PREFACE

The amount of published information about fractures in skeletally immature patients has grown exponentially over the past 5 years, and a number of areas of controversy have been further defined by advocates on both sides of the issues. We have tried to ensure that this edition reflects the current consensus and presents all relevant information so that readers can make informed decisions about fracture management. One of our goals in this edition of *Fractures in Children* was to decrease the overall size of the book, while increasing the amount of information on the critical areas of operative techniques and management of complications while retaining pertinent information about anatomy, etiology, diagnosis, and treatment options. The format of the book, including layout and illustrations, has been updated to be more "user-friendly," and a number of new contributors have been added, each of whom brings their own expertise and experience to the text. As with earlier editions, our purpose is to provide a text that will be useful to medical students, residents, and practicing orthopaedists and will ultimately help ensure that children with musculoskeletal injuries receive the best possible treatment.

James H. Beaty, M.D.
James R. Kasser, M.D.

ACKNOWLEDGMENTS

The publication of this text was the culmination of several years of effort by many people. Without the contributing authors, this volume would not have been possible. They were generous with their time and their knowledge and worked hard to produce excellent chapters. We are most appreciative of their efforts.

The staff at Lippincott Williams & Wilkins provided expert guidance and support, as well as encouragement when needed. Bob Hurley, Susan Rhyner, Julia Seto, and Christopher Granville were always willing to go to extra lengths to make sure deadlines were met and quality standards were maintained. We appreciate their professional acumen that made our job easier, their patience with delays, and their aplomb during potential disasters.

In addition, a number of people at each of our institutions were instrumental in the hands-on production of this text. From the Campbell Foundation in Memphis, Kay Daugherty (Editorial), Barry Burns (Graphics), and Joan Crowson (Library) provided invaluable assistance. From Boston, Theresa Medua (Secretarial) and Alison Clapp (Library).

To those most personally affected by our undertaking of this project —our families—we express heartfelt thanks for their understanding and support during the countless nights and weekends that were consumed by our work on the book. Our wives, Terry Beaty and Candace Kasser, deserve special recognition for always believing we could do this and for supporting us through the long months of production.

DEDICATION

We dedicate this edition of *Fractures in Children* to Charles Rockwood and Kaye Wilkins who began this extraordinary text almost 20 years ago. The addition to the legendary *Rockwood and Green's Fractures in Adults* of a volume focusing specifically on children's fractures expanded the scope of information and provided a much needed compendium on the treatment of fractures involving the immature skeleton. Had these two men not had the foresight and fortitude to embark on that first edition and the dedication to produce subsequent editions, those who treat musculoskeletal injuries in children would not have had this valuable resource. We have been inspired by their example and hope to help continue the tradition they began. In honor of their tremendous contributions, this volume, and all subsequent editions, will be titled *Rockwood and Wilkins' Fractures in Children*.

1
THE PRESENT STATUS OF CHILDREN'S FRACTURES

KAYE E. WILKINS
ALARIC J. AROOJIS

In the past generation there have been many changes in how fractures in children are handled. This has been the result of many factors. First, there has been a drastic change in the dissemination of information regarding the management of children's fractures. Second, there has been a change in the philosophy of how fractures are treated, with more emphasis on operative management. Third, there has been a change in the incidence of fractures in the United States and Europe. Fourth, and finally, in a modern North American environment, there have been changes in the etiology of fractures in children. Each of these factors will be discussed as a separate section in this chapter. The first two factors will be discussed briefly. The third and fourth factors will be discussed in more detail.

The whole goal in studying the incidence of children's fractures is to develop preventative strategies. The experience of others in this aspect will be discussed in the fifth section of this chapter.

THE INFORMATIONAL CHANGES

Single-Authored Texts

At the turn of the century the major fracture texts were authored by single individuals who used their own personal experience as their major reference source. In the more popular single-authored texts by Stimson (10), Scudder (9), and Cotton (3), the trend was to discuss both adult and children's fractures in the same sections on a geographical basis; for example, fractures about the elbow. This single-authored text concept continued into the late 1950s and early 1960s, with the most popular texts of that period being those by Bohler (2), Key and Conwell (4), and Watson-Jones (11).

Multiauthored Texts

With the explosion of orthopaedic knowledge and the development of regional anatomic orthopaedic specialization, it became impossible for one author to produce a fracture text that was all-encompassing. Thus began the trend toward multiauthored fracture texts with two to three editors. The first to start this trend in fracture texts in North America were Charles Rockwood and David Green, who produced the first edition of their multiauthored textbook *Fractures* in 1975 (7). A year later, Wilson had revised Watson-Jones' text with some multiple authors (12). In this text, Chapter 17, authored by Anthony Catterall, focused on children's fractures. The first edition of *Fractures* by Rockwood and Green did not include children's fractures.

Exclusive Children's Fracture Texts

In North America, one of the pioneers in fracture treatment in children was Walter P. Blount, who in 1955 was the first to author a textbook devoted exclusively to children (1). His philosophy of nonoperative management set the standard for treating children's fractures for more than a generation. Almost 20 years later, Mercer Rang authored another textbook devoted exclusively to children's fractures (6). His book has served as a standard reference for the treatment of children's fractures to this day.

Multiauthored Children's Fracture Texts

Again, it soon became impossible for one person to author a textbook on children's fractures that covered each fracture type and its treatment in sufficient detail to satisfy the demands of the present-day orthopaedic surgeon. Thus evolved the multiauthored text on children's fractures. The first edition of a textbook of this type was added as volume III to the two volumes of *Fractures in Adults,* edited by Rockwood and Green in 1984 (8). This multiauthored concept of textbooks on children's fractures has been followed by many other excellent texts. These multiauthored textbooks have been well received; they are now in subsequent editions. These present-day textbooks now serve as a single encompassing reference source for the physician who treats children's fractures.

Emergence of Pediatric Orthopaedics

Consolidation of Information

Pediatric Orthopaedic Journals

In the past, information regarding the management of children's fractures was interspersed in journals and meetings dealing with general orthopaedics. In 1981, *The Journal of Pediatric Orthopedics* was established by Lynn Staheli and Robert Hensinger, and it contained articles devoted exclusively to orthopaedic conditions seen in pediatric patients. It is interesting to note that the first article in their first volume was related to trauma, “The Surgical Treatment of Partial Closure of the Growth

Plate” by Anders Langenskiold (5). Part B of *The Journal of Pediatric Orthopedics* was established in 1992 to allow the expansion of the number of articles from non–North American authors.

Pediatric Fracture Courses

The recognition of the uniqueness of children's fractures has stimulated the production of a number of courses organized world-wide devoted exclusively to the management of children's trauma (see Appendix A). Thus, there has been a concentration of both spoken and written information regarding children's fractures in the modern orthopaedic community.

CHANGES IN THE PHILOSOPHY OF TREATING FRACTURES IN CHILDREN

Blousnt's Nonoperative Axioms

Dr. Walter Blount, in his textbook *Fractures in Children,* emphasized that because of growth, children's fractures have a great potential to remodel (1). In fact, he outlined the rules of remodeling as to what amount of angulation would be accepted in children's fractures. However, he was very opposed to operative intervention. This was especially true in his opinion of intramedullary fixation of femoral shaft fractures in children:

“The operation is unnecessary, however and as such must be condemned. It introduces the hazard of an unnecessary anesthetic, unnecessary exposure of bone ends, and trauma to the entire marrow cavity of the femur. There is no reason for doing it” (1).

Complications with Operative Intervention

It was his experience that nonunions often followed open reductions in children. He went on to delineate the serious other complications that he had seen with open reduction, including death from sepsis. His comment was, “One postoperative osteomyelitis in a lifetime is enough to cure a surgeon of a casual attitude toward open reduction.”

This aversion to operative management of children's fractures set the tone for a generation of orthopaedic surgeons.

Trend Toward Minimal Invasion

Certainly, prior to the mid-1950s, when Blount published his textbook (1), operative procedures usually required large incisions and extensive dissection. In the 45 years since the publication of his book, there has been a trend toward more operative intervention with good results. However, the surgery performed is minimally invasive, and fixation is often only temporary.

Factors Creating a Trend Toward Operative Intervention

This trend toward more operative intervention has been the result of four factors: (a) improvement in technology; (b) rapid healing allowing minimal and temporary fixation; (c) the financial and social pressures to limit the hospitalization of children; and (d) the expectation by the public for a perfect outcome in every case.

Improvement in Technology

The use of the image intensifier has greatly improved the ease with which fractures can be reduced and stabilized internally with percutaneous methods. Other technical advances such as computed tomography (CT), magnetic resonance imaging (MRI), and sonographic imaging have expanded the ability to better define the fracture patterns. The use of powered instruments and cannulated screws has improved the accuracy of applying fixation devices via percutaneous techniques.

Rapid Healing

Because children heal and remodel rapidly, in many cases the fixation devices need to be utilized for only a short period of time. Children tolerate all types of casts well for short periods of time, which allows a minimally stabilized fracture to be immobilized until there is sufficient internal callous to supplement the limited internal fixation.

Minimal Hospitalization

The rising costs of hospitalization have created a trend to mobilize children to an outpatient setting as soon as possible. This has been reinforced by the fact that in two thirds of the families in the United States both parents are wage earners.

Cox and Clarke, in evaluating the fracture management in their hospital in Southampton, England, found a high incidence of secondary hospital treatment for fractures initially managed nonoperatively (15). There was a 12% readmission rate to correct late displacement of fractures of the radius and distal humerus. In addition, 24% of their internal fixation procedures were to salvage unacceptable results of nonoperative management. It was their conclusion that more selective initial operative intervention in radial and distal humeral fractures could decrease the incidence of costly readmissions to the hospital.

There are both social and financial pressures to mobilize the child early. The trend now is to temporarily surgically stabilize these fractures so that the patient can be discharged early.

The Perfect Result

Modern parents have become very sophisticated and now expect a perfect outcome for their child. They inspect the x-rays, question the alignment, and expect the alignment to be perfect or anatomic.

A common statement made by the patient's father is, “He has tremendous potential to be a great athlete.” These pressures often direct the treating physician toward operative intervention to obtain a perfect alignment.

Changes from Previous Editions

The trend toward the establishment of surgical intervention can be seen in the changes in the previous editions of this textbook. In the first edition (19), very little mention was made regarding intramedullary fixation of either femoral or radial and ulnar shaft fractures. There was an extensive discussion of methods of traction for femoral shaft fractures and supracondylar fractures. In the fourth edition (20), the reverse was true. There was considerable discussion of intramedullary fixation and very little mention regarding traction techniques.

Phases in Development of Operative Techniques

Often, a new procedure is proposed and becomes widely used. Initially, there is a wave of enthusiasm for the benefits of the procedure. However, with more widespread use of a procedure, problems become more apparent and thus there often are modifications of the original technique. Thus, it takes a period of time before the technique becomes relatively complication free.

Specific Problems with Operative Techniques

Some of the specific problems that have occurred over the years are listed as follows:

1. Ulnar nerve injury with mediolateral pin fixation of supracondylar fractures (16)
2. High refracture rate with external fixation of femoral shaft fractures (18)
3. Avascular necrosis of the femoral head following use of interlocking intramedullary nails (13,17)

As will be mentioned in the following chapters of this textbook dealing with the specific fractures, there have been recent changes in the operative technique or postoperative management to minimize the development of these problems.

Nonoperative Techniques Need To Be Maintained

Unfortunately, with this emphasis on operative management, the fact that most children's fractures can be managed by nonoperative techniques becomes obscured. As a result, many of the recent orthopaedic trainees are not developing good nonoperative technical skills.

Two recent articles have demonstrated improved results of treating children's fractures by focusing on improvements of prior nonoperative methods. Chess and co-workers (14) have shown that when properly applied, a well-molded short arm cast provides just as good a result as a long arm cast in treating displaced fractures of the distal radial metaphysis. The key to success in using a short arm cast is in a careful molding of the cast at the fractures site so there is a proper cast index of 0.7 or less. Walker and Rang (21) recently revised the concept of treating unstable fractures of the shafts of the radius and ulna with a long arm cast with the elbow in extension. This has resulted in a lower remanipulation rate.

Continued focus on developing and maintaining nonoperative skills such as appropriate cast application and proper moulding techniques needs to be constantly reemphasized as the mainstay of treating children's fractures.

THE PRESENT STATUS OF THE INCIDENCE OF FRACTURES IN CHILDREN

The incidence of children's fractures is extremely variable. It can vary with the child's age, the season of the year, cultural and environmental climates, and the hour of the day, to name just a few factors. As a culture changes from a primarily rural to an urban setting, the injury patterns may change as well. It is important to develop a general picture of how, when, and why fractures occur in children.

Incidence of Fractures

Healing Processes

Early reviews primarily developed a knowledge base of fracture healing in children. Walkling's 1934 review demonstrated that children's fractures heal differently and included such concepts as the overgrowth of long bones after fracture and the ability of children's fractures to remodel significant angular deformities (56). In 1941, Beekman and Sullivan published an extensive review of the incidence of children's fractures (24). Their pioneering work—still quoted today—included a study of 2,094 long bone fractures seen over a 10-year period at Bellevue Hospital in New York City. The major purpose of their study was to develop basic principles for treating children's fractures.

In 1954, two major reports, one by Hanlon and Estes (36) and the other by Lichtenberg (47), confirmed the findings of the previous studies with regard to the general incidence of children's long bone fractures and their ability to heal and readily remodel. These initial reviews were mainly statistical analyses and did not delve deeply into the true epidemiology of children's fractures. In 1965, Wong explored the effect of cultural factors on the incidence of fractures by comparing Indian, Malay, and Swedish children (58). In the 1970s, two other studies, one by Iqbal (34) and another by Reed (50), added more statistics regarding the incidence of the various long bone fractures.

Preventive Programs

Landin's 1983 report on 8,682 fractures established a trend in reviewing the incidence of children's fractures (41). He reviewed the data on all fractures in children that occurred in Malmo, Sweden, over 30 years, and examined the factors affecting the incidence of children's fractures. His study remains a landmark on this subject. By studying two populations, 30 years apart, he evaluated whether fracture patterns were changing, and if so, the reasons for such changes. His initial goal was to establish data for preventive programs, so he focused on fractures that produced clean, concise, concrete data.

In 1997 Landin updated his work, reemphasizing the statistics from his previous publication (40). He felt that the twofold increase in fracture rate during the 30 years from 1950 to 1979 in Malmo was due mainly to an increased participation in sports. In 1999, in cooperation with Tiderius and Duppe, Landin (55) studied the incidence in the same age group again in Malmo and found that the incident rate had actually declined by 9% in the years 1993 to 1994. The only exception was an increase of distal forearm fractures in girls, which he attributed to their increased participation in sporting events.

Cheng and Shen, in their 1993 study from Hong Kong, also set out to define the problems of children's fractures by separating the incidences into age groups (28). They tried to gather epidemiologic data on which to build preventive programs. In 1999 this study was expanded to include almost 6,500 fractures in children 16 and younger over a 10-year period (27). The fracture patterns changed little over those 10 years. What did change was the increased incidence of closed reduction and percutaneous pin fixation of fractures, with a corresponding decrease in open reductions. There was also a marked decrease in the hospital stay of their patients.

In short, the goals for studying children's fractures have changed over the past 60 years. Originally, the goal was to identify the most common bones fractured and how they heal. The goals of present studies are to gather data in an attempt to decrease the incidence of fractures by establishing preventive programs.

Defining the Incidence of Fractures

Variations

Cultural Differences

When one looks at the incidence of specific fractures within a well-defined group of children, the data are usually concise. However, when trying to obtain the global or general incidence of injury or fracture patterns for all types of children, there may be problems. For instance, Cheng and Shen studied children in Hong Kong who lived in confined high-rise apartments (28). Their risk of exposure to injury differed from the study by Reed of children living in the rural environment of Winnipeg, Canada (50). Two separate reviews by Laffoy (39) and Westfelt (57) have found that children in a poor social environment (as defined by a lower social class or by dependence on public assistance) had an increased incidence of accidents. In England, children from single-parent families have been found to have higher accident and infection rates (31).

Thus, in domestic settings where many people are on public assistance or where there is a higher incidence of disruption of family structure, social rather than physical factors may be more of an influence on the incidence of injuries.

Climatic Differences

The climate may be a strong factor as well. Children in colder climates, with ice and snow, are exposed to risks different from those of children living in warmer climates. The exposure time to outdoor activities may be greater for children who live in warmer climates. For example, the incidence of chronic overuse elbow injuries in young baseball players (little league elbow) is far greater in the southern United States than in more northern communities. This is simply because there is greater playing or exposure time.

Difficulties in Comparing Fracture Studies

Defining Age Groups

Another problem with comparing studies is the definition of pediatric age groups. Some use 12 years as a cutoff age; others extend it to 16 or 20.

Inpatient Versus Outpatient Studies

Some studies report only fracture victims admitted to a hospital, which loads them toward the more serious injuries.

Anatomic Location

Reports vary in the precision of their defined types of fracture patterns. In the older series, reports were only of the long bone involved, such as the radius. More recent series have emphasized a more specific location, separating the radius, for example, into physeal, distal, shaft, and proximal fracture types.

Thus, in trying to define the exact incidence of fractures, it is difficult to compare series because of cultural, environmental, and age differences. In this section, these differences were considered in grouping the results and producing average figures. These data are presented in an attempt to provide a reasonable and accurate reflection of the overall incidence of injuries and fractures in all children.

Frequency of Childhood Fractures

In Landin's series from Malmo, Sweden, the chance of a child sustaining a fracture during childhood (birth to age 16) was 42% for boys and 27% for girls (41). When considered on an annual basis, 2.1% of all the children (2.6% for boys, 1.7% for girls) sustained at least one fracture each year. These figures were for all fracture types and included those treated on an inpatient basis and an outpatient basis. The overall chance of fracture per year was 1.6% for both girls and boys in a study from England of both outpatients and inpatients by Worlock and Stower (59).

The chance of a child sustaining a fracture severe enough to require inpatient treatment during the first 16 years of life is 6.8% (28). Thus, on an annual basis, 0.43% of the children in an average community will be admitted for a fracture-related problem during the year.

In a series of 23,915 patients seen at four major hospitals for injury-related complaints, 4,265 (17.8%) had fractures (26,32,33,57). Thus, close to 20% of the patients who present to hospitals with injuries have a fracture.

It is interesting to note that in a follow-up study by Tiderius, Landin, and Duppe (55) in the years 1993 and 1994, 13 years after the termination of the original 30-year study by Landin (41), there was almost a 10% decrease in the incidence of fractures in the 0- to 16-year age group. They attributed this to less physical activity on the part of modern-day children coupled with better protective sports equipment and increased traffic safety (e.g., stronger cars and use of auto restraint systems). The overall incidence of children's fractures is summarized in Table 1-1.

Percentage of children sustaining at least one fracture from 0 to 16 years of age: boys, 42%; girls, 27%
Percentage of children sustaining a fracture in 1 year: 1.6%–2.1%
Percentage of children who are hospitalized because of a fracture: during entire childhood (0–16 years), 6.8%; each year, 0.43%
Percentage of patients with injuries (all types) who have fractures: 17.8%

Data from references 26, 28, 32, 33, 42, 57, and 59.

TABLE 1-1. OVERALL FREQUENCY OF FRACTURES

Age Groups

Correlation With Incidence of Injuries

Starting with birth and extending to age 12, all the major series that segregated patients by age group have demonstrated a linear increase in the annual incidence of fractures with age (Fig. 1-1) (27,28,34,41,59). There seems to be a peak at 12 years, with some decrease until age 16, probably related to a significant decrease in the incidence of fractures in girls over age 12. The percentage of injured boys as compared with girls continues to increase in the older age groups.

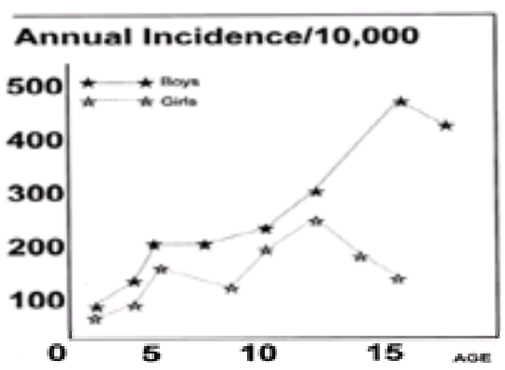

FIGURE 1-1. Incidence of fractures by age. Boys peak at 15 years. Girls peak earlier, at 12 years and then decline. [Reprinted from Landin LA. Fracture patterns in children. *Acta Orthop Scand* 1983;54(suppl 202):13, with permission.]

These fracture statistics differ slightly from the incidence of overall injuries: the incidence of injuries peaks early, at ages 1 to 2 years (Fig. 1-2) (39). Although there is a high incidence of injuries in children ages 1 to 2, the incidence of fractures is low. Most injuries in children of this age are nonorthopaedic entities such as head injuries, lacerations, and abrasions. In fact, the incidence of lacerations in both sexes peaks at this age (51).

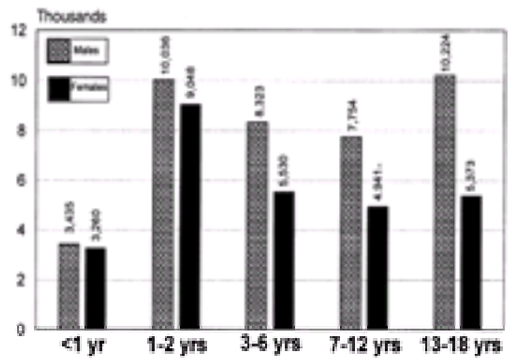

FIGURE 1-2. Injuries per 100,000 children per year. Estimated U.S. injury rates in children by age and sex, 1978. (Reprinted from Rivara FP, Bergman AB, LoGerfo JP, et al. Epidemiology of childhood injuries. *Am J Dis Chila* 1982;136:503; with permission.)

Trauma

In 1962, Kempe and associates (37) called attention to the high incidence of fractures and other injuries in young children that were due to nonaccidental trauma. They termed these injuries part of the battered child syndrome. Akbarnia and colleagues later defined the specific fracture patterns seen in victims of child abuse (22). Not all fractures in the first year of life can be attributed to abuse, however. In a review of fractures occurring in the first year of life, McClelland and Heiple found that fully 44% were from documented accidental and nonabusive etiologies (47). They also noted that 23% of these patients had a generalized condition that predisposed them to fractures. Thus, although nonaccidental trauma remains the leading cause of fractures during the first year of life, other constitutional conditions may predispose children to fractures from accidental causes. The high incidence of fractures from nonaccidental trauma extends to age 3 (38).

Gender

The male predominance of injury and fracture victims has been discussed (Fig. 1-1 and Fig. 1-2, Table 1-1). For all age groups, the overall ratio of boys to girls who sustain a single fracture is 2.7:1 (28). In girls, fracture incidence peaks just before adolescence and then decreases during adolescence (28,41,50). In Cheng and co-workers' 10-year study from Hong Kong (27), the male incidence in the 12- to 16-year age group was 83%. The incidence of fractures in girls steadily declined from their peak in the 0- to 3-year age group.

In some areas there is little difference in the incidence of fractures between boys and girls. For example, during the first 2 years of life, the overall incidence of injuries and fractures in both genders is nearly equal. During these first 2 years, the injury rates for foreign body ingestion, poisons, and burns have no significant gender differences. With activities in which there is a male difference in participation, such as with sports equipment and bicycles, there is a marked increase in the incidence of injuries in boys (27,51).

The injury incidence may not be due to the rate of exposure alone; behavior may be a major factor. For example, one study found that the incidence of auto/pedestrian childhood injuries peaks in both sexes at ages 5 to 8 (53). When the total number of street crossings per day was studied, both sexes did so equally, but despite this equal exposure, boys had a higher number of injuries. Thus, the difference in the rate between the sexes begins to develop a male predominance when behaviors change. The difference in the injury rate between the genders may change in the future as more girls participate in activities with increased physical risk (27,51).

Right Versus Left Frequency

In most series, the left upper extremity demonstrates a slight but significant predominance (27,28,32,34,41,51). The ratio of left to right overall averages 1.3:1. In some fractures, however, especially those of supracondylar bones, lateral condyles, and the distal radius, the incidence is far greater, increasing to as much as 2.3:1 for the lateral condyle. In the lower extremity, the incidence of injury on the right side is slightly increased (32,41).

The reasons for the predominance of the left upper extremity have been studied, but no definite answers have been found. Rohl (52) speculated that the right upper extremity is often being used actively during the injury, so the left assumes the role of protection. In a study examining the left-sided predominance in the upper extremity, Mortensson and Thonell (49) questioned patients and their parents on arrival to the emergency department about which arm was used for protection and the position of the fractured extremity at the time of the accident. They found two trends: regardless of handedness, the left arm was used more often to break the fall, and when exposed to trauma, the left arm was more likely to be fractured. The cause for this latter increased incidence in the left side was thought to be due to either the increased fragility or immature neuromuscular coordination of the nondominant extremity.

Frequency by Season and Time of Day

Fractures are more common during the summer, when children are out of school and exposed to more vigorous physical activities. Four studies from the northern hemisphere have confirmed this summertime increase (Fig. 1-3) (27,28,52,59).

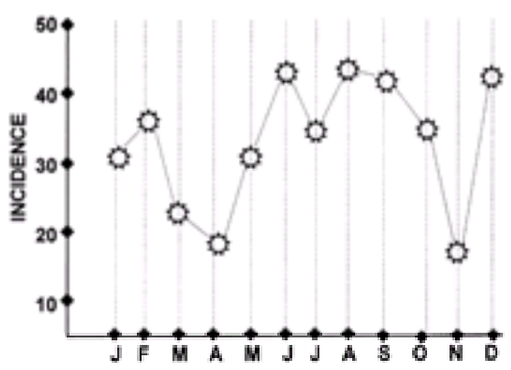

FIGURE 1-3. Distribution of children's fractures on a monthly basis. Note the general increase from May to October. (Reprinted from Reed MH. Fractures and dislocations of the extremities in children. *J Trauma* 1977;17:353; with permission.)

The most consistent climatic factor appears to be the number of hours of sunshine. Masterson and co-workers (46), in an eloquent study from Ireland, found a strong positive correlation between monthly sunshine hours and monthly fracture admissions. There was also a weak negative correlation with monthly rainfall. Overall, the average number of fractures in the summer was 2.5 times that in the winter. In days with more sunshine hours than average, the average fracture admission rate was 2.31 per day; on days with fewer sunshine hours than average, the admission rate was 1.07 per day.

In Sweden, the incidence of fractures in the summer had a bimodal pattern that seemed to be influenced by cultural traditions. In two large series of both accidents and fractures in Sweden by Westfelt (57) and Landin (41), the researchers noticed increases in May and September and significant decreases in June, July, and August. Both writers attributed this to the fact that children in their region left the cities to spend the summer in the countryside. Thus, the decrease in the overall fracture rate probably was due to a decrease in the number of children at risk remaining in the city.

Masterson and co-workers (46) speculated that because the rate of growth increases during the summer, the number of physeal fractures should also increase, because the physes would be weaker during this time. For example, the incidence of a slipped capital femoral epiphysis, which is related to physeal weakness,

increases during the summer (23). However, Landin, in his study of more than 8,000 fractures of all types, found the overall seasonal incidence of physeal injuries to be exactly the same as nonphyseal injuries (41).

Age may affect the seasonal variation of fractures. In children ages 0 to 3, no seasonal variations are seen. The number of fractures in this age group was consistent throughout the year (38).

Thus, it appears that climate, especially in areas where there are definite seasonal variations, influences the incidence of fractures in all children, especially in the older children. However, in small children and infants, whose activities are not seasonally dependent, there appears to be no significant seasonal influence.

The time of day in which children are most active seems to correlate with the peak time for fracture occurrence. In Sweden, the incidence peaked between 2 and 3 P.M. (57). In a well-documented study from Texas by Shank and co-workers (54), the hourly incidence of fractures formed a well-defined bell curve peaking at about 6 P.M. (Fig. 1-4).

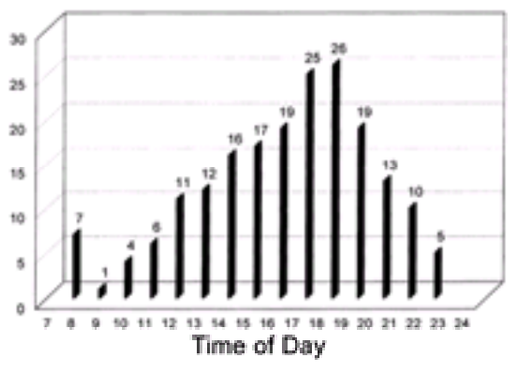

FIGURE 1-4. Incidence of children's fractures per time of day. There is an almost bell-shaped curve with a peak at around 6 P.M. (Reprinted from Shank LP, Bagg RJ, Wagnon J. Etiology of pediatric fractures: the fatigue factors in children's fractures. Presented at the National Conference on Pediatric Trauma, Indianapolis, 1992; with permission.)

Long-Term Trends

Increase in Minor Trauma

Landin's study is the only one that has compared the changes over a significant time span: his data were collected over 30 years (41). He classified the degree of trauma as slight, moderate, or severe. The incidence of all trauma in both boys and girls increased significantly over the 30-year study period, but the incidence of severe trauma increased only slightly. The greatest increase was seen in the “slight” category. Landin attributed the increase in this category to the introduction of subsidized medical care. Because expense was not a factor, parents were more inclined in the later years of the study to seek medical attention for relatively minor complaints. Physicians, likewise, were more inclined to order x-rays. Thus, many of the minor injuries, such as torus fractures, which were often ignored in the earlier years, were seen more often at medical facilities during the later years.

Likewise, the overall incidence of fractures in Malmo, Sweden, (the same city as Landin's original study) (41) significantly decreased (10%) in the more recent years (55).

The one fracture type that exhibited a true increase over this period was that of the femoral shaft. This increase was thought to be influenced by new types of play activities and increased participation in sports.

Increase in Child Abuse

The number of fractures due to nonaccidental causes (child abuse) has risen consistently in the past decades. In Kowal-Vern and associates' study of fractures in children ages 0 to 3 (38), the number of fractures due to abuse increased almost 150 times from 1984 to 1989. This increase was attributed to a combination of improved recognition, better social resources, and an increase in the number of cases of child abuse.

Specific Fracture Incidences

Age Factors

The anatomic areas most often fractured seem to be the same in the major series, but these rates change with age. For example, the supracondylar fracture of the humerus is most common in the first decade, with a peak at age 7. Fractures of the femur are most common in children ages 0 to 3. Fractures of the physis are more common just before skeletal maturity. This variation is best illustrated in Cheng and Shen's data (Fig. 1-5) (28).

FIGURE 1-5. The frequency of occurrence of the most common fracture areas in children. The frequency of each fracture pattern differs with the various age groups. The figures express the percentage of total fractures for that age group and represent boys and girls combined. (Reprinted from Cheng JC, Shen WY. Limb fracture pattern in different pediatric age groups: a study of 3,350 children. *J Orthop Trauma* 1993;7:17; with permission.)

Landin found a similar age variability and divided it into six distinct patterns (Fig. 1-6) (41). When he compared these variability patterns with the common etiologies, he found some correlation. For example, late-peak fractures (distal forearm, phalanges, proximal humerus) were closely correlated with sports and equipment etiologies. Bimodal pattern fractures (clavicle, femur, radioulnar, diaphyses) showed an early increase from lower energy trauma, then a late peak in incidence due to injury from high- or moderate-energy trauma. Early peak fractures (supracondylar humeral fractures are a classic example) were due mainly to falls from high levels.

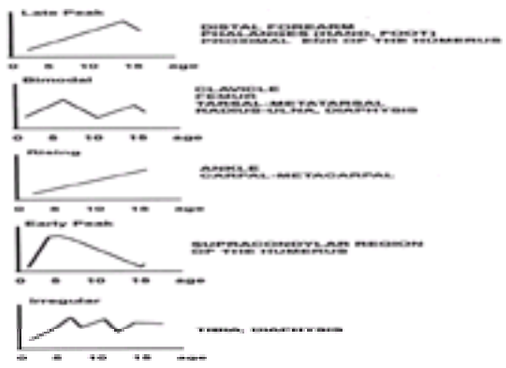

FIGURE 1-6. Patterns of fracture: variations with age. The peak ages for the various fracture types occur in one of five patterns. [Reprinted from Landin LA. Fracture patterns in children. *Acta Orthop Scand* 1983;54(suppl 220):80; with permission.]

Locations

Early reports of children's fractures lumped together the areas fractured, and fractures were reported only as to the long bone involved (e.g., radius, humerus, femur) (24,32,34,43,44,48). More recent reports have split fractures into the more specific areas of the long bone involved (e.g., the distal radius, the radial neck, the supracondylar area of the humerus) (28,34,41,50,59). This change in reporting—from the so-called “lumpers” to the “splitters”—has produced a more accurate picture of the true incidence of each specific fracture type.

Single Bones

In children, fractures in the upper extremity are much more common than those in the lower extremity (32,34). Overall, the radius is the most commonly fractured long bone, followed by the humerus. In the lower extremity, the tibia is more commonly fractured than the femur (Table 1-2).

Bone	%
Radius	45.1
Humerus	18.4
Tibia	15.1
Clavicle	13.8
Femur	7.6

Data from references 24, 32, 34, 43, 44, and 48.

TABLE 1-2. INCIDENCE OF FRACTURES IN LONG BONES

Specific Areas Fractured

In recent years, five reports produced by so-called splitters divided fracture types into many anatomic areas (28,34,41,50,59). In trying to reach a global consensus, the author has identified areas common to all the reports but has taken some liberties to do so. For example, distal radial metaphyseal and physeal fractures were combined to form the distal radius. Likewise, the carpals, metacarpals, and phalanges were combined to form the region of the hand and wrist. All the fractures around the elbow, from those of the radial neck to supracondylar fractures, were grouped as elbow fractures. This grouping allows comparison of the regional incidence of specific fracture types in children (Table 1-3).

Fracture	%
Distal radius and physis	23.3
Hand (carpals, metacarpals, and phalanges)	20.1
Elbow area (distal humerus and proximal radius and ulna)	12.0
Clavicle	6.4
Radius shaft	6.4
Tibia shaft	6.2
Foot (metatarsals and phalanges)	5.9
Ankle (distal tibia)	4.4
Femur (neck and shaft)	2.3
Humerus (proximal and shaft)	1.4
Other	11.6

Data from references 28, 34, 41, 50, and 59.

TABLE 1-3. INCIDENCE OF SPECIFIC FRACTURE TYPES

The individual reports agreed that the most common area fractured was the distal radius. The next most common area, however, varied from the hand in Landin's series (41) to the elbow (mainly supracondylar fractures) in Cheng and Shen's series (27,28).

Physeal Injuries

The incidence of physeal injuries overall varied from 14.5% (29) to a high of 27.6% (45). To obtain an overall incidence of physeal fractures, six reports totaling 6,479 fractures in children were combined (25,29,45,48,50,59). In this group, 1,404 involved the physis, producing an average overall incidence of 21.7% for physeal fractures (Table 1-4).

Total fractures = 6,477
Number of physeal injuries = 1,404
Precentage of physeal injuries = 21.7%

Data from references 25, 29, 30, 45, 48, and 59.

TABLE 1-4. INCIDENCE OF PHYSEAL FRACTURES

Open Fractures

The overall incidence of open fractures in children is consistent. The data were combined from the four reports in which the incidence of open fractures was reported (28,32,45,59). The incidence in these reports varied from 1.5% to 2.6%. Combined, these reports represented a total of 8,367 fractures with 246 open fractures, resulting in an average incidence of 2.9% (Table 1-5).

Total number of fractures = 8,367
Total open fractures = 246
Percentage = 2.9%

Data from references 28, 32, 45, and 59.

TABLE 1-5. INCIDENCE OF OPEN FRACTURES

Regional trauma centers often see patients exposed to more severe trauma, so there may be a higher incidence of open fractures in these patients. The incidence of open fractures was 9% in a report of patients admitted to the trauma center of the Children's National Medical Center, Washington, D.C. (26).

Multiple Fractures

Multiple fractures in children are uncommon: the incidence ranges in the various series from 1.7% to as much as 9.7%. In four major reports totaling 5,262 patients, 192 patients had more than one fracture (Table 1-6) (28,32,34,59). The incidence in this multiple series was 3.6%.

Total fractures = 5,262
Total number of multiple fractures = 192
Percentage = 3.6%

Data from references 28, 32, 45, and 58.

TABLE 1-6. INCIDENCE OF MULTIPLE FRACTURES

Recurrent Fractures

Children with generalized bone dysplasias, such as osteogenesis imperfecta and other metabolic diseases that produce osteopenia, are expected to have repeat fractures. In these patients, the etiology of these recurrent fractures is understandable and predictable. However, some children with normal osseous structures are prone to recurrent fractures, for reasons that remain unclear. The incidence of recurrent fractures in children is about 1% (30).

Landin and Nilsson (42) found that children who sustained fractures with relatively little trauma had a lower mineral content in their forearms, but they could not correlate this finding with children who had repeat fractures. Thus, in children who seem to be structurally normal, there does not appear to be a physical reason for their recurrent fracturess.

Repeat Fractures

Failure to find a physical cause for repeat fractures shifts the focus to a psychological or social cause. The one common factor in accident repeaters has been a high incidence of dysfunctional families (36). In Sweden, Westfelt found that children who were accident repeaters came from “socially handicapped” families (i.e., those on public assistance or those with a caregiver who was an alcoholic) (57). Thus, recurrent fractures are probably due more to behavioral or social causes than physical causes. Landin in his follow-up article (40) followed children with repeat fractures (four or more) into adolescence and adulthood. He found these children had a significantly increased incidence of convictions for serious criminal offenses when compared with children with only one lifetime fracture.

ETIOLOGY OF FRACTURES

While studying the epidemiology of fractures, it is important to focus on the etiology of fractures and the settings in which they occur. In this age of computerized gizmos and the “need for speed,” children are often the victims of the consumer market and unsafe products. Fractures do not occur in a vacuum, and well-researched studies that analyze the physical and social environment in which they occur are extremely valuable. It is a truism that children, unfortunately, learn more from experience than by education, so efforts should be made toward creating a safer environment for play and recreation. Studies that identify risky patterns of use or unsafe playground behavior go a long way in directing specific preventive health measures. Recommendations can be made to manufacturers regarding modification of a product, and education can be imparted to parents, school authorities, health-care professionals, physical trainers, and children.

Broad Causes

Broadly, fractures can occur due to three main causes: accidental trauma, nonaccidental injury (child abuse), and pathologic conditions. Because accidental trauma forms the largest etiologic group, it will be addressed in detail here. Nonaccidental trauma and fractures resulting from pathologic conditions will be addressed in later chapters of this book.

Fractures Resulting from Accidental Trauma

Accidental trauma can occur in a variety of settings, some often overlapping others. However, for purposes of simplicity, fractures can be considered to occur in the

following five environments: home environment; school environment; play and recreational activities; motor vehicle and road accidents; and uncommon causes such as ice cream truck, water tubing, and gunshot and missile injuries.

Home Environment

Fractures sustained in the home environment are defined as those that occur in the house and surrounding vicinity. These generally occur in a fairly supervised environment and are mainly due to falls from furniture, stairs, fences, and trees.

Falls from Heights

Falls can vary in severity from a simple fall while running, to a fall of great magnitude, such as from a third story window. In falling from heights, adults often land on their lower extremities, accounting for the high number of lower extremity fractures, especially the calcaneus. Children tend to fall head first, using the upper extremities to break the fall. This accounts for the larger number of skull and radial fractures in children. Femoral fractures are also more common in children falling from great heights. In contrast to adults, spinal fractures are rare in children who fall from great heights (61,84,97,100).

In one study, children falling three stories or less all survived. Falls from the fifth or sixth floor resulted in a 50% mortality rate (61).

Injury Rate Increases with Age

Injuries also can occur from the unsupervised use of unsafe play equipment, such as trampolines and monkey bars, within the home environment and will be considered in detail later. The overall incidence of fractures occurring because of such play activity in the home environment increases with age. Only 15% occur in toddlers, but 56% occur during older years (110).

Social Factors

Interestingly, a Swedish study (109) showed that an increased incidence of fractures in a home environment did not necessarily correlate with the physical attributes or poor safety precautions of the house. Rather, it implicated disruption of the family structure and presence of social handicaps (alcoholism, welfare recipients, etc.) as the true cause for the increase.

School Environment

The supervised environments at school are generally safe, and the overall annual rate of injury (total percentage of children injured in a single year) in the school environment ranges from 2.8% to 9.2% (63,81,95,109). True rates may be higher because of inaccurate reporting, especially of mild injuries. In one series, the official rate was 5.6%, but when the parents were closely questioned, the incidence of unreported, trivial injuries was as much as 15% (71). The annual fracture rate of school injuries is low. Of all injuries sustained by children at school in a year, only 5% to 10% involved fractures (71,81,95). In Worlock and Stower's series of children's fractures from England (110), only 20% occurred at school. A large incidence of injuries (53%) occurring in school are related to athletics and sporting events (81). These injuries are highest in the middle-school children. The peak time of day for injuries at school is in the morning, which differs from the injury patterns of children in general (81).

Play and Recreational Activities

Playground

Play is an essential element of a child's life. It enhances physical development and fosters social interaction. Noncompetitive sports and recreational activities are enjoyed by all children. Unfortunately, unsupervised or careless use of some play equipment can endanger life and limb. When Mott et al. (86) studied the incidence and pattern of injuries to children using public playgrounds, they found that approximately 1% of children using playgrounds sustained injuries. Sixty-five percent of these children were injured by falling from equipment such as climbing frames, slides, swings, and monkey bars. They found that changing playground surfaces from concrete to more impact-absorbing surfaces such as bark reduced the incidence and severity of head injury but increased the tendency to long bone fractures (40%), bruises, and sprains.

In a study of injuries resulting from playground equipment, Waltzman et al. (106) found that most injuries occurred in boys (56%) with a peak incidence in the summer months. Fractures accounted for 61% of these injuries, 90% of which involved the upper extremity and were sustained due to falls from playground equipment such as monkey bars and climbing frames. Younger children (1–4 years) were more likely to sustain fractures than older children. In their study, the surface below the equipment apparently did not influence the type or severity of fracture; with 30 of the 79 fractures occurring on “soft surfaces.”

Similar observations were made in a study by Lillis and Jaffe (83) in which upper extremity injuries, especially fractures, accounted for the majority of hospitalizations resulting from injuries on playground equipment. Older children sustained more injuries on climbing apparatus, whereas younger children sustained more injuries on slides.

Newer Play Devices

Other recreational activities enjoyed by children, such as bicycling, skating, skateboarding, and sledding, are an important cause of fractures and injuries in children. Several studies have analyzed the incidence and pattern of injuries arising from the unsupervised or careless use of this equipment and have suggested safety precautions and equipment modification to decrease the risk of injury. A disturbing trend is the rekindled enthusiasm toward the use of trampolines, skateboards, and in-line skates over the past decade, and several studies have highlighted their risks and dangers.

Bicycle Injuries

Bicycle injuries are a significant cause of mortality and morbidity for children (92). Bicycle mishaps are the most common causes of serious head injury in children (108). Boys in the 5- to 14-year age group are at greatest risk for bicycle injury (80%). Puranik et al. (92) studied the profile of pediatric bicycle injuries in a sample of 211 children who were treated for bicycle-related injury at their trauma center over a 4-year period. They found that bicycle injuries accounted for 18% of all pediatric trauma patients. Bicycle/motor vehicle collisions caused 86% of injuries. Sixty-seven percent had head injuries and 29% sustained fractures. More than half of the incidents occurred on the weekend. Sixteen percent were injured by ejection from a bicycle after losing control, hitting a pothole, or colliding with a fixed object or another bicycle. Fractures mainly involved the lower extremity, upper extremity, skull, ribs, and pelvis in decreasing order of incidence.

Helmet Use Low. More importantly, the study detected that the use of safety helmets was disturbingly low (<2%). Other studies confirm the observation that less than 13% to 15% of children wear helmets while riding bicycles (72,93). The Year 2000 Health Objectives call for helmet use by 50% of bicyclists (102). Research has shown that legislation, combined with education and helmet subsidies, is the most effective strategy to increase use of safety helmets in child bicyclists (65). As public awareness of both the severity and preventability of bicycle-related injuries grows, the goal of safer bicycling practices and lower injury rates can be achieved (92).

Injuries from Bicycle Parts. Bicycle spokes and handle bars are also responsible for an increasing number of fractures and soft tissue injuries in children. D'Souza et al. (70) and Segers et al. (94) found that bicycle spoke injuries are typically sustained when the child's foot is caught in the spokes of the rotating wheel. Out of a total of 130 children with bicycle spoke injuries, 29 children sustained fractures of the tibia, fibula, or foot bone. Several had lacerations and soft tissue defects. D'Souza et al. (70) suggested that a mesh cover to prevent the toes from entering between the spokes and a plastic shield to bridge the gap between the fork and horizontal upright can substantially decrease the incidence of these injuries.

Skateboarding

Skateboarding and in-line skating have experienced a renewed surge in popularity over the past two decades. With the increasing number of participants, high-tech equipment development and vigorous advertising, skateboard and skating injuries are expected to increase. Because the nature of skateboarding encompasses both

high speed and extreme maneuvers, high-energy trauma fractures and other injuries can occur, as highlighted by several studies (73,89,91). Studies have shown that skateboarding-related injuries are more severe and have more serious consequences than roller-skating or in-line skating injuries (89). In a study of skateboarding injuries, Fountain et al. (73) found that fractures of the upper or lower extremity accounted for 50% of all skateboarding injuries. Interestingly, more than one third of those injured sustained injuries within the first week of skateboarding. Most injuries occurred in preadolescent boys (75%) 10 to 16 years of age, and despite traffic legislation, 65% sustained injuries on public roads, footpaths, and parking lots. Several organizations have recommended safety guidelines and precautions such as use of helmets, knee and elbow pads, and wrist guards, but such regulations are seldom enforced.

Roller Skates and In-Line Skates

In a study of in-line skate and roller skate injuries in childhood, Jerosch et al. (78) found that in a group of 1,036 skaters, 60% had sustained injuries. Eight percent of these were fractures, mostly involving the elbow, forearm, wrist, and fingers (78%). Less than 20% used protective devices, and most lacked knowledge of the basic techniques of skating, braking, and falling. In a larger study of 60,730 skating injuries in children, Powell and Tanz (91) found that 68% of the children were preadolescent boys with a mean age of 11.8 years. Fractures were the most common injury (65%), and two thirds of these involved the distal forearm. Two and a half percent required hospital admissions; 90% of these admissions were for a fracture. Similarly, Mitts and Hennrikus (85) found that 75% of in-line skating fractures in children occurred in the distal forearm as a result of falls on the outstretched hand. One in eight children sustained a fracture during the first attempt at the sport. The orthopaedic community has an obligation to educate the public on the need for wearing wrist guards when using in-line skates or roller skates.

Trampoline-Related Injuries

Trampolines enjoyed increasing popularity in the 1990s and are a significant cause of morbidity in children. Several studies have noted a dramatic increase in the number of pediatric trampoline injuries (PTIs) during the past 10 years, rightfully deeming it as a “national epidemic” (75,98). Furnival et al. (75), in a retrospective study of PTIs over a 7-year period, found that the annual number of PTIs tripled between 1990 and 1997. In contrast to other recreational activities in which males constitute the population at risk, PTI patients were predominantly female, with a median age of 7 years. Nearly a third of the injuries resulted from falling off the trampoline. Fractures of the upper and lower extremities occurred in 45% and were more frequently associated with falls off the trampoline. In another excellent study on PTIs, Smith (98) found that there was virtually a 100% increase in injuries from 1990 to 1995, with an average of greater than 60,000 injuries per year. Younger children had a higher incidence of upper extremity fractures and other injuries. In a later study, Smith and Shields (99) came up with some interesting data. Fractures, especially involving the upper extremity, accounted for 35% of all injuries. Interestingly, more than 50% of the injuries occurred under direct adult supervision. More disturbingly, 73% of the parents were aware of the potential dangers of trampolines, and 96% of the injuries occurred in the home backyard. These researchers, along with others (75), rightly concluded that use of warning labels, public education, and even direct adult supervision were inadequate in preventing these injuries and have called for a total ban on the recreational, school, and competitive pediatric use of trampolines (57,99).

Skiing Injuries

Skiing injuries are seasonal in nature and occur with outdoor winter recreational activity. In a study of major skiing injuries in children and adolescents, Shorter et al. (96) found greater than 90% of injured children to be boys 5 to 18 years of age. Sixty percent of the accidents occurred due to collisions with stationary objects such as trees, poles, and stakes. Most injuries occurred in the afternoon, among beginners, and in the first week of skiing season. Fractures accounted for one third of the total injuries sustained. The two main factors implicated in skiing injuries are excessive speed and loss of control; effective prevention efforts should target both of these factors.

Snowboarding Injuries

Snowboarding runs a similar risk to skiing. Bladin et al. (62) found that approximately 60% of snowboarding injuries involved the lower limbs and occurred in novices. The most common injuries were sprains (53%) and fractures (26%). Compared with skiers, snowboarders had 2½ times as many fractures, particularly to the upper limb, as well as more ankle injuries such as sprains. The absence of ski poles and the fixed position of the feet on the snowboard mean that the upper limbs absorb the full impact of any fall.

Motor Vehicle Accidents

This category includes injuries sustained by occupants of a motor vehicle and victims of vehicle-versus-pedestrian accidents.

The injury patterns of children involved in motor vehicle accidents differ from those of adults. In all types of motor vehicle accidents for all ages, children constitute a little over 10% of the total number of patients injured (79,101). Of all the persons injured as motor vehicle occupants, only about 17% to 18% are children. Of the victims of vehicle-versus-pedestrian accidents, about 29% are children. Of the total number of children involved in motor vehicle accidents, 56.4% were vehicle-versus-pedestrian accidents, and 19.6% were vehicle-versus-bicycle accidents (69).

The fracture rate of children in motor vehicle accidents is less than that of adults. Of the total number of vehicle-versus-pedestrian accidents, about 22% of the children sustained fractures; 40% of the adults sustained fractures in the same type of accident. This has been attributed to the fact that children are more likely to “bounce” when hit (69).

Children are twice as likely as adults to sustain a femur fracture when struck by an automobile, but in adults tibia and knee injuries are more common in the same type of accident. This seems to be related to where the car's bumper strikes the victim (64,102). Motor vehicle accidents do produce a high proportion of spinal and pelvic injuries (64).

Summary

The etiologic aspects of children's fractures are summarized in Fig. 1-7 and Table 1-7.

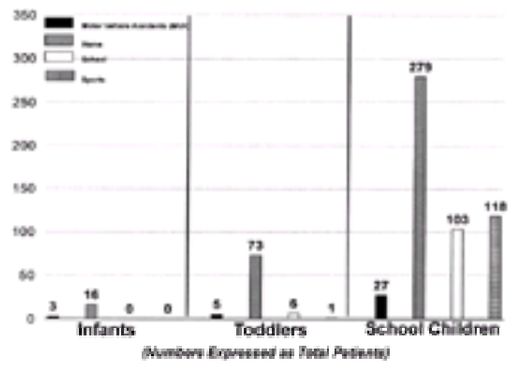

FIGURE 1-7. The incidence of fractures in children expressed as the four common etiologic categories. Most fractures occur at home. The numbers are expressed as total patients per each age category. (Reprinted from Worlock P, Stower M. Fracture patterns in Nottingham children. *J Pediatr Orthop* 1986;6:656; with permission.)

Home environment	
Injuries	
	83% of all children's injuries
Fractures	
	37% of all children's fractures
School environment	
Injuries	
	Overall rate, 2.8%–9.2% annually
	53% related to athletic events
	Peak age: middle-school group
Fractures	
	Occur in only 5%–10% of all school-related injuries
	About 20% of all children's fractures
Motor vehicle accidents (MVA)	
Injuries	
	Children only 10% of all MVAs
	Of children's MVAs, only 17–18% were occupants; remainder were vehicle/pedestrian or vehicle/bicycle
Fractures	
	Higher incidence of femur fractures in vehicle pedestrian accidents in children
	Children have a higher incidence of spinal and pelvic fractures with MVAs than with other mechanisms

TABLE 1-7. SUMMARY OF ETIOLOGIC FACTORS IN CHILDREN'S FRACTURES

Less Common Etiologies

Ice Cream Truck

Mubarak et al. (87) reported on ice cream truck–related accidents in which children, distracted by ice cream trucks, were struck by an oncoming vehicle, sustaining pelvic and lower limb fractures. The vision of oncoming drivers was often blocked by the large size of the ice cream truck parked by the curb.

Water Tubing

Parmar et al. reported serious injuries sustained during water tubing (the pulling of an inner tube behind a power boat) (90).

Gunshot (Missile) Wounds: Definition

Gunshot or missile wounds arise from objects projected into space by an explosive device. The missiles may be single or multiple. Single missiles vary from low-velocity handguns to high-velocity assault weapons. Multiple missiles can result from a shotgun blast or shrapnel from war weapons. Missile injuries represent open fractures with varying degrees of soft tissue injury. The incidence of gunshot wounds in children has become increasingly common in the United States (107).

Gunshot and Firearm Injuries

In a sad reflection of the changing times and the newly pervasive gun culture, firearms are determined to be second only to motor vehicles as the leading cause of death in youths. In considering the prevalence of firearms in the United States, it has been estimated that there are about 200 million privately owned guns in the United States and that approximately 40% of U.S. households contain firearms of some type (66). The incidence of gunshot wounds in children has become increasingly common in the United States (107).

Etiology

In two reports from inner-city hospitals in the United States in the 1990s, most injuries resulted from random violence to innocent bystanders; the prime example was “drive-by shootings” (101,107). Few were self-inflicted, either voluntarily or accidentally. In a 1976 report on patients in a relatively rural setting in Canada, almost all the missile injuries were accidental, having been caused by the patient or a close friend or relative (82).

In the urban setting, handguns and rifles are the most common weapons (101,104,107). In the rural setting, the most common weapon is a shotgun (82). The firepower of these weapons has changed over the years. In one urban hospital reporting gunshot wounds from 1973 to 1983, most of the injuries were from .32- or .38-caliber weapons; only 5% were high-caliber or high-velocity weapons (88). In a later study of gunshot wounds from the same institution from 1991 to 1994, the incidence of injuries from high-caliber and high-velocity weapons (e.g.,, .357 Magnum, AK-47, and other assault rifles) had increased to 35% (108).

In the urban setting, the victims' ages ranged from 1 to 17 years, and most of the injuries were in children 12 to 14 (88,101,104,107). In the rural setting, the patients were younger; the average age was 9 years (82).

Of 839 children sustaining gunshot wounds, 274 (32.6%) involved the extremities (88,101,104,107). Of the gunshot wounds that involved the extremities, 51.3% produced significant fractures (82,101,107). No single bone seemed to predominate, although a great majority of the fractures were distal to the elbow (88,101,104,107).

Complications

The two most common complications were growth arrest and infection. Other complications include delayed union or malunion. Considering the magnitude of many of these injuries, the infection rate for extremity wounds was low (about 7.3%). This low rate was probably due to a vigorous and aggressive program of acute wound management (82,101,107). The type of missile did not seem to have any relation to the development of an infection (107).

In Letts and Miller's 1976 series, one sixth of the patients had some type of growth disturbance (82). In a third of their patients, the missile was only in close proximity to the physis. In a 1995 report by Washington and co-workers, the incidence of missiles affecting the physis was exactly the same (107). However, all were a result of a direct injury to the physis by the missile. None of their patients with growth arrest had proximity missile wounds. The higher incidence of growth abnormalities in the 1976 series was due to the larger number of shotgun and hunting rifle injuries, which dissipate more of their energy peripheral to the missile track.

In two of the studies in which patients were followed closely, all of the fractures ultimately healed (82,107).

Prevention

In an excellent report in 1999, Freed et al. (74) analyzed the magnitude and implications of the increasing incidence of firearm-related injuries in children. They suggested a product-oriented approach, focusing on the gun, in an attempt to provide an efficient strategy of gun control and hence reduce the disturbing trend of firearm-related injuries and death among youths. Rather than modifying behavioral or environmental issues, which are more complex, they suggested focusing primarily on strategies that offset the accessibility and design of firearms. In brief, these strategies included the following:

Reducing the number of guns in the environment through restrictive legislation, gun buy-back programs, gun taxes, and physician counseling.

Modifying the design of guns to make them more child-proof and preventing unauthorized and unintended use.

Falls

Falls can vary in severity from a simple fall while running, to a fall of great magnitude, such as from a third story window. Falls are often classified as the most common cause of injuries. Falls are more likely to be a cause of injury in the younger than in the older child. Falls in the home are usually associated with furniture or stairs; outside the home, most falls involve playground equipment (76,77).

In falling from great heights, adults often land on their lower extremities, accounting for the high number of lower extremity fractures, especially the calcaneus. Children tend to fall head first, using the upper extremities to break the fall. This accounts for the larger number of skull and radial fractures in children. Femoral

fractures are also more common in children falling from great heights. In contrast to adults, spinal fractures are rare in children who fall from great heights (61,84,97,100). In one study, children falling three stories or less all survived (61). Falls from the fifth or sixth floor resulted in a 50% mortality rate.

Intrinsic Causes

Nutrition

In a study in Spain, a significant difference in the fracture rate was found when cities with a high calcium content in their water were compared with those with a lower calcium content. With all other factors being equal (e.g., fluoride content, socioeconomic background), children who lived in the cities with a lower calcium content had a higher fracture rate (105).

An increase in the consumption of carbonated beverages has been shown to produce an increased incidence of fractures in adolescents (111).

Bone Density

Bone density may be a factor, but the data are unclear. Landin and Nilsson (80) found that the mineral content of the forearms was lower in children who sustained fractures from mild trauma than in children who had never sustained fractures. It was not significantly different, however, in those sustaining fractures from severe trauma. This study used measurements of bone density of the cortical bone in the forearms. Cook and co-workers (67), using measurements of bone density obtained from trabecular bone in the spine and femoral neck, found no difference between children who had sustained fractures and those who had not.

Premature Infants

Fractures not related to birth trauma reportedly occur in 1% to 2% of low-birth-weight or premature infants during their stay in a neonatal intensive care unit (60). Using a combination of the clinical history, radiographic appearance, and laboratory data, these infants have been found to have evidence of bone loss from inadequate calcium and phosphorus intake. Correcting the metabolic status of these low-birth-weight infants, with special emphasis on calcium and phosphorus intake, appears to decrease the incidence of repeat fractures and to improve the radiographic appearance of their bony tissues. Once the metabolic abnormalities are corrected, this temporary deficiency seems to have no long-term effects. When premature infants were followed into later years, there was no difference in their fracture incidence when compared with that of children of normal birth weight (68).

PREVENTIVE PROGRAMS

One of the major goals of studying the incidence of fractures is to identify problem areas; it is hoped that by targeting these areas, programs can be designed to decrease the risk factors.

National Campaigns

Several safety programs have been started by national organizations. The foremost is the American Academy of Pediatrics, which has committees on accident and poisoning prevention. This group has produced guidelines for athletics (114), playgrounds (118,121), trampolines (112,113), and skateboards (115). Recently, the American Academy of Orthopaedic Surgeons has produced a program designed to decrease the incidence of playground injuries. These programs offer background data and guidelines for various activities, but their effectiveness has not yet been fully studied.

Local Community Participation

To be effective, accident prevention programs require local participation and cooperation. They must be broad based, and they require considerable effort by members of the local community. In the United States, one effective program is the New York Health Department's “Kids Can't Fly” campaign, developed in response to the large number of injuries and deaths from children falling out of apartment house windows in the 1970s (120). This extensive program consisted of a good reporting system from hospital emergency rooms, with follow-up by public health personnel; a strong media campaign to educate the public; a door-to-door hazard identification program; and the distribution of low- or no-cost, easily installed window guards to families in high-rise apartments. The city required landlords to provide window guards in apartments where children 10 years or younger lived. The success of this program was demonstrated by a 50% decrease in reported falls after 3 years and a 96% decrease after 7 years (116,120).

Over the past 30 years, Sweden has developed broader based, community-oriented programs to decrease the incidence of all types of childhood injuries (117). The development of these pilot programs has been relatively easy in a country like Sweden because the population is homogeneous, the incidence of poverty is low, and the government is stable. The Swedish program had a three-pronged approach: injury surveillance and prevention research; establishment of a safer environment for children through legislative regulation; and a broad-based safety education campaign. These programs have produced positive results. Schelp demonstrated a 27% reduction in home accidents in the municipality of Falkoping only 3 years after the establishment of a community-wide campaign (119).

One of the most dramatic changes came in the prevention of drowning. In Sweden, 100 children drowned in 1954; by 1988, the number had decreased to 10 (117). In the same time period, there was only a 5% decrease in the number of childhood drownings in the United States. The decrease in drowning did not result from establishing new, sophisticated emergency medical services or intensive care units in hospitals; it came by teaching children to swim and promoting the use of life jackets on toddlers playing near the water. In addition, there was a public education campaign in the media locally and nationally.

Effective prevention programs require local community participation and education. All the articles, lectures, and pamphlets in the world cannot help unless local communities make the necessary changes to decrease accident risks.

2
THE BIOLOGIC ASPECTS OF CHILDREN'S FRACTURES

EDWARD W. JOHNSTONE
BRUCE K. FOSTER

THE IMMATURE SKELETON

Compared with the relatively static, mature bone of adults, the changing structure and function, both physiologic and biomechanical, of immature bones make them susceptible to different patterns of failure. Even the types of fracture patterns within a given bone demonstrate temporal (chronobiologic) variations that may be correlated with progressive anatomic changes affecting the epiphysis, physis, metaphysis, and diaphysis at macroscopic and microscopic levels.

Skeletal trauma accounts for 10% to 15% of all childhood injuries (60,128,129,131,171). Fractures of the immature skeleton differ from those of the mature skeleton (6,128,129). Fractures in children are more common and are more likely to occur after seemingly insignificant trauma. Fractures may involve the various growth mechanisms: Physeal disruptions make up about 15% of all skeletal injuries in children (128,129,131,132,157). Damage involving specific growth regions, such as the physis or epiphyseal ossification center, may lead to acute or chronic growth disturbances (127,128,166,190). The physis is constantly changing, both with active longitudinal and latitudinal (diametric) growth and in mechanical relation to other components. Physeal fracture patterns vary with the extent of chondro-osseous maturation. Salter-Harris type I injuries are common in infants, and types II, III, and IV become more common as the secondary ossification center enlarges and physeal undulations develop. Joint injuries, dislocations, and ligamentous disruptions are much less common in children; it is more likely that one of the contiguous physes will be damaged. Changing trabecular and cortical structures affect metaphyseal and diaphyseal fracture patterns, and the variable size of the secondary ossification center affects susceptibility to physeal and epiphyseal injuries.

The options of treatments available for the treatment of skeletal injuries in children are expanding. Most notable is the introduction of growth factors, such as the bone morphogenic proteins (BMPs), for the induction of bone formation either in non-healing defects or for bone fusions. It has become necessary for the orthopaedic surgeon to have a good knowledge of the biological aspects of fracture repair. This chapter covers the basic biology of bone growth and fracture repair, including the roles of growth factors and the extracellular matrix.

ANATOMIC REGIONS OF THE CHILD'S BONE

The major long bones of children can be divided into four distinct, constantly changing anatomic areas: the epiphysis, physis, metaphysis, and diaphysis (86). Each region is prone to certain patterns of injury; the intrinsic susceptibility changes with physiologic and biomechanical changes during postnatal development. The four regions originate and become modified as a result of the basic endochondral ossification process. Subsequently, they are supplemented by membranous bone formation along the metaphyseal and diaphyseal shafts. Finally, the regions are remodeled to create mature cortical and trabecular bone.

Epiphysis

At birth, each epiphysis (except the distal femur) consists of a completely cartilaginous structure at the end of each long bone (Fig. 2-1), the chondroepiphysis. The corresponding ossifying structure is the chondro-osseous epiphysis. At a time characteristic for each of these chondroepiphyses, a secondary center of ossification forms and gradually enlarges until the cartilaginous area has been almost completely replaced by bone at skeletal maturity. This chondro-osseous transformation is vascular-dependent (Fig. 2-2). Only articular cartilage remains at maturity.

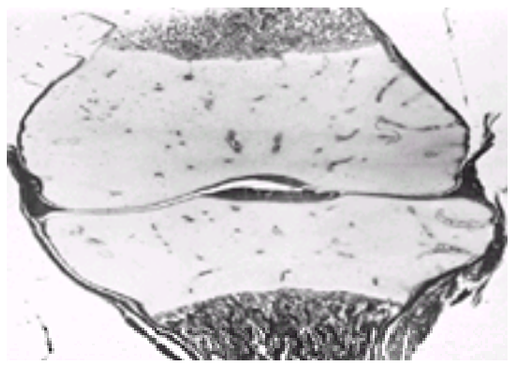

FIGURE 2-1. Chondroepiphyses of the distal femur and proximal tibia. These structures have an extensively developed vascular system (cartilage canals) before secondary ossification.

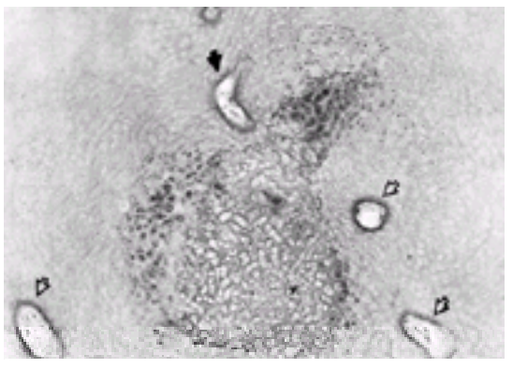

FIGURE 2-2. Early formation of the secondary ossification center within the epiphyseal cartilage. This usually occurs in a region well vascularized by cartilage canals *(open arrows)*. One of the canals sends a branch into the hypertrophic cells *(solid arrow),* triggering the ossification process.

As the ossification center expands, it undergoes structural modifications. The region adjacent to the physis forms a distinct subchondral plate parallel to the metaphysis, creating the radiographically characteristic lucent physeal line. The appearance of the ossification centers differ in certain chondroepiphyses, a factor that must be considered when diagnosing fractures of these regions. The ossification center imparts increasing rigidity to the more resilient epiphyseal cartilage as the secondary osseous tissue expands (176).

The external surface of an epiphysis is composed of either articular cartilage or perichondrium (Fig. 2-3). Muscle fibers, tendons, and ligaments may attach directly to the perichondrium, which is densely contiguous with the underlying hyaline cartilage. The perichondrium contributes to the continued centrifugal enlargement of the epiphysis. It also blends imperceptibly into the periosteum. This perichondrial/periosteal tissue continuity contributes to the biomechanical strength of the epiphyseal/metaphyseal junction at the zone of Ranvier.

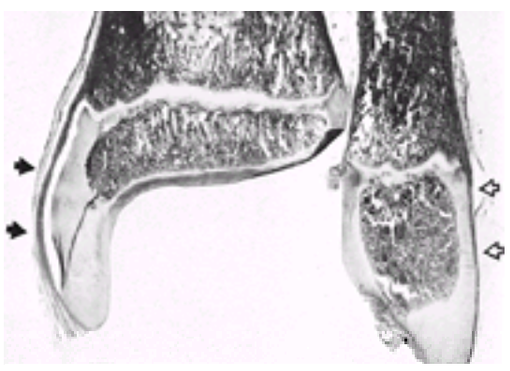

FIGURE 2-3. As the epiphysis matures, the ossification center expands and progressively follows the contours of the chondroepiphysis. The epiphyseal surface is either articular cartilage or perichondrium along the outer surfaces, as in the medial *(solid arrows)* and lateral *(open arrows)* malleoli.

When the hyaline cartilage of the chondroepiphysis first forms, there are no easily demonstrable histologic differences between the cells of the joint surface and the rest of the epiphyseal cartilage. However, at some point, a finite cell population becomes stabilized and physiologically different from the remaining epiphyseal cartilage. McKibbin (104) established that these two cartilage types are different physiologically and, by implication, biochemically. If a contiguous core of articular and hyaline cartilage is removed, turned 180 degrees, and reinserted, the transposed hyaline cartilage eventually will form bone at the joint surface, whereas the transposed articular cartilage remains cartilaginous and becomes surrounded by the enlarging secondary ossification center. Normally, articular cartilage does not appear capable of calcification and ossification. As skeletal maturity is reached, a tide mark progressively develops as a demarcation between the articular and calcified epiphyseal hyaline cartilage.

An important aspect of McKibbin's experiment was an explanation of nonunion of certain fractures in which the fragment may be rotated, causing the articular surface to lie against metaphyseal and epiphyseal bone. Union is unlikely in such a situation because the articular surface is incapable of a reparative osteogenic response, an essential component of bone healing.

Physis

The growth plate, or physis, is the essential structure adding bone through endochondral ossification (121,126,130,166). The primary function of the physis is rapid, integrated longitudinal and latitudinal growth. Injuries to this component are unique to skeletally immature patients.

Because the physeal cartilage remains radiolucent, except for the final stages of physiologic epiphysiodesis, its exact location must be inferred from the metaphyseal contour, which follows the physeal contour. The changing size of the secondary ossification center more effectively demarcates the physeal contour on the epiphyseal (germinal layer) side. As this center of ossification enlarges centrifugally to approach the physis, the originally spherical shape of the ossification center flattens and gradually develops a contour paralleling the metaphyseal contour. Similar contouring also occurs as the ossification center approaches the lateral and subarticular regions of the epiphysis (Fig. 2-4). The region of the ossification center juxtaposed to the physis forms a discrete subchondral bone plate that the essential epiphyseal blood vessels must penetrate to reach the physeal germinal zone (Fig. 2-5). Damage to this osseous plate in a fracture may cause localized physeal ischemia.

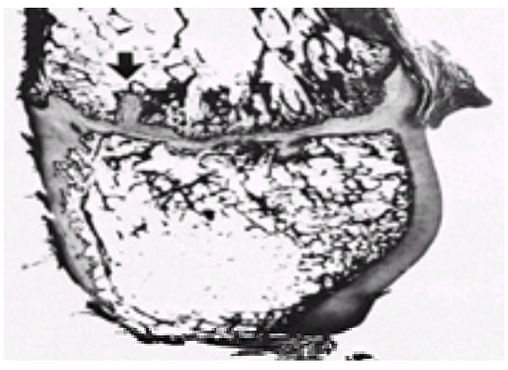

FIGURE 2-4. Distal fibula, showing the variably undulated physis, including a mammillary process *(arrow).* The physeal and epiphyseal cartilage turns proximally at the medial region (lappet formation) to participate in the formation of the distal tibiofibular articulation. Note the difference in the subarticular subchondral bone, which has formed a thick plate, compared with the thin, outer subchondral bone.

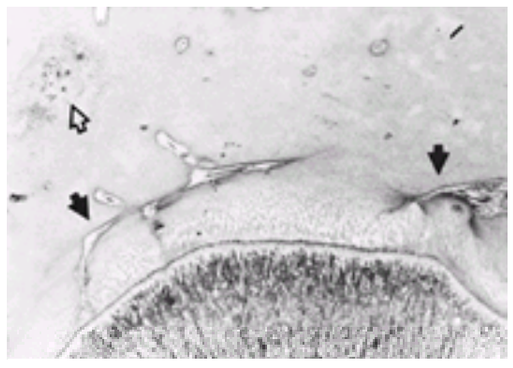

FIGURE 2-5. Epiphyseal circulation *(solid arrows)* in a toddler. These supply the germinal/dividing zones of the physis. The open arrow indicates the early ossification center. As this area enlarges, it will incorporate the epiphyseal vessels.

If a segment of the epiphyseal vasculature is compromised, whether temporarily or permanently, the zones of cellular growth associated with these particular vessels cannot undergo appropriate cell division. In contrast, unaffected regions of the physis continue longitudinal and latitudinal growth, leaving the affected region behind (Fig. 2-6 and Fig. 2-7). The growth rates of the cells directly adjacent to the affected area are more mechanically compromised than cellular areas farther away. The differential rather than uniform growth results in an angular or longitudinal growth deformity, or both (24,132).

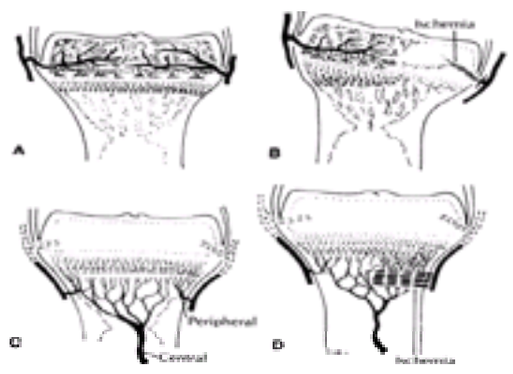

FIGURE 2-6. Patterns of response to ischemia of the epiphyseal **(A,B)** versus metaphyseal **(C,D)** circulatory systems. Metaphyseal ischemia is usually transient; epiphyseal ischemia is usually severe and permanent.

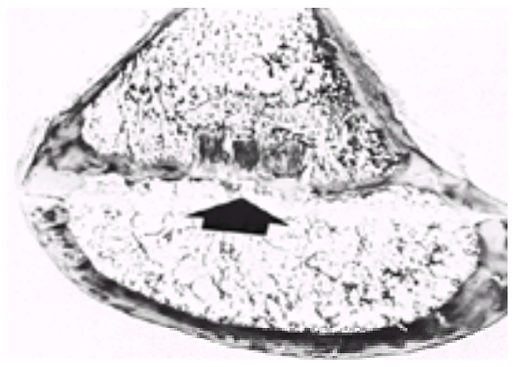

FIGURE 2-7. Histologic section showing an area of central ischemic growth arrest *(arrow).* The infarcted area of cartilage is left behind as the rest of the physis continues longitudinal growth.

Interruption of the metaphyseal circulation has no effect on chondrogenesis within the germinal zone or the sequential cartilage maturation within the hypertrophic zone of the physis (see Fig. 2-6). However, the subsequent transformation of cartilage to bone (primary spongiosa) is blocked (182). This causes widening of the affected area, because more cartilage is added to the cell columns but none is replaced by invasive metaphyseal vessels and bone. Once the disrupted metaphyseal circulation is reestablished, this widened, calcified region of the physis is rapidly penetrated and ossified, returning the physis to its normal width. This is the mechanism seen in growth plate fractures and in fractures of the metaphysis. The metaphyseal blood supply is temporarily blocked by separation or impaction, and requires 3 to 4 weeks for restoration. If the circulatory compromise has been caused by a metaphyseal fracture, there also may be a temporary halt to bone formation in the transiently ischemic portion of the metaphysis. This leads to an apparent sclerosis when the bone is compared with the adjacent vascularized metaphysis, which undergoes a relative disuse osteoporosis. Compromise of the metaphyseal circulation has minimal, if any, effect on physeal development, particularly when compared with the major detrimental effects of epiphyseal circulatory compromise.

The effects of physeal ischemia have been studied extensively by Trueta and coworkers (180,181,182 and 183). Disrupting the epiphyseal circulation leads to either partial or complete cessation of growth. The central region seems more sensitive to ischemia than the periphery, which may have a variable capacity to recover through continued latitudinal growth (112,125). Ischemic compromise leads to different rates of growth across the affected physis and significant changes in physeal contour (19). Some changes may be caused by venous stasis rather than arterial damage (78).

Metaphysis

The metaphysis is a variably contoured flare at each end of the diaphysis. Its major characteristics are decreased thickness of the cortical bone and increased trabecular bone in the secondary spongiosa. Extensive endochondral modeling centrally and peripherally initially forms the primary spongiosa, which then is remodeled into the more mature secondary spongiosa, a process that involves osteoclastic and osteoblastic activity. The metaphyses exhibit considerable bone turnover compared with other regions of the bone, and this factor is responsible for the increased uptake of radioneuclides in technetium 99m bone scans (105).

The metaphyseal cortex also changes with time. Compared with the confluent diaphysis, the metaphyseal cortex is thinner and is more porous (trabecular fenestration; Fig. 2-8). These cortical fenestrations contain fibrovascular soft tissue elements that connect the metaphyseal marrow spaces with the subperiosteal region. The metaphyseal cortex exhibits greater fenestration near the physis than in the diaphysis, with which it gradually blends as an increasingly thicker, dense bone (Fig. 2-9). As temporal longitudinal growth continues, cortical fenestration becomes a less dominant feature, and the overall width of the cortex increases, creating a greater morphologic transition between the juxtaphyseal and juxtadiaphyseal cortices. The metaphyseal region does not develop extensive secondary and tertiary haversian systems until the late stages of skeletal maturation. These microscopic anatomic changes appear to be directly correlated with changing fracture patterns and are the reason why torus (buckle) fractures are more likely to occur than complete metaphyseal or epiphyseal/physeal fractures.

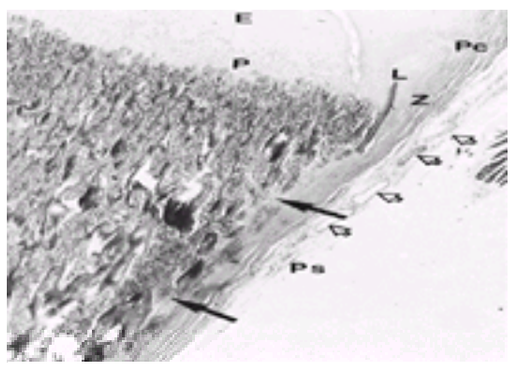

FIGURE 2-8. Cortical fenestration *(solid arrows)* of a metaphysis. Note the interdigitation of periosteal (Ps) tissue with the fenestrations. The periosteum blends into the periochondrium (Pc). Extensive vascularity is often present in this region *(open arrows)*. (E, epiphysis; P, physis; Z, zone of Ranvier; L, ring of Lacroix.)

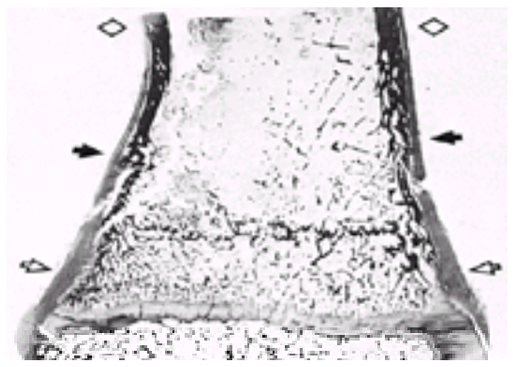

FIGURE 2-9. Section of distal tibia showing the transition *(solid arrows)* of cortical bone from the dense, remodeled diaphysis (diamonds) to the fenestrated metaphysis *(open arrows).* Note the progressive change from a relatively thin periosteum over the diaphysis to a much thicker one at the metaphysis.

Another microscopic anatomic variation in the metaphysis occurs at the junction of the primary spongiosa and the hypertrophic region of the physis. In most rapidly growing bones, the trabeculae tend to be longitudinally oriented. However, in shorter growing bones, such as the metacarpals and phalanges, trabecular formation is predominantly horizontal. As growth decelerates in adolescence, a similar horizontal orientation may be seen in the major long bones. These variations in trabecular orientation affect the responsiveness of metaphyseal and physeal regions to abnormal stress and predispose to certain fracture modes.

Although the periosteum is attached relatively loosely to the diaphysis, it is firmly fixed to the metaphysis because of the increasingly complex continuity of fibrous tissue through the metaphyseal fenestrations. Such intermingling of endosteal and interosseous fibrous tissues with the periosteal tissue imparts additional biomechanical strength to the region (170). The periosteum subsequently attaches densely into the peripheral physis, blending into the zone of Ranvier as well as the epiphyseal perichondrium. The fenestrated metaphyseal cortex extends to the physis as the thin osseous ring of Lacroix.

The metaphysis is the site of extensive osseous modeling and remodeling, both peripherally and centrally (Fig. 2-10). The metaphyseal cortex is fenestrated, modified trabecular bone on which the periosteum deposits membranous bone to thicken the cortex progressively. Similar endosteal bone formation occurs. As this metaphyseal region thickens, the trabecular bone is progressively invaded by diaphyseal osteon systems, not unlike osteons traversing the fracture site in primary bone healing. This converts peripheral trabecular (woven or fiber) bone to lamellar (osteonal) bone, which has different biomechanical capacities, and thus progressively transforms metaphyseal cortex into diaphyseal cortex as longitudinal growth continues. A torus (buckle) fracture is most likely to occur in a metaphyseal region with a trabecular, fenestrated, compressible cortex.

FIGURE 2-10. Extensive modeling and remodeling of the medial (M) versus the lateral (L) cortex of the distal femur may create irregularities that have been misinterpreted as fracture, stress fracture, infection, and tumor. Note the well-formed subchondral bone at the periphery of the epiphyseal ossification center.

As in the diaphysis, there are no significant direct muscle attachments to the metaphyseal bone. Instead, muscle fibers primarily blend into the periosteum. The medial distal femoral attachment of the adductor muscles is a significant exception. Because of extensive remodeling and insertion of muscle and tendon in this area, the bone often appears irregular and may be misinterpreted as showing chronic trauma (i.e., a stress fracture), infection, or a tumor.

Transverse Lines of Park and Harris

Many bones exhibit transversely oriented, dense trabecular linear bone patterns within the metaphysis. These lines usually duplicate the contiguous physeal contour. They may appear after trauma, particularly when the child has been immobilized in bed (e.g., traction for femoral fracture), and they also may appear after generalized illnesses or even localized processes within the bone (e.g., osteomyelitis) (1,62,137,138). The lines result from a temporary slowdown of normal longitudinal growth after injury or illness, and they often are called Harris growth slowdown or arrest lines (Fig. 2-11). Because of the slowdown, the trabeculae of the primary spongiosa become more transversely than longitudinally oriented, creating a temporary thickening in the primary spongiosa adjacent to the physis. Once the normal longitudinal growth rate resumes, longitudinal trabecular orientation is restored. The thickened, transversely oriented osseous plate is left behind, to be gradually remodeled as primary spongiosa becomes secondary spongiosa.

FIGURE 2-11. Histologic section **(A)** and x-ray study **(B)** of a distal femur showing a typical Harris line *(arrows).* This formed during an acute illness and chemotherapy for leukemia. The child then resumed a more normal pattern of growth until her death from leukemia about 14 months later.

Usually, transverse lines are distributed relatively symmetrically through the skeleton and occupy identical sites in the corresponding bones on the two sides of the body. They are thickest in metaphyses that grow most rapidly, such as the distal femur and proximal tibia. In the metaphyses with slowest growth, they may not form at all, or they are exceedingly thin and lie at the very end of the shaft, directly under the provisional zone of calcification. These transverse lines parallel the contours of the physeal provisional zone of calcification. When several transverse lines are present, they tend to be parallel. The lines nearest the end of the shaft ordinarily are the thickest and widest; lines away from the physes tend to be thinner and less distinct and are usually broken and irregular. As they eventually become part of the elongating diaphysis, they disappear completely with endosteal remodeling.

Park (137,138) found that temporary longitudinal growth arrest of a bone was a prerequisite for the formation of a transverse line. During this initial phase of growth stoppage or slowdown, a thin, transverse, osseous template was formed along the zone of proliferative cartilage. When longitudinal growth in the proliferating cartilage resumed (the recovery phase), the process became visible radiographically as a transverse line.

More rapidly growing bones are associated with longitudinally oriented trabeculae in the juxtaphyseal region; slower growing bones, particularly the proximal radius, metacarpals, metatarsals, and phalanges, normally have a greater amount of transversely oriented primary spongiosa (118), making transverse septa a normal finding. These particular bones do not have a sufficient difference in the orientation of trabeculae to manifest transverse lines on radiographs. However, if growth slows in the rapidly growing areas normally characterized by longitudinal orientation of trabeculae (e.g., distal femur), then more primary spongiosa bone is formed in a transverse orientation (127). This bone can be quite thick, and probably relates to the duration of the biologic stress. Once normal rates of longitudinal growth and trabecular orientation are reestablished, the transversely oriented septal, juxtaphyseal plate is a contrast to the preexisting longitudinally oriented trabeculae and appears on radiographs as a specific transverse line. As remodeling occurs, with migration of the epiphysis away from this region, and with conversion of primary spongiosa to secondary spongiosa, there is a gradual breakup of this transverse trabecular orientation.

Useful to Assess Growth After Injury

These biologic marker lines are important in analyzing the effects of a fracture on growth. They can be measured and the sides compared to corroborate femoral overgrowth after diaphyseal fracture and eccentric overgrowth medially after proximal tibial metaphyseal fracture. A line that converges toward a physis suggests localized growth damage that may result in an osseous bridge and the risk of angular deformity.

Diaphysis

The diaphysis constitutes the major portion of each long bone. It is principally a product of periosteal, membranous osseous tissue apposition on the original endochondral model. This leads to the gradual replacement of the endochondrally derived primary ossification center and primary spongiosa; the latter is replaced by secondary spongiosa in the metaphyseal region. At birth, the diaphysis is composed of laminar (fetal, woven) bone that characteristically lacks haversian systems. The neonatal femoral diaphysis appears to be the only area exhibiting any significant change from this fetal osseous state to a more mature bone with osteon systems (lamellar bone) before birth (Fig. 2-12).

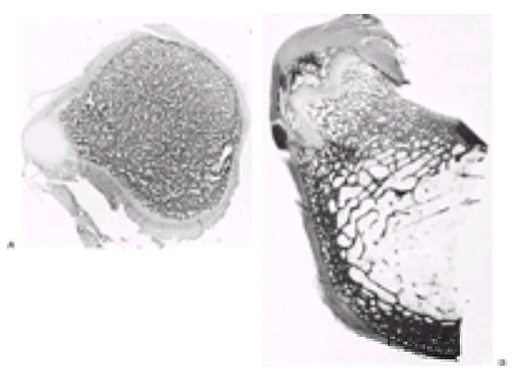

FIGURE 2-12. Sections of the femur at the level of the lesser trochanter at birth **(A)** and age 7 years **(B)**. At birth, some cortical thickening and osteon remodeling is evident laterally; the rest of the cortex is irregular. By age 7 years, extensive thickening and remodeling of the cortex has taken place.

Periosteum-mediated, membranous, appositional bone formation with concomitant endosteal remodeling leads to enlargement of the overall diameter of the shaft, variably increased width of the diaphyseal cortices, and formation of the marrow cavity. Mature, lamellar bone with intrinsic but constantly remodeling osteonal patterns progressively becomes the dominant feature (Fig. 2-13).

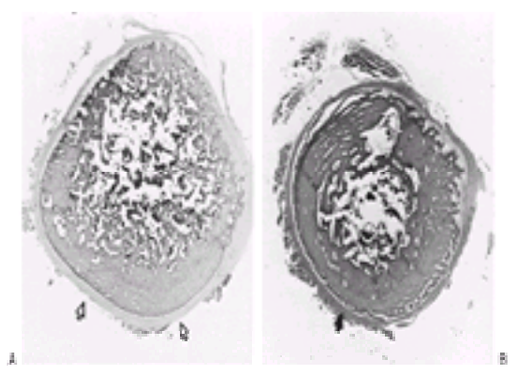

FIGURE 2-13. Transverse sections of the tibial diaphysis in a neonate **(A)** and at age 2 years **(B)**. A thick periosteum is evident in **A** *(open arrows),* in association with a rapidly forming anterior cortex. At age 2 years, new subperiosteal (membranous) bone is being added to the cortex *(solid arrow)*.

The developing diaphyseal bone in a neonate or young child is extremely vascular. When analyzed in cross section, it appears much less dense than the maturing bone of older children, adolescents, and adults. Subsequent growth leads to increased complexity of the haversian (osteonal) systems and the formation of increasing amounts of extracellular matrix, causing a relative decrease in cross-sectional porosity and an increase in hardness, factors that constantly change the child's susceptibility to different fracture patterns. Certain bones, especially the tibia, exhibit a significant decrease in vascularity as the bone matures; this factor affects the rate of healing and risk of nonunion.

The vascularity of the developing skeleton constantly changes. In experimental studies, significant chronobiologic changes in flow patterns were found in the developing canine tibia and femur (89,90,105,106,161). In particular, there was a dramatic decrease in tibial circulation with increasing skeletal maturation. This also occurs in humans, which helps to explain the increasing delay in fracture healing and the increased incidence of nonunion of the tibia in adolescents and adults. A poor vascular response could impair the early, crucial stages of callus formation.

Other researchers have suggested that adequate vascularity was a major factor in fracture healing,(150,151,184,190,194), but they did not consider chronobiologic changes in blood flow patterns.

The Periosteum

A child's periosteum is thicker, is more readily elevated from the diaphyseal and metaphyseal bone, and exhibits greater osteogenic potential than that of an adult (126). The periosteum is loosely attached to much of the shaft of the bone, but it attaches densely into the physeal periphery (the zone of Ranvier; Fig. 2-14) through intricate collagen meshworks, thereby playing a role in fracture mechanics and treatment of growth mechanism injuries (170). The thicker, stronger, more biologically active periosteum affects fracture displacement, reduction, and the rate of subperiosteal callus formation. It also may serve as an effective internal restraint in closed reductions.

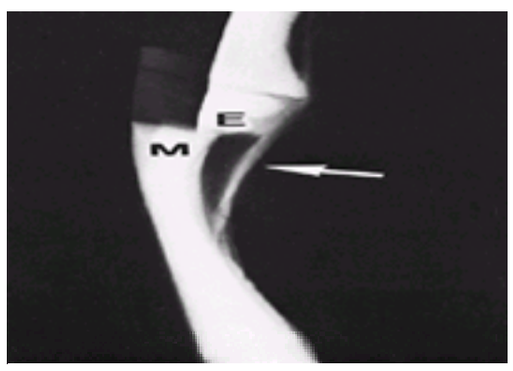

FIGURE 2-14. Simulated type 1 epiphyseal (E) displacement from the metaphysis (M). Note the thick periosteum *(arrow)* and its contiguity with the cartilage of the epiphysis (radiopaque here because of the cartilage and air contrast). In the body, however, the similar soft tissue radiodensities of cartilage, ligament, muscle, and so forth blend together, making them radiolucent.

Because of its contiguity with the underlying bone, the periosteum is usually injured to some extent in all fractures in children. However, because the periosteum more easily separates from the bone in children, there is much less likelihood of complete circumferential rupture. A significant portion of the periosteum usually remains intact on the concave (compression) side of an injury. This intact periosteal hinge or sleeve may lessen the extent of displacement of the fracture fragments, and it also can be used to assist in the reduction, because the intact portion contributes to the intrinsic stability. Because the periosteum allows some tissue continuity across the fracture, the subperiosteal new bone that it forms quickly, bridges the fracture gap and leads to more rapid long-term stability. The periosteum may be specifically damaged, with or without concomitant injury to the contiguous bone. Such avulsion injuries may lead to the formation of ectopic bone (120). In contrast, severe disruption of the periosteum, as in an open injury, may impair the fracture healing response. Complete loss of a bone segment, with the periosteal sleeve reasonably intact, may be followed by complete reformation of the missing bone (16).

The periosteum, rather than the bone itself, serves as the origin for most muscle fibers along the metaphysis and diaphysis. This mechanism allows coordinated growth of bone and muscle units; this would be impossible if all the muscle tissue attached directly to the developing bone or cartilage. Exceptions include the attachment of muscle fibers near the linea aspera and into the medial distal femoral metaphysis. The latter pattern of direct metaphyseal osseous attachment may be associated with significant irregularity of cortical and trabecular bone. Radiographs of this area often are misinterpreted as showing a neoplastic, osteomyelitic, or traumatic response, even though they exhibit only a variation of skeletal development.

Apophysis

Because of the differing histologic composition of the tibial tuberosity (fibrocartilage instead of columnar cartilage; Fig. 2-15), failure patterns differ from those in other physes. This area develops primarily as a tensile-responsive structure (i.e., an apophysis). However, the introduction of an osseous secondary ossification center initially in the distal tuberosity interposes osseous tissue, which tends to fail in tension and which may lead to avulsion of part of this ossification center (Fig. 2-16). Healing of the displaced fragment to the underlying undisplaced secondary center creates the symptomatic reactive overgrowth known as an Osgood-Schlatter lesion (119,123). Similarly, in adolescents, excessive tensile stress may avulse the entire tuberosity during the late stages of closure (124).

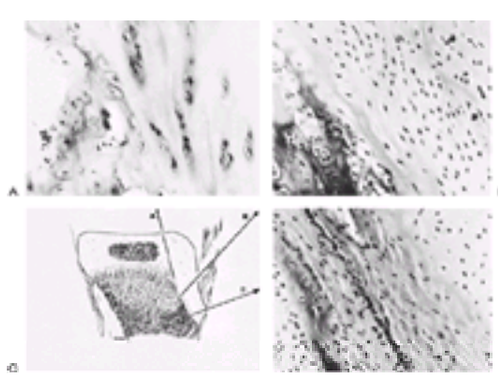

FIGURE 2-15. Histology of a typical apophysis, the tibial tuberosity (tubercle). **A:** Attenuated columnar cartilage adjacent to the main proximal tibial physis. **B:** Fibrocartilage and minimal hypertrophic matrix in the mid-tuberosity region. **C:** Fibrocartilage and membranous ossification in the distal end of the tuberosity.

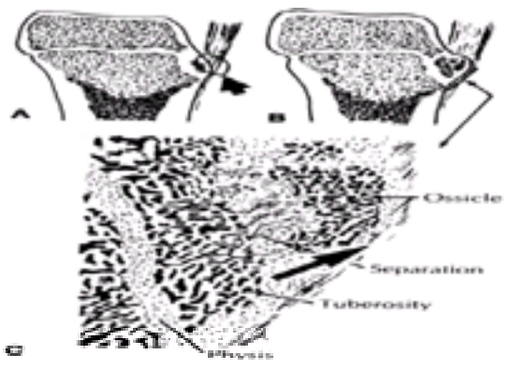

FIGURE 2-16. Avulsion (tension) failure of the developing ossification center of an apophysis. The degree of displacement determines the likelihood of healing and the symptoms and size of the final lump, typical of an Osgood-Schlatter injury.

THE MOLECULAR BONE

Molecules of the Cartilage and Bone Matrices

The Cartilage Matrix

The cartilage matrix is synthesized by chondrocytes. The main constituents of the cartilaginous matrix are collagens (mainly type II) and proteoglycans. Although collagen type II provides structural strength, the proteoglycans have structural and regulatory effects. The structural effects of proteoglycans arise through binding to the collagen components and the water-binding properties that provides resilience to compression. Regulatory effects include growth factor interactions, cell matrix interactions, and regulation of collagen fibril size. Specific molecules expressed and their functions are listed in Table 2-1.

