability for mother and fetus (Figure 9.3.1) [1]. In normal physiology, this increased demand for TH production is mediated by high concentrations of the pregnancy

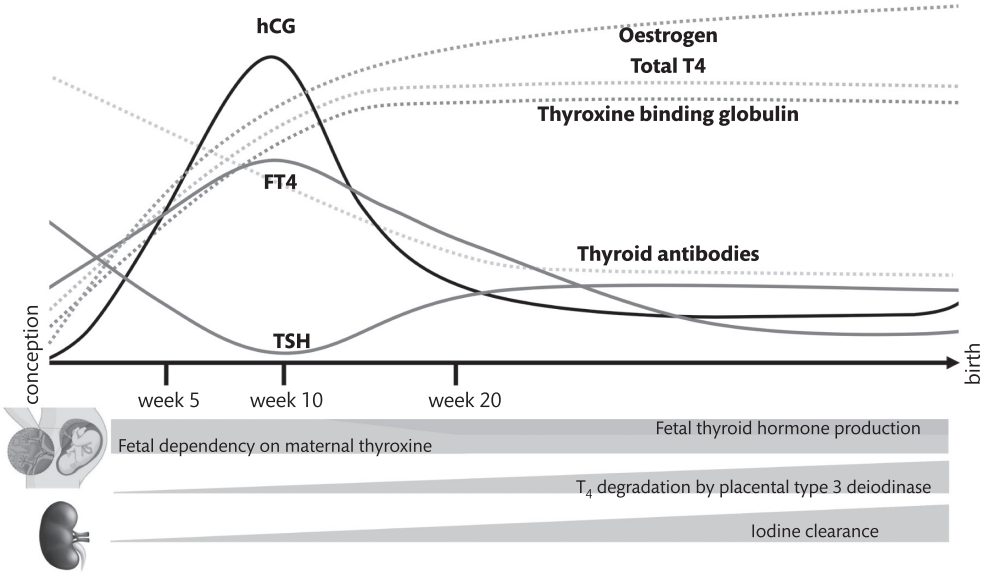

Figure 9.3.1 Gestational changes in thyroid function and related parameters.

hormone human chorionic gonadotrophin (hCG), a weak agonist of the TSH receptor, which stimulates the thyroid and thereby increases TH production (Figure 9.3.1) [2]. These pregnancy-specific changes and increased demand may expose pre-existing mild thyroid dysfunction. We further highlight the role of major gestational thyroid physiology concepts including iodine and thyroid autoimmunity next.

Iodine is an essential trace element that is a major component of TH and essential for its production. During pregnancy, an increase in demand for TH and an increase in renal iodine excretion necessitates a higher iodine intake to maintain adequate iodine availability. Severe maternal iodine deficiency leads to overt hypothyroidism, goitre, and offspring mental retardation (i.e. cretinism) [3]. Because of the crucial role of iodine and thyroid hormone in brain development, the World Health Organization recognizes iodine deficiency as 'the single most important preventable cause of brain damage'. The consequences of severe iodine deficiency are well established and include hypothyroidism, goitre, and child cretinism.

While prevention programs have eradicated severe iodine deficiency in most countries, many pregnant women still reside on areas of mild to moderate iodine deficiency (i.e. pregnant women in approximately 30% of all European countries still have suboptimal iodine status [4–7]). The effects of mild-to-moderate maternal iodine deficiency during pregnancy are less clear. Studies on thyroid function and iodine status have predominantly shown that a low iodine status is associated with a lower thyroid function and mild-to-moderate maternal iodine deficiency seems to impair neurocognitive function of children in some but not all studies. Although some international guidelines recommend the use of iodine supplements, such treatment decisions can only be made in light of local iodine status. Moreover, because the thyroid can store up to 3 months' worth of iodine, iodine status optimization should preferably be achieved before pregnancy. In line with this, a recent study showed that pre-pregnancy iodine deficiency is associated with a roughly 7-point lower child IQ [4]. Notably, also too much iodine intake is associated with lower thyroid function [5]; however, the effects of excessive iodine on offspring neurocognitive development remain largely unknown.

Thyroid hormone is crucial for normal fetal brain development because it regulates migration, proliferation, and differentiation of fetal neuronal cells, as well as synaptogenesis and myelination. In human fetuses, early neurogenesis starts from approximately 5 weeks post-conception and thyroid hormone receptors have been detected in the fetal brain from as early as 8 weeks gestation. Because the fetal thyroid gland is not functionally mature before week 18–20 of pregnancy, the fetus largely depends on the supply of maternal thyroxine during the early stages of intrauterine brain development. Also later in pregnancy, maternal thyroxine still contributes to fetal TH availability (Figure 9.3.1).

Thyroid autoimmunity, generally reflected by thyroperoxidase antibody (TPOAb) positivity, is the most important risk factor for thyroid dysfunction during pregnancy. During pregnancy, TPOAb positivity occurs in 5.6% to 22.1% of all women and is consistently associated with a higher risk of pregnancy complications such as miscarriage and premature delivery in different studies [6]. Another marker of thyroid autoimmunity, thyroglobulin antibody (TgAb) positivity, can occur independent of the presence of TPOAbs [7]. However, studies on isolated TGAb positivity and clinical outcomes are sparse. The pathophysiological mechanism through which thyroid autoimmunity is associated with a higher risk of adverse outcomes remains to be elucidated. Recent studies from our group have shown that the thyroidal response to hCG stimulation is severely impaired in TPOAb positive women (Figure 9.3.2). In addition, we showed that particularly those TPOAb positive women that had a low fT_4 despite a high hCG (i.e. an impaired thyroid functional capacity) had a higher risk of premature delivery suggesting that TPOAb positivity results in adverse pregnancy outcomes via alterations in gestational thyroid function (also see section on thyroid autoimmunity, later on).

Diagnosis of Thyroid Disease

The major changes in thyroid physiology just described necessitate the use of pregnancy-specific reference ranges to diagnose gestational thyroid disease entities. Although many centres in the past used a fixed upper limit for TSH of 2.5 mU/L in the first trimester and 3.0 mU/L in the second or third trimester, data from the last ten years have shown that these cut-offs are too low and may cause considerable overdiagnosis [8]. Therefore, a stepwise approach should be used to define the best possible reference range for each specific institution. Lab-specific TSH and fT_4 reference ranges are considered the gold standard and, when available, are the reference range of choice within a hospital infrastructure. A lab-specific reference range for TSH and fT_4 can be calculated as the 2.5th to 97.5th percentiles for a group of at least 400 women that are free of thyroid function interfering factors (major disease, TPOAb positivity, thyroid (interfering) drug use, higher physiological hCG (e.g. twin pregnancies and/or IVF treatment)) [8]. If it is not possible to obtain local lab-specific reference ranges, lab-specific reference ranges can be adopted from a centre that uses the same assay and has a patient population with similar ethnic background and iodine status. Finally, if appropriate reference ranges cannot be obtained via either of the previous steps, a fixed upper limit for TSH of 4.0 mU/L could be used. Notably, these recommendations are predominantly relevant for thyroid function tests obtained during the first trimester (from 6 weeks onwards) or second trimester. Data on the third trimester remain sparse.

To be able to distinguish between overt and subclinical thyroid disease, which has direct clinical consequences, measurement of fT_4 is required. With current knowledge, it is however not possible to identify an evidence-based fixed lower limit for fT_4 because published reference ranges differ widely and are very assay-specific. Therefore, the lower range for fT_4 is best defined using a lab-specific or 'adopted' reference range approach. Commonly used fT_4 immunoassays have been reported to be less accurate due to a shift in TH binding proteins during pregnancy [9–12]. This shift mostly affects fT_4 measurements during the third trimester and therefore is not likely to be relevant for the majority of thyroid function tests, which typically are taken in the first half of pregnancy. Furthermore, the correlation of fT_4 concentrations between assays is very high, which means that every assay can be used to adequately identify women with an abnormal fT_4 if pregnancy-specific and assay-specific reference ranges are used [13]. Previously, it was suggested that total T_4 concentrations may be used to assess thyroid dysfunction during

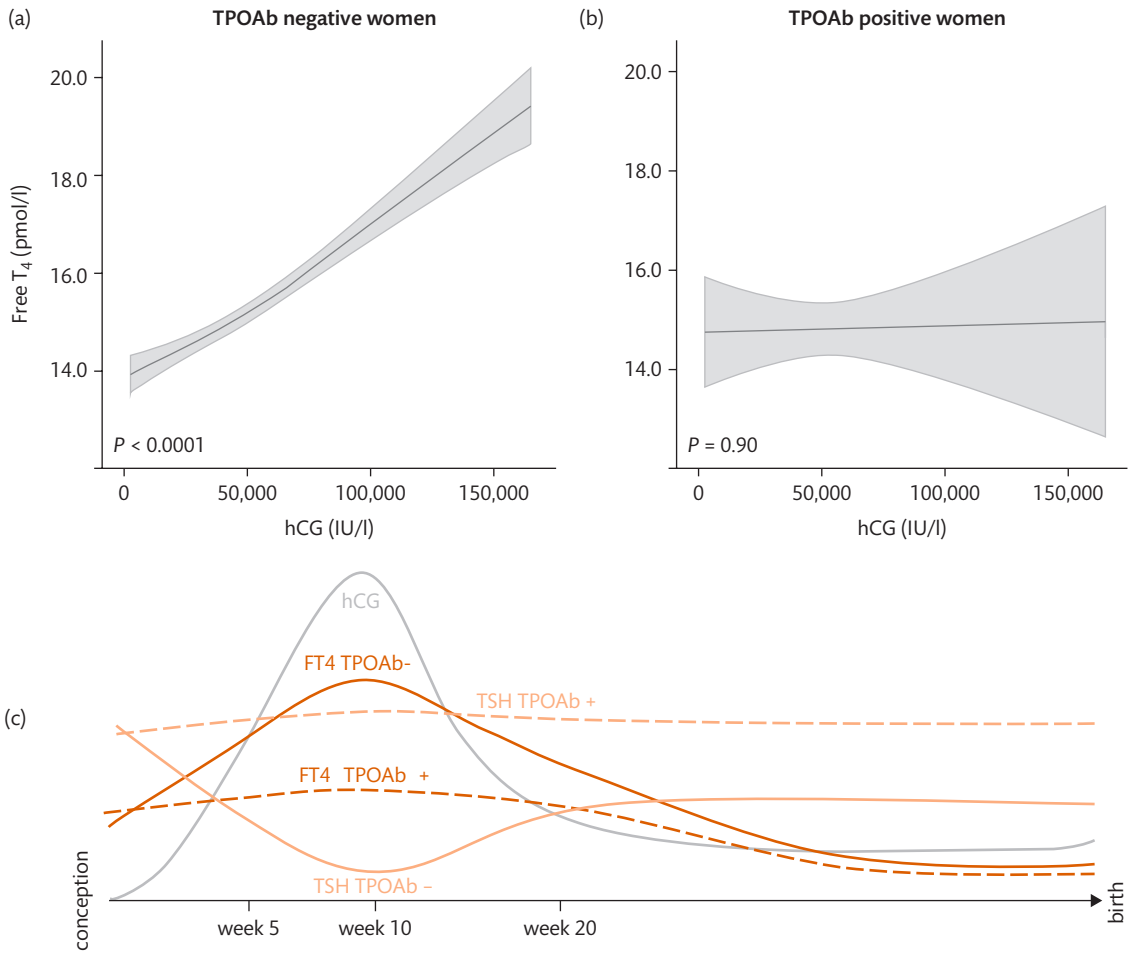

Figure shows association of hCG with FT4 during the first half of pregnancy inTPOAb negative women (A) and TPOAb positive women (B) using cross sectional data from 5,924 women participating in the Generation R study, and a translation of these data through out pregnancy (C).

Figure 9.3.2 The thyroidal response to hCG stimulation in TPOAb negative and TPOAb positive women.

pregnancy by raising the lower limit of the non-pregnancy reference range to 150% [11]. However, total T_4 is only a very crude estimate of the fraction of available TH because >99% of total T_4 is bound to TH binding proteins. This makes total T_4 concentrations highly dependent on changes in TBG [14, 15]. Furthermore, because early pregnancy total T_4 concentrations are not associated with adverse pregnancy or child outcomes [15, 16] fT_4 seems a more clinically relevant measurement of thyroid function [15].

The identification of women with gestational thyroid disease is complicated by the fact that classical clinical symptoms of hypo- and hyperthyroidism may also occur during normal pregnancy. Moreover, the majority of women with biochemical thyroid dysfunction, particularly subclinical forms, are asymptomatic [17]. Studies show that clinical characteristics such as maternal obesity, smoking, ethnicity, and gestational age at presentation are associated with the risk of gestational thyroid disease. However, these clinical characteristics altogether do not accurately predict the risk of thyroid dysfunction in the general population [18].

Screening for thyroid disease during pregnancy has been a topic of debate. On one hand, universal screening would identify a small group of women that would certainly benefit from treatment, e.g. overt hypothyroidism [prevalence ~0.3%] or Graves' disease [prevalence ~0.05%] (see section on overt thyroid disease). However, it remains unknown how many (asymptomatic) women with such disease are currently missed. In addition, screening can also identify women for which there is some evidence that treatment may be beneficial based on small randomized controlled trials, e.g. TPOAb positive women with a TSH above 4.0 mU/L [prevalence ~1.1%] (see part on thyroid antibodies) [19, 20]. On the other hand, there is no good evidence that treatment has beneficial effects for the majority of women that have an abnormal screening result (subclinical hypothyroidism [~3.5%], hypothyroxinaemia [~2.3%], subclinical hyperthyroidism [~2.5%] or overt hyperthyroidism [~1.5%]) (see respective subheadings as follows) which may lead to overtreatment in a substantial proportion of women. Experts agree that targeted screening for thyroid disease during pregnancy seems warranted for women at a high-risk of adverse pregnancy outcomes (for example women with a history of gestational thyroid disease, those with repeated miscarriages or adverse pregnancy outcomes such as pre-eclampsia or preterm delivery). However, the decision to universally screen for thyroid disease during pregnancy currently remains at the discretion of the physician's interpretation of current evidence.

Hypothyroidism

Overt Hypothyroidism

Overt maternal hypothyroidism (elevated TSH with low fT_4) during pregnancy occurs in roughly 0.2 to 0.6% of pregnant women [1, 8, 21]. It has consistently been associated with a higher risk of adverse pregnancy complications including premature delivery, low birth weight, miscarriage, pre-eclampsia [22], as well as negative effects on fetal neurodevelopmental outcomes [23]. A large case–control study demonstrated a seven-point lower child IQ in children born to untreated hypothyroid women compared to euthyroid controls, as well as a delay in motor skill development, language development and attention at 7–9 years of age [23].

Subclinical Hypothyroidism

Subclinical maternal hypothyroidism (elevated TSH with normal fT_4) is much more prevalent than overt hypothyroidism, occurring in roughly 3.5% of all pregnancies. While some studies have reported prevalences up to 18%, it has become apparent that such numbers represent an overestimation due to the use of an inappropriate TSH cut-off (see section on reference ranges). Autoimmune thyroid disease is the main risk factor for subclinical hypothyroidism, and TPOAb positivity occurs in roughly one third of pregnant women with subclinical hypothyroidism [24]. Multiple studies have demonstrated the negative consequences of maternal subclinical hypothyroidism on pregnancy outcomes, as it has been associated with a higher risk of pregnancy loss, placental abruption, premature delivery, and neonatal death [25–27]. Although the risks of these adverse outcomes are generally much lower than in overt disease, the high prevalence makes it a relevant public health issue. In contrast to its association with various adverse pregnancy outcomes, there is virtually no evidence that subclinical hypothyroidism is associated with adverse neurobehavioral outcomes in the offspring. Recent studies have shown that particularly the combination of subclinical hypothyroidism with TPOAb positivity is associated with a higher risk of adverse outcomes such as miscarriage, gestational diabetes and premature delivery, and that this higher risk is also present when TSH concentrations are in the high-normal range (i.e. for TPOAb positive women with TSH >2.5 mU/L) [28–31].

Hypothyroxinaemia

Hypothyroxinaemia (low fT_4 with normal TSH) has been associated with adverse neurobehavioral outcomes in the offspring in multiple studies from different cohorts [30, 32–34].

Initially, hypothyroxinaemia was considered as a pregnancy-specific disease entity that reflects a state of mild iodine deficiency. However, as hypothyroxinaemia also occurs in iodine sufficient areas and since (f)T_4 concentrations typically do not increase following iodine supplementation, it is likely that a much more multifactorial and pregnancy-specific pathophysiology underlies hypothyroxinaemia.

While subclinical hypothyroidism is associated with various adverse pregnancy outcomes, hypothyroxinaemia has predominantly been associated with adverse neurobehavioral outcomes in the offspring [30, 32, 34]. In 3659 mother–child pairs from a prospective birth cohort, hypothyroxinaemia was associated with a 1.8-fold increased risk of expressive language delay at both 18 and 30 months and a 2-fold increased risk of non-verbal cognitive delay [35]. Follow-up data subsequently revealed that maternal hypothyroxinaemia was associated with a 4.3 point lower non-verbal IQ at 6 years of age [36]. When various fT_4 cut-offs were assessed, low maternal fT_4 up to the tenth percentile was associated with a 1.5–3.8-point lower IQ [37]. Similar findings were also reported by Julvez *et al.* who reported a dose-response relationship of low maternal fT_4 with child mental score [34]. Hypothyroxinaemia has also been associated with other postnatal markers of intrauterine brain development, including a 2.6-fold higher risk of clinical autistic symptoms [38], a 1.7-fold higher risk of schizophrenia [39], as well as a higher risk of offspring ADHD, a slower reaction time, suboptimal school performance and lower grey matter and, cortex volume [37, 40–42]. As discussed already, the value of a fT_4 measurement during pregnancy has been questioned. However, a recent individual participant based meta-analysis of three different cohorts with three different fT_4 assays, showed a consistent association of hypothyroxinaemia during early pregnancy with offspring IQ [43]. This suggests that fT_4 is a sensitive marker of thyroid function during early pregnancy independent of the assay used [15].

Should (Subclinical) Hypothyroidism During Pregnancy Be Treated?

When considering treatment with levothyroxine during pregnancy it is important to consider the potential harms, particularly of overtreatment. Although the principle is similar to the potential harms of antithyroid drug treatment in the setting of Graves' hyperthyroidism during pregnancy (see section on hyperthyroidism), the potential for levothyroxine treatment-related harm is much less recognized. Various studies show that high maternal thyroid function is associated with a higher risk of low birth weight, pre-eclampsia and lower child IQ which indicates that levothyroxine treatment aiming for a high-normal thyroid function may carry the risk of overtreatment. While a full dose of levothyroxine based on patient weight in the range of 1.3–1.8 μg/kg is a good starting dosage for women with overt hypothyroidism, for women with subclinical disease a fixed starting dosage of 25–50 μg and titration after approximately 2 weeks is recommended [44].

Overt Hypothyroidism

There are no randomized controlled trials of levothyroxine treatment for overt hypothyroidism during pregnancy. However, given the well-known detrimental effects of untreated overt hypothyroidism on various adverse outcomes and the fact that there is no evidence of a higher risk of pregnancy complications in women with adequately treated hypothyroidism, there is general consensus is that overt hypothyroidism during pregnancy should be treated as early as possible and that it is unethical to perform a placebo controlled trial [44]. This is supported by the fact that in the case–control study showing a seven-point reduction in IQ among children born to untreated hypothyroid women, there were no deficits in children born from mothers who received levothyroxine treatment later in pregnancy [23]. Levothyroxine is the treatment of

choice, considering the important role of maternal T_4 for fetal brain development.

Subclinical Hypothyroidism

Similarly to overt hypothyroidism, there is a lack of data on the effects of treatment for subclinical hypothyroidism. A recent observational study by Maraka *et al.* found that treatment of subclinical hypothyroidism (defined by a TSH between 2.5 and 10 mU/L, fT_4 >0.8 ng/dl and/or total thyroxine >7.5 mcg/dl) with a median dosage of 50 μg (IQR 25–62.5) was associated with lower pregnancy loss (10.6% vs. 13.5%; OR 0.62 [0.48–0.82]) but a higher rate of premature delivery (7.1% vs. 5.2%; OR 1.60 [1.14–2.24]). Interestingly, subsequent stratification revealed that the beneficial effect on pregnancy loss was dependent on the TSH concentrations at baseline and predominantly present in women with TSH concentrations above 4.0 mU/L. No data on TPOAbs concentrations were available, whereas it has been shown that particularly the combination of subclinical hypothyroidism with TPOAb positivity is associated with a higher risk of adverse outcomes (see below in subsection on thyroid autoimmunity). A recent randomized controlled trial from Iran showed that treatment of subclinical hypothyroidism (defined using a TSH cut-off of <4.0 mU/L) with levothyroxine was associated with a 61% lower risk of premature delivery (RR 0.39 [0.15–0.98]) [45]. However, secondary analyses from an American randomized controlled trial could not identify any beneficial effects of levothyroxine treatment in women with subclinical hypothyroidism (LT4 group 9% versus 11% in placebo group, $P = 0.44$) [46]. The main difference between these two studies was the timing of treatment, with the Iranian study starting treatment during week 12 and the American study starting treatment at week 18. This difference suggests that levothyroxine treatment after the critical timeframe of early pregnancy may have no benefit, but further studies are needed to substantiate this. Studies investigating the effects of levothyroxine treatment in women with subclinical hypothyroidism on offspring neurocognition are discussed in the section on hypothyroxinaemia (see next).

Hypothyroxinaemia

Two randomized controlled trials have so far assessed the effects of treatment of mild thyroid dysfunction on offspring IQ. In the CATS trial, women were randomized to no screening or screening and subsequently treated with 150 μg levothyroxine if the TSH concentration was above the 97.5th percentile and/or the fT_4 concentration was below the <2.5th percentile [47]. There was no difference between the 390 children of treated mothers and 404 children of untreated mothers in mean IQ or the proportion of children with an IQ below 85 (also not for the low fT_4 or high TSH groups separately) [47]. Various arguments have been proposed for this negative finding, namely that treatment started too late (median 13 weeks), that IQ cannot be assessed reliably at age 3 and that the loss to follow-up was too high (24%). Alternatively, the relatively high levothyroxine dosage of 150 μg may have contributed to the lack of a net beneficial effect since recent evidence shows that high fT_4 concentrations are associated with suboptimal offspring neurodevelopment similar to the extent of low fT_4 concentrations [37].

The second RCT is a recent multicentre study from the US, in which 526 women with hypothyroxinaemia and 677 with subclinical hypothyroidism were randomized to receive either placebo or levothyroxine treatment (50 or 75 μg) and children underwent IQ testing at the age of 3 or 5 years (92.3% assessed at 5 years). The sample size of this study was defined based on the number of randomized women needed to detect a statistically significant difference of 5 IQ points (see trial registration NCT00388297). However, since the start of this trial, prospective cohort studies have shown that mild maternal thyroid dysfunction is associated with a 3 to 4 IQ point difference [48]. This trial showed that levothyroxine treatment is associated with a median increase of 3 IQ points in the offspring of women with subclinical hypothyroidism and hypothyroxinaemia, a result that failed to reach statistical significance based on the power calculations [49]. This increase in IQ was seen despite a relatively late start of treatment and is in line with what is expected based on observational data [46]. For this reason, further studies are still required to elucidate the effects of levothyroxine treatment in women with mild thyroid dysfunction on offspring neurodevelopment in an adequately powered RCT. Based on current knowledge, it is not possible to advise for or against levothyroxine treatment for women with subclinical disease. Individual risk factors such as a history of pregnancy complications or other comorbidities as well as the potential risk for overtreatment should be taken into account during individualized clinical decision-making.

Overt Hyperthyroidism

During pregnancy, the underlying cause can roughly distinguish overt hyperthyroidism in two major subtypes. On one hand, hyperthyroidism can be transient when it is the consequence of very high hCG concentrations (classically referred to as gestational hyperthyroidism or gestational transient thyrotoxicosis). On the other hand, overt hyperthyroidism can be related to an underlying pathological process as in Graves' disease (newly diagnosed or pre-existing but suboptimally controlled) or due to autonomous TH production (e.g. multinodular toxic goitre or toxic adenoma(s)). The incidence, risk of adverse pregnancy outcomes and the expected treatment differ widely between these two subtypes. Gestational hyperthyroidism is caused by high hCG concentrations, which typically peak at the tenth week of pregnancy, but can be high enough anywhere between the eighth to fifteenth week of pregnancy. Gestational hyperthyroidism has an estimated prevalence of1.5% but it is seen in up to 50% of women with twin pregnancies, IVF pregnancies and/or women with hyperemesis gravidarum. Large observational studies show that gestational hyperthyroidism is associated with a lower birth weight and an up to 2-fold higher risk of pre-eclampsia [50]. Nevertheless, only supportive treatment is advised because the potential harmful side-effects of antithyroid drugs (ATD; see also next) do not weigh-up against any hypothetical treatment benefit. Follow-up assessments could include measurements of TSHRAb (to exclude Graves' disease) and thyroid function test to monitor the transient nature of the disease, additional measurement of total T_4 or T_3 is not beneficial given the changes in TH binding globulins described above. However, there is some evidence that an additional hCG measurement may help to distinguish gestational hyperthyroidism from pathological forms [51]. Pathological forms of hyperthyroidism

during pregnancy are more rare, with estimated prevalence rates of 0.5–1.3% for pre-existing Graves' disease, 0.05% for new onset Graves' disease, and 0.1% for autonomous TH production [52, 53]. These types of hyperthyroidism are associated with a higher risk of pre-eclampsia, preterm birth, low birth weight and cases of maternal heart failure have been reported [52, 54–60]. One case–control study on 208 hyperthyroid women (89.4% diagnosed before pregnancy, 95% received treatment) and 403 matched controls [60] showed that hyperthyroid women had a 3.9-fold higher risk of pre-eclampsia, a 2.2-fold higher risk of fetal growth restriction, a 1.7-fold higher risk of preterm birth and a 3.6-fold increased risk of induction of labour [60]. Observational studies show that the risk of such adverse outcomes is lower when pathological hyperthyroidism is biochemically well-controlled, while the onset of disease (before or during pregnancy) is of less importance.

Specifically for Graves' disease, the different abilities of thyroid-related factors and drugs to cross the placenta (Figure 9.3.3) form the cornerstone for clinical assessment and treatment decision-making. When considering treatment, the potential harms associated with ATD are important to take into account particularly during early pregnancy. The use of propylthiouracil (PTU) during early pregnancy is associated with a higher risk of birth defects such as preauricular sinus/cysts and hydronephrosis and cases of maternal liver injury have been reported [61, 62]. The use of methimazole or carbimazole during early pregnancy has been associated with a higher risk of birth defects such as choanal atresia, aplasia cutis and omphalocele and cases of agranulocytosis are reported [42, 43]. To limit the potential adverse outcomes associated with ATD, several pregnancy-specific ATD strategies can be applied.

First of all, in women of childbearing age with hyperthyroidism, the option of definitive treatment before pregnancy should be discussed. When radioactive iodine is chosen as a definitive treatment, the fact that with TSHRAbs can flare-up and remain high up to 1.5 years after treatment with radioactive iodine but not with other treatment modalities should be taken into account.

Secondly, if the patient prefers ATDs or is already pregnant while on ATDs, therapy should consist of monotherapy with the lowest possible dose, as opposed to a block and replace therapy. As pregnancy progresses, the maternal immune response becomes less active due to a more liberal maternal immune tolerance, this generally leads to a reduction in maternal TSHrAbs (Figure 9.3.1) and thus often necessitates a reduction of the ATD dosage during the (late) second trimester [63, 64]. Large population studies have indicated that the use of PTU during early pregnancy is associated with a slightly lower risk of adverse outcomes, but also with less severe fetal anomalies, compared to methimazole [61]. Therefore, women receiving methimazole who are in need of continuing therapy during pregnancy should be switched to PTU as early as possible. This switch may be beneficial during the critical window of fetal organogenesis lasting up until the sixteenth week of pregnancy.

Third, when Graves' hyperthyroidism is biochemically controlled with a stable low dose of methimazole (5–10 mg) or PTU (100–200 mg) before pregnancy, the risk of relapse is relatively low and will most likely occur after a few months. Therefore, it can be considered

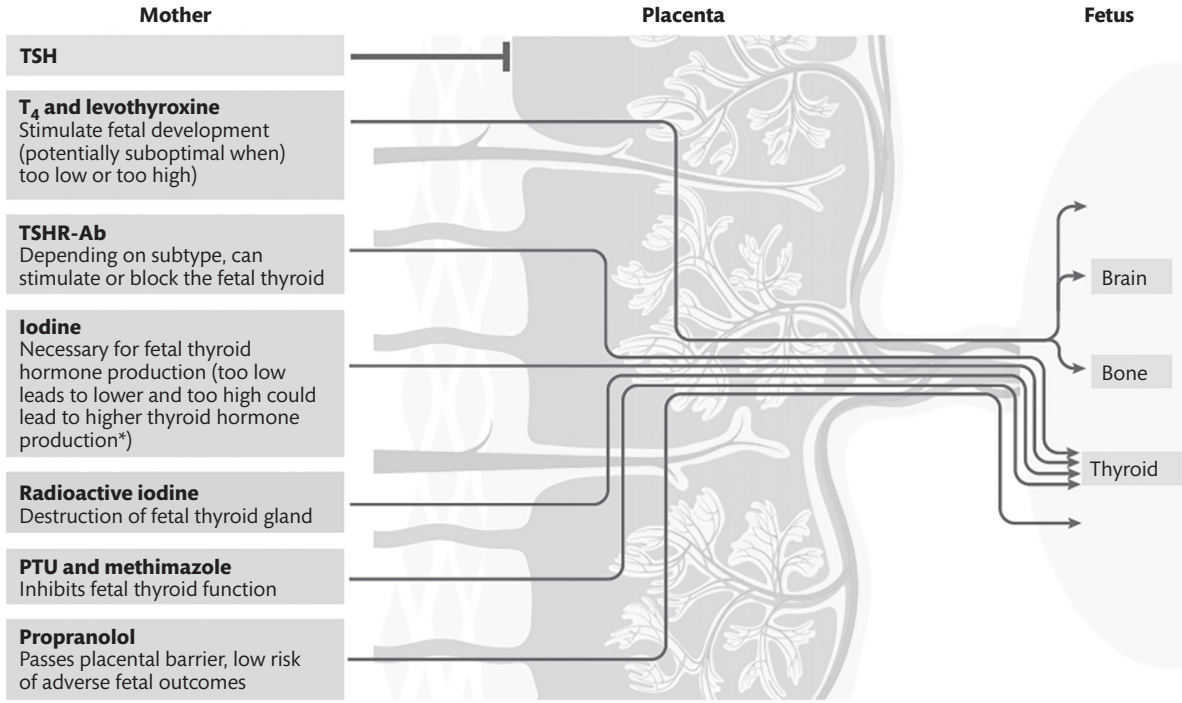

Figure 9.3.3 Thyroid-related substances and crossing of the placental barrier. The figure graphically depicts thyroid-related drugs and substances capable of affecting the function of the fetal thyroid gland as well as other tissues crossing the placenta. Of note, the fetus cannot escape the Wolff–Chaikow effect, that is, a phenomenon in which low iodine concentrations lead to decreased thyroid hormone production and high thyroid hormone concentrations lead to increased thyroid hormone production, until after roughly the 36th week of pregnancy, at which time high iodine concentrations are likely to cause low thyroid hormone production. TSHR-Ab, TSH receptor antibody; PTU, propylthiouracil.

to stop the treatment upon the wish to become pregnant or at the time of the first positive pregnancy test (in case of non-planned pregnancy), and monitor thyroid function closely (i.e. every 1–2 weeks) [65].

Finally, to assess disease severity but also the risk of neonatal Graves' hyperthyroidism, an early pregnancy measurement of TSHRAbs should be performed. If TSHRAbs are elevated, also the fetus should be monitored from mid-pregnancy onwards via fetal heart rate auscultation, fetal growth, and/or fetal thyroid ultrasound. Together with the maternal thyroid function, these measures are a reflection of the fetal TH status [66, 67].

Thyroid Autoimmunity

As a reflection of thyroid autoimmunity, thyroid antibodies (thyroglobulin antibodies TgAbs and thyroperoxidase antibodies (TPOAbs)) are an important risk factor for thyroid dysfunction during pregnancy. While both antibodies are a reflection of thyroid autoimmunity and their occurrence often overlaps, only TPOAbs seem to have clinical value because of a more prominent association with thyroid function and adverse pregnancy outcomes. It has consistently been shown that TPOAb positive women have higher TSH concentrations, lower fT_4 concentrations and also a higher risk of thyroid dysfunction during pregnancy [68, 69]. In general, TPOAbs are measured and then classified into positive or negative based on cut-offs provided by the manufacturer of the different assays. However, an individual participant data meta-analysis of three Dutch birth cohorts recently showed that there is a continuous association of TPOAb concentrations with TSH and fT_4 and that currently used cut-offs may fail to identify relevant thyroid autoimmunity [70]. It is well-recognized that thyroid autoimmunity affects the functional capacity of the thyroid. In line with this, we recently showed that TPOAb positive women have an impaired thyroidal response to hCG stimulation (**Figure 9.3.2**). These and other data indicate that TPOAb positive women lack the hCG-mediated increase in thyroid function during early pregnancy which may lead to a lower TH availability (area under the curve) during pregnancy. This may be the mechanism through which thyroid autoimmunity is associated with adverse outcomes since TPOAb positivity is associated with a higher risk of miscarriage and premature delivery, especially in combination with a higher TSH [70]. Two clinical trials have shown that LT4 treatment in TPOAb positive women markedly decreases the risk of miscarriage and/or premature delivery [52, 53]. Negro *et al.* randomized 115 TPOAb positive women to receive LT4 at a mean gestational age of 10 weeks with a dosage based on their TSH (<1 mU/L: 0.5 μg/kg·d; 1–2 mU/L: 0.75 μg/kg·d; >2 mU/L or TPOAbs >1500 kIU/L: 1 μg/kg·d) [20] In this study, LT4 treatment markedly reduced the rate of late miscarriage (from 13.8% versus 3.4%) and of premature delivery (22.4% vs. 7.0%) [20]. Using the same protocol, Nazarpour *et al.* randomized 131 TPOAb positive women to receive LT4 at a mean gestational age of 11 weeks [71]. This study also found that LT4 reduced the rate of premature delivery (23.7% versus 7.1%) but there was no beneficial effect of LT4 on the rate of miscarriage (3.6% vs. 3.4%) [71]. In addition, Nazarpour *et al.* stratified their analyses based on the TSH concentration at presentation and found that the benefit of LT4 treatment in reducing preterm delivery was mainly present in the group with TSH concentrations >4.0 mU/L (29.4% vs. 5.3%, P <0.01) compared with women with TSH levels <4.0 mU/L (16.7% vs. 11.1%, P = 0.69). These findings fit with the synergistically higher risk of adverse outcomes in women with both TPOAb positivity and a high TSH [29–31, 72]. Taken together, TPOAb positivity is the most important risk factor for thyroid dysfunction during pregnancy at least partly through impairing the thyroidal response to hCG stimulation. Therefore, TPOAbs are an important tool to improve the interpretation of TSH and, to a lesser extent fT_4 concentrations, during pregnancy.

Conclusions

A detailed understanding of pregnancy-specific thyroid physiology can help to interpret gestational thyroid function measurements. While thyroid disease should optimally be defined according to lab-specific reference ranges, the clinical assessment of whether to start treatment or not remains complicated. In part, this is because the risk of adverse outcomes seems to be related to other factors that influence thyroid function (i.e. TPOAb positivity, hCG). Another equally important reason is the lack of adequate randomized controlled trials that investigate the effects of levothyroxine treatment, preferably during early pregnancy. The potential risks associated with LT4 (over)treatment during pregnancy should be taken into account during clinical decision-making.

Management of Thyroid Disorders After Pregnancy

Nobuyuki Amino and Naoko Arata

Postpartum Thyroid Dysfunction

Postpartum thyroid dysfunction is defined as an exacerbation of subclinical autoimmune thyroiditis during the postpartum period [1–3]. Patients do not develop thyroid autoimmunity at the onset of postpartum thyroid dysfunction, but had 'subclinical autoimmune thyroiditis' [4] beforehand and this is exacerbated after delivery. Typically, an exacerbation induces destructive thyrotoxicosis followed by transient hypothyroidism. However, various types of thyroid dysfunction may occur, including Graves' disease. Therefore, any kind of thyroid dysfunction observed during postpartum period, is referred to as 'postpartum thyroid dysfunction'.

Pathogenesis

The pathogenesis of postpartum thyroid dysfunction is similar to that of exacerbation of Graves' disease or Hashimoto's thyroiditis, which occurs by the enhancement of immune activities after parturition. The difference is only their stage of autoimmune disease. In postpartum thyroiditis, immune activation causes the transition of subclinical into overt autoimmune thyroid disease; whereas in previously manifest Graves' or Hashimoto's disease, immune activation results in exacerbation or relapse after parturition. During pregnancy, maternal immune activities are suppressed in order to prevent rejection of the fetus. Sudden release from the immune suppression at the time of delivery intensifies immune activities above the normal level, similar to the sudden cessation of immunosuppressive drugs giving rise to the exacerbation of autoimmune diseases [3]. The serial changes in titres of microsomal (thyroid peroxidase, TPO) antibodies in pregnant women with Graves' disease and Hashimoto's disease (**Figure 9.4.1**) support this view. This immune rebound appears to be a general phenomenon observed in the postpartum period, since serum levels of immunoglobulins, and counts of lymphocytes and NK/K cell activity decrease in late pregnancy and increase after delivery even in pregnant women without thyroid dysfunction [5, 6]. Since the immunological changes following termination of pregnancy are similar to those during the postpartum period, thyroid dysfunction may occur following spontaneous of elective abortion [7, 8].