Component	Site of Expression Within Physis and Proposed Functions	
Collagens		
Collagen II (fibril)	Predominate collagen of all cartilage	Imparts strength, site of initial mineralization (313, 143)
Collagen IX	Proliferative zone of the physis	Associates with the surface of the collagen II fibril (78)
Collagen X (short chain collagen)	Hypertrophic cartilage	Mineralization (52, 71, 80)
Collagen XI (fibril)	Proliferative and hypertrophic zone of the physis	Collagen fibril size (191)
Proteoglycans		
Aggrecan	Throughout cartilage	Imparts resistance to compression. Forms aggregates with hyaluronic acid and link proteins (23, 113, 159)
Decorin (DS-PG2)	Within chondrocytes and the interterritorial capsules of the upper proliferative chondrocytes	Collagen fibril size and TGF-β activity (7, 67, 144)
Biglycan (DS-PG1)	Territorial capsules of the upper proliferative chondrocytes	TGF-β activity (67)
Fibromodulin		Collagen fibril diameter and binding of cells to fibrillar matrix (66)
Matrilin (Cia protein)	Cartilage	Inhibits mineralization (92)

TABLE 2-1. MATRIX MOLECULES OF CARTILAGE

The Bone Matrix

Except for a small percentage of molecules from the circulation and preexistent matrices that may become entrapped, the bone matrix is almost entirely synthesized by osteoblasts. The composition of the bone matrix was outlined by Buckwalter and associates (20). Briefly, bone matrix is a composite material composed of an inorganic (mineral) portion and an organic portion. The composite structure provides physical strength and resilience to fracture. Bone with deficient inorganic mineral content is pliable, and bone with deficient organic content is brittle.

The composition of living bone is 60% to 70% inorganic components, 5% to 8% water, and the remainder is organic (76). The inorganic portion is mainly hydroxyapatite, with some carbonate and acid phosphate groups. It has also been suggested that bone crystals do not contain hydroxyl groups and should be termed apatite rather than hydroxyapatite (20). The organic portion is composed of collagen type I (90%) and noncollagenous proteins. The noncollagenous protein portion includes a number of proteins and proteoglycans that perform structural and regulatory functions. Actual molecules and functions are outlined in Table 2-2 and in the following section.

Component	Proposed Functions
Collagens	
Collagen I	Imparts strength, site of initial mineralization
Collagen V	Provide the inner core of the collagen fibril (8, 46)
Collagen VI	Cell attachment
Collagen XII	Collagen fibril size
Proteoglycans	
Decorin (DS-PG2)	Collagen fibril size, TGF-β activity (162, 163)
Biglycan (DS-PG1)	Collagen fibril assembly, TGF-β activity (164, 195)
Fibromodulin	Collagen fibril diameter, binding of cells to matrix molecules (66)
Osteocalcin (bone Gla protein)	Binds hydroxyapatite (146, 587)
Matrix Gla protein	Controls mineralization (92, 146)
Osteonectin	Binds calcium (11)
Osteopontin	Cell attachment (102).

TABLE 2-2. COMPOSITION OF BONE

Matrix Constituents

Although it is not a complete list, the following provides an example of the major proteins found within bone and cartilage matrices.

Collagens

Collagens are a family of proteins coded by at least 19 distinct genes. Members are expressed in most tissues. Collagens have a triple helical region that arise from the repeated winding of three collagen molecules around a common axis. Collagens are synthesized as a propeptide that is often glycosylated. Collagen is secreted from cells and is processed in the extracellular space. The processed collagen forms into subunits that then undergo fibrillogenesis (Fig. 2-17). The fact that the final fiber is composed of many individual molecules accounts for the observed dominant negative mutations that can be observed within the collagen family (74). The incorporation of individual molecules that contain mutations that affect the packing of the peptides into the triple helix can disturb the structure of the whole fiber. The molecular structures that arise are in the form of fibrils or netlike structures. In reality, the multimeric fibers observed *in vivo* are often composed of a number of different collagens (5).

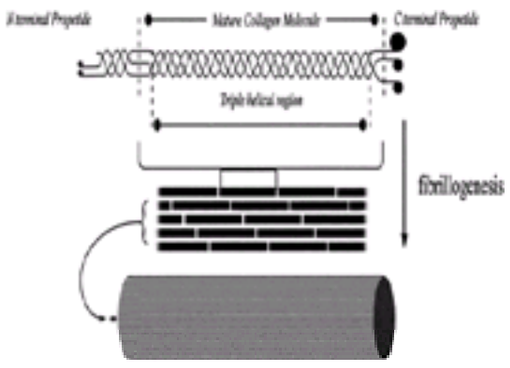

FIGURE 2-17. Collagens are synthesized as a propeptide that is often glycosylated (not shown). The collagen molecule has a triple helical region that arises from the repeated winding of three collagen molecules around a common axisis. The processed collagen forms into subunits that then undergo fibrillogenesis.

Collagen type I is the main collagen found in bone and other tissues. It is composed of two a1(I) and one a2(I) polypeptides. The collagen type I fibers act as sites for initial mineralization and provide tensile strength to the bone. Mutations in the propeptides can cause a variety of phenotypes affecting mineralization and bone fragility, the most severe being osteogenesis imperfecta. In contrast, collagen type II is a triple helical molecule that is composed of three a1 (II) polypeptides and is expressed within cartilage. It is the main fibril-forming collagen in cartilage. Mutations cause Langer-Saldino achondrogenesis and spondyloepiphyseal dysplasia congenita (27,45).

Other collagen types, such as V, IX and XI, associate with the collagen fibers. They may influence collagen diameters and interact with other matrix molecules. Mutations in types IX and XI can result in a number of clinical manifestations (134). Collagen type X is associated with the matrix of hypertrophic chondrocytes and is involved with the mineralization process (80,81,139). Mutation causes spondylometaphyseal dysplasia (74), but the deletion of the encoding gene results in mild changes (73,155).

Proteoglycans

Proteoglycans are present in large amounts within all connective tissues. Proteoglycans are proteins that have either one or a number of polysaccharide chains linked to a protein core. The polysaccharide's glycosaminoglycan side chains are either heparin, heparin sulfate, chondroitin sulfate, dermatan sulfate, or keratan sulfate. The glycosaminoglycans differ in the composition of their constituent disaccharide structures. They can combine with other molecules within the matrix to form macromolecular structures (49) (Fig. 2-18).

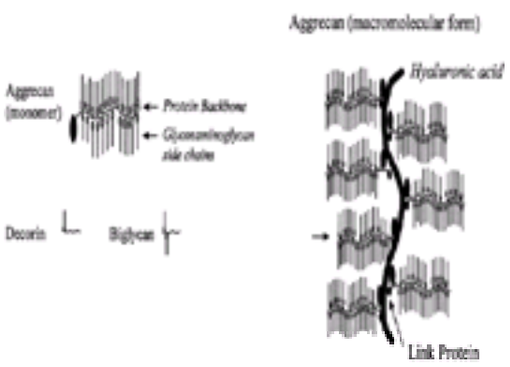

FIGURE 2-18. Proteoglycans are proteins, which have either one or a number of polysaccharide (glycosaminoglycan) chains linked to a protein core. Aggrecan is present in cartilage and has the ability to form macromolecular structures with hyaluronic acid and link protein. Decorin and biglycan are present in bone and cartilage matrix.

Proteoglycans are a critical component of cartilage and bone (23,113,144). The proteoglycans present in the physis include large proteoglycans like aggrecan as well as smaller proteoglycans such as decorin, biglycan, and possibly, fibromodulin. Decorin and biglycan have side chains of dermatan sulfate, and betaglycan has chondroitin and heparin sulfate chains. Fibromodulin has side chains of keratan sulfate. The territorial capsules of the chondrocytes in the upper proliferative region of the physis stains for biglycan, the interterritorial matrix stains for decorin (7). These proteoglycans have a structural role but are also known to interact with growth factors (7,67,144).

Other Noncollagenous Proteins

Osteocalcin is also known as bone Gla protein. It has three residues of gamma-carboxyglutamic acid that enable it to bind to hydroxyapatite. It is thought to play a role in mineralization of the bone matrix (146,147), but the exact mechanism and function are undetermined (35,63).

Osteonectin has the ability to bind calcium and collagen type I, and may enable the process of mineralization that is initiated on the collagen type I fibers (11).

Osteopontin is thought to be critically involved with the binding of osteoclasts (70,149), cells that degrade to the bone matrix (103).

Matrix Gla protein is an inhibitor of calcification. The cartilage of mice lacking this protein undergoes spontaneous calcification (93).

Growth Factors

Within an individual, cell-to-cell communication occurs between neighboring cells and between cells that are separated by an almost complete body length. Communication signals take the form of diffusible molecules which pass between the cells or by cell surface–bound receptor-ligand interactions (88,193). In addition, neighboring cells can pass information between one another via their gap junctions (48). These channels enable the passage of small molecules, including calcium ions, between neighboring cells. Calcium is a key second messenger that provokes a number of cellular events (110).

Hormones are a group of diverse molecules that are secreted by endocrine glands and are transported to their effect target tissues by body fluids. They coordinate body functions in complex organisms. Hormones can be in the form of amino acid derivatives (e.g., epinephrine) polypeptides (e.g., somatotropin or growth hormone), glycoproteins (e.g., follicle-stimulating hormone), steroids (e.g., testosterone), or fatty acids (e.g., prostaglandins).

Growth factors and hormones may circulate in a free form or be bound to carrier molecules or the extracellular matrix (136). The binding of growth factors and hormones to other molecules may result in inhibition of the degradation, delivery, and controlling of activity. Many growth factors, including the fibroblast growth factors, transforming growth factor-b (TGF-b), and insulin-like growth factors, can be bound to the matrix. Cell activation usually requires the factors to bind to receptors on the cell surface, although a number of hydrophobic hormones pass directly through the outer membrane and bind to intracellular receptors (31,44,99,116) (Fig. 2-19).

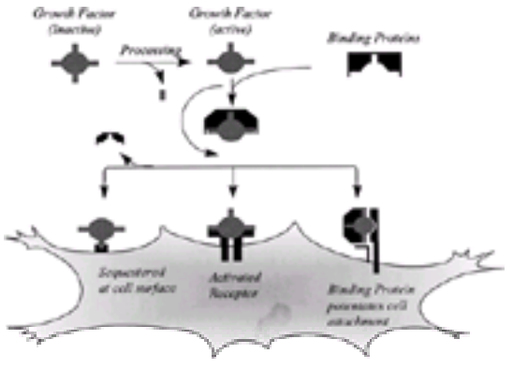

FIGURE 2-19. The figure shows aspects of growth factor interactions. Any particular growth factor will possess only a subset of such interactions. Growth factors may require activation (e.g., TGF-b). Binding proteins may sequester or protect the growth factor. The binding protein may also potentate the binding of the growth factor to the surface receptor (e.g., FGF and heparin). Cells may also sequester the growth factor at the cell surface.

A degree of redundancy often exists in that a gene knockout for one particular growth factor may result in only slight changes in the phenotype observed. A good example is the double mutant of BMP-5 and 7, which is lethal during embryonic development, but a null mutation in either one has little effect (169).

Fibroblast Growth Factors

The biologic effects of the fibroblast growth factors are widespread. Fibroblast growth factors are angiogenic and can influence mitosis and differentiation in many cell types. The receptors to these growth factors have been implicated in a number of skeletal deformities including Pfeiffer's syndrome (FGFR1), Crouzon's and Jackson-Weiss syndromes (FGFR2), and achondroplasia (FGFR3).

To date, the fibroblast growth factor family comprises at least nine members including acidic fibroblast growth factor (FGF-1), basic fibroblast growth factor (FGF-2) (10,15,47,97,111,156,172,174,199). Additional fibroblast growth factors exist that have far less homology. FGF-1 and FGF-2 are present in the extracellular matrix of bone (64).

The FGFs are also complicated by the presence of alternative forms of the specific forms of FGF-1 and FGF-2. FGF-1 is typically 140 amino acids in length, but larger forms of 160 and 154 amino acids have been identified (27,43,53,61). FGF-2 is normally translated as an 155 amino acid molecule, but through the use of alternative start codons, another three higher molecular weight forms have been identified.

The acidic and basic forms of FGFs are well conserved across species. Comparing the amino acid composition of FGF-1 and FGF-2 from different species, Hearn found a 92% sequence identity between human and bovine acidic fibroblast growth factor. Only 2/155 and 3/155 amino acids differ in human and bovine, and human and ovine, forms of basic fibroblast growth factor, respectively (65).

Six receptor molecules have been identified so far. FGF receptors can be divided into two groups by the relative affinity of the ligands to their receptors.

Transforming Growth Factor

The TGF-b superfamily is composed of more than 24 members (68). They are subdivided into families including TGF-b, inhibin, decapentaplegic protein/vegetal hemisphere 1 (DPP/Vg1), and müllerian-inhibiting substance. Members of the TGF-b and the DPP/Vg1 families have critical functions in the development of the skeleton, its growth and maintenance, and fracture repair. The bone morphogenic proteins (except for BMP-1) are members of the DPP/Vg1 family and are discussed in the next section.

All TGF-b family members except TGF-b4 are synthesized as large precursor forms that are processed to active forms. The active form is either a heterodimer or homodimer. It is thought that the pro-region may either help in the folding of the proteins during synthesis or control activity. In the case of TGF-b1, the pro-region and a second glycoprotein can also bind to the active factor to form a latent complex. Members of the TGF-b family are highly expressed in bone (TGF-b1, TBG-b2). Important in fracture repair, TGF-b1 and TGF-b2 are also released in large quantities during platelet activation.

Apart from the presence of the growth factor itself, the presence or absence of the latent complex controls the activity of TGF-b1. TGF-b members can also be sequestered in the matrix. The active TGF-b1 complex can be released from the latent complex by extreme pH or by catalytic methods. This is particularly important in fracture repair and bone remodeling. The activation of latent TGF-b is likely to be critical in the induction of fracture repair and osteoblast function.

The active TGF-b molecules may also be bound and their activity controlled by a number of matrix molecules, including betaglycan and decorin (100,197). Alternatively, the active TGF-b may bind to cellular receptors, of which there are at least nine. However, most of the actions are mediated through two receptors termed receptor 1 and 2. Receptors 1 and 2 are members of the serine/threonine kinase family (100). TGF-b receptor type 3 is a membrane-bound proteoglycan termed betaglycan. Betaglycan is thought to act as a TGF-b cell surface reservoir and is not involved with signal transduction itself. Betaglycan has the possibility of binding FGF through the heparin sulfate chains and may present TGF-b in conjunction with FGF to the cell (100). TGF-b also binds to the small proteoglycans: biglycan, decorin, and fibromodulin (67). The small proteoglycans bind TGF-b through the leucine-rich repeats in their protein cores and are thought to sequester TGF-b in the matrix. They also compete with betaglycan in binding TGF-b. Decorin has the ability to negatively regulate the activity of TGF-b (13,160).

Bone Morphogenic Proteins

The bone morphogenic proteins and their orthopaedic relevance have recently been reviewed by Schmitt and colleagues (160). The bone morphogenic proteins (except BMP-1) represent a group of related growth factors that have critical roles in the cell proliferation and differentiation of a number of cell types including mesenchymal cells, chondrocytes, and osteoblasts (28,82,83,186). They have roles in embryo and fetal development, bone growth, and fracture repair. They also include a number of growth factors (BMP-2, BMP-7) (OP-1), which are being proposed for the treatment of fractures and the establishment of bone fusions.

BMPs exist as glycosylated dimers. Thirteen have been identified so far, but owing to sequence homology, only BMP-2 through 9 can be classed as members of the TGF-b family. Particular BMPs produce ectopic cartilage or bone when implanted subcutaneously (2,188). Like the other growth factors discussed so far, the BMPs have a number of binding proteins both in the intracellular matrix and on the cell surface. A secreted glycoprotein termed noggin can bind and inactivate BMPs (50). Chordin is a similar protein that most likely has a similar function (142). It has been proposed that these proteins control BMP activity and may also serve as a mechanism for establishing gradients of BMPs across the embryo during development. Active BMPs bind to heterotetrameric serine/threonine kinase receptors. The nonactivated receptors exist as type 1 and 2 receptor proteins, the type 2 receptor autophosphorylates. Once the ligand binds, the two receptors are brought together and the receptor type 1 portion is phosphorylated. Only after the receptor type 1 is phosphorylated is a cellular response achieved. Intracellular activation is via the intracellular proteins termed SMADs (the humor equivalent of the MAD (mothers against decapentaplegic) protein), but other inhibitors can still come into play. Exposure of the cell to a number of other growth factors (including cer-1) can inhibit the activation of the cell by BMPs (140,160).

Angiogenic Growth Factors

Angiogenic factors are growth factors that promote neovascularization. They are critical in fracture repair. The invasion of the metaphyseal vascular supply is crucial to endochondral ossification, and fracture repair does not occur without an adequate vascular supply. It is probably not by accident that a number of angiogenic factors such as TGF-b and FGF-2 are sequestered in the bone matrix. Angiogenic factors act directly or indirectly on endothelial cells, promoting proliferation and migration of the cells into areas in which they are released. Angiogenic factors acting indirectly by recruiting macrophages monocytes, in turn, release their own direct-acting angiogenic factors (165).

Direct-acting angiogenic factors include platelet-derived endothelial growth factors (PDEGFs), TGF-b, and FGF-2 to name but a few. Indirect acting angiogenic

factors include TGF-b and tumor necrosis factor-a (TNF-a).

MECHANISMS OF BONE GROWTH

Because bone is rigid, it cannot grow by internal expansion and bone growth is achieved by adding newly synthesized bone to existing bone by two mechanisms: *endochondral ossification* and *intramembranous ossification.* These mechanisms are named by the intermediate structures, that must be passed to form the bone. The production of any particular bone after initial differentiation may involve discrete, juxtaposed, or interspersed areas of each basic pattern. Endochondral-derived bones generally have membranous ossification by appositional bone growth from the periosteum. Similarly, membrane-derived bones may grow and elongate by an endochondral process (126,130).

Endochondral Ossification

Endochondral ossification is the process by which bone forms via a cartilaginous intermediate. The physis best reflects this process. Physes are temporary cartilaginous tissue situated between the primary and secondary ossification centers of all long bones. From 9 to 10 weeks' gestational age to skeletal maturity at 15 to 17 years, they are responsible for the longitudinal growth of bone. The physis can be divided into at least three zones. The reserve zone is situated on the epiphyseal side and contains small, spherical cells randomly distributed throughout the zone. In the adjacent proliferative zone, chondrocytes undergo mitosis and are organized into columns running parallel to the axis of bone growth. Cells in the proliferative zone mature and eventually increase to 5 to 10 times their volume in the hypertrophic region. Matrix vesicles are also deposited within the longitudinal septa of the physis. Matrix vesicles are membrane-encapsulated structures that are thought to concentrate calcium and phosphate. Enzymes such as alkaline phosphatase convert organic phosphates to inorganic phosphate. The longitudinal septum around the terminal hypertrophic chondrocytes mineralizes, and this mineralized matrix forms the template for new bone deposition in the metaphysis (Fig. 2-20).

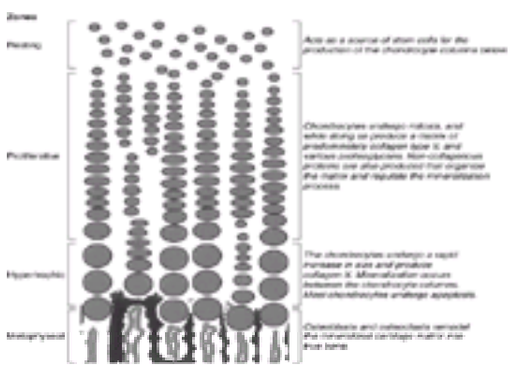

FIGURE 2-20. The figure shows the process of endochondral ossification within the physis. Although not as organized, endochondral ossification follows a similar pattern during fracture repair.

Associated with these changes in cellular arrangement and volume, the matrix in the physis also undergoes a continual modification in content. The two major macromolecules of cartilage matrix produced by the chondrocytes are the proteoglycans (predominantly aggrecan with lesser amounts of decorin, biglycan, and fibromodulin) and the collagens (types II, IX, X, and XI). The major change in physeal proteoglycan structure occurs as chondrocytes organize into columns in the proliferative zone. Additional variation occurs in the hypertrophic region, where the glycosaminoglycan sulfation pattern demonstrates differences between the pericellular and extracellular spaces and the appearance of a unique collagen (type 10) is observed. The small proteoglycans—decorin, biglycan, and fibromodulin—are also differentially expressed across the physis, although detailed studies of these proteoglycans have not been done (see Table 2-1).

The cellular changes and associated matrix alterations are geared toward producing a microenvironment within the hypertrophic zone of the physis, which is conducive to matrix mineralization.

Regulatory Mechanisms in the Physis

Hormones, for example, normal growth hormone, have a global effect on physeal function throughout the body, but many growth factors act locally. The action of these growth factors have often been determined *in vitro* and *in vivo* and can often present conflicting results due to experimental design and models used. Most investigations have concentrated on the effect of single or, in some cases, two growth factors. However, it is likely that endochondral ossification is controlled by a large number of growth factors whose activity is controlled by a large number of binding proteins both within the matrix and on the chondrocyte surface. Cellular response is determined by parallel processing of the intracellular signals that are induced by a number of active growth factors binding to their specific receptors. Presented is an outline of the likely actions of a number of key growth factors on endochondral ossification. It is not complete, and the models will continue to change.

BMP-2 and 7 promote proliferation and matrix synthesis in undifferentiated chondrocytes (40,84). It is believed that once the chondrocytes start differentiating, the expression of noggin inhibits the continual outgrowth of the undifferentiated chondrocytes (18). The prechondrocytes may also respond to growth hormone (117,133). Once the chondrocyte has lost its resting phenotype, insulin like growth factor-1 (IGF-1) may act as a stimulator of proliferation and differentiation (117,176). EGF can augment IGF stimulation by increasing the expression of the IGF-1 receptor (12). Although the chondrocytes synthesize large quantities of matrix molecules, they also synthesize FGF-1, FGF-2, TGF-b, and a number of the BMPs (16,25,29). These molecules can act in an autocrine manner, but many are sequestered into the newly forming cartilage matrix. FGF-2 in low doses is mitogenic for the chondrocytes (94); however, as occurs in achondroplasia, constant activation of FGF receptor (FGFR3) is inhibitory (87,95). FGF/heparin sulfate interaction is probable in the differentiation of the physeal chondrocytes because the continuous exposure of FGF-2 inhibits chondrocyte differentiation *in vitro* and inhibitors of glycosaminoglycan sulfation (including heparin sulfate) restore the differentiation process. Additional sulfate permits glycosaminoglycan sulfation and returns the effect of FGF-2 (30).

Vitamin D metabolites and parathyroid hormone have roles in calcium mobilization within the body, but they also influence endochondral ossification. Parathyroid hormone and parathyroid hormone–related protein (PTHrp) can inhibit the maturation of chondrocytes. It is postulated that physeal chondrocytes regulate the local production of PTHrp by secreting a protein (Indian Hedgehog). This protein stimulates the chondrocyte to produce PTHrp, which slows the maturation of proliferative chondrocytes to hypertrophic form (85,187). Expression of the mRNA for BMP-6 peaks before mineralization (25) (Fig. 2-21).

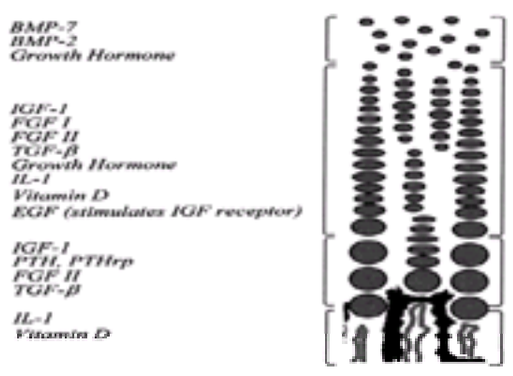

FIGURE 2-21. Growth factors that control or influence maturation and proliferation are shown. See the text for specific actions.

Although the chondrocytes of the physis will proliferate and form a cartilaginous matrix with only the epiphyseal vascular supply, the metaphyseal vessels are critical

for the mineralization process (183). Metaphyseal vascular invasion occurs at the hypertrophic–metaphyseal interface. The endothelial cells most likely invade as a consequence of angiogenic factors present in the matrix or secreted by the chondrocytes themselves. Both TGF-b and FGFs are known to be angiogenic. It is interesting that an oversupply of FGF-2 infused into the physis induces vascular invasion from the metaphysis only; even if the FGF-2 is present at the epiphyseal side of the physis, the epiphyseal vessel will not invade (4). Although it is often stated that the metaphyseal vessels provide the necessary nutrients for the mineralization process, it is possible that they provide additional growth factors that initiate the mineralization process.

The vascular supply also brings osteoblasts, osteoclasts, and other cell types. The osteoclasts degrade the mineralized cartilage matrix while osteoblasts lay down new bone that is also rich in growth factors such as TGF-b, FGF-2 and the BMPs.

Membranous Ossification

All axial and appendicular skeletal elements are involved in secondary membranous ossification. The diaphyseal cortex of developing tubular bone is progressively formed (modeled) by the periosteum and modified (remodeled) by the re-formation of osteons. This peripheral periosteal process of membrane-derived ossification is extensive and rapid in fracture healing in infants and young children. The replacement process also may be seen when portions of the developing metaphysis or diaphysis are removed for use as bone grafts.

Intramembranous ossification occurs when osteoprogenitor cells are formed from the overlying tissue. The osteoprogenitor cells continue to differentiate into osteoblasts, which produce a matrix that undergoes mineralization.

Remodeling of Bones

The first bone to be laid down either from the physis or in the fracture callus is woven bone, which is remodeled to lamellar bone. Although cancellous bone can be remodeled and obtain its nutrients from the surface, cortical bone is remodeled into a complex structure of osteons that together form the cortical bone. Osteons are tubular structures that interconnect. They consist of layers of ordered lamellar bone around a central canal. The central canal contains blood vessels, lymphatics, and in some cases, nerves (20).

Bone is constantly remodeled by osteoclasts and osteoblasts. The bone is encapsulated by bone-lining cells that have the potential to become activated osteoblasts. The bone-lining cells, like osteocytes, have slender cellular processes that make contact with the osteocytes within the mineralized bone. Osteocytes are thought to arise from osteoblasts that have become entrapped during bone formation. It has been proposed that the bone-lining cells need to erode the osteoid that covers the underling bone for osteoclasts to bind (107,108). Osteoclasts are bone-degrading cells that are produced from the hematopoietic pathway. On activation, they bind to the surface of the bone and secrete enzymes into the space beneath. The space is acidic and contains many proteolytic and bone degrading enzymes (98). The acidic pH and proteases are thought to release and activate the sequestered TGF-b, resulting in the differentiation and activation of the bone-lining cells to osteoblasts and onto osteocytes (41,42,101). The osteoblasts then lay down new osteoid, and subsequent mineralization results in bone. Although it is usually accepted that the osteoblast activity and osteoclast activity are linked, discussion still exists about the signals that determine the equilibrium that is required to keep the bone density at functional levels. The osteocytes may be the mechanosensory system. Osteocytes also possess cellular processes that connect osteocytes to one another and to the bone-lining cells above (32) (Fig. 2-22). It is possible that the osteocytes are responsible for sensing bone stress; if undue stress is detected, they favor bone deposition, whereas if a lack of stress is detected, they favor bone resorption.

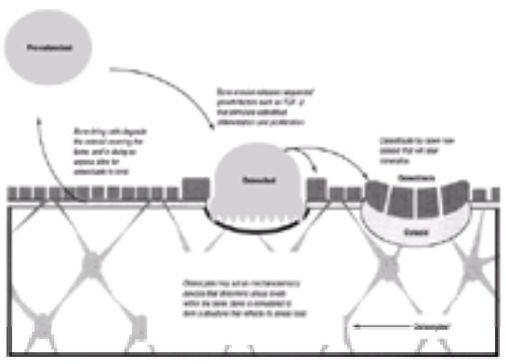

FIGURE 2-22. Osteoclasts and osteoblasts constantly remodel bone. Osteocytes exist within the bone. Bone-lining cells need to erode the osteoid that covers the underling bone for osteoclasts to bind. Osteoclasts bind to the surface of the bone and secrete enzymes into the space beneath. The acidic pH and proteases are thought to release and activate the sequestered TGF-b that results in the differentiation and activation of the pre-osteoblasts to osteoblasts. The osteoblasts then lay down new osteoid, and subsequent mineralization results in bone.

FRACTURE REPAIR

Injuries to the developing skeleton may involve osseous, fibrous, and cartilaginous tissues. Healing of these tissues differs, depending on both the type of tissue and the temporal maturation.

Osseous Healing

The progressive changes of the normal process of osseous fracture healing, whether in the diaphysis, metaphysis, or epiphyseal ossification center, may be grouped conveniently into a series of phases that occur in a reasonably chronologic sequence (104,152,154). Several factors that influence bone healing can be identified from clinical observation as well as experimental work, and these factors must be taken into account when treating childhood fractures on a rational basis. Many experiments have been performed on animals, although because of differences in macroscopic and microscopic bone structure and skeletal homeostatic mechanisms, they may respond differently than skeletally immature humans (137,148,168,171,175,185,196). Furthermore, most experiments have been performed on skeletally mature animals, and such data are not always relevant to fracture healing in the developing skeleton. In addition, certain areas of the developing skeleton, particularly the physis and epiphyseal hyaline cartilage, probably do not heal by classic callus formation. In fact, when this type of osseous (callus) repair occurs in these cartilaginous regions, significant growth deformities may result owing to formation of an osseous bridge between the secondary ossification center and the metaphysis (see Chapter 5).

As in adults, there are three basic mechanisms of fracture repair: primary osteonal, secondary osteonal and nonosteonal. Primary osteonal fracture healing occurs when cortical bone is laid down without any intermediate, and therefore hardly any callus forms; it is only possible if cortical bone is repositioned and fixed in close proximity. Secondary osteonal union occurs if cortical bone is laid down between two segments of fractured cortical bone before callus formation. Nonosteonal union occurs through endosteal and periosteal callus formation (158).

Fracture repair in the immature skeleton can be divided into three closely integrated, but sequential, phases: the inflammatory phase, the reparative phase, and the remodeling phase (Fig. 2-23). In children, the remodeling phase is temporally much more extensive and physiologically more active (depending on the child's age) than the comparable phase in adults. The remodeling phase is further modified by the effects of the physis responding to changing joint reaction forces and biologic stresses to alter angular growth dynamics. This occurs even when the fracture is mid-diaphyseal.

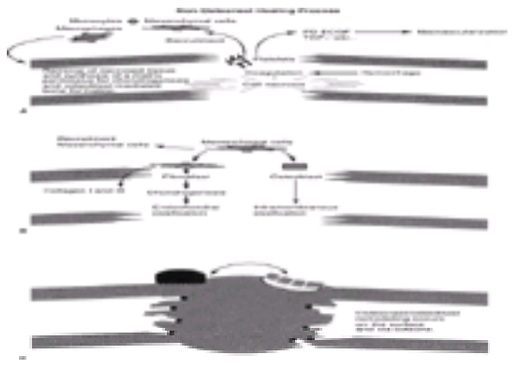

FIGURE 2-23. The figure demonstrates the three phases of fracture repair **(A)** inflammatory phase, **(B)** reparative phase, and **(C)** remodeling phase. The inflammatory cells remove the debris from the fracture site and, together with the fibroblastic cells, develop the site into a matrix that will support the cells that enable new bone to be formed. The mesenchymal cells are recruited by the release of growth factors in the fracture site. The mesenchymal cells may differentiate into osteoblasts that produce bone in a membranous fashion. Alternately the mesenchymal cell may become chondrogenic and produce bone by the endochondral pathway. Remodeling begins with resorption of mechanically unnecessary, inefficient portions of the callus and the subsequent orientation of trabecular bone along the lines of stress.

Cellular Response to Trauma

Inflammatory Phase

Immediately after a fracture through any of the osseous portions of the eveloping skeleton (diaphysis, metaphysis, or epiphyseal ossification center), several cellular processes begin.

Hematoma Formation

Bleeding of the damaged periosteum, contiguous bone, and soft tissues starts the process of repair through the release of growth factors, cytokines, and posteoglandins. If the fracture is localized to the maturing diaphysis, there is bleeding from the haversian systems, as well as from the multiple small blood vessels of the microcirculatory systems of the endosteal and periosteal surfaces and contiguous soft tissue anastomoses (56). In the region of the metaphysis, this bleeding may be extensive because of the anastomotic ramifications of the peripheral and central metaphyseal vascular systems. A hematoma accumulates within the medullary canal at the fracture site, beneath the elevated periosteum, and extraperiosteally whenever the periosteum is disrupted during the fracture. In contrast to adults, the periosteum strips away easily from the underlying bone in children, allowing the fracture hematoma to dissect along the diaphysis and metaphysis; this is evident in the subsequent amount of new bone formation along the shaft.

However, the dense attachments of the periosteum into the zone of Ranvier limit subperiosteal hematoma formation to the metaphysis and diaphysis. Because the perichondrium is densely attached, this type of hemorrhagic response is uncharacteristic of the epiphyseal ossification center, thus limiting its contributions to callus formation and any intrinsic stabilization effect. Further, because of the partially or completely intracapsular nature of some epiphyses, propagation of a fracture into the joint allows decompression of some of the bleeding into the joint, again limiting the potential volume for eventual callus formation.

Coagulation and platelet activation stop the blood loss but also produce both inflammatory mediators and angiogenic factors. Endothelial cells respond and increase the vascular permeability, and allow the passage of leukocytes, monocytes, and macrophages into the fracture site. Neovascularization is also initiated. Angiogenic factors like platelet-derived growth factor (PDGF) and TGF-b, also promote osteoblast recruitment and activation.

Local Necrosis

The blood supply is temporarily disrupted for a few millimeters on either side of the fracture, creating juxtaposed, avascular trabecular and cortical bone (55) and producing local necrosis. It is likely that the necrosis also results in the release of sequestered growth factors (e.g., IGF-1, TGF-b, FGF-1, and FGF-2) from the bone. These growth factors may help in promoting differentiation of the surrounding mesenchymal cells into bone-forming cells.

The inflammatory cells remove the debris from the fracture site and, with the fibroblastic cells, develop the site into a matrix that will support the cells that enable new bone to be formed. This initial matrix often contains collagens type I, III, and V.

Organization of Hematoma

The initial cellular repair process involves organization of the fracture hematoma (39,55,62,69). Fibrovascular tissue replaces the clot with a matrix rich in collagens I, III, and V. This matrix allows chondrogenesis or intramembranous bone formation. Such mechanisms eventually lead to mineralization and the formation of the woven bone of the provisional (primary) callus. Initial invasion and cell division are around the damaged bone ends but proceed centrifugally away from the fracture site, thus placing the most mature repair process closest to the fracture site. However, bone formation occurs only in the presence of an intact, functional microvascular supply. If the vascular supply is deficient, then this modulation of cartilaginous to osseous tissue cannot readily occur.

Reparative Phase

Cellular Organisation

The fracture hematoma is the area in which the early stages of healing occur (145). Osteogenic cells proliferate from the periosteum to form an external callus and, to a lesser extent, from the endosteum to form an internal callus. However, when the periosteum is severely disrupted, healing cells must differentiate from the ingrowth of undifferentiated mesenchymal cells throughout the hematoma. By 10 to 14 days in a child, the fracture callus consists of a thick, enveloping mass of peripheral osteogenic tissue that is beginning to be evident radiographically. This new bone is primarily woven (fiber) bone (101,114,150,151).

The next step in osseous fracture healing is cellular organization (33). During this stage, the circumferential tissues serve primarily as a fibrous scaffold over which cells migrate and orient to induce a stable repair. This pluripotential mesenchyme is theoretically capable of modulation into cartilage, bone, or fibrous tissue (54,57,135). The mesenchymal cells are recruited by the release of growth factors in the fracture site. Members of the BMP family, and possibly their inhibitors, are likely to be involved in the recruitment and differentiation of the mesenchymal cells. The mesenchymal cells may differentiate into osteoblasts that produce bone in a membranous fashion or may become chondrogenic and produce bone by the endochondral pathway. Both mechanisms usually are present in a fracture callus, and the degree to which each is present depends on the type of bone, age, degree of fixation, level of bone loss, and trauma. In children, because of the osteoblastic activity, the periosteum contributes significantly to new bone formation by accentuating the normal process of membranous ossification to supplement the cellular organization within the hematoma, which is going through a cartilaginous phase (58,59). The region around the fracture site thus repeats the process of endochondral ossification, in close juxtaposition to membranous ossification from the elevated periosteum. Similar processes occur within the medullary cavity. An integral part of the reparative process at this stage is microvascular invasion, which occurs very readily in children because of the state of vascularity within and without the bone and surrounding soft tissues (26). Vessels come from the periosteal region as well as from the nutrient artery and endosteal vessels.

Until this bone goes through the final stages of maturation, it is still biologically plastic and, if not protected, may gradually deform, especially in an active young child after early release from an immobilization device. Even in a cast, this plasticity may allow deformation from isometric muscle activity.

Clinical union is attained when the fracture site no longer moves and is not painful to attempts at manipulation, although it is by no means restored to its original strength at this time. With time, the primary callus is gradually replaced. This is enhanced in the child because appositional growth and increasing diameter envelop the original fracture region, the cartilage and woven bone have been replaced by mature, lamellar bone, and the fracture has consolidated and essentially returned to

most of its normal biologic standards and response to stress.

Remodeling Phase

The last phase (remodeling) begins with resorption of mechanically unnecessary, inefficient portions of the callus and the subsequent orientation of trabecular bone along the lines of stress. The remodeling phase is the longest of the three phases and in children may continue until (and beyond) skeletal maturation in response to constantly changing stress patterns imposed by continued skeletal growth and development. Initially, new bone is laid down by both the fracture callus and the more extensive but confluent subperiosteal tissue. This bone is randomly oriented and cannot withstand all biologic stresses imposed on it. However, as the bone grows diametrically in the diaphyseal or metaphyseal regions, this new bone is gradually and increasingly incorporated into the preexisting cortical bone, aligned in accord with predominant stress patterns, and replaced by physiologic remodeling processes. The degree of remodeling and progressive replacement of fracture callus is greater in younger children, who have an immense capacity for growth and change.

The critical step between the reparative and remodeling phases is the establishment of an intact bony bridge between the fragments. Because this involves the joining of separated segments of hard tissue, the whole system must become immobile. Once the bridge has been established—provided that adequate, continued mechanical protection is given—subsequent biologic failure is unlikely. If the two or more fracture fragments remain connected by the periosteum or related material, as is likely in a child, it is easy to see how reparative activity could be conducted from one side to the other relatively easily and rapidly.

The intact bone must then readapt to functional demands. This is much easier in children, whose skeletons are actively and continually remodeling in response to stress, than in adults, who have more static skeletons. The processes of replacement and repair are continuous and concomitant in the normally developing skeleton. The mechanisms involved in fracture healing essentially are no different than most of the active maturational processes. These processes are much more active in children and are more active in the metaphysis than in the diaphysis.

The fracture remodeling process differs in cortical or cancellous bone. Both involve a process of simultaneous bone removal and replacement by the osteoclasts and osteoblasts through the accompanying blood vessels. In cancellous bone of the metaphysis or the endosteal surface of the diaphysis, the cells are never very far away from blood vessels, and the whole process of apposition and replacement may occur on the surface of the trabeculae. However, in compact bone, the more deeply placed cells require the presence of an adequately functioning perfusion system that must be replaced. This is a much longer sequence of events and is not a major method of bone repair in children, except when the fracture involves densely cortical regions such as the femoral or tibial shafts. McKibbin (104) presented an extensive discussion of this process, which is sometimes referred to as *primary bone union* because no intermediate cells are involved.

Physeal Healing Patterns

The physis has a limited ability to repair; it primarily heals by increased endochondral bone and cartilage formation, and gradual reinvasion by the disrupted metaphyseal vessels to replace the temporarily widened physis eventually. Very little experimental work, mostly in rats, has been directed at assessing the posttraumatic cellular response patterns of the physis (17).

Depending on the level of cellular injury within the physis, *three types of chondro-osseous healing* may occur. First, when the fracture occurs through the cell columns, healing occurs primarily by continued, relatively rapid increases in the number of cells within the columns, causing moderate widening of the physis. Because there are some small epiphyseal vessels in this region, some damaged tissue may be resorbed early in the healing process. These vessels also exhibit a hyperemic response, increasing cellular proliferation rates, especially in the peripheral zone of Ranvier. The metaphyseal response parallels this, in that an increased rate of bone replacement of the hypertrophic chondrocyte also occurs. Once the level of fracture fibrosis and debris within the physis is encountered, the vessels rapidly invade to reach the rest of the maturing cell columns. These cellular response patterns lead to restoration of normal anatomy within 3 to 4 weeks (153).

Second, when the fracture occurs through the transition of hypertrophic cells to primary spongiosa (the most commonly involved cellular level), there may be marked separation, with the gap filled by hemorrhagic and fibroblastic tissue. This region may progressively form disorganized cartilaginous tissue, not unlike the initial, disorganized cartilaginous callus around a diaphyseal fracture. Meanwhile, cellular proliferation, cell column formation, hypertrophy, and calcification continue on the epiphyseal side of the disorganized callus, leading to widening of the physis. A vascular invasion of the remnants of hypertrophic, calcified cartilage also rapidly occurs on the metaphyseal side of the fracture. However, once metaphyseal vessel invasion reaches the disorganized cartilaginous callus, vascular-mediated bone replacement is temporarily slowed, because there is no pattern of cell columns to invade in an organized fashion. As the callus cartilage matures and calcifies, the metaphyseal vessels begin to invade and replace the cartilage with bone irregularly (21). This callus may be variably thick, depending on the degree of longitudinal and lateral displacement and periosteal continuity with the physeal periphery. The callus is replaced at different rates, and the invading metaphyseal vessels reach the normal cell columns, which have been maturing in a normal sequence but without osseous replacement. This widened physis is rapidly invaded by the vessels and replaced by primary spongiosa, and normal physeal width is progressively restored.

The callus in the subperiosteal region contributes to early stability. This region heals by vascular invasion of the callus to form trabecular bone between the original metaphyseal cortex and the subperiosteal membranous bone forming continuously external to the metaphyseal cartilaginous callus. These three microscopic bone regions progressively merge and remodel, making the region strong biomechanically. With further growth and remodeling, this coalescent bone is completely replaced. These initial cellular replacement processes in both metaphyseal and physeal regions probably take 3 to 6 weeks. However, remodeling may continue for months to years, and it enhances the capacity for spontaneous correction of many residual deformities.

Third, when the injury extends across all cell layers of the physis, the repair processes differ slightly. Fibrous tissue initially fills the gap between separated physeal components, whereas typical callus formation occurs in the contiguous metaphyseal spongiosa or epiphyseal ossification center. If large surfaces of nonossified epiphyseal cartilage also are involved, fibrous tissue initially forms in the intervening region. The reparative response shows irregular healing of the epiphyseal and physeal cartilage, with loss of normal cellular architecture. Within the central physeal regions, diametric expansion of cell columns is minimal, so closure of a large defect by physeal cartilage is unlikely. The gap will remain fibrous, but with the potential to ossify. Toward the physeal periphery, diametric expansion is more likely, but still may not lead to closure of large cartilage gaps by progressive replacement of fibrous tissue. This replacement process essentially requires the germinal and hypertrophic cell regions to diametrically expand by cell division, maturation, and matrix expansion. The intervening fibrous tissue may disappear through growth, but only if the gap is narrow. Because blood supply is minimal in this region, the fibrous tissue similarly is not well vascularized, and significant cell modulation, especially to osteoblastic tissue, is less likely in the short term. However, the larger the gap filled with fibrous tissue and the longer the time from fracture to skeletal maturity, the greater the likelihood of developing sufficient vascularity to commence an osteoblastic response and to form an osseous bridge. Further, in young children with minimal epiphyseal ossification, the blood supply to the physeal germinal region is not as well defined, whereas once the ossification center expands and forms a subchondral plate over the germinal region, microvascularity probably increases and the chances for vascularization and ossification of the fibrous region increase. This explains the delayed appearance of the osseous bridge.

If accurate anatomic reduction is performed, a thin gap should be present that should fill in with minimal fibrous tissue, allowing progressive replacement of the tissue by diametric expansion of the physis and contiguous epiphysis. However, if the fragment has been partially or completely devascularized by either the initial trauma or subsequent dissection to effect an open reduction, cellular growth and diametric and longitudinal expansion may not occur. This increases the chances of cellular disorganization, fibrosis, and eventual osteoblastic response. Failure to correct anatomic displacement, especially in Salter-Harris type 4 growth mechanism injuries, increases the possibility of apposition of the epiphyseal ossification center and metaphyseal one, and thereby enhances the risk of forming an osseous bridge between the two regions.

Remodeling of Bones in Children After Injury

In a growing child, the normal process of bone remodeling in the diaphysis and metaphysis (particularly the latter) may realign initially malunited fragments, making absolutely accurate anatomic reduction less important than in a comparable injury in an adult. However, although some residual angular deformities undergo spontaneous correction, accurate anatomic reduction should be the goal whenever possible (51,122,129). Bone and cartilage generally remodel in response to normal stresses of body weight, muscle action, and joint reaction forces, as well as intrinsic control mechanisms such as the periosteum. The potential for spontaneous, complete correction is greater if the child is younger, the fracture site is closer to the physis, and there is relative alignment of the angulation in the normal plane of motion of the joint. This is particularly evident in fractures involving hinge joints such as the knee, ankle, elbow, or wrist, in which corrections are relatively rapid if the angulation is in the normal plane of motion. However, spontaneous correction of angular deformities is unlikely in other directions (relative to normal joint motion), such as a cubitus varus deformity following a supracondylar fracture of the humerus. Similarly, *rotational deformities usually do not correct spontaneously.*

Growth Stimulation

Fractures may stimulate longitudinal growth by increasing the blood supply to the metaphysis, physis, and epiphysis, and at least on an experimental basis, by disrupting the periosteum and its physiologic restraint on the rates of longitudinal growth of the physes (34). Such increased growth may make the bone longer than it would have been without an injury (9,36,184). Eccentric overgrowth may also occur; this is particularly evident in tibia valgum following an incomplete fracture of the proximal tibial metaphysis.

THE FUTURE OF FRACTURE REPAIR

Bone grafts contain bone growth factors that normally induce bone formation and have the appropriate osteoconductive matrix. Autogenic grafts also contain osteogenic cells. Bone grafts are effective, but there are difficulties in obtaining safe and reliable tissue. Although the mechanisms of fracture repair are not fully understood, the level of understanding has enabled key molecules to be targeted as therapeutic in controlling and promoting fracture repair. Filler compounds have been developed that either stimulate mesenchymal cells, leading to new bone formation (osteoinductive) or enable the bone-forming cells to infiltrate and incorporate into bone (osteoconductive).

Specific growth factors have been targeted for their ability to promote bone formation. Two growth factors (BMP-2 and Ostegenic Protein-1) (BMP-7) show great promise for their ability to promote fracture repair (83,84,90,96,173,192). A number of others, such as TGF-b, IGF, PDGFs, and FGF-2, also may prove to be useful.

TGF-b plays a major role in fracture repair by promoting proliferation and differentiation of the mesenchymal cells. Exogenous TGF-b administration can initiate the repair process and callus formation in uninjured bone (75). The addition of TGF-b to fractures promotes wound repair and results in a larger, stronger callus (75). It also may be of use in promoting repair in nonhealing bone defects. PDGF also increases callus size but does not improve the fracture mechanically (115). Growth hormone and IGF-1 have also been tested to determine their effects on fracture repair. Although growth hormone produces inconsistent results, the administration of IGF-1 increases intramembranous bone formation (3,179). The FGFs also increase the callus size and mineral content (72,77,189). It is possible that the effect of FGFs and of a number of the other growth factors is a result of the angiogenic properties of such growth factors. There are many reviews on the use of growth factors for fracture repair (37,38,91,178), and more research is required to establish the most useful factors and effective delivery devices (71). However, there is little doubt that in the near future, orthopaedic surgeons will be using growth factor–containing compounds to induce new bone formation and to improve fracture repair.

ACKNOWLEDGMENT

PAIN RELIEF AND RELATED CONCERNS IN CHILDREN'S FRACTURES

JOSEPH R. FURMAN

Providing pain relief is one of the many important parts of the management of children's fractures. In addition, because having a fracture reduced is not only painful but also frightening to many children, providing young patients with adequate sedation and amnesia are additional welcome elements of good care. However, the correct use of any of the available medications for obtaining these goals must involve an appropriate understanding of proper dose, desired effects, and untoward side effects. The purpose of this chapter is to provide a thorough source of information regarding safe and effective analgesia and sedation for children with fractures. This chapter discusses the concept of sedation and its definitions, the various medications used to achieve the sedation state, and the various medications used to achieve analgesia, including both systemic medications and local anesthetics. Intravenous regional anesthesia (Bier Blocks), hematoma blocks, and femoral nerve blocks (for femur fractures) are discussed in depth. The management of postoperative pain is discussed, along with the treatment of the troublesome side effect of postoperative nausea. The author hopes that the orthopaedic practitioner will find this chapter of significant benefit, not only in the emergency room setting but also in the office and on the hospital ward.

GUIDELINES AND PRINCIPLES OF SEDATION IN CHILDREN

Definitions

The practitioner must recognize that sedation describes a continuum ranging from near wakefulness to complete loss of consciousness (Fig. 3-1). Terms used to describe various stages along this continuum have included conscious sedation, deep sedation, and general anesthesia (63).

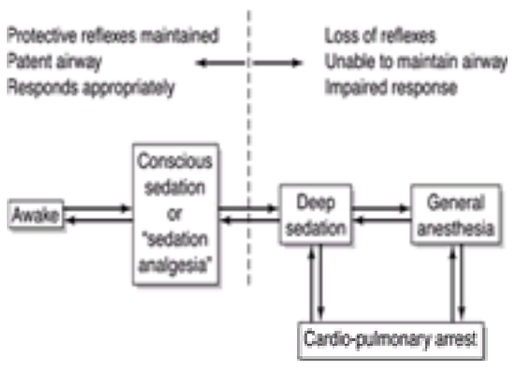

FIGURE 3-1. Sedation and analgesia for procedures is a continuum. (Reproduced with permission from American Society of Anesthesiologists from ASA 1997 Annual Refresher Course Lectures. Sedation and Analgesia in Pediatric Patients for Procedures Outside the Operating Room. Richard F. Kaplan, M.D. No. 221)

Strictly speaking, the term conscious sedation means a pharmacologically controlled altered state of consciousness in which patients maintain their ability to respond purposefully to verbal commands. For nonverbal patients or young infants, conscious sedation implies the ability to respond purposefully to physical stimulation, not simply by reflex withdrawal to pain. Unfortunately, most physician and nursing personnel tend to use the term “conscious sedation” to mean anything short of a general anesthetic. For such reasons, the consensus of the 1996 report by the American Society of Anesthesiologists Task Force on Sedation and Analgesia by Non-Anesthesiologists (108) is that the term conscious sedation, although in common usage, is imprecise. This report recommends replacing the term conscious sedation with the more descriptive term sedation/analgesia (Fig. 3-1). Whatever the preferred term, the important point to recognize is that the safest level of sedation is that which permits purposeful response to verbal or physical stimulation. It is at this level of sedation that the risk of hypoventilation, apnea, or cardiovascular instability is minimal. Unfortunately, and realistically speaking, such relatively light levels of sedation are totally inadequate for the performance of a painful procedure such as the reduction of a fracture. Also the younger and less cooperative the patient, the less likely that so-called conscious sedation can realistically be achieved at all (92). Therefore, it is very likely that for orthopaedic procedures, children may have to be sedated to levels at which they are not easily responsive to verbal stimulation, and as such, at increased risk for respiratory and cardiovascular compromise. Even in children in whom light levels of sedation (true conscious sedation) is possible, unintended oversedation may occur without warning. Oversedation may lead to (a) loss of the airway, (b) impaired protective reflexes leading to the possibility of aspiration of gastric contents, and (c) cardiopulmonary arrest (Fig. 3-1). It is for these reasons that careful monitoring of sedated patients as prescribed in standard guidelines (108) is absolutely imperative.

Monitoring

Obviously, the purpose for monitoring sedated patients is to provide timely detection and correction of abnormalities in respiratory and cardiovascular function. The

monitoring process begins before the administration of any sedative medications. Monitoring continues unabated until the patient returns to baseline presedation level of consciousness and is ready for discharge. Acceptable discharge criteria are noted later (Table 3-1).

1. Cardiovascular function and airway patency are satisfactory and stable.
2. The patient is easily arousable, and protective reflexes are intact.
3. The patient can talk (if age appropriate).
4. The patient can sit up unaided (if age appropriate).
5. For a very young or handicapped child incapable of the usually expected responses, the presedation level of responsiveness or a level as close as possible to the normal level for that child should be achieved.
6. The state of hydration is adequate.*

* Adequate hydration may be achieved with intravenous fluids. There is no specific requirement that children be able to tolerate oral fluids before discharge from a treatment facility. Children who are nauseated, or actively vomiting should be treated and observed until this problem resolves (see section on treatment of postoperative nausea).
Guidelines for monitoring and management of pediatric patients during and after sedation for diagnostic and therapeutic procedures. *Pediatrics* 1992;89:1110–1115, with permission.

TABLE 3-1. RECOMMENDED DISCHARGE CRITERIA AFTER SEDATION

Of vital importance to the monitoring process is the presence of qualified personnel who are competent in the use of monitoring devices, and capable of recognizing the clinical signs of airway or hemodynamic instability. Although skill in at least pediatric basic life support is necessary (63,119), training in pediatric advanced life support (PALS) is certainly desirable. In the author's opinion, this training should be considered absolutely necessary. The orthopaedic surgeon must always demand, and have available, skilled health professionals, either physicians or nurses, to assist in observing the patient and the monitors during procedures requiring medications that are known to depress respiratory or cardiovascular function. Having one person performing both the surgical procedure and monitoring the patient is a practice that should be strongly discouraged in all but the most desperate circumstances.

Oxygenation, ventilation, and circulation are the three parameters that require careful assessment. For the most part, monitoring temperature is usually of minimal importance. The major exceptions, of course, are children who arrive in the hospital either severely hypothermic or febrile.

Monitoring oxygenation requires continuous pulse oximetry and continual visual inspection of the patient. Note that the term continuous monitoring refers to a constant measurement undertaken for a period of time without interruption. Continual monitoring refers to an assessment taken at frequent regular intervals.

The value of pulse oximetry as an early detector of impeding hypoxemia has been well demonstrated (34). The problem with relying on visual inspection alone to determine adequacy of oxygenation is that cyanosis is both a late and variable sign of hypoxemia. Demonstrable cyanosis requires the presence of at least 5 g of desaturated hemoglobin per deciliter. Therefore, for example, a patient with a hemoglobin level of 10 g/dL would theoretically not even appear cyanotic until the oxygen saturation level (Spo_2) plummets to 50%. For this same reason, a severely anemic patient may never develop visible cyanosis even at profound levels of hypoxemia. To add to a potentially confusing situation, the ambient light (especially fluorescent light) in many clinical environments may make any patient appear cyanotic (33). Therefore, pulse oximetry is essential in all heavily sedated patients to detect abnormalities of oxygenation rapidly.

Note, however, that the pulse oximeter is not perfect. Factors that affect the accuracy of the pulse oximeter include patient movement (33), direct bright light on the probe (21), and malposition of the probe (9). Correct probe placement, shielding the probe site from bright light, and gentle restraint of the monitoring site should improve the dependability of this all-important monitor.

Monitoring ventilation goes hand in hand with monitoring oxygenation. Monitoring ventilation requires close observation of the patient and either intermittent or continuous auscultation of breath sounds. A sedated child's head may flex forward easily, producing airway obstruction as the child begins to fall asleep (33). Maintaining patients in the so-called sniffing position helps prevent airway obstruction (Fig. 3-2). The sniffing position consists of elevating the patient's head with pads under the occiput, keeping the shoulders flat on the table, and extending the head at the atlanto-occipital joint (134). hildren younger than 3 years of age have a relatively large head in proportion to the size of their trunk and do not require padding under the occiput (35). Along with continual assessment of the child's head position, any restraining devices should be checked and rechecked to ensure that they are not contributing to either airway obstruction or restriction of chest movement (63).

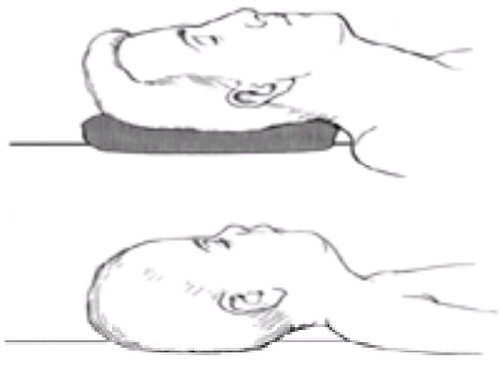

FIGURE 3-2. The sniffing position. In an adult or in an older child, a folded sheet or towel under the occiput, plus moderate head extension at the atlanto-occiptal joint, helps to maintain an open airway. In a child younger than 3 years of age, the relatively large head size in proportion to the trunk makes occipital padding unncessary (35)

Auscultation with the precordial stethoscope is valuable in the monitoring of both ventilation (breath sounds) and circulation (heart sounds). Its use is encouraged in the monitoring of deeply sedated patients (63).

Monitoring circulation for most sedated children consists of intermittent determination of heart rate and blood pressure (63). For children, normal values for heart rate and blood pressure vary with age (Table 3-2 and Table 3-3). A simple formula for calculating the normal systolic blood pressure and lower limit of normal for systolic blood pressure in children by age is worth memorizing (Table 3-4). Electrocardiographic (ECG) monitoring is especially important for the child with an underlying history of a significant cardiac dysrythmia or known ECG abnormality such as long QT syndrome, or history of Wolff-Parkinson-White syndrome. In the absence of monitor artifact, the pulse oximeter provides continuous assessment of heart rate. Deeply sedated children should have blood pressure and heart rate and respiratory rate measurements determined and recorded at least at 5-minute intervals (63). For children under conscious sedation (sedation/analgesia), the frequency of vital sign determination is at the discretion of the physician (63).

Age	Range (beats/min)
Newborn	110–150
1–11 months	80–150
2 years	85–125
4	75–115
6	65–110
8	60–110

TABLE 3-4. CALCULATION OF NORMAL BLOOD PRESSURE BY AGE

It is important to emphasize again that monitoring the patient must continue until the patient meets preset discharge criteria (Table 3-1) (63). Often, when a surgical procedure is over and patients are no longer being actively stimulated, unintentional deep sedation with resulting airway obstruction and apnea may occur. Therefore, it is essential to remain vigilant until the patient recovers completely from their sedative medications. Note that the time to recovery varies depending on the amount and type of sedative medication given, and this point should be taken into account when planning a sedation regimen. The duration of action of particular sedatives and sedative combinations are discussed separately.

Patient Assessment

Only after careful patient assessment can the practitioner decide whether sedation in an emergency room setting, where the airway is uncontrolled and unprotected, is feasible and safe. Administering sedative medications without first evaluating a patient is an invitation for disaster. It is important first to be aware of the child's medical history, previous allergic or adverse drug reactions, current medications, and presence of coexisting diseases before proceeding with deliberate alteration of a patient's state of consciousness (63). In addition to these basic details, the patient with musculoskeletal injuries has to be evaluated for time of last oral intake, hemodynamic status, presence of other injuries, and status of the airway.

Oral Intake Precautions

In the management of elective patients, significant pulmonary aspiration is rare in pediatrics (143).

Note that for elective patients, multiple studies support and encourage the liberal intake of clear liquids up until 2 to 3 hours before scheduled surgery in otherwise healthy children (32,95,122,129). Acceptable clear liquids are apple juice, water, sugar, water, and gelatin. Milk (including breast milk), milk products, and juices with pulp are not clear liquids. For elective patients, most pediatric anesthesiologists now adhere to the so-called 2-4-6-8 rule regarding oral intake. This rule restricts clear fluids to 2 hours before elective surgery, breast milk to 4 hours before elective surgery, baby formula (cow's milk formula) to 6 hours before elective surgery, and solid food to 8 hours before elective surgery (50).

Emergency patients are definitely at risk for aspiration (143). Sedatives depress the protective reflexes (63). Caution is necessary to avoid the morbidity and possible mortality of aspiration pneumonia.

It is known that in trauma patients, the time interval between last oral intake and time of injury is a critical factor in the retention of gastric contents (99). It is clear that children injured within 1 to 2 hours after eating present with large gastric volumes (19). Although fasting can reduce an injured child's gastric volume (95), it is not clear how long of a fast is ideal. Also, in the presence of pain, anxiety, and with the administration of opioid pain relievers, all of which may occur in the patient with a fracture, gastric emptying may be radically slowed (57). If the procedure can wait, it is safe to say that a fasting period is in order. Starting intravenous fluids to prevent dehydration is important. Note that at present, there is no reliable method of assessing the volume of gastric contents, although different methods have been suggested (55). Patient hunger on presentation for surgical treatment is not a good indicator of an empty stomach (95).

In the author's opinion, the safest recommendations regarding sedation of patients with a potential full stomach are as follows:

1. If possible, postpone the procedure, even for as little as 4 hours.
2. Use the lightest effective level of sedation. Titrate sedation to effect, and avoid large bolus doses of medications.
3. Consider the administration of medications to reduce gastric volume (metoclopramide) or to increase gastric pH (histamine-2–receptor blockers). These medications, when indicated, should be administered intravenously 1 hour before sedative medications are given. The appropriate dose of metoclopramide (Reglan) is 0.15 mg/kg. The usual adult dose for metoclopramide is 10 mg, which should be more than sufficient for any child. Famotidine (Pepcid), a histamine-2–receptor blocker, may be given in a dose of 0.3 to 0.4 mg/kg intravenously, with a maximum dose of 20 mg.
4. Within 15 minutes of administering sedation, consider the use of oral nonparticulate antacids (Bicitra, sodium citrate) to raise gastric pH. Unfortunately, these

medications are not very palatable.

5. Note that pregnancy, morbid obesity, gastroesophageal reflux, bowel obstruction, and increased intracranial pressure all magnify the risk of regurgitation and aspiration of gastric contents. Therefore, additional caution is necessary in managing patients with any of these conditions. Patients with coexisting bowel obstruction should not be sedated, and patients with increased intracranial pressure should not be sedated without the input and knowledge of the attending neurosurgical staff.
6. If treatment cannot wait and the surgical procedure or the patient is not amenable to regional anesthesia, the safest approach is a general anesthetic with a rapid sequence induction and a protected airway (endotracheal tube). This approach is also safest for uncooperative children who urgently need a computed tomography (CT) scan, an magnetic resonance imaging (MRI) scan, or other detailed diagnostic studies.

Hemodynamic Status

The magnitude of blood loss from a child's injuries is not always readily apparent. In children, long bone fractures and head injuries may easily have associated large concealed hemorrhages (140,153). It is important to assess the patient's volume status accurately before administering sedative medications. In a hypovolemic child, sedatives may interfere with catecholamine-mediated compensatory mechanisms and produce profound hemodynamic instability, leading to cardiovascular collapse.

Note that in an injured child, blood pressure monitoring alone does not provide a good indication of the patient's underlying volume status (105,155). Children maintain a normal blood pressure for their age in the face of large intravascular volume deficits (155). More reliable signs of ongoing hypovolemia in children include sinus tachycardia, mottling, cool extremities, poor urine output (less than 1 to 2 mL/kg/h), and altered state of consciousness. Each of these signs can imply poor perfusion of different organ systems skin, musculoskeletal system, kidneys, and central nervous system (CNS), respectively). Volume replacement, not sedation, should be the initial goal in the management of hypovolemic children.

Coexisting Nonmusculoskeletal Injuries

Serious head injury accounts for 70% of pediatric trauma deaths (30,105). Respiratory depression from sedation, with resultant hypercapnia and hypoxia, may aggravate an underlying closed head injury and worsen its prognosis (153). In addition, any pharmacologic change in the patient's state of consciousness may confuse the neurologic evaluation. Other injuries to major body cavities or injuries associated with major blood loss should be assessed carefully before any sedative medications are administered.

Status of the Airway

A tenuous airway can easily become a completely obstructed airway in a sedated child. There are common problems in children associated with airway obstruction. For example, children with large tonsils and adenoids may have obstructive sleep apnea (89). Obstructive sleep apnea, which is associated with a history of loud snoring and daytime sleepiness, may be acutely exacerbated with the administration of sedative medications (36). Other potentially dangerous problems include micrognathia (short jaw), limited ability to open the mouth, and limited movement of the neck, either congenital or acquired (12).

Treatment Facility

What about the medical facility where the child is receiving treatment? On-site resuscitation equipment, including equipment for airway management (Table 3-5) and equipment for vascular access (Table 3-6) must be available for children of all ages and sizes (63). In addition, a positive pressure oxygen delivery system capable of delivering at least 90% oxygen for at least 60 minutes must also be readily available (63). A working suction apparatus (63) must be easily accessible to handle patient secretions, as well as for unexpected regurgitation and vomiting. These recommendations are essential for patient safety and for optimum patient care.

Ventilation Face Masks*
Infant, child, small adult, medium adult, large adult
Breathing bag and valve set
Oral airways
Infant, child, small adult, medium adult, large adult
Nasal airways
Small, medium, large
Laryngoscope handles
Laryngoscope blades
Straight (Miller) No. 1, 2, 3
Curved (Macintosh) No. 1, 2, 3
Endotracheal tubes
2.5–6.0 uncuffed
6.0–8.0 cuffed
Appropriate-sized stylets for endotracheal tubes
(*must be lubricated before insertion*)
Appropriate-sized suction catheters for endotracheal tubes
Yankauer-type suction
Nasogastric tubes
(10–18 French)
Nebulizer set-up for treatment of bronchospasm

* The correct sized ventilation face mask will fit over the child's face from the bridge of the nose to the cleft of the chin. This guideline is also correct when using patient-administered nitrous oxide analgesia.
Guidelines for monitoring and management of pediatric patients during and after sedation for diagnostic and therapeutic procedures. *Pediatrics*, 1992;89:1110–1115, with permission.

TABLE 3-5. AIRWAY MANAGEMENT EQUIPMENT

Intravenous catheters
(24–16 gauge)*
Intraosseous bone-marrow needle
Intravenous tubing
Pediatric drip (60 drop/mL)
Pediatric burette-type
Adult drip (10 drips/mL)
Intravenous fluids
Lactated Ringer's
Normal saline
Miscellaneous equipment
Tourniquets
Alcohol wipes
Arm boards

* In resuscitation situations, no more than 90 sec should be spent attempting to gain peripheral venous access. If attempts have been unsuccessful, then central venous cannulation, intraosseous cannulation, or peripheral venous cutdown should be done according to the expertise of available personnel.

SEDATIVE MEDICATIONS

Having now considered the preliminary step of patient assessment, the practitioner must now decide which sedative or sedatives to use. The ideal sedative should be easy to administer, quick in onset, devoid of side effects, and rapid in termination of effects. The abundance of references in the literature extolling the virtues of different sedative drugs and drug combinations is the best indicator that we do not yet have the ideal sedative. Each of the drugs that is discussed has only some of the properties of an ideal sedative medication. Also, patients demonstrate great variability in response to medications. It is important to treat each patient as an individual and to not expect to be able to fit every child with a fracture into any particular sedation regimen. For patients who cannot be adequately sedated, the orthopaedic surgeon should consult an anesthesiologist for provision of a brief, well-controlled general anesthetic.

Nitrous Oxide

Self-administered 50% nitrous oxide (50% nitrous oxide and 50% oxygen) has been found to be moderately useful in providing sedation and analgesia for the reduction of children's fractures. Evans and co-workers (45) found it to be comparable in efficacy to intramuscular meperidine (2 mg/kg) and promethazine (1 mg/kg). However, in a different study, Hennrikus and co-workers noted that 46% of their patients experienced significant pain with nitrous oxide alone as a sedative and analgesic for fracture reduction (67). Patients with completely displaced radius and ulna fractures had a statistically higher incidence of failure to achieve analgesia (67). With the addition of a hematoma block (discussed in a subsequent section), Hennrikus and his coinvestigators were able to obtain a 97% incidence of adequate

sedation and analgesia (66). This study does illustrate the important point that where possible, the use of regional anesthesia, in combination with almost any sedation regimen is an excellent way to enhance pain relief and to minimize the need for systemic sedative and analgesics.

In general, nitrous oxide is a weak sedative and analgesic. It does have the advantages of rapid onset, relative ease of utilization, and rapid termination of effects (88). Because it diffuses rapidly into enclosed air-filled spaces, its use is contraindicated in patients with bowel obstruction or pneumothorax (88). Nitrous oxide is also contraindicated in patients with altered intracranial compliance (88).

Although nitrous oxide is perhaps a useful part of the sedation armamentarium, this author does not believe that the literature supports the use of nitrous oxide alone as a reliable sedative and analgesic for pediatric orthopedic procedures.

Ketamine

Ketamine, which is structurally related to phencyclidine, was first synthesized in 1963. Developed to produce the “anesthetic state (analgesia, amnesia, loss of consciousness and immobility)” without total CNS depression, it was approved for general clinical use in 1970 (31,157).

The commercial preparation of ketamine is a racemic mixture of two optical isomers with differing activity (157). Ketamine is typically administered intravenously or intramuscularly (59,136). Rectal (118), oral (64,145), and intranasal administration (154) have been described in the literature.

Ketamine is metabolized in the liver, primarily by *N*-methylation to norketamine. Norketamine has about one third the sedative and analgesic potency of ketamine. As such, ketamine should be administered cautiously or in reduced doses to patients with impaired hepatic function.

Intravenous ketamine, 1 to 2 mg/kg, produces unconsciousness within 30 to 60 seconds (136). Peak plasma concentrations occur within 1 minute. Return of consciousness occurs within 10 to 15 minutes, although complete recovery may be delayed (136). Dose requirements and recovery times from ketamine are age related (24,87).

Ketamine has been found to have interactions at multiple binding sites, including *N*-methyl-D-aspartate (NMDA) and non-NMDA receptors, nicotinic and muscarinic cholinergic receptors and opioid receptors (83). Agonist actions of ketamine on opioid receptors play only a minor role in its analgesic effects (83). Note that naloxone, a narcotic antagonist that is further discussed in the section on opioids, does not reverse the analgesic effect of ketamine (83). The psychotomimetic effects of ketamine, however, may involve interaction with a specific subclass of opioid receptors known as kappa receptors (83). For analgesia, the main site of action is the NMDA receptor. The reader is referred to other sources for further information on this topic (83).

Central Nervous System Effects of Ketamine

Ketamine produces a state known as dissociative anesthesia. Dissociative anesthesia refers to a cataleptic state characterized by functional and electrophysiologic dissociation between the thalamoneocortical and limbic systems (157). Patients keep their eyes open and exhibit a slow nystagmic gaze. Corneal and pupillary reflexes remain intact. Generalized hypertonicity may be present. Even though ketamine has effects on nicotinic acetylcholine receptors in skeletal muscle, this effect is of minor significance, because ketamine increases muscle tone by central mechanisms (83). Patients receiving ketamine may exhibit purposeful movements but not necessarily in response to surgical stimulation (157).

Ketamine's analgesic effect is intense and may outlast its sedative effect (59). In one study of minor surgical procedures with ketamine anesthesia, no additional analgesics were required for 24 hours postoperatively (69). Amnesia persists for about one hour after apparent recovery from ketamine (136).

Emergence phenomena are relatively rare in children, although young adults are especially susceptible to this problem (69). Changes in mood and body image, out-of-body experiences, floating sensations and frank delirium are all possible (157). Emergence phenomena result from misinterpretation of auditory and visual stimuli at the neurologic level (157). Although usually terminating within 24 hours (136), prolonged emergence phenomena lasting as long as 10 to 12 months have been reported in children (102). An increased incidence of emergence reactions is seen in patients older than 16 years, female patients, patients who have received doses of intravenous ketamine above 2 mg/kg, and patients with a history of abnormal personalities (157). There is no evidence that emergence in a quiet environment decreases the incidence of this problem (157). Benzodiazepines (e.g., diazepam and midazolam) are the most effective treatment for ketamine-induced delirium and hallucinations (157). In fact, the administration of a benzodiazepine 3 to 5 minutes before ketamine is effective in almost entirely eliminating the possibility of emergence delirium (88).

Transient diplopia (31), ataxia (60), and disequilibrium (60) may occur after ketamine use. Early attempts at ambulation should be discouraged (60). Ketamine does not induce seizures and is not necessarily contraindicated in patients with an underlying seizure disorder (157).

Ketamine is contraindicated in patients with increased intracranial pressure or with abnormal intracerebral compliance. Thus, patients who have sustained a head injury as part of their ongoing trauma should not receive this drug (144). It is interesting to note that there are some reports actually suggesting that there is a neuroprotective effect for ketamine (83). However, the recommendation that ketamine be avoided in head-injured patients still stands firm for now.

Respiratory Effects of Ketamine

Ketamine can have some potentially troublesome effects on the airway. It causes the production of increased salivary and tracheobronchial secretions, which can lead to coughing, laryngospasm, and airway obstruction. This problem may be especially treacherous in patients with an ongoing respiratory infection. Glycopyrrolate (Robinul), an antisialogogue, should be administered 3 to 5 minutes before ketamine (at the same time that the benzodiazepine is given) to ameliorate this problem (88). The dose for glycopyrrolate is 5 to 10 μg/kg, given intravenously. For large children, a dose of 0.2 mg (200 μg) of glycopyrrolate given intravenously is sufficient. Unless there is some other strong indication for its use, ketamine should be avoided in patients with ongoing infections of the respiratory tract.

Although ketamine does not usually produce significant depression of ventilation (136), apnea has been reported with its administration (37). Apnea is more likely to occur when the drug is given intravenously in rapid boluses (37) or in combination with other respiratory depressants (136). However, there are reports of apnea in otherwise healthy children sedated in the emergency department with intramuscular ketamine alone in the usual recommended dosage (96,126).

In addition, ketamine does not protect against aspiration of gastric contents (26,141). In this regard, ketamine is no different from any other sedative and analgesic except maybe for self-administered 50% nitrous oxide in oxygen. Ketamine should never be given in an unmonitored setting, such as a patient's room on a regular hospital ward, or a clinic that does not have appropriate monitoring and resuscitation equipment (see the first part of this chapter).

Cardiovascular Effects of Ketamine

Ketamine stimulates the sympathetic nervous system and leads to the release of endogenous catecholamines. Through such an effect, ketamine produces a dose-dependent increase in heart rate and blood pressure (144), and therefore, it is useful in the operating room in patients with mild hypovolemia. As a byproduct of its sympathetic stimulation, ketamine produces bronchodilation, and as such, it has been useful in the anesthetic management of patients with asthma (88). However, because ketamine is a direct myocardial depressant, its administration to patients who are profoundly hypovolemic, and whose sympathetic nervous system is already maximally stimulated, will lead to cardiovascular collapse. The reader is reminded that any sedation given to a hypovolemic patient must be administered very judiciously and preferably after the volume status is corrected.

Review of Relevant Literature (Ketamine)

In 1990, Green and co-workers reviewed a collective experience of nearly 12,000 children sedated with ketamine for various procedures (60,61). In 1998, Green and coworkers (62) published their experience with 1,022 pediatric patients aged 15 years and younger sedated with ketamine 4 mg/kg intramuscularly for a variety of emergency room procedures, consisting mainly of laceration repairs and fracture reductions. From this group of patients, the authors reported two cases of apnea, four cases of laryngospasm, one case of respiratory depression, and seven cases of partial airway obstruction (e.g., airway malalignment) responding to repositioning of the head. They also reported a 6.7% incidence of vomiting but no cases of aspiration. In an interesting study by Kennedy and colleagues (81), intravenous

ketamine combined with midazolam (Versed) was compared with fentanyl combined with midazolam in the management of pediatric fractures. This particular study is further discussed later.

AUTHOR'S PREFERRED METHOD OF TREATMENT

Salient points regarding the safe use of ketamine are summarized in Table 3-7. Monitoring and procedural guidelines for deeply sedated patients (63) should be followed whenever ketamine is used. If used intramuscularly, the dose should be limited to 4 mg/kg. If the drug is used intravenously, the total dose should be limited to 2 mg/kg. The reader is reminded to use glycopyrrolate, and to consider strongly the administration of midazolam (Versed) 0.05 to 0.1 mg/kg for the prevention of agitation and delirium. Note that there is an increased risk of respiratory depression whenever more than one sedative medication is administered. Note also that no reversal drug exists for ketamine.

I. Methods of Administration and Dosage
   A. IM, 4 mg/kg
   B. IV, 1–2 mg/kg
   C. PO, 6–10 mg/kg
   D. Rectal, 5–10 mg/kg
II. Contraindications
   A. Altered state of consciousness
   B. Increased intracranial pressure
   C. Active upper respiratory infections (increased quantity of secretions and possible increased risk of laryngospasm)
   D. Full stomach
   E. Prior unfavorable experience with ketamine
   F. Patients > 16 yr old (increased incidence of emergence phenomena)
III. Advantages
   A. Provides sedation, amnesia, intense analgesia
   B. Sympathetic-mediated activity may be beneficial for children with asthma.
IV. Disadvantages
   A. Increases production of saliva and tracheobronchial secretions. Coadministration of glycopyrrolate 0.01 mg/kg recommended.
   B. Potential for loss of the airway from:
      1. Laryngospasm secondary to increased secretions
      2. Aspiration from laryngeal incompetence
      3. Apnea
   C. Emergence phenomena: Rare in young children. No advantage to quiet environment. Midazolam may help, but may contribute to oversedation.

TABLE 3-7. KETAMINE IN PEDIATRIC SEDATION

Benzodiazepines

Initial interest in the use of benzodiazepines developed when these drugs were noted to exert taming effects in animals (133). Benzodiazepines provide anxiolysis, hypnosis, centrally mediated (40) relaxation of muscle tone, antegrade and retrograde amnesia, and anticonvulsant activity (113). Benzodiazepines have no analgesic activity and require supplementation for painful procedures (133).

Pharmacology

Midazolam (Versed) is the primary benzodiazepine used for pediatric sedation. It offers several advantages over other benzodiazepines (158). It is water soluble and, therefore, usually relatively painless on injection (113,158). It does occasionally cause discomfort on injection, although the pain is not as severe as that with diazepam (Valium). At physiologic pH, midazolam becomes highly lipid soluble, facilitating transport into the CNS and onset of sedative effects (158). Initial recovery, which is due to redistribution of the drug away from the CNS, occurs in about 30 minutes. The elimination half-life of midazolam is significantly shorter than that of diazepam (158). On a milligram-per-milligram basis, midazolam is at least two to three times as potent as diazepam (56). Electroencephalographic (EEG) studies indicate that the blood–brain equilibration time is 4.8 minutes for midazolam versus 1.6 minutes for diazepam (25). Therefore, when titrating midazolam for sedation, it is important to wait 5 minutes between doses.

Central Nervous System Effects

Anxiolysis and centrally mediated relaxation of skeletal muscle tone is presumed to occur from a benzodiazepine-induced increase in the availability of glycine inhibitory neurotransmitter (133). Facilitating the action of the inhibitory neurotransmitter gamma-aminobutyric acid (GABA) is responsible for the sedative effects of benzodiazepines (133). It remains unclear what the site of action is for the production of amnesia (133).

Note that midazolam and diazepam produce direct depression of the central respiratory drive (54) and that apnea may occur (18,72,113), especially after parenteral administration of these drugs. Although it is generally considered very safe, orally administered midazolam has been reported to produce airway obstruction in a child with congenital airway anomalies (85). In general, the incidence of respiratory complications increases with the presence of major vital organ disease (72). However, even in healthy adult volunteers, intravenous sedation with midazolam (0.1 mg/kg) can depress the ventilatory response to hypoxia (3). Concomitant administration of opioids (72,133,161) greatly increases the risk of respiratory complications. Therefore, extra vigilance and careful titration of medications to effect are even more important when using more than one sedative or analgesic medication.

Other Systemic Effects

With careful titration, significant hemodynamic changes are unusual with midazolam (113). Loss of protective airway reflexes is also unlikely under these circumstances (113) as long as the physician pays careful attention to the effects of each incremental dose on the patient's state of consciousness. Caution is always urged if the patient's stomach is full. Slurring of speech is a typical sign of sedation with benzodiazepines (113). Children may also exhibit loss of anxiety, unsolicited smiling, and even laughter.

In reporting their experience with 2,617 children sedated for endoscopic procedures, Massanari and co-workers (91) noted that 36 patients exhibited paradoxical reactions to midazolam, including inconsolable crying, combativeness, and agitation. The authors of this study were able to treat these reactions with flumazenil, a benzodiazepine antagonist, which is further discussed below.

Review of Relevant Literature (Midazolam)

In children, midazolam can be administered by oral, nasal, sublingual, intravenous, intramuscular, and rectal routes (88). A liquid oral formulation, whose concentration is 2 mg midazolam/mL, now exists in the United States. It is marketed as Versed Syrup 2 mg/mL and is manufactured by Hoffman-LaRoche pharmaceuticals. If this formulation is not available at a particular location, then the practitioner can order the parenteral form (usually the 5 mg/mL concentration) to be mixed in 5 to 10 mL of a sweet-tasting syrup (106). Acetaminophen syrup or ibuprofen syrup are useful vehicles for mixing parenteral midazolam, keeping in mind the appropriate pediatric doses of acetaminophen and ibuprofen (Table 3-8). The author's personal preference is to mix the midazolam in 3 to 5 mL of Tylenol syrup. For nasal administration, which the author does not recommend, the parenteral preparation is used with no additives. The reason for discouraging the use of nasal midazolam is because most children find its administration to be very unpleasant. In one study, 84% of children given intranasal midazolam cried in response to administration of the medication (80). Although sublingual administration is a good idea from a pharmacologic point of view (see discussion under morphine), it requires a degree of patient cooperation that may be difficult to reliably obtain in children. In other words, an uncooperative child may be unwilling or unable to hold a medication under his or her tongue.

I. Method of Administration
   A. Diazepam: 0.1 to 0.3 mg/kg IV or PO. IM administration should be avoided because it is painful.
   B. Midazolam
      1. PO, 0.5–0.75 mg/kg
      2. Nasal,* 0.3–0.4 mg/kg
      3. IM, 0.03–0.1 mg/kg
      4. IV, 0.05–0.1 mg/kg
II. Contraindications
   A. Previous unfavorable experience with benzodiazepines
   B. (?) Early pregnancy (possible teratogenicity)
   C. Altered state of consciousness
III. Advantages
   A. Generally provide excellent sedation and amnesia
   B. Reversible if necessary (flumazenil, 10 μg/kg) up to a total dose of 1.0 mg)
IV. Disadvantages
   A. No analgesic effect
   B. Respiratory depression, especially with parenteral administration
   C. Combination with narcotics may lead to oversedation or respiratory arrest

* Many children find the intranasal administration of midazolam to be very unpleasant. This method of administering midazolam is not recommended.

TABLE 3-8. BENZODIAZEPINES IN PEDIATRIC SEDATION

Hennes and colleagues (65) have used oral midazolam to allay the anxiety of children requiring laceration repair in the emergency department. Fatovich and Jacobs (47) also noted decreased anxiety in children requiring laceration repair after oral midazolam versus in a control group that received only a placebo. Note that if the practitioner decides to use orally administered midazolam, the appropriate dose is 0.5 to 0.75 mg/kg (48) and a waiting period of 10 to 30 minutes is required for onset of effects. The maximum amount of midazolam that should be administered orally has not been determined, but in practice, this amount is usually limited to 20 to 25 mg. Note that analgesic supplementation in the form of either local anesthetics, opioids, or both is required for painful procedures. Patients who receive parenteral benzodiazepines must be monitored with pulse oximetry, because oxygen desaturation may occur (125).

Drug reversal

Flumazenil (Romazicon) reverses the sedative effects of benzodiazepines (76,82,107). The flumazenil dose for children is 10 μg/kg intravenously. Flumazenil administration may then be continued at 5 μg/kg/minute until the child awakens, or until a total dose of 1 mg has been given (77). The elimination half-life of flumazenil is 30 minutes, compared with 1 to 2 hours for midazolam. Patients who receive flumazenil should be observed for at least 2 hours before discharge to ensure that resedation from the original benzodiazepine does not occur. In the author's opinion, the use of flumazenil should be limited to situations of relative or absolute benzodiazepine overdose leading to respiratory or hemodynamic compromise. Routinely reversing benzodiazepines is both unnecessary and, in the absence of persistent monitoring, potentially dangerous.

AUTHOR'S PREFERRED METHOD OF TREATMENT

Salient points regarding the use of midazolam and other benzodiazepines are summarized in Table 3-9. Although supplemental analgesia is required for painful procedures, such as the reduction of fractures, the anxiolysis and amnesia that midazolam produces make it an excellent medication for children with orthopaedic injuries. Careful intravenous titration of midazolam in increments of 0.05 mg/kg may be undertaken, combined with a regional anesthetic block (Bier block, hematoma block, for example) for pain relief. The author believes that oral midazolam, with its mandatory 10- to 30-minute waiting period, and with its lack of titratability to effect, is probably best reserved for use as a preoperative medication before elective surgical procedures. Also, for emergency patients, intravenous titration is the best and most efficient way to achieve desirable levels of patient sedation and cooperation. The combination of midazolam and opioids is discussed in the next section.

I. Method of Administration
   A. Morphine: 0.05–0.1 mg/kg IM or IV
   B. Meperidine: 0.5–1.0 mg/kg IM or IV
   C. Fentanyl: in increments of 0.001 mg/kg IV (maximum total dose, 0.004–0.005 mg/kg)
   D. Nalbuphine: 0.1 mg/kg IM or IV
Patients younger than 3 mo old should be given no more than half of these doses initially. IV titration to desired effect is the ideal way to administer all sedative medications.
II. Contraindications
   A. Altered state of consciousness
   B. Previous unfavorable experience (excludes that medication only)
   C. Sedation for nonpainful procedure
III. Advantages
   A. Provide excellent analgesia
   B. Reversible if necessary (naloxone 0.001–0.005 mg/kg IV titrated to effect)
IV. Disadvantages
   A. Risk of respiratory depression and apnea
   B. Increased risk of respiratory depression and apnea when combined with other sedatives
   C. No amnestic effects
V. Additional Side Effects (more likely when used in recurrent doses for treatment of pain)
   Nausea, vomiting, pruritus, constipation, decreased gastric motility

TABLE 3-9. OPIOIDS IN PEDIATRIC SEDATION

Opioids

Opioids include all exogenous substances, natural or synthetic, that bind to specific receptors and produce morphine-like effects (138). There are several types and subtypes of opioid receptors (8,138). Opioids vary in their respective affinity for receptor types, accounting for the difference in side effects. Opioids are classified as pure receptor agonists (e.g., morphine, meperidine, fentanyl), agonist-antagonists (e.g., nalbuphine), or pure antagonists (e.g., naloxone) (138).

Opioid Agonists

All opioid agonists produce dose-dependent respiratory depression and apnea (138). Nausea and vomiting occur because of direct stimulation of the chemoreceptor trigger zone in the floor of the fourth ventricle of the medulla oblongata (138).

Morphine

Morphine is a well-known analgesic. It is usually administered intravenously or intramuscularly, although sublingual and rectal routes have been described (33). Oral morphine is usually used for long-term pain control in patients with severe, chronic pain. Rectal administration of morphine is not recommended because it has been associated with delayed absorption, delayed respiratory depression, and death (33,58). In general, rectally administered medications are absorbed unpredictably (135) and access of the medication to the rectal mucosa may be variably impeded by rectal stool content.

The usual starting dose for intravenous or intramuscular morphine is 0.05 to 0.1 mg/kg. In infants younger than 3 months old, the dose should be reduced by at least one half because of increased susceptibility to respiratory depression (114). Morphine should be reserved for painful procedures lasting at least 30 minutes (33). Morphine is not very lipid soluble, and its delay in leaving the CNS accounts for a potential duration of action of 3 to 4 hours (8,33). Hypotension secondary to vasodilation, histamine release, or vagally mediated bradycardia can occur even with the administration of small doses of morphine (8). Histamine release along the course of the vein into which the morphine is administered is not by itself an allergic reaction (138). The overall incidence of true allergic reactions to opioids is very small (138).

Meperidine

The use of meperidine (Demerol) parallels that of morphine. The initial intravenous or intramuscular dose is 0.5 to 1.0 mg/kg. Again, the dose should be reduced by at least one half in infants younger than 3 months of age (114). Normeperidine, a metabolic breakdown product of meperidine, has been associated with seizures, agitation, tremors, and myoclonus (68,78). Meperidine is not recommended for patients with an underlying seizure disorder. Accumulation of normeperidine is more likely in situations of prolonged meperidine administration. Therefore, meperidine should be used cautiously, if at all, in the treatment of chronic pain (33). As with

morphine, meperidine may produce hypotension due to various mechanisms (8). Histamine release has also been reported with meperidine (8).

Fentanyl

Fentanyl is a synthetic narcotic 100 times more potent than morphine and 1,000 times more potent than meperidine on a milligram-per-milligram basis. Fentanyl is highly lipid soluble and rapidly penetrates the CNS (8). When administered in low doses, its duration of action is from 30 to 45 minutes. For sedation, fentanyl is given intravenously in increments of 0.5 to 1 μg/kg. The maximum total dose is 4 to 5 μg/kg (33). As a preoperative medication, fentanyl is available in an oral raspberry flavored lollipop known as the Fentanyl Oralet (88). Currently available sizes for the Oralet are 200 μg, 300 μg, and 400 μg. As a preoperative medication, the recommended dose ranges from 10 to 20 μg/kg. Troublesome side effects of this preparation include nausea and vomiting, pruritus, and oxygen desaturation (121).

Reonset of respiratory depression up to 4 hours after fentanyl administration has been reported (131). Glottic closure (5), and muscular rigidity (6,120,128) can occur, especially, although not exclusively, with administration of higher doses. Respiratory arrest may occur, especially with the coadministration of other sedatives (161). For these reasons, fentanyl should be titrated slowly to effect.

Opioid Agonist-Antagonists

A so-called ceiling effect or limit on the degree of respiratory depression has been demonstrated for various opioid agonist-antagonists, including nalbuphine (116) and butorphanol (149). Nalbuphine and morphine have the same analgesic potency on a milligram-per-milligram basis (114). Nalbuphine has a shorter elimination half-life (73). Opioid agonist-antagonists have no particular advantage over properly dosed opioids (38). The major problem with opioid agonist-antagonists is that their ceiling effect on respiratory depression is often accompanied by a ceiling effect for analgesia (138). Also, agonist-antagonists reduce the analgesic effectiveness of pure agonists (e.g., morphine, meperidine, fentanyl, codeine) if additional analgesia is required (38). In patients who are receiving opioids on a long-term basis, administration of opioid agonist-antagonists can precipitate acute withdrawal symptoms (38).

Drug Reversal With Opioid Antagonists

Naloxone (Narcan), which has no agonist activity of its own, displaces opioids from opioid receptors (138). Note that rapid reversal of narcotic effects may precipitate severe hypertension, pulmonary edema, ventricular or supraventricular irritability, seizures, and cardiac arrest (7,44). Dysphoria, nausea, and vomiting may also occur. Acute narcotic withdrawal in this situation reflects sympathetic nervous system stimulation from abrupt reversal of analgesia and sudden perception of pain (8). Therefore, naloxone should be titrated to effect (relief of respiratory depression) in increments of 1 to 5 μg/kg intravenously. Naloxone has a duration of action of 30 to 45 minutes, and resedation is possible. Close patient observation is required, and supplemental naloxone doses may be necessary. Current dosage recommendations in cases of frank opioid intoxication are significantly higher (43). Caution is always advised against precipitating acute narcotic withdrawal. The first priority in the treatment of narcotic overdose is a patent, well-maintained airway.

Similar to the situation with flumazenil for reversal of benzodiazepines, the author believes that the routine use of naloxone to reverse narcotic sedative medications is unwarranted and, for reasons noted earlier, potentially dangerous. Naloxone use should be reserved for situations of airway compromise brought on by relative opioid overdose, and it should never be utilized as a way of expediting patient discharge after a procedure requiring sedation.

Review of Relevant Literature (Opioids)

With careful monitoring and judicious administration, combinations of opioids for analgesia and benzodiazepines for amnesia and anxiolysis are probably the most useful sedatives in existence today for the management of children's fractures. Varela and co-workers (150) reported excellent patient and physician satisfaction using intravenous meperidine and midazolam for intravenous sedation for the closed reduction of fractures in children. In this particular investigation, the average meperidine dose was 1.47 mg/kg and the average midazolam dose was 0.11 mg/kg. There were no episodes of apnea or cardiorespiratory complications. These investigators stress that careful patient monitoring is important, not only during but after the procedure as well. Intravenous morphine 0.1 mg/kg plus midazolam 0.1 mg/kg is another useful sedation mixture for children with fractures, especially when combined with a hematoma block (personal communication, J. Edeen, M.D.). The hematoma block is discussed later in the chapter. With this particular approach, the midazolam is administered first, followed by the morphine about 5 minutes later. The hematoma block is performed, and the fracture is then reduced. Again, careful patient monitoring as previously outlined is essential to good care.

In the absence of specific contraindications, including tenuous airway status, unstable hemodynamic status, or history of specific allergic reactions, for the performance of painful procedures in children, a combination of a benzodiazepine and a narcotic is probably ideal (110,127,161), as long as the principles of careful titration and close patient monitoring are observed.

Salient points regarding the use of opioids as well as opioid and benzodiazepine combinations for pediatric sedation are summarized in Table 3-10 and Table 3-11. Opioid and benzodiazepine combinations provide amnesia, analgesia, and sedation. The tradeoff is that of additive respiratory depression and additive depression of protective airway reflexes. In both elective and emergent situations, the practitioner must

I. Method of Administration
   IV titration to effect
   A. Midazolam: In increments of 0.05 mg/kg to a maximum of 0.1 mg/kg. Wait 5 min between doses.
   B. Fentanyl: Begin 5 min after last midazolam dose. Give in increments of 0.001 mg/kg to a maximum of 0.003 mg/kg. Wait 2 to 3 min between doses.
II. Contraindications
   A. Altered state of consciousness
   B. Previous unfavorable experience with either medication
   C. Specific contraindications to benzodiazepines or opioids (see Tables 3-9 and 3-10).
III. Advantages
   A. Provides sedation, amnesia (midazolam), and analgesia (fentanyl)
   B. Reversible if necessary (see Tables 3-9 and 3-10).
IV. Disadvantages
   A. Additive respiratory depressant effects
   B. Additive depressant effects on protective airway reflexes with increased risk for regurgitation and aspiration of gastric contents

* An excellent review of the advantages and problems associated with this drug regimen is provided by Yaster and colleagues[155].

TABLE 3-10. FENTANYL AND MIDAZOLAM IN PEDIATRIC SEDATION*

I. Method of Administration
   20 to 75 mg/kg orally or rectally (maximum single dose, 1.0 g. If a second dose is given, the maximum total dose is either 100 mg/kg or 2.0 g, whichever is lower).
II. Contraindications
   A. Compromised hepatic function
   B. History of obstructive sleep apnea*
   C. Previous unfavorable experience with chloral hydrate
III. Advantages
   No specific advantages for sedation and treatment of children with fractures
IV. Disadvantages
   A. Prolonged time to peak effect (as long as 60 min)
   B. Difficult to titrate
   C. Prolonged observation period required

* Caution is required when using any sedative medication in patients with obstructive sleep apnea.

TABLE 3-11. CHLORAL HYDRATE IN PEDIATRIC SEDATION

1. Thoroughly evaluate the patient, as has been discussed earlier in the chapter.
2. Follow standard practice guidelines for deep sedation (63).

3. Pay careful attention to dosing limits (Table 3-11).
4. Be certain that both flumazenil and naloxone are available. These medications are to be used strictly for the treatment of absolute or relative overdose of benzodiazepines and opioids, respectively. Do not use these medications to expedite discharge from the emergency room.

Midazolam and Ketamine Compared With Midazolam and Fentanyl

While studying a group of 260 children between the ages of 5 and 15 presenting for the emergency room reduction of fractures, Kennedy and coworkers (81) compared the effectiveness of two regimens for sedation and analgesia. For the first reduction attempt in each patient, all of the children initially received midazolam 0.1 mg/kg (maximum dose of 2.5 mg) at 3-minute intervals until either objective signs of onset of drug effect developed (slurred speech, glassy eyes) or until three doses of midazolam were given. One minute after the administration of the last dose of midazolam, half the patients began receiving fentanyl, titrated in increments of 0.5 μg/kg until either a decreased response to verbal or painful stimulation was noted, or a maximum dose of 2 μg/kg had been administered. The maximum amount of fentanyl used was 100 μg. The other half of the patients, instead of receiving fentanyl, were given ketamine, titrated in increments of 0.5 μg/kg, using the same criteria as for fentanyl to determine onset of effect. Ketamine titration continued, if necessary, until a maximum amount of 2 μg/kg had been given. All of the patients who were given ketamine also received glycopyrrolate, 5 μg/kg as an antisialogogue. Additional amounts of midazolam and the study drug were given if analgesia and sedation were judged to be insufficient or if additional reduction attempts were necessary. Treatment failures occurred in those patients who experienced significant adverse drug effects or who obtained insufficient sedation and analgesia.

Patient distress was quantified using various behavioral scales. The reader is referred to the article itself for more detailed information about the measurement process (81). Whereas presedation scores were basically the same for both groups, during fracture reduction, the investigators reported a significantly lower score of patient distress for the children receiving midazolam and ketamine than for those receiving midazolam and fentanyl (81). In general, the ketamine and midazolam combination was favored by parents and by the involved orthopaedic surgeons (81). On the other hand, however, two patients receiving midazolam and ketamine required brief assisted ventilation with a bag, valve, and mask apparatus, and one patient developed laryngospasm. Vomiting occurred more often in the group taking ketamine, and group taking the ketamine had a longer mean time to recovery and discharge.

This is a very detailed study that looks very closely at two viable regimens for sedation of children with fractures. Again, with careful monitoring and careful attention to drug titration, the practitioner may wish to try both to determine which is more useful in their individual practice. The authors of this study favor the ketamine and midazolam regimen and provide good evidence for their conclusions (81).

Pediatric Cocktail

The so-called pediatric cocktail (DPT) or “lytic” cocktail is a mixture of meperidine (Demerol) and two phenothiazines: promethazine (Phenergan), and chlorpromazine (Thorazine). For multiple reasons, this sedative regimen should be avoided. Prolonged and profound sedation occur, often far outlasting the procedure for which the sedation was intended. One study has reported a mean total recovery time of 19 hours, plus or minus 15 hours, in children receiving DPT in the emergency department (142). Orthostatic hypotension is possible, because promethazine and chlorpromazine are alpha-adrenergic blockers (33). Severe respiratory depression and death, both during and after the procedure, have occurred in patients sedated with DPT. All three medications in this mixture lower the seizure threshold, and phenothiazines can produce dystonic reactions (33). Note that there is no reversal agent for phenothiazine overdose.

AUTHOR'S PREFERRED METHOD OF TREATMENT

The author strongly believes that the use of the pediatric cocktail should be abandoned (127).

Chloral Hydrate

Of greatest use in sedating children for nonpainful diagnostic procedures such as radiographic studies, chloral hydrate is administered in a dose of 20 to 75 mg/kg orally or rectally. The maximum single dose is 1 g. If more than one dose has to be given, the upper limit for the total dose is either 100 mg/kg or 2 g, whichever is lower.

Although, theoretically, rectal dosing should be more efficient, because of the lack of a first pass hepatic effect (135), 30 to 60 minutes may elapse before chloral hydrate takes effect no matter how it is administered. Children receiving chloral hydrate must be observed for at least several hours. Respiratory depression is unusual, but children with sleep apnea and adenotonsillar hypertrophy may be particularly vulnerable to airway obstruction after sedation with chloral hydrate (16). At least one death has been reported following its use (74). These problems emphasize that even sedatives thought to have little risk of producing respiratory depression must be administered under properly supervised conditions (63) and with strict adherence to dosage guidelines.

AUTHOR'S PREFERRED METHOD OF TREATMENT

Chloral hydrate is of minimal use in the sedation and treatment of patients with fractures. It provides no analgesia, and it lacks the rapidity of onset and titratability of intravenous opioids and benzodiazepines. The practitioner should be familiar with this medication, however, because it remains in common use for nonpainful pediatric procedures. Salient features regarding its administration are summarized in Table 3-12.

1. Numbness of the lips and tongue, metallic taste in the mouth.
2. Lightheadedness
3. Visual and auditory disturbances (double vision and tinnitus)
4. Shivering, muscle twitching, tremors (initial tremors may involve the muscles of the face and distal parts of the extremities)
5. Unconsciousness
6. Convulsions
7. Coma
8. Respiratory arrest
9. Cardiovascular depression and collapse

* With gradual increases in plasma concentration, these signs and symptoms may occur in order as listed. With the sudden development of high plasma concentrations of a local anesthetic agent, the first manifestation of toxicity may be a convulsion, respiratory arrest, or cardiovascular collapse. In young children, or in children who are heavily sedated, subjective evidence of impending local anesthetic toxicity (manifestations 1, 2, 3) may be difficult to elicit.

TABLE 3-12. MANIFESTATIONS OF LOCAL ANESTHETIC TOXICITY*

Barbiturates

In general, barbiturates have a lower margin of safety than benzodiazepines (132). In addition, barbiturates seem to lower the pain threshold, and are therefore a poor choice for producing sedation in the presence of a painful condition, such as a fracture (132). With these points in mind, barbiturates should not be used for sedating children with fractures.

Propofol

Propofol is a substituted isopropylphenol that is a rapid-acting intravenous anesthetic (136). Because it is virtually insoluble in aqueous solutions, it has to be dissolved in lecithin-containing formulations. The orthopaedist may have seen this whitish medication administered by the anesthesiologist in the operating room, where it has gained the popular name of “milk of amnesia.”

Propofol has a fast onset of action, owing to its high lipid solubility, and an extremely short duration of action. Awakening is rapid, with little to no “hangover” effect as

seen with other drugs (136). It also has antiemetic effects (88).

However, there are several reasons for which the drug should not be used in the management of children with fractures in an emergency room setting. First and foremost, it is easy to suddenly lose the airway in a patient given propofol. Therefore, this drug has really should be administered by an anesthesiologist (79). Second, the drug provides no analgesic effect and, therefore, has to be combined with an opioid, which, in turn, will intensify the respiratory depressant effects of propofol. Third, in children, the administration of propofol is associated with opisthotonic posturing and myoclonus (88), which is certainly not helpful in the reduction of a fracture. Propofol has vasodilatory and negative inotropic effects, which can lead to hypotension (88). Finally, there is some concern that propofol may be associated with seizures (88), although Momota and co-workers (97) have used propofol to stop seizure activity from local anesthetic overdose.

AUTHOR'S PREFERRED METHOD OF TREATMENT

Regarding children with fractures, propofol should be reserved for administration in the operating room as part of a regimen of general anesthesia by an anesthesiologist.

REGIONAL ANESTHESIA IN THE CHILD WITH A MUSCULOSKELETAL INJURY

Within the limitations and guidelines that are discussed later, the use of regional anesthesia to relieve pain in children with musculoskeletal injuries is reasonable and worthwhile.

Regional Anesthetic Agents

Regional or local anesthetic medications prevent nerve impulse propagation by interfering with the function of the sodium channel on the axonal membrane (139). Commonly used local anesthetics have either an amino amide or amino ester linkage in their molecular structure (146). Amino amide local anesthetics include lidocaine (Xylocaine), bupivacaine (Marcaine, Sensorcaine), mepivacaine, prilocaine, etidocaine, and the relatively new agent ropivacaine. Amino ester local anesthetics include procaine (Novocain), chloroprocaine, tetracaine, benzocaine, and cocaine.

Medications within each group have important intrinsic differences in potency, duration of action, and potential for toxicity (36,146). For example, lidocaine is significantly less toxic a drug than bupivacaine but it also has a shorter duration of action. An important feature of ropivacaine is that even though its duration of action is similar to bupivacaine, it produces less CNS toxicity and less cardiac toxicity (123). Duration of action for the various local anesthetic medications is also determined in part by the type of regional block performed. For example, single dose brachial plexus blocks tend to have a far longer duration than do single dose epidural or subarachnoid blocks (36).

Local Anesthetic Toxicity

At least three types of adverse reactions can occur from local anesthetic agents. Clinically, the most important is systemic toxicity of the CNS and cardiovascular system from relative overdose into the circulation. This type of reaction is not a medication allergy but simply a function of placing too much medication into the bloodstream. Note that in the presence of a major artery, even a few drops of local anesthetic can lead to seizure activity. An example of this problem is seen in the performance of stellate ganglion blocks in the neck for the management of reflex sympathetic dystrophy of the upper extremity, where the vertebral artery can be accidentally entered during administration of the medication.

In most cases, however, the severity of systemic toxicity is directly related to the concentration of local anesthetic in the bloodstream (Table 3-13) (36). Seizures and cardiac arrest may be the initial manifestations of systemic toxicity in patients who rapidly attain a high serum level of medication (42,98,109). Agents with greater intrinsic potency, such as bupivacaine and etidocaine, require lower levels for production of symptoms (36). Dysrhythmias and cardiovascular toxicity may be especially severe with bupivacaine, and resuscitation of these patients may be prolonged and difficult (2,36).

Preventive Measures

1. Ensure availability of oxygen administration equipment, airway equipment, suction equipment, and medications for treatment of seizures (diazepam or midazolam, thiopental, succinylcholine).
2. Ensure constant verbal contact with patient (for symptoms of toxicity) and monitor cardiovascular signs and oxygen saturation.
3. Personally prepare the dose of local anesthetic and ensure it is within the accepted dosage range.
4. Give the anesthetic slowly, and fractionate the dose.

Treatment

1. Establish a clear airway; suction if required.
2. Give oxygen by face mask. Begin artificial ventilation if necessary.
3. Give diazepam 0.1–0.3 mg/kg IV in incremental doses until convulsions cease. Midazolam (0.05–0.1 mg/kg) may be used instead, also in increments until convulsions cease.
4. Thiopental in increments of 1–2 mg/kg IV may be used to control the seizures.
5. Succinylcholine (1 mg/kg IV) may be used if there is inadequate control of ventilation with the other medications. Artificial ventilation and possibly endotracheal intubation are required after using succinylcholine.
6. Use advanced cardiac life-support measures as necessary to support the cardiovascular system (crisis likely with local anesthetics of increased potency, such as bupivacaine).

TABLE 3-13. PREVENTION AND TREATMENT OF ACUTE LOCAL ANESTHETIC SYSTEMIC TOXICITY

The prevention and treatment of acute local anesthetic systemic toxicity are outlined in Table 3-14.

Agent	Injection Dose (mg/kg)	
	Plain	With Epinephrine*
Lidocaine† (Xylocaine)	5	7
Bupivacaine‡ (Marcaine, Sensorcaine)	2.5	3
Mepivacaine (Carbocaine)	4	7
Prilocaine§	5.5	8.5

* The addition of epinephrine (vasoconstrictor) reduces the rate of local anesthetic absorption into the bloodstream, permitting use of a higher dose.
† For IV regional anesthesia (Bier blocks), the maximum lidocaine dose is 3 mg/kg. Preservative-free lidocaine without epinephrine should be used for either Bier blocks or hematoma blocks.
‡ Owing to its cardiotoxicity, bupivacaine should never be used for IV regional anesthesia or for hematoma blocks.
§ Of the amide local anesthetics, prilocaine is the least likely to produce CNS and cardiovascular toxicity. However, a byproduct of prilocaine metabolism may lead to severe methemoglobinemia in young children. Prilocaine is, therefore, contraindicated in children younger than 6 mo old.

TABLE 3-14. MAXIMUM RECOMMENDED DOSES OF COMMONLY USED LOCAL ANESTHETICS IN CHILDREN

Although the potential for CNS toxicity may be diminished with barbiturates or benzodiazepines, given either as premedications or during treatment of convulsions, these measures do not alter the cardiotoxic threshold of local anesthetic agents. With rapid and appropriate treatment, the fatality rate from local anesthetic convulsions should be greatly decreased (36).

It is absolutely essential to stay within accepted dose limits when using any local anesthetic (Table 3-15). To aid in dose calculations, a simple formula for converting percent concentration to milligrams to milliliter is provided in Table 3-16.

Percentage concentration × 10 = Number of mg/mL

Examples: 0.25% bupivacaine has 2.5 mg bupivacaine/mL;
2% lidocaine has 20 mg lidocaine/mL.

TABLE 3-15. CONVERSION FORMULA FROM % CONCENTRATION TO MILLIGRAMS/MILLILITER

IM†: Morphine, 0.1–0.15 mg/kg q 3–4 h
Meperidine, 1.0–1.5 mg/kg q 3–4 h

IV: Morphine, 0.05–0.1 mg/kg q 2 h
Meperidine, 0.5–1.0 mg/kg q 2 h

* Infants < 3 mo old should be dosed in increments of one third to one half because of increased risk of respiratory depression.
† Intramuscular dosing should rarely be used.
Adapted from Roger, L. and Moro, M. Acute postoperative and chronic pain in children. In Rasch, D.K. and Webster D.E. eds.: *Clinical manual of pediatric anesthesia*. New York: McGraw-Hill, 1994:297, with permission.

TABLE 3-16. PARENTAL OPIOID DOSING SCHEDULE FOR ANALGESIA IN CHILDREN*

Although rare, true immune-mediated allergic reactions to local anesthetics are possible, more commonly with amino esters than with amino amides (22,52). The reader is referred to other sources for the detailed management of allergic or anaphylactic reactions (28,100).

Local nerve damage and reversible skeletal muscle changes have been reported from the use of local anesthetics (36).

Intravenous Regional Anesthesia

Intravenous regional anesthesia was first described by August Bier in 1908 (15). Although it declined in popularity as brachial plexus blocks were developed, it was revived in 1963, when its safe and successful use for the reduction of forearm fractures in adults was reported (70). Since then, multiple reports have attested to its usefulness in the treatment of upper limb injuries in adults and children (10,17,29,46,53,104,147).

The mechanism of action is uncertain. It may involve both direct transport of local anesthetic to major nerve trunks or the blockade of small nerve endings (53).

Intravenous regional anesthesia is reliable, with a higher success rate than other approaches to upper extremity blocks (53). Other advantages include its simplicity, rapidity of onset, and rapidity of recovery. Rapidity of recovery may be considered both an advantage as well as a disadvantage, because, with local anesthetic alone, the analgesic effect is lost once the tourniquet is deflated. A recent report in adults examined the addition of the nonsteroidal antiinflammatory medication ketorolac (Toradol) to the local anesthetic solution for intravenous regional anesthesia and found that patients did obtain prolonged analgesia after the tourniquet was released (124). However, no pediatric studies have been performed on this drug combination.

Intravenous regional anesthesia is unsuitable for lesions above the elbow (71). In addition, if the fracture involves the supracondylar area of the humerus, the cuff may limit the degree of hyperflexion needed to produce an adequate reduction. Intravenous regional anesthesia is contraindicated in patients with underlying heart block, known hypersensitivity to local anesthetic agents, and seizure disorders (71). Although not totally contraindicated, caution is urged when using this technique in patients with underlying hemoglobinopathies such as sickle cell disease.

AUTHOR'S PREFERRED METHOD OF TREATMENT

The basic steps involved in performing an intravenous regional block are as follows:

1. Confirm the immediate availability of a functioning positive-pressure oxygen delivery system, as well as appropriate airway management equipment (Table 3-5) (63). Also, confirm the immediate availability of medications for the treatment of anesthetic-induced convulsions (Table 3-13).
2. Start an intravenous infusion in the contralateral arm (Fig. 3-3). A patent intravenous line is of paramount importance in treating the complications of this block. Obtain a baseline set of vital signs, including systolic and diastolic blood pressure. Monitor pulse oximetry (Fig. 3-3) as well as the ECG continuously (Fig. 3-4).

FIGURE 3-3. Intravenous infusion for fluids, sedative medications, and if necessary, resuscitative medications has been started in the contralateral hand. A pulse oximeter probe is present on the patient's index finger.

FIGURE 3-4. Continuous display of the electrocardiogram (top waveform) and continuous display of the plethysmographic tracing from the pulse oximeter (second line). Intermittent blood pressure reading is displayed.

3. Select an appropriate tourniquet. An orthopaedic tourniquet that can be fastened securely should be used. Because Velcro may become less adhesive with time, check the tenacity of the tourniquet before use. As an added safety measure, the tourniquet may be covered with strong adhesive tape or an Ace bandage after application. The tourniquet should fully encircle the arm and overlap back on itself by at least 6 cm (personal communication, K.E. Wilkins, M.D.). The arm may be minimally padded with cast padding underneath the tourniquet (17). If a pneumatic tourniquet is used, the physician must be familiar with the location of the tourniquet pressure gauge (Fig. 3-5) (29) and valves, because these features may vary in location from model to model. Narrow-cuffed double tourniquets may not effectively occlude arterial flow, and their use has been discouraged (71). Tourniquet discomfort should not be a problem during short procedures. If this problem develops, a second tourniquet can be applied distally over the anesthetized area of the arm.

FIGURE 3-5. Tourniquet controls may vary in position from model to model. It is imperative for the practitioner to be aware of the function of each of the controls to avoid accidental premature deflation of the tourniquet.

4. Palpate the radial pulse of the injured limb.
5. Place and secure a short 22-gauge cannula in a vein on the dorsum of the hand of the fractured limb. A 23-gauge butterfly needle may also be used (Fig. 3-6). Note that although it may be possible to “thread” a butterfly needle securely into a large vein, butterfly needles may still slip out of the vein more easily than a plastic intravenous catheter. The author recommends the use of intravenous catheters whenever possible. If a distal vein is unavailable, a proximal vein or even an antecubital vein can be used. However, the use of proximal veins in the arm may result in a less effective block (71).

FIGURE 3-6. Venipuncture for administration of local anesthetic has been performed with a butterfly needle. An intravenous catheter may be more secure than a needle, which can become dislodged from within the vein.

6. With the tourniquet deflated, exsanguinate the limb by vertically elevating it above the level of the heart for 60 seconds.
7. Rapidly inflate the tourniquet to a pressure of 225 to 250 mm Hg or 150 mm Hg above the patient's systolic blood pressure (51). Check for disappearance of the radial pulse. Cross-clamping the tubing of the cuff after inflation is discouraged (71), because it might prevent detection of a small leak. Constant observation of the cuff pressure gauge is recommended.
8. Lower the extremity and slowly inject the local anesthetic. It is recommended that this injection be done over a period of 60 seconds. A concentration of 0.5% plain lidocaine (5 mg/mL) is used (Fig. 3-7). Bupivacaine is contraindicated for this block because of its cardiotoxicity. To prevent thrombophlebitis, the local anesthetic solution must be free of any additives or preservatives (71). In different studies, the recommended dose of lidocaine has varied from 1.5 to 3.0 mg/kg (10,17,29,46,53,104,147). A dose of 1.5 mg/kg appears to be safe and effective, and may produce a decreased incidence of complications (17). One study has recommended a maximum lidocaine dose of 100 mg for this block (46). The skin of the extremity becomes mottled as the drug is injected. The patient, unless he or she is very sedated, and the parents, if they are watching, should be warned that the extremity will look and feel strangely (personal communication, K.E. Wilkins, M.D.). Analgesia and muscle relaxation develop within 5 minutes of injection (71). Note that for fractures at the wrist, placement of a regular penrose drain tourniquet around the distal forearm may improve distribution of the local anesthetic solution at the fracture site (Fig. 3-8) (personal communication, K.E. Wilkins, M.D.).

FIGURE 3-7. Preservative-free 0.5% lidocaine without epinephrine for intravenous regional anesthesia.

FIGURE 3-8. Penrose drain tourniquet on the forearm to improve distribution of local anesthetic at the fracture site.

9. To improve analgesia for fracture reduction, the last 2 mL of local anesthetic solution may be injected directly into the fracture hematoma (Fig. 3-9) (personal communication, K.E. Wilkins, M.D.). The technique of local infiltration anesthesia, or hematoma block, is discussed further in a subsequent section of this chapter.

FIGURE 3-9. Hematoma block performed with the last 2 mL of the intravenous lidocaine solution to enhance analgesia at the fracture site.

10. Perform the surgical procedure (Fig. 3-10).

FIGURE 3-10. Fracture reduction under appropriately monitored sedation and intravenous regional anesthesia.

11. Leave the cuff inflated for at least 15 minutes (71), even if the surgical procedure takes less time.
12. Release the cuff at the end of the operation, or at the end of a 15-minute interval, whichever is longer. Cuff deflation, followed by immediate reinflation, as a method of delaying systemic absorption of local anesthetic is impractical because it cannot be done rapidly enough to prevent significant entry of local anesthetic into the general circulation (71).
13. Monitor the patient closely for at least 15 minutes for any complications related to the block. The treatment of local anesthetic-induced systemic toxicity has been discussed (Table 3-13).
14. Of course, depending on whatever sedation has been administered, the patient should be monitored until discharge criteria are met (Table 3-1)

An assistant must be present to watch the patient, the tourniquet, and the monitors at all times.

Local Infiltration Anesthesia: Hematoma Block

Hematoma block has been successfully used in the treatment of distal forearm fractures (27, 94). This simple technique involves injecting local anesthetic into the fracture hematoma, the location of which is confirmed by aspirating blood into the syringe (Fig. 3-9). When done alone, 1% lidocaine in a dose of 1 to 2 mg/kg is used (94). As indicated earlier, when combined with a Bier block, the last 1 to 2 mL of local anesthetic solution are used. Although the medication is rapidly absorbed into the circulation, the resulting systemic blood levels of local anesthetic are well below those required for CNS toxicity (94). Hematoma blocks may be used in patients who have received a regional block yet still have residual pain at the fracture site.

Alioto and co-workers (4) have described the use of an intraarticular hematoma block for the manipulative reduction of ankle fractures in a population group that included both children and adults. The youngest patient in their study group who received a hematoma block was 12 years old. The technique they describe consisted of a direct injection of 2% lidocaine 1 mg/kg (the authors used 2 mg lidocaine per pound) into the tibiotalar joint space. Absolute sterile technique was used, with the skin overlying the fracture site being prepared with a povodine-iodine preparation. A 22- or 25-gauge needle was used for the injection of the local anesthetic solution. The authors of this investigation recommend directing the needle in a slightly cephalad direction to avoid injury to the talar and tibial articular surfaces. Aspiration of blood was used to confirm entry into the intraarticular space. The injection was performed only if no resistance was encountered. A minimum of 15 minutes was allowed to pass after the injection, during which time the patient was closely observed and monitored for any evidence of local anesthetic systemic toxicity (see earlier). The injection was considered adequate if the patient was subsequently able to elevate the injured limb off the bed without assistance and perform active ankle dorsiflexion and plantarflexion. The authors of this investigation found the intraarticular ankle hematoma block to be safe, effective, and well tolerated by patients (4). Although some of their patients tolerated the injection and the subsequent fracture reduction without the use of any other supplemental analgesics or sedatives, most children would probably require the same type of sedation that would be used before performing a Bier block or a hematoma block of the upper extremity.

AUTHOR'S PREFERRED METHOD OF TREATMENT

Full aseptic technique, including adequate skin preparation and the use of sterile gloves, is recommended. The incidence of infection from introduction of a needle into the hematoma is greatly decreased if antiseptic precautions are taken (75). The hematoma is localized by aspirating blood into the syringe. The local anesthetic solution is given gradually by alternate injection (barbotage) of a small amount of medication and withdrawal of a small amount of hematoma until all of the medication has been given (Fig. 3-11). In the case of the intraarticular hematoma block at the ankle (4), a slow direct injection is used, with careful ECG monitoring for any evidence of dysrhythmias.

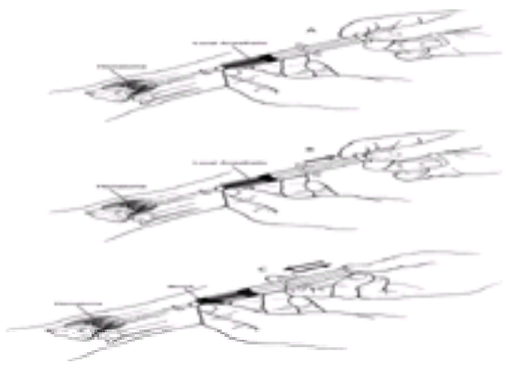

FIGURE 3-11. Barbotage. When performing a hematoma block, the local anesthetic is given by barbotage. A: Half the anesthetic is injected in the hematoma. B: The blood from the hematoma is withdrawn until the original volume is regained. C: This mixed material is repeatedly injected and reaspirated until the anesthetic is dispersed in the hematoma. The final aspirate should contain a volume equal to the original anesthetic. Thus, the final volume of fluid in the hematoma has not been increased.

Reported complications with hematoma blocks in the upper extremity include compartment syndrome (162), temporary paralysis of the anterior interosseous nerve (162), and increased incidence of carpal tunnel syndrome (84).

Femoral Nerve Block

Berry (14) has described a technique of rapid analgesia for patients with a fracture of the femoral shaft using 1% lidocaine with 200,000 epinephrine or 1.5% lidocaine with 1:200,000 epinephrine deposited at the femoral nerve, just below the inguinal ligament (Fig. 3-12). As always, the anesthetic dose should remain within accepted limits. For lidocaine with epinephrine, 7 mg/kg is the permissible dose limit.

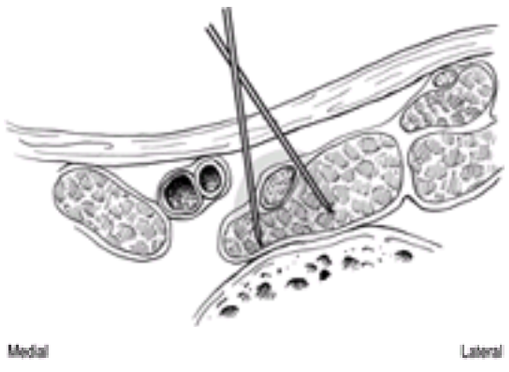

FIGURE 3-12. Section of right thigh immediately below the inguinal ligament, showing femoral nerve under cover of fascia iliaca and its block by a barrage technique. (Reproduced with permission from Anesthesia, 1977, Volume 32, page 577. Analgesia in Patients with Fractured Shaft of Femur. F.R. Berry, M.D.)

Cooperation and tolerance among young children for regional blocks varies, so careful patient selection is advised.

POSTOPERATIVE ANALGESIA IN THE CHILD WITH A MUSCULOSKELETAL INJURY

Safe and effective postoperative analgesia in children with musculoskeletal injuries can be accomplished with opioids, nonsteroidal antiinflammatory agents (NSAIDS), or local anesthetic agents.

Simultaneous use of more than one modality may be beneficial in order to minimize side effects from any one particular approach (e.g., the use of NSAIDS to decrease the incidence of nausea, vomiting, or even respiratory depression from opioids). The end point is to make patients comfortable while minimizing adverse reactions.

Postoperative Analgesia With Opioids

Opioids have long been the mainstay of postoperative analgesia. It is important for the practitioner to understand the rationale behind different dosage regimens to maximize pain relief for the patient.

Intermittent Dosing

Although commonly used, traditional intermittent as-needed dosing of intramuscular and intravenous opioids (Table 3-17) makes little pharmacologic sense for control of severe pain (49,148). Wide variations in plasma opioid levels occur, leading to periods of sedation alternating with prolonged periods of no pain relief at all (49). In addition, for pediatric care, intramuscular dosing is a particularly poor choice (148), because children often chose to hide their pain rather than risk having to undergo an injection. The end result with intermittent dosing, especially with intramuscular narcotics, is unnecessary undertreatment of pain.

Loading dose: Morphine, 0.025–0.05 mg/kg
Maintenance dose: Morphine, 0.01–0.02 mg/kg
Lockout interval: 6–10 min
4-hr maximum: Morphine, 0.4 mg/kg/4 h

Treatment of Side Effects

Pruritus
- Diphenhydramine (0.5 mg/kg IV) OR
- Low-dose naloxone (0.5–1.0 μg/hr)

Nausea/vomiting
- Metoclopramide (0.1 mg/kg IV) OR
- Droperidol (10–30 μg/kg IV or IM) OR
- Ondansetron (0.15 mg/kg IV over 15 min)
- Low-dose naloxone as for pruritus

Urinary retention (<1 ml/kg/h in the face of adequate fluid intake)

Low-dose naloxone infusion as above

Respiratory depression
- Vital signs: specify parameters that require treatment and method for contacting responsible physician.
- Stop PCA pump.
- Give 100% oxygen and maintain the airway.
- Give naloxone (1–5 μg/kg IV bolus). Repeat as needed.
- Consider naloxone infusion (3–5 μg/kg/h).

TABLE 3-17. PATIENT-CONTROLLED ANALGESIA IN CHILDREN

Patient-Controlled Analgesia

Patient-controlled analgesia (PCA) is a sensible approach to the problems inherent with intermittent as-needed dosing of opioids (49). With PCA, intravenous

self-titration of small doses of opioids at frequent intervals eliminates the wide variations in plasma drug levels seen with intermittent dosing (49). It also allows patients to gain control over their pain management (23), which may be of psychological importance to the patient's well-being.

PCA was first evaluated in adolescents in 1987, after several years of successful use in adults (23). Since then, this modality has been used for children as young as 6 years of age (11). Depending on the intelligence and cooperative ability of the child, it is conceivable that PCA could be used for younger individuals, although careful assessment of each individual situation is required.

When compared with traditional intermittent dosing, improved pain control and greater patient satisfaction have been demonstrated (11). Note that further improvement in pain relief may be achieved with the addition of a continuous background infusion of opioids to maintain the plasma concentrations of the analgesic during sleep. However, adding a background infusion may increase the risk of opioid-associated nausea, sedation, and hypoxemia (39,159).

Conceivably, for younger children or for children otherwise unreliably capable of pushing the button on the PCA cord, “parent-controlled analgesia” may be useful. The author has used this approach in a patient as young as 1 1/2 years of age. In this particular situation, however, the parents were very motivated and intelligent, and had done this before for their child after another surgical procedure. In general, PCA is safest when only the patient is operating the device.

Parameters that must be considered are the loading dose, the maintenance dose, and the lockout interval (the period during which no further administration of medication will occur despite attempts to do so by the patient), and the 4-hour maximum dose (Table 3-18). For PCA, morphine is more effective than meperidine (151). Opioids other than morphine should be used only for patients allergic to morphine (20), or for whom morphine produces intolerable side effects. Whenever possible, the persistent use of one medication helps avoid dosing errors (20).

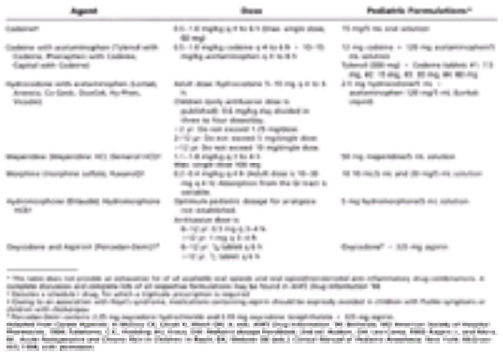

TABLE 3-18. DOSING SCHEDULES AND FORMULATIONS FOR ORAL OPIOIDS IN CHILDREN

The use of the PCA pump should be explained to patients preoperatively. Effective use of a loading dose will avoid the problem of having to play catch-up with out-of-control levels of pain.

Mishaps have occurred with PCA pumps due to programming errors (156), so ward personnel must be totally familiar with the equipment. Treatment of opioid-related side effects is outlined in Table 3-18.

Oral Administration of Opioids

Oral dosing of opioids is extremely useful for the continued management of diminishing postoperative pain, once oral analgesics are tolerated. Several oral analgesics are available, and their appropriate use is summarized in Table 3-19. None of these medications is devoid of side effects, including mood changes, nausea, vomiting, constipation, dizziness, and pruritus. The occurrence and degree of side effects vary from patient to patient, so the physician should be prepared to change dosing regimens based on patient response. The use of NSAIDS (see the following section) as part of the analgesic regimen may be helpful in reducing or eliminating troublesome opioid-related side effects.

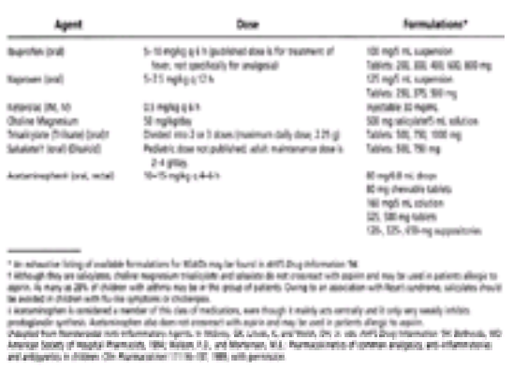

TABLE 3-19. DOSING SCHEDULES AND FORMULATIONS FOR NSAIDS IN CHILDREN

Other Modes of Opioid Administration

Epidural opioids are being used in children after major surgery with excellent results (112). The author encourages close cooperation between surgeons and anesthesiologists to avail children of this modality of analgesia whenever feasible.

Postoperative Analgesia With Nonsteroidal Antiinflammatory Drugs

NSAIDs have moderately good analgesic properties (148). Unlike opioids, which produce analgesia by effects on CNS receptors, NSAIDs act peripherally by inhibiting prostaglandin synthesis and decreasing inflammation (137,152). Inflammatory mechanisms play an important part in the pathogenesis of postoperative pain (148), and therefore, the use of NSAIDs makes good sense in the postoperative setting. Also, although NSAIDs have some troubling side effects of their own, they do not produce respiratory depression, nausea, and vomiting, which are some of the bothersome features of opioids. Thus, using NSAIDs either as an adjunct or as a substitute for opioids where feasible should decrease or eliminate the possibility of drug-induced nausea, vomiting, or respiratory depression in the surgical patient (148).

Potential side effects of this class of drugs include platelet dysfunction, gastritis, and acute renal dysfunction (93,152). A history of sensitivity to aspirin or a history of nasal polyps may be associated with potentially fatal cross-sensitivity to other NSAIDs (1,137). In children with asthma, the prevalence of aspirin sensitivity may be as high as 28% (111). Therefore, asthmatic children should probably receive only those NSAIDs that do not cross-react with aspirin. These medications include acetaminophen, salsalate (Disalcid), and choline magnesium trisalicylate (Trilisate) (130) (Table 3-19).

In a child with a chronic underlying bleeding disorder, NSAIDs are not necessarily contraindicated. Consultation with the child's hematologist is advised regarding the use of specific medications in this class.

Ketorolac, unlike other NSAIDs, can be administered not only orally but also intravenously and intramuscularly. A loading dose of 1.0 mg/kg may provide similar analgesia as 0.1 mg/kg of morphine (90). The pharmacology of ketorolac has been extensively reviewed (86), and both its mode of action and adverse reactions are generally typical of NSAIDs. The major controversy with this drug remains its effect on hemostasis and bleeding. Rusy and co-workers (117) found that ketorolac contributed to increased blood loss and more difficulty in achieving surgical hemostasis in pediatric tonsillectomy patients. Caution is advised in administering ketorolac or any other NSAID in a perioperative situation in which bleeding has been or can be significant. Ketorolac has been associated with an increased incidence of nonunion in patients undergoing spine fusion.

Suggested dosing schedules for some of the more common NSAIDs are listed in Table 3-8. Acetaminophen is considered a member of this class of medications, although its mechanism of action is central and its effects on prostaglandin synthesis and the inflammatory response are comparatively very weak (152).

Postoperative Analgesia With Local Anesthetic Agents

Regional anesthesia is an excellent means of providing postoperative analgesia without respiratory depression and with minimal physiologic alterations (160). Both central (epidural) and peripheral (e.g., brachial plexus blocks) nerve blocks may be used for this purpose. The physician must ensure that the pain relief achieved does not mask the signs and symptoms of developing vascular or neurologic compromise (41,101).

TREATMENT OF POSTOPERATIVE NAUSEA

Postoperative nausea is common in children, although not particularly after peripheral orthopaedic procedures (90). The pharmacologic treatment is outlined in Table 3-20. Additional helpful measures include not forcing intake of oral fluids until the child is hungry, and minimizing early postoperative ambulation, especially when opioids have been given (12).

Agent	Dosage	Route
Promethazine (Phenergan)	0.25–0.5 mg/kg	IV or per rectum
Metoclopramide (Regian)	0.1 mg/kg (maximum dose, 5 mg)	IV
Ondansetron (Zofran)	0.15 mg/kg (maximum dose, 4 mg)	IV

* Additional helpful measures include ensuring adequate IV hydration, avoiding forced oral fluids until the patient is hungry, and avoiding forced early ambulation, especially when opioids are given for pain relief.

4
MANAGEMENT OF THE MULTIPLY INJURED CHILD

VERNON T. TOLO

INCIDENCE OF INJURIES

Trauma

The most common cause of death in children over the age of 1 year is trauma, not only in the United States but worldwide. Estimates of cost to the American public for the care of pediatric trauma range from over $1 billion (53) to $13.8 billion (56) annually. Although isolated long bone fractures still comprise the bulk of orthopaedic injuries in children, a surprising number of these young patients have multiple system injuries.

The cause of death from trauma in children generally is severe head injury. Boys are injured twice as often as girls and may account for even a greater proportion of hospital admissions related to pediatric trauma. Blunt trauma is the mechanism of injury in most children and preadolescents, whereas penetrating trauma more often is the source of multiple injuries in adults. Although blunt trauma in the youngest children often is due to child abuse, vehicular accidents and falls from a height account for the more severe multiple injuries in the rest of childhood (12).

Multiple injuries in teenagers more closely mirror the causes in adults. In the adolescent age group, alcohol abuse now is considered a major factor in over a third of injuries resulting from accidents (55). Orthopaedists treating teenagers involved in vehicular accidents need to be aware of the potential alcohol use in this age group and be prepared to refer adolescents for appropriate counseling to avoid future accidents and injuries.

Fractures

Although they are rarely the cause of mortality in a child with multiple injuries, fractures and other injuries to the musculoskeletal system are commonly a major part of the injuries (12,18,20,63). In one series from a pediatric trauma center treating children with polytrauma, femoral shaft fractures accounted for 22% of the fractures and 9% of the fractures were open (12). Although they are less common, fractures of the spine, pelvis, and scapula and clavicle were associated with longer stays in the hospital and in the intensive care unit, in addition to having the highest associated mortality rates.

Knowledge of fracture associations leads to improved diagnostic skill and fracture care. Femoral and adjacent pelvic fractures often occur together. If a pedestrian child has been struck by an automobile, there often are fractures in the ipsilateral upper extremity and lower extremity (11). The coexistence of a femoral fracture and a head injury indicates substantial high-energy trauma and has a more guarded prognosis than does either of these injuries alone.

Child Abuse

Child abuse continues to be a societal problem that crosses all socioeconomic and ethnic groups. This diagnosis must be suspected in all cases of multiple injuries in children younger than 2 years of age, if there is no obvious and witnessed plausible explanation of the injuries. Abuse continues to be the most common cause of traumatic death in infants and toddlers. Abuse should be considered a possible cause of injury in all young children with multiple long bone fractures in association with head injury. Even a single long bone fracture associated with a head injury or abdominal injury should raise suspicion of child abuse. Although the *corner fracture* usually is thought of as being most characteristic of child abuse, the most common fracture caused by abuse is a single transverse fracture of the femur or humerus, not multiple fractures (42). Although rib fractures occur in only about 5% of children with multiple injuries from trauma of other causes, they are more common in child abuse (25,63). Whereas blunt compressive trauma to the thorax from other causes may result in lateral rib fractures, the rib fractures seen in child abuse are posterolateral and adjacent to the transverse processes of the thoracic spine.

COMMON MECHANISMS OF INJURY

Falls

Falls are one of the two primary mechanisms of multiple injuries in children (12,28,72). Occurring more often in younger children, these injuries are either due to the direct impact or to deceleration forces present at the time of landing. Direct impact usually causes fractures, whereas internal injury more often results from the post-impact forces. Falls through a second floor window that may be next to a bed often occur in toddlers and younger children. Although a variety of injuries can result from these falls, the position of the body at impact and the surface on which the child lands are important factors that affect the injury severity (28).

Motor Vehicles

Accidents involving motor vehicles account for most multiple-system injuries in school-age children and preadolescents. These injuries occur when a vehicle strikes a

child on foot or riding a bicycle, or when the child is a passenger in a car involved in an accident.

Whereas most states require that infants and toddlers be restrained in car seats when riding in a car, standard adult shoulder and lap belts do not adequately restrain children who are too big for car seats and too small for the standard restraints. Adjustable restraints to accommodate the size of the car occupant better have been proposed to solve this problem. In addition, there is increasing public sentiment to require seat belt use on school buses, a policy that has been in place for handicapped student transport for some time.

The most important point is that some type of restraining system should be used by people of all ages when in a vehicle. Although teaching children better safety while on foot or on bicycles may or may not be effective in changing the incidence of injury, the safety of automobile travel can certainly be improved by enforcement of the use of restraints by all—both young and old.

ROLE OF THE PEDIATRIC TRAUMA CENTER

After the rapid transport of wounded soldiers to a specialized treatment center proved very effective in improving survival in the military setting, trauma centers, using the same principles of rapid transport and immediate care, have been established throughout the United States. These trauma centers are supported by the states on the premise that the first hour after injury is the most critical in influencing the rates of survival from the injuries. Rapid helicopter or ambulance transport to an on-site team of trauma surgeons in the trauma center has led to an improvement in the rates of acute survival after multiple injuries have occurred.

The first trauma centers focused on adult patients, because more adults than children are severely injured. However, pediatric trauma centers have been established at several medical centers across the United States with the idea that the care of pediatric polytrauma patients differ from the care given to adults and that special treatment centers are important for optimal results (33,34). The American College of Surgeons has established specific criteria for pediatric trauma centers, which include the same principles of rapid transport and rapid treatment by an in-house surgical team as in adult trauma centers. A pediatric general surgeon is in the hospital at all times and heads the pediatric trauma team. This surgeon evaluates the child first while the other surgical specialists are immediately available as needed. General radiographic services and computed tomography capability must be available at all times for patient evaluation and an operating room must be immediately available.

Although there is some evidence that survival rates for severely injured children are improved if the children are brought to a pediatric trauma center rather than a community hospital (77), the costs associated with such a center (particularly the on-call costs of personnel) have limited the number of pediatric trauma centers. Knudson et al. (44) studied the results of pediatric multiple injury care in an adult level I trauma center and concluded that the results were comparable to national standards for pediatric trauma care. The use of a general trauma center for pediatric trauma care may be an acceptable alternative if it is not feasible to fund a separate pediatric trauma center.

INITIAL RESUSCITATION AND EVALUATION

Regardless of the mechanism causing the multiple injuries, the initial medical management focuses on the life-threatening, nonorthopaedic injuries to stabilize the child's condition (56). The responsibility for the initial life-saving resuscitation rarely is the responsibility of the orthopaedist. The initial role of the orthopaedist generally is to treat the extremity injuries, even if this just consists of temporary splint application to allow patient transport to the trauma center or even around the hospital for imaging studies. It is recommended, however, that the orthopaedist stay up to date in principles of resuscitation of children to be prepared if the occasion arises when these are needed.

The Child Is Different

The initial steps in resuscitation of a child are essentially the same as those used for an adult (2,20,56). In severe injuries, the establishment of an adequate airway immediately at the accident site often means the difference between death and survival. The cervical spine needs to be stabilized for transport if the child is unconscious or if neck pain is present. A special transport board with a cut-out for the occipital area is recommended for children younger than 6 years of age, because the size of the head at this age is larger in relation to the rest of the body. If a young child is placed on a normal transport board, the cervical spine is flexed because of this larger head size, a position that is best avoided if a neck injury is suspected (37).

Fluid Replacement

Once an adequate airway is established, the amount of hemorrhage from the injury, either internally or externally, should be assessed. This blood loss should be replaced initially with intravenous crystalloid solution. In younger children, rapid intravenous access may be difficult. In this situation, the use of intraosseous fluid infusion should be considered for administration of both fluid and medications. Guy et al. (32) reported successful intraosseous infusion into the tibias of 15 children between the ages of 3 months and 10 years. The intraosseous needles were placed by prehospital and hospital personnel, and colloid, crystalloid solution, and blood were all given by this route. No complications occurred in the surviving children. Bielski et al. (7), in a rabbit tibia model, likewise demonstrated no adverse effects on the histology of bone or the adjacent physis with intraosseous injection of various resuscitation drugs and fluids.

Because death is common if hypovolemic shock is not rapidly reversed, the child's blood pressure must be maintained at an adequate level for organ perfusion. Most multiply injured children have sustained blunt trauma rather than penetrating injuries, and most of the blood loss is internal from visceral injury or from pelvic and femoral fractures. Because of this problem, the blood loss may be easily underestimated at first. Despite the need to stabilize the child's blood pressure, caution needs to be exercised in children with head njuries so that over hydration is avoided, because cerebral edema is better treated with relative fluid restriction. Excessive fluid replacement also may lead to further internal fluid shifts, which often produce a drop in the arterial oxygenation from interstitial pulmonary edema, especially when there has been direct trauma to the thorax and lungs. The appropriate amount of fluid replacement can best be guided by early placement of a central venous catheter during initial resuscitation. Similarly, a urinary catheter is essential during the resuscitation to monitor urine output as a means of gauging adequate organ perfusion.

EVALUATION AND ASSESSMENT

Trauma Rating Systems

After the initial resuscitation has stabilized the injured child's condition, it is essential to perform a quick but thorough check for other injuries. A number of injury rating systems have been proposed, but the Injury Severity Score (ISS) is a valid, reproducible rating system that can be widely applied in the pediatric polytrauma setting (Table 4-1) (91). Another injury rating system for children that has been shown to be valid and reproducible is the Pediatric Trauma Score (PTS) (Table 4-2) (81). The injury rating system chosen varies among trauma centers, but whether the ISS or PTS is used, these systems allow an objective means to assess mortality risk at the time of initial treatment, as well as allowing some degree of prediction of future disability.

TABLE 4-1. INJURY SEVERITY SCORE

Component	Category		
	+2	+1	−1
Size	≥20 kg	10–20 kg	<10 kg
Airway	Normal	Maintainable	Unmaintainable
Systolic BP	>90 mm Hg	90–50 mm Hg	<50 mm Hg
CNS	Awake	Obtunded/LOC	Coma/decerebrate
Open wound	None	Minor	Major/penetrating
Skeletal	None	Closed fracture	Open/multiple fractures
Total			

* This scoring system includes six common determinants of the clinical condition in the injured child. Each of the six determinants is assigned a grade: +2, minimal or no injury; +1, minor or potentially major injury; −1, major, or immediate life-threatening injury. The scoring system is arranged in a manner standard with advanced trauma life-support protocol, and thereby provides a quick assessment scheme. The ranges are from −6 for a severely traumatized child to +12 for a least traumatized child. This system has been confirmed in its reliability as a predictor of injury severity. From Tepas, JJ Mollitt DL, Talbert JL and Bryant M: The Pediatric Trauma Score as a predictor of injury severity in the injured child. J Pediatr Surg 22:14–18, 1987, with permission.

TABLE 4-2. PEDIATRIC TRAUMA SCORE*

Head injury is most often evaluated and rated by the Glasgow Coma Scale (GCS), which evaluates eye opening (1 to 4 points), motor function (1 to 6 points), and verbal function (1 to 6 points) on a total scale of 3 to 16 points (Table 4-3) (80). There are some limitations in the use of the GCS in children who are preverbal or who are in the early verbal stages of development, but in other children, this rating system has been a useful guide to predicting early mortality and later disability. As a rough guide in verbal children, a GCS score of fewer than 8 points means a significantly worse chance of survival for these children than for those with a GCS above 8 points. The GCS should be noted on arrival in the trauma center and should be repeated 1 hour after the child arrives at the hospital. Serial changes in the GCS, either better or worse, correlate with improvement or worsening of the neurologic injury. Repeated GCS assessments over the initial 72 hours after injury may be of prognostic significance. In addition to the level of oxygenation present at the initial presentation to the hospital, the 72-hour GCS motor response score has been noted to be very predictive of later permanent disability as a sequel to the head injury (58).

Response	Action	Score
Best motor response	Obeys	M6
	Localizes	5
	Withdraws	4
	Abnormal flexion	3
	Extensor response	2
	Nil	1
Verbal response	Oriented	V5
	Confused conversation	4
	Inappropriate words	3
	Incomprehensible sounds	2
	Nil	1
Eye opening	Spontaneous	E4
	To speech	3
	To pain	2
	Nil	1

* This scale is used to measure the level of consciousness using the eye opening, best verbal, and best motor responses. The range of scores are from 3 for the most severe to 15 for the least involved. This is a measure of level and progression of changes in consciousness. From Jeannett E. Teasdale JR. Galbraith S. et al. Severe head injuries in three countries. J Neurol Neurosurg Psychiatry (1977)40:291–298, with permission.

TABLE 4-3. GLASGOW COMA SCALE*

Physical Assessment

In a child with multiple injuries, a careful abdominal examination is essential to allow early detection of injuries to the liver, spleen, pancreas, or kidneys. Ecchymoses on the abdominal wall must be noted, because this is often a sign of significant visceral injury (75). Swelling, deformity, or crepitus in any extremity is noted, and appropriate imaging studies are arranged to evaluate potential extremity injuries more fully. If extremity deformity is present, it is important to determine whether or not the fracture is open or closed. Sites of external bleeding are examined, and pressure dressings are applied to prevent further blood loss. It has been reported that the presence of a pelvic fracture and one or more other skeletal injuries should serve as a marker for the presence of head and abdominal injuries (89). Major arterial injuries associated with fractures of the extremity usually are diagnosed early by the lack of a peripheral pulse. However, abdominal venous injuries following blunt trauma are less common and are less commonly diagnosed before exploratory laparotomy. About half of abdominal venous injuries have been reported to be fatal, so the trauma surgeon needs to consider this diagnosis in children who continue to require substantial blood volume support after the initial resuscitation has been completed (62).

The initial splinting of suspected extremity fractures is routinely done by the transporting team members at the scene of the accident. However, once the injured child is in the hospital, the orthopaedist should personally inspect the extremities to determine the urgency with which the extremity injuries need to be definitively treated. Most important are whether or not a vascular injury has occurred and whether the fracture is open or closed. Any neurologic deficit also is noted to document the extremity function before any treatment. The back and spine should be carefully examined. If there is not an open fracture and if the distal peripheral vascular function is normal, there is less urgency in treating the fracture and splinting will suffice until the other organ system injuries are stabilized.

Imaging Studies

Radiographs

Imaging studies need to be performed as quickly as possible after the initial resuscitation and physical examination are complete. Any extremity suspected of having a significant injury should be examined radiographically to assess the degree of injury. If the child has a head injury or if neck pain is noted on the examination, a lateral cervical spine radiograph is obtained. If the lateral cervical spine radiograph is normal, no further views of the cervical spine are needed at this stage. If a cervical spine injury is present, the lateral radiograph of this area almost always will detect it. If there is suspicion of a cervical spine injury on the neutral lateral view, a lateral cervical spine radiograph in the flexed position, with the orthopaedist supervising the amount of flexion, will help detect any cervical instability. The cervical spine of a young child is much more flexible than the cervical spine in an adult. Under the age of 12 years, the movement of C1 on C2 during flexion of the neck can normally be up to 5 mm, whereas in adults, this movement should be less than 3 mm. Likewise in this young age group, C2 can move up to 3 mm forward on C3 during neck flexion. No forward movement of C2 on C3 should be present in a skeletally mature individual when the neck is flexed. This so-called pseudosubluxation of C2 on C3 in a child should not be diagnosed as instability that requires treatment because this is a normal finding in most young children (16). Because it is difficult to detect a fracture of the thoracic or lumbar spine clinically, radiographs of this area, primarily a lateral view, should be assessed, particularly in a comatose child.

Computed Tomography

Computed tomography (CT) is essential in evaluating a child with multiple injuries. If a head injury is present, the CT of the head will detect skull fractures and intracranial bleeding. With abdominal swelling, pain, or bruising, a CT of the abdomen provides excellent visualization of the liver and spleen and allows quantification of the amount of hemorrhage present. Because most hepatic and splenic lacerations are treated nonoperatively at present (13,38,71), the CT scan and serial hematocrit levels are used to determine whether surgical treatment of these visceral lacerations is needed. If a pelvic fracture is seen or suspected on the initial radiographs, a CT of the pelvis will help to determine the need for operative treatment of this fracture and the length of time protection from walking is needed. If an abdominal CT is being done to evaluate visceral injury and there is suspicion of a pelvic fracture, it is simple to request that the abdominal CT be extended distally to include the pelvis. A CT of a fractured vertebra will provide the information needed to classify the fracture as stable or unstable and determine whether operative treatment is needed.

Intravenous Pyelography

There is a strong correlation of urologic injury with anterior pelvic fractures, as well as with liver and spleen injury. Although CT and ultrasonography are used to evaluate renal injuries, the intravenous pyelogram still has a role in helping to diagnose bladder and urethral injuries (61).

Radionuclide Scans

Bone scans have a limited role in the acute evaluation of a child with multiple injuries. In conjunction with a skeletal survey, a technetium-99m bone scan is routinely used in children with suspected child abuse to detect previously undetected new or old fractures. Heinrich et al. (36) reported that bone scans in 48 children with multiple injuries often demonstrated an unsuspected injury. Nineteen previously unrecognized fractures were identified by obtaining radiographs of the areas with increased isotope uptake. Of their 48 patients, six had a change in their orthopaedic care as a result of this bone scan, although this treatment was usually simple cast application of a nondisplaced fracture. Nonetheless, the bone scan can be a valuable screening tool in a child with multiple injuries from any cause. In some instances, the bone scan can be useful to differentiate a normal variation in skeletal ossification (normal uptake) from a fracture (increased uptake), particularly in an extremity or a spinal area where pain is present.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is used primarily for the detection of injury to the brain or the spine and the spinal cord. In young children, the bony spine is more elastic than the spinal cord. As a result, a spinal cord injury can occur without an obvious spinal fracture in children with multiple injuries, particularly in automobile accidents (4,24). In the SCIWORA (spinal cord injury without radiographic abnormality) syndrome, MRI is valuable in demonstrating the site and extent of spinal cord injury and in defining the level of injury to the disks or vertebral apophysis. A fracture through the vertebral apophysis is similar to a fracture through the physis of a long bone and may not be obvious on planar radiographs.

MRI also is very useful in evaluating knee injuries, particularly when a bloody knee effusion is present. If blood is present on knee arthrocentesis, MRI can assist in diagnosing an injury to the cruciate ligaments or menisci. In addition, a chondral fracture that cannot be seen on routine radiographs may be demonstrated by MRI.

Ultrasonography

Ultrasound evaluation has been shown to be an accurate means of detecting hemoperitoneum following injury. Some trauma centers have replaced peritoneal lavage and laparoscopy with serial ultrasound evaluations to monitor liver, spleen, pancreas, and kidney injury in children with multiple injuries (13,38,71). One of the problems with ultrasonography is the operator-dependent nature of this imaging study. As a result, CT is more often used for assessment and monitoring of visceral injury in children sustaining multiple injuries, and a recent comparison of CT and ultrasonography demonstrated the superiority of CT for diagnosing visceral injury in children with polytrauma (70).

NONORTHOPAEDIC CONDITIONS IN THE MULTIPLY INJURED CHILD

Head Injury

Prognosis for Recovery

Head injuries occur in children with multiple injuries even more often than orthopaedic injuries. It has been clearly demonstrated that a child recovers more quickly and more fully from a significant head injury than does an adult (18,50,93). Even children who are in a coma for several hours to several days often recover full motor function. Mild cognitive or learning deficits may persist however, so educational testing needs to be considered for children who have had head injury and coma. The two factors that have been identified to produce poorer functional recovery and more severe permanent neurologic deficits are a low oxygen saturation level at the time of presentation to the emergency department or trauma center and a low GCS score 72 hours after the head injury.

Despite the fact that excellent motor recovery is expected in most children after a head injury, Greenspan and MacKenzie reported that 55% of children in their series had one or more health problems at 1-year follow-up, many of which were relatively minor (29). Headaches were present in 32% and extremity complaints in 13% of patients. The presence of a lower extremity injury with a head injury led to a higher risk of residual problems.

Because of the more optimistic outlook for children with head injuries than for adults with similar injuries, orthopaedic care must be provided in a timely way, and the orthopaedist must base the orthopaedic care on the assumption that full neurologic recovery will ensue. Waiting for a child to recover from a coma is not appropriate, and comatose children tolerate general anesthesia well. The orthopaedic injury must be treated in the same way that it would be in an alert injured child to obtain the best outcome. Unless the musculoskeletal injuries are treated with the assumption that full neurologic recovery will take place, long bone fractures may heal in angled or shortened positions. Once neurologic recovery occurs, the primary functional deficit will then be from ill-managed orthopaedic injuries rather than from the neurologic injury.

Intracranial Pressure

After a head injury, intracranial pressure measurements are commonly monitored to prevent excessive intracranial pressure, which may lead to further permanent disability or death. Normally, intracranial pressure does not exceed 15 mm Hg, and all attempts should be made to keep this pressure under 30 mm Hg after a head injury.

This is accomplished by elevating the head of the bed to 30 degrees, lowering the pCO_2, and restricting intravenous fluid administration. Ventilator assistance is used to lower the pCO_2, which, in turn, helps lessen cerebral edema. If the other injuries allow and adequate blood pressure is sustained, fluid restriction is also preferred to lessen the cerebral edema. Elevation of serum norepinephrine has been shown to correlate well with the severity of head injury in patients with injury of multiple organ systems (94).

Motion at the site of a long bone fracture will cause an elevation of the intracranial pressure in children with multiple injuries. Because of this problem, long bone fractures must be immobilized to limit fracture motion until definitive fracture care can be provided. Initial immobilization usually is accomplished by splinting or casting of the fractures, or by use of traction for femoral shaft fractures. The use of external or internal fixation of fractures should be strongly considered to help control elevation of intracranial pressure. Fracture stabilization also aids in dressing changes for the treatment of adjacent soft tissue injury as well as allowing in-hospital transport for imaging studies and other necessary treatments (84,85).

Secondary Orthopaedic Effects of Head Injuries

A head injury can have later impact on the management of musculoskeletal injuries, even after the acute phase has passed. Persistent spasticity, the development of contractures, heterotopic bone formation in soft tissue, and changes in fracture healing rates are all seen in children with sequelae of a head injury.

Spasticity. Spasticity may develop within a few days of head injury. The early effect of this spasticity is to cause shortening at the sites of long bone fractures if traction or splint or cast immobilization is being used. If fracture displacement or shortening occurs in a circumferential cast, the bone ends may cause pressure points between the bone and the cast, leading to skin breakdown at the fracture site, with a higher risk for deep infection. Even with skeletal traction for femoral fractures, fracture shortening and displacement will occur as the spasticity overcomes the traction forces. Once spasticity develops and long bone fractures displace, internal or external fixation is needed to maintain satisfactory reduction. This operative stabilization should be performed as soon as the spasticity becomes a problem for fracture reduction because fracture healing is accelerated by a head injury (83,84 and 85).

Contractures. The persistence of spasticity in the extremities often leads to subsequent contractures of the joints spanned by the spastic muscles. Contractures can arise quite quickly, and early preventative stretching or splinting should begin while the child is in the intensive care unit. Nonselective mass action muscle activity associated with brain injury can be used to help prevent these early contractures. If the child lies in bed with the hips and knees extended, there will usually be a strong plantarflexion of the feet at the ankles from the spasticity. If the hip and knee are placed in a flexed position, it will be much easier to dorsiflex the foot at the ankle, so positioning in this way will prevent early equinus contractures from developing so quickly. Stretching and splinting can often be effective in preventing

contractures, but if these measures are not successful, there should be no hesitation to treat these contractures surgically if they are interfering with subsequent rehabilitation.

Heterotopic Bone Formation. Heterotopic bone may form in the soft tissues of the extremity as early as a few weeks after a head injury with persistent coma. Usually, this is in the vicinity of the hip or elbow but may occur elsewhere as well. There is some evidence that heterotopic bone formation can be stimulated by surgical incisions. In head-injured teenagers who undergo antegrade reamed femoral intramedullary nailing of femoral fractures, heterotopic bone often forms at the nail insertion site that later restricts hip motion (41). Obtaining weekly serum alkaline phosphatase levels on a child with persistent coma may allow early detection of the heterotopic bone, although alkaline phosphatase is also elevated during healing of fractures. A sudden increase of alkaline phosphatase a few weeks after the onset of coma, even with fractures co-existing, may mean that heterotopic bone is starting to form and a more careful examination of the extremities is in order (59). Technetium-99 bone scans show increased isotope uptake in the soft tissue where heterotopic bone forms, and this imaging study should be considered if new swelling is noted in the extremity of a comatose child. Other diagnoses that must be considered in a comatose child with new swelling of the extremity are a new long bone fracture or a deep venous thrombosis (79).

Observation and excision are the two primary approaches taken in managing heterotopic bone formation in an injured child. If the child remains comatose, usually little treatment is administered. There is no conclusive data to support medical treatment if an early diagnosis of heterotopic bone formation is made. However, it may be useful to try to block some of the heterotopic bone formation by use of salicylates or nonsteroidal antiinflammatory medication once an early diagnosis is established. If the child has recovered from the head injury and has heterotopic bone that does not interfere with rehabilitation, surgical excision is not warranted. If there is significant restriction of joint motion from the heterotopic bone, this bone should be excised to facilitate rehabilitation. The timing of the heterotopic bone excision is somewhat controversial, but current thinking leans toward resection whenever heterotopic bone significantly interferes with rehabilitation, rather than waiting for 12 to 18 months until the bone is more mature. After surgical excision, it is essential to use salicylates or nonsteroidal antiinflammatory drugs immediately after the excision and for several weeks thereafter to block new heterotopic bone formation at the operative site. Mital et al. (59) reported success in preventing recurrence of heterotopic bone after excision by use of salicylates at a dosage of 40mg/kg/day in divided doses for 6 weeks postoperatively.

Fracture Healing Rates. For reasons that are not entirely clear, long bone fractures heal more quickly in children and adults who have associated head injuries. It has been demonstrated that polytrauma patients in a coma have a much higher serum calitonin level than do conscious patients with similar long bone fractures, but how or whether this finding influences fracture healing is still unclear (22).

Peripheral Nerve Injuries

Although persistent neurologic deficits in a child who has multiple injuries usually are sequelae of a head injury, peripheral nerve injury should be carefully assessed as the rehabilitation process proceeds. In one clinical review of brain-injured children, 7% had evidence of an associated peripheral nerve injury documented by electrodiagnostic testing (66). The peripheral nerve injury most often is associated with an adjacent fracture or with a stretching injury of the extremity. It is important to recognize these injuries, because surgical peripheral nerve repair with nerve grafts offers excellent chances of nerve function recovery in young patients, if the nerve injury does not recover on its own.

Abdominal Trauma

Abdominal viscera, both solid and hollow, are at high risk of significant injury in children with multiple skeletal injuries. Abdominal swelling, tenderness, or bruising are all signs of injury. CT or ultrasonography evaluation has largely displaced peritoneal lavage or laparoscopy as the initial method of evaluation of abdominal injury. Abdominal injury is not unusual if a child in an accident has been wearing a lap seat belt (87). Bond et al. (10) noted that the presence of multiple pelvic fractures strongly correlated (80%) with the presence of abdominal or genitourinary injury, whereas the child's age or mechanism of injury had no such correlation with abdominal injury rates. The usual practice is to treat hepatic and splenic lacerations nonoperatively, by monitoring the hematocrit, by repeating the abdominal examination frequently, and by serial CT scans or ultrasound examinations (15,17). Once the child's overall condition has stabilized, the presence of abdominal injuries that are being observed should not delay the fracture care as long as the child is stable enough to undergo general anesthesia.

Genitourinary Injuries

Injuries to the genitourinary system generally occur in conjunction with pelvic fractures. Most injuries to the bladder and urethra are associated with fractures of the anterior pelvic ring (5). The injury is usually at the bulbourethra, but the bladder, prostate, and other portions of the urethra can also be injured. If the injury is severe, kidney injury may also occur, but most urologic injuries that occur with pelvic fractures are distal to the ureters (1).

Tears of the vagina and resultant vesicovaginal fistulae may be associated with displaced fractures of the anterior pelvic ring. If the iliac wings are displaced or the pelvic ring shape is changed, it is important to reduce these fractures to reconstitute the birth canal in female patients. There are increased rates of caesarean section in young women who have had a pelvic fracture compared with those without this injury (19).

It is important to inform adolescent females with displaced pelvic fractures of this later potential problem with vaginal delivery.

Fat Embolism

Although fat embolism and acute respiratory distress syndrome are relatively common in adults with multiple long bone fractures, they are rare in young children and uncommon in teenagers (51). When they are present, the signs and symptoms are the same as in adults: axillary petechiae, hypoxemia, and radiographic changes of pulmonary infiltrates appearing within several hours of the fractures (30). It is likely that some degree of hypoxemia develops in some children after multiple fractures, but the full clinical picture of fat embolism seldom develops. If a child with multiple fractures but without a head injury develops a change in sensorium and orientation, hypoxemia is most likely the cause, and arterial blood gases are essential to determine the next step in management. The other primary cause of mental status change after fractures is overmedication with narcotics for pain control.

If fat embolism is diagnosed by low levels of arterial oxygenation, the treatment is the same as in adults. Usually, this management consists of endotracheal intubation, positive pressure ventilation, and hydration with intravenous fluid. The effect of early fracture stabilization, intravenous alcohol, or high-dose corticosteroids on the syndrome of fat embolism has not been studied well in children with multiple injuries.

Nutritional Requirements

Multiple injuries place large caloric demands on the body. If an injured child requires ventilator support for several days, caloric intake via a feeding tube or a central intravenous catheter is necessary to improve healing and help prevent complications from developing. The baseline caloric needs of a child can be determined based on the weight and age of the child. Children on mechanical ventilation in a pediatric intensive care unit have been shown to require 150% of the basal energy or caloric requirements for age and weight (82). The daily nitrogen requirement for a child in the acute injury phase is 250 mg/kg.

ORTHOPAEDIC MANAGEMENT OF THE MULTIPLY INJURED CHILD

Timing

Because fractures are rarely life-threatening in children with multiple system injuries, splinting of the fractures will generally suffice as the initial orthopaedic care needed, while the child's overall condition is stabilized. When is the optimal time for the definitive treatment of the fracture or fractures and what is that optimal treatment? Should the child have all fractures treated operatively to allow mobilization out of bed, as is commonly recommended in adults with multiple fractures, or is a combination of operative and nonoperative management more appropriate? Are there times when implants used in adults can also be used in children, or should separate pediatric implants be used when operative treatment is chosen? How rigid does fracture fixation need to be in children?

Pelvic Fractures

Fractures of the pelvis are common in children and adolescents with multiple injuries. The central injuries to the spine and pelvis have been reported to be associated

with the most intense hospital care and higher mortality rates than other injury combinations (12). The immediate problem often is control of bleeding, either from the retroperitoneum near the fracture or from the peritoneum from injured viscera (40). However, death of children with pelvic fractures appears to be caused more often by an associated head injury rather than an injury to the adjacent viscera or vessels (60).

The fractures of the anterior pelvic ring are the primary cause of urethral injury (1,5). Bilateral anterior and posterior pelvic fractures are most likely to cause severe bleeding (57), although death from blood loss in children is uncommon (60). Injury to the sciatic nerve or the lumbosacral nerve roots may result from hemipelvis displacement through a vertical shear fracture. In fact, nonorthopaedic injuries associated with pelvic fractures led to long-term morbidity or mortality in 30% of patients (11 of 36) in one published review of pediatric pelvic fractures (26).

Most pelvic fractures in children are treated nonoperatively. In a child or preadolescent, an external fixator can be used to close a marked pubic diastasis or to control bleeding by stabilizing the pelvis for transport and other injury care. The external fixator will not reduce a displaced vertical shear fracture, but the stability provided is helpful to control the hemorrhage while the child's condition is stabilized (69,86).

Open Fractures

Background. Most serious open fractures in children result from high-velocity blunt injury involving vehicles. However, many low-energy blunt injuries can cause puncture wounds in the skin adjacent to fractures, especially displaced radial, ulnar, and tibial fractures. It has been estimated that in children with multiple injuries, about 10% of the fractures are open. When open fractures are present, 25% to 50% of patients have additional injuries involving the head, chest, abdomen, and other extremities.

Wound Classification. The classification used to describe the soft tissues adjacent to an open fracture is based primarily on the system described by Gustilo and Anderson (30,31). Primary factors that are considered and ranked in this classification system are the size of the wound, the degree of wound contamination, and the presence or absence of an associated vascular injury (Table 4-4).

Type I	An open fracture with a wound <1 cm long and clean
Type II	An open fracture with a laceration >1 cm long without extensive soft-tissue damage, flaps, or avulsions
Type III	Massive soft tissue damage, compromised vascularity, severe wound contamination marked fracture instability
Type IIIA	Adequate soft tissue coverage of a fractured bone despite extensive soft tissue laceration or flaps, or high-energy trauma irrespective of the size of the wound
Type IIIB	Extensive soft-tissue injury loss with periosteal stripping and bone exposure; usually associated with massive contamination
Type IIIC	Open fracture associated with arterial injury requiring repair

Adapted from Gustilo RB, Mendoza RM, Williams DN. Problems in the management of type III (severe) open fractures: a new classification of type III open fractures. *J Trauma* 1984;24:742–746; Gustilo RB, Anderson JT: Prevention of infection in the treatment of 1025 open fractures of long bones: retrospective and prospective analyses. *J Bone Joint Surg Am* 1976;58:453–458, with permission.

TABLE 4-4. CLASSIFICATION OF OPEN FRACTURES

Type I. Type I fractures usually result from a spike of bone puncturing the skin (inside-out). The wound is less than 1 cm in size, and there is minimal local soft tissue damage or contamination.

Type II. A type II wound is generally larger than 1 cm and is associated with a transverse or oblique fracture with minimal comminution. There is adjacent soft tissue injury, including skin flaps or skin avulsion and a moderate crushing component of adjacent soft tissue is usually present.

Type III and Subgroups. The most severe open fractures are classified as type III, with associated subgroups A, B, or C, with the letters indicating increasing severity of injury. These fractures typically result from high-velocity trauma and are associated with extensive soft tissue injury, a large open wound, and significant wound contamination. In a type IIIA fracture, there is soft tissue coverage over the bone, which often is a segmental fracture. In a type IIIB fracture, bone is exposed at the fracture site, with treatment typically requiring skin or muscle flap coverage of the bone. Type IIIC fractures are the most severe and, in addition to extensive soft tissue loss and contamination, have an injury to a major artery in that segment of the extremity.

This classification is widely used and has been shown to correlate in adults with sequelae of the injury, including the potential for infection, delayed union, nonunion, amputation, and residual impairment. Probably due to the better vascular supply to the extremities of children, the final functional results of type III fractures in children appear to be superior to results after similar fractures in adults.

AUTHOR'S PREFERRED METHOD OF TREATMENT

Three Stages. I consider the treatment of open fractures in children to be similar to that for open fractures in adults. The primary goals are to prevent infection of the wound and fracture site, while allowing soft tissue healing, fracture union, and eventual return of optimal function. My initial emergency care includes the so-called ABCs of resuscitation, application of a sterile povidone-iodine (Betadine) dressing, and preliminary alignment and splinting of the fracture for patient transport. If profuse bleeding is present, a compression dressing is applied to limit blood loss. In the emergency room, masks and gloves should be worn as each wound is thoroughly inspected. Tetanus prophylaxis is provided, and the initial dose of intravenous antibiotics is given. The dose of tetanus toxoid is 0.5 mL intramuscularly to be given if the patient's immunization status is unknown, or if it is more than 5 years since the last dose. The second stage of management is the primary surgical treatment, including initial and (if necessary) repeat debridement of the tissues in the area of the open fracture until the entire wound appears viable. The fracture is reduced and stabilized. If the bone ends are not covered with viable soft tissue, muscle or skin flap coverage is considered. My third and final stage of this management is bony reconstruction as needed if bone loss has occurred and, ultimately, rehabilitation of the child.

Cultures. The role of cultures obtained in the emergency room is controversial. Cultures in this setting are probably of little use in future management of the open fracture. The cultures for characterizing the bacterial contamination present are better obtained in the operating room at the time of debridement (45).

Antibiotic Therapy. Antibiotic therapy decreases the risk of infection in children with open fractures. Wilkins and Patzakis (92) reported a 13.9% infection rate in 79 patients who received no antibiotics after open fractures, whereas there was a 5.5% infection rate in 815 patients with similar injuries who had antibiotic prophylaxis. Bacterial contamination has been noted in 70% of open fractures in children, with both gram-positive and gram-negative infections noted, depending on the degree of wound contamination and adjacent soft tissue injury. I limit antibiotic administration generally to 72 hours after surgical treatment of the open fracture.

For all type I and some type II fractures, I use a first-generation cephalosporin. For type III and some more severe type II fractures, I use a combination of a cephalosporin and aminoglycoside (cephalothin 150 mg/kg/day q8h, and gentamicin). For farm injuries or grossly contaminated fractures, penicillin is added to the cephalosporin and aminoglycoside. All antibiotics are given intravenously and for 72 hours. Oral antibiotics are occasionally used if significant soft tissue erythema at the open fracture site remains after the intravenous antibiotics have been completed.

I continue the antibiotic regimen beyond 48 to 72 hours if there is (a) delayed wound closure, (b) open reduction and internal fixation of fractures, and (c) secondary bone reconstruction procedures.

Debridement and Irrigation. I consider debridement and irrigation of the open fracture in the operating room to be the most important step in the primary management of open fractures in children. Some authors have reported that significantly higher infection rates occurred if debridement and irrigation were done more than 6 hours after open fractures in children (46). A recent report, however, demonstrated an overall 1% to 2% infection rate after open long bone fractures, with no increased rate in infection if the debridement was delayed even as long as 24 hours (76). I believe that it is important to perform the debridement and irrigation as quickly as is feasible, but a modest delay may not lead to severe consequences or chronic infection. The debridement needs to be performed carefully and

systematically to remove all foreign and nonviable material from the wound. My order of debridement typically is

1. Excision of the necrotic tissue from the wound edges
2. Extension of the wound to adequately explore the fracture ends
3. Debridement of the wound edges to bleeding tissue
4. Resection of necrotic skin, fat, muscle, and contaminated fascia
5. Fasciotomies as needed
6. Thorough pulsatile irrigation of the fracture ends and wound

Because secondary infection in ischemic muscle can be a major problem in wound management and healing, I ensure that all ischemic muscle is widely debrided back to muscle, which bleeds at the cut edge and contracts when pinched with the forceps.

When I am debriding and irrigating an open diaphyseal fracture, I always bring the proximal and distal bone ends into the wound for visual inspection. This often means that the open wound needs to be extended somewhat, but that is preferable to leaving the fracture site contaminated. I carefully remove devitalized bone fragments and contaminated cortical bone with curettes or a small ronguer. If there is a possibly nonviable bone fragment, judgment is needed as to whether this bone fragment should be removed or left in place. My experience is that reconstruction of a large segmental bone loss has a better outcome in children than in adults, because children have a better potential for bone regeneration and have better vascular supply to their extremities. As with all diaphyseal debridements, I identify and protect major neurovascular structures in the area of the fracture. I consider the debridement complete when all contaminated, dead, and ischemic tissues have been excised; the bones ends are clean with bleeding edges; and only viable tissue lines the wound bed.

I usually use a pulsed lavage system to irrigate the open fracture with 10 L of sterile normal saline. In the past, I have used bacitracin and polymyxin antibiotics in this irrigation solution but irrigate only with the normal saline. The antibiotic addition is more costly, and I believe that the key is local irrigation and debridement to allow the intravenous antiobiotics to reach the wound and control the infection. I obtain cultures from the depths of the wound near the fracture ends just before the irrigation. If repeat debridement is needed, cultures are again obtained and are often useful in guiding the final antibiotic coverage used.

After the debridement and irrigation are complete, I try to use the local soft tissue to cover the neurovascular structures, the tendons, and the bone ends. If local soft tissue coverage is inadequate, consideration should be given to local muscle flaps or other coverage methods. The area of the wound that has been incised to extend the wound for fracture inspection can be primarily closed with interrupted nylon sutures. The remaining wound that is open is dressed with a moistened Betadine dressing, which is changed the following day. If the wound appears clean, sequential wet-to-dry saline dressings are used until wound healing occurs. If the wound does not appear clean at 48 hours, repeat debridement in the operating room is carried out. This cycle is repeated until the wound can be sutured closed or has a split thickness skin graft or local flap to cover it.

Fracture Stabilization. Fracture stabilization in children with open fractures decreases pain, protects the soft tissue envelope from further injury, decreases the spread of bacteria, allows stability important for early soft tissue coverage, and improves the fracture union rate.

In general terms, my principles for stabilization of open fractures in children include allowing access to the soft tissue wound and the extremity to allow for debridement and dressing changes, allowing weight bearing when appropriate and preserving full motion of the adjacent joints to allow full functional recovery.

I often use casts or splints to stabilize type I fractures and occasionally type II fractures with relatively small wounds and minimal soft tissue involvement. Most of these injuries involve the radius or ulna in the upper extremity or the tibia in the lower extremity. In the forearm, a flexible intramedullary implant in either the radius or ulna or both, provides enough stability of the fracture to allow dressing changes through the cast or splint. Splint or cast immobilization generally is not satisfactory for the more unstable type II and most type III injuries.

For intramedullary fixation, I prefer flexible titanium implants of 2 mm to 4 mm diameter for stabilizing open fractures in the forearm when reduction of either the radius or ulna fracture is unstable. The ulnar implant is inserted proximally, whereas the radial implant is inserted just proximal to the distal radial physis. One or both bones can be stabilized, and the implants removed easily after fracture healing. I also use these flexible intramedullary nails more often for type I and some type II fractures of the femoral shaft. For type III fractures, especially if there is a large or contaminated soft tissue wound present, I still prefer to use external fixation.

External fixation is my treatment of choice for most type II and type III fractures of the tibia and femur in children. The benefits of external fixation include easy access to the wound for debridement and dressing changes plus any soft tissue or bone reconstruction needed. External fixation allows patient transport around the hospital for other reasons associated with the multiple injuries. External fixation preserves the length of the long bone at the appropriate level and allows weight bearing relatively soon after the injury. I find that a uniplanar frame is best for most fractures and is relatively easy to apply. For some segmental fractures in the metaphysis and diaphysis, as well as soft tissue injuries, the Ilizarov device may be a better choice.

I use open reduction and internal fixation for open intraarticular fractures. If the fracture involves the physis, I avoid threaded pins or screws across the physis and use smooth Steinmann pins for stabilization, if needed. For fractures that involve the metaphysis and diaphysis, I may combine open reduction and internal fixation with external fixation. For diaphyseal fractures in preteens, I prefer flexible intramedullary nails to compression plates for internal fixation of type I and type II fractures. For treatment of a *floating joint,* usually the knee or elbow, I carry out operative stabilization of at least one and usually both fractures (9,49).

Wound Management. I prefer to provide soft tissue coverage of the open fracture and adjacent soft tissue defect by 5 to 7 days after the injury. The wound is debrided every 48 hours until it is clean, if the initial dressing change indicates residual necrotic tissue. In the lower extremity, the fractures are externally fixed when appropriate, and I attempt to obtain early soft tissue coverage to limit the risk of later infection. Most type I wounds heal with local dressing changes. For some type II and type IIIA fractures, I use delayed wound closure or a split-thickness skin graft over underlying muscle cover.

Large soft tissue loss is most often a problem with types IIIB and IIIC fractures. In the proximal tibia area, I often work with the plastic surgeons to provide a gastrocnemius rotational flap, followed by secondary coverage of the muscle with a skin graft. In the middle third of the leg, a soleus flap is used with skin graft coverage, whereas a vascularized free muscle transfer is necessary if local coverage is inadequate.

The flaps and grafts I use for reconstructing severe injuries are either muscle flaps or composite grafts. For a massive loss of soft tissue and bone, composite grafts of muscle and bone often are necessary. The younger the child the better the likelihood that autogenous graft will fill in a bone defect if there is a well-vascularized bed from the muscle flap. Free flaps, especially from the latissimus dorsi, are useful in the mid-tibial and distal tibial regions to decrease infection rates and improve the union rates. Vascularized fibular grafts rarely are used acutely to reconstruct bone defects but may be useful in later reconstruction, after soft tissue wounds are healed.

For the rare bone loss defect in a child, I rely on the healing capacity of young periosteum and bone and the vascular supply of a child's extremity. An external fixator is used to hold the bone shortened about 1 to 2 cm to decrease the size of the bone loss. In a growing child, 1 to 2 cm of overgrowth can be expected in the subsequent 2 years after these severe injuries so the final leg length will be satisfactory. Autogenous bone graft can be used early, but if there is surviving periosteum at this site, I have been surprised by how much new bone the child has formed, sometimes to the extent that bone grafting is unnecessary. In teenagers with bone loss, once the soft tissue has healed, bone transport using either a uniplanar lengthening device or an Ilizarov device is my preferred method of reconstruction, although use of an allograft or vascularized fibular graft may be considered.

Amputation. In the most severe of open fractures, attempts should generally be made to preserve all extremities, even with those type IIIC open fractures that are usually treated with primary amputation in adults. Wounds and fractures that do not heal in adults often heal satisfactorily in children and preservation of limb length and physes are important in young children. If amputation is absolutely necessary, as much length as possible should be preserved. For example, if the proximal tibial physis is preserved in a child with a short proximal tibial stump at age 7 years, 3 to 4 inches more growth of the tibial stump can be expected by the time skeletal maturity is reached. As a result, this below-knee amputation would likely be superior in final function to a knee disarticulation done at the time of injury.

Although amputations performed to treat congenital limb deficits are usually done through the joint to limit bone spike formation at the end of the stump, I prefer to maintain maximal possible length if amputation becomes necessary as a result of a severe injury.

Management of Other Fractures. When a child with an open fracture is brought to the operating room for irrigation and debridement of the open fracture, the

orthopaedist should take advantage of the anesthetic and treat the other fractures as well, whether operative treatment or closed reduction and casting is needed.

STABILIZATION OF FRACTURES

Beneficial Effects

In addition to promoting fracture healing, fracture stabilization also provides a number of nonorthopaedic benefits to a child with multiple injuries. Pulmonary contusions at the time of injury often lead to increasing respiratory problems in the first few days after injury (65). If the lungs have been severely contused, protein leaks into the alveolar spaces, making ventilation more difficult. Surfactant dysfunction follows and is most abnormal in patients with the most severe respiratory failure (67). As the time from the injury increases, pulmonary function deteriorates and general anesthesia becomes more risky. In patients with severe pulmonary contusions and multiple fractures, the use of extracorporeal life support may be the only treatment available to allow patient survival (74).

In adults with multiple injuries, early operative stabilization of fractures decreases pulmonary and other medical complications associated with prolonged bed rest that is a part of nonoperative fracture treatment (6). Most adult trauma centers follow the treatment protocol of early fracture stabilization, even though Poole et al. (68) reported that, despite early fracture stabilization simplifying patient care, pulmonary complications in patients with marked chest trauma were not prevented and the course of the head injury was not affected. In children, medical complications are less common so the recommendations to mandate early fracture stabilization are somewhat more difficult to support in the young patients. Nonetheless, bruises on the chest or rib fractures should alert the orthopaedist to potential pulmonary contusions as a part of the injury complex (64). Initial chest radiographs may not clearly demonstrate the degree of pulmonary parenchymal injury, and arterial blood gas determinations are more useful in estimating the anesthetic risk of these patients during operative care of the fractures.

Timing. In a child with multiple closed fractures, splinting is needed at the time of the initial resuscitation. Definitive treatment should proceed expeditiously once the child's condition has been stabilized. Loder (52) reported that in 78 children with multiple injuries, early operative stabilization of fractures within the first 2 or 3 days after injury led to a shorter hospital stay, a shorter stay in the intensive care unit, and a shorter time on ventilator assistance was needed. In addition, there were fewer complications in those who underwent surgical treatment of the fractures less than 72 hours after injury. Although there may have been other factors besides the timing of surgery that affected the eventual outcomes in this study, it would seem prudent to try to complete the fracture stabilization within 2 to 3 days from the time of injury.

Operative Fixation. The type of operative stabilization of closed fractures of long bones in multiply injured children commonly depends, as in other orthopaedic arenas, on the training, experience, and personal preference of the orthopaedist. The most common methods used are intramedullary rod fixation, external fixation, and AO compression plating, though Kirschner wires or Steinmann pins may be used in conjunction with casts.

Intramedullary Rod Fixation. There has been a recent increase in the use of flexible intramedullary rods of 2- to 4-mm diameter for stabilization of unstable closed fractures of the radius and ulna in patients up to the early teenage years and for stabilization of closed femoral shaft fractures in patients between the ages of 5 and 11 years (85,90).

Forearm fractures generally can be reduced closed, with the intramedullary implant passed across the fracture site under fluoroscopy to stabilize the fracture (48). The ulnar implant is placed from proximal to distal and is inserted in the lateral proximal metaphyseal area. The radial implant is contoured before insertion in the radial aspect of the distal radius, just proximal to the distal radial physis. Stability of both fractures may be achieved by instrumenting only the radius or the ulna, but both bones may require implant fixation. A cast is used for further immobilization. The implants are easily removed from the wrist area and the elbow region 6 to 12 months after insertion and after fracture healing has taken place.

Despite the utility of flexible intramedullary implants for stabilizing forearm fractures in children, the radius and ulna in young patients have significant remodeling capacity and not all fractures require anatomic reduction. A closed reduction and cast immobilization often is sufficient treatment. Complications, including loss of reduction, infection, hardware migration, nerve injury, and delayed union, have been reported with the use of pediatric intramedullary implants in the forearm, though 95% of patients (19 of 20) had excellent or good results on follow-up (21).

If flexible intramedullary nails are used in the femur, the most common insertion site is the medial and lateral metaphyseal region of the distal femur, just proximal to the physis. Two rods are used to cross the fracture site and obtain purchase in the proximal femur, usually with one at the base of the femoral neck and the other at the base of the greater trochanter. A cast is not necessary postoperatively, although a fracture brace can be used to help control rotation at the fracture site and provide some patient comfort during early walking. The implants are removed before 1 year from the time of fracture fixation (35,39).

The use of reamed antegrade intramedullary rods to treat femoral shaft fractures in the pediatric population should be reserved, in my view, for those at least older than the age of 11 years who probably have closure of the proximal femoral physis. In younger children, rod insertion at the piriformis fossa may interfere with the vascular supply to the femoral epiphysis, may cause growth arrest of the greater trochanter apophysis with resultant coxa valga, or may interfere with the appositional bone growth at the base of the femoral neck, thereby thinning this region and potentially predisposing the child to a femoral neck fracture (14). The specific indications for intramedullary fixation of the femur are discussed in more detail in Chapter 22.

Compression Plates. Some have advocated the use of compression plates to stabilize long bone fractures, especially in the femoral shaft, in children with multiple injuries. Kregor et al. (47) reported an average overgrowth of the femur of 9 mm, and all fractures healed in a near-anatomic position. The disadvantages of compression plating is the need for more extensive operative exposure at the site of the fracture and the usual need to remove the plate once healing is complete. In addition, refracture may occur through the screw holes left after plate removal if physical activity is resumed too quickly. Stiffness of adjacent joints is rarely a problem in children unless there has been an associated severe soft tissue injury. As a result, the number of cortices the screws cross on each side of the fracture may be fewer in children than in adults, because a cast or splint is routinely used in young patients.

Although some authors have recommended open reduction and compression plate fixation of displaced radial and ulnar fractures (95), I prefer flexible intramedullary nails, as noted earlier. The use of compression plates in the forearm requires a larger operative incision with the resultant scar and a second extensive procedure for plate removal. I do not believe that the healing capability of the young child requires the rigid fixation of compression plating to obtain fracture union.

External Fixation. The most common indications for use of external fixation in a child with multiple injuries include open fractures with significant soft tissue injury, fractures in association with a head injury and coma, and so-called floating knee fractures of the femur and tibia (3,8,9,43,49,69,73,84). The use of an external fixator in these circumstances allows the child to be transported for imaging studies or to the operating room for management of nonorthopaedic injuries. A unilateral fixator generally is sufficient to hold the fracture reduced in this age group.

When applying the external fixator, the pin sites should be predrilled and the pins placed in the operating room under fluoroscopic control. The caliber of the pin should be less than 30% of the diameter of the bone into which it is to be inserted. The distal and proximal pin sites must be chosen at a level to avoid the physis, and I recommend leaving at least 1 to 2 cm between the pin and physis, partly to avoid any adverse effect on the physis should a pin track infection occur. The proximal tibial physis is more distal anteriorly below the tibial tubercle, and this area must be avoided or a recurvatum deformity of the proximal tibia and knee will result.

The external fixator usually is left in place until fracture healing is complete, but it can be removed once the reason for placement has resolved (such as waking from coma or healing of skin wound) (23,84). If the fixator is removed early, a walking cast is applied. Transverse open fractures reduced out to length take longer to heal than do oblique fractures reduced with slight overlap. Once the fixator is removed, there is a risk of refracture that varies widely among the published reports. When a rigid transfixion type of fixator was used, a 21% refracture rate was noted (83). When a more flexible unilateral frame was used, the refracture rate was lower (3,8). A recent report indicated that if three of the four cortices at the fracture site appear to be healing on anteroposterior and lateral radiographs of the fracture, the refracture rate after frame removal should be small (77).

Outcomes of Treatment of the Multiply Injured Child

In one review of 74 children with multiple injuries, 59 (80%) survived, but after 1 year, 22% were disabled, mainly from a brain injury. At 9 years after the injuries, 12% had significant physical disability, whereas 42% had cognitive impairment. In this group, however, the SF-36 or functional outcome survey did not differ from the control population. The best predictor of long-term disability was the Glasgow Outcome Scale from 6 weeks after injury on (88). In a shorter term review, it has been

demonstrated that 6 months after injury 8% to 19% of injured children and adolescents had some significant limitation (27).

Whichever method of fracture treatment–operative or nonoperative–is chosen for a child with multiple injuries, it is important that the orthopaedist be involved in the care of the child from the start. While recognizing the need to care for the other organ system injuries the child has sustained, it is important to advocate for the expeditious and appropriate treatment of the fractures that are present. Failure to do so will leave the multiply injured child with musculoskeletal disability once healing of the other injuries occurs. After multiple injuries, the most common long-term problems relate to either sequelae of the head injury or of the orthopaedic injuries.

5
PHYSEAL INJURIES AND GROWTH ARREST

HAMLET A. PETERSON

The growth plate (physis) of an epiphysis or an apophysis may be injured in various ways (1,2,3,4). The most common injury is fracture, but other insults such as disuse, radiation, infection, tumor, vascular impairment, neural involvement, metabolic abnormality, frostbite, burns, electrical injuries, laser injuries, chronic stress, and iatrogenic injury can also damage the physis sufficiently to interrupt growth.

When the entire growth plate is arrested, bone length is retarded. If the physis at each end of a bone is arrested, longitudinal bone growth ceases completely. When the bone is compared with the contralateral mate, there is a discrepancy in bone length. In the forearm or lower leg, the length inequality can also be relative to the ipsilateral companion bone (the radius and ulna or tibia and fibula, respectively).

When only part of the physis is damaged, length retardation can be accompanied by angular deformity as the undamaged portion of the physis continues to grow. The deformity and length inequality depend on the site (specific bone), the location within the site, the extent (quantity), and the duration of the physeal damage.

This chapter is an overview of physeal injuries and is divided into three parts: physeal fractures, other physeal injuries, and premature physeal arrest. Injuries at specific anatomic sites are discussed in their respective chapters.

PHYSEAL FRACTURES

Historical Review

Fractures of the physis have been of interest since antiquity. Historians note the fable of the Amazons, whose custom of separating the epiphyses of newborn males ensured female supremacy and beauty. Hippocrates receives credit for the first written medical account of this injury (5,6). A Neapolitan surgeon, Marcus Aurelius Severinus, noted the problem of separation of the proximal and distal tibial epiphyses in 1632. Written observations, case reports, articles, theses, and treatises followed and are best summarized in Poland's 1898 book *Traumatic Separation of the Epiphysis* (6).

Classification

Early Classifications

Poland's book (6) established the fracture as a significant and not rare entity. He documented four specific injuries, provided drawings of each, and thereby produced the first true classification (Fig. 5-1). Following Roentgen's discovery of the x-ray (1895), the subject was studied more scientifically; before this, all observations were made from compound fractures, dissections of patients with fatal injuries, or of limbs with traumatic amputations (7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23,24,25,26,27,28,29,30,31,32).

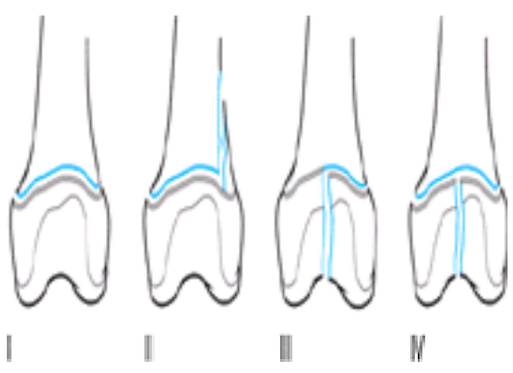

FIGURE 5-1. Classification of Poland (1898). (Redrawn from Peterson HA. Physeal fractures: part 3, classification. *J Pediatr Orthop* 1994;14:439–448; with permission.)

In 1933, Bergenfeldt documented radiographically 310 physeal injuries in 295 patients and defined six types (Fig. 5-2). These six types included the first three of Poland and added a fracture through the epiphysis, metaphysis, and physis. These four fractures subsequently were used by Salter and Harris (28) as their first four types.

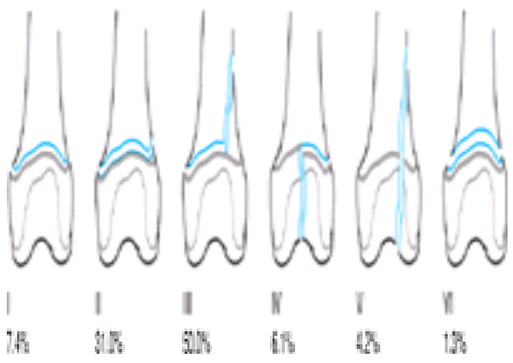

FIGURE 5-2. Classification of Bergenfeldt (1933), with percentage of each type. (Redrawn from Peterson HA. Physeal fractures: part 3, classification. *J Pediatr Orthop* 1994;14:439–448; with permission.)