The postpartum rebound of immune activities comprises two phases. Cytotoxic T cells and natural killer (NK) cells increase from 1 to 4 months postpartum (**Figure 9.4.2**) [9, 10]. The enhancement of cellular immunity may exacerbate tissue injury in Hashimoto's thyroiditis. During the second phase, CD5+B cells, which produce autoantibodies, increase typically at 7 to 10 months postpartum (**Figure 9.4.2**) [9]. The enhancement of humoral immunity may cause postpartum Graves' disease, by an increase of anti-TSH receptor autoantibodies. Hashimoto's thyroiditis is commonly aggravated from 1 to 4 months postpartum and Graves' disease may develop or relapse from 3 to 10 months postpartum (**Figure 9.4.3**).

Studies on the production of cytokines have shown that Th1-type and Th2-type cytokines decrease during pregnancy, Th1-type cytokines increase during early postpartum period and Th2-type cytokines increase during later postpartum period [11], supporting the immune rebound hypothesis [2, 3]. A possible role for fetal microchimerism has been proposed as the mechanism of postpartum exacerbation of autoimmune thyroid disease [12] but insufficient evidence to support this hypothesis is available and further studies are needed.

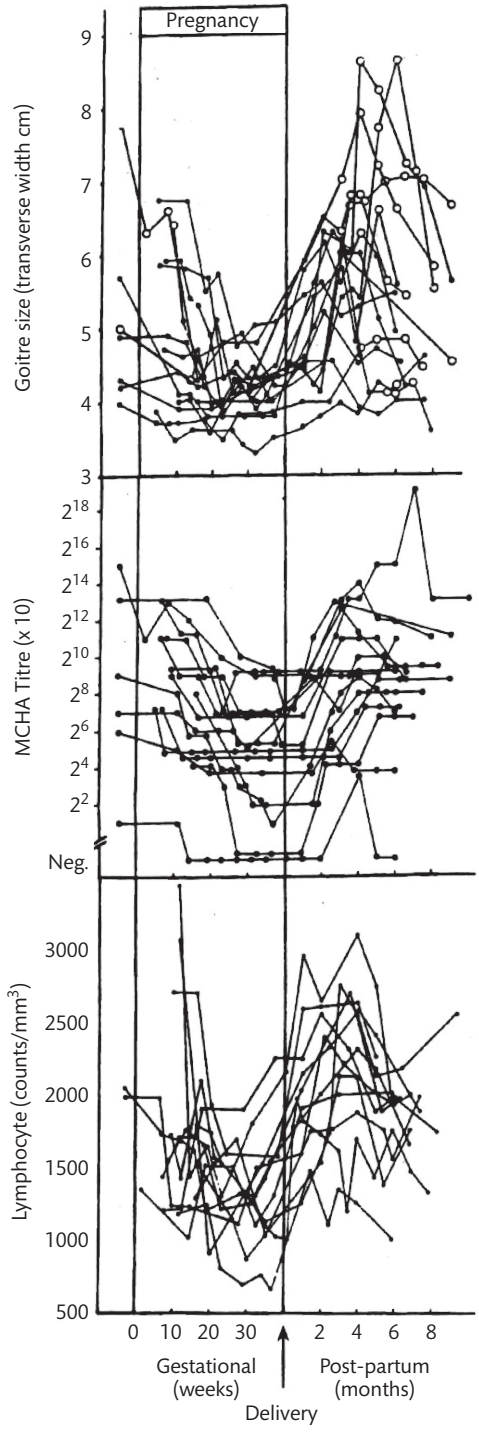

Figure 9.4.1 Serial changes in goitre size, titres of antithyroid microsomal antibody, and the counts of peripheral lymphocytes during pregnancy and postpartum period in patients with Hashimoto's thyroiditis. Open circles denote that TSH was more than 10 mU/l at time of measurement. MCHA: microsomal haemagglutination antibody.

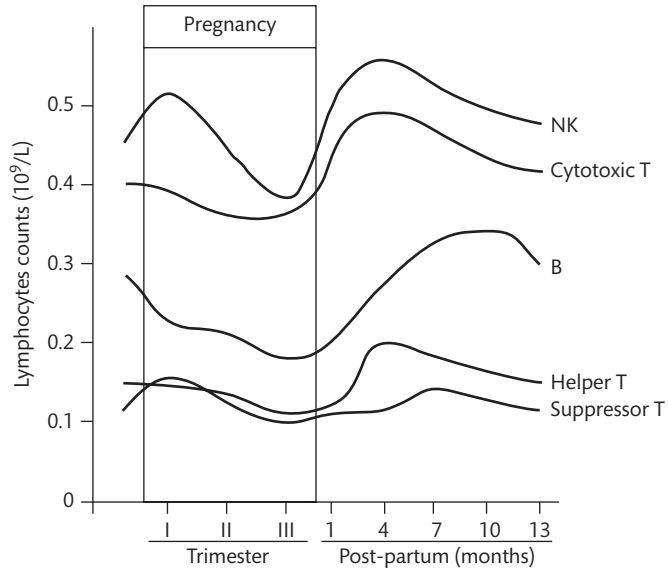

Figure 9.4.2 Changes in peripheral T cells, B cells, and NK cells during pregnancy and the postpartum period in the normal women.

Prevalence

Postpartum thyroid dysfunction is very common [3, 13] with an incidence of about 5% (1.1–16.7) (Table 9.4.1) in mothers in the general population, that is one in 20 pregnant women develop postpartum thyroid dysfunction [13]. Postpartum thyroid dysfunction can be classified into five groups by the clinical features – hyperthyroidism and/or hypothyroidism, transient or persistent (Figure 9.4.4) [2]:

- **I.** Persistent thyrotoxicosis
- **II.** Transient thyrotoxicosis
- **III.** Destructive thyrotoxicosis followed by transient hypothyroidism
- **IV.** Transient hypothyroidism
- **V.** Persistent hypothyroidism

Persistent thyrotoxicosis (group I) and a proportion of transient thyrotoxicosis (group II) reveal a high radioiodine uptake. Transient thyrotoxicosis with a high radioiodine uptake is common in postpartum Graves' disease; the overproduction of thyroid hormones ceases spontaneously within a year. The prevalence of postpartum Graves' disease (both persistent and transient) is estimated at 11% of those with postpartum thyroid dysfunction and 0.54% of the general population [14]. Thyrotoxicosis due to postpartum Graves' disease occurs between 3- and 10-months postpartum.

The other three types of postpartum thyroid dysfunction are associated with thyroid tissue damage due to an exacerbation of autoimmune thyroiditis. They often manifest themselves as transient thyrotoxicosis (destructive thyrotoxicosis) developing at 1 to 3 months postpartum. Depending on the extent of the destruction, transient hypothyroidism may follow (group III) or not (group II, with a low radioiodine uptake).

Occasionally, Graves' disease occurs closely following, or concomitantly with destructive thyrotoxicosis [15]. When cellular damage occurs slowly, hypothyroidism alone, rather than destructive thyrotoxicosis, may be observed after delivery. In many cases, it is transient (group IV). However, it may be persistent in a few cases (group V). Destructive transient thyrotoxicosis (group II, with a low radioiodine uptake, and group III) is the most common form of postpartum thyroid dysfunction, accounting for 50–60% of all postpartum thyroid dysfunction. The rest (group IV, V) only have a hypothyroid phase, however, persistent hypothyroidism is very rare (less than 0.1%).

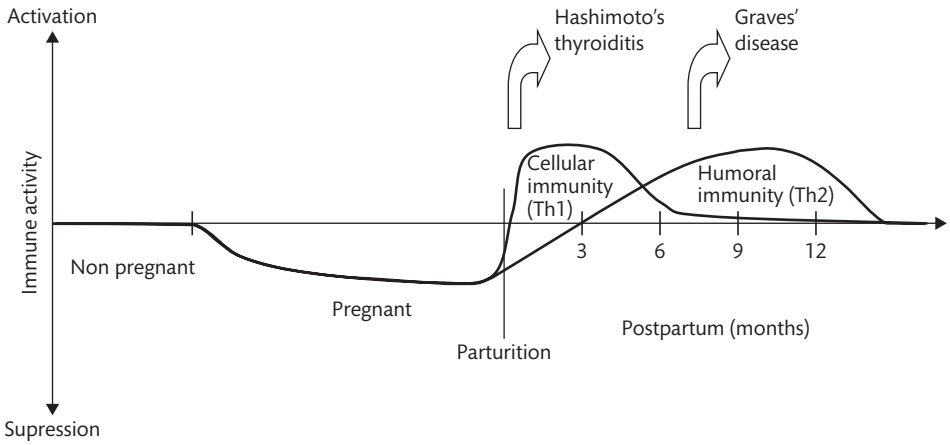

Figure 9.4.3 Immune rebound hypothesis of postpartum autoimmune thyroid diseases. One to 3 months after delivery, cellular immunity dominates, and development or exacerbation of autoimmune thyroiditis is observed. Three to six months after delivery, humoral immunity dominates, and development or exacerbation of Graves' disease is observed.

Symptoms and Signs

Thyroid dysfunction is most often subclinical: the patient usually has no features of hyper- or hypothyroidism, and thyroid function tests reveal only mild changes in serum TSH and thyroid hormones. Symptoms and signs in overt postpartum thyroid dysfunction are the same as in the non-postpartum state. Hypermetabolic and hyperdynamic symptoms, such as palpitation, sweating and tremor can be observed in any type of postpartum thyrotoxicosis.

In postpartum Graves' disease, eye signs and/or pretibial myxoedema may be present. In postpartum hypothyroidism, symptoms such as weakness, fatigue, dry skin, constipation, and cold intolerance, and signs such as cold skin, bradycardia, and thyroid enlargement are common. Since the hypothyroidism is of short duration, there is little risk of myxoedema. Postpartum depression, sometimes found with postpartum thyroid dysfunction [16], may be a significant consequence and is the presence of elevated antithyroid autoantibodies rather than with hypothyroidism [17].

Table 9.4.1 Incidence of postpartum thyroid dysfunction

Year	Author	Country	Prevalence(%)
1982	Amino	Japan	5.5

2001	Bagis	Turkey	5.5

Diagnosis

The diagnosis of postpartum thyroid dysfunction is straightforward when the patient shows abnormal thyroid function tests and positive thyroid autoantibodies during the postpartum period. Thyroid dysfunction, however, is most often subclinical. For the cases with overt thyrotoxicosis, it is essential to differentiate between postpartum Graves' disease and destructive thyrotoxicosis. Usually an educated guess can be made from the time of onset (3–12 months after parturition in Graves' disease versus 1–6 months in destructive thyrotoxicosis). Figure 9.4.5 summarizes the time of onset of four different types of pregnancy-associated thyrotoxicosis [18]. Anti-TSH receptor antibodies and other markers helpful for the differential diagnosis are summarized in Table 9.4.2 [19–22]. Figure 9.4.6 shows measurements of anti-TSH receptor antibody concentrations and thyroid blood flow in postpartum destructive thyrotoxicosis (n = 42) and postpartum Graves' disease (n = 102) [22]. Blood tests, however, are not conclusive since anti-TSH-receptor autoantibodies are sometimes found in Hashimoto's thyroiditis and other tests do not have distinct cut-off values. The quantitative measurement of thyroid blood flow using Doppler ultrasonography is useful for differentiation and typically is high in Graves' disease and low in destructive thyrotoxicosis [23]. The measurement of radioactive iodine uptake provides definitive information in the differential diagnosis between Graves' disease (high uptake) and destructive thyrotoxicosis (low uptake). However, this investigation should not be performed in breastfeeding mothers. Notably, there is no reliable way to differentiate between transient and persistent Graves' disease.

For hypothyroidism, most cases are transient and due to an exacerbation of autoimmune thyroiditis. The finding of positive antithyroid microsomal (peroxidase) antibodies and/or antithyroglobulin antibody supports the existence of autoimmune

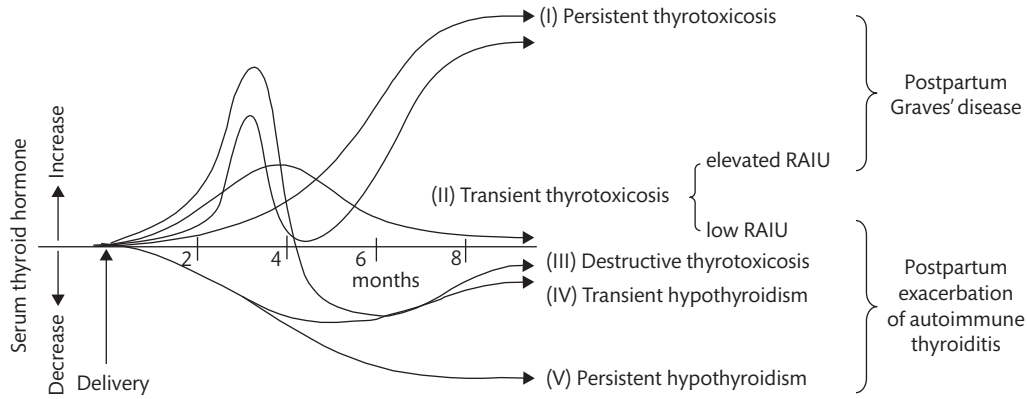

Figure 9.4.4 Time course of five different types of postpartum thyroid dysfunction.

thyroiditis, but negative results are obtained in 5–30%. Cases of iodine deficient hypothyroidism may occur in areas where iodine intake is marginal or mildly deficient, such as some parts of Europe [24], although it is likely that mothers already had hypothyroidism during pregnancy.

Once the diagnosis is established, patients should be followed up for 1 year since Graves' disease may occur shortly after destructive thyrotoxicosis.

In postpartum thyroid dysfunction some immunological abnormalities are observed before the onset of thyroid dysfunction (and therefore, before and during pregnancy). Among these, the finding of raised TPO or microsomal antibodies is the most useful marker for the prediction of the occurrence of postpartum thyroid dysfunction [25]. If TPO antibodies are present, there is always lymphocytic infiltration into the thyroid, and therefore 'subclinical autoimmune thyroiditis' [4] which may be exacerbated after delivery. Sixty to seventy per cent of women with a positive measurement of thyroid peroxidase antibodies in early pregnancy develop postpartum thyroid dysfunction [3], whereas the risk to develop postpartum thyroid dysfunction in TPO antibody negative women is estimated to be 0.6%. Mothers with high TPO titres (> 5000–10 000 reciprocal dilution) almost always develop postpartum thyroid dysfunction. However, the measurement of thyroid peroxidase antibodies does not provide any information on the type of dysfunction that will occur. Although the measurement of thyroid peroxidase antibodies with semiquantitative antimicrosomal particle agglutination (MCPA) tests is simple and cheap, the value of screening for postpartum autoimmune thyroid dysfunction remains unclear [26], and is in part dependent of different healthcare systems [27]. Antithyroid peroxidase antibody measurement is as useful as semiquantitative particle agglutination tests for predicting postpartum thyroid dysfunction [28].

A recent study, using highly sensitive immunoassays, has shown that measurement of antithyroglobulin antibody is more sensitive than that of antithyroid peroxidase antibody to detect thyroid

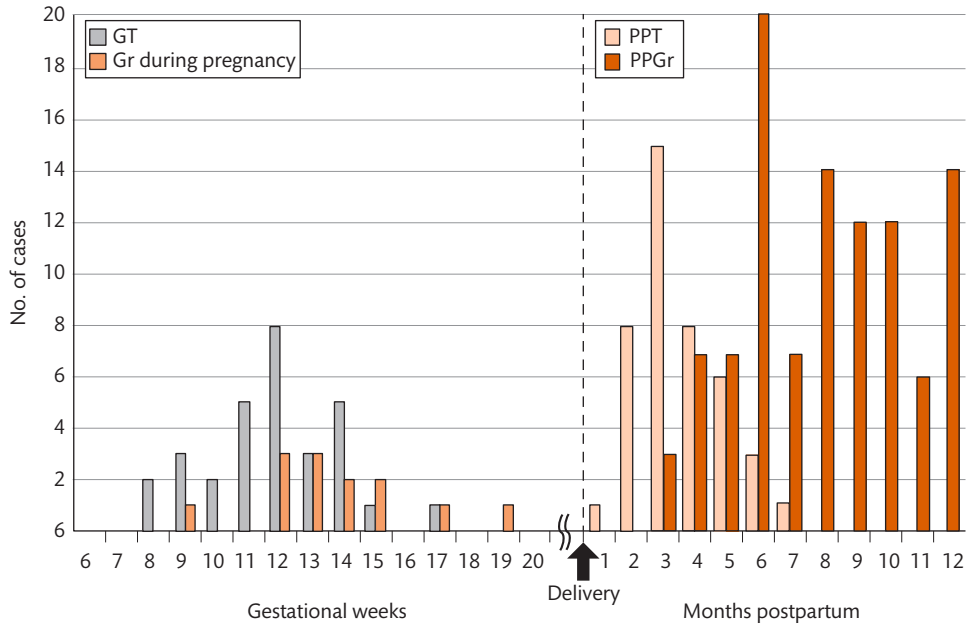

Figure 9.4.5 Time of onset and frequency of four different types of pregnancy-associated thyrotoxicosis. GT, gestational thyrotoxicosis; Gr, Graves' disease; PPT, postpartum thyroiditis; PPGr, postpartum onset Graves' disease.

Table 9.4.2 Differential diagnosis between postpartum Graves' disease and postpartum destructive thyrotoxicosis

	Graves' disease	Destructive thyrotoxicosis
Onset	3–12 months postpartum	1–6 months postpartum
Anti-TSH receptor antibody	Positive	Negative
Eye signs	Yes	No
Total T_3/total T_4 ratio (ng/μg)	>20 in 80% of cases	< 20
FT3/FT4 ratio	>2.8 in 77% of cases	< 2.8
Thyroid blood flow	High	Low
Radioactive iodine uptake*	High	Low
Serial change in serum thyroglobulin**	<50% increase from a month before the onset	>50% increase from a month before the onset

* Contraindicated in lactating mother; ** Thyroglobulin should be measured with a method not influenced by antithyroglobulin autoantibody(TgAb)

autoimmune abnormalities [29]. Further studies are required to confirm the value of sensitive antithyroglobulin antibody measurements in the diagnosis of postpartum thyroiditis.

Graves' disease is aggravated in early pregnancy, ameliorates in the latter half of pregnancy, but often relapses postpartum [30]. Human chorionic gonadotrophin (hCG) plays a crucial role in the exacerbation of Graves' thyrotoxicosis in early pregnancy [31]. Relapse of Graves' thyrotoxicosis after parturition may occur even if mothers are in remission before pregnancy.

The new onset of Graves' disease in the postpartum period is of great interest, since early diagnosis and treatment early during the disease period can result in rapid remission [14]. Overall, 40% of patients with Graves' disease who have had one or more deliveries, develop their disease postpartum [32]. TSH-receptor-stimulating antibodies are a good indicator of postpartum development of Graves' disease, since they are often positive before onset of the disease [33] when measured with a sensitive bioassay. Pregnant women with positive TSH-receptor-stimulating antibodies in early pregnancy have a high-risk of developing postpartum Graves' disease. Seventy-one pregnant women with positive TPO antibodies in early pregnancy were prospectively observed from early pregnancy to the postpartum period [14]. Among them, seven showed positive TSH-receptor-stimulating antibodies, five (70%) of whom developed postpartum Graves' disease. Thyrotoxicosis in three of those five was transient and spontaneously improved within a year. Graves' disease did not occur in the TSH-receptor-stimulating antibody-negative patients. A conventional radioreceptor assay for anti-TSH-receptor antibodies was not able to discriminate postpartum Graves' disease.

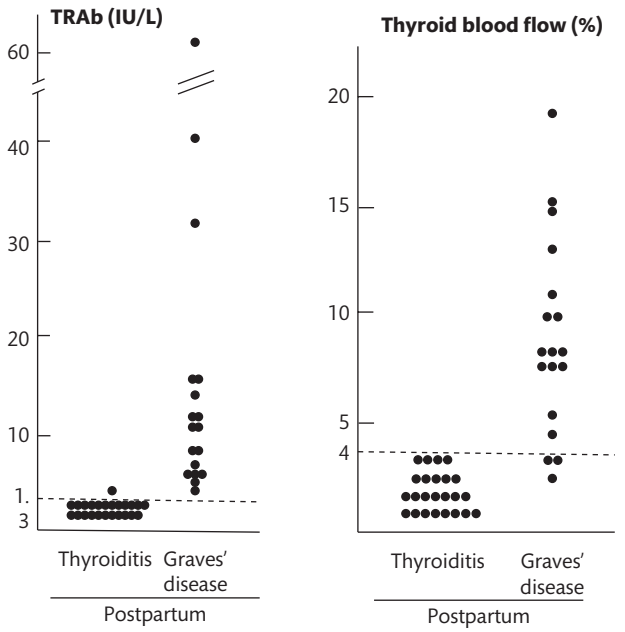

Figure 9.4.6 Differentiation of postpartum Graves' thyrotoxicosis from postpartum destructive thyrotoxicosis (postpartum thyroiditis) using antithyrotropin receptor antibodies(TRAb) and thyroid blood flow.

Management of Postpartum Thyroid Dysfunction

In postpartum Graves' disease, treatment options are antithyroid drugs, radioactive iodine, or subtotal thyroidectomy similar to Graves' disease outside this setting. Antithyroid drug treatment is a good initial choice because (1) postpartum Graves' hyperthyroidism is often transient; (2) even in persistent Graves' disease, those patients diagnosed early are easily controlled with antithyroid drugs [14]; and (3) mothers may not want breastfeeding to be interrupted by radioiodine therapy. Radioactive iodine treatment can still be applied when hyperthyroidism persists after 1 year and has not gone into remission during antithyroid drug treatment.

In destructive thyrotoxicosis, the thyrotoxic phase is always transient and spontaneously ceases in 1–3 months. Treatment should be symptomatic, mainly with ß-adrenergic antagonists for cardiovascular hyperdynamic symptoms. Antithyroid therapy is not indicated. The treatment of hypothyroidism is required only when the patient has symptoms of hypothyroidism. Usually levothyroxine therapy with a gradual reduction in dose may be indicated, but recovery of patient's thyroid function may be difficult to demonstrate. Alternatively, replacement with a submaximal dose of liothyronine (15–50 μg 3 daily by mouth in 1–3 divided doses) is useful in most transient cases, since spontaneous recovery of thyroid function can be monitored by an increase of serum T_4 or free T_4. In permanent hypothyroidism, when serum T_4 or free T_4 does not recover after several months of T_3 treatment, levothyroxine replacement is indicated.

Recently successful prevention of postpartum thyroid dysfunction was achieved by short-term immunosuppressive therapy in patients who were predicted to develop postpartum hypothyroidism [34]. It is also reported that selenium supplementation during pregnancy and in the postpartum period reduces thyroid inflammatory activity and the incidence of hypothyroidism [35].

Prognosis

Little is known about the long-term prognosis of postpartum Graves' hyperthyroidism, although a better outcome than in 'ordinary' Graves' disease might be expected in view of early diagnosis just after the onset of disease. In destructive thyrotoxicosis and/or hypothyroidism due to exacerbation of autoimmune thyroiditis, thyroid dysfunction is transient, and most patients recover spontaneously to euthyroidism. Only in a few cases, hypothyroidism may persist. High titres of thyroglobulin antibodies and/or thyroid peroxidase antibodies are risk factors of persistent hypothyroidism. Even after recovery from hypothyroidism, abnormalities in ultrasonography and/or iodide perchlorate discharge tests may persist for a long time [36, 37], reflecting underlying chronic autoimmune thyroiditis. The patients almost certainly will develop postpartum thyroid dysfunction after the next parturition, with similar time of onset, type of thyroid dysfunction, and duration of dysfunction as in the previous episode.

Late development (after 5 years or more) of permanent hypothyroidism is found in 25–60% of the patients with postpartum thyroiditis [38–40]. Therefore, these patients should be followed up at appropriate intervals (once every 1–2 years) [26, 41]. Othman *et al.* reported that high titres of antimicrosomal antibodies and the severity of the hypothyroid phase of postpartum thyroiditis are risk factors for the late development of permanent hypothyroidism, but there was no association with HLA haplotype or family history of thyroid disease [38]. In contrast, in a Japanese population, high titres of thyroglobulin antibodies and HLA-DRw9 and/or B51 genotype were risk factors of permanent hypothyroidism [39].

Thyroid Disorders and Breastfeeding

The Influence of Thyroid Disease on Breastfeeding

Because hypothyroidism suppresses milk production and may restore with levothyroxine replacement [42, 43], women who have difficulties with lactation should be evaluated thyroid function and started on levothyroxine when hypothyroidism is revealed [41]. Data on the effects of hyperthyroidism on milk production are limited in humans.

Medications in Breastfeeding Women with Graves' Disease

Methimazole (MMI) concentration in breast milk is higher than propylthiouracil (PTU) concentration, with a mean milk/serum ratio of 0.98 in MMI [44] and 0.1 in PTU [45]. Regarding the influence on infants, drug exposure to infants through breast milk is important. When MMI 10 mg/day is administered to a mother, the amount of MMI exposed to infant through breast milk corresponds to 0.6 to 1.6 mg/day in terms of maternal body weight [46], and when 400 mg/day of PTU is administered to a mother, the exposure to infant of 0.8–9.2 mg/day is equivalent [45]. The peak of MMI concentration in blood and milk of 5 lactating women who received a single dose of carbimazole 40 mg (corresponding to 30 mg of MMI) was 1 hour after administration, and the mean blood half-life of MMI was 4.9 hours [44]. When women taking 10 mg of MMI 2 to 3 times per day, breastfeeding was performed 2 hours after taking MMI, and the blood MMI concentration of the infant was measured 2 hours after lactation, the MMI concentration of the infant was negligible [47].

According to several reports by Azizi *et al.*, infant hypothyroidism within one year due to the drug exposure by breast milk following administration of MMI of 10–30 mg/day to mothers was not observed. Growth (monitored postnatally for up to 60 months, somatic and neurodevelopment were also normal in the same series [47–49]. It should be noted that MMI 20–30 mg/day was administered only for the first month, and thereafter the dose was reduced to 10 mg/day or less in these studies. Similarly, hypothyroidism of the offspring following exposure to breastmilk of a mother taking PTU 750 mg daily has not been reported, although there are only a few case reports [50].

Based on these factors, both MMI (up to maximal dose of 20 mg/d) and PTU (up to maximal dose of 450 mg/d) can be administered, when antithyroid drugs is indicated for women with breastfeeding [41]. Monitoring for appropriate growth and development of their children by routine paediatric evaluations should be at least done [41]. It may be necessary to check the thyroid function of the infant when ATD is administered at moderate or higher doses. A mother should take her ATD dose just after breastfeeding, which should provide a 3–4 hour interval before she lactates again [51]. Considering the possibility of side effects of severe hepatic injury of PTU in mothers and infants [52], and high incidence of general side effects with PTU [53], MMI is the preferred drug in hyperthyroid women who is breastfeeding.

The influence on thyroid function of breastfed infants whose mothers were treated with inorganic iodine for postpartum relapsing Graves' disease has been reported from Japan, which is one of country with iodine excess intake [54]. Mothers were taking 37.5 mg per day of the median inorganic iodine, the median iodine concentration in breast milk was 15.1 mg/L, and the median urine iodine concentration of infants was 15.6 mg/L. In spite of extremely high iodine exposure to infants via breast milk, hypothyroidism in breastfed infants was found only in 3.8% (1 out of 26 children) [54]. Due to the presence of the sodium iodide symporter in mammary epithelial cells, inorganic iodine is concentrated and secreted in the milk. Moreover, suppression of thyroid function during infancy caused by excess iodine exposure may be a great negative influence on the growth and development of children. Therefore, inorganic iodine administration to breast-feeding mothers should be avoided, regardless of the report from Japan.

Transfer of Maternal Thyroid Hormone to Newborn via Breast Milk

A small amount of maternal thyroid hormone is present in the breast milk of lactating women. Mean thyroxine concentration in breast milk was reported as 0.83 μg/L [55], which showed maternal

transfer of thyroid hormone does not have a meaningful impact on the infants' thyroid hormone status.

Administration of Diagnostic or Therapeutic Radiopharmaceuticals to Breastfeeding Women

The use of ^{131}I is contraindicated during lactation. If required, ^{123}I can be used if breast milk is pumped and discarded for 3–4 days before breastfeeding is resumed. Similarly, Tc-^{99m} pertechnetate administration requires breast milk to be pumped and discarded during the day of testing [41].

Thyroid Disorders in Newborns

A.S. Paul van Trotsenburg and Nitash Zwaveling-Soonawala

Introduction

Thyroid hormone is essential for normal brain development starting in the early embryonic period and continuing throughout the first years of life [1]. While in adult onset hypothyroidism clinical manifestations are usually reversed with appropriate treatment, untreated congenital hypothyroidism has severe neurological consequences leading to permanent intellectual and motor disabilities. The important role of the thyroid in brain development was already recognized by 1850 when the British surgeon Curlings reported two mentally impaired children with large tongues, who appeared to have no thyroid gland at obduction [2]. In 1871, the British internist Fagge described four other mentally impaired and often deaf children and adolescents who were extremely short (adult height less than 120 cm), and who had a broad face with a flat root of the nose, thick nostrils, a large open mouth and thick lips, short broad hands and feet, and a swollen skin [3]. Although at that time a relationship was suggested between the striking disease and the absence of the thyroid, the function of this organ was still completely unknown. In the 1890s the first treatment trials in adults with acquired hypothyroidism, using thyroid extract from animals, led to improvement of clinical symptoms [4]. Treatment of children with clinically diagnosed congenital hypothyroidism in the 1950's restored growth and many other signs and symptoms [5]. These initial treatment protocols, however, were not successful in preventing mental retardation. In 1972 it was demonstrated that the key to preventing brain damage is treatment started within the first three months of life [6]. Since only one third of patients were clinically recognized as early as that, newborn screening programmes for congenital hypothyroidism were introduced in the late 1970s. These screening programmes have proven to be very effective in preventing brain damage by early detection and treatment [7, 8]. Children with congenital hypothyroidism treated within the first two to three weeks of life have near normal development, although mild neurological deficits and health impairments are observed in the most severely affected [9]. Congenital hypothyroidism has a reported incidence of one in 2000–4000 live births and may be of thyroidal (primary) or of hypothalamic–pituitary (central) origin. Primary congenital hypothyroidism accounts for approximately 90–95% of all cases and may be due to abnormal thyroid gland formation (dysgenesis) or defective thyroid hormone syntheses by a structurally normal gland (dyshormonogenesis). Central congenital hypothyroidism has a reported incidence of up to one in 16 000 live births. Central congenital hypothyroidism may occur in isolation but in the majority of cases (around 75%) is accompanied by additional pituitary hormone deficiencies.

Thyroid Development and Thyroid Hormone Biosynthesis

Thyroid development and thyroid hormone biosynthesis are reviewed in detail in Section 3. In short, the developing thyroid is first visible at the end of the third embryonal week as an endodermal thickening in the floor of the pharynx at the most anterior part of the foregut [10]. This median thyroid anlage enlarges and migrates downward. Initially the thyroid anlage stays connected to the pharyngeal endoderm via the thyroglossal duct but detaches from it by the end of the fourth embryonal week. It migrates further along the neck, forms two lobes and fuses with the lateral thyroid anlagen, the ultimobranchial bodies. The thyroid reaches its final, pretracheal position in the seventh embryonic week. After this, cellular differentiation and folliculogenesis continue. In the tenth embryonal

week, the thyroid is completely formed, and at the end of the first trimester thyroid hormone synthesis is achieved. Various transcription factors are involved in these stages of thyroid development. The four transcription factors NKX2-1, FOXE1, PAX8, and HHEX are expressed from the first development, while the TSH-receptor (TSHR), thyroglobulin (Tg), sodium-iodide symporter (NIS/SLC5A5) and thyroid peroxidase (TPO) are expressed in the stage of folliculogenesis [10]. Mutations in encoding genes may result in thyroid dysgenesis or thyroid dyshormonogenesis.

Development of Thyroid Hormone Synthesis During Gestation

Thyroid hormones are detectable in the fetal circulation at the end of the first trimester, although it is likely that a fraction of these hormones is of maternal origin [11]. Initially the concentrations of thyroxine (T_4) and thyroxine-binding globulin (TBG) are very low but subsequently increase to reach adult values at about 36 weeks. Fetal serum triiodothyronine (T_3) concentrations are low due to relatively low placental deiodinase type D1 activity, while reverse T_3 levels are high due to high placental deiodinase type D3. At term, the T_3 concentration are still low compared to the normal values for infants and adults. Birth induces a number of changes in thyroid hormone production and metabolism within a short period. This adaptation process starts with an acute surge of TSH into the circulation, reaching a maximum level around 30 min after birth. Thereafter, it gradually decreases and stabilizes within 1–2 days at slightly higher values than those in adults. The TSH surge significantly increases the thyroid hormone production. Serum T_4 and T_3 reach maximum levels approximately 24 hours after birth. Serum reverse T_3 concentration decreases rapidly in the first week of life caused by the loss of placental deiodinase D3 activity. In preterm infants, the functional maturation of the thyroid at birth is incomplete. Timing of the TSH surge is similar to that of term neonates, but quantitatively lower, especially in preterm infants with respiratory distress syndrome. During the first day following the TSH surge, increasing T_4 and T_3 concentrations can be observed, but the T_4 and T_3 peak levels are lower as the pregnancy is shorter and in the case of complications, such as intrauterine growth retardation and respiratory distress syndrome, a nadir is observed at about one week after birth, followed by a second TSH increase. This decrease in T_4 concentrations in premature infants, is referred to as transient hypothyroxinaemia of prematurity. Although premature neonates have lower postpartum free T_4 (fT_4) levels than would be normal for intrauterine life at the same age, administration of T_4 immediately after birth has no significant influence on mortality and morbidity, except for extremely premature infants (less than 27 weeks gestation) in whom such a temporary T_4 supplement may be beneficial for brain development [12].

Primary Congenital Hypothyroidism

Thyroid dysgenesis has long been reported to account for 85% of cases of primary congenital hypothyroidism, while dyshormonogenesis only accounts for 15%. However, in the last decade the contribution of thyroid dyshormonogenesis has increased and is reported to be 30–40%. Especially milder and often transient cases are increasingly identified, most likely resulting from the lowering of TSH cut-offs in neonatal screening [13].

Thyroid Dysgenesis

Thyroid dysgenesis may result in mild to severe hypothyroidism. The gland may be completely absent (agenesis) or remnants of variable size may be present along the tract of the thyroglossal duct (see Figure 9.5.1). These structures, called dystopic (synonym: ectopic) remnants are often localized in the sublingual area. Agenesis is characterized by complete absence of any thyroid tissue (indicated by technetium-99m or 123-I scintigraphy and ultrasound imaging), and complete inability to produce thyroid hormone and thyroglobulin. However, patients with negative 123-I scintigram and (almost) complete absence of circulating thyroid hormone, but clearly measurable serum thyroglobulin levels, have been described [14]. As the thyrocytes are the only cells able to produce thyroglobulin, this cell type has to be present, although it cannot be localized. We

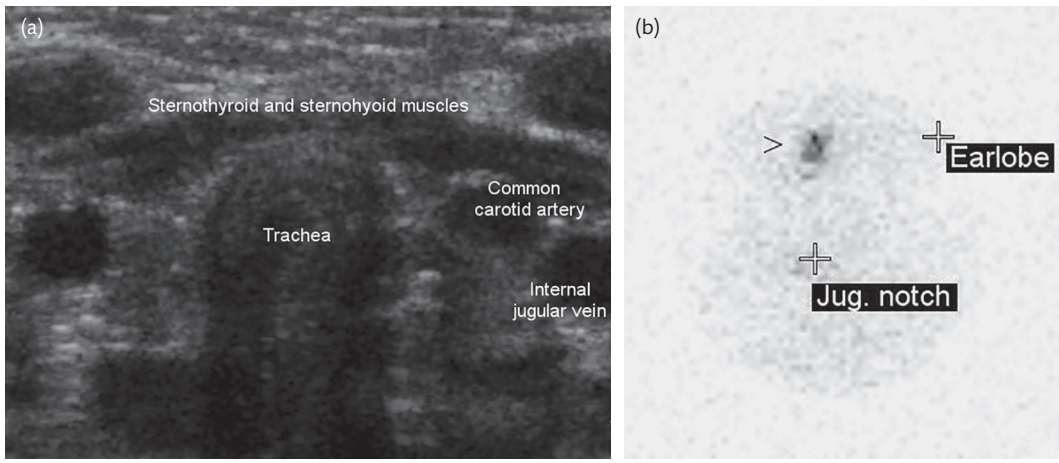

Figure 9.5.1 Ultrasound (a) and thyroid $^{123\text{-}I}$ scintigraphy (b) of the neck and head/neck, respectively, of a 14-day-old boy with primary congenital hypothyroidism due to thyroid dysgenesis. Ultrasonography showed no thyroid tissue in the trachea-'muscles'-carotid artery triangle. Scintigraphy showed a dystopic thyroid remnant (>).

introduced the term 'cryptic thyroid remnant' to describe this type of disorder.