In 1936, Aitken (7) described three types of physeal fractures of the distal tibia (Fig. 5-3), two of which (I and II) were described by Poland, and the third, by Bergenfeldt. Aitken documented the same three physeal fractures in the distal femur (10) and the proximal tibia (9). After his 1965 article (8) discussing these three types of fractures in a general context, Aitken's three types of fractures became the standard by which most physicians reported physeal fractures.

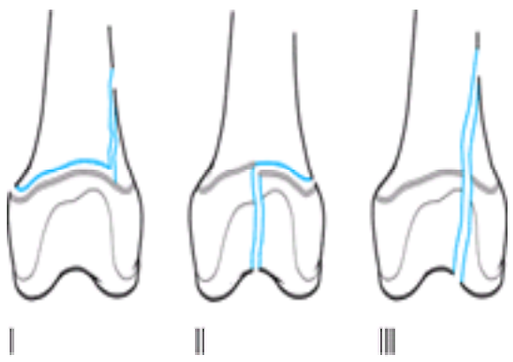

FIGURE 5-3. Classification of Aitken (1936). (Redrawn from Peterson HA. Physeal fractures: Part 3, classification. *J Pediatr Orthop* 1994;14:439–448; with permission.)

Salter-Harris Classification

In 1963 Salter and Harris (28) published their classic article, “Injuries Involving the Epiphyseal Plate,” in which five types of injuries were described (Fig. 5-4). The first four types are a combination of those described by Poland (types I to III), Bergenfeldt (types I to V), and Aitken (types I to III). Salter and Harris added the concept of compression injury, which they designated type V. They proposed that the mechanism of this injury is by longitudinal compression, which damages the germinal layer of physeal cells. Because there was no osseous injury, radiographs at the time of injury were by definition normal. This differs from the crushing of physeal cells that can occur with any physeal fracture, as described by Letts (18). Because no structure is broken, this is not a fracture; the term “injury” seems more appropriate.

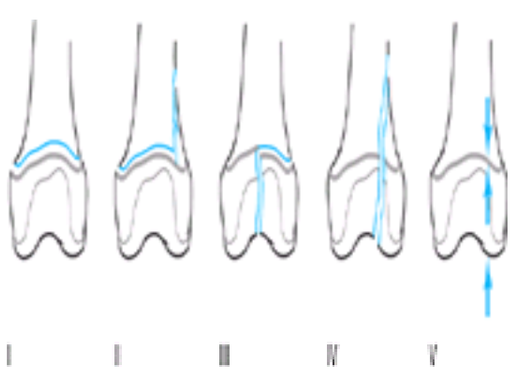

FIGURE 5-4. Classification of Salter and Harris (1963). (Redrawn from Peterson HA. Physeal fractures: part 3, classification. *J Pediatr Orthop* 1994;14:439–448; with permission.)

Salter's associate, Mercer Rang (26) added an injury in 1969 that has become known as a Salter-Harris, or Rang, type VI. This was described as a rare injury produced by a direct blow to the periosteum or perichondrial ring (Fig. 5-5). It was never specified whether the damage was produced by peripheral transverse compression of physeal cells or ischemia due to vascular changes. Because no mention was made of open trauma, it is assumed that these were closed injuries. Like a Salter-Harris type V, this should also be called an injury rather than a fracture, because nothing is broken and the original radiograph is normal. Other authors (2,3,19,20 and 21) have interpreted this injury as an avulsion of the perichondrial ring with portions of attached metaphyseal and epiphyseal bone, while still considering it a Salter-Harris or Rang type VI. Although drawings have been provided, the only case depicted radiographically (3) is an open lawn mower excision of the metaphysis, physis, and epiphysis; this is more appropriately classified as a part missing (see Classification later). None of these Rang type VI injuries were found in a recent population-based study of 951 cases. Neither Salter (29) nor Rang (27) included this type in subsequent publications.

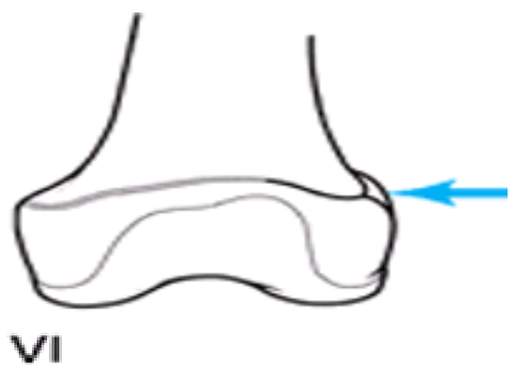

FIGURE 5-5. Physeal injury of Rang (1969). (Redrawn from Peterson HA. Physeal fractures: part 3, classification. *J Pediatr Orthop* 1994;14:439–448; with permission.)

The Salter-Harris classification gained widespread acceptance throughout the world (1,2,3,4). In recent years, however, several authors have deviated from this classification. In 1980, Weber (32), who was unable to find any type V injuries, returned to the Aitken classification. In 1983, Rang (27) noted that the Aitken classification is "widely used," and in 1993, Kling (17) stated that the Aitken classification is "now used in Europe." Other authors (12,13,14,19,20,21,30,32), finding the classification incomplete or lacking in substantiation of prognosis, have developed new classifications, notably Ogden (19,20,21) in 1981 and Shapiro (30) in 1982.

The classification of physeal fractures is a work in progress. This search for a classification that will allow the collection of meaningful statistical data and a better means of communication is a progressive quest for knowledge. This knowledge, in turn, should improve criteria for prognosis, management, and recommendations for follow-up of patients with physeal fractures.

AUTHOR'S CLASSIFICATION

In 1994, a new classification (24) based on the first population-based epidemiologic study (Fig. 5-6) arranged fracture types from the least involvement or damage to the physis (type I) to the greatest involvement (type VI).

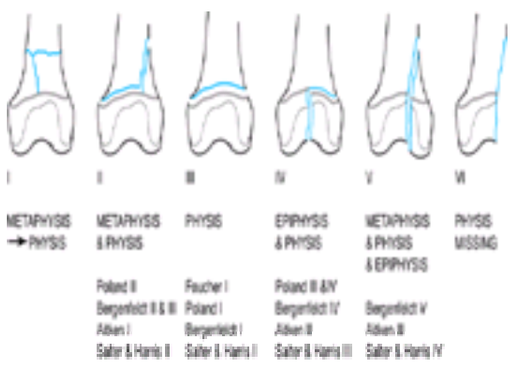

FIGURE 5-6. Classification of Peterson. (Redrawn from Peterson HA. Physeal fractures: part 3, classification. *J Pediatr Orthop* 1994;14:439–448; with permission.)

Type I is a transverse fracture of the metaphysis with fracture line or lines extending to the physis (Fig. 5-7) (23). There is no fracture along the physis and no displacement of the epiphysis on the metaphysis (Fig. 5-8). There may be a small eccentric cortical fragment not attached to either the epiphysis or the metaphysis. Comminution is common (Fig. 5-9), and compounding is rare. The mechanism of injury is most likely longitudinal compression as evidenced by the cortical torus or buckling, widening of the metaphysis, or comminution. Radiographs 2 to 4 weeks after injury typically show transmetaphyseal sclerosis indicative of a healing compression fracture (Fig. 5-8B). This fracture made up 15.5% of fractures in the Olmsted County population study, but it is probably much more prevalent, because metaphyseal fractures were not reviewed and neither the hand surgeons or the pediatric orthopaedists were aware of this fracture before the study. The most common sites are the distal radius, finger phalanges, and metacarpals. Nonoperative treatment by closed reduction and immobilization usually results in a good outcome. Only one patient with this fracture type (0.7%) was treated surgically in the Olmsted County study. Premature physeal closure occurred in five (3.4%) adolescents, none of whom required treatment.

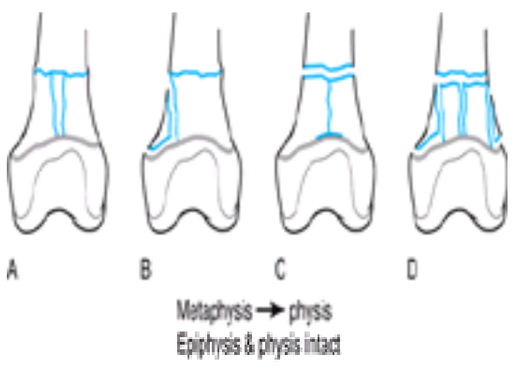

FIGURE 5-7. Peterson type I fracture of the metaphysis with extension to the physis. **A:** Torus or buckle complete transmetaphyseal fracture with one or more fracture lines extending to the physis. The fracture does not extend along the physis, and the epiphysis is not displaced on the metaphysis. The metaphysis is frequently wider than normal. The transmetaphyseal fracture is a compression fracture, often best visualized 2 to 4 weeks postfracture as an increased sclerotic osseous density. **B:** Transverse metaphyseal compression fracture with peripheral cortical fragment. This fragment may be displaced eccentrically, indicating disruption of the physis in this area. **C:** Complete transverse metaphyseal fracture with fracture line extension to the physis. **D:** Comminuted fracture of the metaphysis with multiple fracture extensions to the physis. None of these fractures meets the requirements of a type II fracture, which is a fracture of only part of the metaphysis extending to and along the physis. The designations **A** to **D** are not an attempt to subdivide or classify this fracture type but are used only to show the multiple possibilities. (Redrawn from Peterson, HA. Physeal fractures: part 2, two previously unclassified types. *J Pediatr Orthop* 1994;14:431–438; with permission.)

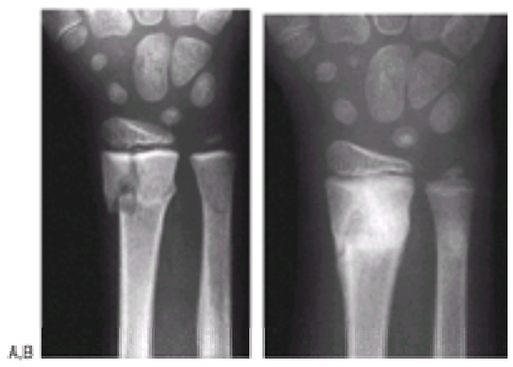

FIGURE 5-8. Peterson type I fracture in the distal radius of a 6+5-year-old boy. **A:** AP view shows complete transverse metaphyseal fracture with longitudinal extension to the physis. The metaphysis is wider than normal, and the epiphysis is not displaced on the metaphysis. **B:** AP view 34 days postfracture shows healing sclerosis transversely and longitudinally at sites of fracture. (From Peterson HA. Physeal fractures: part 2, two previously unclassified types. *J Pediatr Orthop* 1994;14:431–438; with permission.)

FIGURE 5-9. Peterson type I fracture in the distal radius of a 14+1-year-old boy. **A:** AP view shows comminuted displaced fracture of metaphysis. Longitudinal cortical buckling fracture on radial side extends to the physis. **B:** AP view during reduction in fingertrap traction. Transmetaphyseal fracture with extension to physis and no displacement of epiphysis is now evident. The metaphysis is wider than normal. Fractured ulnar styloid. **C:** AP view, 14 months postfracture. There is normal function, and the distal radial physis is open and growing. Nonunion of ulnar styloid is seen. (From Peterson HA. Physeal fractures: part 2, two previously unclassified types. *J Pediatr Orthop* 1994;14:431–438, with permission.)

Type II is a separation of part of the physis, with a portion of the metaphysis attached to the epiphysis (Thurstan Holland sign). Involvement and potential damage of the physis may be minimal (Fig. 5-10) or nearly all the physis may be disrupted, leaving only a small metaphyseal fragment (Fig. 5-10C). Most commonly, the metaphyseal potion attached to the physis is a quarter to a third the width of the physis (Fig. 5-10B). Although attention is usually focused on the size of the metaphyseal fragment, the more important factor is the amount of physeal tissue disrupted. Indeed, the Thurstan Holland metaphyseal fragment may be so tiny that it is not seen on routine anteroposterior or lateral radiographs (Fig. 5-10C). Tangential (oblique) views may be necessary to reveal the fragment. In this context, it differs little from a type III injury (Fig. 5-6), which involves complete physeal disruption with no osseous fracture. Type II (Fig. 5-10C) and III injuries can be managed similarly, usually by closed reduction and immobilization. There are no recorded cases of premature physeal closure between the metaphyseal fragment and the epiphysis. Brashear, applying longitudinal compression by bending the knee joints of rats, produced a type II fracture each time. None of these fractures developed physeal closure at the compression site (metaphyseal fragment/epiphyseal interface). If premature physeal closure occurs, it is at the site of the sharp edge of the fractured metaphysis, which excoriates or compresses the physis (18).

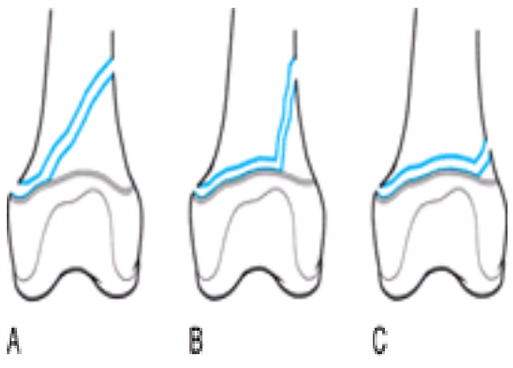

FIGURE 5-10. Peterson type II physeal fracture. See text for discussion. (Redrawn from Peterson HA. Physeal fractures: part 3, classification. *J Pediatr Orthop* 1994;14:439–448; with permission.)

Regardless of the amount of physis disrupted, the essential features of a type II injury are disruption of part of the physis between the epiphysis and the metaphysis, however small this may be; fracture of only part of the metaphysis, with a metaphyseal fragment attached to the physis; and no continuity from the epiphysis to the intact major metaphyseal/diaphyseal complex. Comminution and open fracture are uncommon. This fracture is the most common type in all previous series and is made up 53.6% of fractures in the Olmsted County study. The most common site is in finger phalanges, where it occurred 47.6% of the time. Initial management was surgical for 23 (4.5%) patients. Thirty-three (6.5%) developed premature physeal closure. Twelve (2.4%) underwent late surgical correction.

A type III injury is a separation of the epiphysis from the diaphysis through any of the layers of the physis, disrupting the complete physis (Fig. 5-6). This injury is rarely open and cannot be comminuted. The only anatomic variations are the different layers of the physis through which the fracture traverses. At present, this can be determined only histologically. In two studies, the transphyseal fracture was histologically noted to involve all zones of cartilage cells (germinal, proliferating, hypertrophying, and provisionally calcified) (16,31). This helps explain why premature growth arrest may occur following fractures along the physis (Fig. 5-11). This injury made up 13.2% of physeal injuries in the Olmsted County study. It occurs most commonly in the distal fibula. Thirteen acute fractures (10.3%) were treated surgically. Nine patients (7.1%) had late corrective surgery.

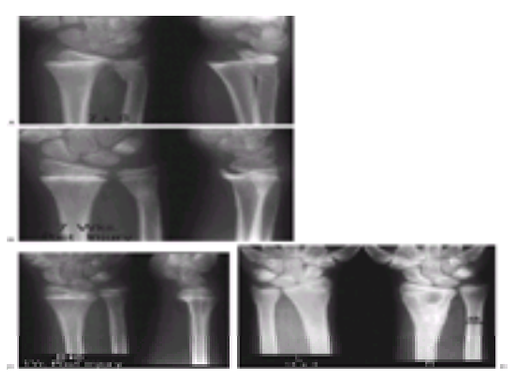

FIGURE 5-11. Salter–Harris I fracture of the distal radial physis in a 7+6-year-old girl with subsequent physeal arrest and bar excision. **A:** AP and lateral show dorsally displaced distal radial epiphysis. **B:** Seven and a half weeks postinjury. Physis and metaphysis are irregular and sclerotic. **C:** One year postfracture there is relative overgrowth of ulna. **D:** Age 14+4 years after physeal bar resection. The patient is normally active, participating competitive volleyball, and is asymptomatic. The distal radius is growing (greater than 100%) faster than the ulna, as evidenced by the reduction of the ulnar plus deformity and the increasing distance between the metal markers. The Cranioplast plug stayed with the epiphysis.

Type IV is a fracture of the epiphysis extending to and along the physis (Fig. 5-6). It may be comminuted or “double.” Open fractures are uncommon. Because this fracture most often occurs when part of the physis, usually central, has begun to close, it is more common in older children. The disrupted articular surface requires anatomic reduction and maintenance of reduction, often by open reduction and internal fixation. Premature growth arrest is common, but it usually is complete rather than partial, and rarely causes angular deformity. Most children with this injury are relatively mature, and bone-length discrepancy is uncommon. Significant length discrepancy occurs only in young patients (Fig. 5-12). This fracture made up 10.9% of fractures in the Olmsted County study. The most common sites are the finger phalanges and the distal tibia (medial malleolus and lateral plafond). Eighteen fractures (17.3%) were treated initially by surgery, and 15 (14.4%) underwent late surgery.

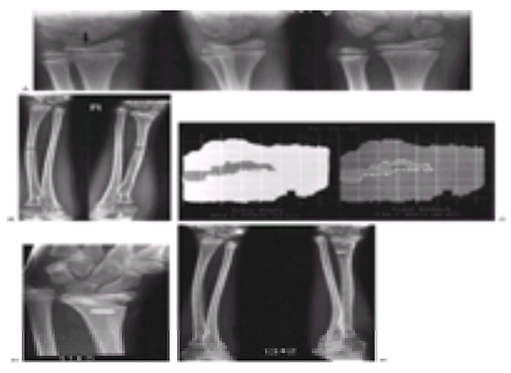

FIGURE 5-12. Salter–Harris III fracture, distal radius in a 9+1-year-old girl with subsequent physeal arrest and bar excision. **A:** Patient fell 8 feet, landing on her outstretched right hand. Fracture of the epiphysis extending to the physis (*arrow*) might be better visualized with additional oblique radiographs or tomograms. **B:** Two years 6 months postfracture (age 11+l7). Physeal bar medial distal radius. The right radius is 23 mm shorter than the left. The ulnae are of equal length. **C:** MRI transverse depiction of distal radial physis using 3-D rendering (ANALYZE) shows linear bar comprising 10.5% of the physis. **D:** Physeal bar excised through peripheral approach and cavity filled with Cranioplast. Metal markers 11 mm apart. Note normal growth (relative overgrowth) of ulna. **E:** Eighteen months after bar excision (age 13+2). The distal right radius has not only resumed normal growth, but is growing faster than normal (greater than 100%), as evidenced by improvement of radial–ulnar length discrepancy. The metal markers are 29 mm apart. The radial articular angle is improved, and remodeling has resulted in a more ulnarward position of the proximal metal marker.

Type V is a fracture that traverses the metaphysis, physis, epiphysis, and usually the articular cartilage (Fig. 5-6). The triplane fracture (22) meets all of these criteria (Fig. 5-13) and is therefore a complex type V fracture, which is otherwise depicted in only one plane, usually the sagittal. Comminution and open injuries are common. Type V fractures are best managed by anatomic reduction and maintenance of reduction to align both the articular cartilage and the growth cartilage. This is particularly true in the young patient with significant growth remaining. This usually requires open reduction and internal fixation. Premature growth arrest is common and occurs even with anatomic reduction. This fracture made up 6.5% of fractures in the Olmsted County study. The most common sites are the distal humerus (lateral condyle), finger phalanges, and distal tibia, where the fracture pattern is variable (11). Twelve fractures (19.4%) were treated initially by surgery, and 12 (19.4%) were treated by subsequent surgery.

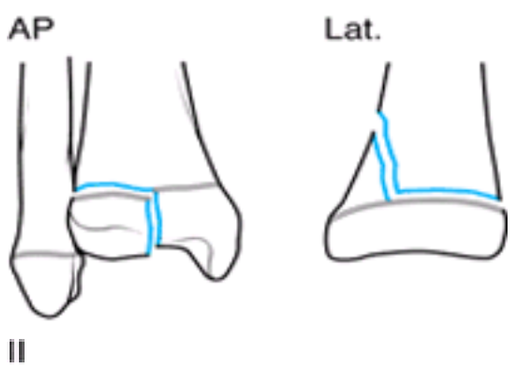

FIGURE 5-13. Triplane fracture (1957). (Redrawn from Peterson HA. Physeal fractures: part 3, classification. *J Pediatr Orthop* 1994;14:439–448; with permission.)

Type VI is a fracture in which part of the physis has been removed or is missing (Fig. 5-14) (23). Usually an accompanying part of the epiphysis or metaphysis, or both, is also missing. This occurs only with open fractures such as those caused by lawn mowers, farm machinery (e.g., auger, corn picker, power take-off, corn sheller), snowmobiles, gunshots, and motorboat propellers (Fig. 5-15). Premature partial closure of the remaining exposed surface of the physis nearly always occurs but sometimes not until years later. This fracture made up only 0.2% of fractures in the Olmsted County study, but it is more common among referral patients. All type VI injuries require initial surgery, at least wound care; most if not all require late reconstructive or corrective surgery, especially those in young children.

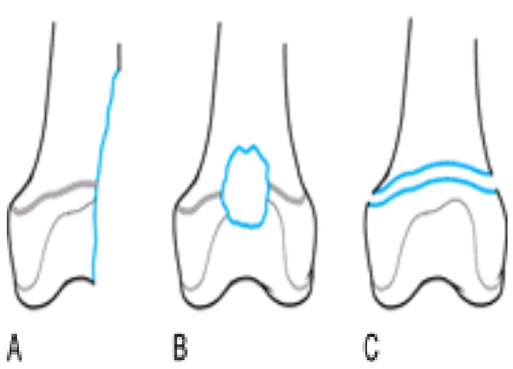

FIGURE 5-14. Peterson type VI fracture of the physis with a portion of the physis missing. **A:** Longitudinal fracture with piece comprising epiphysis, physis, and metaphysis missing. In rare cases a portion of the diaphysis may also be missing. The absent portion may vary in location and in size from small to large. Common mechanisms of injury are from lawn mowers, snowmobiles, automobiles, farm implements, and motorboat propellers. **B:** Penetrating injury may remove physeal cartilage, along with adjacent epiphyseal and metaphyseal bone in any plane. A transverse orientation of penetration causes the most severe physeal damage. The most common penetrating object is a bullet. **C:** Lacerating injury directly in the plane of the physis, removing some or all of the physis with relatively little damage to the epiphysis or metaphysis. This injury is rare. The designations A to C are not an attempt to subdivide or classify the fracture type but are used only to show the multiple possibilities. These fractures have only one criterion: part of the physis is missing. A physeal bar invariably develops, sometimes years postfracture. (Redrawn from Peterson HA. Physeal fractures: part 2, two previously unclassified types. *J Pediatr Orthop* 1994;14:431–438; with permission.)

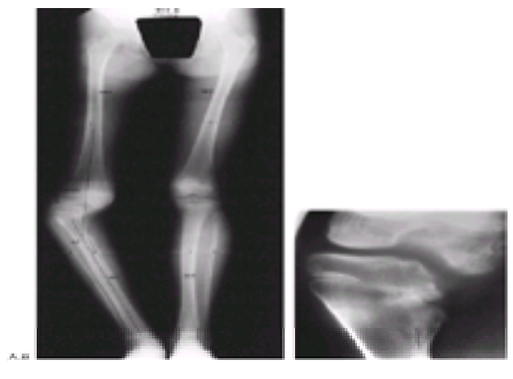

FIGURE 5-15. Peterson type VI fracture of the proximal tibia in a 10+4-year-old girl. **A:** Standing teleoroentgenogram. Right genu varum following removal of right proximal tibial medial condyle in lawn mower accident that occurred at age 4+11 years. Patient had previously undergone proximal tibial valgus osteotomy and

physeal bar excision. Note lateral subluxation of tibia on femur. **B:** Tomogram confirms recurrent physeal bar medially. Note this relative overgrowth of the unopposed medial femoral condyle. This patient was treated by bracing and, at age 13, by medial tibial cadaver allograft and physeal closure of the lateral side of the proximal tibia, with concomitant physeal arrest of the contralateral normal proximal tibial physis.

Salter-Harris Type V, Present Status

The Salter-Harris type V injury is not included in this new classification of fractures because with this injury, there is no fracture. Because the radiograph taken at the time of injury is normal and growth arrest is discovered only in retrospect, this entity, if it exists at all, cannot be suspected during the evaluation or treatment of an acute injury. Therefore, it is included in the later section, “Other Physeal Injuries.”

Comparison of classifications may have more than historical value. New mechanisms of injury and new or improved imaging techniques may lead to the inclusion of new fracture types, or of a previously described but discarded fracture type.

Epidemiology (The Olmsted County Study)

Mann and Rajmaira (35) reported that of 2650 long-bone fractures in children, about 30% involved the physes (33,34,35,36,37,38,39). Worlock and Stower (39) reported that of 826 fractures of all bones in children, 18.5% involved the physes. An epidemiologic study of physeal fractures was performed over a 10-year period in Olmsted County, Minnesota, from 1979 to 1988 (Table 5-1) (38). This was the first population-based study in which both the numerator (fractures) and denominator (population at risk) were known. No referral cases were included, thereby omitting preselected difficult or high-risk cases.

Types	Number (%)	Immediate Surgery (%)	Late Surgery (%)
I	147 (15.5)	1 (0.7)	0 (0)
II	510 (53.6)	23 (4.5)	12 (2.4)
III	126 (13.2)	13 (10.3)	9 (7.1)
IV	104 (10.9)	18 (17.3)	15 (14.4)
V	62 (6.5)	12 (19.4)	12 (19.4)
VI	2 (0.2)	2 (100)	1 (50)
Total	951 (100)	69 (7.3)	49 (5.2)

* Data pertain to physeal fractures among children in Olmsted County, Minnesota, 1979–1988.
From Peterson HA. Physeal fractures: part 3, classification. *J Pediatr Orthop* 1994;14:439–448.

TABLE 5-1. NUMBER AND SURGERY OF PHYSEAL FRACTURES ACCORDING TO PETERSON CLASSIFICATION

Of the 951 physeal fractures in the study, the male-to-female ratio was 2:1. The incidence rates were highest among boys age 14 and girls ages 11 and 12 (Fig. 5-16). The overall age- and sex-adjusted incidence of physeal fractures was 279.2 per 100,000 person-years (95% confidence interval, 261.4 to 296.9). Fractures occurred approximately equally on right and left limbs (52.6% versus 47.4%, $p > .05$). The most common site was the phalanges of the fingers, which accounted for 37% of all physeal fractures, followed by the distal radius (18%) (Table 5-2). The distal end of each long bone was fractured more frequently than the proximal end. Seventy-one percent of fractures occurred in the upper extremity, 28% in the lower extremity, and 1% in the axial skeleton.

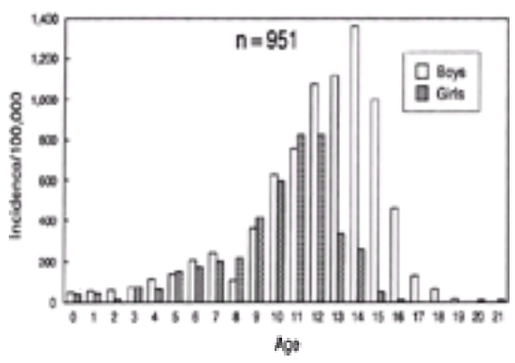

FIGURE 5-16. Incidence of physeal fractures by gender for 1-year age groups with all types of fractures. Boys peak at age 14 years, and girls peak at age 11 to 12 years. (From Peterson HA, Madhok R, Benson JT, et al. Physeal fractures: part 1, epidemiology in Olmsted County, Minnesota, 1979–1988. *J Pediatr Orthop* 1994;14:423–430; with permission.)

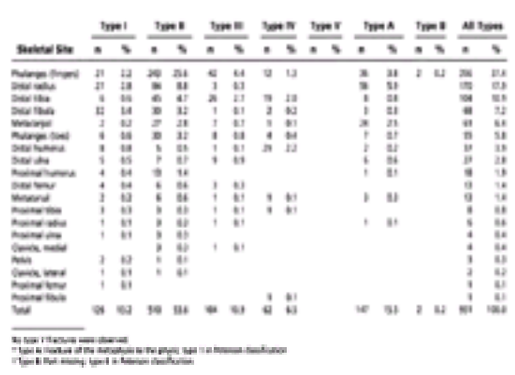

TABLE 5-2. SITES AND TYPES OF PHYSEAL FRACTURES AMONG CHILDREN IN OLMSTED COUNTY, MINNESOTA, 1979–88 AND SALTER-HARRIS CLASSIFICATION WITH TWO NEW TYPES (A AND B)

Evaluation

The history of injury and the clinical evaluation (symptoms and physical findings) usually define appropriate body parts for radiographic evaluation (40,41,42,43,44,45,46,47,48,49,50,51,52,53,54,55,56,57,58,59,60,61,62,63,64,65,66,67,68,69,70,71). Radiographs in two planes, usually anteroposterior and lateral, are sufficient to determine the fracture type and the management plan for most fractures. If the radiographs are indeterminate, oblique or three-quarter views should be taken (51,63,64). Occasionally stress views, tomograms, arthrograms, computed tomography (CT) scans, magnetic resonance imaging (MRI), or ultrasound is needed to adequately display the fracture. Stress views are most useful when the injury is near a uniplanar joint (e.g., the elbow, knee, or ankle) (51). Tomograms help delineate fragmentation and orientation of fragments. CT scans may best reveal the complexities of triplane fractures (22,64). Fractures involving a large volume of cartilage, such as the proximal or distal humerus in infants, in the past were best appreciated by arthrography (40,41,49,56,57,71). Recently, this method has been

replaced by MRI (54,55,64,65,70) and ultrasound (43,52,57). MRI has also been used in older children with acute injuries to identify possible physeal damage (44,53,59,60,67,70) and is recommended primarily to identify complex fractures (60). The role of scintigraphy (47,68) in assessing acute physeal fractures is yet to be determined.

Treatment

The goal of treatment of all physeal fractures is to maintain function and normal growth (72,73,74,75,76,77,78,79). Maintenance of growth is obviously more important in a young child than in an older adolescent, who has little growth remaining. Consistent attainment of these goals is most likely when all structures are anatomically reduced. Thus, the goal becomes to obtain and maintain anatomic reduction. This may be done by closed or open means. All reductions, whether closed or open, should be gentle to prevent damage to the delicate physeal cartilage. Forceful, repeated manipulations should be avoided. During open reduction, placing direct pressure on the physis with instruments should be avoided.

Physeal fractures should be reduced immediately, because delay makes reduction more difficult. The younger the child, the more rapidly the healing callus blends with articular and physeal cartilage, making reduction difficult.

Type I (Metaphyseal Compression With Extension Into the Physis)

The type I fracture has the least potential damage to the physis and therefore needs the least aggressive treatment. Closed reduction and casting usually achieve satisfactory position and alignment of the fragments (Fig. 5-8 and Fig. 5-9). Fractures of the metaphysis and physis heal rapidly, and cast immobilization for 3 to 4 weeks is usually sufficient. Because the physis is involved in the injury, growth arrest is possible (3.4% in the Olmsted study), and these fractures need follow-up long enough to ensure that normal growth has resumed. This period varies depending on the patient's age and the site and severity of injury; at least 3 months is appropriate for most patients, longer for patients with comminuted or markedly displaced fractures.

Salter-Harris II

Most type II fractures can be reduced easily with closed manual reduction. Scraping of the metaphyseal fragment across the intact physis can be decreased by good patient relaxation to reduce muscle tension. This is probably best achieved by general anesthesia or a nerve block such as an axillary or lumbar epidural block. The metaphyseal fragment usually prevents overreduction (Fig. 5-10A and Fig. 5-10B). The intact periosteum on the side of the metaphyseal fragment imparts further stability to the reduced fracture, and internal fixation is often unnecessary.

In a young patient, incomplete reduction may be more acceptable than repeated overzealous manipulation, which may cause gouging of the physis. In an older patient, a more accurate reduction is necessary because spontaneous correction with growth is less likely. Occasionally, a type II fracture cannot be satisfactorily reduced. A common example is the distal tibia, where periosteum becomes impinged at the fracture site. Tendon, nerve, and vascular-structure impingement also has been reported at various sites; these types also need surgical extrication. If the reduced fragments are unstable, internal fixation is appropriate. This is best accomplished by pins or screws from metaphysis to metaphysis, avoiding the physis. Occasionally, the metaphyseal fragment attached to the epiphysis (Thurstan Holland sign) is so small that it cannot be internally fixed to the main metaphysis (Fig. 5-10C). In this case, small-diameter, smooth pins may be placed from the epiphysis, across the physis, and into the metaphysis. Growth arrest is less likely if the pins avoid the perichondrial ring, are as longitudinally as feasible, and remain in place a short time, preferably 3 weeks or less. The insertion of biodegradable pins across the physis is a new concept that is being evaluated, most intensely in Finland (72,74,75,76,78,79). Whether these pins impart adequate stability without predisposing to physeal arrest remains to be seen. In one of the more recent studies, growth arrest was noted and the authors suggested that the procedure be limited to adolescents with little growth remaining (78).

Type II fractures may involve a small (Fig 5-10A) or large (Fig 5-10C) portion of the physis; the more of the physis involved, the greater the chance of growth arrest. The prognosis also depends greatly on the site of injury. When the physis is irregular and undulating, as in the distal femur or proximal tibia, displacement of the metaphyseal surface against the physeal surface produces scraping of these irregular surfaces and an increased likelihood of physeal arrest. A smooth, flat physis, such as the distal radius, is much less prone to arrest. The degree of displacement and the patient's age are also obviously important. Repeated reduction attempts increase the chance of arrest. Type II fractures may involve only a small amount of physis (Fig. 5-10A) or a large amount of physis (Fig. 5-10C); the latter increases the chance of physeal damage.

Salter-Harris I

Type III fractures (Fig. 5-6) are similar to those type II fractures which have a very small metaphyseal fragment (Fig. 5-10C). Because all layers of the physis may be involved (Fig. 5-11), the prognosis for growth arrest is slightly greater than with type II fractures (Table 5-1). Type III fractures should be managed by closed reduction because internal fixation would likely require crossing the physis. In a young child, it is better to accept an imperfect reduction than risk the hazards of internal fixation across the physis.

Salter-Harris III

In type IV fractures, the cartilage of the physis and the articular surface are both disrupted (Fig. 5-6). The best result is achieved by anatomic reduction of the articular surface to reduce the likelihood of degenerative arthrosis and anatomic reduction of the physeal cartilage to reduce the chance of growth arrest. Usubnally, these fractures occur in older children, when the physis is beginning to close and growth arrest is not a problem. Anatomic reduction often requires open reduction to expose the articular surfaces, especially in young children. The most desirable internal fixation is epiphysis to epiphysis, if possible, especially in young children.

Salter-Harris IV

For the type V fracture, anatomic reduction and maintenance of reduction are essential to align both the physis and the articular surface. If there is any displacement, open reduction and internal fixation are usually required. Closed reduction with percutaneous internal fixation may be acceptable in some situations (77). Internal fixation is best accomplished from epiphysis to epiphysis or metaphysis to metaphysis, particularly in young children. Growth arrest is likely, and these fractures need observation for at least a year, even if earlier evaluation is good.

Type VI (Epiphyseal and Physeal Loss)

Because type VI fractures are open injuries, all require initial debridement, often with wound packing and secondary closure and sometimes with skin graft or flap closure. Children with these injuries must be followed until maturity, because most if not all develop angular deformities and relative shortening of the involved bone (Fig. 5-15A). There is a high likelihood of physeal bar formation on the exposed bone surface (Fig. 5-15B).

Prognosis

The prognosis of a physeal fracture depends on the following factors, in descending degree of importance: the severity of injury, including displacement, comminution, and whether it is open or closed; the patient's age; the physis injured; and the radiographic type of fracture (1,2,3,4,24,28,29,38,80,81 and 82). Treatment depends on these factors and in itself has an important bearing on the prognosis.

Severity of Injury

The mechanism of injury may be thought of as the activity the patient was involved in at the time of injury (e.g., automobile accident, football, diving) or as an anatomic description of the injury (e.g., varus, extension, rotation). The term *high-velocity injury* is often used to describe fractures with significant displacement, comminution, and compounding. The term *severity of injury* is used here to include all of these features and is the most important factor in prognosis. Any damage to or loss of the germinal or proliferative layer of physeal cells has a negative implication concerning growth.

Age of Patient

The patient's age is also important. A physeal injury in a 13-year-old girl or a 15-year-old boy rarely results in significant length discrepancy or angular deformity, because little growth remains. Any physeal injury in a young child, however, has the potential for premature arrest, and appropriate follow-up is required.

Site of the Injury

The site of injury influences the outcome. A type I fracture of the distal femur or proximal tibia, both of which have large, undulating, multiplanar physes, are prone to arrest, even with mild separation or displacement. Because these sites contribute more longitudinal growth than any other site in the body, deformity and length discrepancy are common. Conversely, the proximal radius and ulna and distal humerus contribute so little growth to the forearm and humerus, respectively, that injury and premature arrest from any fracture type at these sites rarely causes significant angular deformity or length inequality. A type I fracture of the distal fibula, rarely develops arrest, and ankle valgus deformity would occur only with arrest at a young age. The proximal humerus has such good remodeling potential that significant displacement and angulation can be accepted, even in older children.

The site of the injury also determines the blood supply of the physis. The growth-producing germinal and proliferating cells receive their nourishment through blood vessels from the epiphysis. If this blood supply is destroyed, these cells die and growth ceases. Fortunately, most epiphyses receive their blood supply directly from multiple sources. When the arterial supply is limited to a few arteries that must reach the epiphysis by crossing the periphery of the physis (e.g., the proximal femur), any displacement of the epiphysis may occlude the blood supply, resulting in avascular necrosis of the epiphysis and physeal cell death.

Amount of Physis Injured

The type of fracture is determined by the mechanism of injury, the patient's age, and the site of injury. For example, a type II fracture of the distal radius is common at any age; a type II fracture of the distal humerus is rare at all ages. The type of fracture also relates to the amount of physis damaged. Thus, although this new classification is based primarily on anatomic considerations from the least amount of physis involved (type I) to the greatest amount (type VI), it also was found to be correlated to the prognosis in a general way. In the Olmsted study, the amount of surgery performed, both initially at the time of injury and later to correct a complication, increased as the type number increased (Table 5-1).

COMPLICATIONS

Sepsis can occur in any open physeal fracture, just as in any open diaphyseal fracture (83,84,85,86,87,88,89,90,91,92,93,94,95,96,97,98). Practically speaking, this is seen exclusively in open injuries, primarily type IV and VI fractures. Precautions and treatment are similar to those for any other open bone or joint injury. Overgrowth after physeal fracture is essentially unknown, except of the capitellum in type V fractures of the lateral humeral condyle, where overgrowth is rarely sufficient to cause significant angular deformity or length discrepancy. Hypoplasia of an epiphysis after trauma also is rare, and it is usually associated with damage of the germinal layer of the physis or with vascular impairment that produces avascular necrosis. The accompanying angular deformity usually is minor, but in the trochlea, it can be sufficient to cause ulnar nerve palsy (92). Likewise, malunion of properly recognized and treated physeal fractures is uncommon (86). Delayed union or nonbnunion of type V fractures occurs occasionally, and has been noted in the lateral humeral condyle (85,89), the distal femur (87), and the medial malleolus (Fig. 5-17). Nonunion may also occur after open reduction and internal fixation (Fig. 5-18). This is usually treated by attempts at osteosynthesis or reconstructive surgery.

FIGURE 5-17. Nonunion of type V fracture. **A:** Type V fracture of distal tibial medial malleolus in a 4-year-old boy. The fracture was treated by cast immobilization. **B:** Age 6+10. Union of the small metaphyseal fragment to the metaphysis, but nonunion of the epiphyseal fragment to the epiphysis. There is no physeal bar. The physis is growing more rapidly medially, as evidenced by the growth arrest line in the metaphysis. The upward displacement of the fragment before union of the metaphyseal fragment allows some ankle varus.

FIGURE 5-18. Nonunion of Salter–Harris IV fracture. **A:** Type V fracture of distal tibial medial malleolus in a 3+4-year-old girl. Treatment was open reduction, excision of metaphyseal fragment, and internal fixation. **B:** Five weeks postfracture, medial malleolar fragment is not united. **C:** Five months postfracture there is an established nonunion.

Compartment syndrome and arterial occlusion are not commonly associated with physeal fractures but have been reported with fractures of the proximal tibia (83,93,94,97) (Fig. 5-19) or the distal radius (88,91). Avascular necrosis of the proximal femoral capital epiphysis is a dreaded complication of any fracture of the proximal femoral physis, particularly if the hip is also dislocated (95). Avascular necrosis can occur at the proximal (90) and the distal humerus (98) and at the proximal radius, but it is rare at all other anatomic sites.

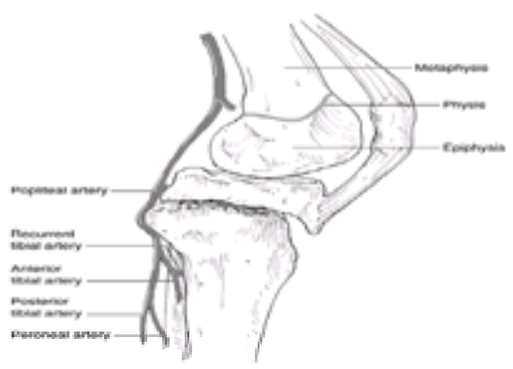

FIGURE 5-19. Occlusion of the popliteal artery by direct pressure from posterior displacement of the proximal tibial metaphysis. (Redrawn from Burkhart SS, Peterson HA. Fractures of the proximal tibial epiphysis. *J Bone Joint Surg Am* 1979;61:996–1002; with permission.)

All of these complications are uncommon. By far, the most frequent complication of a physeal fracture is premature growth arrest, resulting in diminished bone length, angular deformity, or both. This complication is so prevalent that it deserves special attention and is discussed later in this chapter.

OTHER PHYSEAL INJURIES

Physeal injuries, other than fracture, that are sufficient to cause premature partial or complete arrest share two characteristics: normal radiographs at the time of insult, and premature physeal arrest noted weeks, months, or years later. These injuries are uncommon. The injuries that meet these criteria can be classified as follows:

1. Disuse
2. Radiation
3. Infection
4. Tumor
5. Vascular impairment
6. Neural involvement
7. Metabolic abnormality
8. Cold injury (frostbite)
9. Heat injury (burn)
10. Electric injury
11. Laser injury
12. Stress injury
13. Longitudinal compression
14. Developmental
15. Iatrogenic

Disuse

Disuse of an extremity, from any cause, results in atrophy of muscle and other soft tissue (99,100,101,102,103,104,105,106,107,108,109,110 and 111). If disuse is prolonged, growth of bone length also is retarded. If disuse is marked, some or all of the physis may cease growing completely. Bed rest, crutches, cast immobilization, and traction, even in the absence of fracture, are all associated with growth arrest of the distal femoral physis and proximal or distal tibial physis. These modalities have been used in the management of patients with congenital hip dislocation (100,104), rheumatoid arthritis (104), polio (101,108), tuberculosis (107,111), and Perthes' disease, but are now used more sparingly for various reasons, one of which is the possibility of growth arrest.

Complete closure of one or all of the physes in an extremity after a single diaphyseal fracture has been reported and was attributed to disuse of the extremity (3,61,99,102,103,104,105,106,109,110). Some of those multiple physeal closures have been attributed to Salter-Harris type V compression injuries, but it is difficult to envision multiple-site compression injuries with a single femoral or tibial transverse or spiral shaft fracture. Conversely, some Salter-Harris type V injuries reported in the literature may have been caused by posttraumatic disuse rather than sudden traumatic physeal compression.

The precise etiology of physeal arrest associated with disuse is unknown. Gill speculated that the accompanying osteoporosis predisposed the patient to microfractures that traversed the physis. Ross (110) suggested that the partially degenerated cartilage cannot withstand the abnormal stresses of a faulty gait. Diminished arterial supply is a more likely possibility.

Radiation

The growth-inhibiting and destructive effects of x-rays on physeal cartilage have been demonstrated in both animals and humans (112,113,114,115,116,117,118,119,120,121,122,123,124,125,126,127,128,129,130 and 131). Growth-inhibiting effects are common when a physis is in the treatment field during therapeutic irradiation (115,116,119,127,129,130 and 131) but have not been shown to occur with diagnostic x-ray studies or the use of repeated tomograms. The main variables determining the extent of demonstrable bone change caused by radiation therapy are the patient's age at the time of therapy, the amount of the radiation delivered (including both dose per treatment and total dose delivered), the field size, the site to which the radiation was delivered, and the growth potential of this site. The younger the patient and the greater amount of radiation delivered, the greater is the extent of subsequent bone changes (Fig. 5-20). A radiation dose as low as 400 R can produce growth retardation, and as the dose increases, so does the extent of cellular damage and eventual development of dysplastic bone. All physes, including those in the spine, are at risk (120,124,125 and 126).

FIGURE 5-20. Physeal arrest associated with radiation. **A:** A 5+0-year-old with Ewing's sarcoma proximal left fibula; diagnosis was made by open biopsy. Metastasis to lung confirmed by transthoracotomy biopsy. Patient received radiation therapy (5000 cGy to the left leg in 24 fractions over 8 weeks and 1500 cGy to the lungs in 12 fractions over 2 weeks). **B:** The left tibia did not grow, and at age 15+0, it is still 12.2 cm shorter than the right despite numerous corrective surgical procedures. Ankle disarticulation facilitated below-knee prosthetic fitting. The patient is tumor-free at age 22 years.

Infection

Septic arthritis and metaphyseal osteomyelitis often are followed by physeal arrest (132,133,134,135,136,137,138,139,140,141,142 and 143). Because the interval between infection and physeal arrest may be years (Fig. 5-21), intraarticular and osseous infections need long-term follow-up. The arrest is often partial, resulting in both angular deformity and length discrepancy. Typically, there is no residual infection when the arrest is noted. Physeal bar excision in patients with previous infection may, however, have a higher incidence of postexcision infection. Of 178 physeal bar excisions reviewed at the Mayo Clinic, the only three postoperative infections were in patients in whom the bar was due to metaphyseal osteomyelitis.

FIGURE 5-21. Physeal arrest associated with metaphyseal osteomyelitis. **A:** An infant girl had a cutdown inserted into the right ankle saphenous vein on her second day of life. Staphylococcal osteomyelitis in the distal right femur was treated by incision and drainage on day 17 of life. Care was taken to avoid contact of the curet with the physis. A scanogram 4 years 11 months postoperatively demonstrates right distal femoral valgus and relative shortening of femur (1.2 cm). Coronal tomogram of right knee **B:** shows central bar with tenting or cupping. A 4-year follow-up of this case following bar excision is documented in Peterson HA. Partial growth plate arrest and its treatment. *J Pediatr Orthop* 1984;4:246–258; with permission.

Physeal arrest also has been reported after some systemic infections, particularly meningococcemia (61). In this instance, the arrest may be associated with vascular impairment (Fig. 5-22).

FIGURE 5-22. Physeal arrest associated with systemic infection. **A:** A 7+l0-year-old boy had meningococcemia at age 2 years complicated by ischemia of the lower extremities. He underwent fasciotomies, debridement of necrotic tissue, and extensive skin grafting. The legs, however, survived with only the loss of toes. Subsequently he had heel cord lengthenings and soft tissue flap grafts to cover both patellae. **B:** Scanogram show bilateral ankle varus and physeal bars of the distal tibiae. He later developed a bar of the proximal left tibia.

Tumor

Several benign tumors often abut the physis, and the physis is susceptible to injury during curettage and bone-grafting procedures. The physis may close even when the tumor is untreated. In addition to unicameral cyst (145,147,148,149 and 150) and enchondroma (144,146), other childhood tumors that occur near growth plates and might cause growth arrest are aneurysmal cyst, chondroblastoma, chondromyxoid fibroma, and fibrous dysplasia.

Vascular Impairment

The germinal and proliferative layers of physeal cartilage cells are primarily responsible for longitudinal bone growth (151,152,153,154,155,156,157,158,159 and 160). These cells are nourished by vessels in the epiphysis, and any vascular disturbance of the epiphysis can result in physeal damage (157,158,159,160). Some investigators have suggested that the epiphyseal blood supply is probably the most important determinant in the development of bone bridges (3,81). If the blood supply to the metaphysis is also disrupted, the likelihood of a bone bridge increases.

Arterial spasm associated with traction (154) and even the application of a cast reduces blood flow to the extremity (153), which can alter physeal growth (3,158,159). Premature physeal closure has been documented after temporary arterial insufficiency (Fig. 5-23) (155) and after intravenous fluid extravasation (156). Some Salter-Harris type V and Rang type VI injuries reported in the literature may have been caused by vascular dysfunction rather than by physeal germinal cell compression.

FIGURE 5-23. Physeal arrest associated with temporary arterial impairment. At age 13 months, this girl with congenital dislocation of the right hip had an open reduction, complicated by severing of the common femoral artery. Multiple arterial anastomotic grafting procedures were successful in saving the extremity. A progressive asymptomatic right ankle varus developed. This coronal tomogram at age 2+6 shows premature partial closure of the distal tibial physis. Further documentation of this case is provided in Peterson HA. Premature physeal arrest of the distal tibia associated with temporary arterial insufficiency. *J Pediatr Orthop* 1993;13:672–675; with permission.

The exact mechanism of premature physeal closure with thalassemia major is unknown (152). In sickle cell disease (61), there is increased viscosity predisposing to sludging, erythrocyte entrapment in small vessels, and blockade of small vessels producing ischemia.

Neural Involvement

The etiology of impairment of physeal growth linked with nerve deficits associated with poliomyelitis, cerebral palsy (spastic hemiparesis), sacral tumors, and major nerve transection is unknown, but it is probably related to nutrition—more precisely, to diminished vascular supply (161,162). he length inequality in nerve-related disorders tends to progress slowly, and premature physeal closure is unlikely (162). Two exceptions are congenital insensitivity to pain (Fig. 5-24) and meningomyelocele (161). The growth retardation in these conditions is partial or complete arrest and may be caused by increased trauma and repeated transphyseal

fractures in the insensate limb.

FIGURE 5-24. Physeal arrest associated with neural involvement. **A:** A 4+3-year-old boy with congenital insensitivity to pain. The left tibia is 22 mm shorter than the right and has premature physeal closure at both ends. The poorly visualized proximal tibial physis and exuberant metaphyseal bone, as well as the deformity and compression of both tali and os calcis, are typical of this entity. **B:** Coronal tomogram of distal tibia shows central physeal bar without the usual indistinct physis and exuberant metaphyseal bone (see proximal left tibia). The patient was treated with bar excision.

Metabolic Abnormality (163,164,165,167,168,169,170,171,172 and 173)

Vitamin A intoxication can cause premature physeal arrest (167,168,169,170,171,172 and 173). The marked metaphyseal and epiphyseal cupping and growth retardation that sometimes occurs with vitamin C deficiency may also produce physeal closure (170,172), the condition may correct spontaneously with an appropriate diet. Careful serial radiographic studies are necessary before considering bar excision or contralateral epiphyseodesis (171).

Tissue resistance to growth hormone in patients with uremia has been implicated as the cause of growth retardation in patients with chronic renal failure (169). Also, high doses of calcitriol may directly inhibit chondrocyte activity within physeal cartilage and adversely affect linear growth in children with end-stage renal disease (166). Insulin-like growth factor–binding proteins may also contribute to growth inhibitors in children with chronic renal failure (168).

With increasing use and success of bone marrow transplantation, more children survive cancer. Chemotherapy and irradiation both have the potential to damage endocrine glands. which contributes to growth impairment through epiphyseal growth plate dysfunction (164). Immunosuppressive drugs may affect growth by differentially decreasing rates of cellular multiplication in the physis (163). The central portion of the physis is the most sensitive, and a cone-shaped epiphysis develops. This is similar, if not identical, to the changes seen with vascular and metabolic abnormalities.

Cold Injury (Frostbite)

Skeletal abnormalities after cold injury to the hands of growing children are complex and unique (174,175,176,177,178,179,180,181,182,183,184,185,186,187,188,189,190 and 200). Premature closure of the phalangeal physes is believed to result from direct injury to vulnerable chondrocytes in the cartilaginous physis (195) or from ischemic vascular changes (178,182,191,197). Children of intermediate age (5 to 10 years) appear most susceptible, probably owing to a combination of carelessness and decreased adult supervision. Radiographic signs of physeal closure become evident 6 to 12 months after cold exposure, and follow a pattern of decreasing frequency from the distal to the proximal physes (Fig. 5-25). The index and little fingers are most often involved, followed by the ring finger and the middle finger (176). The thumb metacarpal, protected by the surrounding thenar muscles and the proximity of the radial artery, is rarely involved (61,187). Presenting complaints are joint pain, stiffness, and weakness of fingers. Late sequelae include relative shortening of digits, skin redundancy, joint laxity, and degenerative joint changes (184,190,200).

FIGURE 5-25. Physeal arrest due to cold. An 11-year-old boy 1 year after frostbite complains of swelling and tenderness of finger joints accentuated by activity. Radiographs show absence or malformation of the epiphyses of 12 finger phalanges and irregularity of corresponding articular surfaces. The thumbs are normal clinically and radiographically. (From Wenzl JE, Burke EC, Bianco AJ. Epiphyseal destruction from frostbite of the hands. *Am J Dis Child* 1967;114:668–670; with permission.)

The radiographic changes are characteristic. Usually, the physis disappears completely, resulting eventually in a short finger. The physis and epiphysis often have a V shape. There may be no obvious destruction of the epiphysis, but eventual premature fusion of part of the epiphyseal line may lead to angular deformity. The affected phalanges are shorter and smaller than normal, and the juxtaarticular bone is expanded and irregular, with a coarse cancellous spongiosa. The same expanded and irregular appearance is seen on the contiguous articular surface of the more proximal phalanx, where there is no epiphysis (3).

In children, there is a striking lack of correlation between the extent of initial soft tissue injury and eventual skeletal changes. Many patients do not seek medical attention for the initial injury. The relative absence of soft-tissue ischemic changes, combined with late evidence of physeal damage, supports the hypothesis of direct cellular damage to physeal cartilage as the likely etiologic mechanism (190).

Very few children require surgical treatment (184). When deformities do require treatment, physeal arrest, arthrodesis, angular osteotomy, soft tissue arthroplasty, or tenorrhaphy can be performed as indicated (175,189). Function of the hand, however, generally remains satisfactory without surgery.

Heat Injury (Burn)

The mechanism causing physeal damage in severely burned limbs is not well understood (3,201,202,203,204,205,206 and 207). Because physeal cartilage is more sensitive to irradiation and cold than articular cartilage, it may also be more sensitive to heat (207). The peripheral zone of Ranvier, being more superficial, is more readily subject to the effects of heat (3). Prolonged ischemia of soft tissues around the physis might impair physeal growth, or the restrictive or strangling effect of thick scar about the metaphysis and adjacent joint areas might inhibit physeal growth (175,202,205).

Electrical Injuries

Physeal arrest caused by electrical injury, possibly including lightning, is rare (208,209,210,211 and 212). Multiple factors determine the effects of electric current on chondro-osseous tissue: the type of current (alternating current is three to four times as dangerous as direct current), voltage, amperage, duration of contact with the

electric current, the path taken through the body, the resistance at the points of contact and exit, and the patient's general state of health (209). During electrical accidents, tissue temperatures may momentarily reach several thousand degrees Celsius and may cause heat-induced liquefaction and necrosis of cartilage and bone. In general, the tissues offering the greatest resistance to tissue flow suffer the greatest damage. Electrical injury may result in cell death or may alter cellular activity temporarily or permanently (210). After electrical accidents, tissue repair, including callus formation, is poor.

Osseous changes in children are similar to those in adults but may also include additional abnormalities secondary to the effect of the current on the physeal cartilage (211) The epiphyseal center and physeal cartilage may be affected by the current, and the metaphyseal region remodels poorly. Partial premature arrest of the distal femur has been reported (208). There are only two reported cases of excision of physeal bars caused by an electrical burn (212).

Laser Injuries

A laser beam applied directly to physeal cartilage damages the cartilage selectively without affecting the adjacent bone (213). The damaged physis is replaced by bone, which forms a bone bridge between the metaphysis and epiphysis identical to bone bridges after fracture. Care must be taken when using lasers near physes in growing children (Fig. 5-26).

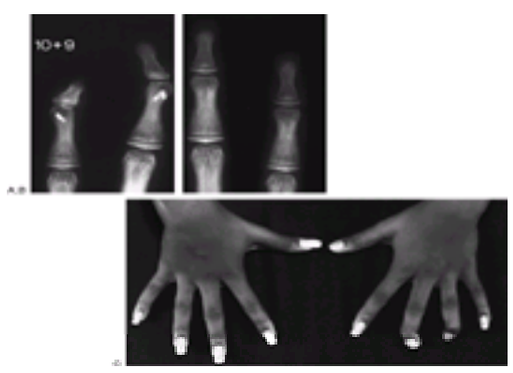

FIGURE 5-26. Physeal arrests from laser injury. At age 5+6 years, this girl had warts removed from the opposing sides of the left dominant ring and long finger at the level of the distal interphalangeal joints. The parents report that the procedure was aggressive and that the wounds took 3 to 4 months to heal. Physical therapy aided in regaining joint motion. Progressive angulatory deformity occurred. At age 6 years 2 months, corrective closing wedge osteotomies on the middle phalanges were performed and internally fixed with internal wire. Angulatory deformity recurred. **A:** By age 10 years 9 months, there is deformity and relative shortening of both distal phalanges. The distal phalanx of the long finger has a physeal bar on the ulnar side, and increasing angulatory deformity is anticipated. The distal phalanx of the ring physis finger developed a bar on the radial side that caused deformity of the distal phalanx. This physis is now completely closed, and no further deformity or growth is anticipated. **B:** Normal right ring and long fingers. **C:** Clinical appearance both hands (age 11 years 4 months).

Stress Injuries

Widening and Irregularity

Widening and irregularity of the physis without accompanying displacement of the epiphysis have been recognized as “stress-induced” changes in adolescent athletes (214,215,216,217,218,219,220,221,222,223,224,225,226,227,228,229,230,231 and 232). These characteristics are common in the distal radial and ulnar physes of elite gymnasts and often are bilateral (214,217,218,221,224,229,230 and 231). Stress injury of the distal radial physis also occurs in a significant percentage (up to 25%) of nonelite gymnasts (223,224). These lesions initially involve the volar aspect of the radial epiphysis and subsequently the entire physis. In about 20% of patients, similar changes are present in the distal ulnar physis. Similar changes involve the physes of the distal femur (226), proximal tibia (219), and distal fibula (226) in adolescent runners, and in the proximal ulna (222) and the proximal humerus in baseball pitchers (220,221) and racket sports (216). The changes are typically unilateral when they are associated with throwing or racket sports.

Signs and Symptoms

Patients describe pain localized to the site of the involved physis. Symptoms usually develop during training and become more intense as the workout progresses. Initially, the pain is relieved by rest. Clinical examination reveals painful limitation of extremes of motion at the affected site. Tenderness is localized to the line of the physis.

Radiographic Changes

Radiographs show evidence of widening of the physis and irregularity and sclerosis of the metaphysis without accompanying displacement of the epiphysis (Fig. 5-27). In patients with long-standing symptoms—implying continued activity—premature physeal arrest may occur (215,218,225). Growth arrest has not been described at sites other than the distal radius.

FIGURE 5-27. Stress injury of the physis. Persistent widening and irregularity of the distal radial physis in a 13-year-old female elite gymnast. A year earlier, right wrist pain resulted in radiographs that showed similar but less severe changes. Treatment consisting of cast and rest resulted in improvement of both pain and radiographic appearance. Return to competition resulted in present picture. Earlier radiographs of this patient were published in Ruggles DL, Peterson HA, Scott SG. Radial growth plate injury in a female gymnast. *Med Sci Sports Exerc* 1991;23:393–396; with permission.

MRI has suggested metaphyseal and epiphyseal ischemia of the physis (223) or metaphyseal injury (232).

Etiology

Most authors assume that these changes are due to repetitive shearing or compressive stresses, as might occur with vaulting or floor exercises. However, traction stress, as could occur with the uneven and parallel bars, is also possible, especially in gym- nasts who use dowel grips (231). Most gymnasts compete in all events. In skeletally immature athletes, the growth plate is weaker than the ligaments, joint capsules, and bone about the joint, so stresses are focused in the physis.

Compressive forces, both intermittent and sustained, have been shown to injure chondrocytes (227).

A single episode of stress or injury could result in occult microscopic fissures within the physis, which could, in time, proceed to widening of the physis and irregularity of the opposing bone margins of the metaphysis and epiphysis. Bright and colleagues (80) reported that histologic examination of the tibiae of rats loaded to 50% failure energy revealed internal cracks within the physis. These cracks appeared in all layers of the cartilage but were most common in the hypertrophic zone. Subsequent growth of the cartilage resulted in widening of the physis. Thus, the initial radiograph would be normal, but a subsequent radiograph 2 to 3 weeks later may demonstrate radiographic changes within the physis.

Treatment

The treatment of stress injuries is symptomatic and consists of reduction or temporary cessation of the activity that created the injury. It may take up to 6 months for the patient to become asymptomatic. An increased prevalence of ulnar positive variance in gymnasts can be attributed to premature closure of the distal radial physis. Surgical arrest of the distal radius and ulna has been used for bilateral irregular closure of the distal radial physis (215). There are no reports of bar excision for this problem.

Longitudinal Compression (Salter-Harris Type V)

The Salter-Harris type V classification (28,233,234,235,236,237,238,239,240,241,242,243,244 and 245) proposes that a single, sudden, longitudinal force applied to an immature bone can compress the physis sufficiently to kill the cartilage growth cells without causing fracture of adjacent trabecular or cortical bone. Radiographs at the time of injury do not show osseous abnormality. The diagnosis is suspected only months to years later, when growth arrest becomes manifest. Salter and Harris's original drawing shows partial arrest with subsequent angular deformity. Their illustrative case (28,29) does not include the initial normal radiographs but does show a healed proximal tibial fracture with many features of their type IV fracture (displacement and angulation of the medial condyle only).

Examples of this compression injury are rare in the literature. Most cases are recorded as part of a series with no individual details; there are a few case reports (233,234,235,236,238,245). When details of individual cases are given, invariably it is an associated nonphyseal fracture in the extremity that has been treated by immobilization, cast, or traction; thus, disuse and possible arterial impairment are also present. In addition, in all reports, the arrest was complete, not partial, as depicted by Salter and Harris, further implicating the possibility of disuse or arterial insufficiency.

Developmental Physeal Abnormalities

Deformities of the proximal tibia (Blount) (246,247) and distal radius (Madelung) (250,251) appear to result from gradually progressing physeal and epiphyseal abnormalities that may eventually result in partial physeal arrest (248). These conditions are never noted at birth, and the etiology is unknown.

A bracket epiphysis or delta phalanx may be noticeable at birth, is therefore most likely congenital, and responds well to excision of the physeal bar (252).

Preexisting bone deformity may predispose the patient to physeal fracture (249). In addition, premature physeal arrest may occur at any physis at any age with no apparent etiology (104), although this is rare.

Iatrogenic Injuries

Surgical Insults

In a sense, several of the above-mentioned “other physeal injuries,” such as those caused by cast application, traction, radiation, the prescribing of drugs (metabolic), and the use of laser can be considered iatrogenic, or physician induced. The ones discussed here (253,254,255,256,257,258,259,260,261,262,263,264,265,266,267,268,269,270,271,272,273 and 274) are primarily problems related to surgery. During the treatment of deformity, fracture, infection, or tumor, the physis may be damaged. Subperiosteal dissection extending to the perichondrial ring of Ranvier may result in premature closure of that area of the physis. It also may be impossible to avoid the physis during curettage of infected tissue or tumors, corrective osteotomy for malunion or deformity (261,265,270,274), or internal fixation of physeal fractures. Each of these procedures can damage a physis sufficiently to affect growth and should be avoided when possible. Injury of the periphery of a physis is more likely to result in physeal arrest than is an insult to its center (3).

Transphyseal Pins

Multiple factors determine whether the presence of a pin or pins across a physis will affect growth (256,271): the presence or absence of threads, the pin's obliquity to the physis, the pin's location in the physis (central or peripheral), the number and size of pins, and the amount of time the pin is left in place. Usually, a single, smooth, small pin perpendicular to the center of the physis, left in place a short time (e.g., 3 weeks), does not result in physeal closure. There are exceptions (Fig. 5-28). Of all of these factors, the presence of threads is most likely to result in physeal closure. The presence of a traction pin across, or even close to a physis, is sometimes associated with subsequent physeal closure, particularly in the proximal tibia (Fig. 5-29) (106,254). Whether the growth arrest is secondary to the pin or is an occult physeal injury associated with diaphyseal fracture is unknown.

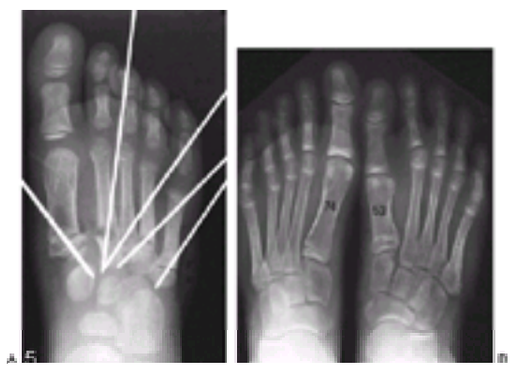

FIGURE 5-28. Physeal arrest from transphyseal pin. This boy with clubfoot was treated in infancy by serial casting. **A:** At age 4+5, he underwent osteotomy of all five metatarsals. The osteotomy of the first metatarsal was 1 cm distal to the proximal physis. The single, smooth 0.062 Kirschner wire was perpendicular to and in the center of the proximal physis of the first metatarsal. **B:** Eight years after surgery, the right proximal first metatarsal physis is closed; the length of the right first metatarsal is 53 mm, and the left metatarsal is 74 mm.

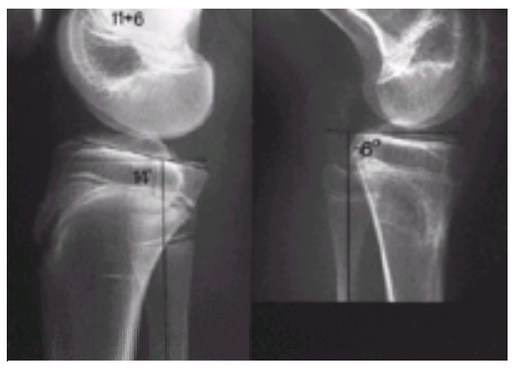

FIGURE 5-29. Physeal arrest from traction pin. This 11+6-year-old girl has developed left genu recurvatum following proximal tibial skeletal traction for a distal femur

fracture 3 years 6 months previously (age 8+0). Lateral x-ray studies of both knees showed that there is 20 degrees recurvatum of the left proximal tibia. There is a physeal bar of the left anterior tibial tubercle.

Staples

Staples are commonly used to retard longitudinal growth or to correct angular bone growth (255,263,273). If they are left in place too long, they can cause permanent arrest (257). Of equal concern is the occasional peripheral bar that forms after staple removal (Fig. 5-30) (264).

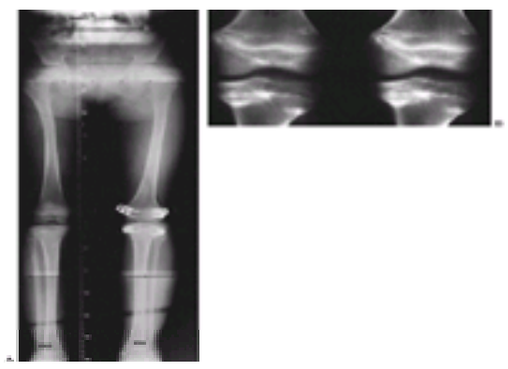

FIGURE 5-30. Physeal arrest associated with staple removal. **A:** Orthoroentgenogram. A 10+11-year-old girl with right spastic hemiparesis. Twenty-one months previously, staples were placed in the normal left distal femur and proximal tibia, resulting in overcorrection of 11 mm (the normal left lower extremity is 11 mm shorter than the right). The staples were removed at this time. **B:** Thirteen months later at age 12+0, there was progressive left genu varum relative shortening (the left lower extremity is now 23 mm shorter than the right). Two coronal tomograms of the left knee confirm physeal bars on the medial side of both the distal femur and the proximal tibia. Note increasing distance between the tracts from the tines of the staples on the lateral side of the distal femur and proximal tibia and no increase in this distance on the medial side. Note that the angles of the tine tracks laterally are parallel, and medially are converging. Also note growth arrest line of the distal femur, with growth present laterally and not medially. Therefore, these medial arrests had to occur at time of staple removal.

Other Iatrogenic Insults

Drilling across a physis is rarely done. The larger and more numerous the drill holes, the greater the likelihood of physeal arrest (259,260,262,269). However, drilling across the distal femoral and proximal tibial physes for anterior cruciate repair has not resulted in premature arrest (253,267,268), probably because the drill hole is filled with a substance (tendon or foreign material) that acts much like an interposition material used for bar excision. The mean growth of the proximal tibial physis of 24 children treated with an uncemented sliding tibial component that crossed the physis perpendicularly was 69% of that of the contralateral normal side (258).

PHYSEAL ARREST

Etiology

Premature complete physeal arrest produces bone-length retardation with no angular deformity (275,276,277,278,279,280 and 281). If the physis at each end of the bone is arrested, there is no growth at all.

Premature partial arrest of growth of a physis retards bone lengthening and may cause progressive angular deformity of the involved bone. The arrest is produced when bone forms from metaphysis to epiphysis, crossing the physis. This continuity of bone is known as a bone bar or a bone bridge. As the remaining physis grows, angular deformity occurs (Fig. 5-31). The site, size, location, and duration of the bar determine the clinical deformity. If the bar is located laterally in a physis—for example, the distal femur—the normal physis medially continues to grow, producing genu valgum deformity (278,279,280 and 281). If the bone bar is anterior, the normal physis grows posteriorly, producing genu recurvatum (Fig. 5-29) (254). If the bar is central, the periphery may grow, causing cupping, tenting, or dip deformity of the metaphysis, combined with relative shortening of the bone but little, if any, angular deformity (Fig. 5-21B and Fig. 5-23) (167,260,275,276).

FIGURE 5-31. Physeal arrest following transphyseal fracture. **Left:** A 3+7-year-old boy sustained a Salter–Harris IV fracture of the distal tibia with proximal displacement of the medial malleolar fragment. Treatment was cast immobilization without reduction. **Right:** Same child 22 months later (age 5+5). Note physeal bar medially, growth arrest line perpendicular to longitudinal axis of the tibia, asymmetric growth of remaining normal physis, producing a 45-degree varus angulation of the physis, and adaptive contouring of the lateral edge of the tibial epiphysis, allowing ankle varus to be less than the physeal varus. There is normal growth of the fibula (not overgrowth). The cartilaginous medial malleolus is unossified. Long-term follow-up of this case has been published in Peterson HA. Operative correction of post-fracture arrest of the epiphyseal plate: case report with 10-year follow-up. *J Bone Joint Surg Am* 1980;62:1018–1020; with permission.

Bone bars may result after any injury to physeal cells. The most common cause is fracture, although bars may occur after other types of physeal damage [e.g., disuse, radiation, infection, tumors, vascular abnormalities; iatrogenic injuries (see previous section)]. For some bone bars, no etiology is apparent; these have been called congenital or developmental (e.g., from Blount-Barber syndrome). However, bone bars have never been reported at birth.

Any fracture that involves the physis may result in a bone bar. Posttraumatic bars result from damage to the germinal or palisading layer of physeal cells. The physeal cell damage probably occurs at the time of injury, but it may occur during fracture reduction (closed or open), or it may be associated with internal fixation. Bone bars can be anticipated after comminuted type IV and VI injuries and, if they are followed closely, they can be detected as early as a few weeks after the injury. Some bone bars do not become clinically evident until years after the injury, underscoring the need to follow any significant physeal injury for years, if not until maturity. This is particularly true after metaphyseal osteomyelitis (Fig. 5-21).

Anatomic Factors

Anatomic differences in the various physes also are important in the production of a bone bar. Factors include the size of the physis, its rate of growth, and the

contours of the physis (that is, whether the physis lies on one plane or is irregular). Although physes of the phalanges and distal radius are by far the most frequently injured (33,36,38), they are small and uniplanar, and are an uncommon site of a bone bar. In contrast, the physes of the proximal tibia and distal femur are large and irregular in contour (multiplanar), and account for 60% to 70% of the growth of their respective bones. Together, they account for only 2.2% of all physeal injuries (Table 5-2) (36,38,281), but they are responsible for 50% of the bone bars requiring treatment (Table 5-3).

	No.	%

TABLE 5-3. PHYSEAL BRIDGE RESECTION

Influence of Age

The patient's age at the time of physeal injury is perhaps the paramount factor. Injury of the physis of a 14- or 15-year-old girl or a 16- or 17-year-old boy is of little consequence because they have so little growth remaining that deformity is unlikely to become clinically manifest. Any bone bar in an infant or young child, however, is a significant problem with wide-ranging clinical effects. Long clinical follow-up is mandatory in these children.

Assessment

Clinical Examination

Bone bars are usually first noted clinically because of the angular deformity or relative shortening of the involved extremity (282,283,284,285,286,287,288,289,290,291,292,293,294,295,296,297,298,299,300,301,302,303, 304,305,306,307,308,309,310 and 311). The history, physical examination, and routine radiographs localize the involved physis. Clinical evaluation of limb-length discrepancy, angular deformity, joint motion, and functional impairment should be recorded. Radiographs of the appropriate body area must be taken in at least two planes, usually coronal and sagittal. The relation of the growth-arrest line, the physis, and the joint surface needs close scrutiny (Fig. 5-31) (50,295,302,303). Much can be learned from good-quality plain radiographs. Depending on these findings, additional studies become appropriate.

Imaging Studies

Skeletal Age

Skeletal age must be determined in older children to assess the potential for remaining growth. There must be enough growth remaining (2 years or 2 cm) to make the option of bar excision worthwhile. Comparison of a radiograph of the hand with an atlas is the most commonly used (291,309).

Leg-Length Measurements

Both the involved and the uninvolved extremity are measured clinically, and the lengths are documented by radiographs. Three radiographic methods are in common use: teleoroentgenography, orthoroentgenography, and scanography.

A teleoroentgenogram (293) is a single radiograph taken from a distance great enough (usually 6 feet) to reduce magnification and to include all long bones of each extremity. It has the disadvantage of magnification, which increases as the child grows, making serial evaluation less precise.

An orthoroentgenogram (290) is a multiple-exposure radiograph designed to obtain a straight projection through each joint of the extremity to obviate magnification. It has the disadvantage of recording an incorrect length if the child moves between exposures. Additional films are necessary to assess alignment.

A scanogram (308) uses an x-ray tube in linear motion with a slit diaphragm. Any movement by the patient is detected by motion. It includes all osseous structures so that any angular deformity or bone abnormality can be detected (Fig. 5-22B). There is no magnification. The film can be measured directly with a tape measure, and thus can be remeasured if there is any discrepancy with the clinical findings. These true measurements may be compared with previous and future scanograms in longitudinal studies. The quality of film detail is sufficient so that no additional coronal view is necessary to assess alignment; this reduces expense. Scanograms are superior to other methods, with the only disadvantage being the modification of radiographic equipment (306,308) (Fig. 5-15A and Fig. 5-30A).

Scanograms, having no magnification, become even more valuable when analyzing growth between two metal markers after treatment (Fig. 5-22B,Fig. 5-32A,Fig. 5-32B and Fig. 5-33A,Fig. 5-33D,Fig. 5-33H) and make more elaborate techniques such as stereophotogrammetry (286) unnecessary.

FIGURE 5-32. Metal markers using Kirschner wires. **A:** Close-up of a scanogram 5 months after bar excision and insertion of Cranioplast in a girl, now age 5+4, whose preoperative radiographs are shown in Figure 5-21. The physis is open, and the two metal markers inserted at the time of bar excision are now 28 mm apart. The Cranioplast plug is close to the proximal marker and to the physis. **B:** Close-up of scanogram 4 years postoperatively. Both femora had grown 9.8 cm; thus, growth of this femur is 100% of the contralateral femur. The metal markers are 83 mm apart, indicating 55 mm of growth from the distal femur since **A**. The use of the scanogram obviates any magnification of distances between markers. Angulation between the Kirschner wires is unchanged. The femoral shaft–femoral condyle angle has improved from 63 degrees to 64 degrees. Note that the plug initially stayed with the epiphysis, as evidenced by the increased distance of the plug from the proximal metal marker (compare with **A**). Later, the epiphysis grew away from the plug, as evidenced by the increased distance of the plug from the distal marker (compare with **A**). The ultimate distance between the markers was 110 mm. This case was illustrated more completely in Peterson HA. Partial growth plate arrest and its treatment. *J Pediatr Orthop* 1984;4:246–258, with permission.

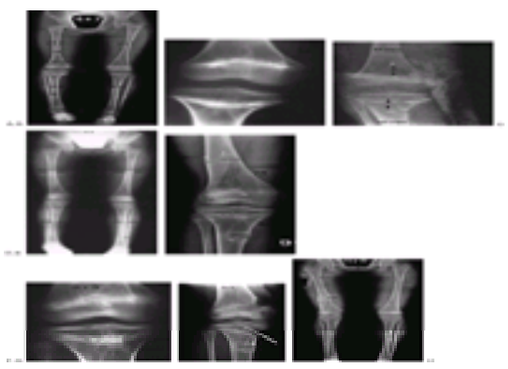

FIGURE 5-33. Bar recurrence successfully treated by bar reexcision. **A:** Scanogram of a girl age 4+7 who had a febrile illness with swelling of the right knee in infancy. The right leg is 35 mm shorter than the left (femur -19 mm, tibia -16 mm). **B:** Coronal tomogram depicts bars of both distal femur and proximal tibia. **C:** At the time of excision of bars and insertion of Cranioplast at both sites, metal markers (half of a silver vascular clip) were inserted in the center, longitudinal to each other. The distance between the femoral markers is 17 mm and between the tibial markers 18 mm. A third marker in the distal femur was inserted too far peripheral, laterally, thereby decreasing its value for measuring future longitudinal growth. With growth and bone remodeling, it became extraosseous, negating its value as a marker. At the time of surgery, a marker was also placed in the mid left contralateral normal tibia, which provided useful information in assessing growth and recurrence later. Scanograms at 6 months showed the right leg to grow faster than the left leg (2 years 3 months postoperatively, the leg-length discrepancy had decreased from 35 to 23 mm, and the growth of the right leg was 121% of the normal left). Subsequently, there was progressively less growth. **D:** Scanogram 4 years 8 months postoperatively (age 9+3) shows continued growth of both operative areas (metal markers farther apart) but with a progressive reduction in the rate. During the previous 6 months, the right femur grew 15 mm, the left 17 mm, 88%; the right tibia 12 mm, the left 14 mm, 86% for this interval. Overall growth of the right leg since surgery is now 102% of the uninjured left leg. **E:** Close-up of **D** shows femoral markers 78 mm and tibial markers 52 mm apart (total growth 95 mm). The Cranioplast plugs stayed in the metaphyses. They did not migrate; rather, the epiphyses grew away from them. Although the metal markers in the proximal tibia were continuing to become farther apart, much of the growth of the tibia was distally, as determined by comparison with the metal marker in the normal mid–left tibia. This caused suspicion of a developing recurrent bar. The lateral peripheral marker in the femur (*arrow*) is now nearly extracortical because of diaphyseal remodeling. **F:** Coronal tomogram confirms recurrent bar formation in both the tibia and femur. Note diminished cupping compared with Figure 5-33B. **G:** Repeat bar excision of both the proximal tibia and distal femur was performed at 9+5 years. Note clear visualization of remaining physes of both bones. **H:** Scanogram at age 11+8 years, 7 years after first surgery. The femoral markers are 109 mm apart, and the tibial markers are 72 mm apart. All physes are closed. There has been no surgery on the left leg and no osteotomies or lengthening on the right leg. The right leg is 26 mm shorter than the left (femur -15 mm, tibia -11 mm). Growth of the right femur from the time of original surgery was 14.5 cm on the right, 14.1 cm on the left (the operated right femur grew 103% compared with the normal left). The operated right tibia grew 12.3 cm, and the left tibia grew 11.8 cm (the right tibia grew 104% compared with the left). An orthoroentgenogram sent from home at age 12+10 showed that the total leg-length discrepancy was 21 mm (compared with 35 mm preoperatively). All physes were closed, and no further treatment was recommended. There was no surgery on the normal left leg. This case illustrates the need to follow patients continuously (6-month intervals) until maturity because bar formation can recur at any time. Scanograms are indispensable for accurate measurement of both total bone length and distance between markers. Placement of a metal marker in the contralateral unoperated bone is the only way to determine accurately the relative growth of the operated physis and its ipsilateral physis (same bone, other end) compared with the two physes of the contralateral bone. The bar recurrence was successfully treated by bar reexcision. At completion of growth, growth of the operated right leg exceeded growth of the normal left leg by 14 mm. This case was illustrated in Peterson HA. Partial growth plate arrest and its treatment. In Morrissy RT, ed. *Lovell and Winter's pediatric orthopaedics,* 3rd ed. JB Lippincott, Philadelphia, 1990:1071–1089.

Additional methods of documenting bone length, including CT scan, MRI, and microdose digital radiography (282,306), are not commonly used because of their cost, poor osseous detail, or alteration of length (too long or too short) on the film, requiring the technician to determine loci for measuring the length at the time of film procurement (306). Usually, films by these techniques cannot be measured directly by ruler.

Localization of the Bar

A documenting image (map) of the location, area, and contours of the bar is essential in determining the feasibility of bar excision and the surgical approach. Several methods are available, including tomography, CT, scintigraphy, and MRI.

Tomography. Until recently, tomography was the most commonly used method of evaluating the location, extent, and contours of the bar. Tomographic techniques include linear, circular, ellipsoidal, spiral, and hypocycloidal (306). The latter two are termed multiplanar (Fig. 5-34). False-positive and false-negative findings have been reported with standard uniplanar tomography. Thin (1-mm) multiplanar tomograms taken every third millimeter in two planes, usually the coronal and sagittal, are used to construct a map of the physis as if it were laid out on a flat surface (287). The contours and area of both the bar and the entire physis can then be determined. Because of the multiple views required, the amount of radiation exposure is high (289) and the mapping is time-consuming and subject to interpretation errors.

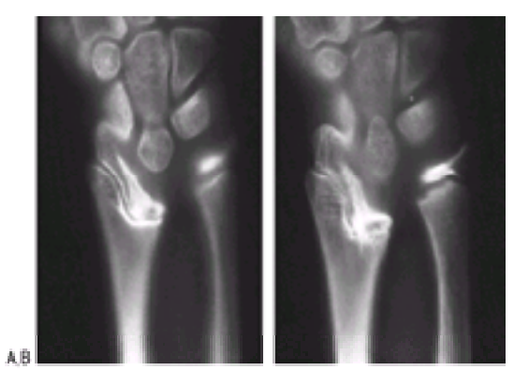

FIGURE 5-34. Physeal arrest visualized by tomography. **A:** An 11+4-year-old boy sustained a type V fracture of the distal radius 3 years earlier. This coronal 1-mm-thick trispiral tomogram shows significant deformity and growth alteration, but no physeal bar. **B:** A cut 3 mm away reveals a large physeal bar. It is difficult to envision a transverse CT scan in any plane that would add information about the location, size, or contours of this bar. (From Peterson HA. Partial growth plate arrest. In: Morrissy RT, ed. *Lovell and Winter's pediatric orthopaedics,* 3rd ed. JB Lippincott, Philadelphia, 1990:1071–1089; with permission.)

CT Imaging. CT images are difficult to make in coronal and sagittal projections because of difficulty placing the body part in the gantry. When possible, CT scans in an axial projection show the bridge, although less clearly than multiplanar tomograms (Fig. 5-35). The cuts are thicker and fewer in number, making map determination less precise than with multiplanar tomography. CT scans made in the transverse plane are difficult to interpret because of normal undulations of the physis, with increased contour irregularity produced by the bar and its accompanying physeal contour abnormality. The entire physis can rarely, if ever, be captured on one cut. The adjacent normal juxtaphyseal bone sclerosis can easily mimic a bony bridge. In the 1980s, CT scanning had no advantage over multiplanar tomography or MRI and were sometimes misleading (288,301,307,310,311). The recent advent of helical computed tomography has significantly improved the images so that they are now superior to tomography and rival MR imaging (299).

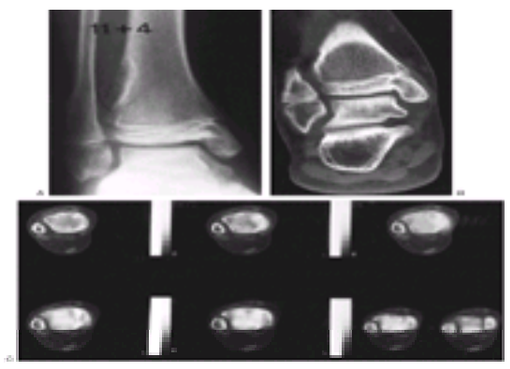

FIGURE 5-35. Physeal arrest visualized by CT scans. **A:** Plain radiograph of an 11+4-year-old boy 4 months after an undisplaced type V fracture illustrates a medial bar. The growth arrest line is wider laterally. **B:** Tangential coronal views of the ankle obtained by flexing the knee maximally in the gantry. This CT scan gives no additional information compared with the plain radiograph or tomograms. **C:** Transverse CT scan through the distal tibia. The physis is not visualized on any cut. The physis and bar are poorly defined despite the fact that this should be an ideal situation (a relatively even-contoured physis with minimal deformity caused by the bar). (From Peterson HA. Partial growth plate arrest. In: Morrissy RT, ed. *Lovell and Winter's pediatric orthopaedics,* 3rd ed. JB Lippincott, Philadelphia, 1990:1071–1089.)

Scintigraphy. Scintigraphy, using technetium, a pinhole collimator, and a gamma camera aimed axially toward the epiphysis, has been used to assess physeal bars (286,294). It can be used only when there is no bone intervening between the epiphysis and the camera—for example, the distal femur with the knee flexed. All other physes would have intervening bone, making the technique inapplicable. The computer-generated maps are imprecise (306).

Magnetic Resonance Imaging. Adaptation of MRI for evaluation of physeal bars (301,307,310,314,315,322) has several advantages. The images are of excellent quality, and there is no radiation (as for tomograms and CT scans). Acquisition time averages 8 minutes, and sedation is usually not necessary. Thin cuts can be assembled contiguously in any plane from the original computerized data. These produce images clearer than reconstructed CT images. The data can be processed to depict the entire physis (and its bar) on one plane, despite contour irregularities caused by the bar. This precludes the laborious and less accurate mapping (287) (which can also be done on the multiple-cut MRI images). Two computerized techniques are available.

Three-Dimensional Rendering. A computer-generated illustration is formed by loading sagittal or coronal images from an orthogonal series into a computer work-station that contains rendering software (the program ANALYZE is an example) (283). Each image is processed (rendered) manually by the technician, defining the physis (this may take several hours of technician time). The rest of the image (bone and all soft tissue) is then discarded. A series of sectional images of the physis is produced. The computer combines successive images into a three-dimensional model. When this three-dimensional model is viewed in an axial plane, the result is a physeal map with a defect corresponding to the physeal bar (Fig. 5-12C). The computer can determine the number of pixels in the entire physis and in the bar, so that the bar can be calculated as a percentage of the entire physis (Fig. 5-11C).

Three-Dimensional Projection. A computer-generated image can also be formed from a fat-suppressed three-dimensional volume acquisition in the axial plane (283,304) (Fig. 5-36). Slice thickness may be as thin as 0.7 mm (skip 0, up to 60 slices total). This three-dimensional information is processed on the MRI console, using maximum-intensity projection image-analysis software used in MR angiography (standard software for all institutions performing MR angiography). No manual segmentation of the physis is required. The clarity of the result is improved by excluding surrounding soft tissues from this projection volume. The result is a true anatomic image based on volume data (voxels), depicting only the physis and the physeal bar, and does not depend on a technician rendering each image. Technician time is needed only to outline the periphery of the physis and of the bar with a computer mouse.

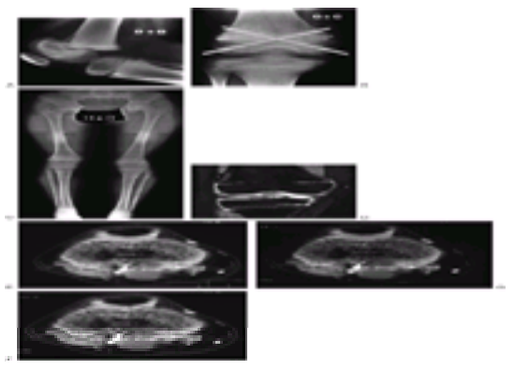

FIGURE 5-36. Physeal arrest visualized by MRI. An 8-year-8-month-old-boy injured his right knee jumping on a trampoline. **A:** He sustained a displaced type III fracture. **B:** Treatment was closed reduction and percutaneous pinning. **C:** Two years 4 months later (age 11+0), the right femur was 32 mm shorter than the left and there was absence of the central portion of the distal physis. Note growth arrest lines on the proximal and distal tibia and the distal left femur but not the distal right femur. **D:** Coronal MR image shows what appears to be multiple central physeal bars. **E:** Projection MRI shows the distal femur and patella cartilage (gray) and central bone (black). This volume acquisition obviates contour abnormalities of the physis and depicts structures as a flat single plane surface. This is not a transverse cut. Thus, it is not necessary to determine the precise longitudinal level (as for a CT scan). The dense white images are vascular structures. **F:** The technician has outlined the entire physis with a computer mouse (*white line*). This technique is much more sensitive than other techniques, and the bars have been found to be much more irregular than had been previously thought. The irregularity of these two bars accounts for the appearance of multiple bars on the coronal MR images (**D**). **G:** The technician has outlined the medial bar with the computer mouse. The number of voxels in the bar compared with the entire physis is 6.3%. The lateral bar measured 3.6% for a total bar of 9.9%. Note position of the bars compared with position of the crossed pins on Figure 5-35B.

In comparing three-dimensional renderings and three-dimensional projections, the results were similar but were more precise using three-dimensional projection. Three-dimensional projections are less expensive because technician interpretation and special software are unnecessary. In all patients who underwent surgery, the bar found surgically, matched the illustration on the image.

We have found the projection method to be the most reliable, safe, cost-effective, and least time-consuming method, and we now use it exclusively for physeal bar evaluation (304).

Management

Complete Arrest

Premature complete closure of a physis causes cessation of growth at that physis (312,313,314,315,316,317,318,319,320,321,322,323,324,325,326,327,328,329,330,331,332,333, 334,335,336,337,338,339,340,341,342,343,344,345 and 346). Because the physis is completely closed, there is no progressive angular deformity. Continuing growth of the contralateral physis produces length inequality between the two bones involved. The amount of inequality is determined by the physis injured (specifically, its contribution to the growth of that bone) and the patient's age at the time of growth cessation. In older children with little growth remaining, no treatment is required. In younger children, consideration for treatment depends on the specific physis injured and the amount of length discrepancy calculated to be present at maturity. Treatment options include a shoe-lift for lower limb discrepancy, physeal arrest of the contralateral or companion (radius/ulna or tibia/fibula) bone, ipsilateral bone lengthening, contralateral bone shortening, or a combination. Because no physis remains, bar excision and physeal distraction are not options.

Upper Extremity Physes

Complete arrest of the proximal humerus physis rarely results in sufficient discrepancy to produce functional impairment. If the discrepancy exceeds 6 cm, bone lengthening may be considered (142). The contralateral humerus should never be arrested or shortened.

Complete arrest of the physes of the proximal radius or ulna likewise never causes sufficient forearm length discrepancy to consider physeal arrest of the contralateral forearm. Arrest of the distal radial physis at a very early age could cause sufficient distal radial–ulnar variance to consider arrest of the distal ulnar physis, ulnar shortening, or even radial lengthening. Because much greater length occurs from the distal ends of these bones than from the proximal ends, postinjury arrest of the distal end of either is often treated by surgical arrest of the other or by lengthening of the involved bone.

Lower Extremity Physes

In the lower extremities, limb-length inequality causes pelvic tilt and spine curvature, which predispose the patient to low back pain. Arrest of the capital femoral physis at a young age (e.g., from hip dysplasia, Perthes' disease, trauma, avascular necrosis, or even slipped capital epiphysis) can result in significant femoral length discrepancy. Surgical arrest of the contralateral capital femoral physis is not warranted because of its surgical inaccessibility and potential for avascular necrosis. It would be more appropriate to have the patient wear a shoe-lift, arrest the contralateral distal femoral physis at a later date, or lengthen the ipsilateral femur at times determined by growth charts or at maturity.

Complete premature arrest of a distal femoral physis can be treated by permanent use of a shoe-lift, physeal arrest of the contralateral femoral physis, femoral lengthening, or contralateral femoral shortening at maturity. The choice depends on the degree of calculated discrepancy at maturity and the body height and desires of the patient.

Complete arrest of the proximal or distal tibial physis can be treated similarly to the distal femur, with the addition of physeal arrest of the ipsilateral fibula if significant relative overgrowth of the fibula is likely. Contralateral tibial shortening should never be undertaken as an elective procedure, because any significant surgical tibial shortening will result in weakness of the anterior tibialis muscle and footdrop.

Partial Arrest

Treatment Alternatives

Premature partial closure of the physis can be treated in many ways (280,331,332 and 333). If the patient is a teenager approaching maturity and little growth remains in the involved physis, no treatment may be necessary. If the patient is young with significant growth remaining, both length discrepancy and angular deformity may occur. Management may require a combination of modalities.

1. Shoe-lift. This is applicable when a lower extremity bar is central and causes no angular deformity and the leg-length discrepancy is expected to be minor at maturity (2.5 cm or less). This is the only effective nonoperative treatment and was used extensively for centuries before the advent of modern surgery.
2. Arrest of the remaining growth of the injured physis. This should be considered in an older child with a beginning or progressive angular deformity when limb-length inequality will be minor (lower extremity) or of relatively little functional consequence (upper extremity).
3. Arrest of the remaining growth of the injured physis and the physis of the adjacent bone (forearm and lower leg).
4. Arrest of the remaining growth of the injured physis, the physis of the adjacent bone if one is present, and the corresponding physis or physes of the contralateral bone or bones.
5. Open or closed wedge osteotomy to correct angular deformity without operative arrest of the remaining normal physis (336,337,346). In a young patient, the untreated bone bar would reproduce angular deformity after osteotomy. Osteotomy can be repeated several times before attainment of full growth if this method is used alone. Some final relative shortening of the involved bone should be expected.
6. Lengthening of the involved bone.
7. Shortening of the contralateral or companion (ulna or fibula) bone.
8. Excision of the physeal bar and insertion of an interposition material (see later).
9. Fracture of the bone bar by physeal distraction using an external distractor, with or without excising the bar (316,317,318,325,330,334). This has been done successfully on small bars in optimal locations. The procedure can be combined with correction of both angulation and length discrepancy, but it should be done only in older children nearing maturity because the procedure is likely to result in complete closure of the physis (312,321).
10. Transplantation of an epiphysis and physis from another bone to fill the defect following resection of a bar. Many experiments using various strategies have been performed, with varying success (313,314,315,319,320,322,323,326,327,328,329,335,338,339,340,341,342,343,344 and 345) In humans, in addition to problems of vascularity, growth, and tissue rejection, a major obstacle is the availability of a suitable, dispensable donor physis. With ongoing advances in microvascular techniques and tissue rejection problems, this method might be considered in the future, but is now not clinically applicable.
11. Combinations of the above-mentioned procedures. It is unusual for a patient to be treated optimally with only one of the above-mentioned modalities. Even when bar excision allows several inches of longitudinal growth, some other modality, such as a shoe-lift, closure of the contralateral physis, or osteotomy to correct angular deformity, is often beneficial.