In most cases it remains unclear why the migration and development of the thyroid becomes disturbed. Approximately 2% of cases are familial [15–17]. Although this familial occurrence strongly suggests the presence of genetic factors, mutations in genes known to be involved in thyroid development still explain not more than ten percent of all cases of dysgenesis. The high discordance between monozygotic twins (92%) suggests the involvement of other mechanisms than mutations in these genes [18]. Thyroid dysgenesis usually occurs in isolation but in very rare cases may be associated with other abnormalities. The most frequently encountered genetic form of isolated thyroid dysgenesis is due to TSH-receptor defects. The phenotype varies from severe congenital hypothyroidism due to a hypoplastic or even absent thyroid gland to mild TSH elevation only. It is an autosomal recessive disorder although a few monoallelic mutations have been shown to cause mild TSH elevation in a dominant way, with intracellular entrapment of wild-type TSH receptors by mutant receptors as the underlying mechanism is [19–21]. Other rare genetic forms of isolated thyroid dysgenesis are due to defects in the *PAX8* and *CDCA8 (or BOREALIN*) genes. Rare syndromic forms of thyroid dysgenesis include Bamforth–Lazarus syndrome (*FOXE1* gene defects), brain–lung–thyroid syndrome (*NKX2-1* gene defects), 22q11.2 deletion syndrome (*TBX1* gene defects), *GLIS3* gene defects (associated with permanent neonatal diabetes) and Alagille syndrome (*JAG1* gene defects) (see Table 9.5.1). The frequency of congenital heart defects is increased in patients with thyroid dysgenesis. This is probably explained by the close relation of thyroid development to the adjacent mesenchyme and the developing heart. Genes associated with both congenital heart defects and thyroid dysgenesis are *NKX2-5* and *NTN1*.

Thyroid Dyshormonogenesis

Dyshormonogenesis is characterized by a defect in one of the molecular steps involved in thyroid hormone synthesis within, and at the apical side of the thyroid follicular cells. In dyshormonogenesis, the thyroid gland has a normal position and structure. However, decreased thyroid hormone levels result in increased pituitary TSH secretion and ongoing thyroid gland stimulation, leading to thyroid gland enlargement (goitre); at birth or developing later on, especially when thyroid hormone treatment is delayed or with low patient compliance. Biochemically, patients present with varying degrees of hypothyroidism (low or normal fT_4, with high TSH). Many dyshormonogenesis cases are detected by neonatal screening but mild cases may be missed. Maternal iodide intake may influence the postnatal thyroid hormone levels. In general, thyroglobulin levels are increased in thyroid dyshormonogenesis, except in thyroglobulin synthesis defects. Thyroid imaging by ultrasound or scintigraphy using 123-I or technetium-99m may distinguish thyroid dysgenesis from dyshormonogenesis. However, radionuclide uptake may be low or absent in sodium-iodide symporter defect, emphasizing the importance of combining ultrasound and scintigraphy in the diagnostic work-up. Administration of perchlorate after 123-I scintigraphy may identify iodide organification defects; perchlorate blocks the sodium-iodide symporter, resulting in discharge of unbound 123-I in case of an organification defect. Normally, discharge is less than 10%. Discharge >90% indicates total iodide organification defect, while values between 10% and 90% indicate partial iodide organification defect (see Figure 9.5.2). Abnormal discharge is expected in *TPO, DUOX2, DUOXA2, SLC26A4*, and *SLC26A7* gene defects, while normal discharge is expected in *SLC5A5, TG*, and *IYD* defects. In contrast to thyroid dysgenesis, which is usually sporadic, most cases of dyshormonogenesis are hereditary in an autosomal recessive manner, with the exception of a few cases of dominant inheritance [22, 23]. Another difference between thyroid dysgenesis and dyshormonogenesis is the large phenotypic variability in thyroid dyshormonogenesis, with variable expression and penetrance of genetic defects. Lack of clear genotype-phenotype correlation may point to a role for other genetic or environmental influences, for instance multigenic involvement or dietary iodine intake. Increasing iodine intake may improve certain forms of thyroid dyshormogenesis (*DUOX2, DUOXA2, SLC26A4, SLC26A7, IYD*, and partial *SLC5A5*).

Defects in Iodine Transport

The first step in thyroid hormone synthesis is the active transport of iodide into the thyrocytes. Iodide transport across the basal membrane is mediated by the sodium-iodide symporter (NIS). NIS is also present in a number of non-thyroidal tissues, like the lactating mammary gland, stomach, salivary and lacrimal glands. NIS deficiency results in insufficient uptake of iodide as substrate for thyroid hormone synthesis. It is an autosomal recessive disorder characterized by goitre and hypothyroidism of variable severity. Diagnostic characteristics are (1) limited or absent radioiodide uptake in a normally positioned thyroid gland; (2) elevated blood thyroglobulin levels; and (3) a low saliva (radio-) iodide concentration resulting in low (radio-)iodide saliva/plasma ratio. Clinically there is marked heterogeneity which may be related to differences in iodide intake. Although high iodide intake may compensate for impaired NIS function, treatment with levothyroxine (LT4) is preferred, especially in young children.

Defects in the Synthesis of Thyroglobulin

Thyroglobulin is a very large glycoprotein homodimer, that serves as a macromolecular precursor for thyroid hormone synthesis and storage. Thyroglobulin deficiency is an autosomal recessive disorder and causes goitre with mild to severe hypothyroidism in combination with typically low or undetectable serum thyroglobulin levels. Abnormal iodoproteins/-peptides may be found in blood and urine. Upon scintigraphy radionuclide uptake (123-I) is high with a normal perchlorate discharge. The estimated prevalence is 1 in 100 000 newborns with a probably somewhat higher prevalence in Japan (1 in 67 000) [24]. *TG* defects show a large clinical heterogeneity, ranging from simple goitre to a very large thyroid with severe hypothyroidism. Molecular studies of different mutations have provided more insight into thyroglobulin transport/trafficking, which explains some of the clinical heterogeneity. For example, mutations in the acetylcholinesterase-like domain and mutations replacing cysteine residues inhibit thyroglobulin from being transported out of the endoplasmic reticulum into the Golgi apparatus, causing premature degradation as seen in other endoplasmic reticulum storage diseases [25, 26].

Table 9.5.1 Genetic causes of primary congenital hypothyroidism

Gene name	Inheritance	Thyroid location and size	Associated characteristics
Thyroid dysgenesis			
CDCA8 (BOREALIN)	AD/AR	Athyreosis Thyroid ectopy Hemiagenesis Asymmetric thyroid size	
FOXE1	AR	Athyreosis Severe hypoplasia/normal position	Cleft palate, choanal atresia, spikey hair, bifid epiglottis (Bamforth-Lazarus syndrome)
GLIS3	AR	Athyreosis Normal size and position	Neonatal diabetes mellitus, renal cystic dysplasia, hepatic fibrosis, congenital glaucoma, skeletal abnormalities
JAG1	AD	Athyreosis Thyroid ectopy Normal size and position	Alagille syndrome
NKX2-1	AD	Athyreosis hypoplasia, normal position Normal size and position	Choreoathetosis, respiratory problems (brain-Lung-Thyroid syndrome)
NKX2-5	unclear	Athyreosis Thyroid ectopy	Congenital heart disease
NTN1	unknown	Thyroid ectopy	Congenital heart disease
PAX8	AD	Athyreosis Thyroid ectopy Hypoplasia, normal position Normal size and position	Renal abnormalities
TBX1	AD	Hypoplasia, normal position Hemiagenesis Left lobe hypoplasia	22q11.2 deletion syndrome (DiGeorge syndrome, velocardiofacial syndrome)
TSHR	AR/AD	Athyreosis Hypoplasia, normal position Normal size and position	

Gene name	Inheritance	Thyroid size	Serum thyroglobulin	Functional study Radioiodine uptake + perchlorate discharge	Associated characteristics
Thyroid dyshormonogenesis					
DUOX2	AR/AD	normal to enlarged	elevated	high uptake, abnormal discharge	
DUOXA2	AR	normal to enlarged	elevated	high uptake, abnormal discharge	
IYD (DEHAL1)	AR	normal to enlarged	elevated	high uptake, normal discharge	
SLC26A7	AR	normal to enlarged	elevated	high uptake, abnormal discharge	
SLC5A5 (NIS)	AR	normal to enlarged	elevated	absent to low uptake	
SLC26A4 (PENDRIN)	AR	normal to enlarged	elevated	high uptake, abnormal discharge	sensorineural deafness
TG	AR	normal to enlarged	decreased/ undetectable	high uptake, normal discharge	
TPO	AR	normal to enlarged	elevated	high uptake, abnormal discharge	

Abbreviations: AD, autosomal dominant; AR, autosomal recessive.

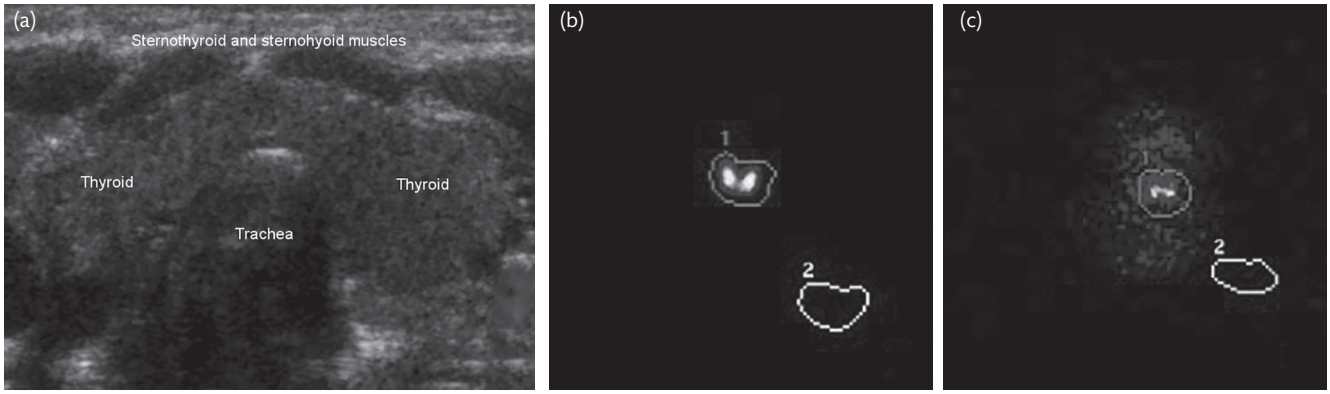

Figure 9.5.2 Ultrasound (a) and thyroid $^{123\text{-}I}$ scintigraphy before (b) and after (c) perchlorate administration in a 14-day-old boy with primary congenital hypothyroidism due to thyroid dyshormonogenesis. Ultrasonography and scintigraphy showed a normally localized thyroid. After the administration of perchlorate, $^{123\text{-}I}$ uptake decreased from 20.7% to 4.3%, confirming the diagnosis iodide organification defect.

Defects in Iodination of Thyroglobulin

Thyroperoxidase (TPO) is an enzyme located at the apical membrane of the follicular cell, and responsible for iodide oxidation, tyrosyl iodination, and iodotyrosine coupling. *TPO* defects are a common cause of permanent congenital hypothyroidism due to dyshormonogenesis. The estimated prevalence in a Dutch cohort was 1 in 66 000 newborns [27]. It is an autosomal recessive disorder usually leading to a total iodide organification defect, but also to partial defects. Hypothyroidism, especially in total iodide organification defects, is severe and associated with goitre. Thyroglobulin levels are elevated. Thyroid scintigraphy shows high radionuclide uptake and an abnormal perchlorate discharge test indicating defective organification. In case of total organification defect (discharge >90%) *TPO* gene defects are the most likely candidate, with *DUOX2* as an alternative. In case of partial organification defects (discharge 10–90%) other causes should also be considered, such as *DUOXA2* and *SLC26A4* mutations [28].

The enzymes dual oxidase 1 and 2 (DUOX1 and DUOX2), are responsible for thyroidal H_2O_2 generation at the apical membrane of the thyroid follicular cell. DUOX2 seems to be the dominant factor since it is more highly expressed in the thyroid than DUOX1. In 2002, the first four cases of *DUOX2* mutation causing congenital hypothyroidism were described [29]. *DUOX2* variants are found in high frequency in cohorts of congenital hypothyroidism patients with partial iodide organification defects and is one of the most frequent causes thyroid dyshormonogenesis. In a Chinese study of patients with overt and subclinical congenital hypothyroidism the *DUOX2* mutation rate was as high as 29% [30]. Recently, *DUOX2* mutations were found in patients with thyroid dysgenesis as well, suggesting a role of *DUOX2* also in thyroid dysgenesis [31]. The phenotypic variability of *DUOX2* mutations may in part be explained by other H_2O_2 generating systems compensating for the defective DUOX2 function, such as DUOX1. The finding of digenic *DUOX1* and *DUOX2* mutations emphasizes that congenital hypothyroidism may be oligogenic and that differences in severity may be explained by the presence of other genetic defects [32]. Other factors possibly explaining the phenotypic variability are thought to be age-related differences in thyroid hormone requirement, and differences in iodide intake [33].

DUOXA1 and DUOXA2 are endoplasmic reticulum proteins that are required for the maturation and plasma membrane localization of the DUOX enzymes [34]. In 2008 the first case of a *DUOXA2* mutation was reported in a case of mild permanent congenital hypothyroidism due to a partial iodide organification defect [35]. Since then only a few cases have been reported. *DUOXA2* mutations also seem to be associated with a variable phenotype, ranging from permanent to transient congenital hypothyroidism in the neonatal period. Just like for DUOX there seems to be an age-dependent decrease in severity and compensating DUOX1/DUOXA1 H_2O_2 generation is thought to influence severity. A high incidence of a specific *DUOXA2* mutation (Y138X) was found in a Korean population, emphasizing ethnic differences in prevalence [36].

SLC26A4 (or pendrin) is a member of the solute carrier family26A. It is localized to the apical membrane of the thyroid follicular cell and mediates iodide efflux from the cellular side to the follicular lumen, making it available for oxidation and tyrosyl iodination. In the inner ear SLC26A4 maintains acid-base homeostasis of the endolymphatic fluid [37]. Pendred syndrome is an autosomal recessive disorder characterized by sensorineural deafness, goitre, and a partial iodide organification defect. Patients present with hearing loss from infancy or later in childhood. Impaired hearing is associated with inner ear malformation (enlarged vestibular aquaduct) which can be visualized by MR or CT imaging. Development of goitre and hypothyroidism is influenced by iodide intake, and usually develops later in childhood or adolescence. Therefore, patients are mostly missed by neonatal screening. The incidence of Pendred syndrome is estimated at 7.5 to 10 in 100 000 individuals and accounts for approximately 10% of all hereditary forms of hearing loss. SLC26A7 is an anion transporter that was recently found to be localized at the apical membrane of the thyroid follicular cells. Although its precise function remains to be elucidated it seems to be involved in iodide transport. *SLC26A7* gene defects have been described in patients with goitrous congenital hypothyroidism exhibiting a partial iodide organification defect.

Defects in the Recycling of Iodide

The enzyme iodotyrosine deiodinase (IYD), also known as iodotyrosine dehalogenase 1 (DEHAL1) degrades monoiodotyrosines (MIT) and diiodotyrosines (DIT) into iodide and tyrosine,

recycling them for hormonogenesis [38]. IYD deficiency leads to increased blood iodotyrosines (MIT and DIT) levels and increased urinary excretion. The resulting urinary iodide loss leads to iodide deficient hypothyroidism and goitre. IYD deficiency is a very rare autosomal recessive disorder with *IYD* defects only reported in seven patients so far (three missense mutations and one deletion). Since the onset of the hypothyroidism and goitre is variable and not always present at birth, IYD deficiency is probably missed in neonatal screening programmes. This genetic form of hypothyroidism should be considered in case of nonautoimmune hypothyroidism and goitre occurring in childhood/adolescence and perhaps even later on in life.

Central Congenital Hypothyroidism

In central congenital hypothyroidism deficient thyroid hormone production is due to insufficient TSH stimulation of an otherwise normal thyroid gland [39]. If the defect is limited to pituitary thyrotrope cells, central hypothyroidism may be isolated. In most cases it is associated with other pituitary hormone deficiencies. In combined pituitary hormone deficiency, growth hormone deficiency and adrenocorticotrophic hormone (ACTH) deficiency are potentially brain damaging and life-threatening, due to hypoglycaemia and circulatory insufficiency. Isolated central congenital hypothyroidism may be due to defects in thyrotropin releasing hormone receptor gene (*TRHR*), thyroid stimulating hormone β-subunit gene (*TSHB*), and the more recently described genes *IGSF1, TBL1X*, and *IRS4* [40–46]. *TRHR* and *TSHB* gene mutations are found only rarely. Since the first cases of *IGSF1* gene mutations were reported in 2012, many new cases have been described making *IGSF1* mutations a frequent cause of isolated central hypothyroidism [47]. *TBL1X* and *IRS4* have been described only very recently and their prevalence still needs to be investigated in large cohorts [45, 46]. The majority of central congenital hypothyroidism cases are not isolated but occur within the framework of combined pituitary hormone deficiencies. Mutations in transcription factors involved in pituitary formation/differentiation are found in less than 5% of patients (see **Table 9.5.2**). Most patients with congenital combined pituitary hormone deficiency exhibit a pituitary malformation characterized by an absent or thin pituitary stalk, a hypoplastic anterior pituitary lobe and an ectopic posterior pituitary lobe (see **Figure 9.5.3**). This malformation is known as pituitary stalk interruption syndrome (PSIS) [48]. PSIS often occurs in isolation but may be accompanied by additional midline brain abnormalities. Since monogenic causes of isolated PSIS are only rarely detected, a polygenic and multifactorial aetiology is more likely [49].

Table 9.5.2 Genetic causes of congenital central hypothyroidism

Gene name	Inheritance	Associated characteristics
Isolated central hypothyroidism		
IGSF1	XL	Prolactin deficiency[1], growth hormone deficiency[2], delayed maturation, macro-orchidism in males, ovarian cysts in females
IRS4	XL	
TBL1X	XL	Hearing deficits
TRHR	AR	
TSHB	AR	
Central hypothyroidism within combined pituitary hormone deficiencies[3]		
CHD7	AD	CHARGE syndrome, PSIS
FGF8	AR	Kallmann syndrome, holoprosencephaly, corpus callosum agenesia
FGFR1	AD	Kallmann syndrome, septo-optic dysplasia, PSIS
FOXA2	AD	Craniofacial and endoderm-derived organ abnormalities, hyperinsulinism
HESX1	AR/AD	Septo-optic dysplasia
LEPR	AR	Severe obesity and hyperphagia
LHX3	AR	Short, rigid cervical spine, variable deafness, small to large pituitary
LHX4	AR/AD	Cerebellar anomalies, PSIS, Arnold-Chiari malformation, corpus callosum hypoplasia
NFKB2	AD	Variable immune deficiency (DAVID syndrome)
OTX2	AD	Ocular anomalies, PSIS
POU1F1	AR/AD	Midface hypoplasia
PROKR2	AR/AD	Septo-optic dysplasia, PSIS
PROP1	AR	Small to large pituitary
SOX2	AD	Microphthalmia, variable learning difficulties, pituitary hypoplasia
SOX3	XL	Variable mental retardation, PSIS

[1] 61% of hemizygous males, and 22% of heterozygous females; [2] 16% of hemizygous males in childhood [47]; [3] combination of hormone deficiencies is variable [39].
Abbreviations: AD, autosomal dominant; AR, autosomal recessive; PSIS, pituitary stalk interruption syndrome; XL, X-linked.

Figure 9.5.3 MRI of the hypothalamic-pituitary region of a 4-week-old girl with pituitary stalk interruption syndrome consisting of the classic triad of a small anterior pituitary lobe, an ectopic posterior pituitary lobe, and an absent pituitary stalk.

Albright's Hereditary Osteodystrophy and Down's Syndrome

Albright's hereditary osteodystrophy (AHO) is characterized by short stature, obesity, round face, subcutaneous ossifications and brachydactyly. In the late 1980s AHO was linked to mutations in the *GNAS* gene, explaining the resistance to parathyroid hormone and TSH often seen in these patients [50]. Nowadays, four types pseudohypoparathyroidism (PHP) are recognized, of which two are associated with hormonal resistance: PHP1a (AHO phenotype plus hormonal resistance to PTH, TSH, GnRH, LH and FSH, and PHP1b (hormonal resistance only). In PHP1a the severity of hypothyroidism ranges from subclinical (elevated TSH with normal fT_4) to manifest (elevated TSH and low fT_4). In PHP1a, congenital hypothyroidism is the earliest clue to this diagnosis in up to 30% of cases, but not in PHP1b which is associated with milder hypothyroidism [51]. Down's syndrome, caused by the presence of (part of) an extra chromosome 21, has been associated with congenital hypothyroidism for many decades [52]. In the last few years, it has become clear that, as a group, Down's syndrome children have a mild form of primary congenital hypothyroidism, probably caused by subtle thyroid dysgenesis which might be caused by overexpression of the chromosome 21 gene DYRK1A [53–55]. Some children have manifest hypothyroidism which is an undisputed treatment indication. However, most children have mild subclinical disease. LT4 treatment of young Down's syndrome children with subclinical disease during their first 2 years of life seemed to improve cognitive and motor development, but in the long term may only result in somewhat better growth [56, 57].

Transient Congenital Hypothyroidism

Exposure of the neonate or fetus to excessive quantities of iodine (e.g. iodine-containing radiographic contrast agents or disinfectants) may lead to transient primary congenital hypothyroidism. Incidentally, maternal TSH receptor blocking antibodies may cause transient primary congenital hypothyroidism for several weeks or months, depending on the initial concentration of circulating antibodies [58]. In both situations affected neonates may be detected by neonatal screening and selected for LT4 treatment during the first months of life. Maternal antithyroid drug use for hyperthyroidism is a third cause transient congenital hypothyroidism.

Transient central congenital hypothyroidism has been reported in newborns of women with uncontrolled Graves' hyperthyroidism during pregnancy. It may be caused by exposure of the fetal hypothalamic–pituitary–thyroid system to higher than normal thyroid hormone concentrations, impairing its physiological maturation during intrauterine life. Although transient, the central hypothyroidism may persist for several months to over a year, necessitating treatment [59].

Signs and Symptoms of Congenital Hypothyroidism

Due to the protective effects of maternal thyroid hormone placental transfer, newborns with congenital hypothyroidism are typically asymptomatic at birth. Classic signs and symptoms of untreated congenital hypothyroidism include large fontanels, macroglossia, abdominal distention, umbilical hernia, lethargy, hoarse cry, poor feeding, hypothermia, constipation, prolonged jaundice, hypotonia with delayed reflexes, bradycardia, and a mottled dry skin. In cases of thyroid dyshormonogenesis, goitre may be present but hardly ever large enough to obstruct neck flexion during delivery or cause airway obstruction. In syndromic forms of primary congenital hypothyroidism certain specific features may be present; cleft palate, choanal atresia, spikey hair and bifid epiglottis (Bamforth–Lazarus syndrome due to *FOXE1* gene defects), neurological and respiratory problems (brain–lung–thyroid syndrome due to *NKX2-1* gene defects), congenital heart disease (*NKX2-5* and *NTN1* gene defects), neonatal diabetes mellitus (*GLIS3* gene defects), renal abnormalities (*PAX8* gene defects), and sensorineural hearing loss (Pendred syndrome due to *SLC26A4* gene defects) (see Table 9.5.1).

In central congenital hypothyroidism signs of additional pituitary hormone deficiencies may be hypoglycaemia due to growth hormone and/or adrenocorticotropic hormone deficiency, or micropenis and/or undescended tests due to gonadotropin deficiency. In rare instance, diabetes insipidus may be present due to vasopressin deficiency (usually in case of septo-optic dysplasia). Other midline abnormalities may be present such as cleft palate, ocular abnormalities, and solitary central incisor.

Neonatal Screening

In the 1970s it became possible to determine T_4 and TSH concentrations in just a few drops of blood, obtained by a heel puncture, and absorbed in filter paper. Since then many countries have implemented neonatal mass-screening programmes for congenital hypothyroidism. Worldwide, the majority of these screening programmes are TSH-based and effectively detect cases of primary congenital hypothyroidism. Central congenital hypothyroidism is only detected

in programmes that also measure T_4 or fT_4 [60]. The Dutch neonatal screening programme consists of a three-step approach with a primary T_4 measurement followed by additional TSH measurement in the lowest 20% T_4 concentrations, and an additional measurement of T_4-binding globulin (TBG) in the lowest 5%. This screening strategy has proven to be effective in detecting both primary and central forms of congenital hypothyroidism [61, 62]. The incidence of permanent central congenital hypothyroidism in the Netherlands is one of the highest in the world, around 1 in 16 000 neonates [63].

Diagnosis and Treatment of Congenital Hypothyroidism

In a newborn with an abnormal neonatal screening result a venous blood sample should be taken for TSH and fT_4 measurement in order to confirm the diagnosis. A low fT_4 in combination with a high TSH level indicates primary hypothyroidism, while a low fT_4 together with a low, normal, or mildly elevated TSH points to central hypothyroidism. A normal fT_4 together with an elevated TSH is referred to as subclinical hypothyroidism. In central hypothyroidism TSH may be mildly elevated due to the presence of TSH with reduced bioactivity. This may complicate distinguishing mild primary hypothyroidism from central hypothyroidism. In a large group of neonates with central congenital hypothyroidism it was found that their TSH levels at diagnosis were never higher than 12.9 mIU/L [64]. Current guidelines advise starting levothyroxine (LT4) treatment immediately without waiting for the venous blood test result unless these results are available the same day [65]. In case of borderline screening results the decision to treat may be delayed until after the venous blood results are known. In these cases, further diagnostic studies may aid in obtaining a definitive diagnosis. Diagnostic work-up includes imaging studies (thyroid ultrasound, or scintigraphy using 123-I followed by perchlorate administration or technetium-99m), measurement of serum thyroglobulin and serum/salivary/urine iodine measurement (see sections on thyroid dysgenesis and thyroid dyshormonogenesis) and measurement of maternal and neonatal anti-TSH receptor antibodies. In case of suspected central hypothyroidism additional pituitary function tests are needed to search for possible accompanying pituitary hormone deficiencies. PSIS can be shown or ruled out by magnetic resonance imaging of the brain.

Treatment for primary congenital hypothyroidism should be started with an initial LT4 dose of 10–15 μg/kg once a day [65]. LT4 tablets should be crushed and mixed with a bit of water, breast milk, or formula and administered on a small spoon. In case of a severely hypothyroid neonate, the body's T_4 deficit can be corrected by one additional LT4 dose, 12 hours after the initial dose. There is no evidence of benefit of adding LT3 (liothyronine) to the LT4 treatment. T_4 absorption may be compromised by certain substances such as soya formulas, iron, and calcium preparations. To prevent under- or overtreatment, the fT_4 and TSH concentrations should be monitored at regular intervals. Recommended follow-up is every 2 weeks until serum TSH is normalized, every 1 to 3 months during the first year of life, every 2 to 4 months between 1 and 3 years of age and every 6 to 12 months thereafter [65]. Due to decreasing T_4 turn over with age, the required dose of 10–15 μg/kg in the first months of life decreases to around 4–5 μg/kg at the age of 5 years and to around 1.6 μg/kg in adults.

The short-term goals of LT4 treatment in the neonatal period are to normalize the fT_4 concentration within 2 weeks and TSH concentration within 4 weeks. When treating children with severe congenital hypothyroidism, normalization of TSH concentrations can sometimes only be achieved by establishing supra-physiological fT_4 concentrations. This seems to be due to an altered TSH-fT_4 set point possibly due to the effect of intrauterine hypothyroidism on the maturing hypothalamic–pituitary–thyroid axis [66]. While this set point change seems to normalize with age there is evidence of persistence [67]. In these cases, we advise keeping fT_4 concentrations around the upper limit of the reference interval and accepting slightly elevated TSH concentrations, although this may lead to goitre in cases of dyshormonogenesis.

In case of primary congenital hypothyroidism without definitive diagnosis, treatment may be safely discontinued at the age of 3 years to evaluate the permanent or transient character of the hypothyroidism.

For the treatment of central congenital hypothyroidism, a starting dose of approximately 6–8 μg/kg per day is suitable. In central hypothyroidism TSH levels are useless for therapy control and one has to rely on fT_4 concentrations. The aim is to keep fT_4 concentrations in the upper half of the age specific reference range. It is important to treat accompanying ACTH deficiency before starting T_4 supplementation. Genetic testing for mutations in *TRHR, TSHB, IGSF1, TBL1X*, and *IRS4* genes will substantiate a diagnosis of isolated central hypothyroidism.

The main treatment goal in congenital hypothyroidism is preventing brain damage, especially in the first 3 years of life when brain development is critically dependent on thyroid hormone. Long-term effect evaluation of the cognitive and motor development of patients with congenital hypothyroidism has demonstrated that timely and adequate LT4 treatment results in neuropsychological test results within the normal range [8, 68]. However, especially in severe cases of congenital hypothyroidism, mild learning disabilities, fine motor impairment and attention problems are still reported [69, 70]. Also, a higher prevalence of sensorineural hearing loss is reported emphasizing the role of thyroid hormone in cochlear development [71].

Congenital Hyperthyroidism

Congenital or neonatal hyperthyroidism is usually caused by maternal TSH receptor stimulating antibodies crossing the placenta and stimulating the fetal thyroid from mid-gestation onwards. Much rarer causes are activating mutations in the genes encoding the TSH receptor or stimulatory G protein (McCune–Albright syndrome) [72]. Although neonatal hyperthyroidism caused by stimulating antibodies affects only 1–2% of the children of mothers with past or active Graves' disease and is a self-limiting disease, it is associated with considerable morbidity and even mortality if not recognized and left untreated [72, 73]. Prenatal signs may be intra-uterine growth retardation, microcephaly, tachycardia, and goitre. After birth, neonates may be extremely restless and irritable, with an exophthalmos-like appearance, and may display signs of hypermetabolism, for instance tachycardia and sweating, and even multiple organ failure.

In the past decades, it has been shown that the key to preventing morbidity and mortality due to fetal and neonatal hyperthyroidism

caused by anti-TSH receptor antibodies is measurement of these antibodies in pregnant women with past or active Graves' disease: early in, and—if detectable—at mid gestation, and (late) in the third trimester. If antibodies are present at mid gestation, the fetus should be closely monitored. When there are signs of fetal hyperthyroidism, antithyroid drug treatment should be started via the mother. At birth, anti-TSH receptor antibodies, and fT_4 and TSH should be measured in cord blood, and thyroid function should be assessed every 2–3 days thereafter. Predictors of neonatal hyperthyroidism are anti-TSH receptor antibodies concentrations higher than three times the upper limit of the reference interval and higher than normal fT_4 levels [74].

If a neonate has clinical or biochemical signs of hyperthyroidism, treatment should be started consisting of methimazole (0.5–1.0 mg/kg per day, orally in three divided doses) and, depending on the severity of the condition, propranolol (2 mg/kg per day, orally in two divided doses) [72]. In severe cases, treatment with iodine (1 drop of Lugol's solution every 8 h after the start of antithyroid drug therapy; Lugol's solution contains 126 mg iodine/ml) and corticosteroids may be necessary. If heart failure is imminent, digitalization is indicated. When euthyroidism is reached, methimazole treatment should be continued for several months, and LT4 should be added to prevent hypothyroidism ('block and replace'). An alternative approach is to taper the methimazole dose to maintain euthyroidism ('titration'). In our experience, this leads to unwanted fluctuating fT_4 concentrations. Therefore, we prefer the block and replace strategy. In most infants the anti-TSH receptor antibodies will have disappeared by the age of 3–4 months, when treatment can be stopped. In case of congenital hyperthyroidism due to gain-of-function mutation of the TSH-receptor gene, remission will not occur. After initial thyreostatic drug treatment, the only reliable long-term treatment is surgical removal of the thyroid gland, sometimes followed by 131I treatment. Mental impairment, microcephaly, and growth problems may occur when treatment is delayed.

Pituitary Tumours in Pregnancy

Wenyu Huang and Mark E. Molitch

Introduction

Pituitary adenomas may cause problems because of over-secretion of hormones by the tumour as well as by causing hypopituitarism, thereby affecting fertility and pregnancy outcome if pregnancy does ensue. In addition, the pregnancy itself alters hormone secretion and pituitary tumour size, complicating the evaluation and management of patients with pituitary neoplasms. The influence on various types of therapy on the developing fetus also affects therapeutic decision-making.

Prolactinoma and Pregnancy

Hyperprolactinemia is responsible for about one third of all cases of female infertility, owing to its inhibition of ovulation [1]. When women with prolactinomas get pregnant, two important issues arise: (1) the effects of the dopamine agonist on early fetal development; and (2) the effect of pregnancy on prolactinoma size [2].

Effects of Dopamine Agonists on the Developing Fetus

For patients with prolactinomas, dopamine agonists are the treatment of choice, as they are effective in correcting the hyperprolactinemia and restoring ovulation in over 90% of women with amenorrhea and anovulation [3–5]. Generally, dopamine agonists should be stopped upon confirmation of pregnancy. Bromocriptine has been shown to cross the placenta in human studies [6]; while cabergoline has been shown to do so in animal studies but such data are lacking in humans. The long half-life of cabergoline means several days of fetal exposure after the drug has been stopped.

With such short-term exposure of generally less than 6 weeks in over 6000 pregnancies, bromocriptine has not been found to cause any increase in spontaneous abortions, ectopic pregnancies, trophoblastic disease, multiple pregnancies, or congenital malformations (Table 1) [7]. A long-term follow-up study of 64 children between the ages of 6 months and 9 years who were exposed to this drug during early gestation showed no ill effects on their development. Bromocriptine has been used throughout gestation in only a little over 100 women, with no abnormalities noted in the infants except for one with an undescended testicle and another with a talipes deformity [8–10].

Experience with the use of cabergoline in early pregnancy is more limited, with just over 1000 cases being reported (Table 1). As with bromocriptine, such use has similarly not shown an increase in adverse pregnancy outcomes (Table 1), including only 2.6% major malformations found in 908 pregnancies [11–20]. Follow-up studies of up to 12 years following exposure to cabergoline during gestation in 232 children showed a slight retardation in verbal fluency in two (0.8%), difficulty in achieving complete continence in one by age 4 (0.4%), seizures in two (0.8%) and 'pervasive developmental disorder', an autism spectrum disorder, in two (0.8%) [19, 21, 22]. A summary of cabergoline use throughout gestation indicated that healthy infants were delivered at term in thirteen and at 36 weeks in one; but one had an intrauterine death at 34 weeks when the mother had severe preeclampsia [20, 23]. Compared to what is expected in the general population in the United States [24, 25], there do not appear to be any increases in adverse pregnancy outcomes with either drug (Table 9.6.1).

In a review of 176 pregnancies, in which quinagolide (not available in the United States) was maintained for a median duration of 37 days into the gestations, Webster reported 24 spontaneous abortions, one ectopic pregnancy, and one stillbirth at 31 weeks of gestation [26]. Nine fetal malformations were reported [26]. Thus, quinagolide does not appear to be safe for the fetus if used when pregnancy is desired.

In contrast to the majority of studies that provide reassuring information regarding cabergoline and bromocriptine, Hurault-Delaure *et al.* reported some adverse outcomes of dopamine agonist use from a French database [27]. Of the 57 408 mother–baby outcome pairs, 183 (0.3%) had received dopamine agonists (bromocriptine 64.5%, cabergoline 20.2%, quinagolide 9.8%) at some time

Table 9.6.1 Pregnancy outcomes summarized for women who became pregnant while taking bromocriptine or cabergoline, compared to what is expected in the normal population

* 14 of these terminations were for malformations; ** 7 of these births were stillbirths.

during their pregnancy (75% in the first trimester) [27]. Compared to a control group of 345 unexposed women matched for age and the month-and-year of the beginning of their pregnancy, dopamine agonist exposure was associated with an increased frequency of preterm birth and an increased rate of early pregnancy loss [27]. There were no differences between the dopamine agonists with respect to these outcomes. No difference in psychomotor development at ages 9 and 24 months was shown between the two groups [27]. The authors mentioned limitations of this study, including the fact that the indication for prescribing dopamine agonists was not known and data about compliance with therapy was not available. Furthermore, exposed and unexposed subjects were not matched for multifetal pregnancy and details of co-existing pathology were not given.

Bromocriptine clearly has the largest safety database and has a proven safety record for pregnancy, the recent French data notwithstanding. The database for the use of cabergoline in pregnancy is smaller, but there is no evidence at present indicating that it exerts deleterious effects on the developing fetus. The risk of malformations with either drug is not greater than that what is found in the general population.

Effect of Pregnancy on Prolactinoma Size

The increasing oestrogen from the placenta stimulates lactotroph hyperplasia and a progressive increase in PRL levels over the course of pregnancy [28, 29]. In normal women, MRI scans show a gradual increase in pituitary volume, beginning by the second month and peaking the first week postpartum with a final height reaching 12 mm [30].

Prolactinomas can enlarge during pregnancy as a result of both the high oestrogen levels and the discontinuation of the dopamine agonist. The risk of symptomatic tumour enlargement in pregnant women with microprolactinomas or macroprolactinomas is presented in Table 2 [2, 31]. In these series, clinically significant tumour enlargement criteria generally consisted of progressive, severe headaches and/or visual field defects. Asymptomatic increases in tumour size without visual defects found on scans were not counted. Furthermore, in some series some pregnancies did not go to term and how tumour progression in such patients was counted was not clear. Table 9.6.2 is a summary of these data but the limitations of these numbers based on the information outlined earlier should be recognized [19–22, 31–42]. The risk of symptomatic tumour enlargement for microadenomas was 2.5% (20/800), for macroadenomas that had not had prior surgery or irradiation was 18.1% (52/288), and for macroadenomas with prior surgery/irradiation was 4.7% (7/148). Another caveat regarding these numbers is that in a small proportion of those cases the tumour enlargement reflected tumour apoplexy. There are a number of additional case reports of pituitary apoplexy occurring in women with both micro- and macroprolactinomas during pregnancy [43, 44], however the true incidence of apoplexy is unknown.