Functional Considerations

Leg-length discrepancy of 2.5 cm or less usually causes little, if any, functional impairment or low back pain and can be left untreated, or a shoe-lift can be used on the short side. Leg-length discrepancy anticipated to be 2.5 to 5 cm at maturity can be managed by arrest of growth of the contralateral bone if the child has sufficient growth remaining to correct the discrepancy. Bone shortening on the contralateral side may be considered if all physes are closed or the child is nearing maturity. Bone shortening should be considered only for the femur, because shortening of the tibia is usually accompanied by uncorrectable muscle weakness, especially of foot dorsiflexion. Lengthening of the femur or tibia, or repeated lengthenings, may be considered for discrepancies of 4 to 5 cm or more. The patient's anticipated height at maturity is a factor in all of these instances.

Arm-length discrepancy results in functional impairment only when the discrepancy is extreme. Discrepancies of 10 cm or less are best left untreated. Surgical shortening of the contralateral upper extremity has never been reported and, to the author's knowledge, has no application. Lengthening of the humerus (142) and forearm has been reported but carries potential morbidity and should be done only by surgeons with experience in the procedure.

All of the above-mentioned treatment options have been used in the management of physeal bars and should always be considered. However, excision of the bar, when successful, may negate the need for the other modalities and their potential morbidity. If excision is unsuccessful, the other options can still be used.

Treatment by Bar Excision

Experimental Studies

In animal studies, several investigators created a physeal bar, allowed the bar to develop, excised the bar and inserted an interposition material, and then sacrificed the animal to observe the result (347,348,349,350,351,352,353,354,355 and 356). Although the results have varied, there has been enough success to confirm that a bar can be successfully excised and growth reestablished. Interposition materials used include bone wax, fat, cartilage, silicone rubber, and polymethylmethacrylate. When no interposition material was inserted, a bone bar promptly reformed (269,356). Because of variables in the experiments, it is difficult to determine superiority of one interposition material over another.

Because cartilage is the damaged tissue, cartilage would seem to be the ideal interposition material. Possible sources of cartilage are another physis, an apophysis such as the iliac crest, and a laboratory-procured chondrocyte allograft transplant (347,352,353 and 354). There are technical difficulties procuring and inserting another physis. Apophyseal cartilage may not have the same growth potential as epiphyseal cartilage. Chondrocyte allograft transplants require initial cartilage procurement, followed by laboratory time for the cartilage matrix to develop. Immune response problems might occur if the material is transferred from one human to another. Nevertheless, as cartilage is the damaged tissue, cartilage would be the ideal interposition material. It is hoped that more investigations will solve this

problem in the near future.

A load-sharing interposition material, such as polymethylmethacrylate, may be superior in resection of large bars in weight-bearing areas (351).

A study in rabbits (356) suggested that re-formation of a bar after excision can be inhibited by the use of oral indomethacin without the use of an interposition material. Indomethacin produces a nonspecific inhibition of osteoblastic activity that is triggered by fracture or postoperative inflammation. No clinical trial using oral indomethacin in conjunction with bar excision in humans has been reported. Whether indomethacin can be given in sufficient doses in humans to prevent the bone bar from re-forming without inhibiting normal bone growth remains to be seen.

Clinical Experience (357,358,359,360,361,362,363,364,365,366,367,368,369,370,371,372,373,374,375,376,377,378, 379,380,381,382,383,384 and 385)

The first bone bar in a human was reported in 1967 by Langenskiöld (374), who described a 15-year-old boy with genu recurvatum secondary to a bone bar in the anterior proximal tibia; the etiology was unknown. The bone bar was excised, and the space was filled with autogenous fat. During the 1.5-year follow-up, the angle of genu recurvatum improved by 10 degrees, but there was no documentation of longitudinal growth.

Longitudinal growth was first documented in the distal tibia of a 5-year-old boy in 1968 (381). During a 10-year follow-up, the involved tibia grew 16.7 cm. Sheet Silastic and Gelfoam were used as interposition materials.

Interposition Materials

Fat (361,368,369,371,372,373,374,384,385), bone wax and fat (212,252), Silastic (349,350,360,365,384), methylmethacrylate (375,376), and Cranioplast (331,332,333,367,377,378,379,380 and 381) are the most popular interposition materials, but too few patients have been followed to maturity to determine superiority of one interposition material over the others.

Fat has the distinct advantage of being autogenous. Langenskiöld used buttock fat because of its more firm and globular consistency. Fat has the disadvantage of a lack of hemostasis in the resected cavity. When the tourniquet is released, fat tends to float out of the cavity. Closing periosteum over the cavity to contain the fat predisposes the patient to new bone formation peripherally. This is undesirable because it tends to tether growth again. The operative defect weakens the structure of the bone, and a cast is used to protect a weight-bearing bone from fracture (385). When fat grafts work well, the intraoperative cavity enlarges as the bone (and fat graft) grow (368,369). Postoperative fracture has been reported (368).

Silastic (1,349,350,360,365,384) has many properties similar to Cranioplast but has not been used since its withdrawal from commercial markets by Dow Corning in 1987.

AUTHOR'S PREFERRED TECHNIQUE OF TREATMENT

The objectives of surgical excision of a bone bar are to remove the bar completely and to preserve as much of the normal remaining physis as possible. This requires knowledge of surgical anatomy (358) and careful preoperative evaluation and planning. The excision may be difficult if the bar is irregular or the epiphyseal/metaphyseal complex is deformed (Fig. 5-34).

THE AUTHOR'S CLASSIFICATION

In 1984, I grouped physeal bars into one of three types based on location and contour: (a) peripheral, (b) elongated, and (c) central (333). Subsequently, Bright (1) and Ogden (3) classified these as types I, II, and III, although they used the terms linear or longitudinal instead of elongated.

Preferred Surgical Approaches

I approach peripherally located bars directly from the periphery (Fig. 5-37). I am careful to excise the periosteum overlying the bar to prevent subsequent bar re-formation. Under direct vision, the bar can then be removed ntil normal physis is visible on all sides of the cavity (Fig. 5-37B). I find that optical loupes are helpful and ordinary surgical light is satisfactory. The bone bar is then removed initially using an osteotome, curet, and rongeur. The final exposure of the normal physis is done more precisely with a motorized bur. This allows excellent visualization of the physis and removal of as little metaphyseal bone as necessary, and facilitates contouring of the cavity in the physis. The heat generated by the bur has no apparent deleterious effect on the viability of the remaining physis.

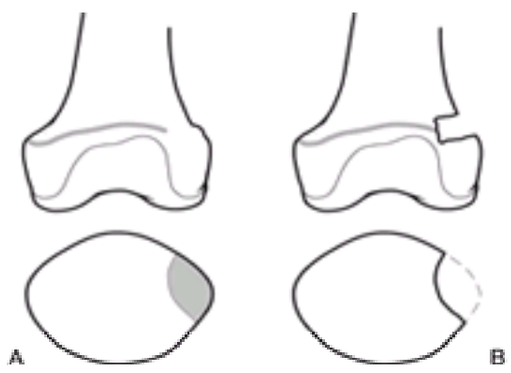

FIGURE 5-37. Peripheral bar shown in AP view (above), transverse section through physis (below). **A:** With map of bar composed from MRI. **B:** Bar exposed by direct approach. (Redrawn from Peterson HA. Partial growth plate arrest and its treatment. *J Pediatr Orthop* 1984;4:246–258; with permission.)

An elongated, linear, or longitudinal, bar extends completely across the physis and is common after Salter–Harris IV fracture (Fig. 5-38A,Fig. 5-38B,Fig. 5-38C). I first carefully evaluate these bars with MRI maps to determine the surgical approach and to ensure complete removal of the bar. Headlamp light to illuminate the depth of the excision is beneficial and is preferable to optic loupes.

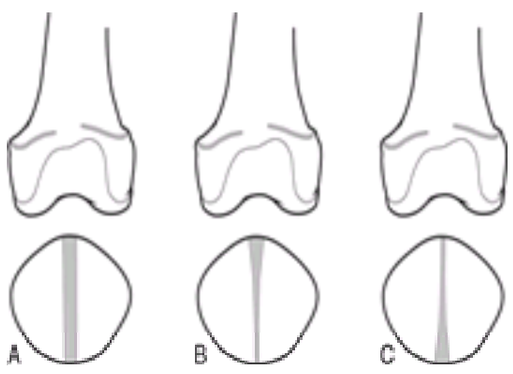

FIGURE 5-38. Elongated bar extending from anterior to posterior surfaces. Although these three bars have the same appearance as the anteroposterior view (above), they have different contours and areas on transverse orientations (below). To achieve complete bar removal with retention of as much normal physis as possible, the

bar in **B** would be optimally approached posteriorly, and that in panel **C** anteriorly. (Redrawn from Peterson HA. Partial growth plate arrest and its treatment. *J Pediatr Orthop* 1984;4:246–258; with permission.)

Centrally located bars have normal physis peripherally and an intact perichondrial ring of Ranvier (Fig. 5-39A). I almost always approach these bars through the metaphysis by removing a window of cortical bone and cancellous metaphyseal bone to expose the bar from inside out (Fig. 5-40; Fig. 5-39B). This preserves the perichondrial ring of Ranvier. Again, headlamp light here is extremely helpful. After removal of the entire bar, I am careful to inspect normal physis circumferentially in the cavity. I have found that using a small (5 mm in diameter) dental mirror (Fig. 5-39C) makes this easier.

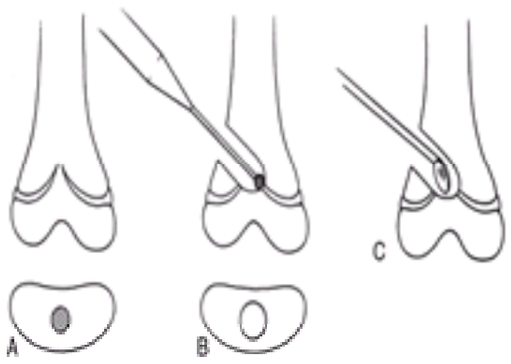

FIGURE 5-39. Central bar as seen anteroposteriorly (above) and transversely (below). **A:** Bar in center with growth peripherally results in cupping or tenting of the physis. **B:** Excision of central bar through window in metaphysis. **C:** Visualization of the entire physis using a dental mirror. (From Peterson HA. Partial growth plate arrest and its treatment. *J Pediatr Orthop* 1984;4:246–258; with permission.)

FIGURE 5-40. AP radiograph of distal femur of an 11+0-year-old boy taken at time of bar excision to document desired depth of bur, removal of bar, and presence of remaining normal physis. Previous radiographs of this patient are shown in Figure 5-36.

Other authors have reported modifications of this basic technique. Some use an operating microscope to aid visualization of the bar (212,252,370,371,373). Ultraviolet visualization of tetracycline-labeled bone in rabbits has been reported to allow complete excision of experimentally created physeal arrests while minimizing excision of normal physis (382). I have not found these modifications to be necessary and have no personal experience with them.

The Final Cavity

I always try to make the sides of the cavity flat and smooth (Fig. 5-41A). Enlarging the cavity in the epiphysis may encourage the interposition material to remain across the physis, but I have not found this feature to enhance results (Fig. 5-41B). Care must be taken not to weaken the epiphysis, predisposing it to fracture. I do not undermine the metaphyseal and epiphyseal bone away from the physis, as advocated by Ogden (Fig. 5-41C) (3). I am concerned that the protruding physis would be deprived of its blood supply and more of the physis would have been removed than necessary.

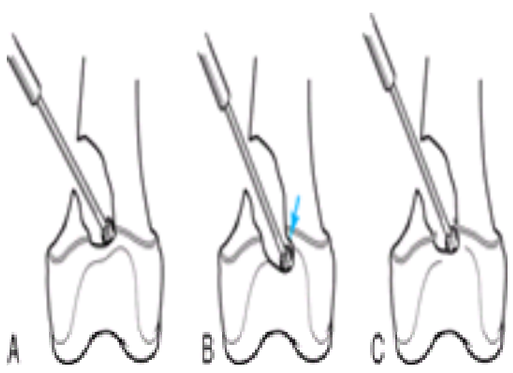

FIGURE 5-41. Contour of cavity. **A:** As normal physis is exposed, a smooth surface helps to identify and visualize the physis. **B:** Bone of the epiphysis may be undermined in an attempt to allow the plug to stay with the epiphysis as the bone grows in length. If this is done, a small rim of epiphyseal bone (*arrow*) should be preserved to maintain viability of the physis. **C:** Undermining bone away from the physis may improve visualization of the physis but will deprive it of its blood supply. (Redrawn from Peterson HA. Partial growth plate arrest and its treatment. *J Pediatr Orthop* 1984;4:246–258; with permission.)

Metal Markers

I place metal markers in the metaphysis and the epiphysis to allow accurate radiographic measurement of subsequent growth (Fig. 5-42). These metal markers in the metaphysis and the epiphysis also help differentiate overgrowth of the physis at the other end of the bone, which may falsely enhance the result. I try to place these markers carefully in cancellous bone, not in contact with the cavity, because they might become attached to the interposition material, or if fat is used, they might migrate into the cavity. I am also sure to place them in the same longitudinal plane proximally and distally to the defect. A position in the center of the bone is preferable because eccentric markers may become extraosseous due to growth and metaphyseal remodeling. Any metal marker will do; half of a vascular clip, stainless steel, or silver was commonly used in early cases. Transversely oriented Kirschner wires (K-wires) parallel with each other and with the physis, one in the metaphysis and one in the epiphysis, allow accurate assessment of angular growth (Fig. 5-32). Titanium Kirschner wires avoid artifact on subsequent MRI evaluation. At present, 10-mm lengths of Titanium 0.062 K-wires are used.

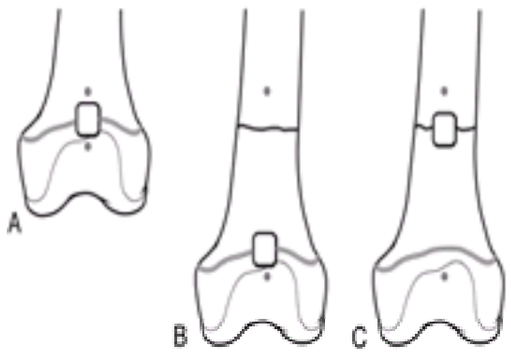

FIGURE 5-42. Metal markers. **A:** Metal markers are placed in cancellous bone of the epiphysis and metaphysis, away from the interposition plug, longitudinally oriented to each other and as close to the center of the bone as feasible. **B:** A plug that stayed with the epiphysis as the physis grew away from the proximal marker and the growth arrest line. **C:** A plug that stayed with the metaphysis as the physis grew. The plug has not migrated. (Redrawn from Peterson HA. Partial growth plate arrest and its treatment. *J Pediatr Orthop* 1984;4:246–258; with permission.)

Preferred Interposition Material

Next, I place the interposition material into the cavity. The object is to fill the cavity to prevent blood from occupying the cavity, organizing, and re-forming a bone bar.

I prefer Cranioplast as an interposition material because of its several advantages. It is easily available and inexpensive, there is no Food and Drug Administration (FDA) control (as for Silastic), and no second incision is needed (as for fat). It is light, easy to handle and mold, thermally nonconductive, and radiolucent. Both the liquid (monomer) and the powder (polymer) are sterile as packaged and can be mixed in the operating room. It is unnecessary to take cultures. It provides hemostasis because it occupies the entire desired portion of the cavity; it is strong, so that no postoperative immobilization is necessary; and there are no apparent side effects. I find it especially useful to support the epiphysis after excavation of a large bar (351,385).

In a cavity that is gravity dependent, I pour the Cranioplast in a liquid state. If the cavity is not in a dependent position, I place the Cranioplast in a syringe and push it into the defect through a short polyethylene tube (Fig. 5-43A). Alternatively, I may allow the Cranioplast to set partially and then push it into the defect like putty. As little Cranioplast as possible should be allowed to remain in the metaphysis. After the Cranioplast has set, the rest of the metaphyseal cavity is filled with previously removed cancellous bone (Fig. 5-43B).

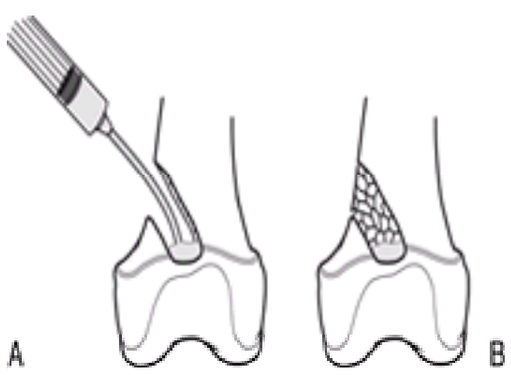

FIGURE 5-43. Insertion of Cranioplast. **A:** Only enough Cranioplast is inserted, here shown by use of a syringe and catheter, to bridge all physeal surfaces. **B:** The remainder of the defect is filled with bone chips harvested at the time of exposure. (Redrawn from Peterson HA. Partial growth plate arrest and its treatment. *J Pediatr Orthop* 1984;4:246–258; with permission.)

Misunderstandings concerning methylmethacrylate are related to terminology. Pure methylmethacrylate, or Cranioplast, was first produced in 1927. It has been used for over five decades by neurosurgeons to repair skull defects and has been found to be an inert and safe material. When used as an isolated substance, it has caused no rejection, infection, or neoplastic change (362). Its thermogenic properties are minor, as evidenced by the neurosurgical practice of pouring it in a semiliquid form directly on dura and brain tissue before setting. It is also radiolucent.

When initial results from total hip arthroplasty revealed prosthesis loosening, a search for a bone cement was undertaken. Cranioplast was found to work well, but the radiolucent property made subsequent loosening difficult to detect. Barium was added to the methylmethacrylate. This achieved radiopacity, but it decreased the setting time and increased the exothermic property significantly. Thus, the material that is now generally referred to as methylmethacrylate is, in fact, Cranioplast with barium added. This type of methylmethacrylate is undesirable as an interposition material for bar excisions because of its radiopacity and possibly because of its exothermic property. The radiopacity obviates detection of recurrent bar formation.

Osteotomy

Mild angular deformity secondary to peripheral bars may correct spontaneously with growth after excision of the bar. Angular deformities of more than 20 degrees will probably not correct spontaneously and usually require osteotomy (212,336,337). This can be done at the same time as bar excision, or later.

Postoperative Care. Postoperatively, if Cranioplast is inserted and no osteotomy is performed, no cast or other immobilization is necessary. Joint motion and weight-bearing are encouraged on the day of operation, or as soon as operative discomfort subsides.

COMPLICATIONS

Bar Re-formation

The major complication of bar excision is bar re-formation. Although this may occur after excision of a bar of any size, in any location, and at any site, it is more likely to occur with large bars (those that occupy 50% or more of the entire physis). A recurrent bar may form at any time, early or late, after initial excision. If it occurs soon after excision and significant growth remains, the recurrent bar can be reexcised with some hope of success (Fig. 5-33F,Fig. 5-33G,Fig. 5-33H). More commonly, when bar formation occurs, it occurs near the completion of growth, which underscores the need for careful follow-up (see the next section). Bar re-formation signals a less-than-desirable outcome but does not preclude application of all other types of bar management (see earlier).

Unhealthy Physis

In addition to the size of the bar and the adequacy of bar removal, other factors that may be associated with bar re-formation are the patient's health and the rate of growth of the physis at the time of excision. A protocol for using growth hormone after bar excision to enhance the short-term growth activity was used in one patient with equivocal results.

Technical Errors

Other complications of bar excision are primarily technical. Fracture of the medial portion of the distal tibial epiphysis has been noted after too-generous removal of epiphyseal bone of a medial distal tibial bar. A referral case, in which a large bar had been completely replaced with bone wax, resulted in recurrent transcutaneous extrusion of small bits of wax until the wax was entirely surgically removed.

Postoperative Infection

Postoperative infection can occur, as in any orthopaedic surgery. However, in the author's experience, it has occurred only in three patients in whom the original cause of the bar was infection. This infection is chronic and requires debridement and antibiotics like other bone infections. Once the infection is cleared, bar management proceeds using any of the previously discussed methods.

Follow-Up

Reexcision May Be Necessary. Follow-up until maturity is essential. Reestablished physeal growth may cease at any time. Recurrent bar formation has been successfully treated by reexcising the bar (Fig. 5-33) (331,364,367). If a bar re-forms near maturity or if the entire physis ceases growing on the injured side earlier than its contralateral counterpart (a fairly common finding), physeal arrest on the contralateral side may be considered.

Scanograms

Scanograms (305,306,308) are the most precise way to measure the increasing distance between the two metal markers (Fig. 5-33A,Fig. 5-33D,Fig. 5-33H). As the child grows, length and circumference of the extremity increase, allowing magnification of the distance between the markers on regular roentgenograms, teleoroentgenograms, and orthoroentgenograms. This magnification falsely enhances the result. Scanograms have no magnification. They can be measured and remeasured directly on the film by tape measure. They also show any deformity or other abnormality of the entire bone.

It is suspected that the physis on the opposite end of an injured or operated bone sometimes overgrows to compensate for any damage at the other end (364). Although the amount of growth of bone attributable to each physis has been fairly well established (for example, distal femur, 70%; proximal tibia, 60%; distal tibia, 40%), the only way to determine precisely the amount and percentage of growth contributed by each physis of a bone after bar excision, compared with its contralateral member, is to place a single metal marker in the diaphysis of the normal contralateral bone. This has been found valuable in determining comparative growth, which aids in finding bar recurrence (Fig. 6-33D and Fig. 5-33H).

RESULTS

Assessing results is difficult because so many factors are involved. When the procedure works well, it is most gratifying and may be the only procedure needed. This renewed growth may diminish the angular deformity and the rate of progression of limb-length inequality; occasionally, there may even be reduction of the length inequality (e.g., the treated limb grows faster than the normal limb; Fig. 5-33A and Fig. 5-33H).

Only patients followed to maturity should be included in any reported series. Some operated physes, although growing well after the procedure, close earlier than their contralateral physes. Thus, in some patients, surgical arrest of the contralateral physis is performed toward the end of growth to negate additional discrepancy. This approach favorably influences the result expressed as a percentage.

Fifty Percent Rule

Excision of bars constituting 50% or more of the entire physis usually fail to restore satisfactory longitudinal growth. Bars more than 50% of the physis may be excised in very young children because the alternatives are undesirable, because the procedure occasionally works, and because if the procedure is unsuccessful, all other methods of management can still be used.

The Mayo Clinic Experience

From 1968 through 1996, 178 patients were treated by bar excision at the Mayo Clinic (Table 5-3). Bar formation was at the knee (distal femur and proximal tibia) in 50% of the cases, whereas these sites account for only 2.2% of all physeal injuries (Table 5-2). This disparity is explained by the anatomy of these physes. Their undulations and irregularities in multiple planes insulate them from injury, but when injury occurs, the same undulations predispose the patient to damage of the growth layer of the physis. All operations were performed by four staff pediatric orthopaedists, with little variation in technique. Cranioplast was used for the interposition material in 153 patients, fat in 23, methyl methacrylate in 1, and sheet Silastic and Gelfoam in 1 (381).

In 98 patients followed to maturity, the average growth of the operated side was 84% of that of the unoperated side. The average was 78% for the distal femur, 88% for the proximal tibia, and 93% for the distal tibia (Table 5-4).

	No.	Growth[a] (%)	Average Age (Yrs)	Time Interval[b] (Yrs)	Bar Area[c] >45%	Bar Area[c] <45%	Central Bars
Distal Femur	43	78	10.45	3	11 (26)	32 (74)	10 (23)
Prox Tibia	18	88	11.66	2.1	2 (11)	16 (89)	6 (33)
Dist Tibia	37	93	11.3	1.9	3 (8)	34 (92)	5 (14)

[a]Growth = % of growth of operated vs. contralateral non-operated physis
[b]Time Interval = interval between injury and bar excision
[c]Bar area = area of bar expressed as a percentage of entire area of physis. Number is number of cases. () = percentage of cases

TABLE 5-4. RESULTS OF 98 MATURE CASES

Thirteen of these 98 patients (13%) had no accompanying surgery. Adjunctive surgery in the remaining 85 patients (87%) was usually performed for length discrepancy and angular deformity existing before the bar excision, which did not correct even with a successful bar excision. Resumption of normal growth that stops progression of angular deformity and length discrepancy is a successful outcome of bar excision. Improvement of angular deformity and length discrepancy (the operated side grows more than the normal side) sometimes occurs, but parents should not be led to believe that it will. There were 37 osteotomies to correct angular deformity, performed either concomitantly with the bar excision or later. Forty patients had epiphysiodeses of the contralateral bone or of the adjacent bone in the case of the lower leg. Thirteen patients had lengthenings of the involved bone. Eighteen recurrent bars were reexcised.

Of the 43 distal femoral lesions, 30 were in boys and 13 in girls. The interval between injury and bar excision was 2.8 years. The average age at time of bar excision was 10.5 years. The area of the bar was more than 45% in 11, less than 30% in 12, and less than 30% in 20. The site of the lesion was medial (13), lateral, central (10), posterior (9), and anterior (6) (some lesions occupied more than one locus). The operated side grew 78% as much as the normal side. Additional procedures included epiphysiodesis (23), osteotomy (11), and lengthening (9). There were nine recurrent bars and two infections (the cause of the bar in these two was osteomyelitis).

Of the 18 proximal tibial lesions, nine were found in boys and nine were found in girls. The interval between injury and surgery was 2.1 years. The average age at time of surgery was 11.7 years. The area of the bar was more than 45% in two patients, more than 30% in one patient, and less than 30% in 15 patients. The site of arrest was central (6), lateral (5), medial (4), anterior (4), and posterior (1) (some lesions occupied more than one locus). The average growth of the operated side was 88%

of the uninjured side. Additional procedures include osteotomy, epiphysiodesis (9), and lengthening (3). There were two recurrences and one infection (the cause of the bar in this case was osteomyelitis).

Of the 37 distal tibial lesions, 26 were in boys and 11 were in girls. The interval between injury and surgery was 1.9 years. The average age at time of surgery was 11.1 years. The area of the bar was more than 45% in three patients, more than 30% in four patients, and less than 30% in 30 patients. The site of the bar was medial (14), anterior (10), central (5), posterior (5), and lateral (3). The average growth was 93% of that of the contralateral nonoperated side. Additional surgery included osteotomy (15), physeal arrest (8), and lengthening (1). There were 7 recurrent bars, 2 fractures, and no infections.

From this data, it can be seen that the more distal the lesion, the better the result (Table 5-4). The overall result, expressed as a percentage of growth of the contralateral normal physis, improves as the site progresses distally and correlates directly with the percentage of lesions smaller than 45% of the physis. Factors favoring the distal tibia were the short time interval between injury and bar excision, the few larger lesions (8%), and the many smaller lesions (92%). Factors contributing to the less satisfactory results in the distal femur include the long time interval, the greater number of large lesions (26%), the fewer small lesions (74%).

There was no correlation of result with gender or location of the bar within the physis. However, several spectacular results were obtained in central bars, and the presence of an intact cartilage ring of Ranvier is believed to be beneficial.

Interposition Material Removal

The criteria for the subsequent removal of interposition material or for bone grafting of defects left by fat have not been established. If the physis grows away from the interposition material, the material becomes located in the metaphysis or diaphysis. As the metaphysis remodels, the interposition material, although remaining the same size, occupies a greater proportion of the transverse plane of the shaft of the bone (compare Fig. 5-33C and Fig. 5-33E). This may predispose the bone to pathologic fracture and has done so in one patient after the Cranioplast was removed. In one patient, remodeling of the cortex allowed the Cranioplast to extrude and become extraosseous. Patients should be advised that the interposition material may have to be removed in the future. All Cranioplast plugs have been embedded firmly in the bone. There has been no loosening, such as occurs when methylmethacrylate is used with a prosthesis. In the few that have been removed, histologic evaluation revealed only a thin surrounding layer of fibrous tissue and no untoward reaction. The material is not easily removed, and usually a thin area of surrounding bone must be excised. A motorized bur or an osteotome has been used to remove Cranioplast plugs. The author's practice is to not remove the Cranioplast.

ACKNOWLEDGMENTS

The author wishes to thank R. A. Klassen, M.D. for compiling the Mayo Clinic experience.

PATHOLOGIC FRACTURES ASSOCIATED WITH TUMORS AND UNIQUE CONDITIONS OF THE MUSCULOSKELETAL SYSTEM

JOHN P. DORMANS
JOHN M. FLYNN

As a child grows, the pattern of injury and the response to injury and treatment change. One of the more difficult situations encountered in caring for children occurs when the diagnosis and treatment of a complex injury are complicated by a preexisting underlying disease process or condition of the skeleton. The diagnosis of both the injury and the underlying condition depends on an accurate understanding of how these conditions alter the presentation of the child, given that evaluation of the traumatic injury may reveal the underlying condition for the first time. This chapter describes the pertinent clinical and radiographic features of the conditions of the pediatric musculoskeletal system that can predispose a child to pathologic fracture, including specific patterns of injury and special concerns of treatment. For most orthopaedic surgeons, experience with these conditions is limited, and diligence is needed to avoid pitfalls of treatment. The physician must always be aware of the possibility of a pathologic fracture, especially when a patient presents with a fracture following minimal trauma.

A pathologic fracture is defined as a fracture that occurs through abnormal bone. These fractures occur in bone that lacks normal biomechanical and viscoelastic properties. Pathologic fractures may result from intrinsic or extrinsic processes. Examples of intrinsic processes include the osteopenia of osteogenesis imperfecta or replacement of bone with tumor. With extrinsic processes, the weakness is caused by something that lessens the inherent structural integrity of bone, such as radiation or a hole in bone from biopsy or internal fixation. Additionally, pathologic fractures may result from localized (a bone cyst, for example) or generalized processes (such as osteopetrosis), and the fracture may be correctable (rickets) or noncorrectable (metastatic cancer). A fracture similar to a pathologic fracture can occur through anatomically normal bone that is weakened by normal structures such as a vascular foramina (Fig. 6-1).

FIGURE 6-1. A fracture through the vascular foramina of this 9-year-old boy's left clavicle. The fracture healed uneventfully.

Pathologic fractures can occur in children with generalized bone conditions and in those with tumors or tumor-like processes of bone. Although the presenting episode of a child with generalized bone disease (osteogenesis imperfecta, osteopetrosis, and rickets) may be a fracture, more commonly, the diagnosis has been made based on clinical findings such as history, physical examination, radiographs, or laboratory findings. Often, the history is most helpful. For example, pathologic fracture secondary to generalized osteopenia associated with chronic drug therapy (steroids or anticonvulsants) may become evident through the patient's history. Some of the key points in analysis of a pediatric patient with a musculoskeletal tumor or tumor-like lesion are shown in Table 6-1.

1. Age of patient (see Table 6-2)
2. Location of lesion (see Table 6-3)
   Epiphysis, metaphysis, diaphysis?
   Central or eccentric?
3. What is the lesion doing to the bone? (Pattern of involvement)
   a. Zone of transition (narrow or wide; can measure)
   b. Geographic versus "moth eaten" versus permeative
4. What is the bone doing to the lesion?
   Periosteal response or "walling off"
   No response?
      Early, immature?
      Late, mature?
5. Is there a characteristic appearance of the lesion, ie matrix?
   Lytic, calcified, ossified, "Ground-glass"

TABLE 6-1. EVALUATION OF A PEDIATRIC PATIENT WITH A MUSCULOSKELETAL TUMOR OR TUMOR-LIKE LESION

Hipp and colleagues proposed a way of quantifying the risk of pathologic fracture in 1995 (3). They defined the *factor of risk* as the load applied to the involved bone divided by the load required for bone failure. Other attempts have been made to measure the risk of pathologic fracture in patients with underlying conditions of bone (5,27,34). Unfortunately, retrospective studies have failed to find any predictive methods based on radiographic findings that can accurately forecast fracture in most situations. New methods that apply engineering principles to information from computed tomography (CT) scans may provide better noninvasive estimates for the risk of pathologic fracture (3).

With pathologic fractures through a tumor or tumor-like lesion, the age of the patient can also be helpful in making the diagnosis (Table 6-2). Most tumors and tumor-like processes are recognizable by radiographic appearance; the location of the lesion can also be helpful (Table 6-3) (2).

Age (years)	Benign	Malignant
0–5	Langerhans cell histiocytosis Osteomyelitis	Ewing's sarcoma Leukemia Neuroblastoma (metastatic) Wilms' tumor (metastatic) Neuroblastoma (metastatic)
5–10	Unicameral bone cyst Aneurysmal bone cyst Noncostifying fibroma Fibrous dysplasia Osteoid osteoma Langerhans' cell histiocytosis Osteomyelitis	Ewing's sarcoma Osteosarcoma Rhabdomyosarcoma
10–20	Unicameral bone cyst Aneurysmal bone cyst Osteoid osteoma Fibrous dysplasia Chondroblastoma Chondrofibroma dysplasia	Osteosarcoma Ewing's sarcoma (Chondrosarcoma) Rhabdomyosarcoma Synovial cell sarcoma

TABLE 6-2. PEAK AGE OF COMMON PEDIATRIC MUSCULOSKELETAL CONDITIONS, (TUMORS AND TUMOR-LIKE LESIONS OF BONE)

Metaphyseal—Any lesion Epiphyseal Chondroblastoma Brodie's abscess of the epiphysis-subacute pyogenic osteomyelitis Giant cell tumor Fibrous dysplasia Diaphyseal Fibrous dysplasia Osteofibrous dysplasia (child), adamantinoma (adult) Langerhans' cell histiocytosis Multiple lesions Histiocytosis Fibrous dysplasia (Albright's syndrome) Leukemia, metastasis Enchondroma (Ollier's disease) Multiple hereditary exostosis Hemangioma of bone Anterior elements spine Eosinophilic granuloma (Langerhans' cell histiocytosis) Leukemia Hemangioma Metastasis Infection (soft plasma, unless tuberculosis) Giant cell tumor Chondroma (usually adult)	Posterior elements spine Aneurysmal bone cyst Osteoblastoma Osteoid osteoma Metastatic (usually adult) Pelvis Ewing's sarcoma Osteosarcoma Osteochondroma Metastasis Fibrous dysplasia Chondrosarcoma (usually adult) Rib Fibrous dysplasia LCH Ewing's sarcoma Metastatic lesions Chondrosarcoma (usually adult) Benign but locally aggressive tumors Chondroblastoma Aneurysmal bone cyst Chondromyxoid fibroma Giant cell tumor Osteoblastoma Chordoma Adamantinoma

TABLE 6-3. LOCATION OF TUMOR AND TUMOR-LIKE LESIONS OF BONE

Biopsy is sometimes needed to determine the cause of a pathologic fracture, especially with pathologic fractures through tumors or tumor-like processes. In this situation, the surgeon must ensure that biopsy is performed on representative areas of the bony lesion.

Pathologic fractures differ from fractures in normal bone in that the etiology, natural history, and treatment of the underlying abnormality of the bone must be taken into account. Accurate and careful determination of these underlying diagnoses is critical for the appropriate care of these fractures. Fracture management principles often are altered for pathologic fractures because of the abnormal condition responsible for the fracture. The treatment plan must consider both the treatment of the fracture and treatment of the underlying cause of the fracture.

Once a fracture occurs secondary to a previously unrecognized condition, subsequent fractures often can be prevented, usually through patient education. Iatrogenic pathologic fracture often can be prevented by the appropriate use of internal fixation (avoidance of unnecessary cortical penetration with drills and guide pins for example), protection of an extremity with internal fixation by cast or brace when appropriate, and the use of rounded edges of bone biopsy sites (1).

FRACTURES ASSOCIATED WITH CYSTS, TUMORS, OR TUMOR-LIKE PROCESSES

Benign tumors can be classified according to their aggressiveness (Table 6-4). Stage 1, or latent benign lesions, are usually asymptomatic, discovered incidentally, and seldom associated with pathologic fracture. Stage 2 lesions are intermediate in behavior, and stage 3, or aggressive benign lesions, are usually symptomatic, grow rapidly, and may be associated with pathologic fracture.

Stage 1, Latent Benign
   Asymptomatic
   Often discovered incidentally
   Seldom associated with pathologic fracture
Stage 2, Active Benign
   Majority
   Tend to grow steadily
   May be symptomatic
Stage 3, Aggressive Benign
   Generally symptomatic
   Discomfort, usually tender
   May be associated with pathologic fracture
   Growth rapid

TABLE 6-4. CLASSIFICATION OF BENIGN LESIONS ACCORDING TO THEIR AGGRESSIVENESS

Unicameral Bone Cysts

Unicameral bone cysts (UBCs) are radiolucent expansile fluid-filled cystic lesions found most commonly in the metaphyses of long bones. The term *unicameral* suggests a single-chambered cyst, but often, especially after treatment or fracture, the lesions are multiloculated with radiolucent fibrous septa segregating the primary lesion into multiple small chambers (11). The cysts usually contain yellow serous fluid. In order of decreasing frequency, the cysts most commonly occur in the proximal humerus, proximal femur, proximal tibia, distal tibia, distal femur, calcaneus, distal humerus, radius, fibula, ilium, ulna, and rib (34). Approximately 70% of these cysts are found in either the proximal humerus or femur. Some authors have suggested that UBCs evolve from an accumulation of interstitial fluid in the bone because of a defect in venous or lymphatic drainage (14,15,24).

Approximately 75% of patients who have UBCs present with pathologic fractures (7,12,18,19,36,44). These cysts usually are diagnosed within the first two decades of life (13,15,21), and the ratio of males to females is about 2:1 (26). Fractures are often incomplete or minimally displaced. Patients with pathologic fractures through UBCs present with mild to moderate pain in the extremity after either mild trauma or no history of injury. In one series (8), 40% of pathologic femoral neck fractures in children were due to UBCs. Pathologic fracture with collapse of the articular surface of the femoral head and joint incongruity also has been reported (17).

Although the fracture commonly heals within 6 weeks of injury, the UBC usually persists, often with further fracture. Only about 10% of cysts heal after fracture. In a 1993 report of 52 pathologic fractures due to UBC, Ahn and Park (4) found that only 8% of cysts healed at an average of 5.5 years after injury.

Radiographic Findings

The classic appearance of a UBC is a centrally located, radiolucent, slightly expansile lesion of the metaphysis (Fig. 6-2) (38). The width of the lesion seldom exceeds that of the adjacent physis [a feature characteristic of the more expansile aneurysmal bone cyst (ABC)]. Occasionally, UBCs are located in the diaphysis when the physis has migrated away from the lesion with growth (Fig. 6-3) (23). The so-called fallen fragment sign, described by Reynolds (38) in 1969, is a fracture fragment seen on plain radiographs at the bottom of a cyst suggesting a hollow cavity in the bone rather than a solid tumor (Fig. 6-4). A cortical fragment also may be tilted into the interior of the lesion. The differential diagnosis of UBC includes ABC, fibrous dysplasia, enchondroma, giant cell tumor, and eosinophilic granuloma.

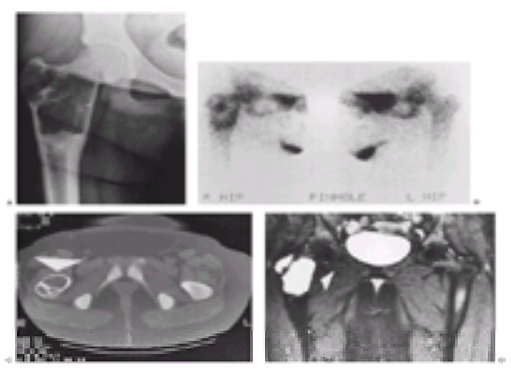

FIGURE 6-2. A: A 14-year-old girl presented with right hip pain. X-ray study reveals a large lytic expansile lesion of the proximal femur. **B:** A technetium scan was performed, and the anterior cortex was thin with fluid within the lesion. **C:** MRI was performed, and signal intensity was equal to that within the bladder, and a diagnosis of unicameral bone cyst was made. **D:** It was treated with curettage and bone graft.

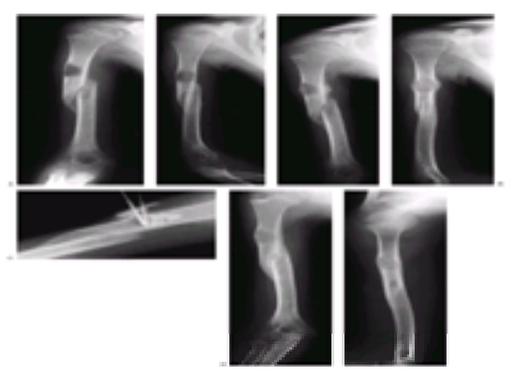

FIGURE 6-3. A 12-year-old boy sustained a pathologic fracture while throwing a tennis ball. **A:** Radiographs at presentation revealed a lytic lesion of the proximal humerus with pathologic fracture seen distal to the lesion. There is also the suggestion of a pathologic fracture through the cyst. The lesion was believed to represent a unicameral bone cyst, and the fracture was treated in a hanging arm cast. **B:** At 8-weeks follow-up, fracture lines were beginning to obliterate but the cyst persisted. A nondisplaced healing fracture through the cyst is also well visualized. **C:** At 8-week follow-up, the patient was believed likely to be prone to have a recurrent fracture and was taken to surgery. With the patient under general anesthesia, the lesion was injected with radiopaque dye and was found to be a cystic lesion. Steroid injection was done. **D:** At 12-week follow-up, the patient is asymptomatic, with radiographic improvement of the lesion.

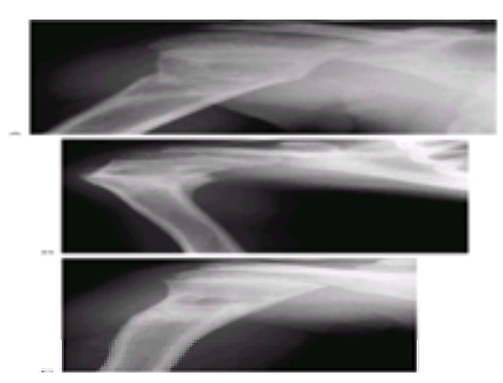

FIGURE 6-4. A 13-year-old boy sustained a pathologic fracture. **A:** X- ray studies at presentation revealed a lytic lesion of the proximal humerus with pathologic fracture. A so-called fallen fragment sign is seen at the bottom of a cyst suggesting a hollow cavity in the bone rather than a solid tumor. The lesion was believed to represent a UBC, and the fracture was treated in a hanging arm cast. **B:** At 8-week follow-up, fracture lines were beginning to obliterate. **C:** At 6 month follow-up, the cyst has partially healed.

Natural History—Predicting Fracture

The natural history of UBCs is variable, but typically they gradually improve with growth. Most UBCs persist into adulthood, but some disappear spontaneously at puberty (24). The cysts are traditionally described as active if they are adjacent to the physis (24) or latent if more than 0.5 cm from the physis (35) (Table 6-5). Ahn and Park (4) noted that pathologic fracture occurred when the transverse diameter of the cyst was 85% or more, whereas Nakamura et al. (33) reported that the

chance of fracture was high if the cyst wall was less than 5 mm in width.

	Active	Inactive or "Latent"
Age of the patient	≤10–12 years	>12 years
Location	Abutting the physis	Separated from physis by a zone of normal cancellous bone
X-ray appearance	Single cavity	Multiloculated cavity
Intralesional pressure	>30 cm H_2O	6–10 cm H_2O
Pathology	Thin shiny membrane, few osteocytes, little or no hemosiderin, osteoclasts	Thick membrane, frequent giant cells, cholesterol slits, hemosiderin, osteoblasts

TABLE 6-5. STAGING OF UNICAMERAL BONE CYSTS

Complications after fracture of the proximal femur include malunion, growth arrest, and avascular necrosis of the femoral head. Kay and Nason (30) noted growth disturbance in five of their 21 patients (24%) with pathologic proximal humeral fracture before treatment of the UBC. Moed and LaMont (31) reported three patients in whom premature closure of the medial proximal humeral physis resulted in humeral shortening of 2 to 5 cm. Malunion may be a problem in fractures through cysts of the proximal femur (15), and avascular necrosis of the femoral head has been reported after displaced femoral neck fractures (26) and after an undisplaced femoral neck fracture in an 8-year-old boy (48). Infrequently, the cyst may extend from the metaphysis into the epiphysis (5,7,20) and collapse of the surface of the femoral head has been reported.

Treatment

Pathologic fractures through UBCs invariably heal with simple immobilization; the cyst, however, persists in nearly 85% of patients, and additional fractures are common. Neer et al. (34) observed an additional 2.5 fractures per patient during observation periods after the initial injury, and Oppenheim and Galleno (36) emphasized that prolonged observation with inevitable refracture may be stressful to patients and may adversely restrict children from normal childhood activities.

In the upper extremity, minimally displaced, stable pathologic fractures through UBCs are treated with simple immobilization for 4 to 6 weeks to obtain healing. Usually, a sling is adequate treatment for stable fractures of the proximal humerus, and once healed, the options for further treatment are discussed with the patient and family (see later).

With pathologic fracture through UBC in the proximal femur, preliminary traction before surgical intervention may be appropriate (49). Most authors recommend internal fixation if the fracture is unstable or displaced (7,26,29,34). Malunion is common in these fractures (15). Intertrochanteric osteotomies may be necessary later to correct alignment (25).

OPERATIVE TREATMENT

Curettage and Bone Grafting. Many surgical techniques have been developed for the treatment of UBCs, with varying rates of success. Earlier interventions consisted primarily of curettage and bone grafting. Lesions treated with this technique have a recurrence rate varying from 18% to 40% (6,7,19,34,35,47). Delaying the treatment until the cyst converts from an active to a latent stage has been advocated by some physicians, but a 2-year period of observation may be necessary (7). ome data suggest that the response to treatment may be the same for latent as for active cysts (23). After fracture, most authors advocate at least a 6-week delay in treatment to allow the fracture to heal before curettage and bone grafting (15,39). There seems to be no substantial difference in the rate of healing with the use of either autogenous bone graft or allograft.

Open curettage and bone grafting has fallen out of favor for the treatment of upper extremity and smaller lower extremity UBCs due to the invasive nature of the operation and also the still significant persistence and recurrence rates associated with this option. Curettage and bone graft remains a popular method of treatment for larger UBCs of the proximal femur, however; the reported recurrence rates range from 10% to 40% (6,7,19,36). Although partial persistence or recurrence of the UBC may occur, interim healing usually occurs such that the risk of pathologic fracture and displacement is lessened and subsequent persistence or recurrence can be treated with corticosteroid injections (Fig. 6-5). Follow-up of the treated lesions with periodic x-ray studies is suggested.

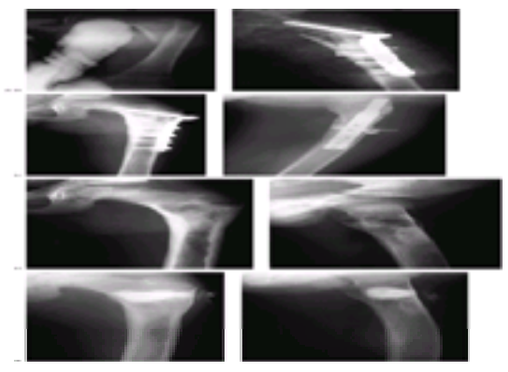

FIGURE 6-5. A 7-year-old boy was playing basketball and felt a severe pain in his left hip and was unable to bear weight on that side. **A:** X-ray studies revealed a comminuted pathologic fracture through a large lytic lesion extending from the base of the femoral neck to the subtrochanteric region (comminuted type I—B hip). The appearance of the lesion is believed to be most compatible with a UBC. **B:** The fracture and cyst were approached laterally. Open reduction and internal fixation were performed using a pediatric hip screw and side plate. The cyst contents were consistent with UBC; it was curetted and packed with cancellous bone graft. The patient was placed in a hip spica cast for 6 weeks with healing of the fracture. **C:** At 4-month follow-up, the fracture has healed and the cyst appears to be consolidating. **D:** At 2-year follow-up, x-ray studies show a partial recurrence or persistence of the cyst. The cyst was subsequently grafted again. **E:** At 4-year follow-up, x-ray studies show no evidence of recurrence or persistence of the cyst. The patient has no discomfort and has returned to full activities.

The patient with a calcaneal UBC usually presents with pain due to microfracture (22,32,37). UBCs in this location may not respond as well to injections with methylprednisolone (22,32), and several authors have recommended primary curettage and bone grafting (22,32).

Because of the high rates of recurrence after curettage and bone grafting, a number of approaches were developed, including intentional fracture of the cyst (46), crushing of the lesion with onlay bone grafting (5), and packing of the defect with plaster of Paris pellets (37). Radical excision of the lesion with or without grafting produced recurrence rates of 9% or less (19,21,30), but this procedure is a larger operation with greater risk, can be difficult technically, and requires substantial bone graft.

Aspiration and Injection. In 1974, Scaglietti et al. began empiric injection of UBCs with methylprednisolone and in 1979 (43), reported healing rates (mostly radiographic improvement of the cyst) of 96% in 72 patients. Two needles were inserted into each cyst, and the initial corticosteroid dose varied from 40 to 200 mgs for large cysts. Complete healing was initially reported in 55% of cysts undergoing this treatment. Local recurrence in 45% of cases was treated with up to five

additional injections of 40 to 80 mg of methylprednisolone at 2- to 3-month intervals until healing occurred.

The mechanism for cyst healing after methylprednisolone injection remains unknown. Scaglietti et al. (43) suggested that an antiinflammatory response initiated by the corticosteroids promoted cyst healing. Shindell et al. (45) observed elevated levels of prostaglandins in cysts; after serial injections of corticosteroid, levels decreased. Because prostaglandins stimulate osteoclastic activity, these authors suggested that a corticosteroid-induced repression of prostaglandins may indirectly aid in cyst healing. In animal experiments, however, corticosteroids are rapidly cleared from the medullary canal of long bones after injection (16). Others have suggested that cyst healing occurs through decompression of cyst fluid pressure by multiple trephination (13,16,42).

Methylprednisolone injection for UBCs became popular because of its relatively low morbidity and an apparent long-term effectiveness approaching that of more invasive techniques. However, incomplete healing and recurrence are common after the initial injection of corticosteroid, and multiple injections of corticosteroid may be necessary in 50% to 92% of patients (intervals ranging from 2 to 6 months) (11,36).

In those cysts that respond to methylprednisolone treatment, the cortical margins of the lesion usually thicken. By 6 months, the central portion of the cyst assumes a frosted-glass appearance, and by 12 months, the cyst may heal with dense sclerotic bone (12,40).

Aspiration and Injection—Operative Technique. A two-needle injection technique is most commonly used. Some authors (36) recommend the use of two Craig-type needles or Jamshidi biopsy needles so that a biopsy specimen can be obtained at the time of injection. The initial dose of methylprednisolone varies from 40 to 200 mgs (11,18,43), and the volume can be adjusted to match radiographic volume of the cyst. The injection can be given under local anesthetic (10), but most prefer general anesthesia. Several authors (11,36,37) have emphasized the importance of outlining the cyst with radiopaque dye injection before placement of the methylprednisolone. With this technique, intracystic fibrous septa were found in 92% of lesions in one series (11) and these may prevent complete filling of the cyst by corticosteroids with later incomplete healing. This cystogram also allows the surgeon to verify that the cyst is indeed fluid filled. If it does not fill with contrast material, other diagnoses, such as fibrous dysplasia or enchondroma, should be considered. Capanna et al. (11) recommend vigorous saline irrigation of the cyst through two needles to lyse the fibrous septa, whereas Oppenheim and Galleno (36) simply reinject the areas of cyst that are not filled by contrast material in the initial injection.

Aspiration and Injection—The Humerus. With fluoroscopic guidance, the humerus is rotated until an area of thin cortex is identified, and two 20-gauge spinal needles are passed through this area into the cyst so that the needle tips are at opposite ends of the cyst cavity. A more stout, disposable biopsy needle can be used for areas of thicker bone. The presence of serous fluid with removal of the needle stylet is indicative of UBC. A cystogram is then performed by injection of several milliliters of Renografin dye both to confirm the fluid-filled nature of the cyst and to ascertain whether the cyst is indeed unicameral or multiloculated. If the dye does not fill a cyst cavity, the diagnosis of UBC should be questioned. If the cyst is multiloculated, the needles can be used to break up any septations that exist. Methylprednisolone is then injected through one of the needles using a dose ranging from 40 to 200 mgs (Fig. 6-6). To guard against recurrent fracture, the arm is protected in a sling for 2 to 6 weeks and x-ray studies are performed every 6 weeks initially to monitor healing. Incomplete healing or persistence of the cyst can be treated with additional injections or with other techniques. Aspiration, cystogram, and steroid injection can also be done for small, stable UBCs of the lower extremity, but if the cyst is potentially unstable and there is a risk of malunion (e.g., varus of the femoral neck), one should consider surgical fixation and bone grafting.

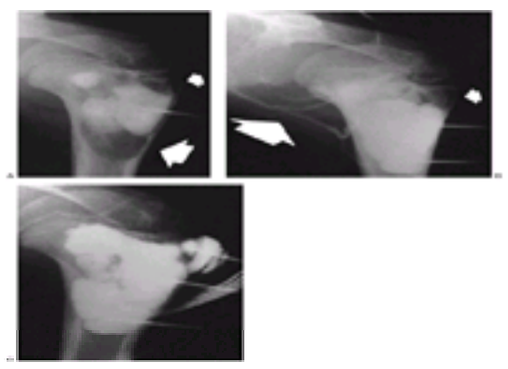

FIGURE 6-6. A: A radiopaque dye injection of a unicameral cyst of the proximal humerus. Note the poor filling of the inferior portion of the cyst (*large arrow*) and the proximal portion (*small arrow*). This suggests that fibrous septa are present in the cyst. **B:** More radiopaque dye was placed in the distal portion of the cyst through a second needle, and a venous drainage of the lesion is now visualized (*large arrow*). The proximal portion of the cyst is still poorly filled (*swag arrow*). **C:** With a third needle superiorly, the proximal portion of the cyst is now filled. The total dose of corticosteroid is divided into equal portions and injected separately through the three needles to ensure complete dispersal throughout the lesion. A single dose through the first needle might not have saturated the entire cyst.

Complications

In addition to recurrence of the cyst, complications that occur with corticosteroid treatment include recurrent pathologic fractures (12,20,36) and avascular necrosis of the femoral head (8,12). Nakamura et al. (33) measured the bone mineral content of the corticosteroid injected cyst by densitometer and found that if there was no increase in density 2 months after injection, then the chance of refracture was high. In one series, growth disturbance was a problem in 20% of 141 patients with bone cysts treated by corticosteroid injection (8). Systemic reactions to the corticosteroid injection, such as corticosteroid flush or increased appetite and temporary weight gain, are rare (16,36).

Newer Methods

Some authors believe that relieving the pressure of the interstitial fluid in the lesions can heal the cyst. Chigira et al. (13) treated six patients by puncturing the cysts with multiple Kirschner wires, which were then left in place; cysts subsequently recurred in 6 to 8 months in two patients. Santori et al. (42) decompressed UBCs with Enders nails or Rush pins without curettage or grafting, and during short-term follow-up, they noted healing in all 11 patients. The effect of the fixation on the adjacent physes awaits long-term follow-up.

New grafting materials also are becoming available. Demineralized bone matrix (DBM) or commercial product paste is composed of demineralized bone particles ranging from 100 to 500 µm in a glycerol base. It has been used in the treatment of delayed unions and nonunion, in some primary bone-healing situations, and more recently, for the treatment of UBCs (27,28,41). Killian et al. (27) used DBM in 11 patients with UBCs, and nine cysts healed (within 4 to 5 months) after a single injection. At 2 years' follow-up, no cysts were deemed active or recurrent (26).

Other materials also have been used. Packing of the defect with plaster of Paris pellets (calcium sulfate) was described by Peltier in 1978 (37). Osteoset pellets bone void filler is a new material made of medical grade calcium sulfate. This radiopaque product can be used in an open grafting situation or can be injected percutaneously. The biodegradable pellets are resorbed in 30 to 60 days when used according to labeling. This product is not intended to provide structural support during the healing process and therefore is contraindicated when structural support is required.

Adjuvants such as liquid nitrogen have been used for the treatment of UBCs (46), but their efficacy or safety has not been established. Current research includes the use of aspirated bone marrow injected into UBCs.

Internal Fixation of Proximal Femoral Pathologic Fractures

If there is a significant loss of proximal femoral bone because of the UBC, there is a high risk of a coxa vara deformity after treatment without internal fixation. Both the location of the UBC and the amount of bone loss dictate whether fixation can stabilize the fracture after grafting and what type of fixation is appropriate. We have classified pathologic fractures of the femoral neck in children into six types (Fig. 6-7) (9).

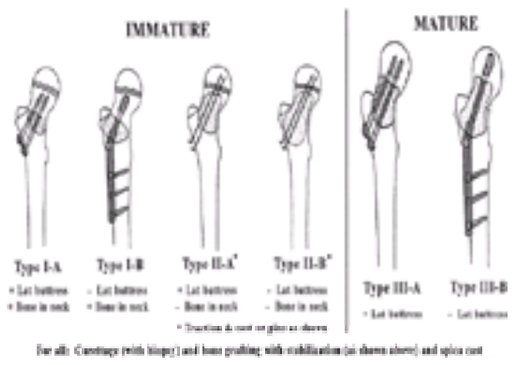

FIGURE 6-7. Our classification system for the treatment of pathologic fractures of the proximal femur associated with bone cysts in children. **A:** In Type IA, a moderately-sized cyst is present in the middle of the femoral neck. There is enough bone in the femoral neck and lateral proximal femur (lateral buttress) to allow fixation with cannulated screws after curettage and bone grafting. **B:** In Type IB, a large cyst is present at the base of the femoral neck. Although there is enough bone in the femoral neck, there is loss of lateral buttress, so a pediatric hip screw and a side plate should be considered rather than cannulated screws, after curettage and bone grafting. **C,D:** In Type IIA-B, a large lesion is present in the femoral neck, so there is not enough bone beneath the physis to accept screws. There are 2 options for treatment of these bone cysts: (1) After curettage and bone grafting, parallel pins across the physis can be used in combination with a spica cast. (2) The patient can be treated in traction until the fracture heals (with subsequent spica cast) followed by curettage and bone grafting. **E,F:** In Type IIIA-B, the physis is closing or closed. The lateral buttress is present in Type IIIA hips, so cannulated screws can be used to stabilize the fracture after curettage and bone grafting. In Type IIIB hips, the loss of lateral buttress makes it necessary to use a pediatric hip screw and a side plate following curettage and bone grafting. In all types, we recommend spica cast immobilization following surgery.

AUTHORS' PREFERRED METHOD OF TREATMENT

Overall, methylprednisolone injection has a favorable rate of success compared with open surgical treatment; the ease of treatment, relatively low operative morbidity, and the information obtained with aspiration and cystogram make it a favorable initial choice for treatment of UBCs in the upper extremity and smaller cysts in the lower extremity. Because incomplete healing and recurrence are common after the initial injection of corticosteroid and because multiple injections of corticosteroid are necessary in most patients, new grafting materials are being used more commonly at our institution, especially if the first steroid injection fails. Grafton demineralized bone matrix (Osteotech, Eatontown, NJ) and Osteoset pellets (Wright Medical Technology, Arlington, TN) are the two most often used at present.

We recommend simple immobilization for most fractures occurring through UBCs. Spontaneous healing of the cyst can occur, although infrequently. Once the fracture has healed, generally by 6 to 8 weeks, further treatment of the cyst can be rendered, if necessary.

Displaced pathologic fractures of the proximal femur are based on the location of the cyst. The amount of bone loss dictates whether fixation can stabilize the fracture after grafting and what type of fixation would be best to use. We use the classification of pathologic fractures of the proximal femur in children shown in figure 6-7.

Aneurysmal Bone Cysts

ABCs are eccentric or central, expansile osteolytic lesions usually occurring in the metaphyseal ends of long bones or in the posterior elements of the spine during adolescence. Nearly 75% of ABCs are found in patients younger than 20 years old, and 50% are seen in individuals between 10 and 20 years of age (50,54). Girls are affected slightly more often than boys. ABCs are relatively rare, accounting for approximately 1.5% of all primary bone tumors (50).

The long bones are involved in 65% of patients. In order of decreasing frequency, the most commonly involved bones are the distal femur, proximal tibia, proximal humerus, and distal radius. The vertebrae are involved in 12% to 27% of patients (54,59), some of whom have symptoms of radicular pain. The lumbar vertebrae are most commonly affected. The primary site of involvement is the posterior elements of the spine with frequent extension into the vertebral body (58).

The lesions are not true cysts but rather sponge-like collections of interconnected fibrous tissue and blood-filled spaces (59). They tend to be destructive lesions, which replace bone and thin the cortices of the host bone. The elevated viable periosteum usually maintains a thin osseous shell.

The etiology of ABCs is unknown. Some have considered them primary lesions of bone (79), whereas others have noted a secondary association with other lesions such as UBCs, nonossifying fibromas, fibrous dysplasia (52), and osteogenic sarcoma. They also can occur in association with fractures of the long bones (58,63). The most common presenting symptom is localized pain of less than 6 months' duration (54,79). Patients with ABCs are three times more likely to have pain during exercise rather than pain at rest (71).

Radiographic Findings

ABCs are eccentric or central lytic lesions of bone, sometimes with extension beyond the cortex (50,52,79). Septation is common, giving rise to the so-called soap bubble or honeycomb appearance. Lesions in the short tubular bones, such as the metacarpals and metatarsals, are commonly more central. Spinal ABCs usually are located in the posterior elements of the spine but may also occur in the vertebral bodies and can be associated with pathologic fracture and vertebral collapse (Fig. 6-8) (66,79).

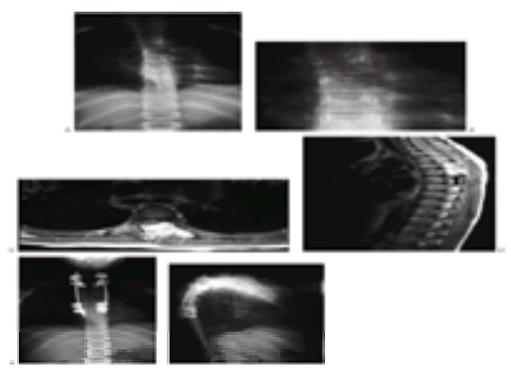

FIGURE 6-8. An 8-year-old girl presented with a 4-week history of back pain. **A:** Radiographs show absence of the pedicle of T5 on the left. **B:** Close-up view of the same areas. **C:** The axial T2-weighted image through the body of T5 shows multiple blood-fluid levels within the left sided expansile destructive mass. **D:** Sagittal proton density MRI of the thoracic spine shows a blood fluid level (*arrow*) within an expansile mass. **E:** Postoperative x-ray studies showing instrumentation and fusion after extended curettage and removal of tumor. The patient is pain free without recurrence or deformity at 4 years after surgery. (From Cohen RB, Dormans JP, Guttenberg ME, Hunter JV. Back pain in an 8-year-old girl. *Clin Orthop* 1997;343:249–252; with permission.)

The x-ray picture often evolves with time. Initially, there is frank osteolysis of the margins of the bone, and periosteal elevation; with growth of the lesion, there is progressive destruction of bone with poorly demarcated margins. A stabilization phase follows, with formation of a bone shell with septa. Later, with further ossification, a bony mass begins to form (59).

Campanacci et al. (54) have classified the ABCs into three groups (Fig. 6-9). An aggressive cyst has signs of reparative osteogenesis with ill-defined margins and no

periosteal shell. An active cyst has an incomplete periosteal shell and a defined margin between the lesion and the host bone. An inactive cyst has a complete periosteal shell and a sclerotic margin between the cyst and the long bone.

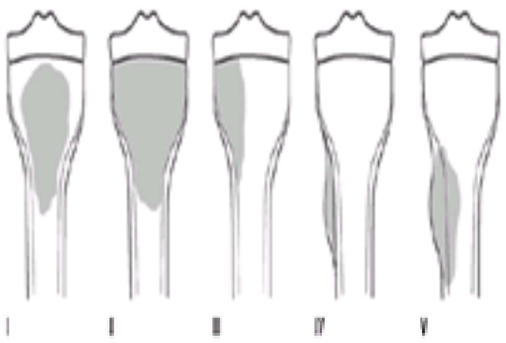

FIGURE 6-9. Classification of morphologic types of ABC. (From Capanna R, Bettelli G, Biagini R, et al. Aneurysmal cysts of long bones. *Ital J Orthop Traumatol*, 1985;XI:421–429; with permission.)

Angiography may aid diagnosis and treatment; abnormal peripheral vascularization is often present (71). Percutaneous dye injection has been used as an additional diagnostic technique and in evaluation of vertebral lesions (72). Technetium bone scan usually shows an increased uptake of the isotope in the periphery of the lesion, but homogeneous uptake is also seen (68). Magnetic resonance imaging (MRI) often is helpful in demonstrating the characteristic septations and fluid levels, but these findings are not pathognomonic for ABC (Fig. 6-8 and Fig. 6-10) (78).

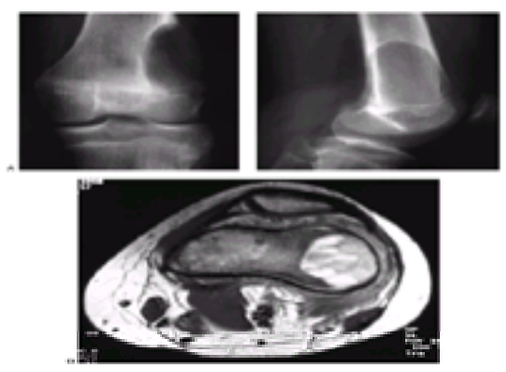

FIGURE 6-10. A 14-year-old-girl presented with distal thigh pain from microfractures through the thinned wall of an aneurysmal bone cyst of the distal femur. **A:** X-ray studies show an eccentric, expansile, lytic lesion of the lateral aspect of the distal femoral metaphysis. There is a narrow zone of transition with a sclerotic border. **B:** MRI shows septation of the lesion with the fluid-fluid levels, which are characteristic of ABC. The patient was treated with extended curettage and bone grafting.

Natural History

ABCs are benign but usually behave in a locally aggressive manner. Pathologic fractures occur in 11% to 35% of patients with ABCs of the long bones (67,71). The humerus and femur are the most commonly fractured long bones (57,71). Other sites of fracture occur, but these are rare. In one series, vertebral body ABC was associated with fracture in 27% of patients (79).

Although rare, epiphyseal involvement by the lesion through metaphyseal extension has been reported (51,60,69). Capanna et al. (56) reported nine patients with invasion of the physis by large metaphyseal ABCs. In five of these patients, growth disturbance of the involved physis subsequently developed.

Conservative treatment with immobilization is inappropriate as a definitive treatment for pathologic fractures of ABCs. Although the pathologic fracture will heal, the ABC will persist and enlarge and a recurrent pathologic fracture will occur.

Treatment

Although ABC healing after simple biopsy has been reported (54), this does not occur often and observation is not recommended because these lesions usually are locally aggressive. Simple curettage and bone grafting have been associated with high recurrence rates (51,54,59,66,79), ranging from 20% to 30% (54,59). There appears to be a higher rate of recurrence in patients younger than 15 years of age (79). Freiberg et al. (62) treated ABCs with curettage and bone grafting in seven patients younger than 10 years of age and noted recurrence in five of the seven patients at an average of 8 months after the first procedure.

Selective arterial embolization is used most commonly in locations where a tourniquet cannot be used and control of bleeding can be difficult (e.g., spine, pelvis, and the proximal portions of the extremities). Green et al. (64) reported on eight patients treated with selective arterial embolization. In seven patients, embolization was performed in conjunction with open bone grafting and, in one patient, as definitive treatment. At a follow-up of 3 years, there were no recurrences and no complications related to embolization.

Treatment of ABCs by cryotherapy in conjunction with curettage has a recurrence rate of between 8% and 14% (51,73,77). Dabezies et al. (58) obtained healing of ABCs associated with fractures by collapsing the cyst manually after curettage. Polymethylmethacrylate cementation also has been described as an adjuvant to curettage for the treatment of ABCs. Ozaki et al. (74) compared curettage and bone grafting in 30 patients with curettage and cementation in 35 patients. At follow-up ranging from 24 to 161 months, the recurrence rate was 37% for curettage and bone grafting compared with 17% for curettage and cementation.

Injection has been used by some physicians (61). Guibaud et al. (65) reported on the use of percutaneous embolization with an alcoholic solution of Zein (Ethibloc; Ethnor Laboratories/Ethicon, Norderstedt, Germany) in 18 patients. In two patients, the cystogram showed marked venous drainage and embolization was not attempted. Six patients underwent repeat embolization. At follow-up ranging from 18 months to 4 years, there were no recurrences.

Complete *en bloc* resection is reserved for active or recurrent ABCs (50,56,66,71) and is most feasible in the proximal fibula, distal ulna, ribs, pubic rami, metatarsals (54), and metacarpals (53). Resection of metacarpal lesions with replacement by a fibular autograft often results in soft tissue scarring with reduced joint motion (53). Campanacci et al. (54) recommended saucerization of peripheral active and aggressive cysts.

Irradiation should be avoided. Its use has been associated with the development of sarcoma (79). It has been used for lesions that are surgically inaccessible (57), but it is contraindicated in the pelvis, where the reproductive organs may be affected, and in areas of active growth of the long bones (54).

ABCs of the spine can be difficult to treat because of the relative inaccessibility of the lesion, proximity of the lesion to the spinal cord and nerve roots, and the potential for spinal instability (75,81). Papegelopoulos et al. (75) reported on 52 consecutive patients with spinal ABCs treated over an 83-year period and recommended preoperative selective arterial embolization, intralesional excisional curettage, bone grafting, and fusion of the affected area if instability is present (Fig. 6-8). Turker et al. (81) described three patients with ABCs of the spine and emphasized the need for spinal stabilization and fusion in conjunction with removal of the

lesion.

AUTHORS' PREFERRED METHOD OF TREATMENT

The first step in effective treatment of a patient with an ABC is to confirm the diagnosis with open biopsy and frozen section; this biopsy usually is done at the same surgical setting as the definitive surgical procedure. It is important to remember that ABC can be secondary to other tumors such as nonossifying fibroma, giant cell tumor, and chondroblastoma; telangiectatic osteosarcoma may be difficult to distinguish from ABC with an inadequate biopsy specimen because the aplastic tumor cells are seen only at the periphery of the lesion (70,76).

Once the diagnosis is made, treatment should be initiated as soon as possible because most ABCs are aggressive and often grow and invade rapidly. Preoperative planning is important to ensure adequate exposure, preparation for blood loss, internal fixation, grafting material, and in selected cases, preoperative embolization.

Achieving adequate exposure with a large cortical window for thorough extended curettage is a key component for successful treatment. The use of a high-speed burr allows systematic intralesional excisional curettage. Adjuvants phenol and alcohol, liquid nitrogen, and polymethyl methacrylate (PMMA) usually are reserved for large or recurrent ABCs but may be considered in the initial management. Bone grafting is done for all lesions and can consist of autograft, allograft, bone substitutes, or a combination of these methods, depending on the circumstances. Most patients with fractures through ABCs have microfractures that do not alter treatment. For those with more significant or unstable fractures, internal stabilization is used when appropriate, particularly in the hip, femur, or tibia. The classification and recommendations in figure 6-7 are applicable for those with proximal femoral fractures associated with ABCs. A walking hip spica cast (i.e., a unilateral hip spica cast with the hip and knee in 20 to 30 degrees of flexion) is sometimes appropriate for young children with stable fractures. Close follow-up is recommended initially because recurrence can be rapid and aggressive.

For ABC of the spine, we recommend preoperative selective arterial embolization, intralesional extended excisional curettage and bone grafting. Instrumentation and fusion of the affected area should be performed if instability or the potential for instability exists. If instrumentation is used, titanium instrumentation allows follow-up MRI with less metal artifact compared with stainless steel implants (Fig. 6-11) (80).

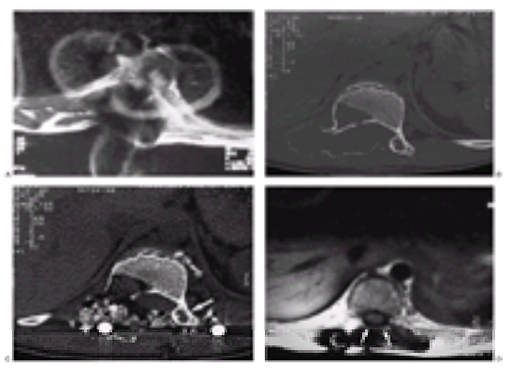

FIGURE 6-11. When dealing with pathologic fractures secondary to tumors or tumor-like processes of the spine, if instrumentation is needed, titanium instrumentation allows much better postoperative visualization with both CT and MRI for the detection of tumor recurrence as compared with standard stainless steel instrumentation. **A:** Postoperative MRI of the spine with standard stainless steel instrumentation showing a large degree of artifact that makes interpretation difficult. **B:** Preoperative CT scan of a patient with an ABC of the spine. **C:** Postoperative CT scan of the same patient showing an adequate view of the surgical area. **D:** Postoperative MRI of a patient with a previous spinal tumor again adequately showing the surgical site to monitor for recurrence or persistent tumor.

Tumors of Bone

Fibrous Cortical Defects and Nonossifying Fibromas

Fibrous cortical defects (FCDs) and a larger variant known as nonossifying fibroma (NOFs) may be associated with pathologic fractures in children. Both lesions contain fibrous tissue, foam cells, and multinucleated giant cells (84). Most pathologic fractures occur in boys (83), and age at presentation varies from 6 to 14 years (91).

FCDs are small metaphyseal lesions ranging from 1 to 2 cm in diameter and most commonly occur in the distal femur, proximal tibia, and fibula. They are eccentric and usually are surrounded by the thinned cortex, with the medullary wall of the lesion tending to be sclerotic. FCDs are common and can be seen on x-ray studies of the lower extremity in approximately 25% of pediatric patients (93). In view of their usually asymptomatic nature, it is difficult to estimate the true incidence. They usually require no treatment other than observation.

Radiographic Findings

NOFs also are eccentric lesions of the metaphysis, but they may achieve a length of 5 cm (90) or more and can extend across a substantial portion of the width of the long bone. They present at a similar age as FCDs, and follow a similar distribution of bone involvement, and multiple lesions are present in approximately one third of patients (83,87). On x-ray study, the lesions are usually eccentric, radiolucent cystlike areas that can be either uniloculated or multiloculated; in small bones such as the fibula, they may occupy the entire width of the shaft (84). Sclerotic scalloping is often present along the endosteal margin (89). Usually, NOFs are asymptomatic unless a pathologic fracture is present (84). They become clinically significant when they present with or predispose to pathologic fracture.

Natural History

Arata et al. (82) found that 43% of pathologic fractures through NOFs were in the distal tibia. Several previous reports suggested that these lesions regress spontaneously (83,84,85,87,90,92) Ritschl et al. (92) described the radiomorphic course of NOFs, demonstrating that the defects become sclerotic and resolve. Typically, this tumor remains asymptomatic and is commonly an incidental radiographic finding. However, lesions with extensive cortical involvement can cause pathologic fractures.

Previous reports suggest that the absolute size of the lesion correlates directly with the risk of pathologic fracture (82). Based on this factor, prophylactic curettage and bone grafting of larger NOFs have been recommended. Arata et al. (82) noted that all pathologic fractures associated with NOFs in the lower extremity occurred through lesions involving *more than 50% of the transverse cortical diameter*. These large lesions were defined as exhibiting more than 50% cortical involvement on anteroposterior (AP) and lateral x-ray studies and a height measurement of more than 33 mm (82). Although the authors recommended careful observation of these large NOFs, they suggested that “prophylactic curettage and bone grafting be considered if there is a reasonable chance of fracture.” Their series does not include any large lesions meeting their size criteria that did not fracture, and their hypothesis has never been tested in any published series. Drennan et al. (87) suggested that large NOFs causing pain may predispose to fracture and recommended prophylactic curettage and bone grafting for selected larger lesions.

Fractures through NOFs exhibit excellent healing potential (82,84,87), but the lesion usually persists after healing of the fracture (Fig. 6-12 and Fig. 6-13). Recurrent fractures have been reported, but the incidence of documented refracture is low (82,87). Fracture union takes place normally, but often multiple radiolucencies remain (84). Overall, fracture healing does not usually obliterate the lesions so recurrent fracture can occur (82,89).

FIGURE 6-12. A: An 8-year-old boy was referred after being casted at another institution for a pathologic fracture of the right femur. The x-ray studies in the cast show a pathologic fracture of the right distal femur through an NOF. **B:** At 14 weeks after the injury, the fracture has united with some posterior displacement of the distal fragment. **C:** At 7 months after fracture, there has been good remodeling at the fracture site with persistence of the NOF. The patient returned to full activities and has had no further problems at 7-year follow-up.

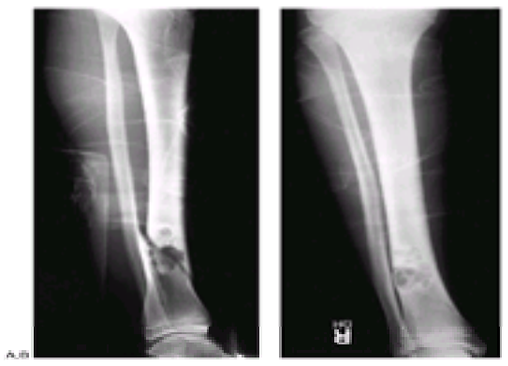

FIGURE 6-13. A 13-year-old athlete presented with a pathologic fracture through the distal tibia after a fall on the ice. **A:** The patient was treated with a long-leg cast immobilization. After the fracture had healed, the patient underwent open currettage and bone grafting of the lesion. **B:** Follow-up x-ray studies show healing of both the fracture and the lesion, and the patient has returned to full activities.

Large lesions, defined as having a diameter more than 50% of the width of a long bone on both AP and lateral x-rays, are believed to be prone to pathologic fracture; most authors have recommended curettage and bone grafting for these large lesions (83,84,86,87,89 and 91).

Easley and Kneisel et al. (88) reported that although absolute size parameters were helpful in predicting pathologic fracture, they did not imply a requirement for prophylactic curettage and bone grafting. In their series, 13 (59%) large NOFs had not had pathologic fracture despite exceeding the previously established size threshold. In the nine (41%) patients in whom pathologic fracture occurred, healing was uneventful after closed reduction and cast immobilization, and no refractures occurred. They suggested that most patients with large NOFs can be monitored without intervention, because previous studies support spontaneous resolution of most of these lesions (82,84,87). All fractured NOFs in their series healed with closed reduction and immobilization. It may be reasonable to restrict the activity of patients with large NOFs based on the nine patients in their study with pathologic fractures caused by trauma.

Fractures usually are treated with immobilization until healing is obtained (83,86). Surgery is necessary only if the residual lesion is of significant size to predispose the patient to further pathologic fractures or there is doubt about the identity of the lesion (84). Displaced pathologic supracondylar fractures of the distal femur may require open reduction, bone grafting, and intramedullary fixation (87). Subperiosteal resection of a pathologic humeral shaft fracture followed by bone grafting has resulted in pseudoarthrosis (89).

AUTHORS' PREFERRED METHOD OF TREATMENT

Treatment is based on the size and location of the lesion and the type of pathologic fracture. Small lesions without fracture can be observed and may require 1 to 3 years to spontaneously resolve (83). Substantial lesions of the lower extremity in active children, even if they are asymptomatic, should either be followed carefully with serial x-ray studies or should undergo curettage and bone grafting to avoid pathologic fracture. Although absolute size parameters may be useful in predicting pathologic fracture, they do not imply a requirement for prophylactic curettage and bone grafting. Most patients with large NOFs can be monitored without surgical intervention, and fractures can be successfully managed with nonoperative treatment. Our experience is that a considerable number of incidentally discovered large NOFs do not fracture. Although we cannot readily identify an accurate denominator, we infer that many large NOFs remain unidentified and nonproblematic. Patient and family wishes and the individual's activity demands also obviously influence the decision. Given the historic evidence for spontaneous resolution and favorable healing characteristics of NOFs, patients with lesions larger than 50% of the width of the bone should be approached individually.

Giant Cell Tumors of Bone

Giant cell tumors of bone are rare in the pediatric population; most occur in skeletally mature individuals. In a series of 221 patients with giant cell tumors of bone (96), only 20% of patients were younger than 20 years of age. In order of decreasing frequency, these tumors most commonly occur in the distal femur, proximal tibia, proximal humerus, and distal radius. The incidence of pathologic fractures with these lesions is approximately 16% (94,95,96,97 and 98).

Radiographically, they are osteolytic, metaphyseal lesions that can extend into the epiphysis, usually after physeal closure (Fig. 6-14). They can be eccentric, but larger lesions can involve the full width of the bone. Little or no sclerosis usually is present around the margin of the tumor. Although heavy trabeculation may be present, new periosteal bone formation is uncommon.

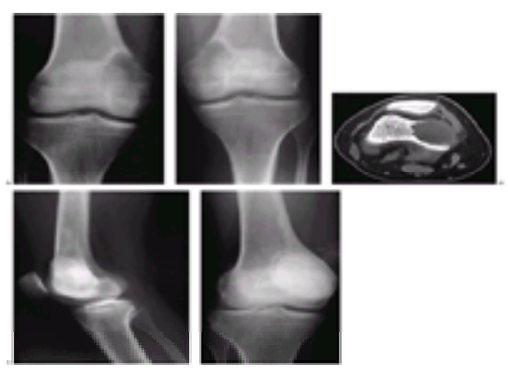

FIGURE 6-14. An 18-year-old girl presented with left medial knee pain. **A:** X-ray studies showed an eccentric, lytic, destructive lesion involving the distal portion of the medial metaphysis with extension into the epiphysis. **B:** CT scan showed the destructive lesion with thinning of the cortex and no external soft tissue mass. Open biopsy and frozen sections were consistent with giant cell tumor of the distal femur. An extended curettage was then performed with phenol as an adjuvant and subsequent cementation using methylmethacrylate bone cement. **C:** Follow-up x-ray studies at 2 years after surgery showing no evidence of recurrence. The patient

is asymptomatic and has full range of motion and function of the knee.

Giant cell tumors usually are treated by extended curettage in combination with adjuvants, such as phenol or liquid nitrogen, and filling with material such as PMMA (Fig. 6-14) (94,95 and 96). *En bloc* or wide resection is a more aggressive option. Simple curettage and bone grafting are associated with a high recurrence rate. In one series (96), simple curettage and bone grafting had a 34% recurrence rate, whereas wide resection of the lesion resulted in only a 7% recurrence rate. Wide resection is most appropriate for giant cell tumors involving expendable bones and for aggressive lesions with significant involvement of the articular surface. The location and extent of the lesion and the proximity of the tumor to articular cartilage and physis influence the treatment of giant cell tumors in children.

Pathologic Fractures Associated With Giant Cell Tumors of Bone

Pathologic fractures are associated with giant cell tumors in 6% to 30% of patients. The complexity of treatment is markedly increased if a pathologic fracture is present. Management depends on the type of fracture and fracture displacement (Table 6-6).

Scenario	Treatment
1. Fracture undisplaced, structurally insignificant, nonarticular	No change in treatment plan (Usually extended curettage and cementation with adjuvant such as phenol)
2. Fracture simple, but displaced	Joint preserving options:
a. Fracture can be reduced closed	a) Closed reduction and delayed extended curettage*
b. Fracture cannot be reduced closed	b) Open reduction, extended curettage, simultaneous internal fixation and cementation*
3. Fracture displaced, intraarticular; Open reduction, extended curettage and internal fixation cannot be achieved satisfactorily (uncommon in children)	Resection or partial resection of the joint

* If a fracture can be reduced and held by closed methods, it may be preferable to delay the definitive surgery until initial fracture healing has occurred. Fracture healing is biologically faster than the growth of the tumor, a delay of 4 to 6 weeks will have a minimal effect on tumor progression.
† A technically demanding and difficult procedure; i.e. mechanically removing all tumor (with curets and high-speed burr), use of adjuvant such as phenol, reduction and fixation of thin "shell" of bone and cementation around the internal fixation device.

TABLE 6-6. TREATMENT OF GIANT CELL TUMORS

A biopsy may be needed before fracture treatment if the diagnosis is not certain. Most pathologic fractures are undisplaced, structurally insignificant, or nonarticular, and require no change in the treatment plan. For more significant fractures, an attempt at preserving the joint should be made. Overall, the presence of a pathologic fracture itself does not seem to directly influence the recurrence rate of giant cell tumor; it may influence the reconstruction options and the overall functional result.

Enchondroma

Solitary enchondroma is a rare lesion in children. In one series of enchondromas (101), 57% of patients were between 11 and 30 years of age. The common presenting symptom is pain, usually associated with a pathologic fracture. Most common sites of involvement in decreasing order of frequency are the phalanges, metacarpals, metatarsals, humerus, and femur. Pathologic fracture is commonly the presenting symptom for enchondromas located in the phalanges of the hands or feet, but is rare for enchondromas in other locations.

On x-ray studies, the lesions can be central or eccentric and a stippled calcification of the cartilage tumor matrix may be seen. In the long bones, lesions tend to be central with only slight bulging of the cortex. The short tubular bones with enchondromas show a cloudy radiolucency with bulging and thinning of the cortex (Fig. 6-15) (101).

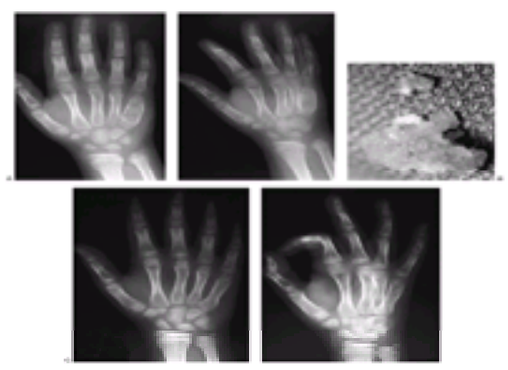

FIGURE 6-15. An 8-year-old boy presents with pain and swelling of the ulnar border of his right hand. **A:** X-ray studies showed and expansile, lucent lesion of the diaphysis of the patient's right fifth metacarpal with microfractures. The patient had an open incisional biopsy with frozen section, which was consistent with enchondroma with subsequent curettage and bone grafting. **B:** Gross appearance of material removed at the time of surgery, which is consistent with enchondroma. **C:** At 6-month follow-up, the fracture is well healed, and there is no sign of recurrent tumor.

Children can also have multiple enchondromas or enchondromatosis (Ollier's disease), which is commonly seen between 2 and 10 years of age (Fig. 6-16). X-ray studies show lesions similar to solitary enchondroma, but usually with deformity and shortening of the extremity due to growth disturbance (Fig. 6-16E). A unique x-ray finding that is believed to be pathognomonic for enchondromatosis is the presence of linear radiolucencies extending from the metaphysis down the shaft of the long bone.

FIGURE 6-16. Multiple enchondromatosis. **A:** A 10-year-old girl with multiple enchondromas sustained a spontaneous pathologic fracture of the femur while running. Nine months before the injury, she had sustained a fracture of the same femur, which had been treated with a one-and-a-half hip spica cast for 3 months. **B:** The lateral x-ray study shows overriding of the fracture. **C:** The fracture was treated with 3 weeks of skeletal traction, and then the extremity was placed in a cast brace for 9 weeks. On x-ray, the excessive anterior bow of the femur has been somewhat corrected by deliberate posterior angulation of the fracture. **D:** At 3-year follow-up, the fracture is well healed. **E:** The anteroposterior x-ray study of the hand in this patient demonstrated multiple expansile enchondromas of the small bones. **F:** An x-ray

study of the humerus shows the streaked-mud appearance of the lateral humerus (*arrow*).

When these lesions are associated with multiple hemangiomas, the general condition is known as Maffucci's syndrome (100,102). In this syndrome, 30% of patients have one or more pathologic fractures (102). Approximately half of these fractures go on to delayed union or nonunion. Unilateral skeletal involvement occurred in 48% of patients, with involvement in the order of frequency of the hand, foot, tibia, femur radius and ulna, humerus, and ribs. Skeletal deformities tend to stabilize at maturity. Sarcomatous degeneration has been reported in approximately 15% of patients.

Asymptomatic lesions can be observed. Biopsy may be necessary when the identity of the lesion is uncertain. Symptomatic lesions respond well to curettage and bone grafting (99,100). Treatment is individualized for displaced fractures (Fig. 6-15).

AUTHORS' PREFERRED METHOD OF TREATMENT

Solitary enchondromas often require biopsy to establish the diagnosis. For asymptomatic patients with small lesions with classic x-ray findings, biopsy usually is not necessary. Curettage and bone grafting is necessary for those lesions with acute or impending pathologic fracture. Fixation is not necessary for those lesions of the short tubular bones but may be necessary for lesions of the proximal femur or long bone of the lower extremity. Standard fracture care is adequate to treat most injuries.

Osteochondromas

Osteochondromas are one of the most common tumors of bone in children, and clinical symptoms usually are related to irritation of the surrounding soft tissue structures. Peroneal nerve palsy may occur in association with osteochondroma of the proximal fibula (103). Radiation induced osteochondromas also can occur (104).

Although they are rare, fractures may occur through the base or stalk of a pedunculated osteochondroma (105); conservative treatment is adequate (Fig. 6-17). Fractures through solitary osteochondromas should be observed, and excision should be reserved for those patients with persistent symptoms after healing.

FIGURE 6-17. A 10-year-old-boy with pain over the right medial tibia after a direct blow. An exostosis is present, and the transverse radiolucency at its base may represent a fracture. The patient continued to have symptoms after healing of the fracture and the osteochondroma was excised.

Eosinophilic Granuloma (Langerhans' Cell Histiocytosis)

Eosinophilic granuloma of bone is a benign condition with either solitary or multiple lytic bone lesions. It is considered part of a general family of diseases collectively known as Langerhans' cell histiocytosis (LCH) or histiocytosis X, which also includes Hand-Schüller-Christian and Letterer-Siwe diseases (111,115). Bone lesions contain large coffee bean–shaped histiocytes, eosinophils, and multinucleated giant cells (117).

Nearly 75% of patients with eosinophilic granuloma of bone are younger than 20 years old, and 34% are younger than 4 years old. The ratio of male to female is approximately 3:2 (117). Nearly 50% of patients present with localized pain and tenderness (108,117); the duration of symptoms ranges from 2 weeks to 2 months, with occasional associated trauma. Swelling may be present over superficial bones such as the skull, clavicle, and tibia (108). In order of decreasing frequency, the sites of involvement are the skull, femur, pelvis, ribs, humerus, spine, clavicle, mandible, tibia, radius, scapula, and fibula. In one series (113), 14% of patients with solitary eosinophilic granuloma of bone had additional lesions within 2 years of diagnosis, whereas 85% of patients with multiple lesions at the time of initial diagnosis had additional bone involvement. The incidence of pathologic fracture in patients with LCH is approximately 14% (108,117). Laboratory tests usually are not very helpful; eosinophilia is infrequent (117).

Patients with vertebral body involvement present with back pain and may have neurologic signs or symptoms. Although the thoracic spine is the most commonly involved part of the spine, both cervical and lumbar lesions have been reported (113).

Radiographic Findings

In children, long bone lesions may occur in both the diaphysis and metaphysis, with destructive osteolysis that erodes the cortex and overlying expansion by periosteal layering (108,113,114). Epiphyseal involvement is rare. Defects in bone may be lobulated, and aggressive subperiosteal bone formation may suggest malignancy. The size of the lytic area may vary from 1 to 4 cm (117).

Classic vertebral plana is uncommon with eosinophilic granuloma of the spine in a child. When present, however, usually only one vertebra is involved, and it assumes a coin-on-end appearance with intact adjacent disk spaces. X-ray studies of patients with skull involvement show characteristic punched-out round lytic lesions that are beveled on tangential views.

The lesion may mimic osteomyelitis, Ewing's sarcoma, Brodie's abscess, metastatic disease, and osteogenic sarcoma (108). Bone scans tend to be unpredictable, with the incidence of false-negative scans ranging from 28% to 35% (106). In one series (106), the increased uptake of isotope was seen in 60% of patients, and there was an 11% incidence of cold lesions found only in the vertebral column and the ribs. Although bone scans may be useful in identifying recurrent lesions (106), the skeletal survey is most valuable in identifying the lesions. A bone scan should be used only when the x-ray studies are normal or equivocal.

Treatment

Biopsy usually is needed for diagnosis because of the lesion's tendency to mimic more serious conditions. Once the diagnosis is established, treatment options may include curettage, curettage and bone grafting, irradiation, chemotherapy (108,117), and corticosteroid injection (115). All of these forms of treatment result in healing of the lesions (108). For small lesions and an established diagnosis, observation may be the best option; marginal sclerosis about the lytic area suggests healing.

Sbarbaro and Francis (117) reported an average healing time of 16 months after curettage without grafting. McCollough (113) noted that if a lesion increased in size after surgery, then additional bone or soft tissue lesions usually appeared. Yasko et al. (119) described a percutaneous needle biopsy technique for diagnosis with subsequent methylprednisolone injection for patients with localized LCH; 34 of 35 lesions injected with methylprednisolone healed, and there were no complications. Other investigators (107) have had similar results. Radiation therapy has been recommended for some inaccessible lesions (108), but one series suggested an

association of this treatment with subsequent lymphosarcoma (108). Chemotherapy, usually consisting of oral methotrexate and prednisone, is used in patients with severe, painful, or progressive lesions or visceral involvement (115).

Fracture bracing is useful for both acute fractures and prophylactic use for impending fracture or after biopsy of lower extremity lesions (109). Surgery may be necessary for unstable fractures (Fig. 6-18). The diagnosis of vertebral lesions usually is best established by biopsy, especially if there are any atypical radiographic feature of a lesion such as a soft tissue mass. After diagnosis, they usually are treated with activity modification and a spinal orthosis (Fig. 6-19) (110,112). Seimon (118) recommended biopsy “only if there is any uncertainty in diagnosis,” and irradiation only for progressive disease. Surgery may be necessary when there are associated neurologic deficits (113). Remodeling is seen with some spinal lesions but does not seem to correlate with patient age (110,112,116).

FIGURE 6-18. Eosinophilic granuloma. **A:** A 4-year-old boy with a pathologic fracture of the right femoral neck secondary to eosinophilic granuloma (*arrow*). **B:** The pins were removed, and at 3-month follow-up, the fracture was healed with acceptable alignment.