In one study, 34 women who stopped cabergoline shortly after conception had MRI scans carried out between weeks 24 and 32. Of the 12 with macroadenomas, 5 had no change in tumour size, none had a decrease in tumour size, 3 had an increase of <5 mm and 4 had an increase of >5 mm in size; of the 22 with microadenomas, 9 had no change in tumour size, 3 had a decrease in tumour size, 8 had an increase of <5 mm in size and 2 had an increase of >5 mm in size [21]. In most cases with tumour enlargement, reintroduction of the dopamine agonist was successful in reversing the problem and surgery was very rarely required. Cabergoline was restarted in 6 of the patients because of symptomatic headaches and/or vision-threatening increases in size of the adenomas [21, 42].

Postpartum PRL levels and tumour sizes are often reduced as compared with values before pregnancy [45], but this has not been observed in all series [46]. In one series of 56 hyperprolactinaemic women, 23 had normal PRL levels postpartum and of the 33 with persistent hyperprolactinemia 31% had levels that had decreased by more than 50% [42]. In another study, no patients with

* Analysis of tumour growth from this series—personal communication from D. Maiter.

prolactinoma showed a sharp increase of PRL levels or complained of symptoms suggestive of tumour enlargement when breast feeding postpartum [47]. Thus, women with prolactinomas can breast-feed. Reinstitution of dopamine agonist has to await the cessation of breast-feeding and should only be done if the woman remains hyperprolactinaemic and anovulatory.

Management of Prolactinoma During Pregnancy

In women with prolactinoma who are anovulatory, the treatment choice is dopamine agonists or transsphenoidal selective adenoma resection. Dopamine agonists seem to be the best primary treatment because of their efficacy in restoring ovulation and very low (2.5%) risk of clinically serious tumour enlargement. The accumulating data for cabergoline suggest that its safety record is equal to that of bromocriptine and generally it is better tolerated and more efficacious. Transsphenoidal surgery causes a permanent reduction of PRL levels in only 60–70% of cases and entails morbidity and mortality, albeit at low rates [4, 48, 49]. Pregnancy can generally be achieved in over 85% of patients with dopamine agonists or surgery [16, 33, 46, 49]. Radiotherapy is not warranted for patients with microadenomas due to the risk of long-term sequelae, especially hypopituitarism [50].

A patient with a microadenoma who was treated only with a dopamine agonist and had medication withdrawal after conception needs only to be followed clinically throughout gestation. PRL levels do not always rise during pregnancy in women with prolactinomas [51]. Usually PRL levels rise over the first 6–10 weeks after stopping the dopamine agonist and then plateau [52]. PRL levels may also not rise with tumour enlargement [51]. Therefore, periodic checking of PRL levels is not recommended [5]. Because of the low incidence of tumour enlargement, routine visual field testing is not cost effective. Visual field testing and MRI scanning are performed only in patients who become symptomatic and when intervention is being considered. It is important to carry out MRI scans this way, as Karaca *et al*. showed MRI confirmed tumour enlargement only in 4 out of 10 patients suspected clinically to have tumour enlargement [20]. There are no data documenting harm to the developing fetus from MRI scans [53–56]. Recently, slight increases in risks of stillbirths, neonatal deaths, and the broad outcome of any rheumatological, inflammatory, or infiltrative skin condition were shown with first trimester gadolinium exposure [57]. No adverse effects from MRIs with or without gadolinium have been shown in the late second or third trimesters. In clinical practice, it is important to document a significant increase in tumour size before instituting an intervention, such as restarting a dopamine agonist or surgery. If the headache is sudden, it may be caused by pituitary apoplexy, which may require an entirely different management course, including hormone replacement if there is sudden onset of hypopituitarism [43, 44]. MRI may be very helpful in distinguishing between haemorrhage into a tumour vs. tumour enlargement [43].

The patient with a small intrasellar or inferiorly extending macroadenoma can probably be managed as those with microadenomas (i.e. with dopamine agonists) before conception, followed by medication withdrawal upon confirmation of pregnancy. The risk that such a tumour will enlarge sufficiently to cause clinically serious complications is probably only marginally higher than the risk in patients with microadenomas.

A woman with a larger macroadenoma, especially one with suprasellar extension, has a 18.1% risk of clinically significant tumour enlargement during pregnancy. It is helpful to have a baseline MRI scan just prior to pregnancy. There is no best therapeutic approach in such a patient and there has to be a highly individualized shared decision-making with the patient with a clear, documented discussion of the various therapeutic alternatives. The most common approach is to stop the dopamine agonist after pregnancy is diagnosed, as in the patient with a microadenoma. Another approach is to debulk the tumour via transsphenoidal surgery. This reduces the risk of serious tumour enlargement, but cases of tumour expansion during pregnancy after such surgery have been reported [58]. After surgical debulking, a dopamine agonist will generally be required to normalize PRL levels and allow ovulation. A third approach, namely giving the dopamine agonist continuously throughout gestation, has been used but data regarding effects on the fetus are quite meagre; therefore, such treatment cannot be recommended without reservation. On the other hand, should pregnancy at an advanced stage be discovered in a woman taking bromocriptine or cabergoline, the data that exist are reassuring and would not justify therapeutic abortion. A special case might be a patient with a very large tumour in whom the growth rate of that tumour was slow and any effects of pressure on surrounding brain structures or the optic chiasm were very gradual and of no consequence. If there was substantial tumour shrinkage with the dopamine agonist, then stopping the drug abruptly might cause a sudden enlargement of the tumour with potential pressure on surrounding structures. In such a case, the wisest course could be to continue the dopamine agonist.

For patients with macroadenomas treated with a dopamine agonist alone or after surgery, careful follow-up with 1–3 monthly formal visual field testing is warranted. Repeat MRI scanning is reserved for patients with symptoms of tumour enlargement and/or visual field defect or both, as outlined earlier for patients with microadenomas. Repeat MRI scanning after delivery to detect asymptomatic tumour enlargement may be useful as well.

Should symptomatic tumour enlargement occur with any of these approaches, reinstitution of the dopamine agonist is probably less harmful to the mother and child than surgery. Any type of surgery during pregnancy results in a 1.5–fold and a 5-fold increase in fetal loss in the first and second trimester respectively, but without risk of congenital malformations [58, 59]. In addition, pregnant (compared to nonpregnant) women have significantly increased risks of postoperative complications, including infections and even mortality [60]. Thus, dopamine agonist reinstitution would appear to be preferable to surgery. However, such medical therapy must be very closely monitored, and transsphenoidal surgery or delivery (if the pregnancy is far enough advanced) should be performed if there is no response to the dopamine agonist and vision is progressively worsening.

Although suckling stimulates PRL secretion in normal women for the first few weeks to months postpartum, there are no data to suggest that breast-feeding can cause tumour growth. Thus, there seems to be no reason to discourage nursing in women with prolactinomas.

Cushing's Disease and Pregnancy

Changes of Hypothalamic–Pituitary–Adrenal (HPA) Axis During Pregnancy

Normal pregnancy is associated with profound changes of the hypothalamic–pituitary–adrenal axis [61], as listed next.

1. Serum free cortisol levels increase by 2–4-fold during pregnancy. Urine free cortisol (UFC) is normal during first trimester but increases by ~ 3-fold by the third trimester [61].
2. Total cortisol levels rise by 2–3-fold towards the end of pregnancy, mainly due to an increase in cortisol binding globulin and free cortisol.
3. The circadian rhythm of cortisol is preserved but blunted.
4. The cortisol response to ACTH stimulation is enhanced.
5. Both CRH and ACTH levels increase during pregnancy, partially owing to placental production of both hormones.
6. CRH and ACTH secretion is desensitized to the negative feedback of cortisol, resulting in failure of suppression by dexamethasone.

Cushing's Disease in Pregnancy

Cushing's syndrome is very rare in pregnancy. Its true prevalence is unknown. Interestingly, unlike in normal population wherein Cushing's disease comprises over 70% of the cases of Cushing's syndrome, Cushing's disease only accounts for 30–40% of Cushing's syndrome during pregnancy [61]. Adrenal causes of Cushing's syndrome, mostly adenoma and hyperplasia but even carcinoma, make up about 50% of the cases first found in pregnancy [62].

Effect of Cushing's Disease on Pregnancy

Untreated Cushing's syndrome exerts a significant negative impact on pregnancy outcomes. Maternal morbidities caused by hypercortisolism occur in 70% of the cases and consist of hypertension, pre-eclampsia, eclampsia, hyperglycaemia or diabetes, and hyperlipidaemia [62]. Other complications include osteoporosis, fracture, impaired wound healing, and psychiatric disorders [61]. Fortunately, maternal mortality is rare. Fetal complications from Cushing's syndrome during gestation include early spontaneous abortion, prematurity, and intrauterine growth restriction [63], with fetal mortality occurring in up to 20% of cases [61].

Diagnosis of Cushing's Disease During Pregnancy

The complex changes of the HPA axis during pregnancy make the diagnosis of Cushing's disease a major challenge. Many of the abnormalities of the HPA axis found in non-gravid patients with Cushing's syndrome can be seen in normal pregnancy, including increased cortisol levels, reduced inhibition of the HPA axis by exogenous glucocorticoid and a blunted circadian rhythm of cortisol. In addition, the symptoms and signs of Cushing's syndrome also overlap with those seen in normal pregnancy (e.g. weight gain, mood changes, fatigue, and hirsutism) [64].

Even though the 24-hour UFC level increases during pregnancy, a level higher than 3-fold of the upper limit of normal has been proposed to suggest Cushing's syndrome during pregnancy [61, 64]. Late night salivary cortisol levels also undergo a gradual increase during normal pregnancy. However, using the cut-off value of 0.255 μg/dl (7.0 nmol/L), 0.260 μg/dL (7.2 nmol/L), and 0.285 μg/dl (7.9 nmol/L) for first, second, and third trimesters respectively yield high sensitivity (>80%) and specificity (>90%) in separating Cushing's disease from normal gestational changes [65]. The 1 mg dexamethasone overnight suppression test is not reliable for the diagnosis of Cushing's syndrome, since more than 60% of normal women may have abnormal cortisol levels after 1mg dexamethasone during pregnancy [61].

Investigations of the differential diagnosis of ACTH-independent and ACTH-dependent Cushing's syndrome can usually start with measurement of the plasma ACTH concentration, performing an adrenal ultrasound scan (due to the high prevalence of adrenal Cushing's syndrome in pregnancy) and an 8 mg dexamethasone suppression test. It should be noted that up to 50% of women with adrenal Cushing's syndrome may have non-suppressed ACTH levels during pregnancy due to placental CRH stimulation and ACTH production [61]. A borderline low or suppressed ACTH, no response to the suppression by 8mg dexamethasone and an adrenal mass on the ultrasound all suggest ACTH-independent Cushing's syndrome [61]. When adrenal ultrasound identifies an adrenal lesion, a non-contrast MRI can also be used to further characterize the lesion. In patients suspected to have Cushing's disease, in addition to the suppressed cortisol level by 8mg dexamethasone, an increase in ACTH after CRH injection usually suggests Cushing's disease. Cushing's syndrome due to ectopic ACTH or an adrenal aetiology usually fail to response to exogenous dexamethasone and CRH. Pituitary MRI without contrast is necessary to evaluate a pituitary lesion during pregnancy but many patients with Cushing's disease may have very small microadenomas [61, 64]. Due to concern for radiation exposure and technical challenges in performing the test in most centres, inferior petrosal sinus sampling (IPSS) should be reserved for the patients who are difficult to diagnose even after the non-invasive tests [61].

Management of Cushing's Disease During Pregnancy

No systematic evaluation of treatments for Cushing's disease is available for pregnant patients. Reported management options include watchful monitoring, surgical, and medical treatments. In a review of 136 pregnancies collected from the literature, Lindsay *et al* found that the frequency of live births increased from 76% to 89% when active treatment was instituted by gestational week 20 [66]. Therefore, treatment during pregnancy has been advocated [66–68]. For patients with mild disease, it may be reasonable to wait until delivery to treat Cushing's disease [69]. However, comorbidities including hyperglycaemia and hypertension from hypercortisolism should be well controlled during pregnancy.

For those with Cushing's disease requiring treatment during pregnancy, transsphenoidal surgery in the second trimester appears to be the treatment of choice [64]. Bilateral adrenalectomy can be considered in those in whom transsphenoidal surgery and medical treatment are not feasible and the patient needs rapid resolution of the hypercortisolism [64]. It should be emphasized that after either pituitary or adrenal surgery, patients may develop adrenal insufficiency and replacement with glucocorticoid and mineralocorticoid (only after adrenal surgery) is required throughout pregnancy [70].

If patient is not eligible for or refuses surgery or has failure of surgery, then medical treatments can be considered for those with severe Cushing's disease in order to achieve improvement of symptoms, control of tumour, or complications and to improve fetal outcomes. Cabergoline, has been used in uncontrolled

Cushing's disease during pregnancy and appears to confer good control of the disease [71–73]. Although ketoconazole can inhibit steroidogenesis, the existing limited data from a few cases suggest that it is safe and not associated with congenital malformation, including sexual development [71, 74, 75]. Metyrapone crosses placenta and has the potential to affect fetal steroidogenesis [64]. Its use has been reported during the second and third trimesters in a patient with Cushing's syndrome and was not associated with fetal complications [74]. However, due to the accumulation of deoxycorticosterone caused by metyrapone, maternal hypertension and pre-eclampsia may be exacerbated [76]. Pasireotide is a newly approved somatostatin analogue by FDA to treat Cushing's disease [50, 77] but its use in during pregnancy has not been reported. Mifepristone has been used in treating refractory Cushing syndrome [78]. However, due to its antagonistic action on the progesterone receptor, it is an abortifacient.

Acromegaly and Pregnancy

Changes in GH, GH-Variant, and IGF-1 During Normal Pregnancy and Pregnancy Complicated by Acromegaly

Placenta-derived GH-variant starts to appear in maternal circulation around gestational weeks 15–17 and is released in a continuous and non-pulsatile manner. It increases throughout pregnancy and becomes the predominant circulating form of GH in the second half of pregnancy. The placental GH-variant is biologically active, stimulating IGF-1 production [79], and cross-reacts with pituitary GH in most assays. In contrast, pituitary GH declines to very low levels in the latter part of pregnancy presumably due to the negative feedback action of increasing levels of IGF-1 [76, 80].

Compared to the decline of pituitary GH in normal pregnancy, autonomous GH secretion from a pituitary adenoma in acromegaly is not suppressed by the rising IGF-1. Placental GH-variant secretion though is similar in both acromegalic and normal pregnancies. Therefore, pituitary GH and placental GH-variant are both present at high concentrations in maternal circulation in late gestation [76]. Interestingly, IGF-1 levels in acromegalic patients may decrease during early pregnancy, even in those without medical treatment [81]. This initial decrease in IGF-1 level is postulated to be caused by stimulation of GH-binding protein production and inhibition of GH signalling pathways by oestrogen [80].

Interaction Between Pregnancy and Acromegaly

Complications associated with acromegaly, including hypertension, hyperglycaemia, and cardiac disease, potentially could worsen during pregnancy [76, 81, 82]. These complications should be closely monitored during pregnancy but, in practice, such exacerbations are rarely seen [81, 82]. Tumour enlargement in patients with acromegaly is uncommon, with only 5 cases having been reported [20, 36, 83–85]. Most studies have shown both biochemical and clinical stability or even improvement in acromegaly during pregnancy [86, 87].

Diagnosis of Acromegaly During Pregnancy

Pregnancy-related changes in GH, GH-variants, and IGF-1 have made the diagnosis of acromegaly very challenging. First, there is steady increase in IGF-1 levels during the second half of normal pregnancies. Second, in patients with acromegaly, both pituitary GH and placental GH-variant are present at high concentrations, especially in late pregnancy. However, the commonly used GH assays do not distinguish between pituitary GH and the placental GH-variant. While GH-specific assays are available, these assays are not readily available. Lastly, both placental and pituitary GH forms have been shown to not be suppressed by oral glucose [80], so an oral glucose tolerance test should not be used to diagnose acromegaly in pregnancy. Therefore, some authors recommend waiting to diagnose acromegaly until after delivery, when the placental GH levels fall precipitously. Pituitary MRI is usually reserved for those with symptoms suggesting acute intracranial processes (e.g. concern for pituitary apoplexy or those with known acromegaly reporting severe headache and newly developed vision defects).

Management of Acromegaly During Pregnancy

Several management options exist for women with acromegaly during pregnancy: expectant approach, transsphenoidal surgery, and medical treatment including somatostatin analogues (SSAs), dopamine agonists and pegvisomant.

An expectant approach is appropriate for patients with mild disease, since spontaneous improvement of acromegaly has been reported during pregnancy [86, 87]. Close monitoring of potential complications from acromegaly, including hypertension, hyperglycaemia, pre-eclampsia and eclampsia, is warranted. In a retrospective, multi-centre study, most of the patients who were treated with dopamine agonists and/or SSA before conception and had medication withdrawal upon confirmation of pregnancy had uneventful pregnancies [81]. Close monitoring of visual fields is necessary for patients with known macroadenomas. In patients with suspected tumour enlargement causing a visual defect or severe headache, an MRI may be necessary to confirm whether an intervention is necessary.

In most patients, medical treatment should be stopped either before planned conception or immediately after confirming pregnancy [70, 88, 89], which is consistent with the Endocrine Society Guideline [90]. Fortunately, most acromegaly patients who had such drug withdrawal did well during pregnancy [81]. Therefore, medical treatment during pregnancy should be reserved for those with active acromegaly requiring treatment due to severe symptoms from large tumours (e.g. severe headache, vision defects, or tumour enlargement) [88]. It is important to note that SSAs, dopamine agonists and pegvisomant are not FDA approved to be used in pregnancy.

SSAs are effective in controlling both tumour growth and IGF-1 levels in non-pregnant acromegalic patients [90]. Since SSAs cross the placenta, potentially affecting fetal brain somatostatin receptors, and decrease uterine artery blood flow, their use during pregnancy is not recommended [91, 92]. However, retrospective studies and small case series have shown that SSAs are generally effective and safe during pregnancy [92, 93], though cases of small for gestational age [81] and shorter birth length [92] have been reported.

Dopamine agonists have been used in the treatment of pregnant women with acromegaly. In the reported case series, the use of dopamine agonists appears to be safe [80, 81, 91]. One retrospective study showed small for gestational age in women taking both SSAs and dopamine agonists. More safety data about the use of DA agonists during pregnancy are from large series involving the treatment of prolactinoma [1, 2] (see previous section).

Pegvisomant acts as a GH receptor antagonist [82, 94, 95] and has shown both efficacy and safety in controlling acromegalic symptoms and IGF-1 levels in non-pregnant patients. Use of pegvisomant during pregnancy was recently assessed in the largest reported case series of 35 pregnancies (27 maternal and 8 paternal exposure), including 3 cases in which pegvisomant was continued throughout pregnancy [95]. This small observational study demonstrated no apparent adverse effect of pegvisomant on pregnancy outcome. However, children with GH-insensitivity syndrome (Laron syndrome) due to GH receptor abnormalities have multiple abnormalities so pegvisomant use cannot be recommended during pregnancy [96].

Considering the prolonged nature of the course of most patients with acromegaly, interruption of medical therapy for 9–12 months should not have a particularly adverse effect on the long-term outcome. On the other hand, these drugs can control tumour growth and for enlarging tumours, their reintroduction during pregnancy may be warranted as a preferable management strategy to surgery. In patients with severe acromegalic symptoms not controlled by, or intolerant to, medical treatments, or with acute symptoms due to tumour enlargement (e.g. vision loss), or concern for pituitary apoplexy, emergent transsphenoidal surgery can be considered, preferably during the second trimester.

Functioning Gonadotropin-Secreting Adenoma in Pregnancy

Most gonadotroph tumours are clinically silent and present as non-functioning adenomas. Functioning gonadotropin-secreting pituitary adenomas are actually quite rare [97]. Due to oversecretion of bioactive gonadotropins, pre-menopausal women with functioning gonadotropin-secreting adenomas commonly have excessive production of oestrogen, leading to secondary amenorrhea, oligomenorrhea, galactorrhoea, infertility, and rarely ovarian hyperstimulation syndrome. In most of these patients, oestrogen levels are elevated, while FSH levels are either normal or mildly raised, and LH levels usually suppressed. In many cases of gonadotropin-secreting tumours, prolactin levels are elevated, likely due to stalk effect or stimulation by high oestrogen [97, 98].

Only two cases of functioning gonadotropin-secreting adenomas recognized during a possible pregnancy have been reported. In one case, the patient conceived naturally but developed ovarian hyperstimulation syndrome at gestation week 5 and had termination of pregnancy at the nineth week due to development of deep vein thrombosis [99, 100]. In another case, the patient presented with positive pregnancy tests and markedly enlarged ovaries. The pregnancy was terminated due to abnormal hCG levels and lack of an intrauterine pregnancy on ultrasound [101].

TSH-Secreting Adenoma in Pregnancy

TSH-secreting pituitary adenomas are rare and account for 0.5–3% of all pituitary adenomas [102, 103]. Clinically, they are characterized by hyperthyroidism with elevated levels of free T_4 and T_3, inappropriately normal or elevated level of TSH, and predominantly pituitary macroadenomas [102–104]. The majority of these tumours only secrete TSH, though 20–25% may cosecrete growth hormone or prolactin [105].

Menstrual irregularity, oligomenorrhea and amenorrhea often can be seen in women with TSH-secreting tumours, owing to the large size of most of the tumours and hyperprolactinemia as a result of stalk effect or cosecretion from the tumour [105]. However, spontaneous pregnancy has been reported in women with TSH-secreting tumour [106].

To the authors' knowledge, only 6 cases of TSH-secreting pituitary adenomas have been reported during pregnancy [106–111]. Pituitary macroadenomas were found in all but one case. In two cases, the macroadenomas were noted to have significant enlargement during pregnancy, which necessitated treatment [107, 108]. In these reported cases, treatment of TSH-secreting adenomas during pregnancy were targeted to the tumour (surgery, radiation, or octreotide) and/or the hyperthyroidism *per se* with thionamides.

Clinically Non-Functioning Pituitary Adenoma (CNFA) in Pregnancy

A CNFA, by definition, does not cause a clinical syndrome due to overproduction of a pituitary hormone. In the non-pregnant population, CNFAs represent about 30%-40% of all pituitary tumours [112, 113] and most stain positively for gonadotropins [113]. In a recent UK Surveillance study over a 3-year period of 71 pregnant women with pituitary tumours, CNFAs made up 23% of cases, whereas prolactinomas made up 69%, and acromegaly and Cushing's disease each comprised 4% [109].

Most CNFAs remain stable in size during pregnancy [76, 109, 112], especially those that were treated with surgery or radiotherapy before conception [109]. In another recent series of 8 cases, none had tumour enlargement during surgery [20]. However, in the UK Surveillance study, tumour enlargement was reported in one of seven non-functioning adenomas diagnosed before conception and in three of five non-functioning adenomas diagnosed in pregnancy [109]. Additionally, significant lactotroph hyperplasia during pregnancy may push the CNFAs up to impact the optic chiasm [114]. Pregnancy outcomes do not seem to be affected by CNFAs [109].

CNFAs usually do not need treatment during pregnancy. However, attention should be paid to symptoms suggestive of tumour enlargement, including severe headaches or vision defects. Pituitary apoplexy has been reported in CNFAs, especially macroadenomas [109].

Other Disorders of the Pituitary and Hypothalamus in Pregnancy

Paul V. Carroll, Niki Karavitaki, and Kirstie Lithgow

Introduction

Pregnancy results in significant alteration of pituitary anatomy and hormone physiology. Prolactin-producing lactotroph cells undergo progressive and significant hyperplasia throughout pregnancy contributing to increase in size of the anterior pituitary. Changes in pituitary hormone production, binding protein levels and target hormone action occur during pregnancy. As a result of these alterations, the assessment of pituitary status in the pregnant woman is complex and differs from the non-pregnant state. Disorders of hormone function may be well established prior to pregnancy or less frequently develop during pregnancy. These conditions may impact on maternal and fetal outcomes and influence pregnancy management. The physiology of pregnancy may also influence behaviour of endocrine conditions. Several disorders are specifically associated with pregnancy, lymphocytic hypophysitis, and Sheehan's syndrome being particular examples.

Pituitary Gland Anatomy and Imaging in Pregnancy

The anterior pituitary increases in size and volume during pregnancy. The upper contour typically becomes more convex in shape. Change in size develops in the first trimester and up to a doubling of size has been reported by the end of pregnancy [1]. Post-delivery normal size and configuration has been demonstrated at 6 months postpartum [2]. Magnetic resonance imaging (MRI) is considered safe during pregnancy but administration of IV enhancing-agents (e.g. gadolinium) should be avoided in most situations (see Chapter 9.10, 'Imaging of Endocrine Disorders in Pregnancy') [3].

Physiological Changes in the Anterior Pituitary Hormone Axes as a Result of Pregnancy

Prolactin levels increase early in pregnancy, and by term are 10-fold greater than in the non-pregnant state, in preparation for lactation [4]. LH and FSH are suppressed by the high levels of placental oestrogen and progesterone. Later in gestation oxytocin levels increase in preparation for labour and lactation [5].

Pregnancy results in increased hypothalamo–pituitary adrenal (HPA) axis activity characterized by increased production of cortisol, cortisol-binding-globulin (CBG), and urinary free cortisol secretion [6, 7]. Oestrogen produced by the placenta is responsible for the increase in CBG, resulting in a transient fall in free cortisol with a resultant rise in ACTH production. The placenta produces CRH and ACTH stimulating the maternal pituitary and adrenal glands. Free cortisol values rise throughout the trimesters reaching a plateau in the third trimester [8]. Similarly, the activity of the renin angiotensin aldosterone system is increased during the first trimester. Systemic vascular resistance falls and these changes result in volume expansion during pregnancy [9]. The circadian production of cortisol is maintained in healthy pregnancy [10–12]. Up to the 33rd week of gestation, 90–95% of fetal cortisol is derived from maternal adrenal secretion; thereafter, fetal adrenal cortisol production is more active. See **Figure 9.7.1**.

Placental growth hormone (GH) differs from pituitary GH by 13 amino acids and is manufactured and secreted by the synctiotrophoblastic epithelium of the placenta [13]. The regulation of placental GH secretion is not understood but this isoform increases throughout gestation [14, 15]. As a consequence, serum insulin-like growth factor 1 (IGF-1) levels increase in the second half of pregnancy [16], and via negative feedback, pituitary GH levels are reduced in later pregnancy and the early postpartum phase [14, 15].

There is a transient fall in TSH in the first trimester as a result of human chorionic gonadotropin (hCG) stimulation of the TSH

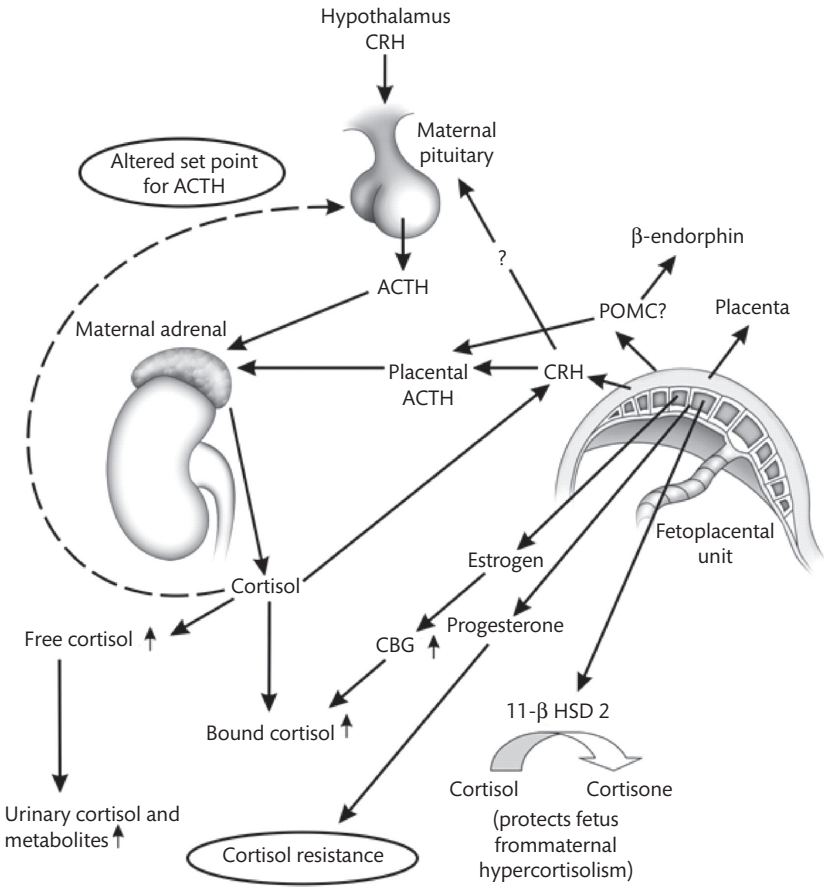

Figure 9.7.1 HPA axis during pregnancy. CRH stimulates ACTH secretion which results in adrenal cortisol production and secretion. Placental CRH stimulates fetoplacental ACTH which further increases cortisol production. Oestrogen increases CBG, with a rise in total cortisol. 11β-HSD 2 protects the fetus from maternal hypercortisolism.

receptor because of the structural homology between TSH and hCG molecules and their receptors [17]. The nadir level of TSH coincides with the peak in hCG [18]. There is a linear relationship between hCG and free T4 concentrations early in pregnancy [18]. For most women this stimulatory effect is transient and not clinically significant but in a significant number the TSH is suppressed at the end of the first trimester, especially in those with the highest hCG [19]. Multiple pregnancy results in higher hCG levels and more marked lowering of TSH [20]. The increase in oestrogens produced by the feto-placental unit stimulates hepatic production of thyroxine-binding globulin (TBG) and increases its sialylation thereby prolonging its half-life [21, 22]. This increase in TBG results in higher levels of total T_4 and T_3, starting at 4–6 weeks' gestation. Free thyroid hormone levels generally remain within the normal range throughout gestation, but pregnancy and trimester-specific references ranges have been developed [23]. A recent study described the methodology for validating local reference ranges for pregnancy [24].

Lymphocytic Hypophysitis

Lymphocytic hypophysitis (autoimmune hypophysitis) is a rare inflammatory/autoimmune disease that involves the pituitary gland and infundibulum resulting in enlargement of the gland and usually hypopituitarism [25]. The clinical features include headache, variable degrees of hormone insufficiency and in some cases diabetes insipidus. Mass effect with visual consequence may be also present. Both genders and all ages may be affected but the condition is classically identified during pregnancy or the early postpartum period [26]. The condition is more common in females. The diagnosis is confirmed histologically and the features include normal pituitary tissue with lymphocytic infiltration, plasma cells, histiocytes, and fibrosis [27]. Magnetic Resonance Imaging features indicative of lymphocytic hypophysitis include a symmetric enlargement of the pituitary gland, a thickened non-tapering pituitary stalk, and an intact sellar floor. There is prompt homogenous enhancement following gadolinium administration [28, 29]. Not all patients have histological diagnosis, as especially in the context of pregnancy a confident clinical diagnosis can be reached, facilitating clinical management. Treatment includes replacement of hormone deficiency (including ADH) and decision-making regarding conservative, medical, and surgical therapies. High-dose suppressive glucocorticoid remains the cornerstone of medical therapy but a variety of immunosuppressive treatments have been used. Surgery is indicated for non-responders, or if there is mass effect, headache, visual failure or when a tissue diagnosis is considered important. Radiotherapy may be useful when there is

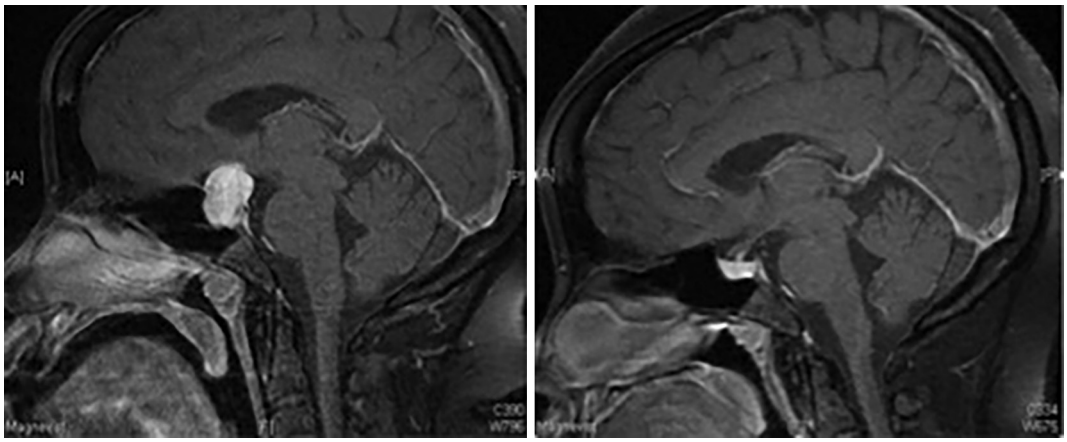

Figure 9.7.2 Sagittal MRI (T_1-weighted, post-contrast) demonstrating sellar and suprasellar enhancing mass, characteristic of lymphocytic hypophysitis in a woman presenting at 40 weeks gestation (left) and 3 months later after treatment with prednisolone 30 mg OD (right). Partial hypopituitarism (ACTH, GH and TSH deficiencies were permanent) but the patient went on to have a further spontaneous pregnancy with recurrence of hypophysitis requiring prednisolone.

relapse of disease and some patients require multimodal treatment [30, 31]. See Figure 9.7.2.

Lymphocytic hypophysitis is associated with other autoimmune disorders [32]. The pattern of involvement of the anterior pituitary, infundibulum and posterior pituitary determine the hormone deficits that are seen in this condition. Lymphocytic adenohypophysitis involves the anterior pituitary leading to loss of anterior pituitary hormone production and secretion. Lymphocytic neurohypophysitis has characteristic imaging findings and results in ADH deficiency with diabetes insipidus (DI). Panhypophysitis involves both anterior and posterior pituitary with panhypopituitarism and DI [33]. See Table 9.7.1.

In pregnancy associated lymphocytic hypophysitis, typically there is adenohypophysitis with characteristic presentation in the last month of pregnancy or within 2 months of delivery [34–36]. The fetus is unaffected by the process. It is not clear why pregnancy is associated with lymphocytic hypophysitis but a number of pathophysiological mechanisms have been proposed including; the physiological increase in size of the gland may result in increased pituitary antigenicity, there may be increased accessibility to immune reaction during pregnancy as a result of increased perfusion, alternatively placental tissue may invoke immune reactivity which cross reacts with pituitary antigenic targets [26, 28, 37, 38].

The pattern of pituitary hormone loss in lymphocytic hypophysitis differs from that seen in pituitary adenoma and other sellar/parasellar tumours. Often ACTH is the first hormone to become deficient and hyperprolactinaemia occurs in approximately 30% of non-pregnant cases [39, 40]. Hypoprolactinaemia with inability to lactate post-delivery is also seen. Lymphocytic hypophysitis may re-occur in subsequent pregnancies (either spontaneous or assisted conception [41]). See Figure 9.7.3.

Table 9.7.1 Classification of 379 patients with primary lymphocytic hypophysitis based on the anatomical location

	n	%
Lymphocytic adenohypophysitis	245	65
Lymphocytic infundibuloneurohypophysitis	39	10
Lymphocytic panhypophysitis	95	25

Management of Lymphocytic Hypophysitis

The treatment of lymphocytic hypophysitis involves initial resuscitation and supportive care with simultaneous replacement of hormone deficiency (especially hydrocortisone). Dopamine agonists can reduce elevated prolactin. High-dose glucocorticoids (typically prednisolone, by mouth or IV) are the mainstay of acute immunosuppressive treatment but there is no consensus on dose or duration. Surgery should be limited to those patients with deteriorating visual function, and /or lack of response to glucocorticoids [42, 43]. Patients are usually left with permanent hormone deficiencies, but

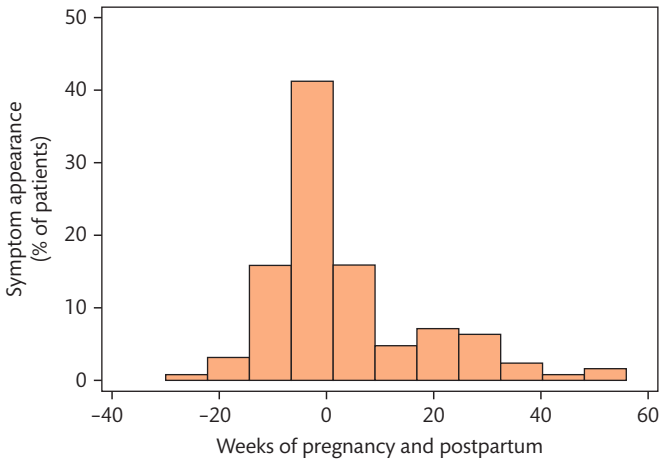

Figure 9.7.3 Typical timing of presentation/ diagnosis of lymphocytic hypophysitis in pregnancy.

follow-up evaluation of pituitary function is necessary as recovery occurs in some cases [44]. The long-term prognosis is good provided pituitary replacement is adequate.