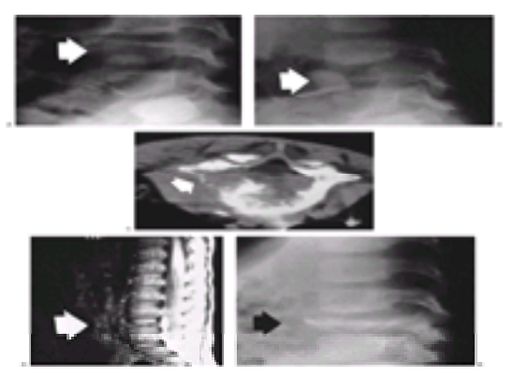

FIGURE 6-19. Eosinophilic granuloma. **A:** A 5-year-old boy presented with mild back pain and normal results of physical examination. A lateral x-ray study showed equivocal posterior wedging of L4 (*arrow*). Bone scan was read as normal. **B:** Nineteen days later on follow-up, he had marked spasm of the lower back. The lateral x-ray study now shows vertebral plana of L4 (*arrow*). **C:** CT scan shows marked expansion and erosion of the pedicle (*arrow*) and vertebral body. **D:** MRI shows marked collapse of L4 with thickening of the adjacent intervertebral disks. Soft tissue mass is also seen adjacent to L4 (*arrow*). Eosinophilic granuloma was diagnosed by Craig needle biopsy guided by CT scan, and the patient was treated with a spinal orthosis. Radiation treatment was also recommended, and a total of 600 rads was given in three divided doses. **E:** At 2-month follow-up, the compressed vertebra was beginning to regain density (*arrow*). The patient was asymptomatic. Bracing was continued for a total of 6 months.

AUTHORS' PREFERRED METHOD OF TREATMENT

Pathologic fracture is uncommon in patients with LCH. The correct diagnosis should be established with biopsy for most lesions, and the use of newer diagnostic methods such as immunohistochemistries (such as CD1A) can be helpful in confirming the diagnosis of these lesions. The natural history is one of gradual regression and healing. Standard fracture care is usually sufficient for pathologic fractures.

Malignant Bone Tumors and Metastasis

The two most common primary sarcomas of the long bones in children are Ewing's sarcoma and osteosarcoma. Destructive lesions also can be caused by metastatic cancer to bone.

Careful staging (124,130) and subsequent biopsy (121,131,132,135) are critical in the evaluation of children with malignant bone tumors. To avoid pathologic fracture from biopsy of bone, an oval hole with smooth edges should be used and should be filled with PMMA (130). Many malignant tumors have a large soft tissue mass that can be biopsied, obviating the need to make a hole in the bone. There has been a great deal of progress in the understanding of the molecular biology and genetics of cancer (125,126,127 and 128). These advances have already led to better diagnostic analysis of these tumors. Immunohistochemical, molecular genetic, and cytogenetic tests often are critical in establishing the correct diagnosis, especially small round blue cell tumors. The evaluation and biopsy of these children should preferably be done at a center where these techniques are known and available (121,129,131,132).

One of the major advances in the care of children with isolated extremity sarcoma has been the development of limb-sparing surgical techniques for local control of the tumors. Pathologic fracture has been cited as a contraindication to this procedure because of concerns about tumor dissemination by fracture hematoma (Fig. 6-20). Until recently, there has been little clinical data in the literature on which to base the treatment of these patients. A number of recent studies, however, have shown that pathologic fractures heal with neoadjuvant chemotherapy and do not affect survival rates (123,133,137). Abudu et al. (120) reviewed the surgical treatment and outcome of pathologic fractures in 40 patients with localized osteosarcomas and found that limb-sparing surgery with adequate margins of excision could be achieved in many patients without compromising survival, but that 19% of those treated with limb-sparing surgery had local recurrences. Scully et al. (134) reviewed the surgical treatment of 18 patients with osteosarcomas pathologic fractures. Of the 10 patients who had limb-sparing surgery, three had local recurrences and six had distant recurrences. Although the distant recurrence rate for patients undergoing amputation was no different from the rate for those undergoing limb salvage, the difference in local tumor control approached statistical significance. All patients who developed local recurrence died. The authors stated that surgical treatment should be individualized (134). Limb-sparing surgery is possible and appropriate in carefully selected patients as long as wide margins can be safely achieved and the function of the child will be better than that achieved with an amputation and a well-fitting prosthesis.

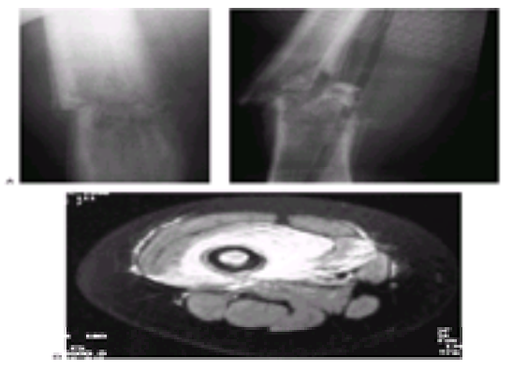

FIGURE 6-20. A 15-year-old girl was referred with a pathologic fracture of the femoral shaft after a fall while going down stairs. On close questioning, she stated that she had had pain in her thigh for several weeks before the fall and that the fall occurred after her leg gave way while going down the stairs. As an infant, she had already been treated with a cast for 2 months. **A:** The patient had been casted at another hospital, and x-ray studies in the cast show a transverse fracture of the mid-femoral shaft with destructive changes and worrisome periosteal elevation. **B:** MRI showed destructive changes of the mid-shaft of the femur with a soft tissue mass and bleeding from the fracture. An open biopsy established the diagnosis of Ewing's sarcoma of the femur, which was treated with neoadjuvant chemotherapy.

Pathologic fracture after limb-sparing surgery is a major complication, occurring most commonly after allograft reconstruction (122,136). Berrey et al. (122) reviewed 43 patients in whom allografts used in reconstruction after resection of tumors had subsequently fractured. Four fractures healed with immobilization alone, and the remainder of patients attained satisfactory results with open reduction and grafting, replacement of the internal fixation device, or total joint replacement (122). San-Julian and Canadell (136) reported on 12 patients with 14 fractures (10.2% of 137 patients with allografts for limb-sparing surgery in their series). They recommended intramedullary fixation whenever possible to reduce the incidence of allograft fracture.

Pathologic fractures also can occur in children with metastatic disease but are less common in children than in adults. Most are microfractures and can be managed with conservative fracture management techniques.

AUTHORS' PREFERRED METHOD OF TREATMENT

In all suspicious lesions, careful staging and biopsy are the appropriate treatments by individuals who have experience in the management of children with musculoskeletal sarcomas. Furthermore, access to special diagnostic modalities, such as immunohistochemistry and cytogenetics, will lessen the chances of misdiagnosis. The decision for or against limb-sparing surgery in patients with pathologic fractures should be individualized based on factors such as the fracture displacement, fracture stability, histologic and radiologic response to chemotherapy, and most important, the ability to achieve wide margins for local tumor control. Pathologic fractures that occur after reconstruction through allograft or endoprosthetic reconstruction often can be successfully treated with bone grafting or exchange of allograft or endoprosthesis.

BONE AND FIBROUS TISSUE DISEASES

Fibrous Dysplasia

Fibrous dysplasia, a developmental abnormality of bone presenting as expansile fibrous lesions, can result in pathologic fracture and deformity. Three forms exist: monostotic fibrous dysplasia, polyostotic fibrous dysplasia, and McCune-Albright syndrome (MAS). In 1937, McCune and Bruch (154) and Albright et al. (138) described patients with these osseous lesions in association with cutaneous pigmentation and endocrine dysfunction. Later, Lichtenstein and Jaffe (152,153) coined the term fibrous dysplasia and further divided the entity into monostotic and polyostotic forms without endocrine disorder. The common factor is expansile fibrous tissue lesions of the bone, which contain woven bone formed by metaplasia with poorly oriented bone trabeculae.

Studies have demonstrated that MAS is caused by activating mutations in the gene for the alpha subunit of the heterotrimeric stimulatory G protein of adenylate cyclase (*GNAS1* gene), located on the long arm of chromosome 20 at locus 20q13.2-q13.3 (139,155). The mutation in this gene likely occurs in embryonic development and is expressed in a mosaic pattern, resulting in the often lateralized pattern of skin and bone involvement in patients with MAS. This mutation is not present in tissue from patients with aggressive fibromatosis involving bone or osteofibrous dysplasia (139).

Monostotic Fibrous Dysplasia

Clinical Presentation

The diagnosis usually is made between the ages of 10 to 15 years of age, although neonatal fibrous dysplasia of the fibula has been reported. The lesions usually are asymptomatic until a fracture occurs, then patients may have pain and swelling (146). Incomplete fractures are most common. The sites of fracture in order of decreasing frequency are the proximal femur, tibia, ribs, and bones of the face (146). Cutaneous lesions usually are not present in monostotic fibrous dysplasia. Although pregnancy may stimulate the lesions (176), overall progression is rare after initial presentation. Sarcomatous degeneration has an incidence of approximately 0.5% and generally occurs approximately 15 years after initial diagnosis.

The central dilemma in monostotic fibrous dysplasia is distinguishing the lesion from other benign disorders. The differential diagnosis usually includes eosinophilic granuloma, UBC, giant cell tumor, enchondroma, solitary fibroma, and osteomyelitis. MRI can be helpful in evaluating these lesions, but biopsy is sometimes necessary to establish the correct diagnosis.

Radiographic Findings

Radiographically, lesions of monostotic fibrous dysplasia usually are elliptical, central lesions in the mid-diaphysis. The borders of the lesion are commonly sclerotic; trabeculation is more common than a ground-glass appearance. There often is a slight bowing of the tibia, but bowing of the femur is uncommon.

With evaluation by CT scan, the extent of cortical thinning can be studied and relative central densities measured. Eosinophilic granuloma, neoplasm, and osteomyelitis have a density on CT scan ranging from 20 to 40 Hounsfield units, whereas fibrous dysplasia has a higher density, ranging from 70 to 130 Hounsfield units. MRI may be useful to differentiate fibrous dysplasia from other lesions, especially UBC.

Injury

Pathologic fractures occur in nearly 45% of patients. Fractures of the long bones are generally not displaced; many are microfractures. Although the fractures heal rapidly, endosteal callus is poorly formed and periosteal callus is normal (148). With mild deformity, the cortex thickens on the concave side of the long bone. Nonunion is rare.

Treatment

Conservative treatment with immobilization is indicated for most fractures that occur in conjunction with monostotic fibrous dysplasia. Traction with subsequent casting can be used for femoral shaft fractures in young children; casts or cast-bracing for upper and other lower extremity fractures is often appropriate (146).

Operative intervention is indicated for fractures of severely deformed long bones and those through large cystic areas. Bone graft can be resorbed, but total obliteration of the lesion often can be accomplished with grafting. Deformity can occur, and internal fixation may be required for stabilization. Complete *en bloc* extraperiosteal excision with grafting has been shown to be successful for severe lesions but is seldom needed. Both painful lesions without fracture and impending pathologic fractures can be treated with bone grafting.

Proximal femoral lesions with pathologic fracture are especially troublesome because of the propensity for malunion with coxa vara. For fractures through small lesions, either cast immobilization or curettage with grafting can be used; osteotomy can be done for residual deformity (145). For larger lesions, internal fixation is necessary. Proximal femoral pathologic fractures have been stabilized with lag screws, blade plates (146), intramedullary nails, and Enders nails. Cast immobilization and protected weight bearing are necessary after these procedures to protect the reduction. Spine fractures are rare but can be treated with bed rest followed by immobilization with an orthosis (146).

Polyostotic Fibrous Dysplasia

Clinical Presentation

Most patients with polyostotic fibrous dysplasia present before age 10 years with pain, limp, deformity, or pathologic fracture (146,152). The bones most commonly affected are the femur, tibia, humerus, radius, facial bones, pelvis, ribs, and phalanges (152). Involvement is often unilateral, usually affecting a single extremity. In one series, 50% of patients had facial involvement (146). Spine involvement occurs with polyostotic fibrous dysplasia, and limb-length discrepancy is common (146,148). Although most laboratory studies are normal, serum alkaline phosphatase levels may be elevated (148). Some authors believe that polyostotic fibrous dysplasia does not usually progress significantly after adulthood (146,158), but others (148) believe that puberty does not affect the bone lesions.

Both intramuscular myxoma and myositis ossificans progressiva have been associated with polyostotic fibrous dysplasia. When it occurs, sarcomatous degeneration of the lesions occurs 10 to 12 years after the initial diagnosis of fibrous dysplasia; osteogenic sarcomas, chondrosarcomas, and giant cell sarcomas also have been reported. The warning signs for sarcoma in existing lesions of fibrous dysplasia are pain and rapid enlargement of the lesion.

Radiographic Findings

Polyostotic fibrous dysplasia appears as multiple expansile lesions with cortical erosion. Most have a multilocular appearance associated with a scalloped pattern of endosteal erosion (175). A ground-glass appearance on x-ray study is caused by the metaplastic woven bone comprising the lesion. A radiolucent cystic appearance also is common. Cartilage may be present in approximately 10% of lesions, and radiographic stippling may be seen (153). In contrast to those in monostotic fibrous dysplasia, the lesions in the polyostotic form have little increased peripheral density, and they usually form a characteristic fusiform expansion of the bone (Fig. 6-21). Bowing of the long bones is common, and normal tubulation may not occur with growth (148).

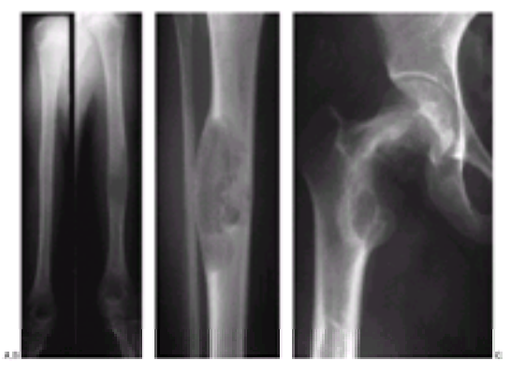

FIGURE 6-21. Polyostotic fibrous dysplasia in a l0-year-old girl. **A:** A fusiform expansile lesion is present in the mid-shaft of the humerus. **B:** A more eccentric expansile lesion is seen in the tibial shaft. There is scalloping due to endosteal erosion with a central ground-glass appearance. The lesion was painful and was treated with curettage and bone graft. (Courtesy of Jack Henry, M.D., San Antonio, Texas.) **C:** Polyostotic fibrous dysplasia in a 26-year-old woman. A large erosive lesion is present in the inferior neck of the femur. This lesion was treated by curettage with both fibula and iliac crest bone graft. (Courtesy of Gregorio Canales, M.D., San Antonio, Texas.)

Distinguishing polyostotic from monostotic fibrous dysplasia may be difficult. Plain x-ray skeletal surveys usually are done; technetium bone scans are helpful in identifying multiple lesions that may not be present on plain x-ray studies (143,149). Harris et al. (148) suggested that the hallmarks of polyostotic fibrous dysplasia is the characteristic long bone lesions with extension from epiphysis to epiphysis and increased density at the base of the skull. They suggest that a survey of the pelvis and femurs is most helpful in noting multiple lesions. Epiphyseal lesions can also occur (148).

Injury

In one series of 37 patients with polyostotic fibrous dysplasia, nearly 85% had at least one fracture and 40% had an average of three fractures (148). Fractures are most common in the femur, humerus, radius, and wrist (152,153). Like fractures in monostotic fibrous dysplasia, fractures in the polyostotic form generally are not displaced and healing is not delayed; nonunion can occur, however (148). Rib fractures are rare, and generally rib lesions are asymptomatic. A shepherd's crook deformity of the humerus associated with polyostotic fibrous dysplasia has been reported (143,157). Compression of the spinal cord by fibrous tissue also has been reported.

Treatment

The fractures of polyostotic fibrous dysplasia usually occur through very diseased bone and are associated with marked deformity. They often require more aggressive treatment than fractures seen in the monostotic form. Conservative immobilization techniques usually are appropriate for most shaft fractures in children before puberty. Fractures of the femur can be treated with traction and subsequent casting in young patients. After adolescence, however, the recurrence of deformity after surgery is less, and curettage and grafting should be considered for fractures, especially for large lesions with associated deformity (148,153). Stephenson et al. (156) found that in patients younger than 18 years of age, closed treatment or curettage and bone grafting of lower extremity fractures gave unsatisfactory results, but internal fixation produced more satisfactory outcomes. A Sofield procedure (osteotomy and intramedullary nailing) can be used for tibial deformity.

The greatest challenge in polyostotic fibrous dysplasia is treatment of fractures of the proximal femur. With recurrent fracture and deformity, a severe coxa vara resembling a shepherd's crook develops. Curettage of the lesion with abundant bone grafting has been recommended for mild deformities (149,153), and fixation usually is needed for large lesions. Femoral neck fracture or osteotomy for deformity can be stabilized with internal fixation. For severe shepherd's crook deformity, medial displacement valgus osteotomies with plate fixations are needed to restore the biomechanical stability of the hip (147). For severe lesions, Funk and Wells (145) recommended complete excision of the intertrochanteric area and advancement of the psoas and gluteus medius tendons. Breck (140) recommended securing the side plate of the femoral nail with bolts and washers rather than with screws to obtain better stability. Massive autogenous bone grafting is believed to be superior to donor bone graft (148), but it may be impractical because the iliac crests of a young child may be small and the pelvis may have coexisting disease.

The use of bisphosphonates may offer hope for a medical treatment for patients with severe fibrous dysplasia. Radiation therapy is not recommended (152).

McCune-Albright Syndrome

Clinical Presentation

McCune-Albright syndrome is a rare variant of fibrous dysplasia associated with endocrine dysfunction (such as precocious puberty in females), characteristic bone lesions (osteitis fibrosa disseminata), and areas of cutaneous pigmentation (138,154). It affects both women and men and has been associated with pituitary adenoma, gigantism, hyperthyroidism, and Cushing's syndrome (150). The skin lesions generally are flat, multiple melanotic areas that stop at the midline and parallel the distribution of bone lesions (146). The irregular margins have been compared to the coast of Maine in contrast to the smoother lesions found in neurofibromatosis, which are likened to the coast of California. Skin lesions may also be absent.

On x-ray studies, a polyostotic presentation is seen. With precocious sexual development, there is rapid bone maturation with early physeal closure and short stature (146). Pathologic fractures in childhood occur with a pattern and appearance similar to those in polyostotic fibrous dysplasia.

Treatment

The literature is limited regarding specific treatment of McCune-Albright syndrome, but both conservative treatment and aggressive surgical intervention have been used with apparent success. Internal fixation may be necessary in severe cases (Fig. 6-22). With the recent progress in understanding the genetic basis of this disorder, newer treatment alternatives may become available.

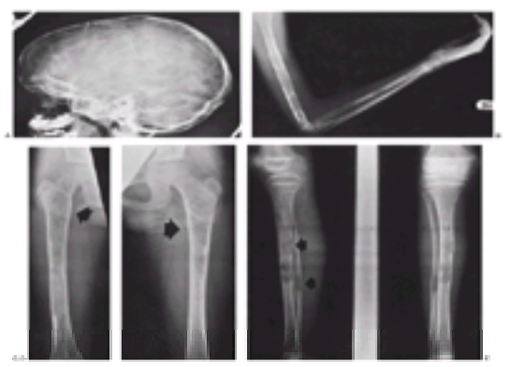

FIGURE 6-22. A: A 7-year-old girl presented with McCune-Albright syndrome. Skull radiographs show multiple lesions consistent with this condition. **B:** Expansile rarefied lesions are present throughout the humerus and the radius. **C** and **D:** Both proximal femurs have areas of rarefaction with expansile lesions (*arrows*). **E:** Both tibiae and fibulae show areas of expansile fibrous dysplasia (*arrows*).

AUTHORS' PREFERRED METHOD OF TREATMENT

Conservative treatment with immobilization is indicated for most fractures in children with monostotic fibrous dysplasia. In younger children, immediate casting, or traction and subsequent casting are used for most femoral shaft fractures. Because fractures in patients with polyostotic fibrous dysplasia usually occur through very abnormal bone and can result in marked deformity, they often require more aggressive treatment (e.g. internal fixation).

After adolescence, the occurrence of deformity after surgery is less frequent. Nonoperative treatment of fractures and curettage and cancellous bone grafting do not generally produce satisfactory results in children with fibrous dysplasia of the lower extremity. Curettage and grafting are indicated for fractures of severely deformed long bones and those through large cystic areas, with internal fixation appropriate for the location and age. Bone graft can be resorbed after placement in extensive lesions, and proximal deformity can occur after corrective osteotomy.

Proximal Femoral Lesions

One of the most common sites of fracture and deformity is the proximal femur. Proximal femoral lesions with pathologic fracture are especially difficult because of the tendency for varus deformity and repeated fracture. Stable fractures through small lesions can be treated with cast immobilization, but one must be vigilant and ready to intervene at any sign of varus displacement.

Femoral neck fractures can be stabilized *in situ* with a cannulated screw, or compression screw and side plate, depending on the extent of involvement and the nature and location of the fracture. Fixation can be combined with valgus osteotomy if there is preexisting deformity or with curettage and grafting if there is a large area of bone loss. Postoperative cast immobilization and protected weight bearing usually are necessary. Varus deformity is best treated with valgus osteotomy of the subtrochanteric region and internal fixation early in the course of the disease to restore the normal neck shaft angle and mechanical axis. Intramedullary load-sharing fixation (such as flexible intramedullary nails) can be used for juvenile patients with femoral shaft fractures.

For larger lesions with more severe deformity, and in older patients, rigid fixation often is necessary. Depending on the situation, intramedullary load-sharing fixation devices that support not only the femoral neck but also the shaft of the femur (such as *custom intramedullary reconstruction nails*) are better and should be used when possible. For severe shepherd's crook deformity, medial displacement osteotomies are needed to restore the biomechanical stability of the hip.

Patients with McCune-Albright syndrome should have careful preoperative evaluation in preparation for anesthesia and surgery. The reader is referred to an excellent review by Langer et al. (151) for further information.

Osteofibrous Dysplasia of the Tibia and Fibula

Clinical Presentation

The term osteofibrous dysplasia of the tibia and fibula is advocated to describe specific, uncommon fibrous lesions of the tibia and fibula in young children (160). These lesions superficially resemble monostotic fibrous dysplasia but exhibit unique natural history, response to treatment, and specific histology.

Most patients present before the age of 5 years, but the range varies from 5 weeks to 15 years of age (160,163). There usually is painless enlargement of the tibia with slight to moderate anterior or anterolateral bowing. The disease process is almost always confined to one tibia, but the ipsilateral fibula can also be involved. Solitary involvement of the fibula is infrequent, and bilateral involvement of both tibias is rare. Both distal and proximal lesions can occur, and with fibular involvement, the lesion is located distally.

Biopsy specimens distinguish this entity from fibrous dysplasia or adamantinoma. The fibrous tissue present is less cellular than in fibrous dysplasia. Woven bone is at the center of the lesion, with newly formed bone trabeculae bordered by active osteoblasts and lamellar structure near the periphery of the lesion. This pattern is unusual in fibrous dysplasia. A particular zonal architecture is present in large biopsy specimens and shows increasing size and maturity of the bone trabeculae toward the edge of the lesion. Some authors believe that osteofibrous dysplasia may be related to adamantinoma (164,165).

Radiographic Findings

An eccentric intracortical lesion of osteolysis usually is present in the middle third of the tibia, with extension proximally or distally (Fig. 6-23) (163). The cortex overlying the lesion is expanded and thinned, and in the medullary canal, a dense band of sclerosis borders the lesion with narrowing of the medullary canal. A single area of radiolucency may be present and has a ground-glass appearance, but often there are several areas of involvement with a bubble-like appearance.

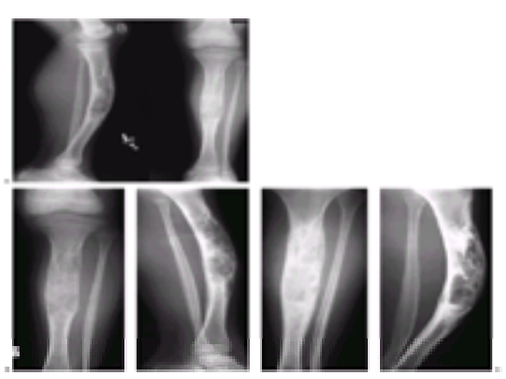

FIGURE 6-23. Osteofibrous dysplasia of the tibia. **A:** An 8-year-old girl presented with slight bowing of the left leg. X-ray study showed a circumscribed sclerotic and lytic lesion of the diaphysis of the tibia. Lateral radiographs show bowing of the tibia with a disphyseal intracortical lesion. The patient was thought to have osteofibrous dysplasia, and was braced and followed yearly. **B:** Eight years later, the lesion has become slightly more extensive and is associated with slight progression of anterior bowing of the tibia. The patient underwent open biopsy, and pathologic diagnosis was consistent with adamantinoma. Chest CT showed no sign of lung involvement. The patient was treated with wide excision of the entire lesion and free vascular fibula bone graft reconstruction. **C:** The patient has had no evidence of further recurrence at 16-month follow-up.

The differential diagnosis usually includes both monostotic fibrous dysplasia and adamantinoma, but some authors (160) believe that the characteristic x-ray appearance and the early onset of the disease effectively exclude these two disorders and that biopsy is not necessary. Others support the need for biopsy to establish diagnosis. Bracing with orthotics is advisable after open biopsy for diagnostic purposes.

Injury

Pathologic fractures are present in nearly one third of patients (160). These fractures are either incomplete or minimally displaced and heal well with both closed and open methods (160), although delayed union may be a problem. Pseudarthrosis is rare.

Treatment

The natural history of this disorder in untreated patients is variable. Most lesions show slight or moderate progression in late childhood, but others may show aggressive expansion with bowing of the tibia in patients up to 15 years of age. Rarely, the lesions may even regress or remain stationary over 3 to 4 years. Most lesions stop expanding after completion of skeletal growth. What appears to be osteofibrous dysplasia may actually be early adamantinoma (164). MRI showing a soft tissue extension is indicative of adamantinoma. Open biopsy also may be needed to establish the biphasic histology of adamantinoma.

Curettage and grafting were associated with a local recurrence rate of up to 64% in children 14 years old or younger in one series (160). Others reported a lower local recurrence rate. Ozaki et al. (162) showed the course of six tibial lesions in five patients with osteofibrous dysplasia who were followed longer than 10 years (average: 16.8 years). Curettage and autogenic bone grafting were performed on two lesions, which then healed. Of four lesions on which curettage and autogeneic bone grafts were performed, three healed and one recurred. The recurrent lesion healed after curettage and xenogeneic bone grafting. Three lesions healed without surgical treatment. During long-term follow-up, this disease showed a clear tendency for healing (162). Wide extraperiosteal resection can be performed, but graft resorption can still occur (160). Some authors (159,161) believe that bracing until skeletal maturity is preferable to surgery.

Pathologic fractures in this disorder should heal with cast immobilization in plaster casts. If fractures recur, or if the lesion is rapidly progressive, wide extraperiosteal resection with grafting is necessary (160). Open reduction with bone grafting and internal fixation is recommended for fractures with angular deformity. Early osteotomy is recommended for severe bowing deformity.

Neurofibromatosis

Neurofibromatosis, also known as von Recklinghausen's disease, is an autosomal dominant condition with variable penetrance that occurs in 1 in 2,500 to 3,000 live births (177). It affects neural tissue, vascular structures, skin, and the skeleton. The diagnosis of neurofibromatosis can be based on the presence of two of the four following criteria, according to Crawford and Bagamery (177):

1. Multiple café-au-lait spots
2. Positive family history for neurofibromatosis
3. Diagnostic biopsy of a neurofibroma
4. Presence of pseudarthrosis of the tibia, hemihypertrophy, or a short, angular scoliosis

Crowe and Schull (178) pointed out that adult patients with neurofibromatosis usually had more than five café-au-lait spots with a diameter of more than 1.5 cm. The presence of café-au-lait spots, however, is not pathognomonic for neurofibromatosis. Whitehouse (214) noted that 23% of normal children have one or two café-au-lait spots with a diameter of more than 0.5 cm, and the presence of five or more café-au-lait spots is needed to suggest the diagnosis of neurofibromatosis. Although café-au-lait spots may be present at birth, usually they are not seen until the patient is 5 or 6 years old (177). Generalized soft tissue hypertrophy of the limbs is present in 37% of adults with neurofibromatosis (196), whereas children have an 11% incidence of limb-length discrepancy and only a 3% incidence of soft tissue enlargement of the extremities (177).

A diagnostic biopsy of a dermal neurofibroma is considered a valuable criterion for the diagnosis of neurofibromatosis. These tumors, however, tend not to be clinically apparent until the child is older than 12 years of age (177). Plain x-ray studies are not helpful in identifying these soft tissue tumors. MRI can be helpful in identifying the soft tissue masses. Technetium 99m–labeled diethylenetriaminepentaacetic acid (DTPA) accumulates in the soft tissue tumors of neurofibromatosis (191,192). Routine isotopic imaging with this technique can identify lesions as small as 1.5 cm. Lesions as small as 0.8 cm were seen through a more advanced technique known as single proton emission computed tomography. Such techniques may be useful in identifying occult neurofibromatosis and pseudarthrosis of the long bones.

Injury

Pseudarthrosis of the long bones in patients with neurofibromatosis can be a therapeutic dilemma. The appearance of pseudarthroses and their resistance to treatment has been postulated to be due to a deficiency of bone formation secondary to mesodermal dysplasia. More recently, the abnormal soft tissue associated with these pseudarthroses has been postulated to be the major associated factor in causing pseudarthrosis (216). Wright et al. (216) developed a rabbit tibia congenital pseudarthrosis model and suggested that a possible underlying abnormality in congenital pseudarthrosis might actually be the abnormal soft tissue surrounding the bone rather than the bone itself (216).

Approximately 5% of patients with neurofibromatosis are thought eventually to have pseudarthrosis of the long bones. The tibia is the bone most often affected, but only 55% of the cases of congenital pseudarthroses of the tibia are thought to be associated with neurofibromatosis (176).

The term congenital pseudarthrosis in neurofibromatosis is misleading because a substantial number of patients do not have a pseudarthrosis at birth but rather develop it later after a pathologic fracture (199). Brown et al. (175) found that in six children with neurofibromatosis, anterior bowing of the leg developed at an average age of 8 months and then went on to fracture and pseudarthrosis an average of 4.5 months after the initial clinical observation of deformity.

The focus of the recent orthopaedic literature has been treatment of congenital pseudarthrosis of the tibia (199), but pseudarthroses in other locations in children with neurofibromatosis also occur and can be a challenge. Pseudarthroses have been reported in the radius (171,175,184,185,186,187,188,189,190,191,192,193,194 and 195), ulna (166,167,170,171,189,200,201), both the radius and the ulna (167,170,193,195,205,207), femur, clavicle, and humerus. Most patients had associated neurofibromatosis, but some with pseudarthroses in each of the above-mentioned locations did not.

Radiographic Findings

Anterolateral bowing of the tibia with loss of the medullary canal usually is present before fracture (Fig. 6-24) (175). Another x-ray characteristic is a prefracture cystic lesion of the tibia with anterolateral bowing (176). Biopsy specimens of these pseudarthroses invariably reveal fibrous tissue, but there are reports of (167,194) found evidence of neural tissue in biopsy specimens. None of these findings, however, has been confirmed by electron microscopy to document the presence of Schwann cells. X-ray findings in patients with established pseudarthroses of the tibia include narrowing or obliteration of the medullary canal at the pseudarthrosis site, with

sclerosis and anterolateral angulation (Fig. 6-25). Pseudarthrosis of the fibula is associated with valgus deformity of the ankle (Fig. 6-26).

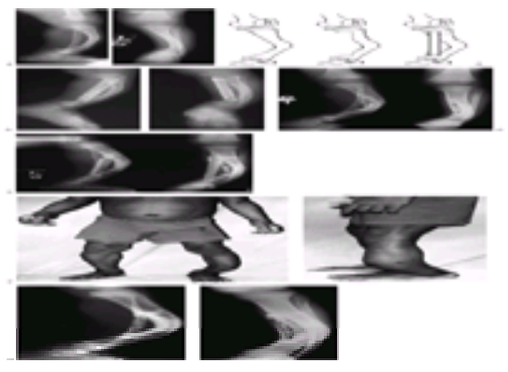

FIGURE 6-24. A: A 2-year-old boy with neurofibromatosis presented with anterolateral bowing, sclerosis, and partial obliteration of the medullary canal of the tibia without fracture. **B:** A modified McFarland technique for prophylactic bypass grafting was performed as shown. **C:** Immediate postsurgical x-ray studies of the tibia after prophylactic bypass grafting. **D:** Three years later, x-ray studies show continued growth of the tibia without fracture but some absorption of the allograft and relative loss of structural support by the allograft related to continued growth. **E:** X-ray studies after a second prophylactic bypass grafting. **F:** Clinical photographs of patient's lower extremities. **G:** Current x-ray study 5 years after the initial presentation. The patient has had no fractures and is functioning well without pain. (From Dormans JP. Modified Sequential McFarland Bypass Procedure for prepseudarthrosis of the tibia. *J Orthop Tech* 1995;3:176–180.)

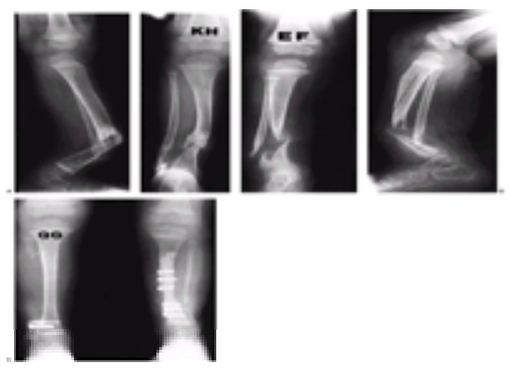

FIGURE 6-25. A and **B:** Two examples of untreated congenital pseudarthrosis of the tibia in children with neurofibromatosis. **C:** After resection and reconstruction with a vascularized free fibula interposition.

FIGURE 6-26. Pseudarthrosis of the fibula is associated with valgus deformity of the ankle.

In upper extremity pseudarthroses of neurofibromatosis, the x-ray signs of the bone at risk are narrowing of the diaphysis (201), sclerosis and hypoplasia with associated absent medullary canal (193), and the presence of a cystic lesion in the bone. Once a fracture has occurred, a pseudarthrosis is likely when the fracture line persists for more than 7 weeks after injury (194). The ends of the fracture gradually become tapered, there is little callus, and the cortex of the healing bone thickens with a decreased diameter of the medullary canal. The cause of these radiographic changes is unclear. Biopsy specimens from upper extremity pseudarthrosis have consistently shown the presence of dense fibrous tissue without evidence of neurofibroma. Pseudarthroses have developed in children with neurofibromatosis after fracture through normal-appearing forearm bones (185,186).

Treatment

A tibia with an anterolateral bow in an infant or child will eventually fracture; corrective osteotomy to correct angular deformity will only accelerate the progression to pseudarthrosis and should not be done. Once the fracture occurs, there is no indication for closed treatment. In conjunction with excision of the hypotrophic bone ends, methods of treatment of this congenital pseudarthrosis include intramedullary fixation with iliac bone graft, fixation with vascularized fibular graft, and Ilizarov's compression of the pseudarthrosis with callotastic lengthening of the proximal tibia. All of these methods may be complicated by further pathologic fracture.

In contrast to pseudarthrosis of the upper extremity, there is substantial experience with treatment of pseudarthrosis of the tibia, but results are also disappointing. Bracing has proved ineffectual in the treatment of an established pseudarthrosis. Surgical procedures have included bypass grafts (197), onlay grafts (173), grafting with small bone chips, intramedullary nailing procedures (168,169), and intramedullary rod fixation after segmental osteotomies (209). The rate of union with these procedures ranges from 7% to 90%, and eventual amputation has been common. Electrical stimulation has been used with some success, but most series reporting its use have short patient follow-up and the electrical stimulation was used in combination with other surgical techniques. In one series, a 20% success rate was achieved using direct-current stimulation (174). In another series, union was achieved in 10 of 12 patients with pseudarthrosis of the tibia through rigid intramedullary rod fixation and electrical stimulation through implanted electrodes (202). The Farmer procedure, a skin and bone pedicle from the contralateral leg, has a reported union rate approaching 53% (198). Free vascularized fibular grafts also have been used for reconstruction after excision of the involved tibia (198). In one series, 11 of 12 patients with neurofibromatosis and pseudarthrosis of the tibia were successfully treated with free vascularized fibular grafts. Union of the pseudarthrosis occurred between 3 to 8 months after surgery (172,179,213). A free vascularized iliac graft has been used in one patient with neurofibromatosis, resulting in union within 10 weeks (188). Fabry et al. (181) obtained union of pseudarthrosis of the tibia in two patients with compression through an Ilizarov fixator. In another series (204), the fractures in three of five patients healed in 4.5 months. The other two patients needed supplementary iliac grafts, and eventually, the bone united. It is important to stress that treatment cannot be considered successful until skeletal maturity has been reached; many of these series included patients with short follow-up, and few included follow-up to skeletal maturity.

A prophylactic bypass grafting of the prepseudarthrotic tibia in neurofibromatosis has been performed with some success. This modification of the original McFarland bypass procedure, which was originally done for established pseudarthrosis, was successful in a series of patients from several centers reviewed by Strong and Wong-Chung (211). A modified sequential McFarland bypass procedure for pre-pseudarthrosis of the tibia also has been described (Fig. 6-24) (180).

Amputation should be considered and discussed with the family early when previous operative interventions have been unsuccessful. Amputation usually is at the

Syme level, with prosthetic fitting around the pseudarthrosis. In a gait analysis study, Karol et al. (187) compared 12 patients with previously operated and healed congenital pseudarthroses of the tibia with four children with amputations for final treatment of congenital pseudarthroses of the tibia. They found marked disturbance of gait and muscle strength in patients with healed congenital pseudarthroses of the tibia. They concluded that patients with early onset of disease, early surgery, and transankle fixation had more inefficient gaits than amputees. Patients with forearm pseudarthroses can be pain free and function may be satisfactory with observation or splinting. However, persistence of an ulnar pseudarthrosis in a growing child often leads to bowing of the radius and posterior lateral subluxation or dislocation of the radial head (166,167,189,201). Healing after 6 months of casting has been reported in a 2-month-old infant with a congenital pseudarthrosis of the radius. There was no clinical evidence of neurofibromatosis at the time of treatment of this patient (183). Union after conventional bone grafting and fixation has been reported in only a small number of patients with congenital pseudarthrosis of the forearm (170,171,185,186,193,208). Many of these patients require multiple conventional bone grafting procedures and often years of immobilization. There are more reports of patients (and probably many more patients) with pseudarthroses of the forearm bones who did not respond to multiple grafting procedures (166,171,175,194,201). The results of treatment of congenital pseudarthrosis of the forearm in neurofibromatosis by free vascularized fibular grafts are encouraging. Allieu et al. (167) treated one patient with radial and ulnar pseudarthroses and another with ulnar pseudarthrosis with free vascularized fibular grafts. They obtained union in the patient with radial and ulnar pseudarthroses in 6 weeks and in the patient with ulnar pseudarthroses in 3 months. Earlier conventional grafting techniques had failed in both. Two additional patients with pseudarthroses of the radius without evidence of neurofibromatosis were treated with free vascularized fibular grafts, resulting union within 6 weeks (207,216). Mathlin et al. (195) reported six pseudarthroses of the forearm bones treated with vascularized fibular grafting with union in five ranging from 6 to 18 months after surgery. Other surgical options include excision of the ulnar pseudarthrosis to avoid a later tethering effect on the growing radius (166) and fusion of the distal radius and ulnar joint (201). Creation of a one-bone forearm is often technically successful, but both length and rotation of the forearm are sacrificed with this procedure (189,201).

Extreme care should be taken in surgical treatment of children with neurofibromatosis, in whom the periosteum of the long bones is believed to be less adherent to the bone than normal periosteum.

Complications

Extensive subperiosteal hemorrhage with subsequent ossification was reported in a 9-year-old patient who underwent surgical epiphysiodesis of the proximal tibia and fibula (217). Massive subperiosteal hemorrhage due to minor trauma in children with neurofibromatosis occurred in the tibia and femur (217). The amount of blood loss in subperiosteal hemorrhages can be life-threatening. Yaghmai and Tafazoli (217) evacuated a subperiosteal hemorrhage of a femur in an 11-year-old boy with neurofibromatosis who presented with a rapidly growing mass of the thigh after a minor fall. An eggshell calcification was visible around the femur within weeks of the trauma. The cyst held 2,100 mL of serous fluid and went on to complete ossification within 12 weeks of surgery with marked thickening and distortion of the involved femur.

It is important preoperatively to rule out hypertension in children with neurofibromatosis because 16% of children with neurofibromatosis had hypertension in one series (212).

Injuries of the Spine in Neurofibromatosis

Spinal deformity is the most common musculoskeletal abnormality seen in individuals with neurofibromatosis. Although scoliosis was present in 64% of patients with neurofibromatosis in one series (177), kyphoscoliosis may be the primary contributor to the development of paraplegia (215). Patients younger than 19 years of age may have paraplegia secondary to vertebral deformity, whereas those patients older than 19 are more likely to have neurologic deficits secondary to a neurofibroma. Complete dislocation of the spine with neurologic defect has been reported in two patients with neurofibromatosis (206). Rib penetration of the enlarged neural foramen with spinal cord compression in neurofibromatosis has also been reported in four patients (182,190). CT scan and MRI are useful for evaluating these patients. Resection through either an anterior or a posterior approach seems satisfactory (190).

AUTHORS' PREFERRED METHOD OF TREATMENT

The treatment of congenital pseudarthrosis of the tibia remains controversial. When a child presents with prepseudarthrosis, (angulation without fracture), either bypass grafting with fibular allograft or bracing are reasonable options. Once pseudarthrosis has developed, our preference is inserting an intramedullary rod and bone grafting of both the tibia and fibula when possible. If these procedures fail, free vascularized fibula transfer or resection and bone transport with circular frame techniques can be considered. Amputation and prosthetic fitting should be considered early in patients with failure of the above-mentioned techniques and severe shortening and a stiff ankle and foot. Conservative options such as bracing or observation for upper extremity pseudarthroses may be justified in a patient with a nonprogressive deformity and a satisfactory functional use of the extremity. Conventional bone grafting and fixation procedures for treatment of pseudarthrosis of the upper extremity have very limited success, and other approaches should be considered. Free vascularized fibular grafts seem the treatment of choice for upper extremity pseudarthrosis associated with neurofibromatosis.

CONGENITAL INSENSITIVITY TO PAIN

Congenital insensitivity to pain is a rare disorder characterized by the absence of normal subjective and objective responses to noxious stimuli in patients with intact central and peripheral nervous systems. The cause is unknown, but sporadic reports have appeared in the orthopaedic literature (219,220,221 and 222).

Orthopaedic manifestations of congenital insensitivity to pain include recurrent fractures, osteomyelitis, and neuropathic joints (Fig. 6-27). Limb-length discrepancy may occur from physeal damage. Lack of pain perception is associated with the development of Charcot's joints, which may lead to later neuropathic arthropathy. The weight-bearing joints usually are affected, especially the knees and ankles.

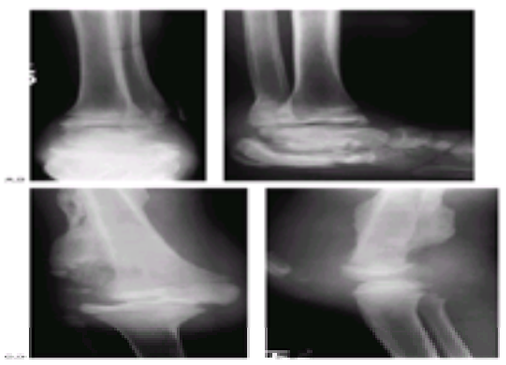

FIGURE 6-27. A: This 6-year-old child with anhydrosis, congenital insensitivity to pain and attention deficit disorder presented with a history of swollen ankles and knees. This AP radiograph and (**B**) this lateral radiograph shows Charcot changes in the subtalar joint with calcaneous and distal fibula fracture. **C:** This AP radiograph of the right knee and (**D**) this lateral radiograph of the right knee show large, loose osteochondral fragments, medial subluxation of the femur on the tibia and extensive periosteal new bone formation in the distal femur. Soft tissue shadows are consistent with her huge knee hemiarthrosis. More than 100 mL of sterile serosanguineous fluid was aspirated from the knee at her initial visit. The effusion quickly returned in the days following the aspiration. Because management with casts at another hospital resulted in significant skin breakdown, we stabilized the knees with removable hinged braces. The effusions improved but did not resolve.

The differential diagnosis includes a spectrum of closely related sensory disorders including congenital sensory neuropathy, hereditary sensory radicular neuropathy, familial sensory neuropathy with anhydrosis, and familial dysautonomia (Riley-Day syndrome). Acquired conditions with pain insensitivity include syringomyelia, diabetes mellitus, tabes dorsalis, alcoholism, and leprosy. Loss of protective sensation promotes self-mutilation, burns, bruises, and fractures. The disease comes to light when the child develops teeth and then bites his or her tongue, lips, and fingers.

Management should aim at education and prevention of injury. Prevention of joint disease is the best early option (219,222). Joint injury should be recognized and

treated early to prevent progression to gross arthropathy. Early diagnosis of injury is important, with signs of instability, swelling, and local warmth prompting early investigation and treatment. Most fractures are treated nonoperatively, when appropriate. Immobilization, bed rest, or appropriate bracing usually is indicated (219,221).

In a severely unstable, degenerated joint, arthrodesis may eventually be appropriate; however, poor healing, nonunion, and pseudarthrosis are common in neuropathic joints. The condition appears to improve with time with the gradual recovery of pain sensation.

MARROW DISEASE OF BONE

Gaucher's Disease

Gaucher's disease is a hereditary disorder of lipid metabolism caused by a deficiency of the lysosomal enzyme glucocerebrosidase resulting in an abnormal accumulation of glucocerebroside (glucosylceramide) in macrophages of the reticuloendothelial system. It is the most common sphingolipidosis and is inherited as an autosomal recessive trait (232). It is very rare, with most cases noted in Ashkenazic Jews of eastern European origin (228). It has three forms of presentation. Type I is a chronic non-neuropathic form (i.e., without neurologic problems) with visceral (spleen and liver) and osseous involvement. This is the most common form (more than 90% of cases) and the type most commonly seen by orthopaedic surgeons. This type is also known as the adult form, but commonly, patients present during childhood (238). Type II is an acute, neuropathic type with central nervous system involvement and early infantile death. Type III is a subacute non-neuropathic type with chronic central nervous system involvement. These later two types, characterized as either infantile or juvenile, are notable for severe progressive neurologic disease and usually are fatal.

Lipid-laden histiocytes, known as Gaucher's cells, provoke clinical symptoms by their accumulation in the liver, spleen, and bone marrow. Osseous lesions result from marrow accumulation and include Erlenmeyer's flask appearance, osteonecrosis (particularly of the femoral head), and pathologic fractures, especially of the spine and femoral neck.

Clinical Presentation

Most patients with Gaucher's disease are diagnosed before age 10 years (236). Common clinical findings include hepatosplenomegaly, yellowish pigmentation of the skin, pingueculae of the eyes (235,237), and bone lesions in 50% to 75% of patients (235). Bone pain, presenting as dull extremity ache, is present in most patients, and joint pain is equally common (228). Hemolytic anemia, leukopenia, and thrombocytopenia result from both hypersplenism and marrow replacement. These factors, along with abnormal liver function, tend to make these patients susceptible to infection and abnormal bleeding (224,225,226,227 and 228). Patients often have an increased serum acid phosphatase level and may have a decreased level of activity of glucocerebrosidase enzyme in white cells.

Bone lesions are most common in the femur, but they also occur in the pelvis, vertebra, humerus, and other locations (235). Infiltration of bone by Gaucher's cells leads to vessel thrombosis; compromise of the medullary vascular supply leads to localized osteonecrosis of the long bones (237), and avascular necrosis of the femoral head occurs in most patients in whom the disease is diagnosed in childhood (238).

Bone crisis and osteomyelitis in patients with Gaucher's disease demonstrate similar symptoms. Nearly half of patients with Gaucher's disease have episodes of bone crisis, also known as pseudo-osteomyelitis, in which they present with acute sharp pains of the extremity with associated local warmth, redness, and tenderness (239). Distinguishing this problem from osteomyelitis can be difficult. With bone crisis, a patient may have severe pain in the back or extremities, rubor, fever, and an elevated white blood cell count (239). Radiographs may show periosteal reaction or lytic lesions that are difficult to differentiate from osteomyelitis. Blood cultures are sterile, and aspiration of the affected bone is often necessary to provide correct diagnosis (224).

Osteomyelitis is present in a significant number of patients with Gaucher's disease. Hematogenous osteomyelitis was found in 10% of 49 patients in one series (224). Acute osteomyelitis is best managed conservatively when possible. Open irrigation and debridement of the bone may result in chronic osteomyelitis. Noyes and Smith (237) reviewed 18 patients with bone crisis who underwent biopsy to rule out osteomyelitis, and 61% of them went on to have postoperative osteomyelitis.

Plain x-ray studies usually are not helpful in differentiating crisis from infection (224). Technetium 99 bone scanning often demonstrates no increased uptake with a crisis (224) and shows decreased uptake in the area of osteonecrosis secondary to bone crisis, usually within 1 to 3 days after onset (225). Gallium 67 scintigraphy may be useful in differentiating crisis from infection by showing a lack of uptake in osteonecrosis and bone crisis, which may prove useful in excluding the presence of osteomyelitis (236). Bell et al. (224) recommended the use of CT scans to document the presence of purulent exudate in osteomyelitis in patients with Gaucher's disease. Recently, some authors have found MRI useful for excluding osteomyelitis in patients with Gaucher disease (237), but others (225) believe that MRI cannot distinguish between osteomyelitis and pseudo-osteomyelitis of bone crisis.

Radiographic Findings

Radiographically, three patterns of bone involvement have been described. (a) Generalized infiltration of the bone marrow of long bones by Gaucher cells causes a decreased density and cortical thinning. There is a general tendency for failure of tubulation (229), and this problem is most pronounced in the distal femur, where it produces an Erlenmeyer's flask appearance (Fig. 6-28). (b) The bone is moth-eaten with occasional osteosclerosis, and a centrally located curvilinear or vertical radiolucent streak is seen in the distal femur. (c) Dense collections of Gaucher cells form localized bubbly expansile lytic lesions in the bone, and associated areas of aseptic necrosis with medullary infarction form diaphyseal lytic lesions with reparative periosteal reaction surrounding them (229).

FIGURE 6-28. A 2-year-old child with Gaucher's disease. Early flaring of the distal femur is already present and will likely develop into a classic Erlenmeyer's flask deformity. Note the moth-eaten appearance of the metaphysis (*arrow*).

Avascular necrosis of the femoral head is similar to that seen in Legg-Calvé-Perthes disease, and vertebral plana may be present with lesions of the spine (229). MRI is more sensitive than radiographs or CT in demonstrating marrow involvement.

Injury

Pathologic fractures, especially of the femoral neck or shaft after biopsy and of the spine, usually are best managed conservatively. Katz et al. (232) reported 23 pathologic fractures in 9 children with Gaucher disease; 7 had multiple fractures. In decreasing order of frequency, the site of involvement included the distal femur, basilar neck of the femur, spine, and proximal tibia. Fractures also occurred infrequently in the distal tibia, proximal humerus, rib, and acetabulum. Fractures of the long bones were transverse and usually in the metaphysis. Fractures of the spine were either wedge shaped or centrally depressed at the end plate. The factors predisposing these children to fracture included significant medullary space infiltration, cortical bone erosion, osteonecrosis, and associated disuse osteoporosis

(232).

In another report of 53 patients with Gaucher's disease aged 9 to 18 years (234), 11 had vertebral fractures, usually at two or three sites in each patient, with either anterior wedging, central vertebral collapse, or total rectangular collapse. Most patients had relief of their pain after 1 to 4 months of conservative treatment; two required decompression laminectomies, and one had a posterior lateral fusion to stabilize the spine.

Katz et al. (233) found that fractures of the upper extremities in Gaucher's disease were prone to occur in areas of prior crisis. Although external callus formed in 6 to 8 weeks in most patients, complete healing with internal callus took almost 2 years in some. Other authors have found fracture union to be rapid (229). Both delayed union and nonunion (237) have been reported in older patients with Gaucher's disease.

Pathologic femoral neck fractures with minimal associated trauma in children with Gaucher's disease often heal with a varus malunion and minimal subsequent remodeling; avascular necrosis of the femoral head also can be associated with femoral neck fractures (229,235). Goldman and Jacobs (229) stated that the presence of a mixed density of bone of the femoral neck on x-ray with narrowing of the medial cortex was a risk factor for fracture.

Treatment

In the past, there was no specific treatment for Gaucher's disease. Splenectomy was often performed to help correct thrombocytopenia (228), but some authors believed that splenectomy worsened the orthopaedic complications of Gaucher's disease and recommended that it should be delayed as long as possible (332). Enzyme replacement therapy for the deficit found in Gaucher's disease has been developed (230). It is known as alglucerase (Ceredase) and is given in intravenous infusions every 2 weeks, with most patients having a decrease in the size of their livers and spleens, and improvement in their anemia. With the recommended dosage of 60 units of alglucerase per kilogram, a 30-kg child requires a yearly amount of enzyme costing $163,800 (227). Low-dose imiglucerase (Cerezyme, Genxyme), a placental recombinant human-derived beta-glucocerebrosidase enzyme replacement, is also being used to treat patients with type I Gaucher's disease (244). Studies have shown that either a reduced dose or a low-dose–high-frequency regimen can achieve similar clinical effects with less cost (227,243). Less costly home intravenous enzyme replacement treatment is possible (245). After 1 year of treatment with replacement enzyme, patients with Gaucher's disease seem to have a decreased tendency for infection (243). The effects of the enzyme on the bone disease are unclear. Zevin et al. (242) found no change in bone appearance after 1 year of replacement therapy, whereas Hill et al. (231) noted improved appearance of the long bones and involved spine after 16 months of enzyme replacement therapy. Bone marrow transplantation also has been shown to be helpful in reversing the medical effects of Gaucher disease (241), but the mortality rate of patients undergoing allogenic marrow transplantation is greater than 15% (227).

Fracture Management

Pathologic fractures of the upper extremities and the spine respond well to conservative immobilization techniques. For fractures of the lower extremity, prolonged bed rest is to be avoided because of the additional complication of disuse osteoporosis. Early mobilization with non–weight bearing casts is necessary to avoid angulation of the fractures. Complete healing as defined by the appearance of internal callus may require from 10 to 32 weeks of immobilization. Corrective osteotomy may be necessary for residual angulation. Some authors have recommended conservative treatment with non–weight bearing for minimally angulated femoral neck fractures (228,232), with internal fixation reserved for unstable femoral fractures with progressive or marked displacement (232,235).

All patients with Gaucher's disease considered for a surgical procedure should undergo extensive preoperative evaluation of their abnormal clotting function. Excessive bleeding may even occur when clotting tests are normal (224). It is important for the anesthesiologist to recognize that patients with Gaucher's disease may be prone to upper airway obstruction because of infiltration of the upper airway with glycolipids and commonly may have an airway up to 50% smaller than predicted for age (240). These patients are prone to infection, likely due to abnormal neutrophil chemotaxis (223), and needle biopsy under operating room conditions is preferable to open biopsy (237).

AUTHORS' PREFERRED METHOD OF TREATMENT

Conservative immobilization with non–weight bearing is suggested for long bone fractures when appropriate. Stable fractures of the femoral neck should be treated by guarded immobilization with frequent follow-up x-ray studies. Internal fixation should be used in femoral fractures that show signs of or potential for displacement. Preoperative planning is important, with careful evaluation of clotting function and preoperative consultation by the anesthesiologist. Femoral head osteonecrosis is managed symptomatically, at first with osteotomy or joint replacement later when necessary.

Sickle Cell Disease

The term sickle cell disease (SCD) characterizes conditions caused by the presence of sickle cell hemoglobin (HbS). Variants of these conditions include sickle cell anemia (HbS-S), the less severe sickle cell disease (HbS-C), and the often asymptomatic sickle cell trait (HbA-S). The most common type of SCD, HbS-S, is a homozygous recessive condition in which individuals inherit the beta S globin gene from each parent. SCD has systemic effects particularly on splenic function and on the central nervous, renal, hepatic, and musculoskeletal systems. SCD affects approximately 1 in 400 African-Americans. Sickle cell trait affects 8% to 10% of the African-American population and other groups less frequently (267). With sickle cell trait, each individual has inherited a beta-S globin gene and a beta-A globin gene. Clinical manifestations of sickle cell trait usually are not apparent. The presence of these abnormal hemoglobins in red blood cells causes them to be mechanically fragile, and when they are deoxygenated, the cells assume a sickle shape, which makes them prone to clumping with blockage of the small vessels of the spleen, kidneys, and bones (262,263). Chronic hemolytic anemia is present in most severely affected patients, and marrow hyperplasia is found in both the long bones and the short tubular bones. These disorders are diagnosed by hemoglobin electrophoresis (252).

Clinical Presentation

Musculoskeletal involvement results from small vessel occlusion by clumped sickle cells with bone infarction, avascular necrosis, and increased susceptibility to infection. These problems are most commonly seen in sickle cell anemia and sickle cell disease. Bone infarction is caused by blockage of marrow vascular channels by sickled erythrocytes. It is seen in patients as young as 6 to 12 months of age. Ultimate infarction occurs in as many as 74% of patients. Patients with acute long bone infarctions present with pain and swelling of the affected extremity and a low-grade fever. The long bone usually is tender, and infrequently, both erythema and warmth also are present (257). Acute symptoms usually resolve within a week. One presenting sign of sickle cell disease in an adolescent is an indolent ulcer over the lateral malleolus of the ankle with surrounding areas of patchy hyperpigmentation (260). Sickle cell dactylitis, or infarction of the small bones of the hands and feet, may resemble infection and is common in infancy and childhood (259). Young children getting their feet wet or walking in the snow can initiate episodes (253). Pain and swelling may last for 1 to 2 weeks. X-ray studies may show osteolysis and periosteal new bone formation.

Acute bone infarct in patients with SCD may be difficult to distinguish from osteomyelitis. Osteomyelitis occurs in fewer than 1% of affected patients. Acute long bone infarctions are 50 times more common than bacterial osteomyelitis in patients with sickle cell disease (257), but in Africa, osteomyelitis is 200 times more common in patients with SCD than in normal individuals (256). Osteoarticular bacterial infection was diagnosed in 1.6% of 247 admissions in one series of children with sickle cell disease admitted to the hospital for musculoskeletal complaints (261). These authors recommended aspiration as the diagnostic procedure of choice for infection. Clinical and x-ray presentations in both of these conditions are quite similar, except that high fevers are more common in osteomyelitis. Patients present with a warm, swollen, painful extremity. Multifocal bone involvement was reported in 73% of patients with osteomyelitis in one series (265), and the most common sites in decreasing order of frequency were the humerus, metatarsals, tibia, femur, radius, metacarpals, and ulna. Routine evaluation should include blood cultures and needle aspiration of the affected area. Typical causative organisms in osteomyelitis include *Staphylococcus aureus, Salmonella,* and *Streptococcus pneumoniae.* Bennett et al. (247) reviewed bone and joint manifestations in 57 patients with sickle cell anemia and found that osteomyelitis occurred in 61% and that *Salmonella* was the causative organism in 71% of these patients. Others have also found that *Salmonella* is a common organism seen in osteomyelitis in SCD (256,265), but Epps and co-workers (255) found that *Staphylococcus* was the most common organism in their patients with SCD osteomyelitis. Al-Salem (246) also found that *Staphylococcus* was the most common organism in osteomyelitis in those patients with sickle cell trait. Both the metaphysis and diaphysis are common locations of infection (250,265). Septic arthritis is rare in patients with SCD. Surgical drainage of septic joints, osteomyelitis, and subperiosteal abscesses is indicated.

Other common problems in SCD include avascular necrosis of both the femoral head and proximal humerus. Wedging or flattening of the vertebral bodies is also seen in older patients (253). Fat emboli, secondary to marrow infarcts, can occur in patients with less severe SCD (HbS-C) and less frequently in patients with sickle cell

anemia. Pneumococcal sepsis is the leading cause of death in young children with SCD.

Radiographic Findings

In young patients, marrow hyperplasia results in a generalized osteoporosis with widening of the medullary canal and thinning of the cortex. As the patients become older, endosteal bone apposition causes sclerosis (Fig. 6-29) and the medullary canal may actually become narrowed with thickening of the cortex. Large bone infarctions may not be visible on plain x-ray studies because of limited circulation, but commonly within 2 weeks of onset of symptoms, areas of involvement appear moth-eaten, with irregularly distributed translucent areas commonly bound by elevated periosteum with new bone formation (252). Widespread involvement may form a “bone within a bone” appearance (253). Nearly 85% of long bone infarcts are found at the junction between the metaphysis and diaphysis, and 10% are centrally located (248). Plain x-ray studies cannot distinguish between osteomyelitis and bone infarction in these patients. Although Keeley and Buchanan (257) believe that bone scans are not helpful in the diagnosis of bone infarction, Koren et al. (258) noted that in the first 48 hours of symptoms, there was decreased uptake in the affected area of bone infarct by technetium bone scan. Normal isotope uptake developed approximately 1 week later. They found that increased isotope uptake was common 2 to 4 weeks after the onset of symptoms. Gallium bone scan was thought to be a helpful adjunct to this technique when osteomyelitis was suspected. MRI has not been found useful in distinguishing osteomyelitis from acute infarcts (251), but contrast material–enhanced CT scan can aid in diagnosis of osteomyelitis in these patients by its ability to visualize subperiosteal abscess (266). Differentiation from infarction can be aided by aspiration and by comparing the results of technetium 99 scans with those of a bone marrow scan. Both partial and full femoral head involvement can occur in avascular necrosis of the capital femoral epiphysis in SCD (253), and coxa vara also has been reported (259).

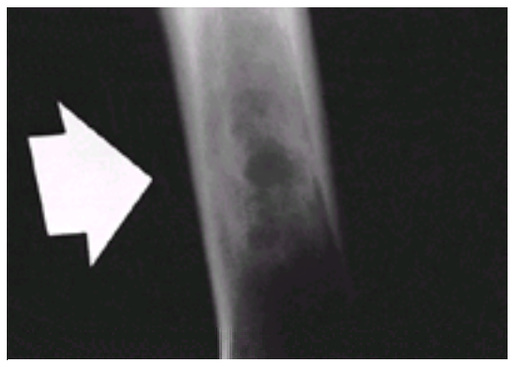

FIGURE 6-29. A young man with sickle cell disease. The lateral x-ray of the femur shows evidence of past avascular necrosis, and scalloping and radiolucencies of the shaft with sclerosis are seen posteriorly (*arrow*). This x-ray appearance can mimic osteomyelitis.

Injury

Pathologic fractures of the long bones in SCD frequently may be the first symptom of the disorder (262), and many authors report pathologic fractures in their series (247,250,252,254,259,264). In a series of 81 patients with 198 long bone infarcts with occasional concurrent osteomyelitis, Bohrer (248) found evidence of fracture in 25% of femoral lesions, 20% of humeral lesions, and a significant percentage also in tibial bone infarcts. Ebong (254) reported pathologic fractures in 20% of patients with SCD and osteomyelitis. The most common site of fracture was the femur. The fractures are transverse and commonly located in the shaft of the long bone (253), and although minimal trauma is needed to cause them (259), they often have significant displacement (248,249). The exact mechanism for pathologic fracture in these patients is unclear; although it is often associated with bone infarct, the fracture itself is seldom through the area of infarction (259). Marrow hyperplasia may be a major contributing factor; not only does the hypercellular bone marrow expand the medullary canal with thinning of both trabecular and cortical bone, but it also extends into widened haversian and Volkmann canals (253). This process probably weakens the bone sufficiently so that fractures occur. The healing process seems unaffected, and union usually occurs normally (262).

Treatment

Vaso-occlusive episodes are managed with nonsteroidal antiinflammatory medications, oxygen, and hydration. Symptomatic bone infarction should be treated with bed rest, analgesics, and intravenous or oral administration of fluids (257). If osteomyelitis is suspected, identification of the organism should be attempted by both blood cultures and aspiration of subperiosteal fluid (265). The choice of antibiotics is based on Gram's stain. For Gram-positive organisms, either cephalothin or nafcillin is used initially, and for Gram-negative organisms, either ampicillin or chloramphenicol is used. Changes in antibiotics are based on later culture results and sensitivities. The patient is monitored by C-reactive protein or sedimentation rate, and intravenous antibiotics usually are continued for at least 6 weeks. Operative treatment of patients with SCD is potentially hazardous. Extreme care must be taken to oxygenate the patient's tissues adequately during the procedure, and ideally, elective procedures should be preceded by multiple transfusions to reduce hemoglobin (S) to less than 30% of total hemoglobin levels. A randomized multicenter study found that a simple conservative transfusion regimen to raise Hb levels to 10 g/dL was as effective as an aggressive exchange transfusion regimen (to reduce HgS to less than 30%) in preventing perioperative complications. The conservative approach resulted in only half as many transfusion-associated complications (268). Intravenous hydration also is important, with one and a half to two times the daily fluid requirements needed in addition to routine replacement of fluid losses. The use of a tourniquet in surgery for patients with SCD is somewhat controversial. Some authors believe that it is not indicated because it is potentially dangerous (253,255); others found no increased risks associated with its use in these patients (259,267).

AUTHORS' PREFERRED METHOD OF TREATMENT

Pathologic fractures in patients with SCD usually heal well with conservative immobilization techniques (253). Customary precautions should be followed in those patients who require open surgical procedures for displaced or unstable fractures. Osteonecrosis of the femoral head is an especially difficult problem in patients with SCD. Treatment options include conservative measures and core decompression (a multicenter trial is under way). Total joint replacement is occasionally indicated in young adults. Before general anesthesia, the patient's hematocrit should be raised to ³30 Hb to ³10 g/dL.

Leukemias

Leukemia accounts for over 30% of cases of childhood cancer. Acute lymphocytic leukemia (ALL) is one of the most common malignant diseases in childhood and accounts for 80% of pediatric leukemias. There is an increased occurrence of lymphoid leukemias in patients with Down syndrome, immunodeficiencies, and ataxic telangiectasia. The peak incidence is at 4 years of age.

Leukemic involvement of bones and joints occurs frequently in patients with leukemia. Skeletal lesions occur more frequently in leukemic children than in adults because a child's small marrow reserve can be replaced quickly by leukemic cells. Approximately 50% to 75% of children with acute leukemia develop radiographic skeletal manifestations during the course of their disease (277,280). Rogalsky et al. (282) reported a 12% incidence of fracture associated with acute leukemic lesions.

Clinical Presentation

Patients present with fatigue, pallor, purpura, fever, hepatosplenomegaly, or bone and joint pain; 20% to 60% of patients present with musculoskeletal signs or symptoms (275). In one series, bone pain was a presenting symptom in 59% of patients (284,285). Rogalsky et al. (282) reported a 20.6% incidence of reports of problems with the skeletal system at initial presentation. Migratory arthritis may be present in some patients; point pain is believed to be secondary to leukemic cell infiltrate of the metaphyseal periosteum (285). Leukemia may mimic osteomyelitis, rheumatic fever, septic arthritis, and tuberculosis (283). Either leukocytosis or leukopenia is present, and the presence of immature leukocytes in the peripheral blood smear should suggest a diagnosis of leukemia. In the early phase of the disease, anemia, neutropenia, and thrombocytopenia occur in 80% of patients; 10% of children have normal peripheral blood counts. Bone marrow aspirate usually is

diagnostic.

Radiographic Findings

No pathognomonic osseous manifestations occur in acute leukemia. Skeletal involvement occurs in approximately 50% of patients, and diffuse osteopenia is the most frequent manifestation. Lucencies and periostitis may mimic osteomyelitis.

Nonspecific juxtaepiphyseal lucent lines are a result of generalized metabolic dysfunction. Sclerotic bands of bone trabeculae are more typical in older children. A characteristic lesion seen within a month of onset of symptoms is a radiolucent metaphyseal band adjacent to the physis. These are usually bilateral and vary from 2 to 15 mm in width (285). Similar radiolucent bands are seen both in infants with scurvy and in older children with neuroblastoma.

Osteolytic lesions with punctate areas of radiolucency are found in the metaphyses and can either appear moth-eaten or as a confluent radiolucency. Similar lesions can be present in the diaphysis (273), the skull, pelvis, ribs, and bones of the hands and feet. Large geographic lesions also may be seen. Periosteal reaction often is present with osteolytic lesions and is most common in the posterior cortex of the distal femoral metaphysis, the medial neck of the femur, and the diaphyses of the tibia and fibula (286).

Medical management protocols usually include vincristine, prednisone, and L-asparaginase (VPL) or methotrexate, vincristine, L-asparaginase, and dexamethasone (MOAD) (272). Remission rates are now up to 98%, with cure rates approaching 80% (272).

The complication seen most commonly by orthopaedic surgeons is avascular necrosis (AVN) of the femoral head (278,287). This may occur after chemotherapy, after chemotherapy and allogenic bone marrow transplantation (BMT), or after graft-versus-host disease (GVH) related to BMT. (270) Although most AVN is attributed to glucocorticoid therapy, L-asparaginase can contribute to thrombophilia and has been implicated in the production of AVN. The risk of AVN is especially high after BMT in boys older than 16 years who are treated for GVH with steroids or irradiation. MRI is best for the early detection of AVN. Treatment modalities include weight relief, symptomatic treatment, core decompression, and total hip replacement. Bizot et al. (271) described the results in 27 patients treated with total hip arthroplasty for AVN after allogenic BMT.

Most bone lesions in leukemia improve during remission after treatment and tend to progress with worsening of the disease. The radiolucent metaphyseal bands usually are not affected by treatment, however, and further demineralization of the skeleton may occur with both corticosteroid use and methotrexate therapy. Diffuse demineralization of the skeleton occurs in almost all patients with widening of the medullary canal and thinning of the cortex (285). Although increased uptake of isotope is seen on technetium bone scan in 80% of patients, positive areas of isotope uptake correlate poorly with both sites of clinical bone pain and the presence of lesions on x-ray study (274).

Several authors (269,276,277,279) have attempted to evaluate the prognostic significance of the extent of bone involvement in childhood leukemia. Hughes et al. (278) reported that major skeletal involvement, in fact, may correlate with a better overall outcome in childhood leukemia. Heinrich et al. (277) concluded that children without radiographic skeletal abnormalities have an aggressive form of acute leukemia that results in a worse prognosis.

Injury

Pathologic lesions predisposing children to a fracture usually resolve during treatment. Fracture is most commonly associated with osteoporosis of the spine, resulting in vertebrae plana. Fractures occasionally occur at other locations and usually after minor trauma.

Vertebral compression fractures are the most commonly reported fractures associated with leukemia. The thoracic vertebrae are the most commonly involved; uniform spinal osteoporosis often is present (278,281). A bone scan may aid in identifying clinically silent areas but may not correlate with areas of obvious destruction on radiographs. Spastic paraparesis has been reported in one patient with vertebral fracture due to leukemia (278).

Treatment

Most fractures are treated using standard methods (Fig. 6-30). Newman and Melhorn (281) noted a prompt decrease in pain in four patients with vertebral fractures due to leukemia once chemotherapy was initiated. No bracing was used in these patients, and full activity was encouraged. In one of their patients observed for more than 5 years, there was no evidence of healing of the fractured vertebra on x-ray study. There are no specific treatment recommendations for any other associated pathologic fractures of leukemia in the literature.

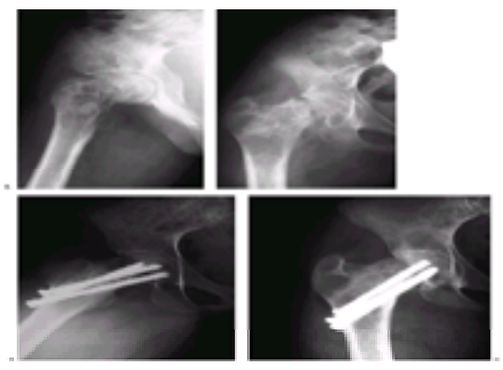

FIGURE 6-30. A: A 13-year-old girl with acute lymphocytic leukemia presented with a pathologic fracture of the right hip. Note the destructive changes associated with the displaced femoral neck fracture. **B:** The patient subsequently underwent *in situ* screw fixation of the hip fracture with postoperative hip spica cast immobilization and subsequent continuation of chemotherapy. **C:** Follow-up x-ray studies 1 year after surgery shows healing with slight varus and without evidence of avascular necrosis. At present, the patient is alive and well, has no hip pain and walks with a very slight Trendelenburg gait.

AUTHORS' PREFERRED METHOD OF TREATMENT

Prompt diagnosis and initiation of chemotherapy is the first step in the treatment of pathologic fractures associated with leukemia. Most fractures are stable microfractures and can be treated with conservative immobilization techniques with emphasis on early ambulation to avoid further problems with disuse osteoporosis. Most vertebral fractures can be treated nonoperatively with close observation.

Hemophilia

Hemophilia is a sex-linked recessive disorder of clotting mechanism that presents most commonly as a functional deficiency of either factor VIII (hemophilia A) or factor IX (hemophilia B). Classic hemophilia, or hemophilia A, (factor VIII deficiency) is an inherited sex-linked recessive disorder. The incidence is 1 per 10,000 live male births in the United States (291). Christmas disease, or hemophilia B, is a sex-linked recessive factor IX deficiency and occurs in 1 per 40,000 live births.

When hemophilia is suspected, screening tests should be performed, including platelet count, bleeding time, prothrombin time, and partial thromboplastin time. Deficiency of factor VII, the most common form of hemophilia, causes a marked prolongation in the partial thromboplastin time (337). Once the disease is suspected, specific factor assays can document the type of hemophilia.

Musculoskeletal complications in a child with hemophilia include acute hemarthroses (knee, elbow, and ankle, in decreasing order of frequency), soft tissue and

muscle bleeds, acute compartment syndrome, carpal tunnel syndrome, and femoral nerve neuropraxia. The severity of the deficiency often is correlated with circulating levels of factor VIII or IX (Table 6-7). The disease is classified as severe when clotting activity is less than 1%, moderate when clotting activity is 1% to 5%, and mild when clotting activity is more than 5%. By definition, each milliliter of normal human plasma contains one unit of factor activity, and the clinical severity of hemophilia correlates with the patient's percentage of normal levels of plasma factor activity (Table 6-7). Early diagnosis and aggressive management are the keys to lessening complications.

Degree of Hemophilia	Percentage of Factor	Clinical Characteristics
Mild	20%–60%	Usually clinically occult, excessive bleeding after major trauma or surgery
Moderate	5%–20%	Excessive bleeding during surgery and after minor trauma
Moderately severe	1%–5%	Excessive bleeding with mild injury and infrequent spontaneous hemarthrosis
Severe	Less than 1%	Frequent excessive bleeding with trauma and spontaneous bleeding into the soft tissue and joints

TABLE 6-7. SEVERITY OF HEMOPHILIA CORRELATED WITH PLASMA FACTOR ACTIVITY LEVELS

Treatment—Bleeding Episodes

During bleeding episodes, the primary therapy is intravenous replacement of the deficient factor. Several different treatment plans exist: On-demand therapy is the traditional method of hemophilia management; factor replacement is given at the first sign of a bleeding episode. Primary prophylaxis involves initiation of regular factor replacement therapy soon after the diagnosis of severe hemophilia (usually when the child is 1 to 2 years of age) with the intention of preventing joint bleeds. Secondary prophylaxis is used after a child has established a pattern of frequent bleeding but before frequent joint bleeds occur.

Empirically, one unit of factor VIII per kilogram of body weight will raise plasma activity by 2%, and a similar dose of factor IX will elevate the plasma level of that factor by 1.5% (291). The usual half-life of factor VIII varies from 6 to 12 hours and that of factor IX varies from 8 to 18 hours. Routinely in the nonbleeding patient, factor VIII must be given every 8 hours and factor IX must be given every 12 hours to maintain a stable factor level. Higher than usual dosages given more frequently are necessary in patients with active bleeding. In the past, factor replacement was accomplished through plasma transfusion, but the quantities necessary for adequate factor levels may result in circulatory overload and pulmonary edema (331). This problem was eventually solved through the use of cryoprecipitate, protein prepared from plasma that is rich in factor VIII and fibrinogen. More concentrated forms of both factor VIII and factor IX (Konyne 80) have become available. The reader is referred to an excellent review by Connelly and Kaleko (298) for a current state of the art review of gene therapy for patients with hemophilia A.

Complications

Significant complications are caused by the use of replacement therapy in hemophiliacs. Antibodies to replacement factor, known as factor inhibitors, develop in 15% to 25% of patients with severe factor VIII deficiency (up to 50% if transient or insignificant inhibitors are included) (291,331). When inhibitors are present in quantities higher than 5 Bethesda units, very high doses of factor may be necessary to achieve significant activity levels. Many children with high titer factor VIII inhibitors are treated with daily high doses of factor VIII (immune tolerance) to reduce or eliminate the inhibitor. The level of inhibitors rises sharply 6 to 10 days after initial treatment (301), and the effectiveness of replacement therapy gradually deteriorates. In patients with hemophilia A with inhibitor levels greater than 20 Bethesda units, factor VIII replacement is ineffective. There has been some success in treating these patients with alternative therapy such as nonactivated factor IX concentrates, activated factor IX, porcine factor VIII (340), and activated prothrombin complex concentrate (Autoplex T) (288). Desmopressin (L-deamino-8D-arginine vasopressin) is becoming a treatment of choice in patients with mild hemophilia A and also has an effect on patients with von Willebrand's disease as well as platelet disorders (401,404). Patients can have an approximate threefold increase in factor VIII. Studies have shown effectiveness of this medication through administration by intravenous route or subcutaneous injections, as well as intranasal administration by spray.

A large percentage of the adult hemophiliac population treated with concentrated plasma-derived factor before 1985 became human immunodeficiency virus (HIV) positive. Because replacement therapy for 1 year (or one surgery episode) may expose hemophiliacs to the equivalent of 3,200 units of donor blood (291), these patients have been particularly susceptible to both hepatitis and HIV infection. The annual rate of hepatitis in hemophiliacs is estimated to be 5% (294). In a study of 181 patients with either hemophilia A or B, Ragni et al. (332) found that 45% were HIV seropositive, and 82% of patients treated with factor VIII concentrate were HIV positive. In this study, the peak of seroconversion occurred in 1982, with declining rates in the ensuing years, presumably owing to HIV antibody donor screening and heat inactivation of blood products. The overall incidence of acquired immunodeficiency syndrome (AIDS) for all these patients was 5.5%, but in patients who were HIV seropositive for more than 5 years, the incidence of AIDS approached 32%. All hemophilia patients are monitored for development of treatment-related viral infection; the incidence of infection today is extremely low. Serial examinations of T4 counts are performed for patients at risk. Medical therapies are still evolving for AIDS patients with hemophilia. Current gene therapy efforts are focused on developing a vector that is safe and gives long-term expression of the missing factor at levels that will significantly change the phenotype (289).

Surgery in Hemophilia

In preparing a patient with hemophilia for surgery, the orthopaedist and the hematologist should work closely together. Preoperatively, the patient should be tested for the presence of inhibitor and a test dose of factor replacement should be given to determine the biologic half-life of that factor for that particular patient (291). Elective surgery usually is contraindicated in the presence of inhibitor. Most authors recommend a level of factor activity during surgery ranging from 70% to 100% (291,317,331), although others believe that approximately 50% is adequate (328,330). The initial dose is usually 40 units/kg (331), and it should be given 1 to 2 hours before surgery (308,317). In prolonged procedures with active bleeding, the factor level should be checked as often as every 3 hours and appropriate factor supplementation given as necessary (331). Tourniquets are recommended for extremity surgery. Although some authors believe electrocautery is adequate for obtaining hemostasis (308,317), others consider ligation of vessels preferable (291,331). The use of routine drains is not advised, but 24 hours of suction drainage is favored by some (291,317,331). Factor levels are checked immediately after surgery and then at least daily. Factor VIII is given every 6 hours, and factor IX is given every 8 hours. It is useful to check a trough level factor activity immediately before the next dose of factor supplementation. In the immediate postoperative period, factor levels are maintained at 30% to 40% (291,317), and these levels should be maintained until sutures are removed (317). During the rehabilitative period, maintenance levels of factor ranging from 20% to 50% immediately before sessions of physical therapy should be maintained (291,317,328,331). Intramuscular injections of analgesics should obviously be avoided, as should aspirin compounds and nonsteroidal antiinflammatory medications that affect platelet function. Both acetaminophen (Tylenol) and codeine medications are safe oral analgesics (312). In the past, hemophiliac patients had an increased risk of operative infections and delayed wound healing, but aggressive replacement therapy has minimized those problems (331).

Injury

Fractures and Dislocations

Clinical Presentation. Most, but not all authors, believe that hemophiliac patients have an increased incidence of fracture (290,301,308). These patients have been predisposed to fracture because of poor muscle function, limitation of joint movement, and osteopenia secondary to recurrent joint hemarthrosis. Most authors have noted that healing of fractures proceeds primarily with endosteal callus and very little periosteal callus (301,313,339), but Lancourt et al. (317) observed significant periosteal calcification in these fractures with a normal rate of healing. Fractures occur in both the upper and lower extremities (290,295,301,313,333). Joint dislocations are rare in hemophiliac patients. Floman and Niska (302) reported on a 6-year-old boy who sustained a posterior dislocation of the hip with mild trauma that required a closed reduction under general anesthesia and immobilization in a hip spica cast. The joint was found to be ankylosed at 6-year follow-up. Ackroyd and Dinley (289) reported on two patients who had their patellas locked into the intercondylar notch of the distal femur after sustaining hyperflexion injuries of the knees, which had limited range of motion owing to arthropathy. These injuries were treated by flexion of the knee under general anesthesia, depression of the inferior

pole of the patella to unlock it, and then extension of the knee followed by splinting.

Treatment. Most fractures in hemophiliac patients are treated conservatively with immobilization. Factor replacement is important for about the first week after the fracture, and levels of factor activity recommended vary from 20% to 50% (290,291,295,301,308,317). Circumferential plaster casts are extremely hazardous in the treatment of these fractures because of the risk of swelling from bleeding as well as subsequent compartment syndrome and skin necrosis (338). A Robert Jones dressing may be preferable for fracture immobilization immediately after injury, and a cast should be applied once active swelling has stopped (308). All casts applied should be well padded and split, and the patient should be monitored carefully for swelling. Fractures of the femur can be treated with traction and subsequent spica casting (295). Some authors consider skeletal traction to be hazardous because of the risk of infection or bleeding (291,308), but Boardman and English (295) believe that with proper replacement therapy, skeletal pins can be used in the hemophiliac. In the presence of inhibitor, a large blood loss owing to fracture should be treated with transfusion with saline-washed packed red blood cells (313). Replacement therapy is advisable while fractures are manipulated and casts are changed. Most authors think that open reduction and internal fixation should be performed in hemophiliac patients for fractures that would customarily be treated with such methods (291,295,317).

Muscle Hematoma

Clinical Presentation. Hematomas of the soft tissues in hemophiliacs occur in superficial tissues but are more of a clinical problem when they develop in muscle (317). Although most are spontaneous, a history of trauma was noted in 24% of 178 episodes of muscle hematoma in one series (292). In order of frequency, the most common sites of involvement in that series were the quadriceps, calf, anterior compartment of the leg, thigh adductors, hamstrings, and sartorius muscle. The first clinical symptoms are tenderness, stiffness, and swelling of the involved muscle group with pain on motion (292). Early volar compartment syndrome of the forearm, which responded to factor replacement, has been reported in a young child (322), and before the advent of replacement therapy, Volkmann ischemic contracture of the forearm could evolve from this injury (291). A hematoma in the iliacus muscle can present as severe groin pain, flexion deformity of the hip, and a tender mass palpable along the iliac crest. Passive extension of the hip increases pain, and significant swelling of the muscle can cause compression of the femoral nerve (with subsequent femoral nerve palsy and quadriceps muscle paralysis) by the inguinal ligament superiorly and the iliopectinel ligament medially. X-ray studies usually are not helpful in the diagnosis of intramuscular hemorrhage in the hemophilic. Ultrasound (316), CT scan (336), and MRI are useful in documenting the presence of muscle hematoma. Wilson et al. (341) noted that in early hemorrhage of the muscle, the ultrasound shows increased echogenicity, but in established muscle hematoma, the echogenicity is decreased. This may be helpful in recurrence, because fresh hemorrhage into an organizing hematoma can be distinguished by this technique. One should not assume that all groin pain in hemophilia is due to an iliacus muscle hematoma. Although rare, hip hemarthrosis can occur, and septic arthritis of the hip has also been reported in hemophiliac patients. In this clinical situation, a hip ultrasound and aspiration can help make the correct diagnosis (341).

Treatment. The most important consideration in the treatment of a patient with muscle hematoma is early initiation of replacement therapy. Aronstam et al. (293) found that if replacement therapy was initiated within 2 hours of onset of symptoms, then excellent recovery ensued. The only exception to this finding was hematomas of the calf muscles, which responded equally well to replacement therapy if it was treated within 3 hours of the onset of symptoms. Most authors recommend raising factor levels to between 20% and 50% (291,292,308,320,325) and continuing treatment for 24 hours (292) to 5 days (317). The patient should not bear weight on the extremity (292), and the affected joints should be placed in a position of comfort, with a compression dressing and ice packs applied to the swollen muscle (292,308). Serial casting may be useful in regaining joint motion after active bleeding has ceased (308), and light traction may be useful for regaining hip motion in patients with iliacus hematoma. Quadriceps muscle function usually returns with recovery from quadriceps hematoma. Infrequently, ectopic bone may form in the soft tissues after hematoma (309). In severe cases of muscle hemorrhage that do not respond to conservative treatment, fasciotomy and neurolysis (with proper replacement therapy) may be necessary (317).

Neurapraxia

In addition to the compression of the femoral nerve seen in iliacus hematoma, neurapraxia in hemophiliacs can occur in the peroneal, sciatic, median, and ulnar nerves (291). Carpal tunnel syndrome due to hemorrhagic compression of the median nerve has been reported (317,326). Factor levels for these patients should be raised to 80% to 100% of normal for 2 days and then maintained at 40% of factor levels for another 7 days with splinting of the extremity (291). Another neurologic complication in patients with hemophilia is significant intracranial bleeding from minor head trauma. This has been reported in 2% to 13% of children who have hemophilia and von Willebrand's disease (299).

Pseudotumor of Hemophilia

Clinical Presentation. The pseudotumor of hemophilia is a cystic swelling of the muscle due to hematoma. Adjacent bone erosion is often evident on plain x-ray study and is seen most frequently in the ilium and femur (335). In children, a pathologic fracture can occur after a destructive pseudotumor of the femoral shaft. Pseudotumors can also evolve after fracture of the femur (296). These lesions may develop through subperiosteal hemorrhage, which causes pressure necrosis of the overlying muscle and underlying bone (339). Progressive enlargement can compress surrounding vital soft tissue structures, and extreme enlargement may eventually result in skin perforation, with infection and possible death (296). In children, the peripheral skeleton is most commonly affected by pseudotumor (308), and the small bones in the hands and feet are the most common sites; the prognosis is better with these sites than with more centrally located pseudotumors (290). Large pseudotumors may develop calcific deposits that are visible on plain x-ray studies. An established cyst may be associated with semilunar struts of bone projecting from the adjacent bone at the proximal and distal ends of the pseudocyst (296). With involvement of the small bones of hands and feet, interosseous expansile lesions with surrounding periosteal elevation are seen (317). The CT scan is useful in delineating the extent of pseudotumor (329).

Treatment. Aspiration is contraindicated in treatment of pseudocysts because not only does the needle track fail to heal but hematoma soon recurs, with the possibility of infection and bleeding from the needle wound (291,296,325,339). Very early treatment of small pseudotumors with replacement therapy, compression dressings, and prolonged immobilization may arrest their development (290,308,315,317). Factor levels of 50% were used in one series (290). Radiation therapy has been used to treat pseudotumors of hands and feet successfully but should be discouraged in children (368,375,376,400). Surgical excision of the pseudotumor may be necessary if the diagnosis is in question or if the lesion is enlarging with danger of skin perforation (291,297). Malignant degeneration is unlikely, and only one case of fibrous sarcoma has been associated with a pseudotumor of the chest wall (319). Surgical removal of a pseudotumor is quite demanding, and often residual cyst must be left behind when it is connected with vital structures. Amputation may be necessary if the lesion is complicated by infection (317).

Hemarthrosis

Clinical Presentation. Patients with severe hemophilia have a high rate of hemarthrosis. The joints most commonly involved in decreasing order of frequency include the knees, elbows, ankles, hips, and shoulders (291). There usually is a prodrome of stiffness and pain before clinical swelling, and trauma usually is absent. The joint is held in a position of flexion that is most comfortable, and eventually, the joint becomes tense and swollen with decreased range of motion. A subacute hemarthrosis of the knee is said to be present when two or more episodes of acute hemarthrosis have preceded it. On clinical examination, the synovium is very thick and boggy with decreased range of motion of the joint. Pain is uncommon. In chronic hemarthrosis, generally a subacute arthrosis has been present for at least 6 months, and destructive changes are present on the x-ray studies of the knee with osteoporosis, overgrowth of the epiphysis with subchondral cysts, and eventual narrowing of the joint space (Fig. 6-31) (291). MRI was found to be useful in examining both the hypertrophied synovium in hemophilia arthropathy as well as subchondral cysts (311,327). Various systems of classification of joint arthropathy of the knee in hemophilia have been proposed (291,306). The chronic phase of articular involvement for patients with hemophilia can lead to articular cartilage degeneration from recurrent bleeds and effusions. Initially, synovial hypertrophy and chronic hyperemia occur, followed by epiphyseal overgrowth. Articular involvement may be graded as shown in Table 6-8. A diagnostic dilemma that can occur is septic arthritis in HIV-positive hemophiliacs with existing joint effusion. Merchan et al. (324) reported four patients with this complication, of which one was a 15-year-old boy with a septic elbow due to *Streptococcus pneumoniae* that was treated with 3 weeks of penicillin G therapy.

FIGURE 6-31. A 22-year-old man with hemophilia had frequent hemarthrosis of the knee. Moderately severe arthropathy is present, with joint space narrowing, spurring, and subchondral cyst (*arrow*).

Grade 1	Transitory synovitis; no bleeding sequelae, and with no more than three episodes in 3 months
Grade 2	Permanent synovitis with increased joint size, synovial thickening, and limitation of movement
Grade 3	Chronic arthropathy with axial deformity and muscular atrophy
Grade 4	Ankylosis

TABLE 6-8. GRADES OF ARTICULAR INVOLVEMENT

Treatment. The first step in the treatment of joint hemarthrosis is prompt factor replacement with levels ranging from 30% to 50% (291,307,334,337), and these levels may need to be maintained for up to 4 days for severe cases (307). Home care factor replacement provides a means of rapid initiation of therapy (291). With effective treatment, usually prompt pain relief is achieved in minutes after initiation of replacement therapy, and the extremity should be splinted and ice should be applied to the joint (291). In acute hemarthrosis of the knee with a very tense, swollen joint that is not responding well to replacement therapy, early aspiration may be of some value. For aspiration to be successful, a large needle such as a 16-gauge needle must be used (317), and aspiration must be accomplished within 24 hours of the onset of swelling because the clot begins to loculate after that time (308). Factor replacement must not be given before the aspiration because this will promote clotting of the hemarthrosis fluid and prevent removal; ideally, therapy is initiated at the same time as aspiration (320). The value of aspiration is uncertain because there was no difference in the range of motion between aspirated and unaspirated knees at 5-day follow-up in one controlled trial (310). In addition to factor replacement, splinting, ice packs, and compression bandages are helpful (317).

Intraarticular dexamethasone and nonsteroidal antiinflammatory drugs (NSAIDs) are used by some. A short course of corticosteroids seems to reduce the need for long-term replacement therapy (314). In subacute hemarthrosis, aspiration is not necessary, and factor replacement with levels from 20% to 30% is used three times weekly to protect the patient from further bleeding during physical therapy sessions (300). Mobilization should continue for 3 to 4 weeks, and if there is no response to therapy, synovectomy may be indicated (317). A target joint is defined as one with four bleeding episodes in a 6-month period. Treatment involves regular replacement therapy for at least 6 to 12 weeks to interrupt bleeding cycles. Replacement therapy can include recombinant or plasma-derived factor; most patients use recombinant factor. In general, 1 unit per kg of body weight of factor VIII concentrate provides a 2% increase in the factor VIII plasma activity. Today, acute joint bleeds are treated with a more intensive therapy than was used previously (334,337).

Management of the patient with chronic articular involvement is aimed at stopping this phase with a prophylactic factor replacement regimen (334,387). Greene et al. (304) reviewed their experience with prophylactic transfusions for hypertrophic synovitis in 19 children with severe hemophilia and found mixed results. Persistent, painful, or progressive synovitis can be managed with open or arthroscopic synovectomy, especially for the knee and elbow of those with breakthrough bleeds. Greene (305) reported good results in five children who underwent synovectomy of the ankle with a decreased rate of hemarthrosis episodes. Chemical (Rifampicin) or radioactive (Au-198) synovectomy has also been used. Erken (300) reported 35 patients who underwent medical synovectomy by intraarticular injection with the radiocolloid yttrium-90 silicate. Of these patients, 21 were younger than 10 years, and at a mean follow-up of 7 years, 47 joints were pain free and 13 joints had not experienced another hemorrhagic episode. There was no change in the radiographic appearance of the joints at follow-up. Erken suggested that this form of treatment is for patients who have failed to respond to intensive physical therapy as well as those patients who have inhibitors to factor replacement. Fixed joint contractures can be treated with reversed dynamic slings (308,338) or a turnbuckle-type cast (291). Slow continuous passive motion may be useful after surgery of the knee in hemophiliacs (303). Joint contractures resistant to these conservative therapies can be treated with either soft tissue procedures, osteotomies, arthrodesis, or joint replacement (291). Total joint arthroplasty may be helpful in selected candidates.

AUTHORS PREFERRED METHOD OF TREATMENT

Collaboration between the orthopaedist and the hematologist is important in providing care for children with hemophilia. Most fractures in children with hemophilia can be treated with either traction or cast techniques. Care must be taken to avoid complications related to compression in these patients, and a monovalved, well-padded plaster cast provides a safe means of treatment. A fiberglass cast is not as desirable because a simple monovalve will fail to expand the cast completely. Operative treatment should be reserved for fractures that normally require surgery, and the usual precautions for hemophiliac patients for surgery are observed. Muscle hematomas are treated with a combination of replacement therapy, ice packs, bed rest, and a particular emphasis on rehabilitation. CT scans are extremely helpful in following the course of an iliopsoas muscle hematoma. Pseudotumors of the small bones of the hands and feet can be treated with excision and bone grafting. Hemarthrosis of the knee responds well to prompt factor replacement therapy and immobilization; aspiration is seldom needed. The orthopaedic surgeon caring for patients with hemophilia must be ever mindful of the possible presence of both hepatitis and HIV, and the utmost care should be used in any sort of invasive procedure with these patients.