Anterior Hypopituitarism in Pregnancy

Significant hypopituitarism with gonadotrophin deficiency results in infertility, and the majority of women with hypopituitarism in pregnancy have been identified and treated prior to conception. Rarely hypopituitarism develops during pregnancy or in the early postpartum period. Specific conditions resulting in loss of pituitary function include lymphocytic hypophysitis and postpartum pituitary necrosis, known as Sheehan's syndrome. This occurs as the anterior pituitary is vulnerable to abrupt hypotension due to the increased perfusion and expanded size seen in pregnancy. Sheehan's syndrome usually presents in the early postpartum period, as a result of volume loss due to postpartum haemorrhage (PPH, [45]). The patient may be acutely unwell with features of adrenal insufficiency or have a delayed presentation with fatigue, failure of lactation, and persistent amenorrhoea. Sheehan's syndrome is less common in developed countries where there is access to rapid and effective management of postpartum haemorrhage.

Whatever the aetiology of hypopituitarism, treatment with hormone replacement, should be continued or initiated in the pregnancy, depending on the hormone deficits. For most women this includes hydrocortisone and thyroxine. Internationally prednisolone and cortisone acetate are also used as replacement glucocorticoids. Most women with pre-existing hypopituitarism are also gonadotropin (follicle-stimulating hormone (FSH) and luteinizing hormone (LH)) deficient. Outside of assisted conception the majority of younger women receive oestrogen replacement, using oral or transdermal products. Most need assisted conception in the form of gonadotrophin injections, often with *in-vitro* fertilization. Therefore, if a woman with hypopituitarism wishes to conceive then she may require ovulation induction with gonadotropins, and successful pregnancies have been reported after both Sheehan's and lymphocytic hypophysitis [46].

It is thought that GH deficiency leads to difficulty with conception [47] and that GH administration increases effectiveness of gonadotrophins in ovulation induction [48]. The placenta synthesizes and secretes GH throughout pregnancy and in standard clinical practice GH replacement is discontinued once pregnancy is achieved [47].

Prior to the availability of glucocorticoid replacement therapy Addison's disease was associated with a high maternal mortality (~40%) and pregnancy was discouraged [49, 50]. Untreated adrenal insufficiency (AI) contributes to increased morbidity and mortality in pregnancy, [51]). Recognizing AI is not straightforward as the symptoms and signs (fatigue, nausea, reduction in serum sodium) are common in pregnancy. In general use of the synacthen (cosyntropin) test is avoided in pregnancy and most clinicians rely on measurement of early morning cortisol and ACTH to assess adrenal function. However, it can be used in the context of managing a woman with high index of suspicion for AI where the benefit of making a maternal diagnosis of this condition outweigh the theoretical risks of the test. Salivary cortisol may be a useful test in assessing the HPA axis [52]. The glucocorticoid requirement increases by the third trimester, typically with a 50% increase in dose. Parturition and labour should be covered with additional hydrocortisone in women with adrenal insufficiency (see Chapter 9.8, 'Adrenal Disease in Pregnancy' for precise details of recommended doses of glucocorticoid replacement) [53, 54]. The caesarean section rate is significantly higher in hypopituitary patients than in uncomplicated pregnancy. Exogenous glucocorticoid is excreted in breast milk, but at amounts that do not cause neonatal adrenal suppression [55].

Hypopituitary women usually have secondary hypothyroidism, characterized by low, or low 'normal' range serum TSH with low free thyroid hormones. The TSH level cannot be used to guide thyroxine dose adjustment and prior to conception most clinicians aim to maintain the serum free T_4 in the upper part of the reference range [56]. In early pregnancy the fetus is dependent on placental transfer of maternal thyroxine for neurodevelopment and often an early increase in thyroxine dose is required [57, 58].

Breastfeeding in the postpartum period depends to a great extent on the prolactin level of the mother. Although failure of milk production is a typical symptom of Sheehan's syndrome, hyperprolactinemia has also been reported in patients with hypopituitarism. Prolactin deficiency is common in hypopituitary patients and reflects the severity of hypopituitarism [59]. Deficiency of prolactin can lead to failure of lactation, alternatively hypersecretion can lead to galactorrhoea and nipple tenderness, neither of which is suitable for breastfeeding. Hypopituitary patients generally do not have sufficient milk production to breastfeed effectively.

Management of Pituitary Replacement in Pregnancy

The Endocrine Society has produced guidelines for the management of hypopituitarism and these include guidance on the management of hormone deficiencies in women with hypopituitarism [60]. The guidance recommends that hydrocortisone is the preferred glucocorticoid for use in pregnancy and that the dose required is individual. Higher doses than outside of pregnancy may be required, especially in the third trimester. The guidance recommends that close monitoring for clinical features of over- and under- replacement is performed. Dexamethasone is not inactivated by placental tissue action and is not recommended for routine use in pregnancy. Stress doses of hydrocortisone are recommended for labour/ delivery, similar to those used in major surgery (see Chapter 9.8). The Endocrine Society guidelines recommend that thyroid status is assessed 4–6 weekly when there is pituitary insufficiency with central hypothyroidism. Increased levothyroxine doses may be required to achieve target levels appropriate for pregnancy. The guidance recommends discontinuation of GH during pregnancy as there is a lack of information regarding efficacy and safety and the placenta produces GH throughout pregnancy [60].

Diabetes Insipidus in Pregnancy

Physiology of ADH Secretion and Action, Sodium Levels, and Resetting of the Osmostat in Pregnancy

Antidiuretic hormone (ADH, also known as vasopressin) is a nine amino acid peptide, secreted by the posterior pituitary and acting on the vasopressin (G protein-coupled) receptors. Release is regulated by hypothalamic osmoreceptors, arterial baroreceptors and renal blood supply [61, 62]. ADH stimulates V2 receptors resulting in insertion of aquaporin-2 in the cells of collecting ducts. This facilitates resorption of water and concentration of urine, maintaining electrolyte concentration and circulating volume [62]. Oxytocin and vasopressin are similar in structure and ADH can activate the oxytocin receptor [63].

During pregnancy there is a significant increase in circulating (plasma) volume with a decrease in plasma osmolality (approximately 10 mOsm/kg [64]). Total body water is increased by approximately 8 L in pregnancy, in part due to hormone mediated systemic circulation vasodilation [65]. The reduction in osmolality, and lower blood pressure result in a resetting of the osmostat and thirst perception, with desire to drink and secretion of vasopressin occurring at lower osmolality than occurs in the non-gravid state [65]. Changes in osmotic threshold occurs early (6–8 weeks gestation) and persists throughout the duration of pregnancy. Oxytocinase (cysteine aminopeptidase) is produced by the placenta and degrades vasopressin rendering it inactive [66]. Placental vasopressinase is most active from the middle of the second trimester to the end of pregnancy, normalizing quickly post-delivery [67]. ADH secretion therefore increases during pregnancy and by the third trimester there is a four-fold increase in ADH secretion. Vasopressinase is metabolically degraded by liver action and diseases that interfere with liver function result in increased vasopressinase and can contribute to DI or worsen symptoms in the patient with established DI [68, 69].

Diabetes Insipidus in the Pregnant Woman

The aetiology and incidence of diabetes insipidus (DI) in pregnancy are similar to those of the non-pregnant population. A number of pregnancy-specific conditions can result in transient DI; including pre-eclampsia, HELLP (haemolysis, elevated liver enzymes, and low platelets) syndrome and acute fatty liver of pregnancy (AFLP [69]). Gestational diabetes insipidus (GDI) is a pregnancy specific condition where metabolism of ADH by the placental enzyme vasopressinase results in reduced ADH action with polyuria. In this condition production of and sensitivity to ADH are unimpaired. Vasopressinase levels are usually even higher in multiple pregnancies [70]).

Established DI may become uncontrolled during pregnancy, due to physiological changes affecting vasopressin (anti-diuretic hormone (ADH)), including increased glomerular filtration rate, placental production of vasopressinase (responsible for ADH breakdown), and increased renal resistance to ADH [71]. Affected women present with worsening of previously controlled thirst and polyuria.

Outside of pregnancy the diagnosis of DI is usually confirmed by fluid deprivation testing, but clinicians typically avoid this test in pregnancy. Measurement of copeptin may become a further clinical tool to aid in the diagnosis [72]. Measurement of serum and urine osmolality and sodium is usually sufficient to allow sufficient judgement on the presence of DI and need for treatment.

Adequately treated DI should not have adverse effects on the pregnancy. Women diagnosed with diabetes insipidus should have regular consultant review in clinic with monitoring of serum electrolytes and hydration status. Antenatal anaesthetic review is important and labour should be managed on the delivery suite with adequately experienced obstetric and anaesthetic oversight. Conversely, if DI is undiagnosed or inadequately treated then there are the risks of severe dehydration and electrolyte disturbances, which may lead to maternal seizures or oligohydramnios [61].

Management of Diabetes Insipidus in Pregnancy

Desmopressin (DDAVP) is the most appropriate treatment of DI during pregnancy. DDAVP is a synthetic form of ADH with a different N-terminal that renders it less susceptible to degradation by vasopressinase [73, 74]. DDAVP can be administered orally, sublingually, intranasally or by subcutaneous, intramuscular, or intravenous injection. It is safe throughout pregnancy and breastfeeding, with no known adverse effects upon delivery of the neonate [75].

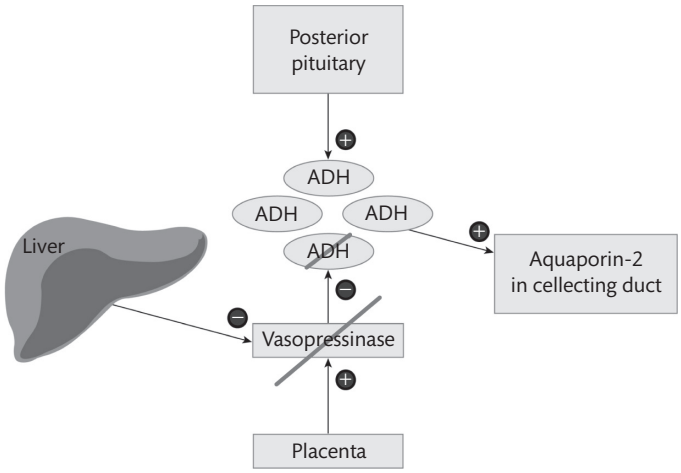

Figure 9.7.4 ADH physiology in normal pregnancy. In healthy pregnancy, the posterior pituitary produces ADH that acts to prevent the loss of water via aquaporins in the kidney. The placenta produces vasopressinase, which degrades ADH. In normal pregnancy, the liver degrades vasopressinase, and the posterior pituitary produces significant amounts of ADH, so that the effect of vasopressinase is not clinically significant. In conditions associated with liver dysfunction increased vasopressinase activity occurs, which can result in new-onset DI or an increased requirement for DDAVP.

Desmopressin has less affinity for the uterine oxytocin receptors then lysine or arginine-vasopressin [76]. As the circulation is expanded in pregnancy and the osmostat reset the desmopressin dose should be titrated to facilitate thirst management and maintain appropriate electrolyte levels. Desmopressin is not heavily metabolized by placental oxytocinase [77]. If desmopressin is being used care must be taken when IV fluid is administered as water intoxication can occur. In patients with new-onset DI the on-going need for desmopressin should be reviewed in the clinical context, and with appropriate investigations post-delivery. In general, the DDAVP requirement is unchanged during pregnancy, but a modest increase in dose may be required. If the dose of DDAVP is increased in pregnancy, it is usually possible to reduce back to the pre-pregnancy dose soon after delivery. DDAVP is safe for breastfeeding the newborn in lactating mothers [78]. See Figure 9.7.4.

Adrenal Disease in Pregnancy

David J. Torpy, Michael W. O'Reilly, and Sunita M.C. De Sousa

Introduction

Adrenal gland dysfunction in pregnancy is rare, but fetal and maternal complications are significantly increased, and prompt diagnosis and treatment are therefore critical to prevent morbidity and mortality. Adrenal disease may present for the first time during pregnancy, or may be diagnosed before conception and require careful monitoring and management throughout gestation [1]. Diagnosis of adrenal disorders during pregnancy is frequently confounded by physiological changes in maternal adrenal hormone metabolism as pregnancy progresses [2], which complicates interpretation of biochemical investigations. The hypothalamic–pituitary–adrenal (HPA) axis and renin-angiotensin-aldosterone system (RAAS) are significantly upregulated in pregnancy, although adrenomedullary function is not dramatically altered. Furthermore, dynamic endocrine testing is generally contraindicated in pregnancy. Symptoms of adrenal gland dysfunction may also mimic typical symptoms of pregnancy. The aim of this chapter is to review clinical aspects of the most common adrenal disorders in pregnancy, and to discuss approaches to diagnosis and management.

Addison's Disease—Primary Adrenal Insufficiency

Primary adrenal insufficiency (PAI) is glucocorticoid deficiency due to direct adrenal disease. Prevalence is 90–140 per million in Western countries. Predominant aetiologies are autoimmunity in adults and congenital adrenal hyperplasia in children; tuberculosis is important in prevalent areas [3–9]. Autoimmune PAI is associated with antibodies to the adrenal steroidogenic enzyme, 21-hydroxylase, and 50% of cases have autoimmune comorbidities [7]. Less frequent causes of PAI include adrenalectomy, adrenal haemorrhage, infiltration/infections, drugs, and genetic disorders. Characteristic presenting symptoms of adrenal insufficiency include fatigue, postural dizziness, nausea, abdominal pain, and weight loss, which may culminate in shock, known as an adrenal crisis [10]. Cortisol deficiency produces hypersecretion of ACTH/POMC peptides with consequent hyperpigmentation, and is often associated with deficient aldosterone which may cause hyperkalaemia and exacerbate hyponatraemia. Treatment, available since the 1950s, comprises glucocorticoid and mineralocorticoid (fludrocortisone) replacement. Fludrocortisone is monitored using electrolytes, BP, and plasma renin [11]. Glucocorticoid replacement is monitored clinically to avoid overdose (Cushing's syndrome) and underdosing (recrudescence of adrenal insufficiency). There has been a trend towards use of short-acting natural glucocorticoids in lower dose to avoid osteoporosis and cardiovascular effects, in the context of previous studies that overestimated natural cortisol (hydrocortisone) production rates [12–15]. Prognosis of PAI is generally good but all-cause mortality is slightly higher than the population; of that increase, adrenal crisis, which has an annual risk per PAI patient of approximately 8%, contributes to 15% of all deaths in autoimmune AI [3, 16–18], and 42% in CAH [19]. Despite standard hormone replacement, a substantial minority of PAI patients experience reduced quality of life, the basis of which is uncertain [20–22].

Untreated PAI may impair ovulation [23], folliculogenesis [24], and libido/sexual activity [25]. These factors together with the effects of associated autoimmunity, with or without ovarian immunological damage, result in reduced fecundity [23–25]. Untreated Addison's disease was previously associated with 35% maternal mortality, but fatalities are now rare [23]. Obstetric outcomes in treated PAI are now similar to normal pregnancies, apart from increased rates of preterm birth and Caesarean section [24, 25]. Speculatively, preterm birth may relate to disturbances of placental CRH secretion [25]. In a study of 517 women who gave birth after PAI diagnosis or within 3 years prior to diagnosis, maternal, and neonatal mortality, Apgar score and congenital malformation rates were similar to controls. Birth weight was also similar in women diagnosed with PAI prior to pregnancy but it was reduced in women

diagnosed after pregnancy, indicating that treatment mitigates the risk of hypocortisolism-induced low birth weight [25].

Pregnancy is a state of physiological hypercortisolism, with ACTH, total and free plasma cortisol, and corticosteroid-binding globulin (CBG), rising progressively during gestation, reaching 2- to 3-fold by parturition [26, 27]. Pregnant women with PAI should undergo endocrine review each trimester with titration of steroid hormone replacement [11]. Hydrocortisone is the preferred glucocorticoid because inactivation by placental 11β-hydroxysteroid dehydrogenase 2 (11βHSD2) protects the fetus from glucocorticoid excess, it has a shorter half-life allowing diurnal variation in dosing, and modification is not required for the drug to be active which may be important in adrenal crises [11, 24, 28]. Prednisolone, which has a longer plasma half-life than hydrocortisone (150 vs. 90 mins) is an acceptable alternative in pregnancy as it has comparable metabolism. Dexamethasone is avoided as it is not inactivated by 11βHSD2 and may have adverse fetal effects. As in non-pregnant individuals, glucocorticoid dose titration is individualized, based on avoidance of the clinical features of adrenal insufficiency or Cushing's. In pregnancy, this requires particular judgment as features of pregnancy such as postural hypotension and fatigue, or striae, oedema, and hyperglycaemia, may suggest under- or over-replacement, respectively. As a rule of thumb, the consensus-based increment of glucocorticoid is a 20–40% increase in total daily dose, roughly equating to 5–10 mg hydrocortisone, from 24 weeks onwards [11, 24]. Pregnancy is a state of secondary hyperaldosteronism. Elevated renin and aldosterone levels are seen in normal pregnancy; hence, renin cannot be used in dose titration, but urinary sodium and potassium levels may be informative. Generally, fludrocortisone dose does not need to be altered in pregnancy [11].

Labour or Caesarean section is a physiological stressor and glucocorticoid dosing should be increased as per major surgery guidelines and the NIHR guideline on the management of medical disorders in labour (https://www.nice.org.uk/guidance/ng121), incorporating a 100 mg IV hydrocortisone injection followed by 200 mg/24 h (50 mg q6hr or infusion 8.3 mg/h) for 24 hours, then double usual dose for 48 hours, then return to usual dose [11]. 'Sick day' management should be refreshed in pregnancy, incorporating increased glucocorticoid dose with fever (2-fold if temp >38°C, 3-fold if >39°C) for 2–3 days until recovery, use of home parenteral hydrocortisone IM/SC 100 mg when oral medication is not possible, a Medic Alert® bracelet, and a card/letter informing healthcare providers of the need to administer hydrocortisone with illness [11].

Adrenal crisis treatment in pregnancy does not differ from usual measures, but shock has fetal risks, which may be greater early in the first trimester when the fetal HPA axis is not yet producing substantial quantities of cortisol. A reliable treatment protocol follows: hydrocortisone 100 mg IV stat followed by up to 200 mg/24 hours by continuous infusion or IV/IM 50 mg boluses q6 hr, tapering rapidly depending on patient response with BP and symptoms followed closely. Intravenous glucose may be needed in rare cases with concomitant hypoglycaemia. Transfer to oral hydrocortisone within 24 hours is advisable unless there is an ongoing underlying inflammatory precipitant. Intravenous fluids, generally normal saline, are given: 1000 ml within the first hour, with further crystalloid fluid being administered according to standard resuscitation guidelines, taking into account the patient's circulatory status, body size, and relevant comorbidities. Treatment of the precipitating cause is essential [11].

PAI is rarely diagnosed in pregnancy. If suspected, blood should be drawn for simultaneous cortisol and ACTH measurements and the woman empirically treated with physiological or stress dose steroids, depending on clinical severity [11]. If the woman is haemodynamically stable, basal morning cortisol and ACTH should be measured, followed by a 250 mcg short synacthen (cosyntropin) test if results are equivocal [11, 28]. Because of total cortisol excess due to CBG and free cortisol excess due to placental CRH and ACTH, higher cut-off levels are required to diagnose PAI in pregnancy with basal plasma cortisol cut-offs of <300, <450, and <600 nmol/L in the first, second, and third trimesters, respectively [24, 27]. Normal pregnancy is associated with progressively rising ACTH [27]; however, plasma ACTH greater than 2-fold normal at any gestation is consistent with PAI [24, 28]. ACTH samples should be sent on ice and repeat measurement reduces the impact of physiological fluctuations [28]. Post-cosyntropin cortisol cut-offs of 700, 800 and 900 nmol/L should be used in the first, second and third trimesters, respectively, rather than typical non-pregnant thresholds around 500 nmol/L [24]. A single dose of cosyntropin appears to be safe in pregnancy [24]. Aldosterone and renin values need to be interpreted with caution, as they are elevated in normal pregnancy and reference ranges have not been established [28]. Women diagnosed with PAI should be screened for relevant autoimmune comorbidities, noting that untreated hypocortisolism may transiently increase TSH and that thyroxine commencement may precipitate an adrenal crisis due to increased cortisol clearance [23, 24].

Other Causes of Hypoadrenalism

Secondary hypoadrenalism (SAI) is 2-fold more common than PAI, but perhaps not in women in their childbearing years. SAI refers to hypocortisolism due to ACTH deficiency from a wide range of pituitary/hypothalamic disorders, most often pituitary adenomas and their treatment with surgery/radiotherapy, craniopharyngiomas, granulomatous/infiltrative disorders, autoimmunity (which may cause isolated ACTH deficiency) and mutations of pituitary developmental genes [29]. In contrast to PAI: SAI does not result in mineralocorticoid deficiency hence fludrocortisone treatment is not required; there is no ACTH/POMC hypersecretion so hyperpigmentation does not develop; and other pituitary hormones, particularly TSH, gonadotropins and growth hormone may necessitate hormonal replacement. Generally, SAI has a lower risk of adrenal crisis than PAI, although the quantitative risk of adrenal crisis specifically in pregnancy is not well described.

Glucocorticoid-induced adrenal insufficiency (GC-AI) refers to the prolonged ACTH deficiency and adrenal atrophy that follows long-term supraphysiological glucocorticoid therapy [30]. The risk of adrenal crisis among these patients appears to be very low, reflecting often incomplete cortisol suppression [30]. Use of systemic glucocorticoids (oral, inhaled) for inflammatory disorders is frequent (3% population), making GC-AI common, although data in pregnancy are limited. In potential GC-AI, the measurement of morning cortisol, taking into account the effect of pregnancy on cortisol and CBG, may often be reassuring about the presence of endogenous cortisol, perhaps assisted by placental CRH acting on the

pituitary as well as putative placental ACTH [31]. The ongoing use of systemic glucocorticoids is guided by the activity of the underlying inflammatory disease, which often improves in pregnancy.

Phaeochromocytoma

Phaeochromocytomas are catecholamine-producing tumours which originate histologically from chromaffin cells of the adrenal medulla. Extra-adrenal catecholamine-producing lesions typically originate from the sympathetic paravertebral ganglia, and are termed paragangliomas. Collectively, phaeochromocytomas and paragangliomas are referred to as PPGLs [32]. Phaeochromocytomas have an incidence of 2–8 million/year in the background population. In pregnancy, phaeochromocytoma has been estimated to occur in approximately one in 54 000 pregnancies [33]. Hereditary PPGLs are observed in up to 40% of cases, with up to 15 well-recognized PPGL driver genes and 12–15 genetic syndromes. Although rare, expedient diagnosis of an underlying phaeochromocytoma in a pregnant woman is critical, as maternal and fetal mortality may be as high as 50% in untreated cases [34]. Maternal mortality improved from 48% before 1969 to 4% in the 1990s; fetal outcomes remain poor, despite significant advances in diagnosis and treatment [35].

Physiological Changes in Adrenomedullary Function in Pregnancy

Active catecholamines such as adrenaline and noradrenaline play a major role in cardiovascular homeostasis, and are a reflection of global sympathetic and adrenal-medullary function. Pregnancy is not associated with dramatic alterations in catecholamine metabolism. In healthy pregnant women, plasma and urinary catecholamine levels approximate those of non-pregnant women [36]. The placenta is also an effective barrier to maternal catecholamines [37]. The placenta expresses the catecholamine-metabolizing enzymes catechol-O-methyltransferase (COMT) and monoamine oxidase. Intriguingly, maternal COMT deficiency is associated with pre-eclampsia (PE), and levels of COMT are significantly lower in women with severe PE variants [38]. This may be due to catecholamine-induced vasoconstriction in the uteroplacental circulation.

Clinical Manifestations and Associated Risks of Phaeochromocytoma in Pregnancy

Clinical signs and symptoms of phaeochromocytoma are driven by paroxysms of tumoral catecholamine production, and include headaches, hypertension, sweating, and palpitations. One small study has suggested that the prevalence of classic symptoms in pregnancy is lower than in non-pregnant patients [35]. However, as pregnancy progresses the incidence of symptoms increases; in a series of 35 pregnant women with phaeochromocytoma, 66% reported symptoms in the third trimester, compared to 11% and 20% in the first and second trimester, respectively [39]. Alongside tumour expansion, catecholamine surges may be driven by uterine growth, fetal movement and abdominal palpation as pregnancy progresses. In undiagnosed women, differentiating signs of catecholamine excess from PE and pregnancy-induced hypertension (PIH) may pose a challenge, resulting in a delayed diagnosis. Onset of hypertension before 20 weeks' gestation is not consistent with PE or PIH. A number of genetic susceptibility syndromes associated with significant familial risk of PPGL have been identified. These include multiple endocrine neoplasia type 2 (MEN2) and neurofibromatosis type 1 (NF1); also, mutations in mitochondrial succinate dehydrogenase (SDH) genes (A, B, D, and AF2), which encode subunits of the mitochondrial succinate dehydrogenase complex, confer a significant lifetime risk of PPGL. Evidence to support a structured surveillance strategy in pregnant mutation carriers is lacking, but clinical intuition would suggest close clinical and biochemical monitoring is warranted.

Adverse fetal and maternal outcomes in pregnant women with phaeochromocytoma are mediated by excessive tumoral catecholamine adrenoceptor stimulation. Similar to non-pregnant patients, cardiovascular complications in pregnant women include hypertensive crises, tachyarrhythmias, and left ventricular failure due to catecholamine-induced cardiomyopathy. The maternal mortality rate in undiagnosed or untreated phaeochromocytoma in pregnancy is as high as 50% in historical cases, with the greatest risk in the peripartum period [34]. Early antepartum diagnosis, with appropriate α-adrenoceptor blockade, has resulted in significantly improved maternal outcomes in the last 50 years. Fetal mortality remains high, even in the context of appropriate alpha blockade and specialist management.

Diagnosis

Phaeochromocytoma should be considered in pregnancy in the context of classic signs and symptoms of catecholamine excess. Biochemical testing for catecholamine excess should involve measurement of plasma metanephrines and normetanephrines, which are O-methylated metabolites of adrenaline and noradrenaline, respectively; these have the highest sensitivity (95–100%) and therefore best negative predictive value for diagnosis of phaeochromocytoma [40]. Urinary fractionated metanephrines are also highly sensitive. Specificity for both tests ranges between 85% and 90%; false positive results may be observed in the context of medications such as sympathomimetics, paracetamol, selective serotonin reuptake inhibitors, and methyldopa.

In pregnant women, due to concerns around radiation exposure, the radiological investigation of choice for tumour localization should be T_2-weighted magnetic resonance imaging (MRI) with gadolinium enhancement. Ultrasonography may be useful for localization of larger tumours, but has poor sensitivity for small lesions. Scintigraphy with ^{123}I-metaiodobenzylguanidine (MIBG) is contraindicated in pregnancy [41].

Management

Pharmacological α-adrenoceptor blockade is the cornerstone of preoperative phaeochromocytoma management in pregnant and non-pregnant patients, and is associated with significant reductions in fetal and maternal mortality compared to untreated patients [42]. There are no studies in pregnant women that can help to inform on the optimal duration of α-blockade before surgery. Endocrine Society guidelines recommend treatment for a minimum of 10 days before surgery in non-pregnant patients [43]. Preoperative α-blockade with either phenoxybenzamine or doxazosin appears safe in pregnancy. Phenoxybenzamine can cross the placenta, and therefore poses a theoretical risk to fetal cardiovascular stability [44]. Phenoxybenzamine is a non-competitive α_1- and α_2-adrenoceptor antagonist, with a starting

dose of 10 mg twice daily, increasing upwards to 1 mg/kg/day until blood pressure is controlled. There are no studies that inform on the optimal blood pressure target in either pregnant or non-pregnant patients. Phenoxybenzamine has a long duration of action due to the formation of a permanent covalent bond with α-adrenoceptors, which increases the likelihood of significant intra- or postoperative hypotension after tumour removal. Doxazosin is a selective α_1-adrenoceptor antagonist with a significantly shorter half-life, which results in significantly less reflex tachycardia and a shorter duration of postoperative hypotension. There are no head-to-head randomized studies comparing the efficacy of phenoxybenzamine with doxazosin in either pregnant or non-pregnant patients.

ß-blockade is contraindicated in the absence of haemodynamically effective α_1-receptor antagonism. This is due to the theoretical risk of unopposed α-adrenoceptor stimulation and consequent hypertensive crisis induced by tumoral catecholamines after ß-adrenoceptor blockade. Where appropriate, and in the context of pretreatment with α-blockade, ß-blockers are effective for treatment of catecholamine-induced arrhythmias and reflex tachycardia. Propranolol and the combined α- and ß-blocker labetalol may be used safely in pregnancy. For emergency perioperative management in untreated pregnant and non-pregnant patients with phaeochromocytoma, intravenous phenoxybenzamine, or phentolamine may be used.

Surgical resection is the only definitive treatment for phaeochromocytoma. The optimal timing of adrenalectomy in a patient diagnosed during pregnancy is the second trimester, before 24 weeks [35]; this reduces the risk of miscarriage associated with abdominal surgery in the first trimester, and avoids the anatomical complications associated with an enlarged uterus in the third trimester. In tumours diagnosed after 24 weeks, surgery should be delayed until after pregnancy where possible, and a prolonged period of treatment with α-blockade can be safely instituted until the fetus is viable. Laparoscopic surgery in a centre of expertise should be the gold standard intervention, although open surgery may be required in larger tumours. Elective caesarean section should be offered as the preferred mode of delivery in patients who have not undergone adrenalectomy. Although large data are lacking, a number of small previous studies identified increased maternal mortality with vaginal delivery [34]. Labour itself may result in significant catecholamine excursion due to pain and uterine contractions, and should be avoided in patients with tumours in situ.

Primary Aldosteronism

Fewer than 50 cases of primary aldosteronism (PA) in pregnancy have been reported in the literature since the 1960s [45]. While hypertension affects 6–8% of pregnant women, and the prevalence of PA in young hypertensive patients is estimated at up to 10%, published data do not currently support the inference that 0.6–0.8% of all pregnant women harbour an underlying diagnosis of PA. However, the likelihood is that a large proportion of cases of PA remain undiagnosed prior to and during pregnancy. The majority of published cases of PA in pregnancy are due to unilateral aldosterone-producing adenomas (APAs, or Conn's syndrome) rather than idiopathic bilateral adrenal hyperplasia, but prevalence data in large cohorts are lacking [46]. Furthermore, 65 pregnancies have been reported in women with familial hyperaldosteronism type 1 [47].

Patient cohorts with glucocorticoid-remediable aldosteronism (GRA) have provided further insights into the consequences of PA in pregnancy. In this condition, fusion of the 5' regulatory region of adrenal CYP11B1, which is a critical regulator of glucocorticoid production, with the coding region of CYP11B2 (aldosterone synthase) results in expression and activity of the latter falling under the control of pituitary adrenocorticotropic hormone (ACTH). The consequence is a subtype of PA with hypokalaemic hypertension, which is treatable with low-dose dexamethasone. In a case series of 29 pregnancies in a total of 8 women with GRA, one study observed deterioration of hypertension in 39%, with 23% requiring the addition of antihypertensive medication in tandem with conventional dexamethasone treatment [48].

Diagnosis

The renin-angiotensin-aldosterone system (RAAS) is upregulated in pregnancy. Plasma renin levels increase significantly from the first trimester onwards, due to direct extra-renal oestrogen-stimulated renin secretion in the ovaries and decidua. Plasma aldosterone levels are increased 3–8-fold during gestation, which is largely a compensatory response due to competitive inhibition of the mineralocorticoid receptor (MR) by progesterone in the renal tubular apparatus. Hepatic angiotensinogen production is also increased in pregnancy, resulting in elevations of both angiotensin II and aldosterone. These physiological biochemical changes mean that securing the diagnosis of PA in pregnancy is challenging.

PA in pregnancy should be considered in women with onset of hypertension before the 20th gestational week. Intuitively, the coexistence of hypokalaemia in pregnancy may increase the pretest probability of PA. A gestational biochemical diagnosis of PA is dependent on the presence of a low or suppressed plasma renin on repeated samples, as this should be physiologically elevated in healthy pregnant women. The aldosterone-to-renin ratio (ARR) should be theoretically normal or low in normal pregnancy, and elevated in those women with PA. However, caution must be exercised interpreting the ARR, and this parameter must be assessed in tandem with a suppressed renin. Although the Endocrine Society advises confirmatory testing in non-pregnant patients with saline suppression testing or a captopril challenge [49], these investigations are relatively contraindicated in pregnancy due to concerns about plasma expansion and teratogenicity, respectively. Imaging strategies for lateralization are limited to MRI or ultrasonography due to the risk of excessive radiation exposure with CT. Excessive radiation exposure associated with adrenal vein sampling (AVS), which is the gold standard technique for lateralization in non-pregnant patients, means that this technique is contraindicated in pregnancy. However, on the proviso that blood pressure is optimized and serum potassium levels are stable, investigations to lateralize a source of aldosterone hypersecretion, and, where appropriate, adrenalectomy *per se*, can often be deferred until after delivery.

Treatment

Therapeutic management of PA in pregnancy applies to women with a new diagnosis of PA during their pregnancy, as well as to

those with a pre-existing diagnosis who have either not had an adrenalectomy for unilateral disease, or who are medically treated for bilateral disease. In the majority of situations, intensive blood pressure control and tailored oral potassium replacement are the cornerstone of treatment for PA in pregnancy. MR antagonists are the drugs of choice for medical management of non-pregnant patients with PA. However, spironolactone has significant antiandrogenic effects, and is classified as FDA pregnancy category C. Spironolactone crosses the placenta [50], and therefore is not recommended for use in pregnancy due to concerns about undervirilization of the male fetus. Data to support this are not entirely consistent. Feminization of male fetuses has been reported in studies of female rats treated with high doses of spironolactone [51], but this has not been replicated in mice or rabbits. In humans, spironolactone therapy at doses below 400 mg/day did not result in male fetus feminization in six pregnancies from three patients with Bartter syndrome, or in two pregnancies from two patients with Gitelman syndrome. However, there is currently insufficient data to support safe use of spironolactone in pregnancy. Eplerenone does not have antiandrogenic action, and is entirely selective for the MR. It is classified as pregnancy category B by the FDA, but once again controlled safety studies in humans are lacking.

In women with a pre-existing diagnosis of PA, pregnancy should ideally not be contemplated until lateralization has been assessed by AVS. Those with unilateral disease should undergo adrenalectomy before conception in order to normalize blood pressure and reduce fetal and maternal risks. Women with bilateral adrenal hyperplasia should have optimization of their blood pressure before trying to conceive, at which point substitution of MR antagonists with antihypertensives known to be safe during pregnancy can be considered after discussion with the patient [45]. In those with poorly controlled hypertension or resistant hypokalaemia, conception should be discouraged until optimization has been achieved. Where this is not possible, or where the patient is unwilling to wait to conceive, complete discontinuation of MR antagonists is not advisable; eplerenone should be substituted for spironolactone. Similarly, eplerenone can be considered for use in pregnant women with pre-existing PA, or in women with a new pregnancy diagnosis of PA, if blood pressure cannot be controlled with conventional antihypertensive medications known to be safe in pregnancy, or if normokalaemia cannot be maintained. Laparoscopic adrenalectomy in the second trimester for patients with unilateral disease is a feasible option for patients with refractory hypertension and hypokalaemia [52]. A number of cases of laparoscopic adrenalectomy between 14- and 24-weeks' gestation for unilateral aldosterone-producing adenoma have been reported in the literature, with adverse fetal outcomes reported in four out of nine cases [46].

Adrenal Cushing's Syndrome

Cushing's syndrome has a predilection for women of childbearing age; however, it is a rare disorder and fertility is often impaired by hypercortisolism-induced hypogonadotropic hypogonadism and impaired folliculogenesis [28]. As of 2017, 263 pregnancies had been reported in 220 women with active or cured Cushing's syndrome [53]. Maternal complications from retrospective data include hypertension (41–68%), dysglycaemia (25–37%), pre-eclampsia (14–26%), osteoporosis (5%), psychiatric illness (4%), cardiac failure (3%), wound infection (2%), and maternal death (1–2%). Fetal complications include prematurity (43–66%), intrauterine growth restriction (15–21%), miscarriage/stillbirth (11–24%), and fetal mortality (up to 20%) [28, 31, 53]. Neonatal complications include hypoglycaemia, respiratory distress, jaundice, sepsis, intraventricular haemorrhage, and congenital malformations including cleft lip [31, 53]. It may be that milder degrees of hypercortisolism are less harmful to the fetus than expected due to placental 11βHSD2 inactivation of cortisol, perhaps explaining the low rates of hypocortisolism in neonates [28]. Long-term health outcomes in infants born to mothers with Cushing's syndrome are unclear [54]. Onset in pregnancy predicts worse outcomes [53], possibly because women with Cushing's syndrome prior to pregnancy have milder hypercortisolism that permits ovulation.

Cushing's syndrome in pregnancy has several features of special note. Firstly, clinical diagnosis of hypercortisolism is fraught due to pregnancy effects such as centripetal weight gain, striae, oedema, and fatigue as well as pregnancy complications such as diabetes mellitus and hypertension [20, 28]. Catabolic features of Cushing's such as proximal myopathy and fractures, often involving the feet, are more discriminatory [20]. Secondly, biochemical diagnosis of Cushing's must take into account the hypercortisolism of pregnancy [27]. Thirdly, approximately 50% of Cushing's in pregnancy is of primary adrenal cause, usually an adrenal adenoma, compared to 15% of non-pregnant cases and the attendant low ACTH levels are usually absent in pregnancy. Finally, treatment must take into account the special risks of surgery and medications in pregnancy [28].

Aetiologically, Cushing's in pregnancy is most commonly due to an adrenal (40–60%) or pituitary adenoma (33%). Rare causes include adrenocortical carcinoma where there may be evidence of prominent bi- or multihormonal adrenal hormone secretion as well as characteristic findings on imaging and perhaps worse prognosis than in non-pregnant individuals [54]. Bilateral macronodular adrenal hyperplasia is an exceptional cause of adrenal Cushing's in pregnancy as it may very rarely arise due to LH/HCG-stimulation of presumed aberrant receptors that may also be activated postmenopausally [53]. Ectopic ACTH secretion from neuroendocrine tumours is exceedingly rare as the hypercortisolism is often severe, inhibiting pregnancy.

Pregnancy-induced alterations in the HPA axis include increased CBG due to placental oestradiol, in turn elevating plasma total cortisol [54]. By mass spectrometry, plasma total cortisol rises 1.6-, 2.4- and 2.9-fold above non-pregnant controls during the first, second and third trimesters, respectively, commensurate with rising CBG [27]. Later in pregnancy, free cortisol rises due to placental CRH and ACTH [27, 28]. There is evidence suggesting that placental CRH and ACTH are stimulated by cortisol, resulting in a positive feedback loop, and the maternal adrenals have heightened sensitivity to ACTH [27, 28]. Compared to controls, 24-hour urinary free cortisol excretion is 1.7-, 2.4- and 3.1-fold higher during the first, second and third trimesters, respectively [27].

To avoid false-positive results for Cushing's syndrome due to increased CBG, HPA activation, and blunting of normal feedback loops and diurnal variation, urinary free cortisol and late-night salivary cortisol should be interpreted with trimester-specific

normative data [28, 55]. The primary screening test for Cushing's syndrome in pregnancy is urinary free cortisol [27]. Normative data should be derived from the same platform as urinary results by immunoassay are 50–100% higher than mass spectrometry due to cortisol metabolite cross-reactivity [27]. Though urinary free cortisol may overlap between pregnant women with and without Cushing's syndrome, the mean elevation in urinary free cortisol in affected women is higher, at 8-fold normal [31]. Diurnal variation persists in normal pregnancies, albeit with a higher nadir, but it is abolished in pregnancies complicated by Cushing's syndrome, making late night salivary cortisol an adjunct test [31]. Though late night salivary cortisol is highly assay dependent and there was previously insufficient evidence to guide decision-making thresholds [55], recent data suggest late night salivary cortisol normal ranges of <6.9 nmol/L, <7.2 nmol/L and <9.1 nmol/L in the first, second and third trimesters, respectively, to be 80–92% specific for Cushing's syndrome [56]. Dexamethasone suppression of cortisol secretion is blunted in pregnancy with post-DEX cortisol levels >50 nmol/L in over 60% of healthy pregnant women [54], hence the low-dose test is not useful for Cushing's diagnosis in pregnancy [31]. Moreover, this test usually relies on plasma total cortisol, which is misleadingly elevated by CBG in pregnancy [31].

Upon biochemical confirmation of hypercortisolism, plasma ACTH should be measured, noting that the physiological ACTH elevation of pregnancy may hinder identification of ACTH independence with non-suppressed ACTH levels in 50% of pregnant women with adrenal Cushing's [31]. Whilst the high-dose dexamethasone suppression test is typically used to distinguish pituitary versus ectopic causes of ACTH-dependent Cushing's syndrome, it may be used in pregnancy to differentiate adrenal from pituitary Cushing's as pregnant women with Cushing's disease typically suppress whereas pregnant women with ACTH-independent Cushing's syndrome typically show <80% cortisol suppression [31]. Hypercortisolaemic women with low or normal plasma ACTH, and non-suppressible cortisol following high-dose dexamethasone, should be investigated for adrenal Cushing's syndrome [31]. Adrenal ultrasound is safe but only 73% sensitive for adrenal lesions and non-contrast MRI may be required [31]. MRI appears safe in pregnancy but because of potential teratogenicity its timing should be considered [28]. Gadolinium is avoided as it crosses the placenta and pregnancy safety data are limited [31]. Pregnancy-related adrenal hypertrophy and background rates of adrenal incidentalomas should be taken into account [20]. Pregnant women with Cushing's syndrome and high plasma ACTH should be further investigated for ACTH-dependent causes [31], as discussed in other chapters.

Pregnant women with Cushing's syndrome may be treated medically or surgically, or conservatively managed with treatment of complications such as diabetes and hypertension [20]. There are no prospective studies to guide management but there are trends towards higher live birth rates following cortisol-lowering treatment compared to conservative management [31, 53]. Women with relatively mild hypercortisolism in late gestation may nonetheless be better suited to conservative management [54]. Surgery is preferred to medical therapy in women with an identifiable, irreversible and resectable cause of Cushing's syndrome who are in their second trimester of pregnancy, when maternal and fetal surgical complication rates are lower [20, 31]. Unilateral or bilateral adrenalectomy for adrenal Cushing's yields high cure rates and live birth rates of 87% [31]. Though some data show excess prematurity rates after third trimester surgery, laparoscopic adrenalectomy has been performed successfully and safely up to 32 weeks with no change in rates of prematurity or intrauterine growth restriction [54]. In the limited data on adrenocortical carcinoma in pregnancy, resection is often incomplete and surgical risks are greater [54]. Anaesthetic risks pertaining to pregnancy include aspiration pneumonitis due to decreased lower oesophageal sphincter activity and increased intra-abdominal pressure from the gravid uterus, and challenging airway management because of oropharyngeal oedema. No medication has been approved for the treatment of Cushing's syndrome in pregnancy [55], but several agents have been utilized. Metyrapone use in pregnancy is well described in case reports and series; it is often well tolerated and effective [53, 57]. However, metyrapone risks hypertension and pre-eclampsia due to accumulating 11-deoxycorticosterone with mineralocorticoid effects [31]. Metyrapone also can be transferred across the placenta and fetal hypocortisolism has been reported [28, 54]. Ketoconazole crosses the placenta and is teratogenic and abortifacient in rat studies but it has occasionally been used in pregnancy without adverse events [31, 54]. In addition, ketoconazole has the potential to feminize the male fetus due to inhibition of the adrenal 17,20 lyase enzyme [20, 28]. Cabergoline has been used in pregnancy to treat Cushing's disease [20]. Contraindicated approaches in pregnancy include radiotherapy and mitotane due to teratogenicity, and mifepristone as it is a direct abortifacient from progesterone receptor antagonism [20]. Spontaneous remission of Cushing's syndrome has been reported in pregnancy [31]. Remission of Cushing's syndrome is associated with trends towards improved obstetric outcomes with reduced fetal loss, preterm birth, and low birth weight [53]. Remission may lead to hypocortisolism, requiring hydrocortisone and sometimes fludrocortisone therapy with adjustments during pregnancy [54].

Congenital Adrenal Hyperplasia

More than 95% of congenital adrenal hyperplasia (CAH) is due to 21-hydroxylase deficiency, thus studies in pregnancy focus on this aetiology [58]. 21-hydroxylase deficiency is due to mutations of both *CYP21A2* alleles. Such mutations are common (1–10% population, with ethnic variation), but CAH incidence is approximately 1/10 000 births [59]. Genotype/phenotype variation relates, to an extent, to the more functional *CYP21A2* allele [59]. The phenotype involves: PAI due to impaired cortisol and aldosterone synthesis; hyperandrogenism due to accumulation of androstenedione, then converted by 17-ketosteroid reductase to testosterone (or via direct multistep conversion of 17OH progesterone to testosterone), leading to masculinization of the female infant genitalia (commonly clitoromegaly, labial fusion), then later hirsutism and in severe cases virilism; precocious puberty; adrenal enlargement and hyperpigmentation from excess ACTH; and ultimately short stature in males. Classical CAH (childhood features) can be categorized into simple (isolated) virilizing (25%) and more severe salt-wasting (75%) forms. Females may be detected at birth from genital inspection but males may not present for several days until an adrenal crisis develops, which may be fatal. Treatment involves glucocorticoid and mineralocorticoid

replacement, with careful dosing and timing to reduce ACTH and therefore adrenal androgen production. Non-classical CAH refers to adult-onset disease, generally milder than classical CAH, where a decision to pursue adrenal replacement/glucocorticoid suppression treatment should take into account the individualized risk and benefits.

Women with CAH face potential challenges in reproduction [60, 61]. Lower fecundity in CAH may result from a range of reasons including: possible androgenization of the brain affecting psychosexual development with reduced partnering; difficulties or perceived limitations arising from vulvovaginal function despite surgery, usually performed in childhood; anovulation due to androgen excess or exogenous Cushing's, with polycystic ovaries in some cases; ovarian adrenal rest tissue; and progesterone excess increasing cervical mucus viscosity. The greatest impediment to fecundity may be intercourse frequency—only 56% of women with simple virilizing CAH and 11% with salt-losing CAH ever attempt to conceive [62]. Women receiving adequate adrenal hormone treatment and having regular intercourse have pregnancy rates >90% [62], although miscarriage rates are higher than the general population (23% vs. 10.9%, P <0.001) [60]. In a study of 62 CAH women and 62 age-matched controls, CAH women were less likely to have been pregnant and they had fewer total pregnancies and fewer term pregnancies. Reproductive outcomes were worse in salt-wasting CAH than simple virilizing or non-classical CAH. Some women conceived spontaneously while others required increased glucocorticoids, concomitant fludrocortisone or assisted reproductive technologies. CAH pregnancies were characterized by more frequent Caesarean section, mostly due to past genital surgery, and gestational diabetes [61]. Contrary to earlier data, low birth weight was no more common in CAH, and there was no difference in birth weight between CAH subtypes. Postnatal development appeared normal on long-term follow-up [61]. A predominance of female offspring has been observed, which may reflect referral bias as girls face the risk of virilization but uterine changes favouring implantation of female embryos have been proposed [58, 61].

It is often necessary to increase glucocorticoid treatment prepregnancy to better suppress androgens and maximize ovulation frequency. Increasing glucocorticoid dose to achieve follicular phase progesterone concentrations <2 nmol/L is recommended [63]. Once pregnant, women with classical CAH and non-classical cases receiving adrenal hormone replacement are managed along similar lines to women with PAI, including personalized glucocorticoid dosing, increasing in the latter half of gestation [63]. Testosterone levels may be followed in pregnancy but not 17-hydroxyprogestrone as levels are elevated normally in pregnancy [59]. Delivery is generally by Caesarean section due to vaginal stenosis. Maternal androgen excess does not affect the female fetus due to placental aromatization.

Attempts to prevent masculinization of CAH female children have included trials of prenatal dexamethasone, commenced in early gestation prior to potential diagnosis of the fetus as a female *CYP21A2* mutation homozygote, with some, but incomplete benefit [58, 59]. This strategy exposes unaffected female and male fetuses to adrenal suppression and excess glucocorticoids with uncertain long-term consequences, and subjects pregnant women to glucocorticoid excess side effects. This approach is experimental only. Prevention may also be pursued through preimplantation or prenatal genetic diagnosis, in cases where the father has a mutant *CYP21A2* allele.

Miscellaneous Adrenal Disorders in Pregnancy

Adrenal Adenomas and Incidentalomas

The prevalence of adrenal adenomas in the background population is between 3% and 5%, increasing to 10% above the age of 70 years [64]. Detection of adrenal incidentalomas in pregnancy is rare, almost certainly due to the limited number of abdominal scans performed in the gestational period outside of obstetric ultrasound. The objectives of investigations of an incidental adrenal lesion diagnosed in pregnancy are to differentiate benign from malignant lesions, and to exclude adrenal hormone hypersecretion. In general, current imaging strategies are sensitive but poorly specific for malignancy in an adrenal mass [65], and several modalities such as FDG-PET and CT are relatively contraindicated in pregnancy. Radiological observation for stability of any detected lesion, such as MRI or ultrasound every 3 months, may be the most sensible management strategy for lesions not definitively proven to be benign on initial imaging [66]. Biochemical investigations for hormone excess should in general mirror those performed in the non-pregnant patient [67], with the caveat that the physiological perturbations in adrenal hormone metabolism described earlier may confound interpretation of results. Dexamethasone suppression testing for adrenal hypercortisolism should be avoided due to the confounding effect of increased oestrogen levels on hepatic CBG levels. Lesions with a biochemical signature suspicious for adrenocortical carcinoma may warrant closer observation or more definitive intervention such as adrenalectomy in the second trimester or the early postpartum period.

Adrenocortical Carcinoma

Adrenocortical carcinoma (ACC) is a rare malignancy, with an annual incidence of approximately one per million. Incidence is, however, higher in women than men, and is frequently diagnosed in women of reproductive age. Detection of ACC in pregnancy is extremely rare, and associated with a poor prognosis. Raffin-Sanson *et al.* reported outcomes in 12 female patients who were diagnosed either during pregnancy or in the first 6 months after delivery, and compared them to age-matched non-pregnant females [68]. Overall survival was worse, with a more advanced tumour stage in the pregnancy group. Unsurprisingly fetal outcomes were also poor. Some studies have speculated that ACC in pregnancy may display more aggressive properties due to oestrogen stimulation, but there are no conclusive data to support this. The clinical suspicion of ACC should be high in any patient with androgen excess associated with an adrenal mass, by the coexistence of cortisol and adrenal androgen hypersecretion, or in any adrenal mass greater than 4cm in transverse diameter.

Despite a recent report of normal pregnancy in a patient with metastatic ACC taking adjuvant mitotane up until the sixth gestational week, the latter is not recommended in pregnancy due to concerns about placental transfer [69]. In 17 women previously treated for ACC before conceiving, pregnancy did appear to be associated with worse clinical outcomes, and overall survival was not significantly different between the pregnancy group and matched

controls [70]. However, the authors caution about the potential bias introduced by a 'healthy mother effect', and recommend that women previously treated for ACC wait for a remission period of 5 years before trying to conceive.

Endocrine Bone Disease in Pregnancy

Jeremy Cox and Stephen Robinson

Vitamin D and Pregnancy

Introduction

Vitamin D and calcium metabolism is important both in health and disease, within normal and complicated pregnancy. There is an association between 25-hydroxyvitamin D (25-OHD) levels and intrauterine growth restriction, vitamin D is crucial to the fetus for growth and calcium accretion to bone. Vitamin D has effects beyond calcium homeostasis, maternal vitamin D concentrations are associated with increased risk of adverse pregnancy outcome including gestational diabetes, pre-eclampsia, and infections *in utero* and childhood. The concentrations of vitamin D need to be reviewed in terms of their appropriateness to ambient calcium concentrations and the homeostatic mechanisms involved. Therefore the changes that pregnancy brings to calcium physiology are reviewed before discussing the impact of maternal vitamin D status on the fetus, the mother, obstetric outcomes and the long-term health of the mother and child.

Epidemiology of Maternal Vitamin D

Vitamin D insufficiency and deficiency are common in Northern Europe, especially in women who have coloured skin or cover their skin. In Dutch women studied at 12 weeks of gestation the 25(OH)D was 15 ± 12 nmol/L in Turkish women, 20 ± 14 nmol/L in Moroccan women, and 53 ± 22 nmol/L in Western women [1]. There was an association with deprivation as well as reduced exposure to sunlight. In 970 Australian women 15% had a 25(OH)D less than 25nmol/L, whilst 11% of the neonates had a 25(OH)D less than 25nmol/L [2]. Vitamin D deficiency again was related to skin phototype, wearing a veil and young age. In 180 women studied in inner city London (n = 45 each group), the median 25(OH)D was 14 in Arab-Mediterranean, 21 in south Asian, 14 in African, and 48 nmol/L in Caucasian women (25(OH)D<25 nmol/L deficient, 25–75 nmol/L insufficient) [3]. Untreated, these are levels that are associated with a high parathyroid hormone (PTH) level in the mother (Figure 9.9.3).

Vitamin D and Calcium Physiology in Pregnancy

Calcium and bone metabolism in humans rely on adequate concentrations of vitamin D and its activated metabolite $1,25(OH)_2D$. This allows active calcium absorption from the gastrointestinal tract. Deficiency of $1,25(OH)_2D$ leads to secondary hyperparathyroidism in order to maintain plasma calcium concentration at a safe level for neuromuscular function, at the expense of bone mineral loss. The fetus at term will have accreted 30 g of calcium, 99% in the skeleton. Women transfer 300 mg daily to their fetus at term, and 210 mg/day in lactation [4]. Given that intake of calcium ranges from 800 mg to 1000mg in USA/Canada, and less elsewhere, calcium dynamics need to change in pregnancy and lactation to allow this transfer (Figure 9.9.1).

Therefore, during pregnancy adaptations of maternal physiology allow for enhanced uptake of calcium from the gut to support the fetus [4], and during lactation calcium mobilization from the bone to support breastfeeding the neonate. Normal calcium physiology with the changes of pregnancy and lactation are shown in Figure 9.9.2.

The normal range for vitamin D can be defined by hard outcomes, but this is difficult in humans with such long-term outcomes and the evidence base is suboptimal. It can also be defined by adaptive response, e.g. the rise in PTH concentrations that occurs when 25(OH)D falls below 30ng/ml (75nmol/L). In pregnancy there is an increase in $1,25(OH)_2D$ production from the maternal kidney, rather than decreased clearance, with a doubling of concentrations by 12 weeks, although the mechanisms that underlie control of this process are unknown [4]. Maternal PTH concentrations fall in early pregnancy, returning to non-pregnant values at term. Second trimester PTH suppression may not occur with low maternal calcium intake. Maternal parathyroid hormone related peptide (PTHrP) concentrations rise threefold by the third trimester, probably from placenta and breast, and may help maintain ionized calcium and stimulate calcitriol production [4].

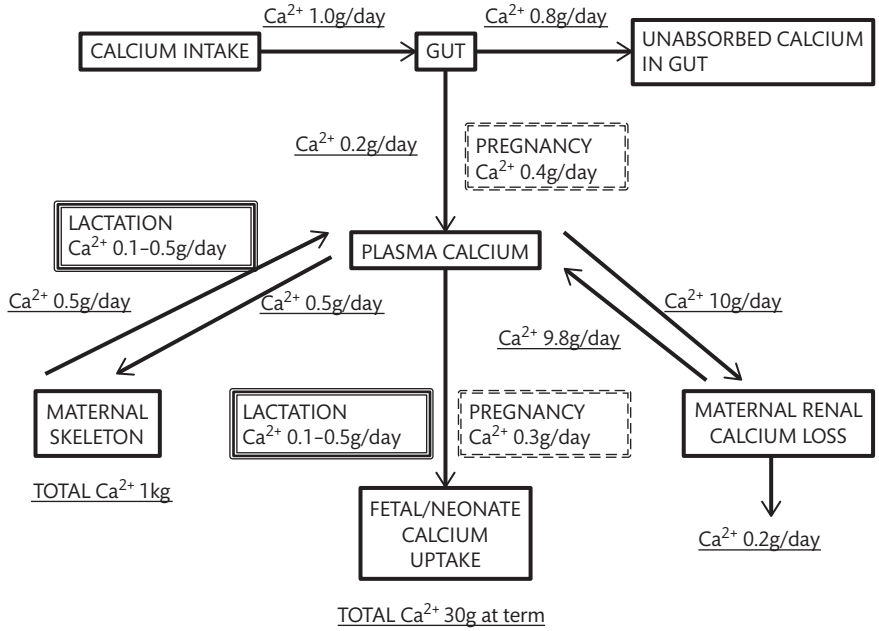

Figure 9.9.1 Normal calcium dynamics with the changes of pregnancy and lactation. Calcium is essential in bone and to neuromuscular function. Humans consume about 1.0 g calcium/day absorbing up to 20% of this. In steady state about 0.2 g calcium are lost in the urine each day. Normally the calcium taken up and released by the skeleton is in balance, but in the event of hypocalcaemia PTH causes increased osteoclast calcium release. During pregnancy higher levels of active vitamin D increase the fractional absorption of calcium from the gut, allowing for fetal calcium uptake. During lactation PTHrP increases osteoclast calcium release to the circulation allowing for the neonatal calcium uptake.

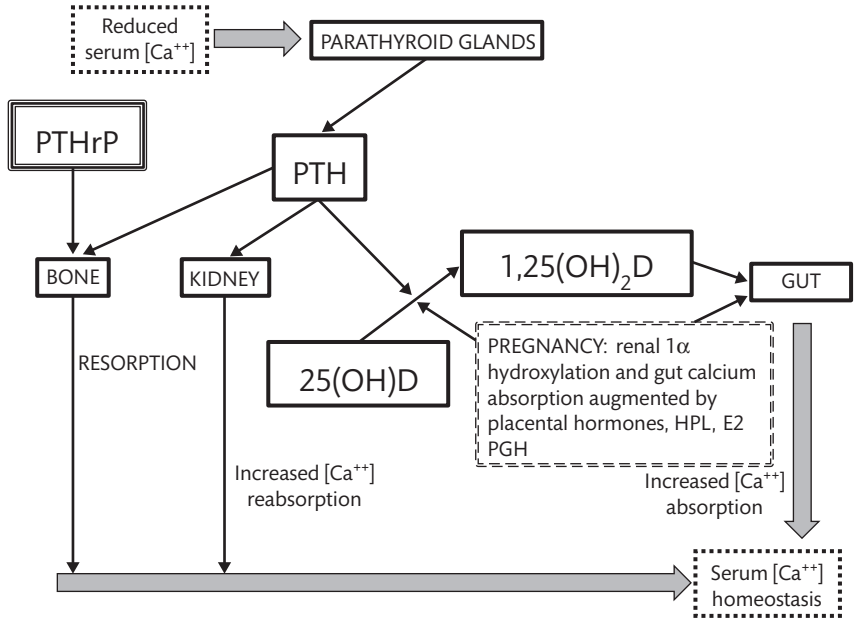

Figure 9.9.2 Normal calcium physiology with the changes of pregnancy and lactation. Normally reduced serum ionized calcium is detected by the calcium sensing receptor causing PTH release. This directly has effects on bone causing osteoclast activity with calcium release. PTH also increases renal calcium reabsorption from filtrate, thereby maintaining plasma calcium. In addition, PTH acts within the proximal tubule of the kidney to increase hydroxylation of 25(OH)D (calcifediol) in the 1 alpha position to produce $1,25(OH)_2D$ (calcitriol). Calcitriol increases fractional calcium absorption from the gut. The fundamental process in maternal physiology that drives this process in pregnancy is increased $1,25(OH)_2D$ action in the gut facilitating a twofold increase in calcium absorption. Placental hormones (HPL human placental lactogen, E2 oestradiol, PGH placental growth hormone) acting in the maternal kidney may increase vitamin D activation and also directly increase gut calcium absorption. When a mother is vitamin D replete and has good calcium intake this process can more than adequately allow for the fetal demands. Indeed in pregnancy the mother herself can drive a positive calcium balance. Parathormone related peptide (PTHrP) produced from the placenta in late pregnancy and then breasts in pregnancy and lactation increases osteoclast resorption and possibly osteocytic osteolysis, freeing calcium from maternal bone for the suckling neonate.

Fetal Outcomes

Birth weight can be defined by absolute weight or that corrected for gestational age; low birth weight and small for gestational age (SGA) have interconnected implications. Two meta analyses have shown an association between low 25(OH)D concentrations and low birth weight; RR 0.40 (95% CI 0.23–0.71) and RR 0.40 (95% CI 0.24–0.67), but one did not, RR 0.72 (95% CI 0.44–1.16) [5]. Possibly differing background risks and vitamin D ranges lead to these discrepancies.

Data regarding vitamin D concentration and small for gestational age (SGA) infants are similarly contradictory. One meta-analysis has shown an association between low 25(OH)D concentrations and SGA, RR 0.67 (95% CI 0.40–1.11) but vitamin D still thought to be protective; another did not, RR 0.78 (95% CI 0.50–1.21) [5]. In a study of nearly 4000 mother and 10-year-old offspring pairs there was no association between maternal vitamin D status and offspring total body or spinal bone mineral content [6].

Low maternal concentrations of 25(OH)D are associated with low neonatal concentrations of 25(OH)D [3] and neonatal hypocalcaemia. In a prospective study of severe deficiency, 59 Asian women were given 1000 IU vitamin D daily and compared to 67 untreated controls [7]. Vitamin D deficiency progressed in those who were untreated compared to an excellent response in mothers and neonates in terms of vitamin concentrations; none of the neonates of treated mothers developed symptomatic hypocalcaemia compared to five neonatal controls. Neonatal calcium in controls was <2.0 mmol/L in 24.6% compared to 6.3% in the treatment group.

Low maternal and neonatal vitamin D levels may be associated with increased childhood respiratory infections, through altered immunomodulation or bronchial development. Maternal intake of vitamin D was associated with reduced risk of recurrent wheeze at 3 years of age, OR 0.39 (95% CI 0.25–0.62) although there were multiple potential confounders [8]. However, in 436 Dutch children there was no association between vitamin D levels and lung function aged 6 years [9]. In a study of 3000 women the risk of later pre-eclampsia was reduced in those supplemented with vitamin D in the first year of life, OR 0.49 (95% CI 0.26–0.92) [10].

Maternal Outcomes

Low maternal 25(OH)D concentrations are associated with pre-eclampsia. Fifty-five singleton mothers with pre-eclampsia had 25(OH)D levels of 45nmol/L compared to 53 nmol/L in 219 controls [11]. Maternal 25(OH)D concentration was also associated with early onset severe pre-eclampsia; 25(OH)D <20 ng/ml was found in 54% of women with pre-eclampsia and 27% of controls [12]. Two trials have shown a lower risk of pre-eclampsia with vitamin D supplementation in pregnancy (8.9% vs. 15.5%; RR 0.52, 95% CI 0.25–1.05) [5]. Three trials have shown a lower risk of pre-eclampsia with vitamin D and calcium supplementation in pregnancy (5% vs. 9%; RR 0.51, 95% CI 0.32–0.80) [5].

When 23 423 women had their vitamin D intake estimated, there appeared to be a protective effect on hypertension of consuming 15–20 μg/d compared to 5 μg/day, OR 0.76 (95% CI 0.60–0.95) [13].

Some studies in the general population have shown an association between vitamin D concentrations and insulin resistance, T2DM and prediction of future T2DM [14]. However, Vitamin D supplementation has no effect on insulin sensitivity, insulin secretion or glycaemic control in subjects with existing type 2 diabetes. Studies have shown an inverse association between vitamin D concentrations and gestational diabetes and studies are investigating the therapeutic possibilities within these observations. Two have shown no benefit from maternal vitamin D supplementation and risk of gestational diabetes [5].

Obstetric Outcomes

Hypovitaminosis D has been investigated as an associate of preterm delivery. One metanalysis showed a clear significant association between 25(OH)D <37.5nmol/L and preterm delivery, RR 0.36 (95% CI 0.14–0.93); however, another did not show this, RR 1.26 (95% CI 0.60–2.63) [5].

Vitamin D deficiency was associated with primary caesarean section (CS) in 17% of 253 women having the procedure. Twenty eight percent had CS when 25(OH)D<37.5nmol/L but 14% when 25(OH)D>37.5nmol/L [15].

Outcome for Vitamin D in Mother

Both pregnancy and especially lactation are states that deprive a woman of vitamin D resources. Vitamin D insufficiency is particularly common in woman with multiple pregnancies or prolonged lactation. Calcium intake appears to have little effect on breast milk calcium output.

Supplement and Treatment Guidance

Vitamin D supplementation during pregnancy is associated with a significant increase in maternal and neonatal 25(OH)D levels (Figure 9.9.3). This in turn reduces the risk of neonatal hypocalcaemia and maternal pre-eclampsia. However, there are no clear data to show that vitamin D supplementation is associated with reduced risk of SGA, preterm delivery, or glucose intolerance. It is not known whether screening pregnant women has a clear utility, nor the method and dosing of a safe supplementation strategy.

In the absence of clear information there are sensible guidance documents.

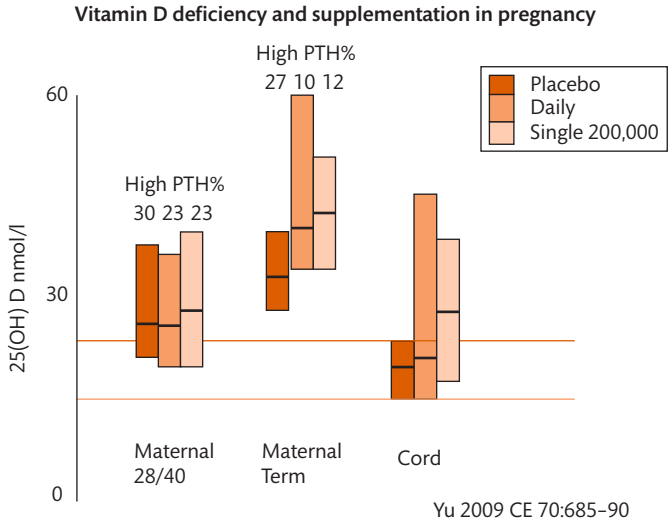

Figure 9.9.3 Vitamin D supplementation and PTH. 180 women were randomized to three groups. Daily ergocalciferol 800 IU, a single calciferol 200 000IU dose at 28 weeks and a no treatment group (routine advice and care). Either supplementation group was associated with a significant increase in term maternal and cord blood 25(OH)D levels. This was associated with a significant reduction in elevated PTH concentrations in the mother.

The current recommendation is for all pregnant and breastfeeding women to take 400 IU (10 μg) vitamin D daily. (NICE guidance 2017: https://www.nice.org.uk/guidance/ph56.) There is particular risk in some family origins, BMI>30kg/m², indoor lifestyle, covered skin, and certain diets. Dosing of up to 6000 IU/day appears safe in pregnancy and lactation [16]. Pregnant women with Vitamin D deficiency and increased one alpha hydroxylation are susceptible to sudden changes in calcium intake causing temporary hypercalcaemia, presumably related to high PTH concentrations removing ability to achieve homeostasis.

There is no recommendation for universal screening in pregnancy, so it is not recommended that vitamin D status is routinely assessed in pregnancy unless symptomatic (e.g. with bone pain) or particularly high risk (e.g. greatly reduced skin sunlight exposure). If a woman is found to be vitamin D deficient or insufficient she can be treated with 20 000 IU a week for 4 weeks, then continuing with a normal supplemental dose.

Primary Hyperparathyroidism

Introduction

Primary hyperparathyroidism (PHPT) is the third commonest endocrine disorder, however incidence rates increase markedly with age and so it is infrequent in pregnancy. Women of childbearing age have an annual incidence of about 6 per 100 000, compared to 99 per 100 000 in the age group 65–75 [16], and represent only 11% of the total incidence. The prevalence on routine biochemical screening of nearly 300 000 young Israeli women was 0.05% [17]. Its importance lies in the fact that about 50% of cases go undiagnosed, yet fetal and maternal complications are common [18].

Effect of Pregnancy on Primary Hyperparathyroidism

PHPT is under diagnosed, partly because of the dilutional effect of increased circulating volume and consequent hypoalbuminaemia from early pregnancy. Corrected or ionized calcium levels are unaffected by this. Pregnancy has variable effects on the course of the disease; although overall the peak recorded corrected calcium levels tend to be lower [17], critical elevations are often reported. In the first 12 weeks, there is a doubling of both calcitriol levels and gut calcium absorption, independent of PTH, resulting in a maternal positive calcium balance. The excess is not required by the fetus, so excretion increases, causing a state of absorptive hypercalciuria [4] and increasing renal stone risk. The high oestrogen levels may be thought to reduce excess bone resorption, but bone resorption markers increase steadily from the first trimester in normal pregnancy, so it is likely there is some increase in calcium flux out of bone [19]. In the third trimester calcium shunting across the placenta to the fetus increases markedly, but 300 mg per day is not sufficient to cause a substantial drop in maternal serum calcium, as is observed in rodents [4]. Simultaneously, increasing parathyroid hormone-related protein (PTHrP) levels from breast and placenta may reduce renal calcium loss and mobilize bone; these processes have been reported to cause hypercalcaemic crises in their own right [4]. This is particularly acute at delivery, when elevated PTHrP levels, the loss of the calcium shunt across the placenta and the sudden drop in oestrogen levels may result in an abrupt surge in calcium levels. Also during breast feeding, the average loss of 200 mg calcium daily into breastmilk may not offset the bone mobilizing effect of high PTHrP levels, resulting in worsening hypercalcaemia.

Maternal Complications

Most cases are asymptomatic to the mother or at least the symptoms are not distinguished from those of pregnancy; non-specific fatigue, nausea, vomiting, constipation, emotional lability, muscle aches, and urinary frequency [20]. In 124 affected pregnancies in 74 Israeli women, with a mean corrected calcium of 2.67 mmol/L, no increase in maternal complications was seen when compared to 431 pregnancies in 174 age matched normocalcaemic women [17]. However, the serum calcium concentration in this cohort was generally lower than in other reports of primary hyperparathyroidism in pregnancy. This may be because historical case reports and small series have a bias to report the more severely hypercalcaemic cases and their symptoms, and maternal complication rates have been reported to be high. There are increased rates of nephrolithiasis, acute pancreatitis, severe hyperemesis gravidarum and hypercalcaemic crises [20] whilst treatment of these poses significant challenges. Retrospective case control studies from Sweden show a marked increase in pre-eclampsia risks with PHPT diagnoses both up to 5 years before or after the affected pregnancies [21] and historical series suggest a 25% incidence [22].

Pregnancy and Fetal Complications

The risk to the pregnancy itself is the primary concern. In a large, single-centre series from Florida, in 62 affected pregnancies in which there was no operative intervention, 30 were lost, 3.5 times the rate in the general population [18]. Nine of these occurred later than is expected, during the second trimester. Importantly, the study linked the rates of loss to the calcium levels, with the percentage of pregnancies ending in miscarriage rising progressively from 12.5% at a serum calcium of 2.59–2.67 mmol/L to 80% at 3.04–3.24 mmol/L. The normal rate of fetal loss in mild hypercalcaemia that they demonstrated is consistent with the large series from Israel, where no increase was seen at a mean corrected calcium of 2.67mmo/L [17]. Other well-documented risks to the pregnancy include stillbirth, intrauterine growth retardation, preterm delivery, and low birth weight [20].

Neonatal Complications

The early neonatal time period has a high risk of hypocalcaemia in the baby, with symptoms such as opisthotonos, tetany, or seizures occurring in up to 50% in early series [20]. Fetuses run an elevated serum calcium and ionized calcium, typically 0.30–0.50 mmol/L above the maternal level, which is maintained by active calcium transport across the placenta. There is not a set gradient of serum calcium relative to the maternal serum calcium, but a fixed level independent of the maternal calcium value, which is maintained stable despite maternal hypercalcaemia [4]. The calcium-sensing receptor (CaSR) is not responsible for this and the higher fetal calcium levels stimulate the fetal CaSR, causing PTH secretion to be suppressed into the low range. Continued maternal hypercalcemia seems to enhance the transplacental flow of calcium to the fetus, further suppressing the fetal PTH level, even if the fetal serum calcium does not change. Post-delivery the neonatal parathyroid function is

impaired and hypocalcaemia ensues. This typically presents in the first two weeks, but may be delayed up to 2 months. It may occur even in asymptomatic PHPT or mild cases. Treatment is fortunately highly successful and spontaneous recovery normally occurs by 3 to 5 months, although damage can occasionally be permanent [4, 18]. Timely operative intervention in the mother does prevent this.

Diagnosis and Investigations

There are no specific guidelines on the diagnosis and treatment of primary hyperparathyroidism in pregnancy. The standard guidelines from the 4th international Workshop on Asymptomatic Hyperparathyroidism should therefore be followed [23]. Diagnosis is based on an elevated ionized or corrected serum calcium with PTH levels inappropriately elevated or in the upper half of the normal range. There is no specific PTH range for pregnancy and it should be noted that normally PTH levels are in the low normal range [4]. The differential diagnosis from familial hypocalciuric hypercalcaemia (FHH) and of other genetic conditions is thorny; in FHH the expected hypocalciuria is not present during pregnancy, with an increased fractional excretion of calcium by the kidneys [24]. Overall, one would expect an increased incidence of genetic conditions given the young age of diagnosis, perhaps as high as 20% [25] but this has not been borne out by the incidence of multigland disease on operation [18]. A proper family history is therefore critical and, if suspicious, urgent genetic screening is now possible, so avoiding unnecessary surgery.

Localization studies are normally limited to an ultrasound of the neck. Sensitivities are extremely user dependent, so a dedicated neck ultrasonographer is required; sensitivities are then above 60% [18]. There are case reports of modified dose ^{99M}Tc-Sestamibi scanning being used successfully, with estimated fetal exposure of < 5mGy, and 4D-CT at 10 mGy, much lower than known fetal toxicity cut-offs. These cannot yet be standardly recommended, but may have their place in complex cases [26].

Management

Noting that all pregnant women are operative candidates due to their young age and the risks to the pregnancy, a conservative approach may be followed if the mother is asymptomatic and calcium levels remain <2.75 mmol/L or <0.2 mmol/L above the upper limit of normal. Oral fluid intake should be encouraged and a low calcium diet followed. The mother should be counselled, meeting the surgeon and perinatologist. Regular maternal and fetal surveillance should be in place in a joint medical and obstetric antenatal clinic.