OSTEOMYELITIS

The character of pediatric acute hematogenous osteomyelitis in North America has changed somewhat during the past several decades. Although the typical clinical picture of acute osteomyelitis in children is still seen, more subtle presentations are more frequent. This may be due to a variety of reasons, including modification of the clinical course by antibiotics given before admission (351) and, possibly, increased awareness and an earlier presentation to a medical facility resulting in earlier diagnosis. Children often present with subacute osteomyelitis (Fig. 6-32, Table 6-9). Less common variants include Brodie's abscess, subacute epiphyseal osteomyelitis, viral osteomyelitis (365), and chronic recurrent multifocal osteomyelitis (354). Some patients present with a bone lesion that may be confused with other disease entities, including neoplasm (345). All can masquerade as osteomyelitis with fever and tenderness over areas of focal leukemic bone destruction (366). Biopsy often is needed to clarify the diagnosis. Even with appropriate antibiotic therapy, some patients have recurrent infection, growth disturbance, or pathologic fractures.

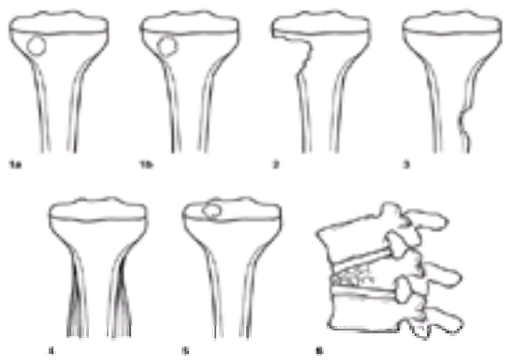

FIGURE 6-32. Classification of subacute osteomyelitis. (From Dormans JP, Drummond DS. Pediatric hematogenous osteomyelitis: new trends in presentation, diagnosis, and treatment. *J Am Acad Orthop Surg* 1994;2:333–341.)

Presentation	Subacute	Acute
Pain	Mild	Severe
Fever	Few patients	Majority
Loss of function	Minimal	Marked
Prior antibiotics	Often (30%–40%)	Occasional
Elevated WBC	Few	Majority
ESR	Majority	Majority
Blood cultures	Few positive	50% positive
Bone cultures	60% positive	85% positive
Initial x-ray study	Frequently abnormal	Often normal
Site	Any location (may cross physis)	Usually metaphysis

TABLE 6-9. COMPARISON OF ACUTE TO SUBACUTE OSTEOMYELITIS

Definitions

Acute hematogenous osteomyelitis can be classified by age (neonatal, childhood, and adult osteomyelitis), organism (pyogenic and granulomatous infections), onset (acute, subacute, and chronic osteomyelitis), and routes of infection (hematogenous and direct inoculation). Chronic osteomyelitis is defined by most authors as osteomyelitis with symptoms that have been present for longer than 1 month.

Clinical Presentation

Most patients with acute hematogenous osteomyelitis present with fever, pain, and localized tenderness at the site of infection. In order of decreasing frequency, the most commonly involved bones include the femur, tibia, humerus, fibula, radius, phalanges, calcaneus, ulna, ischium, metatarsals, and vertebral bodies. Although the erythrocyte sedimentation rate is commonly elevated in osteomyelitis, the white blood count is normal in 40% to 75% of patients (353). Blood cultures are positive for the infecting organism in 40% to 50% of patients (364), and direct cultures of the site of infection are positive in no more than 70% (353). The most common organism in hematogenous osteomyelitis is *Staphylococcus aureus.* In very young children, both *Haemophilus influenzae* type b and *Streptococcus pneumoniae* have a significant prevalence (353), but *Haemophilus influenzae* has virtually been eliminated as a musculoskeletal pathogen by immunization. Table 6-10 shows the most common organisms affective individuals by age.

Patient Type	Probable Organism	Initial Antibiotic
Neonate	Grp. B Strep, s. aureus, Gram-negative rods (H. influenza)	Cefotaxime (100–120 mg/k/24 h) or oxacillin and gentamicin (5–7.5 mg/kg/24 h)
Infants & children	S. aureus (80%)	Oxacillin (150 mg/kg/24 h)
	If allergic to penicillin[a]	Cefazolin (100 mg/kg/24 h)
	If allergic to penicillin and cephalosporin[a]	Clindamycin (25–40 mg/kg/24 h) or Vancomycin (40 mg/kg/24 h)
Sickle cell disease	S. aureus or Salmonella	Oxacillin and ampicillin or chloramphenicol or cefotaxime (100–120 mg/kg/24 h)

[a] Overall 80% due to S. aureus

TABLE 6-10. INITIAL ANTIBIOTIC THERAPY FOR OSTEOMYELITIS

Radiographic Evaluation

Only 20% of patients have plain x-ray findings of osteomyelitis within 10 to 14 days after onset of symptoms; the earliest finding is loss of defined deep soft tissue planes (353). Because of this early insensitivity of plain x-ray studies, isotope scanning techniques have been used to aid in diagnosis with varying rates of success. In proven osteomyelitis, abnormal technetium scans are seen in 63% to 90% of patients (352,358). In one study (358), gallium scans were abnormal in all patients with osteomyelitis, but they were also abnormal in 30% of patients without a bone infection. In neonates with osteomyelitis, only 31.5% had abnormal technetium bone scans in one series (342). Although somewhat technically difficult, indium-labeled leukocyte scans are usually abnormal at sites of osteomyelitis. CT scans have proved to be helpful in the evaluation of primary epiphyseal bone abscess (343). MRI is becoming the study of choice for defining the stage and extent of osteomyelitis, after plain x-ray studies (350). Bone infection can be identified by soft tissue changes through MRI techniques in 92% of patients, but the presence of prior surgery or coexisting fractures affects the accuracy of this study (344).

Injury

In 1932, Capener and Pierce (347) reviewed 1,068 patients with osteomyelitis and found only 18 pathologic fractures, 13 of which occurred in the femur. They thought these fractures were due to delayed recognition of the infection or inadequate treatment. Other factors were disuse osteopenia, presence of a weak involucrum, and excessive surgical removal of involved bone. In this preantibiotic era, most of these fractures were sustained after surgical treatment of the osteomyelitis, and the authors believed that conservation of the involucrum and proper immobilization could have prevented these injuries. White and Dennison (371) noted that before antibiotics, pathologic fractures of osteomyelitis were common, but union occurred with certainty in the presence of dense involucrum. Daoud and Saighi-Bouaouina (348) reported on 34 patients with hematogenous osteomyelitis complicated by pathologic fracture, pseudarthrosis, or significant segmental bone loss. The tibia was affected in 24 cases, the femur was affected in 8 cases, and the humerus was affected in 2 cases. A pathologic proximal femoral fracture has been reported in neonatal osteomyelitis (342). Although the condition is rare, hematogenous osteomyelitis can also evolve at the site of a closed fracture from 1 to 6 weeks after injury (346,355,363). Canale et al. (346) reported three children with osteomyelitis after closed fracture. They pointed out that progressive pain and swelling at a fracture site during healing are suggestive of possible osteomyelitis. Daoud et al. (349) reported 35 children with upper femoral osteomyelitis with associated septic arthritis. The incidence of AVN of the femoral head was approximately 50% both in the group that was treated with arthrotomy and in the group in which no surgery had been done. They postulated that AVN of the femoral head may be due to compression by abscess of the vessels lying on the posterior superior femoral neck. The complications

of fracture, dislocation, and displacement of the capital femoral epiphysis occurred in two thirds of their patients, and these usually were patients who presented long after an acute phase of the disease. They recommended surgical drainage of septic hips, and reduction and stabilization of hips with AVN using skin traction and plaster immobilization for 40 to 60 days. Lewallen and Peterson (357) documented osteomyelitis in 40% of 20 nonunions of diaphyseal open fractures in children. They believed that the presence of infection was a significant factor in their failure to heal. Long bone lesions also may be present in congenital rubella (361), and pathologic fractures have been reported in congenital cytomegalic inclusion disease (367).

Treatment

Once osteomyelitis is clinically suspected, needle aspiration of the area of maximal tenderness of the long bone is recommended to obtain the causative organism either from subperiosteal fluid or from the metaphysis directly. If gross purulent material is obtained, surgical drainage should follow (353). Ultrasound or MRI may be helpful in evaluating equivocal cases. With the increased concern about medical economics, recent trends to decrease the duration of intravenous antibiotic treatment of these infections appear to be appropriate as long as certain criteria are met. If oral antibiotics are inappropriate or the organism is not isolated by culture, then longer term parenteral antibiotics must be considered. Total length of therapy is based on the type of organism isolated and the patient's response to treatment. Unkila-Kallio et al. (370) found that in acute hematogenous osteomyelitis in children, the serum C-reactive protein correlated more closely than erythrocyte sedimentation rate to the clinical course of osteomyelitis, with rapid elevation at the onset of disease and a significantly faster decline with effective treatment than the erythrocyte sedimentation rate.

Fracture Management

Fractures associated with osteomyelitis may be difficult to treat and may be associated with complications such as malunion and growth disturbance (359). Pathologic fractures associated with osteomyelitis are rare in North America and usually are associated with neglected or chronic osteomyelitis, neonatal osteomyelitis, or septic arthritis. In children with chronic osteomyelitis, the purulent material elevates the periosteum and a supportive involucrum develops. Sequestrectomy of a portion of the necrotic diaphysis while leaving the supportive involucrum is often needed to bring the infection under control, but the timing of this procedure is controversial. Langenskiold (356) delayed sequestrectomy of a necrotic femoral shaft for 10 months in a 6-year-old patient to allow the involucrum to develop, but Daoud and Saighi-Bouaouina (348) recommended much earlier debridement. In patients with active infection, they performed sequestrectomy with debridement, followed by antibiotic therapy for up to 6 months. Prolonged cast immobilization was necessary. They obtained healing in 33 of 34 patients with pathologic fractures or pseudarthroses due to osteomyelitis. The mean healing time of fractures was 5 months in patients with involucrum. Patients with active infection without involucrum required debridement, antibiotics, and subsequent treatment with corticocancellous iliac graft. The mean healing time was 8.7 months. Their patients without active infection and no involucrum were treated with prolonged immobilization and cancellous bone graft supplemented by fixation. Angular deformities were treated with cast manipulation. Tudisco et al. (369) reported on 26 patients with chronic osteomyelitis with average follow-up of 23 years. Approximately 15% had shortening and angular deformity of the affected limb. Newer techniques for difficult cases have also been developed (Fig. 6-33).

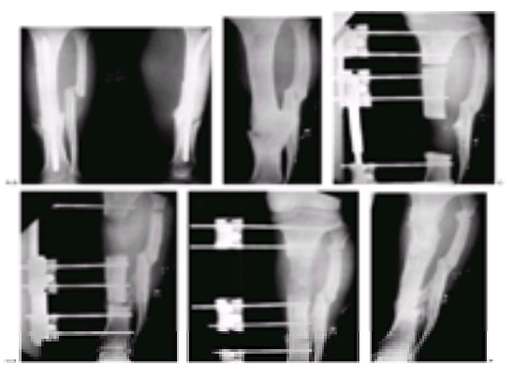

FIGURE 6-33. A 20-year-old patient presented with recalcitrant chronic draining osteomyelitis of the left tibia 4 years after a grade 3A open tibia fracture treated with an intramedullary nail. **A**, **B:** X-ray studies at presentation show healing of the fracture but changes consistent with chronic osteomyelitis. **C:** X-ray studies after resection of the involved segment of bone and sequestrum, with early bone transport from above and below a corticotomy. **D:** Early regenerate is seen at the time of docking of the transported segment and the distal tibia. **E:** Healing at the docking site is seen after posterolateral bone grafting. **F:** X-ray studies 6 years after the resection and bone transport showing healing and remodeling of the tibia. The patient has returned to work, is free of pain, and has no signs of active infection.

Pathologic fractures also can occur in association with advanced or neglected septic arthritis in older children and in association with neonatal osteomyelitis and septic arthritis. Infants with septic arthritis, especially of the shoulder or hip, present with pseudoparalysis of the extremity. In the upper extremity, this can be confused with Erb's palsy. Plain x-ray studies may show only soft tissue swelling and equivocal widening of the joint (362); technetium bone scans often are unreliable in neonates (362,368). Ultrasound and MRI can both be helpful; aspiration should be done if clinical suspicion exists. Schmidt et al. (362) found that more than half of their patients with septic arthritis of the shoulder also had osteomyelitis, and they recommended arthrotomy of the shoulder with drilling of the proximal humeral metaphysis if aspiration of the joint was positive.

AUTHORS' PREFERRED METHOD OF TREATMENT

With early recognition and appropriate treatment, osteomyelitis leading to pathologic fracture is uncommon. When osteomyelitis is associated with pathologic fracture, it usually is neglected chronic osteomyelitis, or rarely, neonatal osteomyelitis or septic arthritis. The most important step in the treatment of fracture associated with osteomyelitis is to control the underlying infection. At a minimum, this requires drainage and debridement of the infection with immobilization in association with antibiotic therapy. In advanced infections, sequestrectomy may be necessary. MRI is useful in identifying the sequestrum; an attempt should be made to leave as much supporting involucrum as possible at the time of sequestrectomy. Bone transport and lengthening also are occasionally useful. Prolonged immobilization with either plaster casts or external fixation devices may be needed, and segmental bone loss can be treated with bone transport or grafting.

PATHOLOGIC FRACTURES AFTER LIMB LENGTHENING

Limb lengthening has evolved dramatically over the past several decades. Surgeons experienced with lengthening techniques can now correct problems that previously had no satisfactory solution. The very high complication rate that has come with these advances has decreased with newer techniques and more extensive surgical experience. Complications with the Wagner method, popular 20 to 30 years ago, were as high as 92% (375,377). Newer techniques, using gradual lengthening with either monolateral fixators or fine wire fixators such as the Ilizarov fixator, have decreased the complication rate.

Fractures that occur in association with limb lengthening fall into three general categories: (a) fractures through pin tracks, (b) fractures through regenerate bone, or (c) fractures through bone weakened by disuse osteoporosis. Fractures that occur through holes left after removal of screws or fine wires generally occur a few weeks after device removal. The incidence of these fractures can be minimized by protective weight bearing after removal of the device and using the smallest possible screw diameter that is appropriate for the fixation device needed.

Fractures through regenerate bone are true pathologic fractures. The bone that is formed by distraction callotasis must be subjected to normal weight-bearing forces over a period of time before normal bony architecture is established. Fractures that occur through the lengthening gap can occur soon after removal of the fixator or years later. Various reports describe fractures through regenerative bone occurring as late as 2 to 8 years after lengthening (376,377 and 378). The incidence of fractures has been reported to be as high as 18% for Wagner lengthenings but only 3% for newer techniques (373,374,375,378,379 and 380). At present, most lengthenings are performed through the metaphysis, which has a larger bone diameter and better blood supply than the diaphysis, where Wagner lengthenings were done. When fractures occur in regenerate bone, they can be treated with simple cast immobilization. However, because this method further promotes osteopenia, many surgeons reapply a fixator, correct any malalignment caused by the fracture, and compress at the fracture site until healing. To ensure that the regenerate bone can bear the forces of normal activity, a variety of imaging methods have been used (372,376). When the regenerate bone attains the density and ultrastructural

appearance (development of the cortex and the medullary canal) of the adjacent bone, fixator removal is generally safe.

Pathologic fracture also can be caused by the osteopenia and joint contractures that can occur after months in an external fixation device. Some children, because of pain or anxiety, are reluctant to bear sufficient weight on their fixator devices, putting them at risk for disuse osteoporosis. Joint contractures can be related to either the lengthening itself or insufficient rehabilitation during and after lengthening. Many of the fractures due to these causes are avoidable; when they do occur, appropriate immobilization or internal fixation is used.

FRACTURES IN CONDITIONS THAT WEAKEN BONE

Osteogenesis Imperfecta

Osteogenesis imperfecta (OI) is a heterogenous group of inherited disorders in which the structure and function of type I collagen is altered. The fragile bone is susceptible to frequent fractures and progressive deformity (390,405). OI is identifiable in 1 in 20,000 total births, with an overall prevalence of approximately 16 cases per million index patients (405,423). The wide spectrum of clinical severity—from perinatal lethal forms to clinically silent forms—reflects the tremendous genotypic heterogeneity (more than 150 different mutations of the type 1 procollagen genes *COL1A1* and *COL1A2* have been described). As the molecular basis of this continuum of severity is further elucidated, the phenotypic groupings of the various classifications and subclassifications may seem arbitrary. However, these classifications facilitate communication, predict natural history, and help the clinician plan management strategies (405). From a practical viewpoint of orthopaedic care, patients with OI can be divided into two groups. One group of patients with severe disease develops long-bone deformity through repetitive fractures, eventually requiring open treatment with intramedullary fixation. Another group of patients has mild disease with frequent fractures, but their injuries usually respond well to closed methods of treatment and there is less residual deformity.

Clinical Presentation

Children with severe OI may present with a short trunk, marked deformity of the weight-bearing lower extremities, prominence of the sternum, triangular facies, thin skin, muscle atrophy, and ligamentous laxity; some develop kyphoscoliosis (386,397,410), basilar impression (408,417), and deafness (due to otosclerosis) (398). Despite this multitude of physical problems, children with OI usually have normal intelligence. Blue sclera, a classic finding in certain forms of OI, can also be present in normal infants, as well as in children with hypophosphatasia, osteopetrosis, Marfan's syndrome, and Ehlers-Danlos syndrome (402). Histologic findings in severe cases reveal a predominance of woven bone, an absence of lamellar bone, and thinning of the cortical bone with osteopenia.

Patients with OI may present with swelling of the extremity, pain, and low-grade fever and a radiograph showing exuberant, hyperplastic, callus formation (Fig. 6-34). The callus may occur without fracture and can have a distinct butterfly shape (402), as opposed to the usual fusiform callus of most healing fractures. The femur is most commonly involved, but cases noting involvement of the tibia and humerus have been reported (416). The sedimentation rate and serum alkaline phosphatase may be elevated. Because osteosarcoma has been associated with OI (401,403), aggressive-appearing lesions may occasionally require biopsy to confirm their benign nature.

FIGURE 6-34. A: This 10-month-old boy with a history of osteogenesis imperfecta presented with a right thigh pain and swelling and refusal to bear weight. This AP radiograph and (**B**) this lateral radiograph of the right femur show the extraordinarily abundant, hyperplastic callus—with the characteristic butterfly shape—that can occur in osteogenesis imperfecta. This appearance may be mistaken for an infection or a neoplastic process.

Radiographic Findings

Radiographic findings vary. In severe involvement, there is marked osteoporosis, thin cortical bone and evidence of past fracture with angular malunion (Fig. 6-35). Both anterior and lateral bowing of the femur and anterior bowing of the tibia are common. The long bones may be gracile with multiple cystic areas. Spinal radiographs may show compression of the vertebrae between the cartilaginous disk spaces (so-called codfish vertebra). The presence of wormian bones on a skull radiograph is relatively specific for OI. Subsequent development of multiple pathologic fractures with callus and deformity firmly establishes the diagnosis (Fig. 6-36).

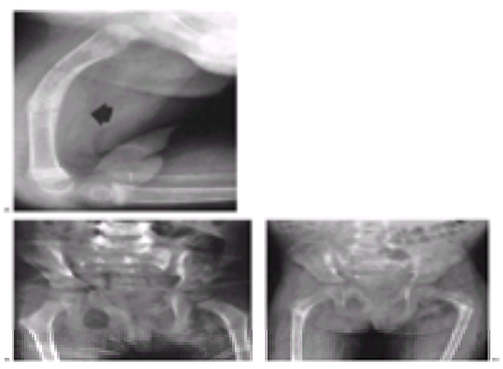

FIGURE 6-35. A: X-ray study of a nondisplaced transverse femoral shaft fracture (*arrow*) in a 6-year-old boy with osteogenesis imperfecta. Mild anterior bowing of the femoral shaft is already present, and with further fractures, this deformity will worsen. **B:** X-ray study of a 5-year-old ambulatory girl with osteogenesis imperfecta. Note the marked osteopenia of the proximal femurs. **C:** Thirteen months later, the patient sustained bilateral proximal femoral stress fractures, which eventually required treatment with Bailey-Dubow rods.

FIGURE 6-36. A: This 6-week old girl presented with multiple fractures in different stages of healing. She was evaluated for osteogenesis imperfecta and nonaccidental injury. She had a strong family history of osteogenesis imperfecta. An AP radiograph of the left upper extremity shows marked osteopenia and a nondisplaced spiral fracture of the left proximal humerus. **B:** An AP radiograph of the right lower extremity showing osteopenia and healing fractures of both the femur and the tibia. There is already some varus angulation and bowing to the mid-shaft of the right femur.

The diagnosis of OI is based on clinical and radiographic findings. There is no specific laboratory diagnostic test, although fibroblast cell culture can detect the collagen abnormality in 85% of OI patients (389). In the absence of multiple fractures, the initial radiographic diagnosis can be difficult. It is crucial, but often difficult, to distinguish OI from nonaccidental injury (404,409). Unexplained fractures in mild, undiagnosed OI can drag a family through unnecessary legal proceedings; conversely, a child with OI may be abused but not exhibit classic fracture patterns (e.g., corner fractures) owing to the fragility of their bones. Although no test or finding is specific, skin biopsy plays an important role (414,421).

Treatment

The multiple fractures in OI usually are transverse, diaphyseal, and seldom displaced, and they usually heal at a relatively normal rate in most patients (402,417). Most fractures in patients with OI occur before skeletal maturity. In a series of 31 patients, Moorefield and Miller (410) noted 951 fractures, 91% of which occurred before skeletal maturity. Fractures of the femur and tibia predominate. The humerus is the most commonly fractured bone in the upper extremity. Multiple long bone fractures may result in coxa vara, genu valgum, and leg-length discrepancy. Lateral dislocation of the radial head has been noted in some patients (402). Olecranon fractures, which are rare in unaffected children, are more common in patients with OI, especially the tarda form (391,422). Di Cesare et al. (391) reported an infant whose presentation with bilateral isolated olecranon fractures led to the diagnosis of OI.

Nonunion is more common in OI than in similar fractures in unaffected children. Although nonunion was mentioned in several series (410), Gamble et al. (393) emphasized the problem with a report of 12 nonunions in 10 patients. Almost all had type III OI (419) and presented with nonpainful clinical deformity and decreased functional ability. A history of inadequate treatment of the initial fracture was seen in 50% of these nonunions. One patient eventually required an amputation for a painful nonunion of a distal femoral supracondylar fracture.

Prevention

The role of medical therapy to limit the fracture frequency in OI should be considered investigational but promising (396,413). The tremendous genotypic and phenotypic variations in OI must be considered as the results of these trials are analyzed: A drug that works well for children with certain forms of OI may be ineffective for others. Sodium fluoride, growth hormones, and anabolic steroids have all been shown to be ineffective. Calcitonin, which limits osteoclasts, has had variable success. Nishi et al. (413) reported that the fracture rate decreased in 10 patients with OI treated with either calcitonin injection or nasal spray.

At present the most promising agents are the bisphosphonates (385,396). Pamidronate, like other bisphosphonates, is a potent inhibitor of bone resorption. In a trial of 30 children with severe OI, Glorieux et al. (396) showed that cyclic intravenous administration of pamidronate every 4 to 6 months resulted in a 41.9% increase per year in bone mineral density, an increase in metacarpal cortical width, and a decrease in fracture incidence of 1.7 fractures per year. Mobility improved in 16 of the 30 children, and all reported substantial relief of chronic pain.

Closed Methods

The orthopaedist caring for children with OI must balance good, standard fracture care (satisfactory reduction and casting) with the goal of minimizing immobilization to avoid a vicious circle: immobilization, weakness and osteopenia, then refracture (381,405,410). Plaster splints and casts, braces, and air splints have all been used (387,388,392,410,417).

Protected weight bearing is thought to reduce the incidence of lower extremity fractures (395). Customized splints and braces can add support to limbs weakened by fragile and deformed bone. Letts et al. (406) encouraged weight bearing in patients by protecting them with vacuum pants. The splinting system is a two-layer set of pants with Styrofoam beads between the layers. By evacuating the interval between the layers, a form-fitting orthosis results, much like the bean bag seating systems. Both decreased frequency of fracture and increased bone density were reported after use of this support system.

OPERATIVE TREATMENT

Load-sharing devices (such as intramedullary rods) are used for internal fixation of long bone fractures or osteotomies in children with OI. Plates and screws should be avoided. In patients with OI, most internal fixation is used for stabilization after corrective osteotomies. The goals of these osteotomies are to improve function and reduce fractures in weight-bearing bones by correcting angulation. Porat et al. (415) found that the percentage of ambulatory patients in their series went from 45% to 75% after intramedullary rodding. The amount of bowing that requires osteotomy has not been defined. In one series (411), the average preoperative bowing was 71 degrees for the femur and 40 degrees for the tibia, but many patients had much less angulation.

Traditionally, multiple osteotomy and rodding procedures (Sofield technique) involved extensive incisions with significant soft tissue stripping and blood loss. Sijbrandij (418) reported a percutaneous technique in which the deformity is straightened by closed osteoclasis and Rush pins are inserted along the proximal axis of the long bones, partially transfixing them to stabilize them in a new alignment. Most centers now use limited incisions, thus minimizing blood loss and periosteal stripping, while ensuring optimally placed osteotomies and efficient, controlled instrumentation. The choice of fixation device should be based on the age of the patient and the width of the medullary canal of the bone. Both fixed-length rods (402,415,420) and extensible Bailey-Dubow rods (382,383,384,393,394,411,412,415) are used. Skeletally mature patients and patients with very small medullary canals are best treated with nonelongating rods, whereas skeletally immature patients with adequate width of the medullary canal are best treated with extensible rods (394). Luhmann et al. (407) reported a 20-year experience with extensible nails: both overlapping Rush rods and Bailey-Dubow rods. They first implanted the rods at an average age of 7 years old and averaged more than 5 years before the first revision. They recommended a posterior position in the canal and using the stronger overlapping Rush rods technique in the femur whenever the canal diameter permitted; they advised against using overlapping Rush rods in the tibia.

Displaced fractures of the apophysis of the olecranon in patients with OI can be treated with open reduction and stabilization by resorbable suture in infants and with open reduction and internal fixation with two Kirschner wires and tension band technique by figure-of-eight absorbable suture in older children (422) (Fig. 6-37). Tibial tubercle avulsion injuries should be treated by surgical stabilization if displaced.

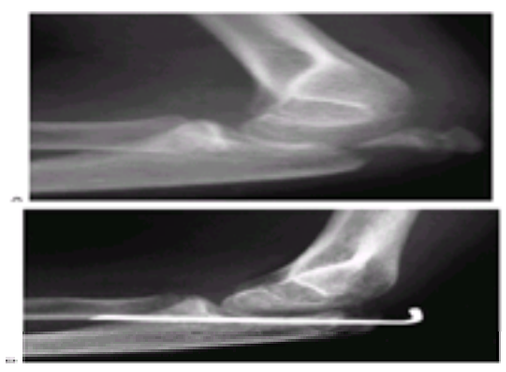

FIGURE 6-37. This 10-year-old girl with osteogenesis imperfecta presented with a displaced olecranon sleeve fracture of the left elbow. This was her first fracture. **A:** This lateral radiograph shows a widely displaced fracture involving the posterior portion of the articular surface. **B:** She was treated with open reduction and internal

fixation with two K-wires and tension band construct using #2 Vicryl suture. She was maintained in a cast for 3 weeks and then started on range-of-motion exercises.

Complications

Complication rates are high (Fig. 6-38). Problems include fracture at the rod tip (Fig. 6-39), migration of the fixation device, joint penetration, loosening of components of extensible rods, and fractures through the area of uncoupled rods (Fig. 6-40). Harrison and Rankin (399) compared the complications of 23 extensible rods with those of 27 fixed length rods. They found that the refracture rate was higher in the fixed length rods and fewer surgical interventions were necessary when extensible rods were used. Gamble et al. (394) reported that, although the complication rate approached 69% for Bailey-Dubow rods (mostly due to loosening of the T-piece), the fixed length rods had a complication rate of 55%; however, the replacement rate for nonelongating rods was 24% but only 12% for the Bailey-Dubow rods. They recommended crimping the T-piece to the sleeve and burying it slightly under the bone of the greater trochanter to prevent displacement. Jerosch (400) found a similar 63.5% complication rate for Bailey-Dubow rods but also thought that they were the best device available. Porat et al. (415) found that the complication rate was 75% for Bailey-Dubow rods and 50% for nonelongating rods, with a similar percentage requiring reoperation for both types of nails. Zionts et al. (424) reported 40 complications in 40 extensible nailings of 15 children, finding a much higher complication rate when insertion of the rods was initiated before 5 years of age. Complications were also higher for tibial nailings.

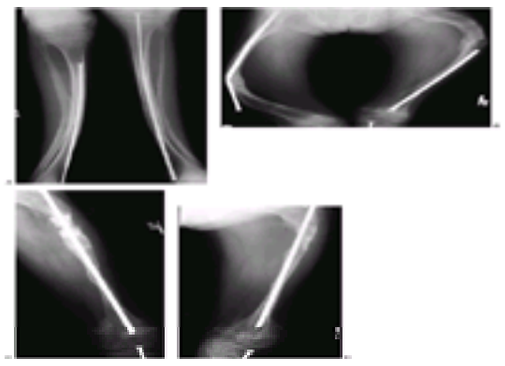

FIGURE 6-38. A: The lower extremity deformities of this 14-year-old girl with severe osteogenesis imperfecta were managed throughout childhood with Bailey-Dubow rods. This AP radiograph of both legs shows successful lengthening and maintenance of alignment of the left tibia but failure of rod lengthening with valgus angulation of the right tibia. **B:** The AP radiograph of both femurs, also taken at age 14, shows signs of several of the problems in the management of the femoral deformities throughout childhood. The right Bailey-Dubow rod protrudes into the soft tissues distally. There is femoral bowing with a fracture and bending of the Bailey-Dubow rod at the junction of the male and female ends. In the left femur, part of the Bailey-Dubow rod has been removed because it was protruding into the soft tissues. There is a pathologic fracture through the bowing of the proximal femur. **C:** Deformities of both femurs were treated by osteotomy and exchange of the Bailey-Dubow rods for a Rush nail. **D:** One year after the exchange, the osteotomy has healed. The femoral alignment is good, but the proximal portion of the Rush rod is prominent in the soft tissues.

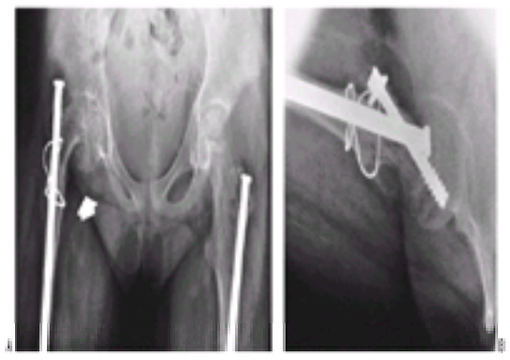

FIGURE 6-39. A: An 11-year-old boy with osteogenesis imperfecta fell and sustained a right subcapital femoral neck fracture (*arrow*). **B:** The fracture was reduced with gentle traction by a fracture table under general anesthesia and was stabilized with a cannulated screw, which was placed with difficulty through an open approach, just anterior to the Bailey-Dubow intramedullary rod.

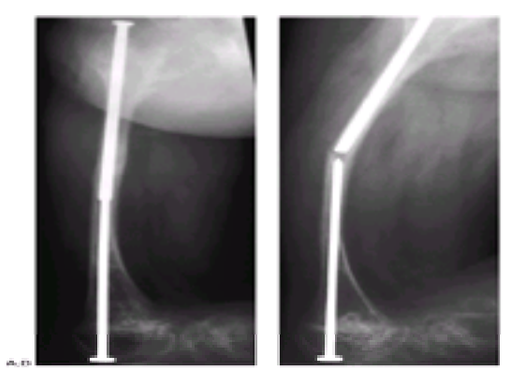

FIGURE 6-40. A: This 10-year-old with severe osteogenesis imperfecta presented several years after Bailey-Dubow rod treatment for fractures and deformity of the right femur. This lateral femoral radiograph shows osteopenia, good position of the Bailey-Dubow rod, and signs that the rod has allowed significant lengthening of the femur without deformity. **B:** This lateral radiograph of the right femur, taken 2 years later at age 12, shows that the rod has separated. There is now a fracture in the gap between the male and female ends of the Bailey-Dubow rod. (Courtesy of Brian Grottkau M.D. and Michael Goldberg, M.D., Boston, Mass.)

Postoperative bracing is suggested for lower extremity fractures (411). Upper extremity fractures should also undergo prolonged splinting after removal of fracture fixation. Immobilization also may be adequate to treat stable, minimally displaced fractures just distal or proximal to the intramedullary rods (394).

Nonunions, after fracture or surgical intervention, may cause difficulty in both ambulation and transfer. In one series of nonunions (393), the average age at diagnosis was close to 10 years and most patients responded to treatment with intramedullary rods and bone grafting, with healing in approximately 9 weeks. Nonunion can occur after insertion of rods for upper extremity fractures. Growth arrest also can follow the use of intramedullary rods in the lower extremities (Fig. 6-41).

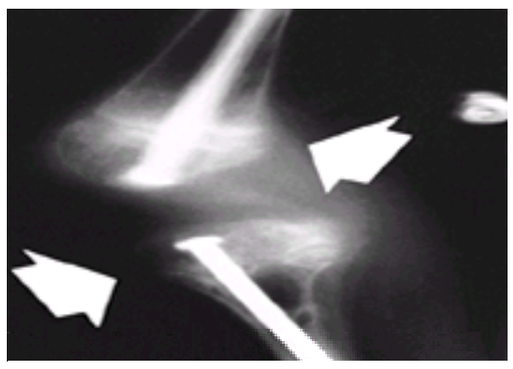

FIGURE 6-41. An 8-year-old girl with osteogenesis imperfecta with limb-length discrepancy. Lateral tomograms of the knee show a central physeal arrest of the proximal tibia and early physeal arrest of the distal femur (*arrows*). Such complications are not infrequent with the use of Bailey-Dubow rods.

AUTHORS' PREFERRED METHOD OF TREATMENT

Protected weight bearing is the goal for patients with severe OI. Close follow-up is necessary in the first few years of life, with protective posterior plaster splinting for fractures. Orthoses are constructed for bracing of the lower extremities to aid in both standing and ambulation. Standing frames also are used. Once he or she is ambulatory, the patient is advanced to the use of a walker or independent ambulation.

Severe bowing of the extremities after recurrent fractures is an indication for osteotomy and intramedullary rodding. Whenever possible, surgery is delayed until the child is 6 or 7 years old. We recommend extensible rods in skeletally immature patients and nonelongating rods both in older patients and in younger patients whose canal is not wide enough for insertion of Bailey-Dubow rods. When possible, we use limited incisions for insertion of Bailey-Dubow rods to minimize blood loss and to avoid devascularization of the long bones, which occurs commonly in the so-called open shish-kabob technique.

Operative Technique–Bailey-Dubow Rod

Multiple small skin incisions are made at the point of maximal deformity of the long bones, and a small periosteal incision is made to permit introduction of a drill bit. After the cortex is drilled repeatedly, manual osteoclasis completes the osteotomy and the long bone is straightened. A guide pin is drilled in to the medial edge of the tip of the greater trochanter, and down into the intertrochanteric femur, and then is tapped distally through the intramedullary canal through the knee. If callus from old fracture halts progress, the guide pin can be drilled through the obstruction and then tapped farther distally into the middle of the distal flexed knee joint. Next, the reamer is advanced over the guide pin and the female portion of the Bailey-Dubow rod is threaded over the guide pin and driven down the canal. The guide pin is pulled out of the knee joint through a small arthrotomy incision, and the T-piece is attached to the Bailey-Dubow sleeve. The T-piece is tapped down into the greater trochanter. The male portion is then slid into the sleeve to complete assembly of the expandable rod.

The patient is immobilized for approximately 4 weeks in a hip spica cast and then in a brace for 3 to 6 months. When there are fractures associated with intramedullary rods, these are treated with either rod revision or immobilization. Every effort should be made to keep patients ambulatory early after fractures occur to minimize disuse osteoporosis.

Osteopetrosis

Osteopetrosis, also known as Albers-Schönberg disease, is a condition in which excessive density of bone occurs as a result of abnormal function of osteoclasts (425,442). The resultant bone of these children is dense, brittle, and highly susceptible to pathologic fracture. The incidence of osteopetrosis is approximately 1 per 200,000 births. The inherent problem is a failure of bone resorption with continuing bone formation and persistent primary spongiosa. The disorder classically has been divided into a severe infantile malignant type and a milder form that presents later in life. Intermediate forms have been identified in which osteopetrosis presents as renal tubular acidosis (448). Although the number of osteoclasts present in the affected bone is variable (408,435), in the severe form of this disease, the osteoclasts may be increased but function poorly (446).

Radiographically, the bones have a dense, chalklike appearance (Fig. 6-42). The spinal column may have a sandwich or rugger jersey appearance because of dense, sclerotic bone at each end plate of the vertebrae and less involvement of the central portion. The long bones tend to have a dense, marble-like appearance and may have an Erlenmeyer's flask shape at their ends owing to deficient cutback remodeling. Radiolucent transverse bands may be present in the metaphysis of the long bones, and these may represent a variable improvement in the resorption defect during growth of the child (441). There may be bowing of the bones due to multiple fractures (432), spondylolysis (440), or coxa vara (442). The small bones of the hands and feet may show a bone-within-bone appearance with increased density around the periphery. The unusal radiographic appearance may initially obscure occult, nondisplaced fractures.

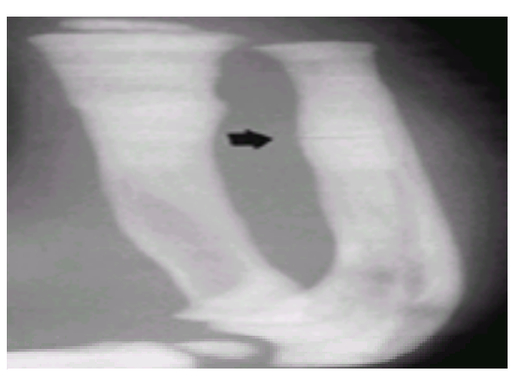

FIGURE 6-42. This 2-year-old with osteopetrosis presented with forearm pain. An AP radiograph shows the characteristic increased bone density and absence of a medullary canal, especially in the distal radius and ulna. There is a typical transverse, nondisplaced fracture (*arrow*) in the distal ulnar diaphysis.

Treatment

Pathologic fractures are quite common in patients with osteopetrosis (408,427,432,436,438,445,448). Patients with a severe form of the disease have more fractures than those with presentation later in childhood. Concurrent blindness can make patients more susceptible to accidental trauma. Patients with autosomal dominant osteopetrosis with rugger jersey spine and endobones of the pelvis (type II) are six times more likely to have fractures than patients with only sclerosis of the cranial vault (type I) (427).

Patients with the severe, congenital disease have transverse or short oblique fractures of the diaphysis, particularly the femur (Fig. 6-43). Distal physeal fractures with exuberant callus may be confused with osteomyelitis (441). Common locations for fractures include the inferior neck of the femur, the proximal third of the femoral shaft, and the proximal tibia (425,441). Although most fractures involve the long bones of the lower extremities, upper extremity fractures also occur frequently (425,432). The onset of callus formation after fracture in osteopetrosis is variable (425,432,435). Although many studies state that fractures in osteopetrosis heal at a normal rate (435,442), others report delayed union and nonunion (425). In a rat model of osteopetrosis, Marks and Schmidt (439) found delayed fracture healing and remodeling. Hasenhuttl (432) observed that in one patient with recurrent fractures of the forearm, each succeeding fracture took longer to heal, with the last fracture

taking nearly 5 months to unite.

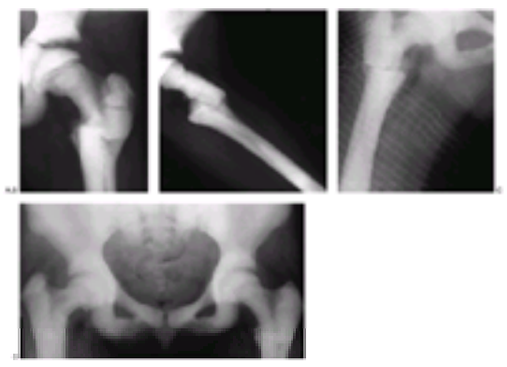

FIGURE 6-43. A: This 9-year-old with osteopetrosis sustained similar bilateral subtrochanteric fractures of the femur over a 2-year period. This AP femoral radiograph and (**B**) this lateral femoral radiograph shows a healing transverse subtrochanteric fracture of the left femur. **C:** One year later, at age 10, she sustained a similar right transverse minimally displaced subtrochanteric femur fracture, which was treated with reduction and a spica cast. **D:** This AP radiograph taken at age 14 years shows that both proximal femur fractures have healed and there is mild residual coxa vara, especially on the right side.

The orthopaedist treating fractures in children with osteopetrosis should follow the principles of standard pediatric fracture care, with additional vigilance for possible delayed union and associated rickets (432,445). Immobilization is prolonged when delayed union is recognized. Armstrong et al. (425) surveyed the membership of the Pediatric Orthopaedic Society of North America and compiled the combined experience of 58 pediatric orthopaedic surgeons with experience treating pathologic fractures in osteopetrosis. In this comprehensive review, they concluded that nonoperative treatment should be strongly considered for most diaphyseal fractures of the upper and lower limbs in children, but surgical management is recommended for femoral neck fractures and coxa vara.

Open treatment of these fractures with fixation is technically difficult. One author (431) described insertion of fixation into this bone like “drilling into a rock.” In intramedullary fixation of femoral fractures, extensive reaming may be required because the intramedullary canal can be completely obliterated by sclerotic bone (428). Other authors have found fixation of hip fractures with fixation to be a formidable task (425,441), with damage occurring to the fixation devices on insertion. The bone is hard enough to break the edges off both chisels and drill bits. Armstrong et al. (425) cautioned that “the surgeon should expect to use several drill bits and possibly more than one power driver.”

In addition to these technical difficulties, patients with osteopetrosis are at risk for excessive bleeding and infection, probably related to the hematopoetic dysfunction caused by obliteration of the marrow cavity (445). Procedures should not be performed unless the platelet count is greater than 50,000 mm^3, and preoperative platelet transfusions may be necessary (445). Prophylactic antibiotic coverage is advised. Minor procedures should be performed percutaneously whenever possible (445).

In the past, primary medical treatment for osteopetrosis included transfusions, splenectomy, calcitriol, and adrenal corticosteroids, but these techniques have proved ineffectual (444,447). Bone marrow transplantation for infant malignant osteopetrosis has proved to be an effective means of treatment for some patients, but it is not possible in all patients, it does not guarantee survival, and it may be complicated by hypercalcemia (425,429,430,443).

Pyknodysostosis

Pyknodysostosis is a rare syndrome of short stature and generalized sclerosis of the entire skeleton. The dense brittle bones of affected children are highly susceptible to pathologic fractures. Henri Toulouse-Lautrec was thought to be afflicted by this disorder (452). Pyknodysostosis is inherited as an autosomal recessive trait, with an incidence estimated as 1.7 per 1 million births. The long bones are sclerotic, with poorly formed medullary canals; histologic section show attenuated haversian canal systems.

Patients with pyknodysostosis have short stature, a hypoplastic face, a nose with a parrot-like appearance, and both frontal and occipital bossing. Bulbous distal phalanges of the fingers and toes with spooning of the nails are common. Coxa vara, coxa valgum, genu valgum, kyphosis, and scoliosis may be present. Failure of segmentation of the lower lumbar spine has been reported. Results of laboratory studies usually are normal.

Radiographs show a sclerotic pattern very similar to that of osteopetrosis. In pyknodysostosis, however, the medullary canals, although poorly formed, are present and a faint trabecular pattern is seen (Fig. 6-44). Such sclerotic bone is also seen in Engelmann's disease, but clinically those patients are tall and eventually develop muscle weakness. The distal femur in a patient with pyknodysostosis usually has an Erlenmeyer's flask deformity similar to that found in patients with Gaucher's disease (449).

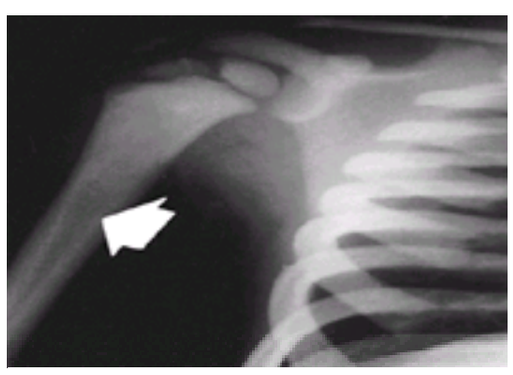

FIGURE 6-44. A young boy with pyknodysostosis. Although bone density is increased overall, a medullary canal is present in the proximal humerus with faint trabecular lines (*arrow*) in contrast to osteopetrosis, in which the medullary canal is usually completely obliterated. (Courtesy of John D. McKeever, M.D., Corpus Christi, Texas)

Treatment

Although pathologic fractures are thought to be less common in pyknodysostosis than in OI, almost all patients with pycnodysostosis reported in the literature have had pathologic fractures. By age 22 years, one patient had sustained more than 100 fractures (450). The fractures are usually transverse and diaphyseal, and heal with scanty callus (453). The fracture line can persist for nearly 3 years after clinical union, with an appearance similar to a Looser line. Lower extremity fractures are the most common (450), and clinical deformity of both the femur and tibia is frequent.

Fracture healing has been described as both normal (455) and delayed (450). Nonunion is reported in the ulna, clavicle, and tibia (453). One series (453) with long-term follow-up suggests that fractures tend to heal readily in childhood, but nonunion can be a problem in adulthood. Edelson et al. (451) reported 14 new cases of pyknodysostosis from a small Arab village. They described a hangman's fracture of C2 in a 2-year-old child that went on to asymptomatic nonunion. There was 100% incidence of spondylolysis in their patients aged 9 years or older, with most located at L4–L5. None of the spondylolytic lesions showed uptake on technetium 99m bone scan. Treatment was conservative, with one patient with symptomatic spondylolysis responding to bed rest.

Cast immobilization is successful in the treatment of most of these fractures. Taylor et al. (456) treated a femoral fracture in an 11-year-old boy with skin traction and a

one-and-a-half hip spica cast. At 6-month follow-up, clinical union with persistent fracture line was seen. In adults, both plates and screws and hip screws have been used for proximal femoral fractures (454). Delayed union of tibial fractures has been treated with both compression plating and bone grafting (453) and intramedullary nailing with cast immobilization. Roth (454) noted that treatment of a hip fracture with fixation was technically difficult. Cervical immobilization through a Minerva cast and soft cervical collar has been used for a C2 fracture in a child, and the patient did well, although immobilization was prematurely discontinued (450).

Rickets

Rickets is a disease of growing children caused by either a deficiency of vitamin D or an abnormality of its metabolism. The osteoid of the bone is not mineralized, and broad unossified osteoid seams form on the trabeculae. With failure of physeal mineralization, the zone of provisional calcification widens and the ingrowth of blood vessels into the zone is disrupted. In the rickets of renal failure, the effects of secondary hyperparathyroidism (bone erosion and cyst formation) also are present. Before widespread fortification of common foods, vitamin D deficiency was a common cause of rickets, but other diseases affecting the metabolism of vitamin D have become a more common cause. Regardless of the underlying cause, the various types of rickets share similar clinical and radiographic features. Although many of the metabolic findings are the same, there are some differences (Table 6-11).

Disorder	Cause	$1,25(OH)_2$ Vitamin D	PTH	Ca^{2+}	P	Alk Phos
Vitamin D deficiency rickets	Lack of vitamin D in the diet	↓	↑	↓ or –	↓	↑
Gastrointestinal rickets	Decreased gastrointestinal absorption of vitamin D or Ca^{2+}	↓ or –	↑	↓	↓	↑
Vitamin D–dependent rickets	Reduced $1,25(OH)_2$ vitamin D Production	↓	↑	↓	↓	↑
Vitamin D–resistant rickets–end-organ insensitivity	Intestinal cell insensitivity to vitamin D causing decreased Ca^{2+} absorption	↓ or –	↑	↓	↓	↑
Renal osteodystrophy	Renal failure causing decreased vitamin D synthesis, phosphate retention, hypocalcemia and secondary hyperparathyroidism	↓	↑	↓	↑	↑

TABLE 6-11. RICKETS: METABOLIC ABNORMALITIES

Both pathologic fractures (435,457,464,466,468) and epiphyseal displacement (458,465) can occur in rickets with associated renal disease. The treatment of rickets with associated pathologic fractures depends on identification of the underlying cause. In addition to nutritional rickets, many diseases of the various organ systems can affect vitamin D metabolism, and their treatment is necessary before the clinical rickets can be resolved.

Nutritional Rickets

Inadequate dietary vitamin D and lack of exposure to sunlight can lead to a vitamin D deficiency (Fig. 6-45). Pathologic fractures from vitamin D deficiency rickets also occur in children on certain diets: unsupplemented breast milk (463), diets restricted by religious beliefs (457), and fad diets (460).

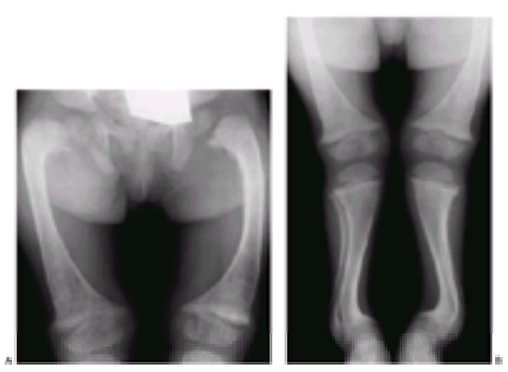

FIGURE 6-45. A: This 3-year-old girl presented with extremely severe nutritional rickets. An AP radiograph of the pelvis and both femora shows severe coxa vara, widening of all physes, and osteopenia of the distal femora, with flaring of the distal femoral methaphysis. **B:** Standing lower extremity radiograph shows further deformity of the distal tibia with Looser lines visible on the concavity of the deformity of the right distal fibula.

Fractures are treated with both cast immobilization and correction of the vitamin deficiency by oral vitamin D supplementation. Oral calcium supplements also may be necessary, and patients should consume a vitamin D–fortified milk source (457).

Rickets in Malabsorption Diseases

Celiac disease caused by gluten-sensitive enteropathy affects intestinal absorption of fat-soluble vitamins (such as vitamin D), resulting in rickets. Biopsy of the small intestine shows characteristic atrophy of the villi. Treatment is oral vitamin D and a gluten-free diet. Infants with short gut syndrome may have vitamin D–deficiency rickets. This syndrome may develop after intestinal resection in infancy for volvulus or necrotizing enterocolitis, in intestinal atresia, or after resection of the terminal ileum and the ileocecal valve (471). Pathologic fractures have been reported, and treatment is immobilization and administration of vitamin D^{2} with supplemental calcium gluconate.

Hepatobiliary disease also is associated with rickets (459,462) (Fig. 6-46) With congenital biliary atresia, the bile acids, essential for the intestinal absorption of vitamin D, are inadequate. By age 3 months, nearly 60% of patients with biliary atresia may have rickets (461). Intravenous vitamin D often is needed for effective treatment of these patients. After appropriate surgical correction of the hepatic syndrome, the bone disease gradually improves. The pathologic fractures that develop in these disorders (459) can be treated with immobilization.

FIGURE 6-46. A: This 18-year-old boy with sclerosing cholangitis and a history of steroid use presented with several months of worsening low back pain. This lateral radiograph of his lumbar spine shows marked osteopenia, collapsed codfish vertebra with sclerotic end plates and widened disc spaces and Schmorl's nodes. **B:** This MRI shows flattened concave vertebra that are smaller in most locations than the adjacent intervertebral disc. He was successfully treated with 3 months in a

thoraco-lumbar-sacral-orthosis (TLSO) brace, followed by weaning from the brace and conditioning exercises.

Anticonvulsant therapy can interfere with the hepatic metabolism of vitamin D and result in rickets and pathologic fractures. Fewer fractures occur in institutionalized patients receiving vitamin D prophylaxis (467). In a study of 20 children with epilepsy, there was no difference in the bone mineral density of the femoral neck in patients on either phenobarbital or phenytoin compared with control subjects (470).

Ifosamide, a chemotherapeutic agent used for treatment of Ewing's sarcoma, can cause hypophosphatemic rickets in children. The onset of rickets may occur anywhere from 2 to 14 months after chemotherapy and can be corrected with the administration of oral phosphates (469). Other mineral deficiencies such as magnesium (a cofactor for parathyroid hormone) can cause rare forms of rickets (Fig. 6-47).

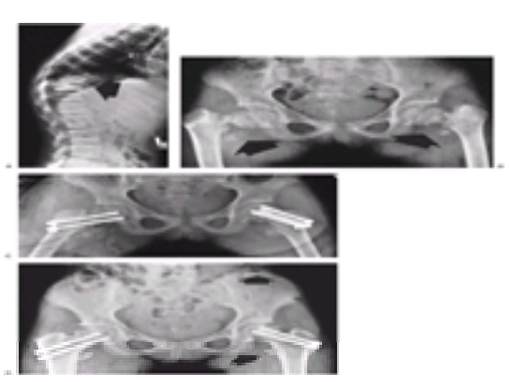

FIGURE 6-47. A: A 13-year-old girl presented with rickets caused by magnesium deficiency. She had back and hip pain after a seizure; the x-ray study shows compression fractures of the thoracic vertebrae (*arrow*). **B:** Displaced femoral neck fractures are also present with periarticular calcification (*arrows*). **C:** The fractures were openly reduced with fixation by multiple cannulated screws. She was placed in a hip spica cast to protect the fixation. **D:** At 12-month follow-up, the femoral neck fractures have united, with no evidence of avascular necrosis of the femoral heads. With medical treatment of the rickets, new bone has been added to the pelvis (*arrows*.)

Rickets and Very-Low-Birth-Weight Infants

Very-low-birth-weight infants (1,500 g or less) can have pathologic fractures. In one study of 12 very-low-birth-weight in- fants, the incidence of pathologic fracture was 2.1%, nearly twice the rate of other premature infants with a birth weight of more than 1,500 g (472). The fractures are likely caused by a nutritional osteomalacia that may evolve into frank rickets in nearly 30% of very-low-birth-weight infants (472,474,476,478) (Fig. 6-48). During the last trimester of pregnancy, intrauterine growth rate is exponential and almost two thirds of the birth weight is gained at that time (480). Eighty percent of both calcium and phosphorus is acquired then (475). Bone loss can be graded by either loss of cortical bone of the humerus (479) or loss of bone of the distal radius (476). Other than craniotabes (thinning and softening of the skull bone, with widening of the sutures and fontanelles), the clinical signs of rickets are generally lacking in these patients (574). The risk factors predisposing these patients to both rickets and fractures include hepatobiliary disease (461,462,472), prolonged total parenteral nutrition (472), chronic lung disease (472), necrotizing enterocolitis (471), patent ductus arteriosus (473), and physical therapy with passive range-of-motion exercises (474,477). In a prospective study of 78 low-birth-weight infants, Koo et al. (477) observed a 73% incidence of rickets with associated pathologic fractures in patients with a birth weight of 800 g or less and only a 15% incidence of rickets with fractures in patients with a birth weight ranging from 1,000 to 1,500 g.

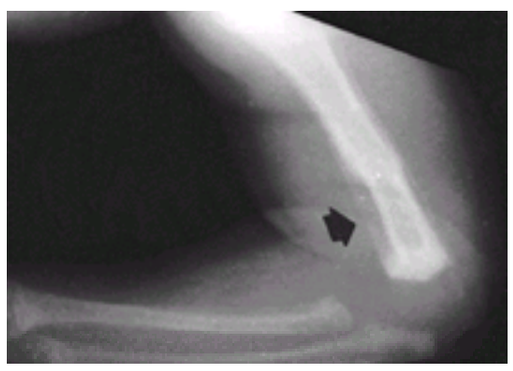

FIGURE 6-48. A 4-month-old premature infant of low birth weight with healing rickets. New periosteal bone is cloaking the humerus (*arrow*).

Treatment

In most cases, pathologic fractures in very-low-birth-weight infants are found incidentally on chest x-ray or gastrointestinal studies. The fractures may be suspected when physical examination reveals swelling and decreased movement of an extremity. The differential diagnosis of these fractures is limited but important: OI, copper deficiency syndrome, child abuse, and pathologic fracture from overzealous physical therapy (474). Recurrent fractures, physical findings, and a positive family history are the hallmarks of OI; serum copper levels are useful in establishing copper deficiency syndrome. Neonatal osteomyelitis may also present a similar x-ray appearance. If risk factors for infection are present, the bone lesion should be aspirated and cultured (472).

In the series reported by Amir et al. (472), 12 (1.2%) of 973 preterm infants had fractures; 11 of 12 had more than 1 fracture. Radiographically, osteopenia is first seen at the fourth week of life. Typically, rib fractures are next seen at 6 to 8 weeks of life, then fractures of the long bones at 11 to 12 weeks (480). In one study, 54% of fractures were in the upper extremities, 18% in the lower extremities, 22% in the ribs, and approximately 6% in either the scapula or the clavicle (477). Most long bone fractures are metaphyseal and may be transverse or greenstick with either angulation or complete displacement (472). Callus is seen at the fracture site in less than a week, and complete remodeling occurs in 6 to 12 months (472,477). Passive range-of-motion exercises for these infants, by both physical therapists and parents, should be avoided unless it is absolutely necessary (474). Rib fractures have been associated with vigorous chest physiotherapy (477,478). Care also should be taken even with routine manipulation of the extremities during nursing care, and special care should be taken in restraining the extremities during surgical procedures (477).

Splinting is the treatment of choice for pathologic fractures of the long bones in very-low-birth-weight infants (Fig. 6-49). Hip spica casts are contraindicated because they may compromise cardiopulmonary support and hamper nursing care (477). Regardless of the means of immobilization, the prognosis is excellent for most of these fractures because they go on to complete remodeling within 12 months; prolonged follow-up is advised. Preventive measures are important to minimize the risk of fracture in low-birth-weight infants. Their nutritional need for high levels of calcium, phosphorus, and vitamin D should be recognized. Alternating high levels of calcium with low levels of phosphorus in hyperalimentation solutions can help meet these needs. Because growth arrest is possible after fractures, follow-up over the first 2 to 3 years of life is advised.

FIGURE 6-49. A tibia splint has been constructed for this premature infant by wrapping a tongue blade in a heavy layer of Webril and then fracturing the tongue depressor so that it assumes a sugar tong appearance. Tape is gently wound around the splint to hold it in place.

Rickets and Renal Osteodystrophy

Renal osteodystrophy is common in patients with end-stage renal failure; it was diagnosed in 79% of patients in a series of 50 children (490). Typically developing about 1.4 years after diagnosis of the kidney disease (490), the clinical syndrome is a combination of rickets and secondary hyperparathyroidism with marked osteoporosis. These children present with short stature, bone pain, muscle weakness, delayed sexual development, and bowing of the long bones (483). The underlying renal disease may be chronic nephritis, pyelonephritis, congenitally small kidneys, or cystinosis (468). Identification of the renal disorder is important because patients presenting with rickets due to obstructive uropathy may respond to surgical treatment of the renal disease.

Specific clinical deformities include genu valgum (most common), genu varum, coxa vara, and varus deformities of the ankle (482,483,485). These deformities are most common in patients diagnosed before 3 years of age. Davids et al. (485) showed that periods of metabolic instability, characterized as an alkaline phosphatase of 500 U for at least 10 months, were associated with progression of deformity. With the adolescent growth spurt, osseous deformities can accelerate rapidly over a matter of weeks (485).

Radiographs show rickets and osteopenia with osteitis fibrosa cystica (482). Osteoclastic cysts (brown tumors) may form. Metaphyseal cortical erosions occur in the lateral clavicle, distal ulna and radius, neck of the humerus, medial femoral neck, medial proximal tibia, and middle phalanges of the second and third fingers (490). The proximal femur may become so eroded with tapering and thinning that it has been likened to a rotting fence post (502). In renal osteodystrophy, the Looser zone may represent a true stress fracture and, with minor trauma, may extend across the full thickness of the bone with development of a true fracture. Callus may be scanty in patients with fractures who have untreated renal disease, but in patients on hemodialysis, abundant callus may form at the fracture site (466).

Treatment

In renal osteodystrophy, pathologic fractures of the long bones, as well as rib fractures, vertebral compression fractures, and displacement of the epiphyses, occur frequently. Fractures occur in areas of metaphyseal erosion or through cysts. Immobilization is used to treat pathologic fractures through both generalized weakened bone and brown tumors.

Once the underlying bone disease is under control, open procedures such as curettage of cysts with bone grafting and open reduction of fractures may be considered when appropriate (466). Internal fixation is preferable to external fixation (484). Preoperative tests needed for these patients before surgery include electrolytes, calcium, phosphorus, and alkaline phosphatase. Before surgery, these patients may need dialysis, phosphate adjustment, either medical or surgical correction of hyperparathyroidism, or chelation therapy for aluminum toxification. Supplemental vitamin D should be discontinued or the dose halved 2 to 4 weeks before any procedure that may require immobilization (483). It is important to rule out dental abscess, which may be present in as many as 25% of patients with vitamin D–resistant rickets (494). Postoperative infection may be more common in patients who are on corticosteroid therapy after renal transplantation (496). Prophylactic antibiotics are highly recommended for surgery of all patients with renal osteodystrophy (487).

Osteonecrosis may occur in weight-bearing bones, with the femoral head most often symptomatic (501). Other sites of involvement include the distal femoral condyles and the talus (482,499). Osteonecrosis may result from the use of immunosuppressive corticosteroids, because there is less osteonecrosis when the corticosteroid dose is decreased (486). Ferris et al. (488) described osteochondritis dissecans lesions of the medial femoral condyles in young adults with hypophosphatemic rickets. Both loose bodies and so-called trap-door lesions were seen in these patients. Older patients developed calcification of the ligaments about the hip, knees, and spine. Lesions of bilateral osteochondritis dissecans may require repeated arthroscopic irrigations and removal of loose bodies (488). Joint stiffness in older patients due to ligamentous calcification about the knees, hips, and spine can be minimized if early corrective osteotomies of the lower extremities are performed to place them in the optimal position for function. Osteonecrosis in renal osteodystrophy can be treated with repeated joint aspiration, crutch ambulation, and physical therapy (485).

Rickets and Renal Osteodystrophy—Slipped Capital Femoral Epiphysis

The incidence of epiphyseal displacement in children with renal osteodystrophy ranges from 20% to 30% (465,491). Sites of involvement include the distal femur, proximal femur, and proximal humerus, the heads of both the metatarsals and metacarpals, and the distal radial and ulnar epiphyses, which tend to displace in an ulnar direction (491). In the proximal femur, both femoral neck fractures (458) and slipped capital femoral epiphysis occur (Fig. 6-50).

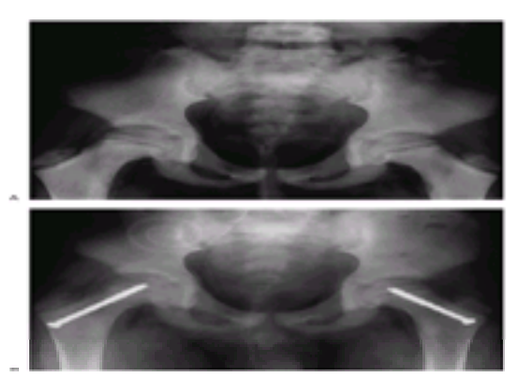

FIGURE 6-50. A: This 13-year-old boy with renal osteodystrophy presented with bilateral hip and thigh pain. This AP pelvis radiograph shows widening of the proximal femoral physes with sclerosis. Slipped capital femoral epiphyses were diagnosed. **B:** This AP pelvis radiograph taken 9 months after surgery shows narrowing of the physis and no evidence of further displacement of the capital femoral epiphyses.

Possible explanations for displacement of the proximal femoral epiphysis include metaphyseal erosion with subsequent fracture (458,491), and a layer of fibrous tissue that forms between the physis and the metaphysis because of the destructive effects of the renal osteodystrophy (492). The warning signs and risk factors for slipped capital femoral epiphysis in renal osteodystrophy include subperiosteal erosion of the medial femoral neck, increasing width of the physis, bilateral coxa vara, male gender, and an age between 10 and 20 years (458). With erosion of the cortex of the inferior medial femoral neck, the femoral head collapses, decreasing the neck shaft angle, and subjecting the physis to shear forces as it assumes a vertical orientation.

The aggressive medical treatment of renal osteodystrophy, including administration of vitamin D (493), calcitriol, hemo- dialysis, renal transplantation, and

parathyroidectomy, has improved the long-term survival and quality of life for these patients. Temporary limitation of weight bearing is recommended if there is little metaphyseal erosion, minimal coxa vara, and fusion of the physis is expected within 1 to 2 years (466). Goldman et al. (458) recommended prophylactic hip pinning or close follow-up if risk factors are present for slipped capital femoral epiphysis in patients with renal osteodystrophy. With continuing slippage after medical treatment, most authors recommend *in situ* fixation (458,483,497). Continuing displacement of the proximal femoral epiphysis may occur even after pinning. Fixation holds poorly, possibly because the wide radiolucent zone of the femoral neck in this disorder is not true physis but rather poorly mineralized woven bone and fibrous tissue (465). In a very young child, threaded pin fixation of the proximal femoral epiphysis may result in growth abnormality with trochanteric overgrowth.

Smooth pins can be used to stabilize the epiphysis temporarily until medical treatment resolves the underlying bone disease. For patients younger than 5 years, Hartjen and Koman (489) recommended treatment of slipped capital femoral epiphysis with reduction through Buck's traction and fixation with a single specially fabricated 4.5-mm cortical screw. The distal threads of the screw were machined off so that only the smooth shank of the screw extended across the physis. Subtrochanteric osteotomy with fixation or total hip arthroplasty may be necessary in older patients with severe coxa vara after slipped capital femoral epiphysis (458,483). Medical management of the underlying renal disease and of hyperparathyroidism is mandatory. Pinning of the proximal femur may not be necessary.

Renal Osteodystrophy Complicated by Aluminum Toxicity

Oppenheim et al. (498) noted the contribution of aluminum toxicity to the development of fractures in renal osteodystrophy. Because phosphorus restriction is important in children with renal disease, aluminum hydroxide has been commonly used as a phosphate binder (481). Aluminum intoxication causes defective mineralization. Multiple pathologic fractures may occur with poor healing. Serum aluminum levels are not diagnostic, but the use of deferoxamine, a chelation agent, in an infusion test may provide the diagnosis (495). A bone biopsy often is necessary.

After treatment of the renal disease with correction of the aluminum toxicity by chelation agents, acute fractures will heal. Severe bowing of the long bones due to fractures can be treated with multiple osteotomies with intramedullary Rush rod or plate fixation (498). Recurrence of the syndrome is prevented by use of aluminum-free phosphate-binding agents such as calcium carbonate (500).

AUTHORS' PREFERRED METHOD OF TREATMENT

Recognition of the underlying metabolic abnormalities is the most important aspect in the care of all of these injuries. Slipped capital femoral epiphysis may be the first presenting sign of renal failure (458). A slipped capital femoral epiphysis should be stabilized with *in situ* screw fixation in older children if progression is noted despite medical treatment. Multiple screws should be considered because the underlying metaphyseal bone is quite soft. For treatment of progressive slipped capital femoral epiphysis in very young children, some form of unthreaded fixation seems most logical.

Most fractures of the long bones respond readily to cast or splint immobilization with concurrent aggressive medical treatment of the underlying metabolic disease. Femoral neck fractures are treated with anatomic reduction and internal fixation. The underlying bone disease should be medically treated to ensure success of open procedures. Significant cysts should be treated with curettage and bone grafting. Angular deformities of the long bones should be corrected when the patient is close to maturity.

Idiopathic Osteoporosis

Osteoporosis in a child generally is associated with either congenital disease such as osteogenesis imperfecta or metabolic disorders such as Cushing's syndrome. Rarely, children develop idiopathic osteoporosis with pathologic fractures (Fig. 6-51). Idiopathic osteoporosis is characteristically seen 2 years before puberty, but age at presentation may range from 4 to 16 years (515). Unique metaphyseal impaction fractures are a hallmark of this disorder (509). Biopsy specimens show a quantitative decrease in the amount of bone that has been linked to both increased resorption (510) and primary failure bone formation (515). Osteoblasts in this disorder seem to function normally when stimulated by oral 1,25-hydroxyvitamin D_3 (504). Symptoms can persist for 1 to 4 years after diagnosis, with spontaneous resolution in most patients after the onset of puberty. The only consistent metabolic abnormality is a negative calcium balance with high rates of fecal excretion of calcium (509). This finding supports the hypothesis that idiopathic juvenile osteoporosis results from intestinal malabsorption of calcium (507).

FIGURE 6-51. A: This case demonstrates multiple pathologic fractures in a previously healthy teenage boy who developed idiopathic osteoporosis. This AP radiograph of the right knee and (**B**) this lateral radiograph demonstrates a displaced distal femoral metaphyseal fracture with apex posterior angulation. **C:** This was treated with closed reduction and percutaneous pinning and application of a cast. **D:** This lateral radiograph shows satisfactory alignment with the pins in place. **E:** A few months later, he sustained a left proximal femur fracture, which was treated with a spica cast. **F:** This AP pelvis radiograph taken 3 years later shows healed proximal femoral fractures with varus angulation, and severe osteopenia of the pelvis and femora with profrusio of both acetabuli.

Although many children present with back pain as the only complaint, the most severely affected present with generalized skeletal pain (503,506,507,508,509 and 510,515). Patients have difficulty walking, and their symptoms may be initiated by mild trauma. In a review of 40 patients with idiopathic osteoporosis, Smith (515) observed that 87% had vertebral fractures and 42% had metaphyseal fractures. Symptoms of back or extremity pain can predate fractures by 6 months (503).

Generally, 30% of bone mass must be absent before osteoporosis is detected on radiographs (511). Serum calcium, phosphorus, and alkaline phosphatase levels are usually normal (509). Low plasma calcitriol, a vitamin D metabolite that aids calcium absorption in the gut, has been observed in juvenile osteoporosis (512).

Radiographs of the spine show decreased density in the central areas of the vertebral bodies, and clarity of the dense vertebral end plates is increased. The long bones lose trabecular anatomy and show thinning of the cortex (509,514). Once symptoms begin, a mildly lucent area of newly formed bone, a so-called neo-osseous porosis, is observable in the metaphysis. This is considered weaker than the surrounding bone, which formed before onset of the disease (515).

Treatment

Lower extremity and vertebral fractures (513) are common, although fractures of the proximal humerus, radius, ulna, and ribs are frequent (509). Nonunions of the tibia, radius, and ulna have been reported (507,509). Spinal cord compression has also been reported with vertebral fractures of osteoporosis in a child (505). Metaphyseal fractures can start as hairline cracks that gradually extend across the width of the shaft, and with further collapse in the femoral shaft, the cracks may telescope into the distal femur, with later distortion of the femoral condyles (509). Tibia and femoral shaft fractures may heal with bowing. Long bone shaft fractures are either transverse or oblique (509), and the callus formed seems to be normal (509,512). A technetium bone scan may be useful in showing healing fractures that are not obvious on plain x-ray studies (512). No clear-cut effective medical treatment has been found for idiopathic juvenile osteoporosis (508,509 and 510). Many patients have been treated by both vitamin D and calcium supplements with equivocal benefit, and usually mineralization of the skeleton does not improve until puberty, when the disease spontaneously resolves.

Dent and Friedman (507) summarized the treatment of fractures in juvenile osteoporosis when they stated that these fractures should undergo anatomic reduction with immobilization “as little as practical.” They noted both severe deformity of the long bones and pseudarthrosis when the fractures could not be immobilized. The

bones usually are so soft that they are thought to be unsuitable for the usual forms of fixation, but femoral neck fractures in this disorder have been treated with internal fixation (509).

Iatrogenic Osteoporosis

Osteoporosis of Chemotherapy

Osteoporosis is common in association with chemotherapeutic agents. Methotrexate, for example, is believed to inhibit osteogenesis, causing both delayed union and nonunion of fractures (520). The incidence of pathologic fractures after methotrexate use ranges from 19% to 57% (518,520,522). Generalized demineralization of the skeleton is seen with marked radiolucency of the metaphyseal regions of the long bones. Radiographic changes in the metaphysis and epiphysis resemble those seen in scurvy (520). Minimally displaced transverse fractures occur in the long bones of both the upper and lower extremities, and the small bones of the feet (520,522). Schwartz and Leonidas (521) caution that stress fractures of the long bones that can occur after methotrexate therapy can be mistaken for recurrence of leukemia. If feasible from an oncologic viewpoint, methotrexate should be discontinued to allow these fractures to heal in a cast. The cast immobilization itself may result in additional osteopenia and fractures even though methotrexate is discontinued (521). Persistent nonunions require open reduction and internal fixation with bone graft (522). Patients with severe osteoporosis and bone pain without fracture also respond to a halt in methotrexate therapy (520).

Immobilization Osteoporosis

Immobilization of an extremity for fracture treatment can result in loss of as much as a 44% of mineralization of trabecular bone. In some patients, osteoporosis may persist for 6 months after injury (516). Immobilization leads to bone resorption, especially in unstressed areas (517). In one study (516), bone density of the distal radius returned to normal in all patients at l-year follow-up. Nilsson and Westlin (519) found a residual decrease in bone mineralization of the distal femur of 7% at nearly 11 years of follow-up in a study of 30 patients. It is likely that persistent osteoporosis after cast immobilization for fracture can contribute to refracture.

Hyperparathyroidism

Primary hyperparathyroidism in childhood results from either hyperplasia of the parathyroid gland in very young children or parathyroid adenoma in older children (525). Increased parathyroid hormone increases osteoclastic activity, leading to general demineralization of the skeleton. In severely affected patients, osteitis fibrosa cystica may develop with fibrous tissue replacement of bone and formation of cysts (531). Hypercalcemia is common.

A particularly severe form of primary hyperparathyroidism seen in infants is congenital primary hyperparathyroidism, which results from an autosomal recessive trait (529) and is lethal without parathyroidectomy. These patients present with respiratory difficulty, hypotonia, poor feeding with constipation, and failure to thrive (536). Serum calcium is markedly increased in most patients, but a gradual rise above normal serum levels may occur in some infants with serial measurements (535). Radiographs reveal demineralization of the skeleton. Marked resorption is present in the femoral necks and distal tibiae, with decreased trabeculae and poorly defined cortices (529). Periosteal elevation is common, and when it is severe, the long bones may actually look cloaked with new bone (Fig. 6-52). Periosteal resorption of the bone of the middle phalanges is believed to be characteristic of this disease. Brown tumors are rare in infancy.

FIGURE 6-52. A: Newborn with hyperparathyroidism. There is marked demineralization of bone, and marked resorption is present in the proximal femora (*arrows*). **B:** Periosteal elevation is present along the ulna (*arrows*). (Courtesy of Bruce Mewborne, M.D., San Antonio, Texas.)

In older children and adolescents, the clinical presentation is more subtle. Weakness, anorexia, and irritability are present in 50% of patients, and constipation is present in 28% (525). Renal calculi also are present in 25% of patients, and polyuria, excessive thirst, bone pain, abdominal distention, pancreatitis, and swelling of the knees are occasionally present (524,525,528). Approximately 50% of older patients have osteopenia and other osseous signs of hyperparathyroidism (525). The serum calcium is only moderately elevated in many patients, but 24-hour urine calcium excretion is abnormally high (525,534). If the diagnosis is uncertain, selective venous catheterization for parathyroid hormone can be done, localizing the gland by either ultrasound, CT scan, or MRI (526).

Treatment

Pathologic fractures of the long bones are common in patients with hyperparathyroidism (523,534), especially in infancy. Vertebral fractures, which occur in 4.4% of adult patients (527), are rare in infancy. Increased levels of parathyroid hormone results in decreased function and numbers of osteoblasts, and hence delayed union of pathologic fractures (533), but this problem has only been reported in adults; healing occurred after parathyroidectomy (532).

Most fractures are successfully treated with simple immobilization. Occasionally, a fracture through a cyst requires curettage and bone grafting after a period of initial healing (537). Partial or total parathyroidectomy is the primary treatment for hyperparathyroidism (526,530). Solitary bone cysts often heal after parathyroidectomy.

Cushing's Syndrome

Cushing's syndrome results from excessive production of cortisol and its related compounds. If the hyperactivity of the adrenal cortex is due to pituitary gland stimulation, the syndrome is most precisely known as Cushing's disease (541). In children, hypercortisolism is most often caused by carcinoma, adenoma, hyperplasia of the adrenal cortex (540,543,547), Ewing's sarcoma (549), or exogenous corticosteroid therapy (538,550,551). The elevated adrenal corticosteroids inhibit the formation of osteoblasts (544), resulting in increased resorption of the bone matrix and decreased bone formation (546).

In infancy, carcinoma and adenoma are the primary causes of Cushing's syndrome; the remaining cases are secondary to hyperplasia of the adrenal cortex (543). Presenting symptoms include failure to thrive, short stature with excessive weight gain, moon facies, presence of a buffalo hump, hirsutism, weakness, and hypertension (543,547). Cutaneous striae are rare, and the genitalia are of normal size. Mortality is well over 50% (547). In older children, the clinical picture is somewhat different: truncal obesity, short stature, a lowered hairline, acne, weakness, emotional lability, hirsutism, cutaneous striae, hypertension, and ecchymosis (538). Patients with Cushing's syndrome due to adrenocortical neoplasm may have a palpable abdominal mass at an average age of approximately 5 years (540). Diagnosis usually is made by elevation of plasma 17 hydroxy steroids or increased 24-hour urinary excretion of 17-keto steroids (543). Cushing's syndrome also has been associated with hemihypertrophy (539). Corticosteroid therapy in children, both oral and inhaled (538,550,551), can also cause Cushing's syndrome, as well as the development of cataracts, ulcers, pancreatitis, myopathy, and hepatomegaly (542).

Radiographic findings may include severe osteopenia and a retarded bone age (543). Fractures of the ribs, vertebrae, and long bones have been reported in children with Cushing's syndrome (545,548).

Treatment

The primary treatment of Cushing's syndrome of childhood is total adrenalectomy (548). The associated fractures usually can be treated with standard immobilization techniques, but care should be taken not to increase the extent of osteopenia through excessive immobilization. In patients on corticosteroid therapy, the dose should be reduced, converted to an alternate-day schedule, or discontinued, if possible (538,549,550 and 551).

Scurvy

The rarity of scurvy makes its diagnosis difficult. In children, scurvy may follow 6 to 12 months of a vitamin C–deficient diet (556). Because vitamin C is essential for normal collagen formation, deficiency of the vitamin results in defective osteogenesis, vascular breakdown, delayed healing, and wound dehiscence (553). With abnormal crosslinking, the defective collagen formed inhibits formation of osteoid matrix. Meanwhile, the chondroid tissue continues to be mineralized and can become completely calcified (559). Increased resorption and decreased formation of bone lead to generalized skeletal demineralization. The ends of the long bones resorb, leaving only a cuff of thickened periosteum to stabilize the epiphysis (552). Although scurvy is often due to a dietary deficiency of vitamin C (553,559,560), both aspirin and phenytoin are associated with decreased plasma levels of ascorbic acid. Vitamin C deficiency also is present in patients with myelomeningocele (558), although its contributions to fracture in that population is unclear.

Infants with scurvy present with irritability, tenderness of the lower extremities, weakness, pseudoparalysis, and possibly bleeding gums (if teeth have erupted). Subperiosteal hemorrhages may exist as well as hemorrhage into the subcutaneous tissues, muscles, urinary system, and gastrointestinal tract (555). Anemia also is a common finding. In older children, tenderness and swelling of the extremities are the most common findings. Fever was noted at the time of presentation in 70% of 52 patients in one series (557). Therefore, both osteomyelitis and septic arthritis must be initially considered in the differential diagnosis. In developing countries, older children with scurvy presenting with inability to walk may be misdiagnosed as having poliomyelitis (562).

Radiographs show profound demineralization. In advanced disease, the long bones become almost transparent with a ground-glass appearance and extreme thinning of the cortex. Calcium accumulates in the zone of provisional calcification adjacent to the physis and becomes densely white (Fränkel's line). Fractures generally occur in the scurvy line (Trummerfeld zone)—the radiolucent juxtaepiphyseal area above Frankel's line where the matrix is not converted to bone. Dense lateral spurs, known as Pelken's sign, may be seen (553). A characteristic finding of scurvy is the corner sign, in which a peripheral metaphyseal defect exists where fibrous tissue replaces absorbed cortex and cartilage (552). Cupping of the metaphysis is common in both scurvy and rickets; in rickets, the metaphysis is ragged, whereas in scurvy, the metaphysis is sharply outlined (553). The epiphysis becomes ringed with a thin, dense line (Wimberger's sign). The periosteal elevation caused by hemorrhage calcifies within 10 days of treatment with vitamin C (Fig. 6-53).

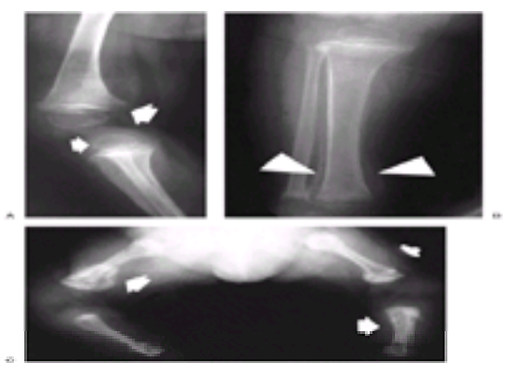

FIGURE 6-53. Scurvy. **A:** A 10-month-old boy presented with a 2-week history of refusal to walk with tenderness of the lower extremities. He had a history of milk and cereal intake only. There are signs of scurvy in the metaphysis (*large arrow*). The dense white line in the zone of the provisional calcification of the distal femur is known as Fränkel's line. The radiolucent juxtaepiphyseal line above the white line is known as the scurvy line. The peripheral metaphyseal defect, where fibrous tissue replaces absorbed cortex in cartilage, is known as the corner sign. Wimberger's sign is a thin, dense line surrounding the epiphysis (*small arrow*). **B:** This is a child with healing scurvy. There is marked periosteal calcification around the distal tibia (*arrows*). **C:** A newborn with scurvy. Periosteal hemorrhage has become calcified in the bones of the lower extremity (*arrows*). Treatment

Fractures and epiphyseal displacement occur in both infants and older children with scurvy (552,556,557,563,564). The most common sites of fracture, in order of frequency, are the distal femur, proximal humerus, costochondral junction of the ribs, and distal tibia (553). Fractures of the long bones generally are nondisplaced metaphyseal buckle fractures with mild angulation. In contrast, marked epiphyseal displacement occurs with a moderate amount of callus present even in untreated patients. Exuberant callus forms once vitamin C is administered. Standard immobilization, with administration of vitamin C, is adequate for most fractures. Remodeling potential is high in these patients (563). Even healed fractures that appear to have undergone growth arrest should just be observed, because the potential for continued growth with medical treatment of the vitamin C deficiency can be nearly normal (565). For infants who are older than 12 months of age and have begun weight bearing, spine films are recommended to rule out vertebral fractures (556).

The literature of fracture treatment in scurvy consists primarily of case reports. Hoeffel et al. (554) reported on a 14-month-old girl with scurvy with bilateral distal femoral epiphysis displacement. This condition resolved after treatment with vitamin C, but limb-length discrepancy developed on one side (561). In two patients with distal femoral fractures, healing went on to cupping of the metaphysis with an appearance similar to that in central growth arrest (557,564).

Copper Deficiency and Scurvy-like Syndrome

Copper is a vital trace element needed in the production of collagen. Copper deficiency results in a decreased number of collagen crosslinks, with adverse effects on both bone and blood vessels (568). Copper deficiency can occur by 3 months in low-birth-weight infants (569) and after prolonged total parenteral nutrition. Copper deficiency can also develop as a result of excessive supplemental zinc ingestion (566).

Infants at risk for this syndrome are those who are primarily milk fed and are on semistarvation diets with concurrent vomiting and diarrhea (567). Both rib and wrist enlargement are frequent, (568) and neutropenia is common (569). The diagnosis is commonly based on clinical presentation and decreased levels of serum copper.

Radiographic findings in copper deficiency syndrome are very similar to those in rickets, including metaphyseal cupping, flaring, demineralization of the skeleton, and subperiosteal elevation with calcification (501). There are some radiographic differences between scurvy and copper deficiency syndrome (568). The corner sign is frequently absent in copper deficiency, the metaphyseal spurs are not strictly lateral but sickle shaped, and radiolucent bands of the metaphysis are absent. Bone age also is frequently retarded.

Pathologic fractures have been reported in copper deficiency syndrome. Cordano et al. (567) noted prompt healing of a distal femoral fracture in an infant, but the fracture recurred before treatment of the copper deficiency. Such injuries could be treated like those in scurvy, with simple immobilization and concurrent correction of the copper deficiency.

FRACTURES IN NEUROMUSCULAR DISEASE

Cerebral Palsy

Fractures of the extremities in patients with severe cerebral palsy are relatively rare, but their treatment can prove challenging. In a review of 1,232 institutionalized patients with cerebral palsy, McIvor and Samilson (575) documented 134 extremity fractures, primarily in quadriplegics. When the mechanism of injury was known, most of these fractures were the consequence of a fall, often associated with seizure activity. Approximately 46% of these fractures involved the femoral shaft, 6% were fractures of the head or neck of the femur, 15% involved the tibia and fibula, and 13% were humeral fractures. These authors believed that contracture or

paralytic dislocation of the hip joint predisposed these patients to femoral fractures (Fig. 6-54).

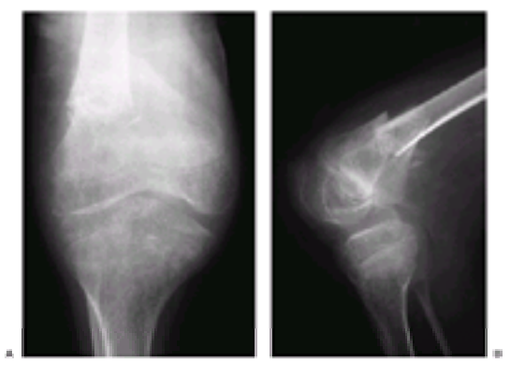

FIGURE 6-54. A: This 11-year-old boy with quadriplegic cerebral palsy had a varus derotatior osteotomy followed by spica casting. Two weeks after cast removal, he sustained this distal femoral fracture during physical therapy. An AP radiograph of the right knee and (**B**) a lateral radiograph of the right knee show a distal femoral metaphyseal fracture in a location typical for insufficiency fractures in children with neuromuscular disease. The fracture was minimally displaced and was treated with closed reduction and a carefully applied, well-padded spica cast. Note the osteopenia and the typical changes around the knee associated with long-standing knee flexion contracture.

Miller and Glazer (578) emphasized that spontaneous fractures can occur in patients with cerebral palsy without episodes of trauma, and factors such as disuse atrophy, nutritional deficiencies, and preexisting joint contractures contributed to these injuries. Nearly 50% of the full-time bedridden patients they studied developed spontaneous fractures. The diagnosis usually was delayed because the patients were noncommunicative. Anticonvulsant therapy may contribute to osteoporosis in patients with multiple fractures—low levels of serum vitamin D were seen in 42% of patients in one series (573). Fractures through osteoporotic bone can occur both above and below fixation devices.

Although long bone fractures in patients with cerebral palsy heal quickly with abundant callus (578), their treatment through either closed or open methods can be quite difficult. In a large series of patients, McIvor and Samilson (575) recommended closed treatment through skeletal traction, hip spica cast, or long-leg cast. Approximately 65% of the femoral shaft fractures and 86% of distal femoral fractures went on to malunion. Despite malunion, most patients regained their prefracture function. Nearly 21% of their patients had refractures, and the authors believed that this was due to disuse osteopenia, inadequate reduction, or joint contractures. Closed treatment of these fractures can be complicated by the development of decubitus ulcers. Closed fractures, especially those of the femur, can become open injuries during treatment owing to spasticity or inadequate immobilization (575,578). Hip spica casts are difficult to use in patients with severe flexion contractures or dislocation of the hip. The healing time of femoral fractures treated through immobilization varies from 1 to 3.5 months (575,578). Fractures of the humerus have been treated with light hanging-arm casts or sling-and-swath bandages (578). Hip nails with side plates, compression plates, and intramedullary fixation also have been used for femoral shaft fractures in patients with cerebral palsy. The mean healing time has been 5.3 months (575).

Numerous reports note success in treating fractures of neurologically impaired children with internal or external fixation (570,571). Heinrich et al. (571) treated four femoral fractures in young patients with cerebral palsy with flexible intramedullary nails with good outcomes. Femoral neck fractures may require *in situ* pinning, but observation may be adequate in asymptomatic bedridden patients. Although he advocated open fixation of some lower extremity fractures in patients with mental retardation, Sherk (580) cautioned that some patients may have inadequate motivation to resume ambulation even with successful healing of their injuries. Medical management of these patients must also be emphasized. In patients with cerebral palsy and multiple fractures, Lee and Lyne (573) recommended metabolic supplementation, along with traditional fracture care.

Fractures of the distal pole of the patella have been reported in children with cerebral palsy due to spasticity of the extensor mechanism of the knee in the presence of established knee flexion contracture (572,574,579). Lloyd-Roberts et al. (574) reported on eight patients with this injury who presented with deterioration in walking and decreased endurance. All had knee flexion contractures. Seven of the eight patients complained of pain and local tenderness at the distal pole of the patella. In a series of 88 patients, fragmentation was seen in only 8% (579). Patella alta and elongation of the patella are frequent in affected patients (Fig. 6-55) (572,579). Children predisposed to distal pole patellar fractures are spastic ambulators with flexion contractures of the knees, patella alta, and a history of falls (572). Extension casting may be helpful in symptomatic patients (579). If conservative treatment is unsatisfactory, then hamstring lengthening with correction of the knee flexion contracture can result in both healing of the fracture and relief of symptoms (574,579). Some authors (572,574) also have excised the avulsed distal pole of the patella to relieve chronic symptoms.

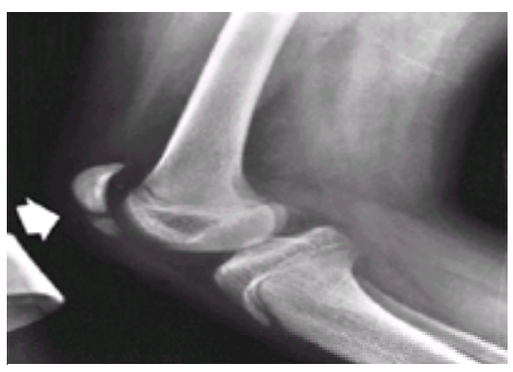

FIGURE 6-55. A 10-year-old girl with cerebral palsy had a healing stress fracture of an elongated patella (*arrow*). Patella alta is also present. The injury responded to conservative treatment.

AUTHORS' PREFERRED METHOD OF TREATMENT

The goal of fracture treatment in cerebral palsy is to restore the child to his or her prefracture level of function. If the patient is ambulatory, conventional forms of fracture treatment should be used. In nonambulatory children with cerebral palsy, a goal of fracture care should be to preserve the ability to transfer. Special precautions should be used in closed treatment of fractures in these patients. The patients' spasticity and inability to communicate make them prone to skin problems, so casts should be properly applied and well padded, usually with felt and polyurethane foam. Extra padding should be placed over the patella, anterior ankle, and heel, and a snug cast mold should be placed above the calcaneus to prevent proximal migration of the heel (Fig. 6-56). When indicated, operative fracture fixation should be used in ambulatory patients. Elastic intramedullary nails can be a very effective way to treat femoral fractures in children with spasticity (Fig. 6-57).

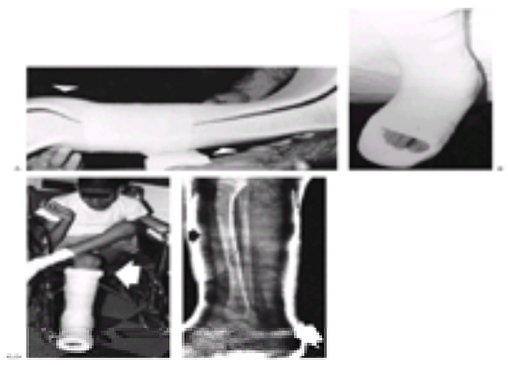

FIGURE 6-56. Casting in neuromuscular fractures. **A:** A polyurethane foam short-leg cast is being placed on a patient. Two long rectangular sheets of foam (*arrows*) are placed anteriorly and posteriorly over the stockinette, and Webril padding is wrapped around the foam. **B:** A long toe plate is needed to prevent injury to the foot of the patient. **C:** A thick, protective cuff of foam is formed by folding the polyurethane toward the center of the cast with the stockinette (*arrow*). **D:** The Webril must be wrapped quite snugly to compress the foam against the underlying extremity evenly (*black arrow*). Extra foam is placed over the anterior ankle and over the Achilles tendon to prevent proximal migration of the foot in the cast. A plaster cast is usually applied and covered with a layer of fiberglass for strength. A lateral x-ray verifies the position of the heel in the cast (*white arrow*).

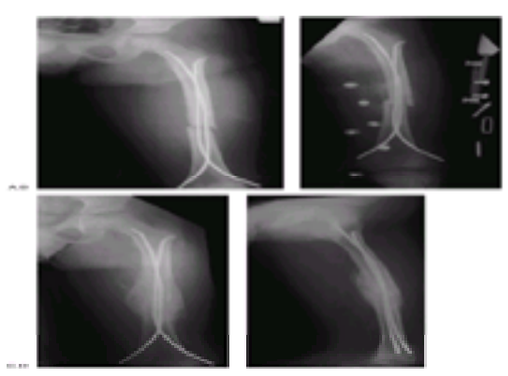

FIGURE 6-57. A: This 6-year-old boy sustained a severe closed head injury and left femur fracture when he was struck by a car. His femur was shortened 4 cm. His involuntary movements made management in traction very difficult. He was treated with retrograde titanium elastic nailing. **B:** At 13 days, early callus is seen. He was standing with a brace. **C:** At 3 months, AP and (**D**) lateral radiographs show a healed femur fracture in anatomic alignment. Nails were removed 6 months later. (From Flynn JM: Current treatment options for pediatric femur fractures. *U Penn Orthop J* 1998;11:27–35; with permission.)

Prevention should be an important part of managing fractures in children with cerebral palsy. Traditionally, long-leg casts or spica casts were used after multiple muscle lengthenings or hip osteotomies, then after several weeks, the cast was removed and therapy begun. After cast treatment, however, the osteopenia was worse, the joints were stiff, and fractures—especially in the distal femoral metaphysis—occurred during therapy or transfers. We and others (576,577) use foam abduction pillows and knee immobilizers and an intensive therapy program in the immediate postoperative period to avoid the deconditioning, osteopenia, and joint stiffness that develop after prolonged cast immobilization. In ambulatory children who need hip osteotomies, use of rigid internal fixation allows standing and gait training within 2 weeks, preventing not only osteopenia but also the risk that the child may never regain the full level of preoperative function after a prolonged period of cast immobilization.