Medical Intervention

There are no pharmacological interventions proven safe in pregnancy, so the need for their introduction should be the signal for arranging a parathyroidectomy. Oral phosphate supplements of up to 9g per day have been used as a conservative option, but are poorly tolerated, cause diarrhoea and may precipitate hypokalaemia [20]. Cinacalcet, a calcimimetic suppressing PTH production, has been used in a number of case reports. It is poorly tolerated at the higher doses often needed, due to nausea and gastro-intestinal side-effects. Its efficacy has been limited in cases reports. It crosses the placenta and will stimulate the CaSR, which has a wide distribution in the fetus; parathyroid function will be suppressed, placental active calcium transport may be reduced and fetal bone accretion may theoretically be affected. In case reports neonatal hypocalcaemia has not been prevented [26]. Bisphosphonates are absolutely contraindicated in pregnancy, as they cross the placenta and have been shown to decrease fetal bone growth in animal studies, despite re-assuring data in accidental human usage [27].

In the acute scenario, whilst controlling severe hypercalcaemia before surgery, typical supportive management is indicated. Inpatient monitoring is used, with high volumes of intravenous normal saline, and once volume replete simultaneous IV furosemide boluses to promote calcium excretion. Subcutaneous calcitonin, at doses of up to 8 units 6 hourly, may be used, but tachyphylaxis occurs rapidly [20].

Surgical Intervention

Parathyroidectomy is generally carried out in the second trimester [22]. This can be individualized. Given the high rate of fetal loss in the late first trimester, there is an argument to intervene early in severe cases, with successful outcomes reported as early as at 11 weeks [18, 28]. Delayed operations in the third trimester have been felt to be associated with higher rates of complications, particularly pre-term labour, but these may be more related to the PHPT than the surgery. In an analysis of 16 reported cases with third trimester operations, the major complications were from pre-eclampsia (25%), pancreatitis and renal failure, which are likely to relate to the hypercalcaemia. There were no cases of anaesthesia induced premature labour and the main surgically related complication was transient maternal hypocalcaemia [22]. If hypercalcaemia therefore becomes problematic late in the pregnancy, operation is still indicated.

Pseudohyperparathyroidism

Pseudohyperparathyroidism is a very rare cause of hypercalcaemia in pregnancy and during lactation. In normal pregnancy PTHrP levels rise threefold from the first trimester to term, mainly coming from the breast and the placenta [4]. Breast hyperplasia can cause further elevation of levels and there have been rare cases reports of pregnancy hypercalcaemia being driven by markedly elevated PTHrP levels, whilst PTH is suppressed. Mastectomy has been required [29]. More cases have been reported during lactation, mostly presenting as osteoporosis, with the hypercalcaemia resolving on cessation of breastfeeding. Lactational PTHrP induced hypercalcaemia may be occurring more frequently than is appreciated [4, 30].

Familial Hypocalciuric Hypercalcaemia

Introduction

Familial hypocalciuric hypercalcaemia (FHH) is an autosomal dominant disorder most commonly resulting from heterozygous germline inactivating mutations in the CASR gene, and less frequently from mutations of GNA11 or AP2S1 [31]. It is responsible for up to 3% of cases of PTH-related hypercalcaemia in the under 45 age group [25] and needs to be borne in mind, so as to avoid an unnecessary operation.

Effect of Pregnancy on FHH

Outside of pregnancy, most cases are asymptomatic and mild biochemically. Two-thirds of cases will have serum corrected calcium

levels <10% above the upper limit of normal, and in almost 80% PTH levels will be in the normal range [32]. There is a theoretical risk of worsening hypercalcaemia in pregnancy, for similar reasons to those in PHPT. Interestingly, absorptive hypercalciuria still develops, despite patients normally having a low urine fractional calcium excretion. The 24-hour urine calcium/creatinine clearance ratio rises well above 0.01 [24], so that urine testing cannot be used to differentiate from PHPT, and genetic testing should be used if there is a suspicious family or clinical history.

Fetal Complications

Although the pregnancy is not affected, the maternal hypercalcaemia can cause suppression of the fetal parathyroid glands and temporary neonatal hypocalcaemia, dependent on the fetal genotype. Unaffected and heterozygote fetuses are at risk of hypocalcaemia, which in heterozygotes will turn to hypercalcaemia in the neonatal time period. Homozygote or compound heterozygote fetuses, inheriting a second mutation from the father or de novo, are at risk of neonatal severe hyperparathyroidism, which may require urgent parathyroidectomy. Rarely, heterozygotes may also present in this way [31]. Affected pregnant women should therefore be offered genetic counselling and the neonates have close calcium monitoring.

Effect of Lactation on FHH

During breastfeeding, PTHrP levels are normally under negative feedback control by the CaSR in mammary tissue. Inactivating mutations will lead to increased PTHrP levels and could worsen hypercalcaemia, but this has not been reported [4].

Hypoparathyroidism

Introduction

Hypoparathyroidism rarely presents during pregnancy [33], although it may be picked up in the mother when neonatal complications arise, including neonatal hypercalcaemia and fractures. It is normally known about before pregnancy, with the mother established on treatment, and the challenge is to maintain normocalcaemia despite the major alterations in calcium homeostasis that occur during pregnancy and breastfeeding. Failure to achieve this can have serious consequences.

Animal Hypoparathyroid Models

Data from parathyroidectomized rat and mouse PTH null models, show that PTH is not required for the marked increase in calcitriol levels and gut calcium absorption that occur in pregnancy. Pregnancies proceed to term without needing intervention, with no fetal or maternal adverse consequences. There is a dependence on the calcium content of the diet in rats, and if this is limited, maternal hypocalcaemia may occur [4].

Effect of Pregnancy on Hypoparathyroidism

In affected human mothers, case reports and series show that maternal symptoms tend to improve in pregnancy, with fewer episodes of tetany, cramps or paraesthesiae. Although animal data suggests activated Vitamin D supplements can be discontinued, and series prior to the introduction of Vitamin D analogues demonstrated successful outcomes [34], this approach is not used, as maternal dosing requirements seem to be extremely variable. Even within the same patient, different pregnancies may require dose titration in opposite directions [35]. This may partly be because dietary calcium intake is not controlled.

Pregnancy Complications

The consequences of unintended hypocalcaemia can be serious for the pregnancy. Spontaneous midterm abortion, premature labour and stillbirths have been reported in severe cases [33]. These may occur because hypocalcaemia increases uterine muscle excitability. A higher incidence of small for gestational age fetuses has also been suggested [35].

Fetal Complications

The fetus can maintain its own calcium levels despite maternal hypocalcaemia. The fetoplacental unit upregulates mechanisms to maintain the fetal blood calcium and increase placental calcium transport, with animal models showing increased PTHrp and PTH levels [36]. This marked increase in fetal PTH levels though is accompanied by parathyroid gland hyperplasia, and increased bone resorption, so that the skeleton is undermineralized. The skeletal consequences include reduced bone mass, neonatal rickets, and fractures in utero and on delivery [37]. Chest wall deformities may lead to respiratory distress. Neonatal hypercalcaemia secondary to parathyroid hyperplasia may occur.

The consequences of unintended hypercalcaemia have already been discussed under primary hyperparathyroidism.

Effect of Lactation on Hypoparathyroidism

Lactation results in an improvement in calcium homeostasis in hypoparathyroid mothers. Breast PTHrP production rises with breastfeeding, causing increased bone turnover, particularly in the trabecular compartment, and releasing calcium. PTHrP acts on the kidney to increase calcitriol production to normal levels and increase renal tubular calcium reabsorption. Patients can therefore go into positive calcium balance and lactation can result in hypercalcaemia if pregnancy doses of calcitriol or 1α calcidiol are continued. The rapidity of the decline of this state on weaning is variable. It may occur whilst breastfeeding frequency is reducing or be delayed post-weaning by weeks, but usually occurs within a few days [4, 38].

In the transition between delivery and initiation of breastfeeding, PTHrP levels from the placenta drop, before rising again from the breast. Temporary maternal hypocalcaemia has been reported at this time [4].

Treatment

There are no management guidelines published for hypoparathyroidism in pregnancy. Management is usually conservative, continuing on pre-pregnancy doses of 1α calcidiol or calcitriol and calcium supplementation to start with. Total calcium intake should be at least 1.2 g per day. Corrected or ionized calcium levels should be followed, as total calcium levels will drop with dilutional volume expansion in the first trimester and dose adjustments made on this basis will be erroneous. Change should be watched for with monthly calcium monitoring from 12 weeks. Dose titration is often required during the second trimester. Changes in urine calcium excretion

should not be monitored. Maintenance of normocalcaemia is the aim, but avoidance of hypocalcaemia is particularly important, so calcium levels should be run within the low-mid normal range (2.2–2.4 mmol/L) [4], rather than borderline low as is frequently practised outside of pregnancy. Mothers should be aware of the symptoms, so be able to seek help, and followed in a joint obstetric clinic with endocrine input. At delivery, it is advisable to at least return to prepregnancy doses if they have been increased, and then to watch closely with the establishment of breastfeeding, when dose reductions should be expected, moving to monthly monitoring again through lactation.

Pseudohypoparathyroidism

Introduction

Pseudohypoparathyroidism (PHP) refers to the metabolic picture of hypocalcaemia with hyperphosphataemia but unexpected high PTH levels, due to resistance to the action of PTH in target tissues, in the context of normal magnesium levels.

PHP type 1a patients have heterozygous mutations affecting the maternally inherited allele of GNAS, encoding the $G\alpha_s$ subunit, hence show resistance not only to PTH, but also to other hormones in tissues where the maternal allele of GNAS is preferentially expressed. Typically, this would include the pituitary, with resistance to gonadotropins and GHRH, and the thyroid with resistance to TSH, so that pregnancies are rare. These patients also show the somatic features of Albright's hereditary osteodystrophy (AHO). In PHP type 1b, patients have mainly PTH resistance due to methylation loss in the maternally inherited GNAS allele, resulting in decreased transcription levels. The AHO phenotype is not seen. Partial TSH resistance is commonly seen [39].

Effect of Pregnancy on Pseudohypoparathyroidism

Case reports in pregnancy are few, but suggest that the expected PTH independent increase in calcitriol levels does still occur, and therefore patients may remain normocalcaemic despite discontinuation of their normal calcitriol [40]. As with hypoparathyroidism, though, cases reports show that maternal dosing requirements are very variable and calcium content of the diet is probably critical [4].

Treatment

The basic management should be the same as for hypoparathyroidism. Additional factors though need to be considered in pregnancies affected by PHP. Thyroid status should be tracked and adequate replacement given. Counselling and prenatal diagnosis of the fetal genetic status are required, not just to predict neonatal issues such as hypocalcaemia, but also to predict changes in intrauterine growth [41].

Osteoporosis in Pregnancy and Lactation

Introduction

Osteoporosis is uncommon in women of child-bearing age and infrequently thought of at the time of pregnancy. Rarely, though, fractures may occur, typically during the third trimester or early in lactation, presenting with back pain and single or multiple vertebral compression fractures. It was recognized to be associated with the temporary changes in bone metabolism in pregnancy and lactation, and first proposed as a distinct syndrome in 1955.

Animal Bone Metabolism in Pregnancy

In rodent studies it is estimated that up to 92% of fetal skeletal calcium content comes from the maternal diet during pregnancy, with just a small amount near term from skeleton. When bone mineral density (BMD) is measured sequentially through pregnancy in a mouse model there is a continuous gain in total body mineral content from early pregnancy to up to 20% by birth. In rats measured at the start and end of pregnancy, there is no change in whole body BMD, a good marker for overall mineral balance, but small significant declines in lumbar spine BMD. These vary by study, with the calcium content of the diet being a significant factor. This remarkable conservation of the skeleton is achieved by a large increase in gut absorption of calcium, which doubles from mid-pregnancy, allowing the pregnant mother to accrete extra bone mineral in preparation for the higher fetal demands in late pregnancy and lactation [4].

Maternal Bone Metabolism and Mineral Density in Pregnancy

The physiology in human mothers is similar (Figures 9.9.1 and 2). The marked increase in gut calcium absorption during the first 12 weeks, allows the mothers to go into positive calcium balance by mid-pregnancy. Whether mothers accrete new bone mineral in preparation for late pregnancy and lactation is not clear [4]. Studies of bone markers show that resorption markers increase steadily from early pregnancy, being significantly elevated by 10 weeks [19, 42]. Bone formation markers, such as carboxy-terminal propeptide of type 1 procollagen (P1CP), are reduced in the first two trimesters, then climb rapidly in late pregnancy [19, 42]. There is therefore some uncoupling of bone resorption and formation in the first two trimesters, but overall this is consistent with a more marked increase in bone turnover in the last trimester.

Longitudinal bone mineral density measurements during pregnancy are limited, with variable results between and within studies [43]. One Sheffield study, looking at 16 Caucasian women with BMDs performed prior to and 2 weeks post-pregnancy, showed that overall BMD of total body changes little, but there does seem to be mineral redistribution occurring, with the BMD at sites rich in cortical bone increasing, 2.8% at the arm and 1.8% at the leg, and the BMD at sites rich in trabecular bone decreasing, with a 4.5% decrease at spine and 3.2% at pelvis [44]. The two largest controlled studies show differing results. One from Nottingham looked at 46 women, comparing them with 30 controls [45]. There was a small non-significant decline in BMD in the pregnant group at all sites, performed prior to pregnancy and within 2 weeks of delivery. A second larger study from Denmark also looked at forearm BMD in each trimester [42]. Of the 92 women recruited, 73 completed and were compared to 57 controls. DXA measurements at 2 weeks post-delivery, with all women having started breast-feeding, showed a 4% decrease at the ultradistal radius, a mainly trabecular site, and 0.5% gain at the distal proximal 1/3 forearm, a mainly cortical site. The rate of loss at the ultradistal radius was increasing through the trimesters and the magnitude significant by the 10-week visit. This mirrored changes seen at the total hip and spine, done only prior to

and post-pregnancy, where a 3.2% and 1.8% loss were seen respectively. Whole body BMD decreased by 2.4%.

These data suggest that there is normally only a small loss of maternal bone to help obtain the mineral for the formation of the fetal skeleton, and that this loss is mainly in the third trimester, as in animal models. Likely risk factors for increased loss include a low calcium diet and secondary hyperparathyroidism. Normally, due to the marked increase in gut calcium absorption and calcitriol levels, PTH levels are in the low normal range. However, in populations with low calcium intake or severe vitamin D deficiency secondary hyperparathyroidism still occurs [3]. Twin pregnancies, that would require a greater calcium shunt, have been shown to have elevated bone turnover markers [43].

Maternal Calcium and Bone Metabolism in Lactation

Lactation poses a greater burden on the mother. By 9 months a neonate will require another 30 g of calcium for skeletal development, which is provided by an average maternal shunt of 210 mg per day in breast milk. This essentially comes from her bone. The picture of absorptive hypercalciuria during pregnancy switches to a bone resorptive picture during breast feeding. Prolactin secretion in response to suckling suppresses the GnRH generator, dropping LH, FSH, and E2 levels, so that E2 related restraint on bone turnover is removed. PTHrP production from the breast, stimulated by both suckling and prolactin, enters the systemic circulation and causes bone mobilization, particularly in trabecular bone. This provides calcium for secretion into breast milk, under feedback control through the CaSR in mammary tissue. Stimulation of this CaSR by mobilized calcium causes both a reduction of PTHrP release into the systemic circulation and breast milk with increased secretion of calcium into the breast milk [4].

Other calcium regulatory systems play little role. The increased gut calcium absorption characteristic of pregnancy rapidly disappears, as calcitriol levels drop to the middle of the non-pregnant range. With the high systemic calcium load coming from bone, PTH is suppressed into the low normal range, but PTHrP does act on the kidney, increasing calcium conservation, so that hypercalciuria resolves.

Maternal Bone Mineral Density in Lactation

Women showed a marked loss in BMD with this resorptive phase, typically between 5% and 10% at trabecular sites [43]. This is most pronounced in the first 3–6 months, and with prolonged breastfeeding some regain actually starts to be seen at the lumbar spine, although loss continues at the hip [42]. Whereas in animal studies cortical bone loss is marked, with osteocytic osteolysis allowing resorption of pericanicular and lacuna spaces around the embedded osteocyte, in women this does not seem to be occurring and cortical bone is relatively spared, with cortical forearm sites showing little change [42]. Risk factors for greater bone loss include adolescence, continued amenorrhoea, prolonged breastfeeding and high PTHrP levels [43]. Calcium supplementation does not seem to alter the loss [46, 47].

BMD recovers by 12 months after weaning [47], with studies showing different rates at different sites. In the largest controlled cohort study, Moller showed that if breastfeeding stopped by 4 months, there was full recovery of whole body and lumbar spine densities to pre-pregnancy levels by 9 months, but that at this time it was less than 50% at the hip and minimal at the ultradistal radius [42]. Overall recovery is also not affected by a repeat pregnancy within 18 months. In rodent studies, there is never full recovery in some trabecular sites in the long bones, but bone dimensions change, with an increased cross-sectional diameter, such that bending and torsional strength are maintained [43]. Recent high resolution peripheral quantitative CT confirms that there is microarchitectural deterioration post-lactation in women, with trabecular loss and thinning as well as increased cortical porosity at the distal radius and distal tibia [48]. Strength analyses are not available from this study, but other reports show that high parity is associated with increased radial torsional bending strength, increased femoral neck size, and increased tibial cross-sectional area, paralleling the rodent data [49, 50]. A number of epidemiological studies show that increased parity is not associated with low BMD or fracture risk, with a recent meta-analysis suggesting no effect on femoral neck or lumbar spine density, and a small positive effect at total hip BMD [43, 51]. Calcium supplementation of 1000 mg daily post-weaning has been shown to speed up regain of BMD at lumbar spine, but it is not known if this will translate into a long-term benefit, especially at other sites [46].

Investigation of Pregnancy-Associated Osteoporosis

On discovering a case of postpartum osteoporosis, it should not be assumed that this is pregnancy or lactation related. This may be true, as there is wide variation in the rate of bone loss between individuals, prolonged breastfeeding or twins may increase loss, and certain medications used in pregnancy may enhance loss, such as LMWH or prednisolone, but other factors need to be considered. These would include typical risk factors for osteoporosis such as prior low BMI or anorexia, severe childhood illnesses meaning that normal peak bone mass was never achieved, systemic inflammatory conditions such as rheumatoid arthritis, malabsorptive disorders such as coeliac disease, drugs such as glucocorticoids, antiepileptics and depot progesterone, HIV, and a maternal history of fractures. More specific congenital or metabolic bone disorders may also first present this way, and should be considered, including primary HPT, idiopathic hypercalciuria, juvenile idiopathic osteoporosis, LRP5 mutations, and osteogenesis imperfecta [43].

Treatment of Pregnancy-Associated Osteoporosis

The management should ideally be conservative, as full recovery of bone density should occur rapidly on recommencement of menstruation. Although a number of pharmacological interventions have been reported, it is difficult to know if they were of benefit as regain occurs spontaneously. Indeed, they may impair bone regain and be contra-indicated in the context of further expected pregnancies, as bisphosphonates. Return of oestrogen effect is what is required. Breastfeeding should be discontinued with cabergoline being given if required. Calcium and vitamin D supplementation should be given; the trial evidence available is with 1000 mg calcium and 400 IU vitamin D_3 daily [46], but the latter should be titrated to bring 25(OH)vitamin D levels at least above 50 nmol/L. Mobilization should be encouraged. Depot progesterone contraception should be avoided. Mothers can be reassured that this will be unlikely to recur in future pregnancies [43].

On tracking BMD, full recovery should have occurred by 12 months. If osteoporosis still persists, further investigation for rarer conditions is indicated and a full family history desirable. A plan for future pregnancies would then be indicated.

Transient Osteoporosis of the Hip

Introduction

Transient osteoporosis of the hip was first described in three cases during pregnancy in1959, but has since been found to occur outside of pregnancy, at other weight-bearing joints and in older men [52]. It has an incidence of 6 per 10 000 pregnancies, but this is likely to be an underestimate, as joint pains are common in pregnancy [53].

Presentation

Typically it presents with spontaneous pain in the hip in the third trimester or early puerperium. This may come on suddenly or gradually, be felt in the groin or anterior-laterally in the thigh and worsens on weight-bearing or exercise. The patient may limp and on examination there may be soft tissue swelling, joint effusions and occasionally muscle wasting. Both hips may be affected and in rare cases hip fracture may occur [52].

Diagnosis

Diagnosis is based on clinical suspicion, followed by appropriate radiological investigation. X-rays show osteopaenia or radiolucency, and DEXA will show markedly reduced hip BMD on the affected side, especially when compared to the lumbar spine BMD. The magnitude of loss is such that from 20% to 40% regain of BMD has been seen on recovery [43]. MRI is diagnostic, showing epiphysial bone marrow oedema extending into the subchondral bone, and can be used to differentiate it from osteonecrosis of the hip, which can also present in pregnancy [52].

Aetiology

Although pregnancy may be a precipitating factor, transient regional osteoporosis (TRO) is not necessarily associated with the bone changes seen in pregnancy and lactation. The aetiology is poorly understood and histological studies have been conflicting. Venous stasis may be a critical component and it has been suggested that it is a variant of reflex sympathetic dystrophy [43].

Treatment

Treatment is supportive, as the changes typically resolve in a number of months, with MRI showing resolution of the bone marrow oedema. Reduction of weight-bearing activities and bedrest may be necessary. Adequate opioid analgesia is given. Pharmacological treatment is not indicated given the natural history of resolution. Women should be warned that recurrence can occur in later pregnancies.

Imaging for Endocrine Diseases in Pregnancy

Sandra Lowe

Introduction

The pregnant woman is exposed constantly to a range of ionizing, non-ionizing, and electromagnetic radiation in both her own environment and as a result of medical interventions [1]. Imaging techniques that do not involve electromagnetic radiation such as ultrasound and magnetic resonance imaging (MRI) are considered safe in pregnancy.

X-rays, computerized tomography (CT) with and without iodinated contrast, nuclear scanning, and positron emission tomography (PET) scanning all involve potential exposure of both mother and fetus to ionizing radiation. Such imaging may occur inadvertently or by intention during pregnancy, necessitating appropriate counselling. In addition, CT, MRI, or even ultrasound may require administration of a contrast agent to improve image definition or other additional information

For particular endocrine diseases, imaging involving radiation may be the gold standard (e.g. for pituitary or adrenal tumours), although non-ionizing options such as MRI or ultrasound may be an alternative in certain situations. Similarly, nuclear scanning is a standard modality for thyroid and parathyroid assessment. In more serious conditions such as phaeochromocytoma, a number of imaging modalities may be required including specialized nuclear and positron emission tomography (PET) scans, with or without CT.

The following chapter provides an overview of the principles and practical application of imaging modalities for endocrine disorders in pregnancy.

Medical Imaging Without Radiation

Ultrasound and magnetic resonance imaging (MRI) are considered safe modalities for imaging in pregnancy because of the absence of ionizing radiation. With MRI, heating of the fetal tissues by radiofrequency fields might theoretically lead to impairment of cell migration as demonstrated in animal models. Even with whole body imaging at the recommended allowable maximum specific absorption rate, the mother's body temperature might increase 0.6°C for 20–30 minutes but the maternal tissues dissipate this heat and the fetus is exposed to a much lower temperature and no adverse fetal effects have been reported [2]. As a precaution, the recommendation is to use 1.5-Tesla (T) scanners compared with 3.0-T scanners because the specific absorption rate quadruples when the magnetic field doubles [3].

Various guidelines have been published expressing confidence in the use of MRI throughout pregnancy, including the first trimester, with no evidence of adverse outcomes on pregnancy or the fetus/neonate [3–5].

Ionizing Radiation During Pregnancy

Box 9.10.1 describes the ways radiation exposure can be defined in pregnancy.

Recent data has estimated that total radiation exposure for an individual is made up of background exposure at 50%, medical exposure at 48% and radiation from consumer products and industrial, research, and occupational exposures, amounting to a

Box 9.10.1 Definitions

Absorbed dose:
- mean energy imparted per unit mass

Units of radiation:
- 1 gray (Gy) = 1000 milligray (mGy) = 100 rad

Radiation weighting factor:
- Equal doses of different types of energizing radiation do not necessarily lead to equal detrimental effects. These differences relate to microscopic energy dissipation and are corrected for by a radiation weighting factor (w_R) which when multiplied by the dose produces a quantity expressed as the sievert (Sv)
- Most diagnostic imaging the weighting factor is 1 (from photons and electrons)

Nuclear scanning with radiopharmaceuticals:
- fetal dose is expressed as mGy per megabecquerel (mGy/MBq), i.e. absorbed dose to the fetus per unit activity administered to the mother

2% [6]. The major radiation source for most women during pregnancy is environmental, arising from a number of sources including cosmic, gamma and radon. The magnitude of the exposure varies with a global average estimated radiation dose over the 9 months of pregnancy being 2.3 mSv (Table 9.10.1) [1, 7]. For a fetus, the dose is much smaller, 0.5–1 mSv, because of attenuation through the mother's tissue [8]. When a pregnancy is declared, by a female working in the presence of radiation, the embryo or fetus is afforded the same level of protection as the general public (i.e. 1mSv per year).

Fetal and Maternal Radiation Doses During Diagnostic Imaging

The calculation of radiation dose, both maternal whole body and organ specific as well as the estimated fetal absorbed dose may be derived from established dosimetry tables and/or by specific calculations/measurements made by a medical physicist on a case by case basis. All radiation does are potentially additive and where multiple procedures are performed, cumulative dosage should be calculated.

Table 9.10.1 Environmental radiation sources

Environmental exposures	mSv/exposure or per year
Airport scanner	0.005
Air travel: • at higher latitudes multiply by a factor of 2 or 3.	0.005 short flight 0.03 long flight
Aircrew/frequent flyers	1–5

Much research has been undertaken on the effects of low-level radiation which is the level most relevant when discussing risks of diagnostic imaging. It has generally been assumed that the relationships observed between radiation dose and adverse effects at high levels of radiation exposure also apply to low levels: the linear no-threshold (LNT) hypothesis. This concept remains a source of controversy among experts although the International Commission on Radiological Protection recommends that the LNT model should be assumed for the purpose of optimizing radiation protection practices, including protection during pregnancy [7, 9].

A number of national and international bodies have issued guidelines or policy documents which indicate a negligible risk to the fetus for radiation doses below 50 mGy. This is well above the dose from almost any single diagnostic imaging event although cumulative studies could lead to such a dose [10–12].

Risks of Ionizing Radiation in Pregnancy

In the assessment of any adverse effects of radiation upon the fetus it is necessary to consider:

- Absorbed dose
- Timing of the exposure relative to conception and
- Form of administration

Appropriate adjustments to standard X-ray and CT procedures can be made to lower the fetal absorbed dose without impairing image quality [8]. For most standard radiography, the fetal dose is very low (Table 9.10.2) [13].

In addition to the radiation technique, site and dose administered; maternal factors will influence the fetal absorbed dose. During X-rays and CT scanning the 'thickness' of the mother, which alters as pregnancy progresses, will influence the penetration of the dose and hence the fetal absorbed dose. The use of appropriate shielding will significantly reduce the fetal absorbed dose as well as the dose to adjacent maternal tissues.

In the case of nuclear medicine studies, fetal absorbed dose will represent the cumulative effect of external irradiation from the maternal tissues as well as placental transfer and fetal uptake of radiopharmaceuticals (Table 9.10.3) [14–16]. For radioisotopes

Table 9.10.2 Examples of fetal radiation doses for imaging of endocrine disease in pregnancy

Examination	Clinical scenario	Typical fetal dose range (mGy) in early pregnancy
CT head and/or neck	Thyroid or parathyroid	0.001–0.01
Xray hip	Avascular necrosis of hip	0.1–1.0
^{99}Tc thyroid scan	Thyroid toxic nodule	0.1–1.0
CT abdomen	Adrenal mass	1.0–10
^{18}F-FDG PET/CT	Malignancy Phaeochromocytoma and paragangliomas	10–50
Dual X-ray absorptiometry (DEXA): Posterior-anterior spine Proximal femur	Osteoporosis	1.7–4.9 1.0–2.7

Table 9.10.3 Fetal whole body dose from common nuclear medicine examinations for endocrine disorders comparing early pregnancy and at term. Dose includes maternal and fetal self-dose contributions

		Administered activity (MBq)	Early pregnancy (mGy)	Late pregnancy (mGy)
^{99m}Tc	Bone scan (phosphate)	750	4.58	1.8
^{99m}Tc	Thyroid scan (pertechnate)	250	3.45	0.41
^{99m}Tc	Sestamibi –parathyroid		6.0	10–50
^{123}I	Thyroid uptake[a]	30	0.4–0.6	0.3
^{131}I	Thyroid uptake[a]	0.55	0.03–0.04	0.15
^{131}I	Metastases imaging[a]	40	2.0–2.9	11.0

[a] Fetal thyroid doses are much higher than fetal whole body dose.

that are excreted in urine, radiation from bladder contents or the placenta will have a greater impact in early pregnancy compared with later pregnancy. This leads to a decline in fetal absorbed dose as pregnancy progresses for most nuclear imaging [15]. By using smaller administered doses and longer imaging times, the fetal absorbed dose may be further reduced, but there is concern that this may compromise the value of the study. The estimated fetal radiation doses quoted in Table 9.10.3 need to be adjusted for administered dose which may vary significantly between institutions. Although a reduction of the injected dose can be compensated for by increasing the scanning time, if the acquisition time is longer patients are more likely to move or ask to interrupt the scan to void the bladder (not a rare occurrence in pregnant women) [17]. Strategies to aid excretion of radiopharmaceuticals such as ensuring prompt and complete bladder emptying will reduce the fetal absorbed dose without compromising image quality and should be encouraged.

Older techniques for estimating fetal absorbed dose based on phantoms and models of the pregnant woman are being replaced by combinations of geometric constructs based on medical image data that are far more realistic [18]. However, estimating the absorbed dose to individual fetal organs remains difficult [19].

Nuclear scanning has been enhanced by the addition of hybrid SPECT/CT camera technology that allows simultaneous acquisition of combined multimodality imaging, with seamless fusion of three-dimensional volume datasets. The combination provides enhanced information with imaging of functional information and anatomy/localization. In endocrine disease, this may be particularly helpful for parathyroid and thyroid imaging as well as imaging for rare neuroendocrine tumours, adrenal cortical hyperfunction, phaeochromocytoma, and paraganglioma [20]. The fetal radiation dose from such procedures will be greater than from any single modality but the additional information may be critical.

Specific Risks of Diagnostic Radiation in Pregnancy

Experimental assessment of high dose radiation has identified seven specific areas of potential concern to the pregnant woman and her fetus.

- Lethality
- Genetic damage/epigenetic change
- Teratogenicity
- Growth impairment
- Sterility
- Oncogenicity

The effects of radiation exposure in pregnancy depend on the time of exposure as well as the fetal absorbed dose. Until the placenta implants, the cells of the conceptus are hypoxic and therefore less radiosensitive. In the very early embryo, the effect of radiation is more likely to be failure to implant or undetectable death of the embryo (i.e. an 'all-or-none' phenomenon) [21].

With regard to potential fetal dosage from diagnostic radiation, there is no evidence for any increase in lethality (miscarriage or stillbirth), teratogenicity, genetic damage/epigenetic changes, growth impairment, mental retardation, or sterility [9, 22, 23].

A large number of epidemiological studies have been performed to assess the possible effects of prenatal radiation on the incidence of malignant disease. All are flawed by problems such as retrospectivity, small study size, inadequate or inappropriate case and control selection, and variability in the determination of radiation exposure and measurement of outcome parameters. The studies in which prenatal radiation exposure has been associated with an increased incidence of malignancy have found a relative risk ratio (RR) of all cancer of between 1.5 and 2.4 [24]. However, a number of other studies have failed to establish any statistically significant association between prenatal exposure to radiation and childhood malignancy [25, 26]. At least part of the increased risk associated with irradiation could be accounted for by the fact that mothers with a higher incidence of illness during pregnancy (a susceptibility which might be associated with an increased risk of tumour in their offspring) had a greater incidence of exposure to diagnostic radiation. Court Brown noted that amongst the offspring of the 750 pregnant women identified as having been irradiated in the first trimester, there were no cases of leukaemia with an average follow-up period of 6 years [27].

There continues to be debate about whether a radiation dose estimated to be approximately 10 mGy could give rise to cancer as suggested by the widely quoted Oxford Survey of Childhood Cancer based on a Linear No Threshold assumption [28]. More recent assessment based on biologic and epidemiologic data suggests this model may be incorrect and there is no carcinogenic risk below 20 mGy [29]. Despite this, the National Radiological Protection Board has adopted an estimated additional risk (EAR) coefficient for cancer incidence under 15 years of age following low dose irradiation *in utero* of 0.006% per mGy compared with a risk of 0.0018% per mGy for a dose received just after birth. Given a baseline risk of childhood cancer of between 1.0 to 2.5 per 1000, the following

Table 9.10.4 Excess risk of cancer from fetal radiation, based on a lowest risk versus highest risk estimation

Fetal dose (mGy)	Low risk model	High risk model
10	1 in 4545	1 in 1667
20	1 in 2272	1 in 834
30	1 in 1515	1 in 556
40	1 in 1136	1 in 417
50	1 in 909	1 in 334

estimates of risk reflect a low risk versus the highest risk modelling based on available data (see Table 9.10.4) [30].

Perhaps, a simpler statistic is that quoted by Tirada *et al.* of an EAR of cancer following a **50 mGy** *in utero* exposure of 1.1–3.0 cases per 1000 patient exposures [8]. The data regarding the risk at different gestations and on various systems and organs is imprecise with wide confidence intervals owing to the low doses and the limited sample sizes in available studies [31].

Contrast Agents

A number of X-ray and CT procedures require the administration of iodine containing contrast agents. There are **no** reports of teratogenesis from iodinated contrast agents but the amount of inorganic iodine available to interfere with thyroid metabolism is about 0.1% of the dose administered. Non-ionic contrast agents have been shown to cross the placenta and inhibit type II and III deiodinases which can reduce intracellular triiodothyronine. In addition, depending on the dose of iodine, there is theoretical risk of fetal thyroid blockade, although this has not been reported to date. Breastfeeding may continue after administration of iodinated contrast as <0.01% of the maternal dose is absorbed by the feeding infant [4]. The use of gadolinium, although not teratogenic, has generated concern as gadolinium has been shown to cross the placental barrier and will remain in the amniotic fluid indefinitely with a potential for the toxic gadolinium ion to dissociate from its chelate molecule raising concerns of possible secondary adverse effects [5]. Expert bodies have concluded that the effects of MRI contrast agents remains unknown and may be harmful. There is no requirement to cease breastfeeding following the administration of gadolinium to a lactating woman as <0.0004% is transferred through breast milk [4].

Contrast enhance ultrasound is a technique that has been used in specific conditions to improve diagnostic information. Although the European Federation of Societies for Ultrasound in Medicine and Biology (EFSUMB) have recommended against its use because of limited experience, small studies in human pregnancy have demonstrated no harm [32, 33].

Stabin has published comprehensive data regarding interruption or cessation of breastfeeding following administration of nuclear pharmaceuticals [16].

Imaging for Specific Endocrine Conditions

Thyroid and Parathyroid

Thyroid ultrasound is the major modality used for thyroid imaging in pregnancy. It can allow detection of structures as small as 2 mm in diameter, in the thyroid or parathyroid glands. It can also be used to assess gland texture and blood flow.

In pregnant women with goitre, ultrasound may identify diffuse enlargement, non-palpable thyroid nodules, or much more rarely, features of lymphoma. It may also be used to detect or monitor lymph node status in patients with thyroid nodules, or suspected or known thyroid cancer.

In chronic autoimmune thyroid disease including Hashimoto's thyroiditis, Graves' disease, and subacute thyroiditis, the thyroid may be diffusely enlarged and have low echogenicity. In a study of subjects referred for ultrasound with goitre, thyroid dysfunction, neck discomfort, and/or difficulty in swallowing, hypoechogenicity was associated with a positive predictive value for autoimmune thyroid disease of 88.3% (85–91%) and a negative predictive value of 93% (88–98%) [34].

Thyroid ultrasound is the most accurate tool for detecting thyroid nodules, determining their sonographic features and pattern, monitoring growth, and evaluating cervical lymph nodes [35]. Certain sonographic patterns can be used to help predict the risk of malignancy [36] but with variable accuracy [37]. The American College of Radiology has introduced an imaging staging system called the Thyroid Imaging Reporting and Data System (TIRADS) [38]. TIRADS is based on ultrasonographic characteristics in the nodule to predict the risk of malignancy

Suspicious features include solid hypoechoic nodules, microcalcifications, irregular margins, a taller than wide shape, and absence of elasticity. For example, a sonographic pattern that includes solid hypoechoic nodules with irregular borders and microcalcifications correlates with a >70% risk of malignancy compared to a very low suspicion pattern of a noncalcified mixed cystic solid or spongiform nodule which has <3% cancer risk. Although some experts have recommended triaging the need for FNA based on ultrasound features and nodule size [35], the results of thyroid ultrasonography do not correlate perfectly with histopathologic findings [39] and are not adequate to replace cytologic examination for nodules >1–1.5 cm [40].

Thyroid ultrasound may be useful to assess for the presence of a toxic nodules or autoimmune thyroid disease but will not differentiate the various autoimmune causes of hyperthyroidism. Colour flow doppler imaging (CFD) with measurement of peak systolic, end diastolic, and mean velocities of inferior thyroid artery may offer additional clinical information. In one study CD was found to have a sensitivity of 88.9% (67.2–96.9%) and specificity 87.5% (52.9–97.8%) to differentiate between Graves' disease (increased vascularity) and thyroiditis (low vascularity) when compared with thyroid scanning by technetium-99m pertechnetate (^{99m}Tc) [41]. In pregnancy, CFD is a cheap simple technique with no ionizing radiation exposure and is cost-effective in the diagnosis of thyrotoxicosis.

In pregnant women with Graves' disease, ultrasonography of the fetal thyroid gland is an excellent diagnostic tool that can facilitate assessment of fetal thyrotoxicosis or goitre [42, 43]. Ultrasound may also be used to monitor fetal growth and well-being as well as features of fetal thyroid hormone dysfunction. Different expert bodies have suggested fetal monitoring in all cases of Graves' disease [44] while the ATA guideline only recommends monitoring in women with uncontrolled hyperthyroidism in the second half of pregnancy, and in women with high thyrotropin receptor antibody (TRAb) levels detected at any time during pregnancy (greater than 3 × the upper limit of normal) [36].

Nuclear Scanning for Thyroid Disease in Pregnancy

Thyroid nuclear scans are useful in the assessment of thyrotoxicosis, thyroiditis, the assessment of thyroid nodules, and goitre. In view of the potential radiation risks to the fetus, and the availability of other diagnostic approaches, nuclear scanning of the thyroid is generally avoided in pregnancy [36]. However, inadvertent scans do occur in early pregnancy and the following data is helpful when counselling such women.

Scintigraphy utilizes one of the radioisotopes of iodine (usually ^{123}I) or ^{99m}Tc. Fetal dose estimates from maternal thyroid nuclear scanning vary depending on the technique used. Motavalli has calculated fetal estimated doses of 5.52 mGy in early pregnancy and 0.66 mGy in later pregnancy from ^{99m}Tc thyroid scanning and 0.31 mGy (early) and 0.51 mGy (late pregnancy) with ^{123}I thyroid scanning [15]. In all cases, ^{123}I will produce a significantly greater fetal thyroid dose if administered after 12 weeks and therefore ^{99m}Tc is the preferred technique if thyroid scanning is required. Imaging with ^{99m}Tc should be delayed until after the first trimester because of the significant decrease in fetal dose.

CT, MRI, and Positron Emission Tomography (PET) and Thyroid Cancer

Although ultrasound is the main imaging modality used for thyroid assessment, in certain circumstances further diagnostic imaging is required. Preoperative ultrasonography of the central and lateral neck identifies abnormal lymph nodes in as many as 20–30% of patients and this may alter the planned surgical procedure [45, 46]. However, ultrasonography can miss as many as 50% of the involved lymph nodes in the central neck because the overlying thyroid gland hinders adequate visualization. In addition, patients with lymphadenopathy or other evidence of extensive lymph node involvement may have nodal involvement in regions inadequately evaluated with ultrasound (e.g. mediastinal, infraclavicular, retropharyngeal, or parapharyngeal lymph node chains). In addition, if there are signs or symptoms of locally invasive disease or if ultrasound suggests extrathyroidal extension, further perioperative imaging is indicated.

In these circumstances, CT or MRI imaging with intravenous contrast of the central and lateral neck is recommended [35]. In pregnancy, this will generally be performed with MRI although the fetal radiation dose from CT in this region is very low at all stages of pregnancy. Although positron emission tomography (PET) with the radioisotope fludeoxyglucose (^{18}FDG) is sometimes used for the assessment of thyroid nodules outside of pregnancy it is not recommended during pregnancy [35].

Parathyroid Disease

If hyperparathyroidism is suspected in pregnancy, imaging for localization and surgical planning may be required. The safety and success of minimally invasive and selective techniques for parathyroid exploration is dependent on accurate preoperative localization of the affected gland. There is no universally accepted algorithm for imaging of the parathyroid glands, and the choice of imaging approach is largely based on surgeon preference and local expertise.

In pregnancy, neck ultrasonography is preferred for parathyroid localization. The ultrasound characteristics of parathyroid adenomas include homogeneous hypoechogenicity and an extrathyroidal feeding vessel with peripheral vascularity seen on CFD. Ultrasound is operator dependant but in experienced hands, the sensitivity is excellent with a reported ability to localize the adenoma to a specific quadrant of the neck in 87% of cases and to a specific side of the neck in 94%. Sensitivity was not reduced by the presence of nodular disease of the thyroid gland [47]. Disadvantages to the use of ultrasound alone include decreased accuracy in patients with smaller parathyroid gland size, obesity, or mediastinal glands located behind the clavicles [48].

In the non-pregnant population technetium-99m scintigraphy (^{99m}Tc sestamibi) scanning combined with single photon emission computed tomography (SPECT) has the highest positive predictive value for localizing parathyroid tumours **Table 9.10.5** [49]. The estimated of fetal radiation dose from this procedure can be calculated based on the administered dose and the estimated fetal dosimetry at that stage of pregnancy [50]. If nuclear imaging of the thyroid is the only appropriate technique, a medical physicist should be consulted to calculate the potential fetal dose and allow appropriate counselling. In addition to SPECT, a subtraction thyroid scan, or fusion with computed tomography images (MIBI-SPECT-CT) may be useful, especially if there is concurrent nodular thyroid disease [51]. Other modalities such as four-dimensional computed tomography, MRI, or PET-CT may be required but have not been reported in pregnancy [49].

Adrenal Disease/Masses

In the course of obstetric ultrasound, occasionally adrenal masses will be detected. In most cases, adrenal 'incidentalomas' are non-functioning adrenocortical adenomas, but may also represent conditions requiring therapeutic intervention (e.g. adrenocortical carcinoma, phaeochromocytoma, hormone-producing adenomas, or metastases). The European Society for Endocrinology (ESE) along with the European Network for the Study of Adrenal Tumours have recently published guidelines which recommended aiming to establish if an adrenal mass is benign or malignant at the time of initial detection [52].

Although the visualization of retroperitoneal structures is difficult on US, it still has a role in incidentally detecting adrenal masses and in monitoring changes during treatment of already established

Table 9.10.5 Diagnostic accuracy of imaging modalities for preoperative parathyroid localization. SPECT: sestamibi-single photon emission computed tomography; CT: computed tomography; MRI: magnetic resonance imaging; N/A: not applicable; MET-PET-CT scan: 11C-methionine positron emission tomography and computed tomography

Imaging modality	Sensitivity (%)	Positive predictive value (%)
^{99} Tc Sestamibi	71–79	72–95
^{99} Tc Sestamibi-SPECT	70–81	91–95
Ultrasound	64–91	83–96
4D-CT	83–95	88–99
MRI	40–85	N/A
11C-methionine PET/CT	79–90	93–94

pathology. Contrast-enhanced ultrasonography using phospholipid stabilized microbubbles filled with sulphur hexafluoride is comparable to CT and MRI for detection of adrenal malignancy with sensitivity of 100% and specificity of 82% [53]. Outside of pregnancy, the recommended imaging is with non-contrast CT assessing for tissue density. Studies have shown the optimal sensitivity (71%) and excellent specificity (98%) for differentiating benign from malignant adrenal masses is achieved using a threshold attenuation value of 10 Hounsfield units (HU) on non-contrast CT [54]. This implies that some 30% of benign adenomas have an attenuation value of >10 HU and will not be distinguishable from malignant lesions or phaeochromocytomas. In pregnancy, non-contrast CT of the adrenals would potentially result in a fetal dose of up to 10 mGy [16].

In pregnancy, assuming a low likelihood of malignancy, the ESE recommend MRI with chemical shift imaging, a non-contrast technique to assess lipid content. The normal adrenal has low to intermediate signal intensity on both T_1- and T_2-weighted sequence. During chemical shift imaging, a drop in signal intensity has sensitivity (81–100%) and specificity (94–100%) similar to unenhanced CT densitometry for the differentiation of incidental adrenal lesions (**Figure 9.10.1**) [55]. For lipid-rich adenomas, there is effectively no difference between CT and MRI. When evaluating lipid-poor adenomas, CSI might be superior although quantitative assessment of loss in signal intensity is not well standardized meaning the interpretation of the images might be more dependent on the experience of the radiologist. Accuracy may be improved by sampling the in-phase and opposed-phase echoes in the correct order and during the same breath-hold and using the first echo pair [56]. If malignancy is suspected, imaging should be optimized to enhance diagnosis including CT and or ^{18}FDG PET (estimated fetal dose 7 mSv) combined with CT (estimated fetal dose up to 10 mSv).

In the special case of phaeochromocytoma, imaging should only be performed where the clinical picture and biochemical findings are suggestive of this rare diagnosis. If suspected, localization is critical. About 95% are within the abdomen and pelvis, with only 10% being extra-adrenal, usually in the superior and inferior abdominal para-aortic areas. In pregnancy, ultrasound and MRI are again the preferred modalities although if not definitive, then multidetector CT or nuclear scanning may be required because of the critical nature of the diagnosis.

On MRI most phaeochromocytomas demonstrate high signal intensity on T_2-weighted images, described as a 'light bulb' and regarded as characteristic for phaeochromocytoma. (**Figure 9.10.2**) [57]. However, recent studies found that 30% of phaeochromocytomas demonstrate intermediate to low signal on T_2-weighted images or are inhomogeneous secondary to haemorrhagic [58]. Ultrasound has proved its accuracy in detecting phaeochromocytoma confined to the adrenal, as these are usually large and well-marginated masses. However, ultrasound has a limited role in detecting small adrenal tumours and extra-adrenal phaeochromocytomas such as those found in the retroperitoneum [53].

Nuclear medicine imaging can be used when CT or MRI does not demonstrate a mass in patients with high index of suspicion. Meta-iodo-benzylguanidine (MIBG) labelled with ^{131}I has sensitivity of 80–90% for detection of a phaeochromocytoma with a specificity of 90–100%. A minority (25%) of phaeochromocytomas are not detected by MIBG scanning but may be seen using ^{111}In octreotide.

For malignant phaeochromocytomas, ^{18}F-fluoro-dopamine positron emission tomography appears to be very helpful [53]. More recently, positron-emitting radiolabelled somatostatin analogues have emerged which, in combination with high-resolution PET integrated with CT (PET/CT), may improve the detection and staging of a variety of neuroendocrine tumours, including paraganglioma. Estimates of fetal radiation doses from these procedures have not been published but can be calculated if the procedures were considered essential.

In a systematic review of published cases of phaeochromocytoma in pregnancy, imaging modalities used during pregnancy included MRI 36%, ultrasonography 26%, MRI and ultrasonography 30% and CT plus one of the above 9% [59].

Pituitary Disease

The investigation of suspected pituitary masses, hypophysitis, tumours, or monitoring of existing pituitary tumours requires an appreciation of the normal anatomical changes of the pituitary throughout pregnancy. The size of the pituitary gland increases in three dimensions with a maximum volume in the first three postpartum days, returning to normal within 6 months [60]. Asymmetrical growth, deviation of the stalk, and height greater than 9–10 mm during pregnancy are not normal and should be further investigated [10]. The enlargement of the pituitary makes assessment of microadenomas more difficult. Monitoring of existing macroadenomas for growth, infarction, or haemorrhage is generally only performed if symptoms consistent with visual field impairment or, rarely, pituitary apoplexy occur.

The mainstay of imaging of the pituitary in pregnancy is non-contrast MRI. Normal pituitary tissue and most sella lesions, pituitary adenomas, and other tumours, have a signal that is similar to or slightly greater in intensity than that of central nervous system tissue. Cystic lesions, such as Rathke's cleft cysts, often have a low-intensity signal on T_1-weighted images and high intensity on T_2-weighted images. Haemorrhage into the pituitary gland results in a high-intensity signal on both T_1- and T_2-weighted images.

Imaging for Sheehan's syndrome will usually reveal an empty or partially empty sella with a normal sella size. Pituitary MRI is the most sensitive method of imaging, but CT may also be helpful. In the early stages, the pituitary gland shows non-haemorrhagic enlargement. Subsequently, the gland atrophies, and an empty sella develops.

Lymphocytic hypophysitis is characterized by diffuse, symmetrical pituitary enlargement, thickening of the pituitary stalk without deviation, and uniformly flat sella floor. Without contrast, the characteristic enhancement of the gland, and loss of the neurohypophyseal 'bright spot' will not be evident. MRI is also able to detect blood if pituitary haemorrhage is suspected. CT of the pituitary may be useful to assess calcification (e.g. with suspected craniopharyngiomas). Although MRI is the gold standard imaging

modality for the diagnosis of sella/suprasella lesions, some surgeons recommend additional imaging with thin-cut CT through the sella/sphenoid region and/or CT angiogram for preoperative planning and intraoperative navigation. Pituitary surgery is rarely required in pregnancy, but CT can safely be performed in the head as fetal radiation dose is minimal and in these circumstances, the use of iodinated contrast would be appropriate to optimize surgical planning [61, 62].

Multiple Endocrine Neoplasia and Pregnancy

Imaging for multiple endocrine neoplasia (MEN) syndromes may be required during pregnancy because of elevated biochemical markers or symptoms/signs of tumour (Figure 9.10.3). A number of these tumours may significantly impact pregnancy and urgent investigation is required if this is suspected. In the rare case when a MEN syndrome is suspected in pregnancy, multiple imaging may be required and should be performed in a timely manner. The specific imaging required will depend on the results of symptoms, signs, and biochemical testing, and multidisciplinary input is required.

Osteoporosis and Associated Syndromes

The standard screening test for osteoporosis is dual X-ray absorptiometry (DEXA). Studies (using phantoms) of DEXA of the posteroanterior lumbar spine/proximal femur during pregnancy generated estimated radiation doses of 1.7/2.7 mGy in the first trimester, 1/4/2.7 mGy in the second trimester, and 1.0/4.9 mGy in the third trimester. These were all well below the 10 mGy counselling threshold [63].

Investigation of suspected osteoporotic or stress fractures in pregnancy may require a range of imaging options. Reluctance to image pregnant patients due to concerns over radiation exposure is a major factor contributing to the delayed diagnosis of osteoporotic related fractures in pregnancy. In transient osteoporosis of pregnancy, plain X-rays may be normal initially, with a lag of weeks to months before osteopenia can be demonstrated. Osteopenia differentiates transient osteoporosis and other bone marrow oedema syndromes. Plain X-ray provides an overview of the region of concern and assessment of alignment, and allows screening for other causes of pain such as bone tumour.

MRI can be used for safe and reliable imaging in situations where multiple x-rays are required (e.g. for oedema), or if the initial X-rays are normal but there is suspected non-displaced fracture [64–65]. Although altered gadolinium enhancement may be seen in osteonecrosis of the femoral head (OFNH), the use of gadolinium is not recommended in pregnancy.

A bone scan with ^{99m}Tc m-methylene diphosphonate (MDP) may give a fetal absorbed dose up to 4.7 mSv in early pregnancy but much less in late pregnancy (1.8 mSv) and if clinically indicated, should be performed [16]. One of the main indications for further imaging in the setting of pregnancy is to differentiate hip pain due to transient osteoporosis of pregnancy (TOP) from ONFH. In early stages of the disease, X-ray findings will be indistinguishable [66]. ONFH is an idiopathic form of avascular necrosis which exhibits lack of uptake on bone scan and may show a characteristic 'double line sign' on MRI. In contrast, MRI of TOP shows diffuse homogenous marrow oedema of the involved segment. The appearance is not specific with radiological differentials including transient bone marrow oedema (without osteoporosis), osteonecrosis, infection, and tumour infiltration. If diagnosed early, ONFH may be amenable to a core decompression or revascularization procedures to avoid progression to arthritis.

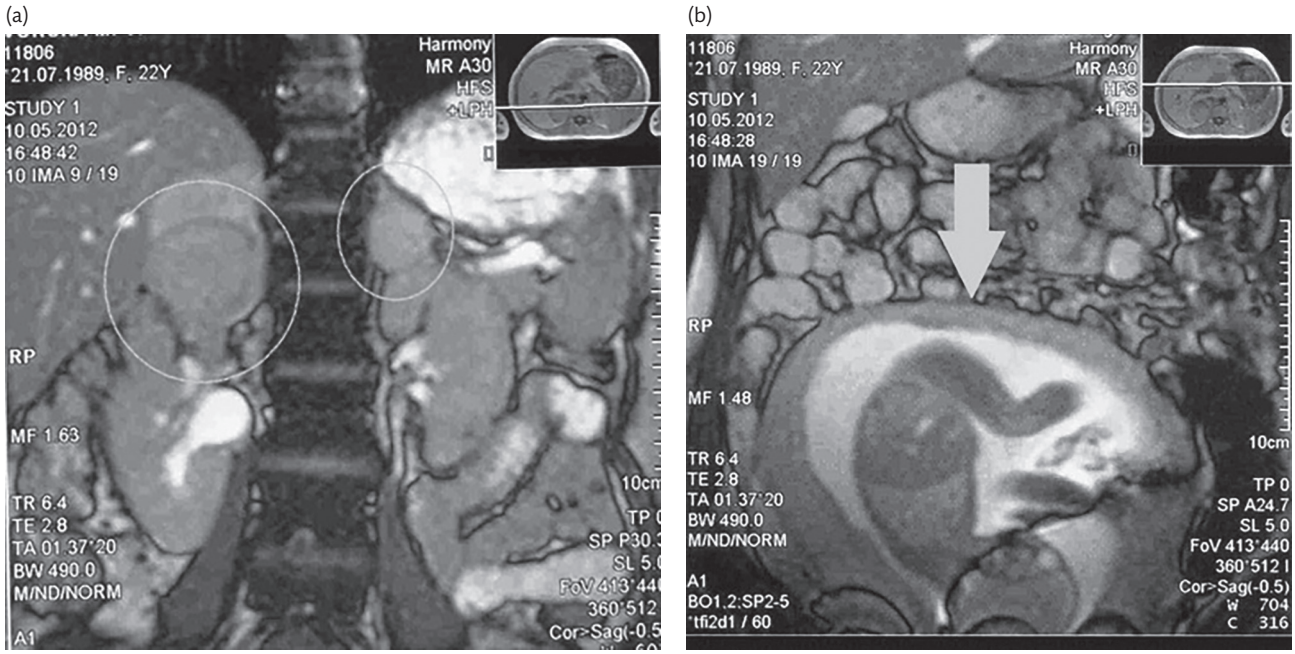

Figure 9.10.3 MRI of a women with MEN 2A at 27 weeks' gestation demonstrating bilateral adrenal tumours. These were proven to be phaeochromocytomas measuring 4 × 2.3cm on the left and 6.4 x 4.4 cm on the right. Below is an MRI of her fetus at the same examination.

Counselling for Diagnostic Imaging for Endocrine Conditions in Pregnancy

Informed consent for X-ray, CT, MRI, or nuclear scanning will be required if these investigations are ordered during pregnancy or breastfeeding. Counselling should be provided initially by the clinician ordering the investigation and then by the radiologist/nuclear physician performing the procedure. All involved allied staff must also be well informed to ensure the patient receives a consistent message about the risks and benefits of the proposed test(s).

Whether particular institutions use written consent forms or verbal consent, this interaction should be documented in the patient's medical record and in compliance with local law. The American College of Radiology provides a sample consent from which may be useful to your Institution [21].

For practical purposes, no specific counselling is required for women undergoing diagnostic imaging with a predicted fetal absorbed dose of less than 10 mGy. This includes all X-ray and CT scanning not involving the abdomen and most nuclear scans. For direct exposures or nuclear scanning with a potential exposure >10 mGy, the women should be counselled on a risk/benefit basis. The specific risk appears to be childhood malignancy, but, as described earlier, for each 10 mGy exposure, theoretical projections based on a LNT assumption indicate a likely **maximum risk** of 1 additional case of childhood cancer (not death) per 1700 exposures of 10 mGy [23]. This must be balanced against the benefit of the imaging or treatment in terms of management of the maternal condition.

There are no diagnostic imaging procedures that can be considered a risk factor for genetic damage, malformation, or neurodevelopmental effects based on current knowledge. It is particularly important to liaise with the radiologist or nuclear physician to ensure the most appropriate imaging is performed to obtain maximal information with minimal fetal absorbed dose. If possible, diagnostic imaging should be delayed until after delivery if the information is not likely to alter immediate management.

Summary

The detailed review of medical imaging in pregnancy given in this chapter should prevent the reflex 'no radiation' approach to selection of diagnostic imaging modalities in pregnancy. As in the non-pregnant subject, the principle of 'as low as reasonably achievable' (ALARA) should be applied in the pregnant subject, ensuring that non-ionizing radiation options are considered first. In almost all cases, radiation and contrast risks are negligible and therefore the most sensitive and specific imaging should be performed at the most appropriate time, whether during or after pregnancy where applicable. However, when X-ray, CT, nuclear scan, or ET are the most suitable modality; these should be applied with appropriate care and counselling. As pointed out by Zanotti-Fregonara, 'pregnant women should be imaged using the standard imaging protocols used for any other patient' [17]. The American College of Radiology particularly note that 'It is best to create written protocols for all imaging of pregnant patients to avoid reactive, non-optimal protocol adjustments by physicians attempting to reduce radiation exposures' [21]. If dose reduction strategies that do not compromise image quality are available for pregnant women, then these strategies should be used for all patients [17].

Endocrine conditions during pregnancy may require a range of imaging techniques but with care and consideration, an appropriate diagnostic and management plan can be achieved if required.

SECTION 10

Male Reproductive Endocrine Disorders

10.1

Normal Male Reproductive Endocrinology

10.1.1 Endocrine and Local Regulation of Testicular Hormone and Sperm Production

Ilpo Huhtaniemi and Jorma Toppari

Introduction

The two main functions of the testis are androgen production and spermatogenesis, and the key role in their **endocrine** regulation is played by the two pituitary gonadotrophins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Other hormones and growth factors also influence testicular function, often by modulating gonadotrophin action. In addition, a plethora of other bioactive molecules mediate regulatory signals within and between the testicular cell compartments. They can be **paracrine** (between two dissimilar neighbouring cells), **autocrine** (the same or a similar cell is the origin and target of the regulating factor) or **intracrine** (the factor functions within the cell of its synthesis without being secreted). The main testicular hormone is testosterone (T), a product of Leydig cells located in the testicular interstitial cell compartment. T regulates spermatogenesis that takes place in testicular seminiferous tubules in paracrine and indirect fashion, by stimulating the functions of Sertoli cells in the adjacent seminiferous tubules. Following its secretion into the peripheral circulation, T exerts its endocrine actions, androgenic and anabolic, in various extratesticular tissues.

Endocrine Regulation of Testicular Function

The Hypothalamic–Pituitary–Testicular (HPT) Axis

The HPT axis is a typical endocrine regulatory circuit with hierarchical cascades of forward and feedback regulatory events (Figure 10.1.1.1). According to the classical concept, specific hypothalamic nuclei synthesize the decapeptide gonadotrophin-releasing hormone (GnRH). Axon terminals of the GnRH neurons make contact in the median eminence with hypophyseal portal vessels, which transport GnRH to the anterior pituitary gland where it stimulates the synthesis and secretion of LH and FSH [1, 2]. These two gonadotrophins are the key endocrine regulators of testicular function.

Several other hypothalamic hormones regulate the maturation and fine-tuning of GnRH neurons [3], including glutamate and γ-aminobutyric acid (GABA), and a plethora of neuropeptides such as neuropeptide Y, galanin-like peptide, opioid peptides, and orexins. Most importantly, however, it has been recently discovered that the GnRH neurons are under regulation of an upstream neuronal system where the gatekeeper role is played by the neuromodulatory peptide kisspeptin, encoded by the *KISS1* gene (Figure 10.1.1.1) [4]. Some kisspeptin neurons coexpress neurokinin B and dynorphin, and are hence collectively termed kisspeptin-neurokinin B-dynorphin (KNDy) neurons [5]. Kisspeptin functions through a G-protein-coupled receptor (GPCR) originally called GPR54, but now termed

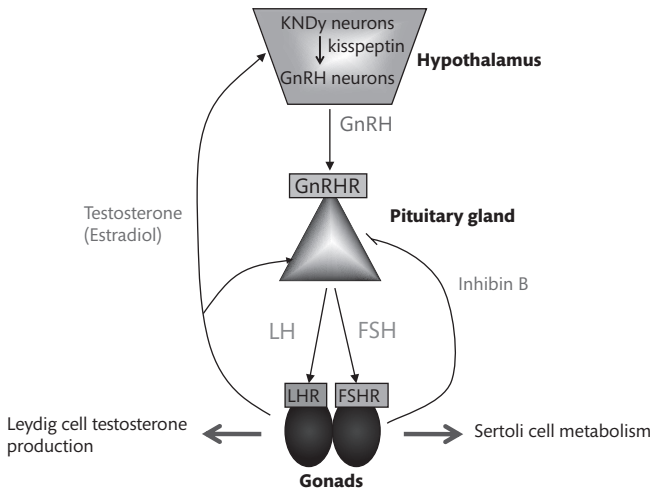

Figure 10.1.1.1 The hypothalamic–pituitary–testicular (HPT) axis. The main hormones functioning in the axis are depicted, as well as the functions of LH and FSH in the testis. GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; FSH, follicle-stimulating hormone; KNDy, kisspeptin/neurokinin B/dynorphin; inhibitory signal, ⟍, stimulatory signal ⟶.

KISS1R, expressed in GnRH neurons, where its activation stimulates *GnRH* expression.

The *GnRH* gene encodes a propeptide that is cleaved into a 24-amino acid signal peptide, the GnRH decapeptide, and a 56 amino acid GnRH-associated peptide. GnRH is secreted in short pulses of varying amplitude, in adult men with 1–2-hour interval. A recent study has demonstrated that kisspeptin neurons in the hypothalamic arcuate nucleus may be the anatomic site of the GnRH pulse generator [6].

GnRH interacts in the anterior pituitary gonadotroph cells with a high-affinity receptor (R) belonging to the GPCR gene family. Pulsatile GnRH secretion is vital for GnRHR activation, since tonic GnRH stimulation (e.g. during GnRH agonist treatment) downregulates the GnRHR signalling, thus suppressing gonadotrophin synthesis and release. The secretory peaks of LH are more distinct, due to their shorter half-life than those of FSH in the systemic circulation. Pulsatile release, however, is not important for gonadotrophin action at the gonadal level.

Both LH and FSH are glycoproteins with molecular mass of 30–40 kDa. They are synthesized in pituitary gonadotroph cells as heterodimers of the common α-subunit and a hormone-specific β-subunit (**Figure 10.1.1.2a**). More extensive glycosylation of FSH makes its half-life longer vis-à-vis LH (3–4 h vs. 20 min). In addition, the carbohydrate side chains in LH are heavily sulphated (50%), and there is a specific hepatic receptor for sulphated glycoproteins accelerating their elimination [7].

Like their ligands, the receptors (R) for LH and FSH are structurally related glycoproteins with a molecular mass of about 80 kDa, and belong to class A rhodopsin-like GPCRs (**Figure 10.1.1.2b**) [8, 9]. The molecular events mediating the actions of LH and FSH on Leydig and Sertoli cells, respectively, are in principle similar [8, 9]. The main, and most extensively studied signalling mechanism uses the classical adenylyl cyclase/cAMP/G-protein cascade, but other signalling mechanisms are also employed in gonadotrophin action; further details are presented in **Figure 10.1.1.3a**.

In Leydig cells, cell differentiation, growth, and steroidogenesis entail the important responses to LH stimulation. FSH function in the testis is age-dependent, and in prenatal and prepubertal life, it stimulates Sertoli cell proliferation. This influences fertility, since the Sertoli cell number correlates with total length of the seminiferous epithelium and testicular sperm production capacity. In adulthood FSH maintains the functions of Sertoli cells thus indirectly supporting spermatogenesis.

The reverse side of the HPT function is the negative (inhibitory) feedback of gonadal steroid and peptide hormones at the hypothalamic and pituitary levels, to maintain a physiological balance of gonadotrophin secretion (**Figure 10.1.1.1**) [1, 2]. T, partly after conversion to oestradiol, exerts its negative feedback action on GnRH secretion indirectly through KNDy neurons, by suppressing kisspeptin and neurokinin B release, since GnRH neurons do not express sex steroid receptors [4]. Sex steroids also directly suppress gonadotrophin synthesis in the pituitary gland [10]. Although testicular steroids also regulate FSH, this hormone is mainly under negative control at the pituitary level by Sertoli cell-derived inhibin B, a glycopeptide hormone of the TGF-β family (see next) (**Figure 10.1.1.1**).

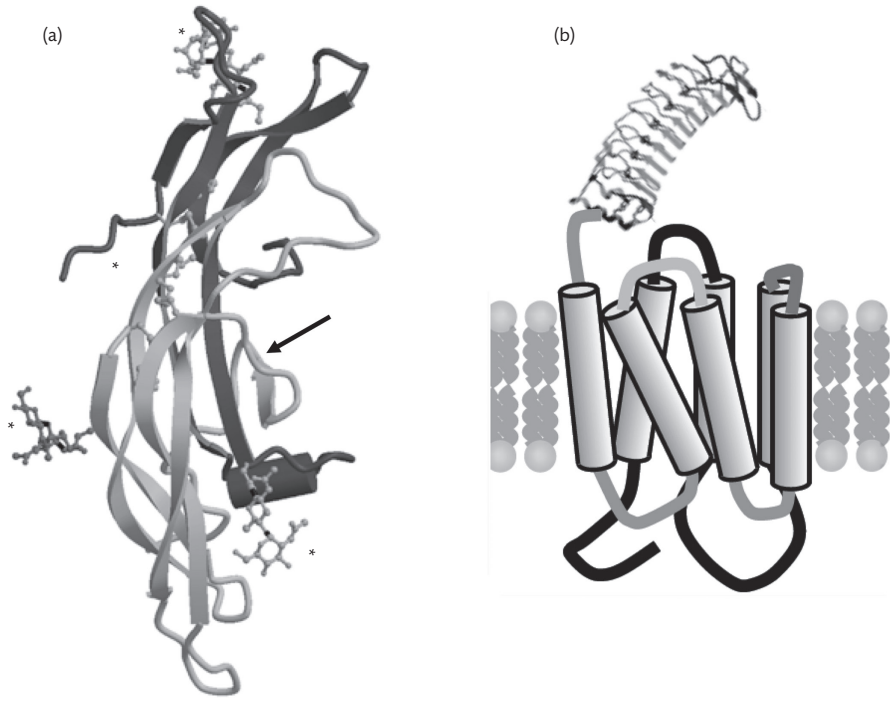

Figure 10.1.1.2 Schematic 3D structures of LH (a) and LHR (b). In panel A black colour depicts the α-subunit (CGA) and dark grey colour the β-subunit (LHB). The arrow points to the 'seat belt' structure of the β-subunit, which stabilizes the dimeric structure of the hormone. The asterisks depict the carbohydrate moieties attached to the hormone molecule. In panel B, the structure in the top part depicts the leucine rich repeats of the extracellular receptor domain, which forms the primary binding site of the hormone. The cylindrical structures in the middle of the picture depict the seven transmembrane domains of the receptor molecule. *For a colour version of this figure, please see colour plate section.*

Figures are courtesy of Drs. J. Dias and E. Reiter.

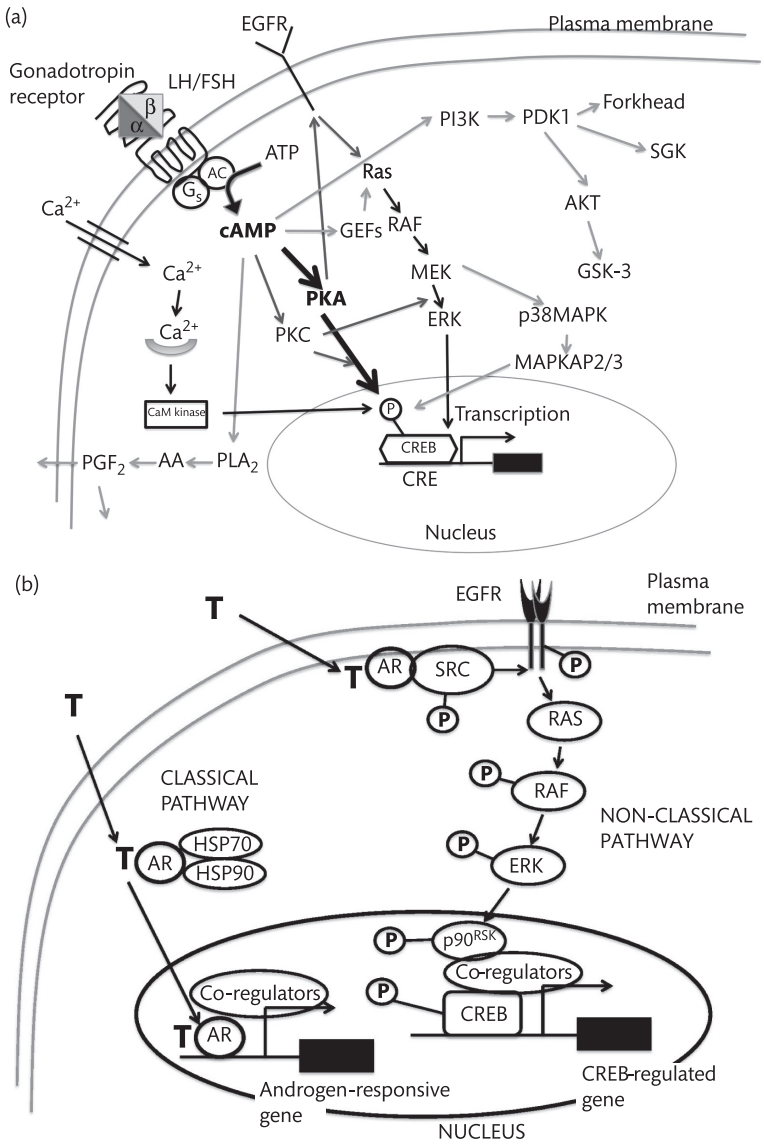

Figure 10.1.1.3 The main signalling cascades employed in LH and FSH action. Black arrows depict pathways common for both hormones, red arrows those specific for LH and light grey arrows those specific for FSH. AA, arachidonic acid; AC, adenylyl cyclase; ATP, adenosine trisphosphate; CaM, calmodulin; cAMP, cyclic adenosine-3':5'-monophosphate; CRE, cAMP response element; CREB, cAMP response element binding protein; EGFR, epidermal growth factor receptor; ERK, extracellular signal-regulated kinase; Forkhead, forkhead transcription factor; GEF, guanine nucleotide exchange factor; G_s, stimulatory guanine nucleotide binding protein; GSK-3, glycogen synthase kinase-3; MEK, mitogen/extracellular signal-regulated kinase; PDK1, phosphoinositide-dependent protein kinase; MAPK, mitogen activated protein kinase; MAPKAP, MAPK activated protein kinase; PGF_2, prostaglandin F_2; PI3K, phosphoinositide 3 kinase; PKA, protein kinase A; PKC, protein kinase C; PLA_2, phospholipase A_2; RAF, rapidly accelerated fibrosarcoma—Ser/Thre specific protein kinase; Ras, small GTPase family; SGK, serum glucocorticoid-regulated kinase. *For a colour version of this figure, please see colour plate section.*

Effects of Other Hormones on Testicular Function

Besides LH and FSH, several other circulating hormones affect testicular function. Since many 'extragonadal' hormones are also synthesized within the testis, it is difficult to delineate whether their testicular actions, mostly documented *in vitro*, are endocrine or para/autocrine *in vivo*.

Prolactin regulates Leydig cell function in rodents, but whether it has direct effects on the human testis remains unclear. Hyperprolactinaemia in man impairs testicular function, most likely indirectly through inhibitory action of prolactin on gonadotrophin secretion (see chapters in Section 10.3.2, 'Adult Hypogonadism: Aetiology').

Growth hormone (GH) stimulates the formation of insulin-like growth factor-I in the testis. Evidence for testicular effects of GH/IGF-1 comes from observations in rodents that GH deficiency or resistance are associated with delayed puberty and poor Leydig cell function.

Insulin receptors are found in Leydig cells, insulin and LH reciprocally upregulate the receptor of each other, and insulin augments basal and LH-stimulated Leydig cell steroidogenesis [11].

Thyroid hormones have an important role in the maintenance of Leydig cell steroidogenesis [12]. They increase, in additive fashion with LH, the level of steroidogenic acute regulatory protein (StAR) expression in Leydig cells. Without optimal thyroid hormone action, the steroidogenic capacity of Leydig cells is severely compromised.

Two hormones important in bone metabolism, osteocalcin, and vitamin D, may also have direct testicular effects. The former stimulates Leydig cell T production in rodents [13], and the latter may improve semen quality in humans [14].

Steroid hormones also modulate Leydig cell functions. Androgen and oestrogen receptors are expressed in Leydig cells, and thus these hormones can have para/autocrine regulatory effects in their site of synthesis [15, 16]. Glucocorticoids of adrenal origin also influence the endocrine regulation of the testis [17]. High systemic glucocorticoid levels, for example, in Cushing's syndrome and during physical and mental stress, suppress Leydig cell androgen production by inhibiting the conversion of cholesterol to steroid hormones.

Despite direct testicular actions of numerous blood-borne non-gonadotrophic hormones, their physiological role remains obscure and the dogma still prevails that gonadotrophins provide the main driving force for testicular function. The role of the other regulators is likely to fine-tune gonadotrophin actions.

Testicular Hormone Production

Testicular Steroidogenesis