In nonambulatory children with severe cerebral palsy, some degree of both malunion and shortening may be accepted. Well-padded splints or casts are adequate treatment for many displaced fractures. Acute femoral shaft fractures can be treated with a heavily padded hip spica cast and distal fractures of the femur by a long-leg cast. Distal femoral buckle fractures in non-ambulatory children are safely treated with a knee immobilizer. If a long-leg cast is used for a fracture of the lower extremity and the joint of the involved side is dislocated, the rigid cast may function as a lever arm, with the posterior fracture of the proximal femur beyond the cast.

Myelomeningocele

Insufficiency Fractures

Children with myelomeningocele sustain fractures of the lower extremities through bone weakened by either disuse or immobilization after reconstructive surgical procedures. The incidence of fractures in several series of patients with myelomeningocele ranges from 12% to 31% (586,588,592,594,592,603). The locations of these fractures, in order of decreasing frequency, are mid-shaft of the femur, distal femur, mid-shaft of the tibia, proximal femur, femoral neck, distal femoral physis, and proximal tibia (586). Fractures of the distal tibia also have been reported in numerous series (590,594,595,602,603). Both metaphyseal and diaphyseal fractures, usually resulting from minor trauma, are often either incomplete or impacted with intact periosteum (597). They tend to heal rapidly—nonunion is rare (586). Physeal fractures, however, may take 3 to 33 months to heal (603).

Numerous factors predispose these patients to fracture. Children with flail limbs tend to pick up one leg and drop it out of the way when they roll over in bed or twist around while in a sitting position, and this may be enough force to cause a fracture (594). Because protective sensation is absent, the child can neither anticipate impending injury nor be aware of injury once it has occurred. The level of neurologic involvement also affects the incidence of fractures. In a series of 76 fractures, Lock and Aronson (597) found that 41% occurred with neurologic deficit at the thoracic level, 36% occurred with deficit at the upper lumbar level, and only 13% occurred in patients with lower lumbar or sacral deficits. Nearly 86% of these fractures occurred before 9 years of age, and 76% were associated with cast immobilization. Most fractures after immobilization occur within 4 weeks of cast removal (588), and in one series (597), 30% of patients with casts had multiple cluster fractures of either the casted extremity or the partially casted contralateral extremity. In addition to the inherent disuse osteoporosis from immobilization, casting causes stiffness of joints, with concentration of force on the osteoporotic bone adjacent to the joints (597). Boytim et al. (583) reported neonatal fractures in 6 infants with myelomeningocele and concluded that the risk of fracture was 17% for patients with thoracic or high lumbar level deficits with significant contracture of the lower extremities. The authors cautioned that particular care must be used to avoid fractures in these patients during physical therapy, x-ray positioning, or surgical procedures.

Stable fractures of the long bones may not require complete immobilization (588). Femoral shaft fractures have been treated with padding and sandbags (591). Skin traction of anesthetic limbs may cause massive skin necrosis (586,591). Skeletal traction usually is inadvisable because of problems with decubitus ulcers and poor fixation in atrophic bone (586,591). However, Drummond et al. (588) treated 9 of 18 patients with skeletal traction without mention of failure or fixation.

Preventive measures include limiting cast immobilization after reconstructive surgery (587,588). Solid side cushions may prevent fractures that occur when patients catch their lower extremities in bed rails (600). The most important consideration was noted by Norton and Foley (599) in 1959, when they stated “the quality of bone developed by activity appears to be the best protection against pathologic fractures,” and the orthopaedist should assist these patients in maintaining the highest activity level possible.

Physeal Fractures

Fractures of the physes in patients with myelomeningocele are relatively uncommon, but for the unwary, the diagnosis can be difficult. The clinical presentation may mimic infection, with elevated temperature and swelling, redness, and local warmth at the fracture site (601,602). Fractures of the proximal tibia may be confused with septic arthritis of the knee, with swelling up to the mid-thigh and limited knee flexion. Both the white blood cell count and erythrocyte sedimentation rate are often elevated. Immobilization of these injuries usually results in a dramatic decrease in swelling and redness of the extremity within 2 to 3 days of casting. With healing, the

x-ray picture can be alarming, with epiphyseal plate widening, metaphyseal fracture, and periosteal elevation (593). The radiographic differential diagnosis should include osteomyelitis, sarcoma, leukemia, and Charcot's joint (601,602 and 603).

Recurrent trauma to the physis, from either continued walking or passive joint motion after injury, results in an exuberant healing reaction (Fig. 6-58) (590). Repetitive trauma delays resumption of normal endochondral ossification, resulting in abnormal thickening of the cartilage in the zone of hypertrophy and the physeal widening seen on radiographs (Fig. 6-59) (603). In a study of 19 chronic physeal fractures, Rodgers et al. (601) compared MRI with histology and found that adjacent to this thickened, disorganized zone of hypertrophy is juxtametaphyseal fibrovascular tissue that enhances gadolinium on MRI. Delayed union is common, and premature growth arrest occurs in 29% to 55% of patients (597,603). Anschuetz et al. (582) reported a unique syndrome in three patients with myelomeningocele and fracture. These children sustained fractures of the lower extremities during long-term immobilization and with cast removal went on to dramatic cardiopulmonary distress with increased pulse rate, hypotension, and increased respiratory rate. Fever also developed with decreased hematocrit levels. They suggested that the etiology of this problem was loss of intravascular volume into the fracture sites and recommended intravenous replacement of fluid losses, along with careful splinting of associated fractures.

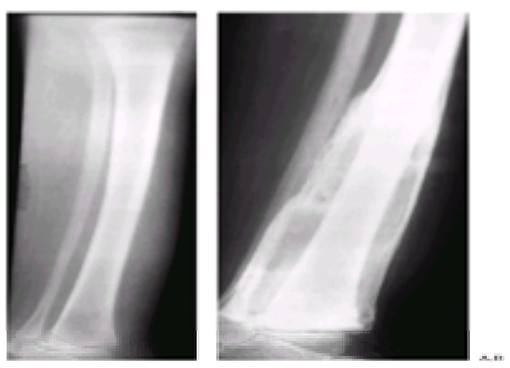

FIGURE 6-58. A: This 7-year-old boy with spina bifida presented with a increasing swelling of the distal tibia. This lateral radiograph of the entire tibia shows slight widening of the distal tibial physis with subtle signs of posterior displacement of the distal tibial physis. There was a high suspicion of a fracture, so the leg was treated with a well-padded cast. **B:** This lateral radiograph, taken 2 months later, shows slight physeal widening with extraordinary periosteal new bone formation.

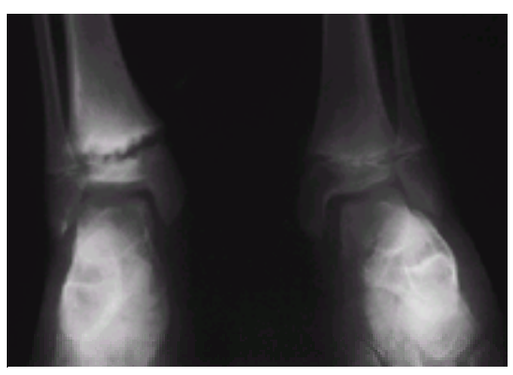

FIGURE 6-59. This 11-year-old boy with L4 myelomeningocele presented with a warm, swollen right ankle and no clear history of trauma. This AP radiograph of both ankles shows right distal tibial physeal widening with adjacent sclerosis, consistent with a chronic physeal injury. The child was treated in a well-padded, non–weight-bearing short-leg cast. He had complete resolution of symptoms when the cast was removed 6 weeks later.

Physeal injuries in patients with myelomeningocele are more difficult to treat than metaphyseal or diaphyseal long bone fractures and require lengthy immobilization with strict avoidance of weight bearing to avoid destructive repetitive trauma to the physis (590). Either a plaster cast or a snug-fitting total-contact orthosis is suggested for immobilization, and union can be determined by return of the physis to normal width on x-ray study (603). Kumar et al. (595) emphasized that application of a long-leg cast for 8 to 12 weeks is necessary to obtain satisfactory healing of physeal fractures of the tibia, and weight bearing is to be avoided until union occurs.

Cast Technique

Immediate casting (588) and bivalved casting (591) have been used for long-bone fractures in children with myelomeningocele. A bilateral hip spica cast is suggested for supracondylar fractures of the femur, because use of a one-and-a-half hip spica cast may predispose the uninjured side to fracture (586). A bulky Webril dressing approximately 1.5 cm thick wrapped with an elastic bandage can be used instead of a plaster or fiberglass cast. Lock and Aronson (597) used Webril immobilization for an average of 1 to 3 weeks in their patients with fractures and discontinued immobilization when callus was visible. They found similar outcomes in patients treated with Webril dressings and those treated with casts; however, there was much less difficulty with pressure sores in the group treated with Webril dressings. Kumar et al. (595) used a polyurethane padded long-leg posterior plaster splint for metaphyseal and diaphyseal fractures for 3 weeks, followed by bracing.

Drennan and Freehafer (586) recommend a well-padded cast for 2 to 3 weeks for infants with fracture and braces or Webril immobilization for incomplete fractures that followed surgery. Injuries with deformity were placed in a cast. Mobilization was begun as soon as practical to prevent further osteopenia—patients with shaft fractures began ambulation 2 weeks after injury. Shortening was not a problem in their series. Lock and Aronson (597) cautioned that brace treatment of acute fractures may cause pressure sores. Drummond et al. (588) reported on 18 fractures treated by closed techniques that resulted in three malunions, two shortenings, and two episodes of pressure sores; one patient had four refractures. Drabu and Walker (585) noted a mean loss of knee movement of 58 degrees in 67% of fractures about the knee. The stiffness began 2 months after fracture and was well established by 6 months but resolved almost completely in all patients 3 years after injury. They suggested that aggressive physical therapy to restore knee motion is probably not necessary in these injuries.

OPERATIVE TREATMENT

Operative fixation of fractures in children with myelomeningocele is associated with a high rate of infection (591). Wenger et al. (603) reported that most patients with proximal femoral epiphyseal displacement can be treated with hip spica casts. Reduction and pinning with subtrochanteric osteotomy may be necessary in certain patients. Bailey-Dubow rods may be valuable in multiple recurrent pathologic fractures of the femoral or tibial shaft (596). If operative treatment is necessary, it should be noted that the incidence of malignant hyperthermia seems to be higher in patients with myelomeningocele than in other children (581).

Latex Allergy

Life-threatening anaphylactic reactions due to latex allergy in children with myelomeningocele have been reported with increasing frequency (584,597). Minor allergic reactions, such as rash, edema, hives, and respiratory symptoms are common when children with myelodysplasia are exposed to latex products such as gloves, catheters, and balloons. Between 18% and 40% of children with myelodysplasia are allergic to latex (589). Meeropol et al. (598) emphasized that every child with myelomeningocele should be screened for latex allergy, and those with a positive history should be evaluated individually by the anesthesiologist for preoperative prophylaxis. Current preoperative prophylaxis begins 24 hours before surgery and is continued for 24 hours after surgery. Medications used include diphenhydramine, 1 mg/kg every 6 hours (maximum 50 mg); methylprednisolone, l mg/kg every 6 hours (maximum 125 mg); and cimetidine, 5 mg/kg every 6 hours (maximum 300 mg). A latex-free environment must also be provided throughout the hospitalization.

AUTHORS' PREFERRED METHOD OF TREATMENT

In nonambulatory patients, mild malunion and shortening can be tolerated, and stable or minimally angulated fractures can be treated with either polyurethane splints or Webril dressings. Fractures with significant deformity may require reduction and immobilization in a cast heavily padded with polyurethane foam. In children who walk, fractures should be carefully aligned with heavily padded casts that allow continued protective weight bearing, if possible. Hip spica casts may be necessary for femoral shaft fractures. Fractures of the proximal femur should be treated by immobilization and any later deformity corrected by osteotomy. Any patient considered for operative intervention should be screened for latex allergy, and if needed, given appropriate prophylaxis. Physeal fractures are treated with padded long-leg casts and non–weight bearing. Long-term follow-up is encouraged for physeal injuries because of the risk of growth arrest. Significant discrepancies can be addressed through contralateral epiphysiodesis or bridge resection.

Muscular Dystrophy

Fractures of the lower extremity in children with Duchenne muscular dystrophy must be managed so as not to cause premature loss of the ability to walk (609) or transfer (606). In patients 9 to 10 years old, increasing muscle weakness and joint contractures contribute to falls, and a loss of normal muscle bulk and fat limit the cushioning on impact (608). Patients in lower extremity braces seem to sustain few fractures in falls (609), probably because the overlying orthoses provide some protection (608). Patients confined to a wheelchair can fall because they have poor sitting balance, and fractures are frequent because these patients are more osteoporotic than ambulatory individuals (608).

Concentric “osseous atrophy” occurs in the long bones of patients with Duchenne muscular dystrophy; osteoporosis is also common (604,607). Fractures are seldom displaced and are frequently minimally painful because there is minimal muscle spasm (608). Fractures tend to heal rapidly. The most commonly fractured bone is the femur (Fig. 6-60) (605,606,608), followed by the proximal humerus (608).

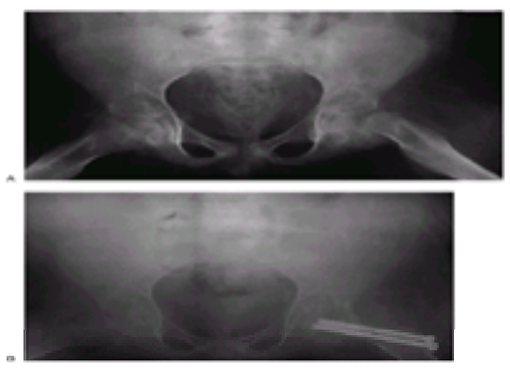

FIGURE 6-60. A: This 14-year-old nonambulatory boy with Duchenne muscular dystrophy crashed his wheelchair into the bumper of a stationary car, sustaining a displaced subcapital femoral fracture. This AP pelvis radiograph at the time of injury shows a displaced fracture and marked osteopenia of the pelvis and proximal femur. **B:** The fracture was treated by reduction and internal fixation with two cannulated screws.

There are two goals of fracture care in children with muscular dystrophy: limb stability and maintenance of maximal function during fracture healing. In ambulatory patients, treatment methods should allow children to maintain the ability to walk as the fracture heals. When ambulatory ability is tenuous, even minor bruises or ankle sprains (609) may end walking ability. As little as 1 week in a wheelchair can prematurely end ambulation (609); patients at bed rest for more than 2 weeks will likely lose the ability to ambulate (606). Hsu (605) reported that 25% of ambulatory patients with muscular dystrophy lost the ability to walk after sustaining fractures. In one of these patients, the ankle was casted in 20 degrees of plantar flexion, and the resulting contracture prevented ambulation at the end of treatment.

Treatment of specific fractures should be individualized. Upper extremity fractures can be treated with lightweight slings (608). Lower extremity fractures can be treated with either light walking casts or long-leg double upright braces (608,609). Splints also can be used until the patients are pain free. Routine activities are begun as soon as possible (605). Protected standing and ambulation with physical therapy are crucial in maintaining independent ambulation (609).

Hsu and Garcia-Ariz (606) reported on 20 femoral fractures in 16 patients with muscular dystrophy. Six of the seven ambulatory patients were able to walk after treatment. In the nonambulatory patients in this series, most had supracondylar femoral fractures (Fig. 6-61), which were splinted for 2 to 3 weeks, with emphasis on physical therapy to maintain functional abilities. Although union was achieved rapidly, hip and knee flexion contractures often increased in these patients, and up to 20 degrees of angulation of the fracture was routinely accepted. One patient with slipped capital femoral epiphysis was treated successfully with pinning *in situ*.

FIGURE 6-61. This 13-year-old nonambulatory boy with Duchenne muscular dystrophy sustained this typical impacted, minimally displaced distal femoral metaphyseal fracture when he fell from his wheelchair. Note the marked periarticular osteopenia.

AUTHORS' PREFERRED METHOD OF TREATMENT

The first goal of fracture treatment in children with muscular dystrophy is to avoid making matters worse. The patient should be mobilized as soon as possible in a lightweight cast or orthosis. Aggressive physical therapy should be used to maintain functional status. In a very young child, mid-shaft femoral fractures can be treated by traction and hip spica techniques, but in an older patient, ambulatory cast bracing might be a better choice.

Arthrogryposis and Poliomyelitis

Arthrogryposis is a rare disorder with an incidence of 3 in 10,000 live births (614). In this disease, muscle fiber is lost in utero, joint motion is limited during development, and taut ligaments and capsular tightness result in joint stiffness. Dislocations can occur with severe shortening of the involved muscles. Fractures may occur in 25% of infants with arthrogryposis multiplex congenita (610). Both difficult delivery and forceful manipulation of the extremities in these children can lead to fracture (610). Diamond and Alegado (610) reported on 16 fractures in 9 infants with arthrogryposis; an ipsilateral dislocated hip was present in 35% of patients. Most fractures involved the femur, with the remainder mostly tibial fractures, one humeral fracture, and one clavicular fracture. Epiphyseal separations occurred in the proximal tibia, distal femur, and proximal humerus. Clinical symptoms included poor feeding, irritability, and fussiness when handled. The involved extremity was

thickened, and there was often an increased white blood cell count. Plain radiographs after acute injury, especially with epiphyseal separations, were not helpful, and arthrography was used in one patient to evaluate a distal femoral epiphyseal separation. With healing, these fractures develop exuberant callus with rapid union, and ready remodeling of angulated mid-shaft fractures.

Short-term immobilization is adequate to treat undisplaced fractures in these patients. Heavy plaster splints are not necessary (612). Some authors (611) recommend closed reduction of acutely displaced epiphyseal fractures and fractures with rotatory malalignment. Postnatal fractures are most common in patients with either knee contracture or dislocation of the hip, and postnatal injury could possibly be reduced by avoidance of forceful manipulation of these extremities. Older patients with lower extremity contractures do not seem to have difficulty with pathologic fractures (613).

Acute poliomyelitis has become a relatively rare disease in most Western countries but occasionally occurs in children who live in less developed countries. There are few reports in the literature concerning fractures in patients with poliomyelitis. Robin (612) reported 62 fractures in patients with poliomyelitis. More than half were fractures of the femur, and 90% of those injuries were supracondylar fractures. More than half of the fractures occurred after cast immobilization, and joint stiffness also was associated with a significant number of fractures. There were no epiphyseal injuries in this series.

Treatment of these fractures is simple immobilization. Because most fractures have very little displacement, reduction is seldom necessary; if there is preexisting deformity, manual osteoclasis through the fracture site can be used to correct deformities. Robin (612) stressed that joint mobility must be obtained before general mobilization of the patient to reduce the incidence of fracture after plaster immobilization. He also emphasized that fractures in these patients heal rapidly, and immobilization times should be reduced accordingly, with walking or standing in casts to decrease osteoporosis.

Spinal Cord Injury

Fortunately, childhood spinal cord injury is rare, and reports of pathologic fractures usually are included in larger series of patients with fractures and myelomeningocele because of the clinical similarities in presentation (621,622). Fractures of the femur, especially supracondylar fractures, are most common (619), but tibial fractures also are common (619). In most patients, these are pathologic fractures through osteoporotic bone. Children may be much more susceptible to these fractures than adults. Although fractures in paraplegics appear to heal rapidly with abundant callus (619), animal experiments suggest that in denervated limbs, the quality of the callus in fractures is compromised (620). Children with traumatic peripheral nerve lesions may have distal tibial physeal lesions similar to those in patients with myelomeningocele, neuropathic arthropathy of the small joints of the foot, and soft tissue ulcers (623).

Conservative treatment of fractures in patients with spinal cord injury is most commonly recommended. Skin traction is contraindicated because of the possibility of skin necrosis (618). Comarr et al. (616) also use pillow sandbag splints and, for certain fractures, treat patients with a turning frame. Open reduction and internal fixation of these fractures is controversial. The conservative techniques used for the treatment of similar fractures in children with myelomeningocele might best be applied to fractures in children with traumatic paraplegia (617,621,622).

Although crutch and brace ambulation in paraplegics reportedly restores bone integrity (615), fractures continue to occur through osteoporotic bone in children actively ambulating with brace support (621). Some authors advocate light protective braces (616), but Katz (621) suggested that continuous splinting will worsen the disuse osteoporosis. He recommended careful manipulation of the lower extremities when they are out of ambulatory braces to reduce the incidence of fracture. Robin (622) emphasized that immobilization should be discontinued as soon as possible after fracture healing. Patient activity should be limited until knee motion is restored.

AUTHORS' PREFERRED METHOD OF TREATMENT

Heavily padded casts or splints are recommended for most lower extremity fractures in children with traumatic paraplegia. Returning to ambulation with protection by walking braces is permitted once callus and joint motion are adequate. Every effort should be made to restore the child's prefracture function. Moderate malunion and shortening are acceptable in patients who are nonambulatory. Operative treatment of such fractures should be reserved for selected patients whose function would be significantly compromised by less than anatomic reduction.

7
CHILD ABUSE

ROBERT M. CAMPBELL, JR.

EPIDEMIOLOGY

Child abuse is maltreatment of the child by either parents or caretakers, and includes physical, sexual, and emotional abuse, as well as emotional and physical neglect. The epidemic of child abuse continues to worsen in the United States, with approximately 2.9 million reports now filed annually compared with 1.2 million in 1982 (151). The incidence of physical abuse nationally is estimated to be 4.9 children per thousand, and one of every 1,000 abused children die (76). In Texas alone, 50,746 children were confirmed victims of child abuse or neglect in fiscal year 1995, with 101 deaths recorded (152). The types of abuse these children were subjected to included physical abuse in 31.5%, sexual abuse in 15.6%, emotional abuse in 6.8%, abandonment in 2%, medical neglect in 4.7%, physical neglect in 15.4%, and neglectful supervision in 40.3%. The minimal annual cost of child abuse in the United States is estimated to be 9 billion dollars (151). The long-term social costs of child abuse are impossible to estimate: one third of the victims of child abuse grow up to be seriously inept, neglectful, or abusive parents; one third are at high risk for eventually becoming abusive parents; and only one third do not repeat the destructive patterns they were exposed to as children (120). The orthopaedist becomes involved in the care of 30% to 50% of abused children (2). Early recognition of these abused patients by the orthopaedist is critical, because the children who are returned to their homes after an unrecognized episode of child abuse have a 25% risk of serious reinjury and a 5% risk of death (132).

HISTORICAL OVERVIEW

In 1946, Caffey (28) described six infants with long bone fractures, chronic subdural hematomas, and intraocular bleeding without a history of trauma to explain the injuries. Although his work is often cited as the first report in the English literature of child abuse, Caffey did not speculate about the etiology of the children's injuries. In 1953, Silverman (139) characterized the unique metaphyseal fractures found in abused children in the pediatric literature and clearly emphasized that these were due to nonaccidental trauma. Altman and Smith (8) in 1960 published the first series in the orthopaedic literature of injuries caused by child abuse. General public awareness of child abuse increased with the 1962 publication of a report by Kempe et al. (79) characterizing the problem as *the battered child syndrome.* In 1974, Caffey introduced the term *whiplash-shaken infant syndrome* to the literature to emphasize the etiology of subdural hematomas in infants caused by shaking episodes (29). In 1974, Congress acknowledged the national importance of the prevention of child abuse by the passage of the Child Abuse Prevention and Treatment Act.

THE HOMES AT RISK

In assessing where abuse of children may occur, households in turmoil from marital separation, job loss, divorce, family death, housing difficulties, or money problems are more likely to have abusive episodes (49). Families with two unplanned births are 2.8 times more likely to have an episode of child abuse than families with no unplanned births (164). In these homes at risk, stepparents, babysitters, boyfriends, relatives, and even larger siblings frequently are abusers (1,69,121). The parents of battered children may themselves have been abused when they were children (63). Parental substance abuse, whether alcohol or other drugs, makes child abuse more likely (67). The risk of physical child abuse is fivefold more likely with maternal cocaine use (158). Young, unmarried mothers are more likely to have their infants die from intentional injury, with a peak incidence of 10.5 intentional deaths per 10,000 live births in one study (136). Violence in the home is not directed solely toward the child; in one study (30) of families with substantiated child abuse, 30% of the mothers had been battered. Although the youngest, poorest, most socially isolated and economically frustrated caretakers are the most likely to act violently toward their children (161), any adult from any social or economic level may be guilty of abusing a child (1).

THE CHILDREN AT RISK

Certain children of all ages are more likely to experience abuse, and younger children are particularly at risk. Most reported cases of child abuse involve children younger than age 3 years (61). In one report (18) of child abuse 78% of all fractures reported were in children less than 3 years of age and 50% of all fractures occurred in children younger than 1 year of age. Infants younger than 1 year are especially at risk for the most severe form of child abuse: infant homicide (44,86). With severe shaking injuries by caretakers, 30% of infants are disabled and another 30% die (25). The problem probably is more widespread than suspected. There is evidence to suggest that in the United Kingdom, 10% to 20% of children diagnosed as having sudden infant death syndrome may be intentional infant homicides (56). In one report (131), covert video recordings of adults attending their children who were hospitalized for suspicious illness documented 14 separate instances of caretaker attempts at upper airway obstruction. First-born children (18), premature infants, stepchildren, and handicapped children are at a greater risk for child abuse (2). Benedict et al. (19), in a longitudinal study of 500 handicapped children followed from birth to age 10 years, documented a 4.6% incidence of physical abuse. Surprisingly, they found that the most severely involved children were less likely to be abused, whereas the marginally functioning children were at greater risk, with parental frustration possibly being a factor.

Children who are persistently presented by parents for medical assessment of vague illness and have a history of multiple diagnostic or therapeutic procedures with unclear outcome are at risk for having a form of child abuse known as Munchausen's syndrome by proxy (14,111). Munchausen's syndrome is named for Baron von Munchausen, an 18th century mercenary whose exaggerated tales of adventure were viewed with great suspicion. Asher, in 1951, described Munchausen's syndrome in adults who presented with apparent acute illness accompanied by dramatic, untruthful medical histories to gain attention (14). In Munchausen's syndrome by proxy, children become the victims of this adult behavior when parents with a misguided sense of purpose fabricate a wide range of childhood illnesses for their children, often subjecting them to needless diagnostic work-ups and treatment (111). Symptoms of the child's “illness” are based on an imaginary medical history given by the

parent, with signs of the illness either simulated or induced by the parent. For example, a child may be brought into the emergency room by a parent with a complaint of vomiting. In Munchausen's syndrome by proxy, this complaint may either be a total fabrication by the parent or the parent may simulate the complaint by producing “vomitus” from some source as proof of the illness. In the most abusive of situations, the parent induces vomiting in the child by the administration of salt (110) or ipecac. Over half of reported cases of Munchausen's syndrome by proxy involve induced symptoms, whereas another 25% involve a combination of both simulation and induction of symptoms (21).The biologic mother is almost always the perpetrator of this pattern of abuse and often has a medical background: 35% to 45% are nurses, 5% are medical office workers, 3% are social workers, and 1% are orderlies (129). Extreme examples of this syndrome include a rodenticide-induced coagulopathy in a two-year-old child (16), a deliberate self-induced preterm delivery (62), and chronic illicit insulin administration to a 1-year-old child by the caretaker (111). The perpetrator of the child's illness denies knowledge of its etiology, but the acute signs and symptoms of the child's illness in Munchausen's syndrome by proxy will resolve if the syndrome is recognized and the child is separated from the parent (129). Failure to diagnose this condition places a child at risk for either serious long-term sequelae or death in approximately 9% of cases.

Bizarre forms of child abuse may cause a confusing illness or injury. There are reports of young children forced to aspirate pepper, of intentional burns of infants by placing them in microwave ovens (7), of children denied water who developed hypernatremic dehydration, and of infants poisoned with cocaine given to them by caretakers (126). A high index of suspicion is needed to avoid missing the diagnosis of nonaccidental trauma in these situations.

SEXUAL ABUSE

Although the orthopaedist usually considers child abuse in the context of fractures and other obvious injuries, an increasingly important aspect of child abuse to recognize is sexual abuse. It is estimated that 25% of abused or neglected children have been sexually abused (96). Physically abused children have a 1:6 chance of being sexually abused, whereas sexually abused children have a 1:7 risk of being physically abuse (70). Children living with nonbiologic parents or with caretakers who are substance abusers are most at risk. The child usually discloses sexual abuse under three types of circumstances: The child may have just experienced an argument with the abuser and may “accidentally” reveal the existence of the abusive relationship, the child is permanently separated from the abuser, or the abusive adult is shifting attention to a younger sibling (160). The incidence of sexual abuse of handicapped patients has been estimated as ranging from 25% to 83%, with handicapped males being more likely to be sexually abused than nonhandicapped males in the general population (148). Both sexual and physical abuse may be associated with cults, which may be identified by their symbols. Satanic cults may use a pentagram (an encircled five-pointed star with an inverted apex), the eye of Horus (an eye within a triangle), or various symbols that modify a cross, and the middle or little finger of the left hand may be painted black (76). Sadistic ritual abuse has been reported in preschool and elementary school children (162).

OBTAINING THE HISTORY

The history is critical in the diagnosis of child abuse. It usually is taken in the chaotic environment of a busy emergency room, so it is important to find a quiet area for the interview where tempers can cool and distractions can be minimized. In addition to taking a thorough history with regard to the mechanism of injury, the orthopaedist must question the patient and the family in an investigative fashion to establish accurately the circumstances of the injury and the environment in which the child lives. These skills are seldom taught in residency training. In a survey of pediatric residents (48), 42% of them had 1 hour or less in training for detection of child abuse and most orthopaedic residents likely have even less training in this area. The extensive history needed to detect child abuse is termed the investigative interview. It begins with documenting the history (or the lack of history) of the injury and, more importantly, goes on to uncover enough details about the child's life so that plausible scenarios can be created to explain the injury. A full physical examination and skeletal survey should precede this interview to search for any possible evidence of additional undocumented child abuse. The orthopaedist must become both social worker and detective, calmly and methodically establishing how the injured child lives; finding out which family members, friends, or other caretakers have access to the child; and how likely it is that they might have contributed to the child's injuries. A detailed history of injury is obtained individually from each adult family member in a private setting. If the patient and siblings can communicate, they should be interviewed separately from the parents and other members of the family.

The Investigative Interview

Once a full injury physical and radiographic assessment of the child is complete, the investigative interview is begun by asking the primary caregiver in a nonjudgmental way how the child was acutely injured. To avoid provoking emotions, any additional soft tissue or skeletal trauma discovered should be brought up at the end of the interview for explanation once the presentation injury has been thoroughly discussed. Each investigative interview should follow a systematic review of symptoms: what happened, who was there, when was the injury recognized, and how long before medical treatment was sought. Inconsistencies are not challenged. Leading questions are avoided in favor of open-end questions. Medical terms should be explained in plain English, with care taken to avoid medical jargon. More plausible explanations for the injury are not volunteered. The place where the injury occurred and which individuals who were actually present is determined. Leading questions should be avoided: Never ask who caused the injury, but rather ask what they saw or what they think happened. Exactly who discovered the injury and how soon the child received medical care after onset of symptoms are established. Delays in seeking medical care for an injured child are very suggestive of child abuse (49). The crucial questions to be answered are not only whether the given history of trauma is sufficient to explain the severity of injury but what other possible scenarios could explain the injury if the volunteered explanation is not plausible. This requires acquiring a working knowledge of the child's environment, which can be obtained by asking specific, detailed questions (Table 7-1).

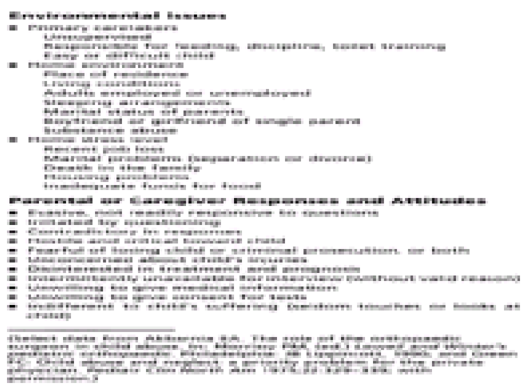

TABLE 7-1. CHILD ABUSE: INVESTIGATIVE INTERVIEW

When interviewing injured children, it is essential to be as gentle as possible, asking how they got hurt rather than who hurt them. Any question asked should be appropriate for the child's age. The child's account of what he or she was doing at time of injury should be compared with the accounts of the adult witnesses. If possible, the siblings of the injured child should be interviewed because they also are at risk for child abuse. Nonvisual clues during the interview also may be helpful (Table 7-1).

To make the diagnosis of child abuse, the orthopaedist must make one crucial decision: Is the history of trauma adequate to explain the severity of injury? That decision should be based on experience in the care of fractures with knowledge of their mechanisms of injury and special insight into the types of trauma most likely to cause significant injury. In addition, it is also extremely important to have knowledge of the developmental abilities of a child when a caretaker states the child's injuries are self-inflicted (76). It is patently absurd for the parents to explain that an infant's femoral fracture occurred in a fall while the infant was standing alone when the infant is too young to even roll over. Details of the accident given as the reason of the injury should be carefully considered. Although it is not unusual for a young child to sustain an accidental fall, it is unusual to sustain a serious injury from that fall alone. Infants fall from a bed or a raised surface during a diaper change fairly frequently. In a study of 536 normal infants (95), nearly 50% of them had fallen accidentally from an elevated surface, usually after the first 5 months of life, when the children were able to roll over and pull themselves up. Significant injury after such falls is, however, extremely rare. Combining two studies (68,94) of 782 children younger than 5 years of age who accidentally fell off an elevated surface, such as bed or sofa, injuries were limited to three clavicular fractures, six skull fractures, one humeral fracture, and one subdural hematoma. More injuries occur in falls from greater heights. In a report (75) of 363 stairway injuries, 10 were in infants who fell with their caretaker while being carried on stairways, and four of those sustained skull fractures. In patients aged 6 months to 1 year, 60% were using walkers at time of injury. Only 4% of patients had extremity fractures, and 1% had skull fractures. Abrasions and contusions were present in 55% of patients, whereas 26% had lacerations. In another study (116) of 76 children who had fallen from a bed, a crib, or a chair (estimated height 1 to 3 feet), while in the hospital for other illness, 18%

had scalp or facial hematomas and 12% had lacerations about the head. There was only one nondisplaced skull fracture and one long bone fracture in a patient with osteogenesis imperfecta.

Additional important information about the child and the family may be obtained by a review of past medical records or by contacting social workers who may have been involved with the family. Conferring with the family's primary health care provider also may be extremely helpful. A medical release from the family is necessary before these sources of information can be explored (49). The physician or social worker should be asked if there have been prior concerns regarding abuse or neglect; whether there has been a suspicious pattern of injury, illness, ingestion of objects, or medications or noncompliance with health care recommendations; whether the family is receiving counseling or other support from any community groups; and whether the family has any previous involvement with child protective services or the police (49).

Documentation

Careful documentation is critical. Chart notes may later be needed in court as evidence for either custodial hearings or criminal trial (101), and defending inaccurate or partial chart notes in court can be extremely embarrassing. Each account should be recorded in as much detail as possible, using quotation marks for exact quotes and specifying who is giving the history. Particularly with crucial answers, the exact question preceding the response should be documented. In addition, the general emotional state of the individual providing the account, as well as the individual's reaction to emotionally charged questions should be documented to assist in later evaluation of the credibility of the account. If the family wishes to change their story after the initial account, no changes should be made to the earlier record, but an addendum should be placed detailing the new account. The completed record should include several specific items (Table 7-2). If child protective services recommends emergency transfer of custody of the child to a foster home or a shelter, then the orthopaedist should summarize chart documentation in a separate notarized narrative, which is preferred by most courts.

- Mechanism of injury
- Family social history
- Past medical history
- Family history of diseases such as osteogenesis imperfecta or other metabolic disease
- Physical examination findings (positive and negative)
- X-ray findings
- Laboratory results
- Photographs of soft tissue injuries
- Results of consultations
- Diagnosis of child abuse
- Teatment recommendations
  - Acute injuries
  - Investigation by child protective services

TABLE 7-2. DOCUMENTATION OF CHILD ABUSE

PHYSICAL EXAMINATION

After the initial musculoskeletal evaluation for acute fracture assessment, an extremely thorough physical examination of the patient should follow, systematically going from the head to the toes, to detect any signs of additional acute or chronic injury. Additional acute fractures may cause local tenderness and swelling, whereas chronic fractures may produce swelling from the presence of callus and clinical deformity from malunion. Specific radiographs should detect clinical fractures, with skeletal surveys showing most occult fractures. Other body areas commonly involved in child abuse include the central nervous system, the skin, the abdomen, and the genitalia. These areas should be carefully evaluated for signs of acute and especially chronic injury, because 50% of verified abuse cases show evidence of prior abuse (63).

Neurologic Injuries

Head injuries are the leading cause of death in child abuse (21). When an infant with musculoskeletal injury presents with altered mental status, whiplash-shaken infant syndrome should be suspected. Violent shaking of a small child whiplashes the relatively large head back and forth over the thorax with possible development of subdural hematomas (Fig. 7-1). Some authors (50) believe these head injuries actually occur when the child's head is slammed onto a soft surface such as a mattress. On impact, deceleration forces approaching 400 Gs may be seen, tearing the bridging vessels between the skull and the brain, and producing intracranial hemorrhage and cerebral edema. Skull fractures, though, are rare unless the child is thrown onto a hard object. Simple linear skull fractures usually are due to a fall of less that 4 feet and may be accidental, but complex skull fractures without a history of significant trauma, including comminuted, diastatic (separated sutures), displaced fractures, and fractures crossing suture lines, are suspicious for abuse (21). Children with head injuries caused by direct impact trauma are described as having shaken impact syndrome (50). Children with head injuries have fevers, bulging fontanelles, and sometimes enlargement of the head. A pattern of paresis may be present, and reflexes may be increased (29). Skull fractures generally are uncommon, and either ultrasound or computed tomography (CT) scans are used to diagnose subdural hematomas. Cerebral edema may be lethal (37), and emergency neurosurgical consultation is needed. Funduscopic examination by an ophthalmologist is indicated because concurrent retinal hemorrhage is common (29). The examiner should be aware, however, that retinal hemorrhages due to normal vaginal birth are present in 40% of newborns, but these injuries resolve by 3 to 4 weeks of age (53). Shaken baby syndrome has a high mortality rate: Thiry percent of infants die of their injuries (25).

FIGURE 7-1. Violent shaking of a small child held by the chest whiplashes the head back and forth over the thorax, with the possible development of subdural hematomas as well as rib fractures. Infants held by the extremities are also at risk for long bone fracture.

Fatal cerebral injury also occurs in the abusive tin ear syndrome: a clinical triad of unilateral ear bruising, CT scan evidence of ipsilateral cerebral edema, and hemorrhagic retinopathy, with a 100% mortality rate in one series (66).

Spinal fractures occur in child abuse when a child is forcibly slammed onto a countertop with hyperflexion of the spine (1). Although neurologic deficit with this type of injury is uncommon (41), children should be carefully evaluated for signs of spinal cord injury secondary to spinal fracture when abuse is suspected.

Soft Tissue Injuries

In addition to examination of the soft tissue around the acute fracture site for swelling and bruising, the patient's entire body should be carefully and systematically evaluated to detect acute and chronic soft tissue trauma. Deliberate soft tissue injuries are present in 81% to 92% of abused patients (61,109). The types of skin

lesions commonly encountered in child abuse include ecchymosis, welts, abrasions, lacerations, scars, and burns.

The typical toddler often has multiple bruises over bony prominences such as the chin, brow, knees, and the shins (1,132). Bruises on the back of the head, neck (1), buttocks, abdomen, legs, arms, cheeks, or genitalia may be suspicious for abuse, although accidental bruises can occur in all these locations (132). Accidental bruising of the head or face, though, is much less common. In a study of 400 nonabused children, Robertson (128) found an overall incidence of just 7% for accidental soft tissue injuries of the face and head, with the peak incidence of 17% seen in toddlers. Soft tissue injuries were present on the lower extremities and buttocks in only 31% of children and on the upper extremities of only 9%. The configuration of the bruise due to abuse may resemble the implement used to inflict the injury (Fig. 7-2), but usually the soft tissue injuries of abuse are “weapon” specific in fewer than 10% of patients (109). Although bruises often are concentrated on the trunk and buttocks, they also can be present on the head and proximal extremities. The weapons used to abuse children can be almost any common object, but they often include belt buckles, staplers, ropes, switches, coat hangers, ironing cords, and the open or closed human hand (77,149). Bruises inflicted by an open hand may appear on the face or a flat area of skin from a slap and grasp marks may appear as ovoid lesions when the fingertips are deeply embedded in the extremities or the shoulders of the child during extreme shaking (72). The injury pattern and the severity of the ecchymosis depends on the amount of force used, how directly the instrument made contact, and the specific type of implement used to strike the child (72). Welts are more complex skin lesions in which swelling accompanies bruising from injury through lashing or whipping.

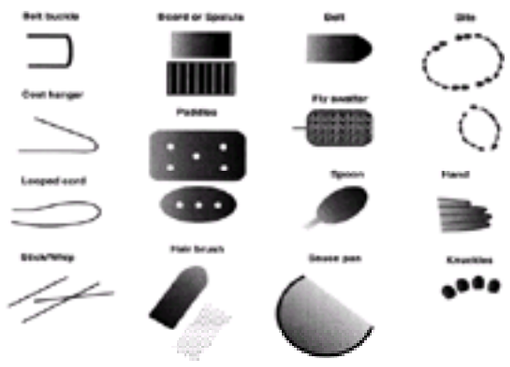

FIGURE 7-2. Healing soft tissue injuries may resemble the instrument used to inflict the lesion.

The type of soft tissue injuries in child abuse may depend on the age of the child (Table 7-3). In the pediatric dentistry literature, in a series of 266 children suspected of being abused, Jessee and Rieger (74) also found that bruises were the most common soft tissue injury, with the most common facial injury ecchymosis of the cheek, forehead, periorbital area, or the lip.

Age	Bruises	Abrasions	Lacerations	Scars	Burns	Head/neck injury
<5 mos	71%	8%	–	–	16%	50%
10–25 mos	64%	13%	6%	6%	12%	38%
>36 mos	61%	21%	4%	11%	3%	24%

Data from McAlister P, Grossman W, Gaffney M, and Starnfeld C. Soft tissue injury as an indication of child abuse. J Bone Joint Surgery Am 71:

TABLE 7-3. DISTRIBUTION OF SOFT TISSUE INJURIES IN 371 ABUSED CHILDREN

The age of a cutaneous contusion reportedly can be estimated by a change in its color over 2 to 4 weeks after injury, with fading of the lesions beginning at the periphery. An acute contusion is blue or reddish purple; it gradually changes to green, then to yellow, with final resolution as a brownish stain as the hemoglobin is finally broken down (159). Langlois and Gresham (97) noted that a yellowish bruise must be older than 18 hours; a red, purple, blue, or black coloration of the bruise may be present from 1 hour after injury to resolution; red is always present in bruises regardless of the age; and bruises of identical age and etiology on the same person may be of different appearances and may change at different rates. Although the age of a superficial contusion may be approximately dated by its appearance, a deep contusion may take some time to rise to the skin surface because of fascial planes and thus delay visible ecchymosis.

Natural skin lesions should not be mistaken for bruises. Mongolian spots are naturally occurring deep-blue pigmented areas that are present on the lower back at birth , usually just proximal to the buttocks. They occur more commonly in black and Asian infants than in white infants (15). Unlike traumatic bruises, they do not change in color but gradually resolve as the child matures (72). Cultural differences should always be considered when unusual skin lesions are noted. Vietnamese children may be subjected to a folklore medical practice known as cao-gio, which causes suspicious scratches and bruises on the back and may be mistaken for child abuse (13).

Acute lacerations in various stages of healing and chronic scarring may be present in an abused child. Like bruises, the configuration of the injury can resemble the weapon used to inflict the injury on the child. Although minor lacerations around the eye are fairly common, multiple scars due to either lacerations or burns (125) are suspicious for abuse.

Burns

Burns are found in approximately 20% of abused patients (61) and are most likely to be found in patients younger than 3 years of age (109). Burn evaluation should include configuration, approximate percentage of body surface area, location, distribution, uniformity, length of time the child was in contact with the burning agent, temperature of the burning agent, and presence or absence of splash marks when hot liquids are involved (72). Most self-inflicted accidental pour or spill burns occur anteriorly on the child, but accidental burns can also occur on the back. In accidental burns, the injury usually has an arrowhead configuration in which the burn becomes shallower and more narrow as it moves downward, and there may be splash marks surrounding the lesion (72). Abuse should be suspected when deep second- or third-degree burns are seen well demarcated with circumferential definition. In accidental hot water immersion, an indistinct stocking or glove configuration may be seen with varying burn depths and indistinct margins. In deliberate immersion burns, the burn demarcation shows uniform depth and a well-demarcated water line (72). Particularly severe burns occur when a child's buttocks are immersed in hot tap water as abusive punishment. The central aspect of the buttocks may be spared, giving a doughnut-like appearance to the burn. Galleno and Oppenheim (61) noted that in accidental hot water immersion, the child is uniformly scalded about the lower extremities as the legs are quickly extended by the child to climb out of the water, but in deliberate, abusive immersion the children are lowered into the water, so they instinctively pull up their legs to avoid the scalding hot water, and knee flexion may protect the popliteal areas from burn (Fig. 7-3). The average child abused by scalding burns is an undernourished 2-year-old child with burns involving 15% to 20% of the body, usually the buttocks; these children have a 10% to 15% mortality rate from burn owing to sepsis (127).

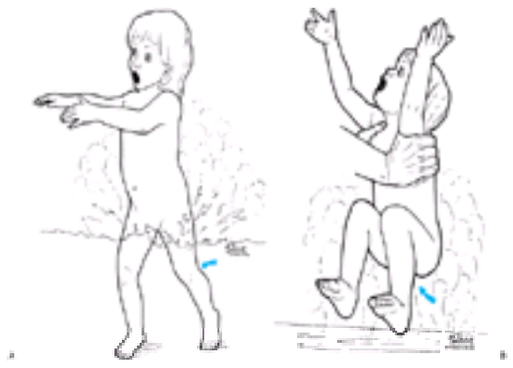

FIGURE 7-3. A: In accidental hot water immersion, the child is uniformly scalded about the lower extremities as the legs are extended quickly by the child to climb out of the water, with burns occurring behind the knee (*curved arrow*). **B:** In nonaccidental immersion, the child instinctively pulls up the legs to avoid the hot water, and knee flexion may protect the popliteal areas from burn (*curved arrow*)

Burns also can be inflicted by many objects commonly found in the household. Sometimes the object can be identified by the configuration of the burn. Intentional burns by cigarettes are circular, deeply excavated, and sometimes repetitive, usually about 8 mm in diameter (72). Isolated cigarette burns may be accidental, and in such cases, they are usually superficial, pointing downward, and often appearing triangular. Lesions of impetigo resemble those of cigarette burns, but they are much more superficial.

Contact with heated objects may cause burns of unique shape that allow identification of their etiology (Fig. 7-4). Children accidentally grasping curling irons sustain burns of the palms, whereas burns on the dorsum of the hands are more suspicious for abuse (76). Hair dryers can be used to inflict burns on children, and full-thickness skin burns can result from contact with the grill of a dryer up to 2 minutes after it has been turned off (124). Such burns can resemble those caused by hot water or could have a grill pattern caused by direct contact with the dryer. Abuse burns have also been inflicted by stun guns (59). These devices deliver a high-voltage impulse of up to 100,000 volts at 3 to 4 mA, incapacitating the individual and leaving hypopigmented burn scars on the skin 0.5 cm apart. Rope burns, sustained when children are restrained about the wrists for beatings, may be seen as circular scars about the wrists (76). Full-thickness skin burns have been reported in small children who were placed in microwave ovens (7).

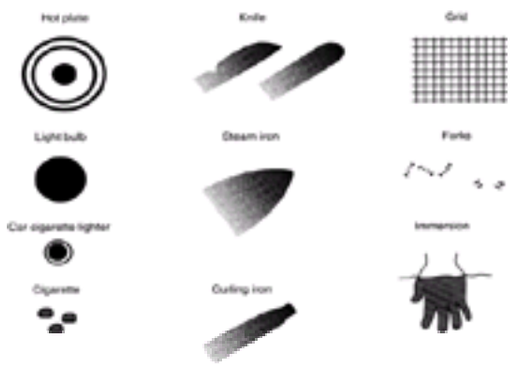

FIGURE 7-4. Contact burns by heated objects may cause burns of unique shape that allow identification of their cause.

Certain folklore practices may cause lesions simulating abusive burns. Round burns on the abdomen, buttock, or between the thumb and forefinger of Southeast Asian children may be due to a variant on the Chinese medical practice of moxibustion. Folk medical practitioners burn balls of the moxa herb on the surface of the skin for therapeutic purposes, and both cigarettes and yarn have been similarly used in refugee camps. The knowledge of these practices may help to avoid inappropriate accusations of child abuse (57). Infants may sustain second-degree burns when they accidentally come in contact with the hot vinyl upholstery of a car (133).

Abdominal Injuries

Trauma to the abdomen is the second most common reason for death from child abuse (21). Careful evaluation is needed to rule out occult abdominal injury in the abused child. These are injuries due to beatings with the hand or fist and also can occur when the child is thrown into a fixed object. External abdominal bruising is present in only 12% to 15% of cases of major abdominal injuries (72). Patients with abdominal injury due to child abuse may have fever, vomiting, and anemia, with abdominal distention, localized involuntary spasm, and absent bowel sounds (121). One of the most common abdominal injuries is a ruptured liver or spleen, and the hypovolemic shock from blood loss can be fatal (156). Blunt trauma to the abdomen also may cause intestinal perforation, usually involving the large intestine, and the physical examination suggests peritonitis with free air seen on abdominal radiograph. Intramural duodenal hematoma may cause obstruction and projectile vomiting (72). More severe trauma may cause duodenal avulsion or transection with nausea, vomiting, and clinical acute abdomen (155). Severe blunt trauma to the abdomen or a blow to the back may cause renal or bladder contusion with hematuria. Blunt trauma to the abdomen also may result in shearing of the mesenteric vessels, leading to hypovolemic shock due to blood loss. Pancreatic transection can occur where the pancreas overlies the vertebral column, and a pseudocyst may form (72).

Liver function tests are useful in detecting abdominal injury due to occult liver injury in child abuse. In one study (39), elevated aspartate aminotransferase, alanine aminotransferase, and lactic dehydrogenase enzyme levels were useful markers for occult liver lacerations in abused children who had false-negative abdominal examinations. A CT scan is used to define liver injury. If a bone scan is obtained to diagnose occult fracture, there may be abnormal patterns of isotope uptake in the abdomen due to intestinal injury, renal contusion, or muscle trauma of the abdominal wall (71).

When abdominal injury is suspected in an abused child, the hematocrit and hemoglobin levels are checked, the child is typed and crossmatched for blood, and an intravenous line is placed to provide replacement fluids. Emergency general surgery consultation should be obtained. The overall mortality rate associated with visceral injury in child abuse is 40% to 50% (39).

Genital Injuries

Sexual abuse should always be considered when evaluating a physically abused child. Children who have been sexually abused can have symptoms of bed wetting, fecal incontinence, painful defecation, pelvic pain, abdominal pain, vaginal itching and bleeding, sexually transmitted diseases, and pregnancy in postmenarchal women. Types of sexually transmitted diseases found in abused children include gonorrhea, syphilis, chlamydiasis, trichomoniasis, and lymphogranuloma venereum. Although the percentage of sexually assaulted children with obvious physical trauma to the genitalia is low, failure to document such findings is a serious matter because sexual abuse is always a criminal offense and must be reported to legal authorities.

The genitalia should always be examined in a chaperoned setting. Infant and toddler girls are placed in a supine frog-leg position, and boys are placed in either a prone knee-chest position or in a lateral decubitus position (140). Patterns of injury that suggest sexually motivated assault include bruises, scratches, and burns around the lower trunk, genitalia, thighs, buttocks, and upper legs, including the knees. Pinch or grip marks may be found where the child was held. Attempted or achieved penetration may involve the mouth, vagina, or anus (70). Sexually abused boys may have poor rectal sphincter tone, perianal scarring, or urethral discharge. Female genital examination findings that are consistent with, but not diagnostic of, sexual abuse include chafing, abrasion, or bruising of the inner thighs or genitalia; distortion of the hymen; decreased or absent hymen; scarring of the external genitalia; and enlargement of the hymenal opening (10). The examination of the female genitalia can be normal even when there has been penetration, because hymenal tissue is elastic and there can be rapid healing of trauma. There also is a wide variability of appearance of normal female genitalia (31,55), but posterior hymen disruption is rare and is suspicious for abuse (20). If the sexual assault occurred

within 72 hours of evaluation, then a rape kit must be used by the evaluating physician or nurse examiner to provide medical evidence of the attack (96).

The physical signs of sexual abuse, including genital trauma, sexually transmitted diseases, or presence of sperm are present in only 3% to 16% of verified sexual assaults (17,140), but even this minority of patients will be undiagnosed if sexual abuse is not considered when a child presents with musculoskeletal injury due to abuse. The orthopaedist or a consultant such as a pediatrician or a gynecologist must perform and document the genital examination in children with physical abuse.

FRACTURES IN CHILD ABUSE

Fractures documented on plain x-ray studies are present in 11% to 55% of abused children and are most common in children younger than 3 years of age (1,43,63). Fractures due to abuse should be suspected in a young child if the caretaker brings in the child for evaluation, reporting no accident, but does report a change in the child such as extremity swelling or decreased movement of the limb (99). Infants in the first year of life with a fracture of the skull or the extremities have an equal risk of the etiology being either accident or abuse (107). Femoral fractures are especially suspicious for child abuse in younger children. One study (12) found that 79% of patients younger than 2 years of age with femoral fractures were battered, and of those, two thirds had femoral fractures as their only sign of abuse. Accidental femoral fractures can occur in children old enough to stand or run who fall with a twisting injury to the lower extremities, but femoral fractures in children younger than 1 year of age are most likely due to abuse (154). Fractures of both the lateral clavicle and the scapula are suggestive of abuse in young children (94). Infants may normally have a separate ossification center adjacent to the tip of the acromion, simulating a fracture (92), but a true fracture has sharp, demarcated edges; may be positive on bone scan; and will show callus on healing (Fig. 7-5). Fractures of the hands and feet are most commonly due to accidental trauma in older children (113) but are suspicious for abuse in infants. Nimkin et al. (117) reviewed 11 hand and foot fractures in abused children younger than 10 months of age and found mostly torus fractures either of the metacarpals or the proximal phalanges of the hand and similar fractures of the first metatarsals of the feet. Clinical signs of fracture were present in only one patient, and bones scans were insensitive to the presence of the fractures in all patients.

FIGURE 7-5. A: A 7-week-old girl was seen in the emergency department with swelling of the left shoulder. History revealed her being roughly grabbed by the shoulder by one of her parents. The anteroposterior x-ray study shows a transverse lucency of the acromion, which was thought to represent either a congenital lesion or a traumatic fracture (*arrow*). **B:** A technetium bone scan was obtained. Although the delayed anterior image was normal, the posterior view showed increased uptake in the left shoulder in the area of the acromion (*arrow*) and a fracture was diagnosed. The incident was investigated. **C:** A follow-up x-ray study 9 days later showed callus bridging the fracture site of the acromion (*arrow*).

All types of fractures have been reported in the child abuse literature. In one of the largest series, King et al. (80) reported 429 fractures in 189 abused children. Fifty percent of these patients had a single fracture, and 17% had more than three fractures. Approximately 60% of fractures were found in roughly equal numbers in the humerus, femur, and tibia. Fractures also occurred in the radius, skull, spine, ribs, ulna, and fibula in order of decreasing frequency. Another study (121) found a similar incidence of fractures of the humerus, femur, and tibia in abused children, with skull fractures seen in 14% of patients (Fig. 7-6). In contrast, Akbarnia et al. (3) found that rib fractures in abused patients were twice as prevalent as fractures of any one long bone; the next most frequently fractured bone was the humerus, followed by the femur and the tibia. Nearly a third of their patients had skull fractures. Loder and Bookout (102) found the tibia to be the bone most commonly fractured in their series of abused children, followed by the humerus, the femur, the radius, and the ulna. Skull fractures were the most commonly reported fracture in one series (109), but only 10% of their patients underwent x-ray evaluation.

FIGURE 7-6. A: A 4-month-old male without history of trauma was brought into the emergency department by his parents with a history of decreased use of the arm. This distal humeral shaft fracture was seen on x-ray study. **B:** Skeletal survey disclosed a posterior skull fracture (*arrow*), and the injuries were investigated.

Rib Fractures

Rib fractures are uncommon in childhood accidents, so their presence is very suspicious for child abuse, especially when other long bone fractures are present (147). Abusive rib fractures may be caused by squeezing of the chest by a caretaker (29), hitting the child from behind, or stepping on the chest (90,143). Kleinman et al. (90) postulated that severe shaking of an infant (see Fig. 7-1) can cause front-to-back chest compression, which levers the posterior rib over the transverse process of the vertebral body, causing fractures of the posterior rib shaft at the transverse process and of the rib head adjacent to the vertebra (Fig. 7-7). These posterior rib fractures are difficult to diagnose acutely because of a lack of displacement. Even with healing, the callus on x-ray study may be obscured by the overlying transverse process (86), and a bone scan may be needed to make the diagnosis (Fig. 7-8). Posterior rib fractures are believed to be most common in child abuse, but fractures may occur anywhere along the arc of the rib, including disruption of the anterior costochondral junction. Posterior paraspinal rib fractures tend to occur between T4 and T9, rib fractures in the axillary line occur mostly in the lower rib cage, and disruption of the anterior costochondral junction usually occurs from the second to the ninth ribs (40).

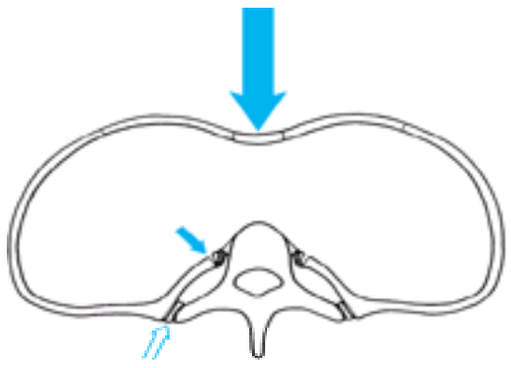

FIGURE 7-7. With anterior compression of the chest, the posterior rib is levered over the transverse process of the vertebral body (*open arrow*), causing fractures of the rib head adjacent to the vertebra (*shaded arrow*) as well as avulsion fractures of the rib at the transverse process.

Lateral rib fractures, both acute and chronic, may be difficult to see on standard anteroposterior (AP) x-rays, so oblique views may be necessary. Healing fractures show early callus, but healed fractures may be subtle, with only a fusiform thickening of the rib (see Fig. 7-8). Old fractures of the ribs in child abuse may form lytic, expansile lesions that mimic a tumor (104). Fractures along the lateral arc of the rib are likely due to AP compression of the chest (Fig. 7-9A), while lateral compression of the chest likely causes fractures of the rib along its posterior arc lateral to the transverse process as well as disruptions of the costochondral junction (Fig. 7-9B).

FIGURE 7-8. A: This 5-week-old infant was presented by her parents with a complaint of irritability when her left leg was handled. Her mother stated the infant's 18-month-old sibling may have “kicked” her in the leg. X-ray studies showed an acute fracture of the proximal tibia. **B:** Skeletal survey showed a healing fracture of the left distal clavicle (*arrow*), a healed fracture of the anterior left 5th rib (*arrow*), and question of healing posterior right 6th, 7th, 8th, and 9th ribs (*arrow*). **C:** The posterior image of the delayed phase of the bone scan confirmed the presence of healing posterior rib fractures (*arrow*).

FIGURE 7-9. A: Anteroposterior compression of the infant chest causes fractures both at the rib head and adjacent to the transverse processes (*open arrow*), but fractures along the lateral arc of the rib are also possible because of the acute bending of the ribs at this point by compression (*shaded arrow*). **B:** Lateral compression of the chest likely causes fractures of the rib along its posterior arc lateral to the transverse process, as well as possible disruption of the costochondral junction (*open arrows*).

Acute anterior costochondral separations of the ribs may be difficult to see on x-ray study, but ultrasound can show costochondral dislocation (141) and, with healing, the anterior end of the osseous rib becomes widened and clubbed on x-ray study (94,121).

In the rare instances when rib fractures are discovered in abused infants undergoing resuscitation for cardiac arrest, there may be confusion about the etiology of the fractures (42), but the elasticity of the infant chest seems to enable it to tolerate compressions, with only 2% of 94 nonabused infants resuscitated having rib fractures in one series (23). In addition to rib fractures, abused infants can sustain severe lung contusion and respiratory distress from chest wall trauma (108), with fatal fat embolus reported (115). Necklace calcifications may be present in strangulation cases (33).

In the case of infant fatalities of suspicious origin, postmortem high-detail skeletal surveys and specimen radiography can be helpful in diagnosing child abuse (83). In a postmortem study of 31 infants who died of inflicted skeletal injury, Kleinman et al. (88) found a total of 165 fractures (51% rib fractures, 39% metaphyseal long bone fractures, 5% long bone shaft fractures, 4% fractures of the hands and feet, 1% clavicular fractures, and less that 1% spinal fractures). It is important to obtain skeletal radiography before autopsy to avoid artifact (P. Kleinman, Personal communication, 1998).

Spinal Fractures

Spinal fractures in child abuse are rare but can occur when a child is forcibly slammed onto a flat surface with hyperflexion of the spine (1). Based on autopsy findings (84), spinal fractures of fatally abused children generally involved 25% or less compression of the vertebrae. Half of the fractures involved the anterosuperior end plate associated with a compression deformity, 30% had pure compression fractures, and 20% had fractures of the superior end plate without significant compression. In another study of fractures of the cervical spine, prevetebral soft tissue edema on x-ray study was the only sign of cervical injury, because spontaneous reduction of the cervical vertebrae after dislocation was common (150). Thomas et al. (153) reported a 9-week-old boy with spinal cord injury due to cervical spine fracture who presented as a floppy infant. Although routine cervical radiographs were normal, magnetic resonance imaging (MRI) studies showed retropulsion of a fragment of the primarily cartilaginous C3 vertebrae into the spinal canal. Carrion et al. (32) reported circumferential physeal fractures of the spine associated with child abuse that required open reduction. Bone scans using single photon emission computed tomography can be helpful for diagnosing occult compression fractures of the thoracic spine (40). Although neurologic injury in spinal fractures due to child abuse is uncommon (41), any patient with abusive spinal injury should undergo complete neurologic examination.

ADDITIONAL IMAGING STUDIES

In addition to standard x-ray studies of the acute injury, a skeletal survey is used to detect the presence of additional fractures in battered children. The skeletal

survey should include separate AP and lateral views of the skull and the entire spine, and an AP view of the chest and extremities that includes the shoulders, pelvis, extremities, feet and hands (98). Oblique x-ray studies of the hand are recommended to detect subtle torus fractures of the metacarpals and the phalanges (117). A single AP x-ray study of an entire infant, the so-called baby gram, is not adequate because the obliquity of the angle at which the x-ray transverses the skeleton may obscure subtle fractures (40). The indications for skeletal survey are not completely clear. Merten et al. (112) recommended skeletal survey in infants 1 year of age or younger when there is evidence of neglect and in children age 2 years or younger when clinical abuse is evident. The American Academy of Pediatrics Section on Radiology (11) considered a skeletal survey mandatory in all cases of suspected physical abuse in children younger than 2 years of age, but the sensitivity of skeletal surveys was unclear in older patients. The cost-effectiveness of such skeletal surveys appears to be low because in one study of 331 children, only eight patients without overt physical signs of child abuse had occult fractures revealed by the survey (54), but the use of the skeletal survey in these eight patients possibly prevented both reinjury and death. Perhaps when the death of a child is the ultimate risk of the misdiagnosis of child abuse, we should not play the odds but use every medical test at our disposal to identify the child at risk for abuse so we can try to protect him or her from further possible fatal abuse.

Sty and Starshak (145) reported a false-negative rate of 12.3% in skeletal surveys of abused children, and suggested that a technetium bone scan is the best screening test for occult fractures. Technetium bone scans, however, may fail to diagnose either epiphyseal or metaphyseal fractures and often fail to show skull fractures (113,145). Jaudes (73) found that when results of either a bone scan or a skeletal survey were normal in an abused child, the use of both tests often revealed additional occult fractures. Technetium bone scans are especially useful in the diagnosis of occult rib fractures (40,143), but consistent interpretation is difficult in children younger than 18 months of age. Technetium scans are not useful for dating fractures, because increased isotope uptake may occur at a fracture as early as 24 hours after injury and scan abnormalities may persist for years (58). Kleinman et al. (91) reported that a follow-up skeletal survey 2 weeks after the initial series detected 27% more fractures and provided assistance in dating in 20% of previously detected fractures.

Other imaging techniques may be useful in investigating suspicious x-ray study or bone scan findings. Markowitz and co-workers (105) found that sagittal and coronal sonograms of injured knees in abused children were helpful in diagnosing epiphyseal fractures when compared with the normal side. They cautioned that epiphyseal fractures due to rickets in neonates can be confused with child abuse on ultrasound evaluation. Rogers and Poznanski (130) pointed out that acute interruption of the physis in trauma of any etiology can be seen on MRI. They recommended multiplanar gradient-echo imaging with a repetition time of 50 to 700 ms, an echo time of 200 ms, and a flip angle of 20 degrees for optimal imaging of the physis.

INTERPRETING IMAGING STUDIES IN CHILD ABUSE

There is no predominant pattern of diaphyseal fracture in child abuse. Traditionally, a mid-shaft spiral fracture is believed to be caused by a violent twisting injury to the extremity of the child. In a study of 23 long-bone fractures in battered children, Herndon (69) found spiral fractures in 78%. He suggested that in children younger than 3 years of age, a spiral fracture of a long bone is highly suggestive of child abuse. Other authors (61), however, found that 71% of diaphyseal fractures were transverse in abused children. In another study of 34 patients in the first year of life, there was no difference in fracture patterns between those injured by trauma and those injured by abuse. Loder and Bookout (102) reviewed 69 long bone fractures in abused children and found that 56% were transverse, 36% oblique, and only 8% spiral. In another study of 429 fractures (80), 48% of fractures were transverse and 26% were spiral. Most of these long bone fractures were in either the middle or distal third of the shaft. Transverse fractures are most commonly associated with either a violent bending force or a direct blow to the extremity, whereas spiral or oblique fractures of the long bones are due to twisting injuries or a fall. Significant rotational force is required, however, to produce a spiral fracture with a fall (1). Another author (154) emphasized that children old enough to run can fall and fracture their femurs if there is a significant twisting motion at the time of injury. In delayed follow-up, long bone fractures may show exuberant callus because of a lack of immobilization, and multiple fractures may be present in different stages of healing (2). Juxtacortical calcification may be seen without fracture when there is diaphyseal periosteal separation due to tractional or torsional force when the limb is grasped or pulled along the shaft of the bone (112).

Metaphyseal and epiphyseal fractures of the long bones are classically associated with child abuse (28,139). In toddlers, these fractures can occur when the child is violently shaken by the extremities (Fig. 7-10) with direct violent traction on or rotation of the extremity (113). Metaphyseal fractures may be characterized by impaction into the epiphysis, with profound production of new periosteal bone. Buckle fractures may be present in multiple sites, and these injuries seldom produce exuberant callus. Repeated injury causes irregular metaphyseal deformities. Periosteal avulsion produces new bone formation within 2 to 3 weeks of injury and can be confused with osteomyelitis (2). New bone formation may be delayed, however, in children with malnutrition. Metaphyseal fractures composed 40% of fractures in one series (61) but less than 15% in another (94).

FIGURE 7-10. When a toddler is violently shaken by the extremities, long bone fractures can occur through either direct violent traction or rotation of the extremity. These children are also at risk for closed-head injury because of violent motion of the head during the shaking episode (*arrow*).

Kleinman (81) ranked the specificity of skeletal trauma for abuse (Table 7-4). Distinguishing between an accident and child abuse is based on both location and type of fracture. He cautioned that both moderate- and low-specificity x-ray findings of child abuse become more highly specific when there is an inadequate explanation for the injury.

High Specificity
- Any metaphyseal lesion
- Posterior rib fracture
- Scapular fracture
- Spinous process fracture
- Sternal fracture

Moderate Specificity
- Multiple fractures, especially bilateral
- Fractures of different ages
- Epiphyseal separation
- Vertebral body fracture or subluxation
- Digital fracture
- Complex skull fracture

Low Specificity
- Clavicular fracture
- Long bone shaft fracture
- Linear skull fracture

Data from Kleinman PK, ed. Diagnostic imaging of child abuse. Baltimore: Williams & Wilkins, 1987.

TABLE 7-4. SPECIFICITY OF SKELETAL TRAUMA FOR ABUSE

The Corner Fracture of Child Abuse

The so-called pathognomonic fracture of child abuse is the corner or bucket-handle fracture of the metaphysis (1,2). On x-ray study, there is no gross displacement of the epiphysis, but a corner or chip fracture is seen at the edge of the involved metaphysis (Fig. 7-11). If a significant portion of the metaphyseal rim is involved, a bucket-handle fracture pattern is produced. Another fracture pattern that may be seen is a faint metaphyseal lucency just adjacent to the physis. Classically, these

fractures have been believed to result from avulsion of metaphyseal fragments through the periosteal attachment of the epiphysis (28,98). Kleinman et al. (85,87) challenged this view based on their histopathologic study at autopsy of metaphyseal fractures of abused infants. They found that in bucket-handle or corner fractures, there was actually a full-thickness metaphyseal fracture extending through the primary spongiosa of bone just above the zone of provisional calcification. This fracture corresponded to the zone of metaphyseal lucency occasionally seen on x-ray. Centrally, the amount of metaphysis remaining attached to the physis was thin, but peripherally, the fracture line curved away from the physis so that a substantial metaphyseal rim remained attached to the physis. On x-ray study, this metaphyseal rim formed the basis for both corner and bucket-handle fractures (Fig. 7-12). In healing fractures, biopsy specimens showed metaphyseal extension of hypertrophied chondrocytes (89,122). These fractures are most likely caused by either violent shaking or traction injuries to the extremity and are specifically suggestive of child abuse (1) (see Fig. 7-10); however, they are not the most common fractures in abused children, with their incidence in large series ranging from 15% to 32% (61,80,94,102). Subepiphyseal-metaphyseal lucency can also be caused by systemic diseases such as rickets and leukemia.

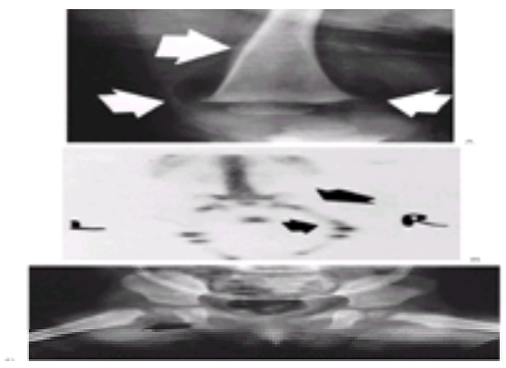

FIGURE 7-11. A: An 11-month-old girl with a history of right thigh swelling was seen. X-ray studies of the right femur show corner or “chip” fractures of the distal femur (*bottom arrows*). Faint periosteal calcification is also visible along the lateral cortex (*top arrow*). Such fractures are suspicious for child abuse. **B:** A technetium bone scan showed increased uptake of isotope in the distal and proximal femur (*arrows*). **C:** A healing epiphyseal plate fracture of the proximal femur is seen (*arrow*).

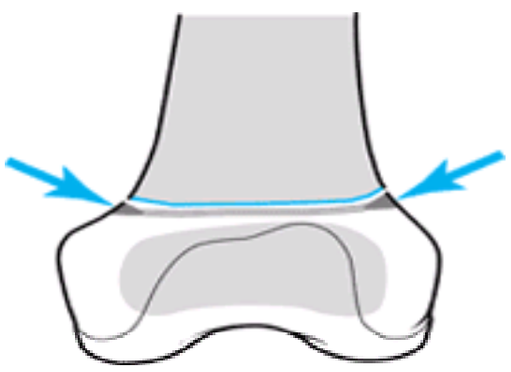

FIGURE 7-12. In the corner or bucket-handle fracture, full-thickness metaphyseal fracture extends through the primary spongiosa just above the zone of provisional calcification. Centrally, the amount of metaphysis remaining attached to the physis is thin, but peripherally, the fracture line curves away from the physis so a substantial metaphyseal rim remains attached to the epiphyseal plate (*arrows*). On x-ray study, this metaphyseal rim (*dark shaded area*) forms the basis for both the corner and bucket-handle fractures.

DATING FRACTURES

X-ray proof of unexplained fractures in various stages of healing is believed to be strong evidence of child abuse (3) (Fig. 7-13). The orthopaedist often is asked to estimate the age of fractures with some certainty to corroborate a history of injury given by caretakers (Fig. 7-14). Whereas most experienced orthopaedists can roughly estimate the age of fractures based on x-ray appearance, specific guidelines have been established for estimating the age of fractures in children (118) (Table 7-5). Both age and nutritional status can affect the appearance of callus around healing fractures (47). Growth lines present on radiographs may be helpful in dating fractures (52). In general, fractures on x-ray study are acute until callus appears, then their age is based on the presence of either soft or hard callus some weeks later (Fig. 7-15). The most difficult fractures to date are those that are completely healed with substantial remodeling, and often the only sign of fracturing is a thickened cortex (Fig. 7-16).

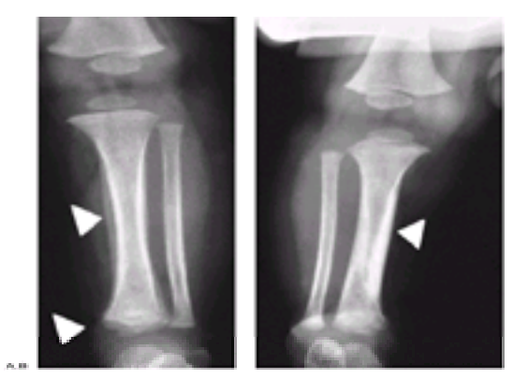

FIGURE 7-13. A: A 7-month-old boy presented with a nondisplaced left distal tibial fracture with periosteal calcification extending up the tibial shaft (*arrows*). **B:** A skeletal survey revealed dense, sclerotic cortical thickening of the contralateral tibia consistent with healed fracture (*arrow*). The presence of multiple fractures in different stages of healing is very suggestive of child abuse.

FIGURE 7-14. A 3-year-old female was brought to the clinic with a swollen elbow. The mother stated that the child had fell only a week ago, but x-ray studies of the elbow showed a healing supracondylar fracture of the distal humerus that was likely 2 to 3 weeks old based on presence of soft callus (*arrows*). Child protective services was contacted and a full examination including skeletal survey was performed. No other signs or risk factors for child abuse were detected. The mother then admitted that the child had indeed fallen 3 weeks ago. She was allowed to take her child home after treatment and was counseled about the need for prompt medical

care when her children were injured.

X-Ray Appearance	Peak Changes
Resolution of soft tissue swelling	4–10 days
New periosteal bone	10–14 days
Loss of definition of fracture line	14–21 days
Presence of soft callus	14–21 days
Presence of hard callus	21–42 days
Remodeling of fracture	1 year (early—3 months; late—2 years to maturity)

After O'Connor, JF, Cohen J. Dating fractures. In: Kleinman PK, ed. *Diagnostic imaging of child abuse*. Baltimore: Williams & Wilkins, 1987.

TABLE 7-5. GUIDELINES FOR ESTIMATING THE AGE OF FRACTURES IN CHILDREN

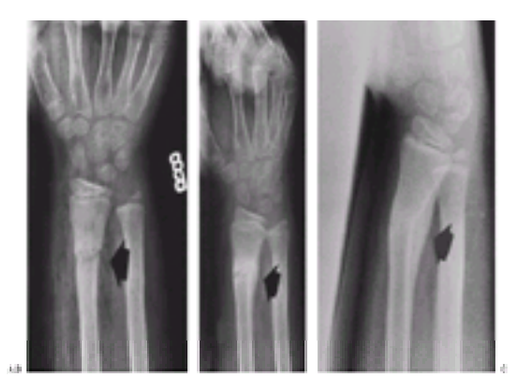

FIGURE 7-15. A: A 6-year-old patient presents with a nondisplaced transverse fracture of the distal radius (*arrow*). **B:** At 4-week follow-up, soft callus is seen enveloping the fracture site (*arrow*). **C:** At 6-week follow-up, hard callus is seen and early remodeling is occurring at the fracture site.

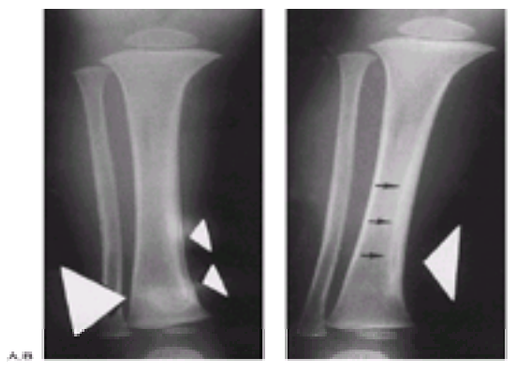

FIGURE 7-16. A: An 18-month-old child presents with a 1-month-old nondisplaced fracture of the distal tibia (*large arrow*). The fracture line is beginning to fade, but periosteal calcification is seen medially (*small arrows*). **B:** At 5 months after injury, the fracture shows almost complete remodeling (*large arrow*) with the only sign of past injury a thickened medial cortex of the tibia (*small black arrows*). Subtle signs of past fracture are best noted by comparing the x-rays of the injured side to the contralateral uninjured side.

LABORATORY STUDIES AND CONSULTATIONS

An abused child should have a complete blood cell count with sedimentation rate, liver function studies, and urinalysis. Clotting studies should be performed routinely, especially in patients with ecchymosis, to rule out a blood disorder as a cause for the bruises. If there is any suspicion of substance abuse by any family member, a toxicology screen should also be performed on the patient (61). Any significant nonorthopaedic injury should prompt appropriate consultations by neurosurgery, general surgery, plastic surgery, or ophthalmology (2). Any female patients who require pelvic examination to rule out sexual abuse should have a gynecologic consultation.

THE DIFFERENTIAL DIAGNOSIS

Although it is extremely important not to miss the diagnosis of child abuse, it is equally important not to make the diagnosis in error. Kaplan pointed out that overdiagnosing battered child syndrome can be harmful to the family, with the parents being placed at risk of losing custody of their child and also facing criminal charges (78). Even direct allegations of child abuse may turn out to be false. Bemet (22) pointed out that patients or family friends may make false statements about an abuse situation through misinterpretation, confabulation, fantasy, delusions, and other mechanisms. The American Academy of Child and Adolescent Psychiatry (9) has published guidelines for the evaluation of abuse that state that the possibility of false allegations needs to be considered, particularly if allegations are coming from the parent rather than the child, if the parents are engaged in a dispute over custody or visitation, and/or the child is a preschooler.

Normal metaphyseal radiologic appearance should not be confused with child abuse. The radiologic metaphyseal variants include acute angulation of the ossified peripheral tip of the metaphysis adjacent to the physis (most commonly seen in the proximal tibia, distal femur, proximal fibula, distal radius, and distal ulna), which is bilateral in 41% of individuals. A bony beak may be seen medially in the proximal humerus and tibia in rare cases and is bilateral in 77% of individuals. Cortical irregularity in the medial proximal tibia may be seen in 4% of individuals and is bilateral in 25%. Spurs may extend beyond the metaphyseal margins in both the distal radius and lateral aspect of the distal femur, with bilateral variants in 25% of individuals (82).

The signs of child abuse found on x-ray study also can be mimicked by systemic diseases such as scurvy, osteogenesis imperfecta, Caffey's disease, osteomyelitis, septic arthritis, fatigue fracture, osteoid osteoma and other tumors, rickets, leukemia, hypophosphatasia, neuromuscular disease, metastatic neuroblastoma, congenital indifference to pain, osteopetrosis, kinky hair syndrome, and prostaglandin therapy (2,21). Fractures due to both vitamin D deficiency rickets and drug-induced rickets have been mistaken for child abuse (163). There has been an increase in the incidence of syphilis in females of childbearing age, and congenital syphilis can mimic fractures of child abuse with diaphysitis, metaphysitis, and multiple pathologic fractures in different stages of healing (100). McClain et al. (106) reported a 2-year-old child who died of undiagnosed acute lymphoblastic leukemia. The child had been reported as a possible victim of child abuse because of ecchymosis on the back and extremities. They emphasized that the clinical signs of leukemia, including fever, pallor, petechia, purpura, adenopathy, hepatosplenomegaly, and bone pain, should be sought in children with bruising of unknown origin. Physiologic periostitis (Fig. 7-17), in contrast to lesions from child abuse, is usually bilateral with no excessive uptake of isotope on bone scan (40). The presence of metabolic disease and pathologic fractures does not exclude the possibility of child abuse. Duncan and Chandry (51) reported a 3-month-old girl with multiple fractures associated with rickets who died suddenly at 5 months of age. Child abuse was suspected but not proven. Three years later, evidence of child abuse was found in a subsequent sibling in the same family. Several diseases are

commonly brought up in custodial hearings as alternative possibilities to child abuse to explain trauma findings, and these diseases should be carefully explored in the differential diagnosis.

FIGURE 7-17. A 10-month-old infant with physiologic periostitis of the femurs (*arrows*). This type of x-ray appearance may be confused with fractures of child abuse, but this periostitis tends to be bilateral with a uniform appearance in contrast to multiple fractures in different stages of healing seen in battered children.

OSTEOGENESIS IMPERFECTA

Undiagnosed osteogenesis imperfecta should always be considered when a child presents with multiple fractures of unknown etiology, but it may be a very difficult diagnosis clinically. Osteogenesis imperfecta due to spontaneous mutation can occur without a family history (123). The so-called hallmark of osteogenesis imperfecta is an intensely blue sclerae, but this feature is consistently present only in type I (137) and may be completely absent in patients with type IV osteogenesis imperfecta (123). Sillence and Butler (138) noted that patients with either type II or III osteogenesis imperfecta may have blue sclerae at birth but the sclerae can become normal by adolescence. The rare type II osteogenesis imperfecta has normal sclerae, but bone abnormalities and osteopenia are severe and early death is likely (123). Blue sclerae may be present in normal young children and can be misleading as a sign of pathologic bone fragility. The presence of abnormal teeth, known as dentinogenesis imperfecta, may be helpful in a diagnosis of osteogenesis imperfecta if the child is old enough for teeth to have erupted. Plain x-ray studies, however, may show long bones of normal density in both types I and IV osteogenesis imperfecta. Another radiographic sign of osteogenesis imperfecta, wormian bones of the skull, is consistently present only in type III and is often absent in types I and IV (123). Some authors believe that the presence of metaphyseal fracture is pathognomonic for child abuse and, therefore, helpful to distinguish abuse from osteogenesis imperfecta (5), but other authors (45,123) believe that there is no particular fracture pattern that renders the diagnosis of osteogenesis imperfecta likely. Patients with osteogenesis imperfecta tend to bruise to excess, which simulates lesions of child abuse (135), and sudden infant death has also been recorded in patients with undiagnosed osteogenesis imperfecta (119).

Sometimes, when the diagnosis of osteogenesis imperfecta cannot be made on clinical grounds, the diagnosis can be made by biochemical assay. Gahagan and Rimsza (60) stated that 87% of patients with osteogenesis imperfecta have abnormal procollagen that can be detected by current techniques. A skin biopsy is performed for fibroblast culture, and fibroblasts are assayed for both abnormally low levels of procollagen and primary abnormal procollagen (27). Steiner et al. (146) reported that over a 4-year period, 48 patients were referred to them for collagen analysis to rule out the presence of osteogenesis imperfecta in cases of suspected child abuse. Only six of these children had abnormal collagen test results, and in five of those six patients, the diagnosis of osteogenesis imperfecta could have been made on clinical and radiographic grounds. They concluded that routine collagen biochemical testing for osteogenesis imperfecta is unwarranted in these children and collagen analysis should be reserved for the rare instances when diagnostic uncertainty persists in cases of suspected child abuse.

Even when a child has osteogenesis imperfecta, fractures may be due to abuse. Knight and Bennett (93) reported on a young child with osteogenesis imperfecta whose abuse could not be proved until linear bruising of the face suggestive of slapping was documented.

Temporary Brittle Bone Disease

In 1993, Patterson et al. (123) described 39 patients with a variant of osteogenesis imperfecta that they described as a temporary brittle-bone disease in which fractures were limited to the first year of life and then there was spontaneous improvement. These patients presented with vomiting, followed by diarrhea, anemia, hepatomegaly, episodes of apnea, neutropenia, and edema. The most common x-ray findings were metaphyseal corner fractures, rib fractures, diaphyseal fractures, periosteal reaction of long bones, expanded costochondral junctions, and delayed bone age. Only 31% of patients had osteopenia on x-ray study. They suggested that a self-limiting period of copper deficiency was the cause of this problem, but limited serum copper assays were inconclusive. Other authors (4,6,36) doubt the existence of “temporary” brittle-bone disease because of the rarity of fractures associated with proven copper deficiency syndrome. Judicial authorities (34,103,160) have commented that although one patient in the series of Patterson et al. had injuries due to child abuse, this fact was not included in the report, and they had concerns that assumptions proposed by medical experts that injuries may be considered solely due to disease may inhibit full investigation of such injuries by civil authorities and place children at risk for further abuse.

Sudden Infant Death Syndrome

In sudden infant death syndrome (SIDS), there is a distinct possibility of child abuse (56), but other causes of sudden death must be excluded. Byard et al. (26) reported a 5-month-old girl who died suddenly because of spontaneous subarachnoid hemorrhage from undiagnosed Ehlers-Danlos syndrome. They recommended collagen analysis in patients with unexplained multifocal spontaneous hemorrhages to exclude this rare syndrome. Sperry and Pfalzgraf (144) reported a 9-month-old infant whose diagnosis of sudden infant death syndrome became uncertain when postmortem x-rays showed healing symmetric clavicular fractures and a healing left medial humeral epicondyle fracture. Subsequent investigation showed that the child had undergone “chiropractic” manipulation 4 weeks before death by an unlicensed therapist to correct “shoulder dislocations,” and the parents were exonerated of abuse charges.

Accidental Trauma

In considering the differential diagnosis of child abuse, accidental trauma should always be considered. The orthopaedist, however, should be comfortable with the diagnosis of accidental trauma only when the acute injury is brought promptly to medical attention and has a plausible mechanism of injury and there are no risk factors for child abuse.

TREATMENT AND LEGAL REPORTING REQUIREMENTS

Once child abuse is recognized, the first step in treatment is hospital admission. This is therapeutic in that it places the child in a safe, protected environment and provides the opportunity for additional diagnostic work-up and, more importantly, investigation of the family's social situation by appropriate personnel. In university settings, multidisciplinary teams often are available to evaluate and treat such children, but in other circumstances, the orthopaedist may be primarily responsible for coordinating both evaluation and treatment. Court custody may be required for children of uncooperative families who refuse admission, and hospitalization should be continued until a full investigation is completed by the appropriate child protective services. In the United States, the physician is required by law to report all suspected child abuse to appropriate child protective services or legal authorities. When the reporting is done in good faith, the physician has immunity against criminal or civil liability for these actions, but only in three states—Ohio, California, and Alabama—is this protection extended to include absolute immunity (38). The distinction is critical. Absolute immunity means that the physician who reports suspected child abuse cannot ever be held for damages sought by families for allegedly inappropriate reports of child abuse or neglect. The granting of absolute immunity, even for physicians, is not encouraged by the American legal system because in theory it would protect individuals who make false reports of child abuse in order to harass families and would deprive the injured parties their legal right to seek damages for harmful actions. In contrast, physician immunity based on good faith reporting of suspected child abuse is contingent on the physician having a reasonable belief that abuse or neglect has occurred. Although in theory this protection seems to be quite adequate, recently there has been a dramatic rise in the number of lawsuits filed by families seeking damages for alleged, unfounded reports of child abuse and neglect. Although it is true that by the time these lawsuits are eventually resolved, physicians have almost never been held liable for good faith reports of child abuse; in a substantial number of these cases, the physicians first lost at trial level before eventually prevailing at appeal. Considerable expense, frustration, and loss of time can be experienced by the physician in defending against

such allegations as the families and their attorneys pursue multiple forms of legal theories in court in an attempt to evade the immunity provisions (38). On the other hand, failure to report suspected child abuse may expose the physician to charges of malpractice (1). All states require physicians to report not only cases of definitive child abuse or neglect but also cases when abuse is just suspected or is considered a possibility. Physicians have been held liable for damages for their negligence in failing to diagnose child abuse when the child subsequently was reinjured by more abuse, and ironically, the parents also may be able to collect additional compensation for losses due to medical expenses. In order for families to be successful in these lawsuits, they must be able to prove that the failure to make the diagnosis of child abuse was negligent and that, had the diagnosis been made, steps would have been taken to protect the child from additional abuse. Although the probability of a physician being held liable under such circumstances is low, the amount of damages can be high if the family does prevail when the child has suffered permanent sequelae (38).

After admission, the orthopaedist proceeds with care of the child's musculoskeletal injuries and coordinates various medical consultations. There should be frequent communications with child protective services to stay current with the results of their investigations. Recommendations for disposition of the child after completion of medical treatment may be a group decision through a multidisciplinary team or, more often, the decision of the primary physician, who may be the orthopaedist. Final disposition choices may include return to the family, return to a family member who does not live in the child's home, or placement in a shelter or a foster home setting. The risk of reinjury and death is significant if the abused child is returned to the unsafe home, so the orthopaedist must strongly support child protective services in custodial actions when it is believed that the child's injury truly occurred from abuse at home. Not only must the definitive diagnosis of child abuse be documented in the chart but a separate notarized affidavit may be necessary. Commonly, custodial actions by child protective services are reviewed in a court hearing in a matter of weeks, and the physician is likely called to testify in the hearing. Criminal charges also may be brought against the perpetrator of the child abuse, and the physician likely also serves as a witness in these proceedings.

THE COURTROOM

The orthopaedist fills a dual role in the courtroom in child abuse proceedings. First, he or she serves as a material witness whose testimony is confined to the physician's personal involvement in the legal matter. The testimony may include clarification to the court of information contained in progress notes in the chart or of other past documentation. As a material witness, the physician, like the layman, cannot render opinions about the facts as stated during his or her testimony. In addition, however, the physician may also be sworn in as an expert witness (64). This is an individual considered by the court to have special knowledge and experience that qualifies him or her to render opinions about certain facts presented in the courtroom. The limits of the physician's expertise are usually defined by the attorneys in court before the testimony of the expert witness.

Physicians usually are reluctant to testify in court for many reasons. The courtroom is an unfamiliar setting for almost all physicians, and the adversarial nature of the American law system makes it a hostile environment. In the courtroom, the perception of truth is just as important as the truth itself, and opposing attorneys will search for inconsistencies in the testimony or unfamiliarity with the record to discredit the physician witness. To avoid being a poor witness, the orthopaedist must meticulously prepare to give testimony.

The orthopaedist preparing to testify in a child abuse case should begin with a thorough review of the child's medical records and a review of recent medical literature on the subject of child abuse (64). Often, there is a pretestimony discussion with child protective services counsel in family court cases or the district attorney's office in criminal cases. Such meetings should preferably be in person, and the orthopaedist's professional training and expertise are examined to determine whether he or she may serve as a material witness, an expert witness, or both. The attorney should be provided the orthopaedist's curriculum vitae, and another copy should be made available to the court. If the orthopaedist is to serve as a material witness, the factual information of the case as well as the limitations of the physicians' knowledge are discussed, as are questions that may be posed during testimony. Orthopaedists functioning as expert witnesses should indicate relevant information that should be provided through questioning during testimony. In addition, anticipated testimony from any opposing expert witness and cross-examination questions from the opposing attorney should be discussed. The opposing attorney also may request an informal pretestimony meeting. The orthopaedist should request a list of questions that will be asked in this session ahead of time and request that both the prosecution attorney and the opposing attorney be present during the session, which is often recorded. The next step may be a deposition in which both attorneys question the witness under oath to “discover” the testimony that the witness will provide in court. The primary purpose for a deposition in the discovery process is to keep attorneys from later being surprised in court by testimony of witnesses (35). Preparations for depositions should be meticulous. Any testimony the physician gives during the deposition will be recorded, and later in court, any inconsistencies between testimony and prior depositions will be vigorously attacked by attorneys in cross-examination. Depositions are rarely used in criminal prosecutions (64).

A subpoena is issued requiring a physician witness to appear at the courtroom at a certain time, but often there may be hours of delay before the testimony actually begins. Through prior arrangements with the attorney, the orthopaedist may be placed “on call” if he or she works within a reasonable distance of the courtroom and can be available a short time before their actual testimony is needed. The physician has no legal right to such treatment and must be prepared to honor the exact conditions of the subpoena if alternative arrangements cannot be made. If significant delays are encountered to giving testimony and the attorneys are not responsive to physician hardship, then the orthopaedist should contact the judge directly to remedy the situation (35). In the courtroom, the orthopaedist should be conservatively dressed and appear attentive, competent, poised, and at ease (35,64).

Once called to the stand, the orthopaedist is sworn in and identified. Next follows qualification, direct examination, and then cross-examination. In the qualification process, the attorney asks the physician fairly detailed questions about the orthopaedist's training and background to establish whether he or she is a credible witness (64). The attorney wishes to impress the judge or jury with the orthopaedist's qualifications as a witness, whereas the opposing attorney may challenge the witness with questions to cast doubt on his or her expertise (35). During this phase, the attorneys also may establish the limits of the physician's expertise as an expert medical witness. Next, the attorney will proceed with direct examination. A series of questions are asked that aim at developing a logical and progressive line of thought leading to a conclusion (35). In child abuse cases, in particular, the testimony will lead to the fact that the abuse has occurred and that it has been appropriately diagnosed. In addition, the physician expert witness may be asked to give an opinion of the risk for subsequent abuse if the child returns to the home where the alleged abuse occurred. Almost never will the physician witness be asked about the guilt or innocence of the caretaker accused of abuse, but the orthopaedist in certain circumstances will come close to answering the “ultimate question” (35), by testifying about a child's statement of history if it identifies the abuser. Some states, however, restrict such testimony. In Maryland, a physician may not testify regarding any disclosures made by a child abuse victim unless the disclosure is admissible under a recognized exception to the rule prohibiting hearsay evidence (46). The orthopaedist should ask about any possible restrictions on his or her testimony with the attorney in pretrial discussion. In testimony, the orthopaedist will want to use the courtroom setting to advocate for the safety and well-being of the child (64). Questions regarding medical findings will often be prefaced in the courtroom by the words “reasonable medical certainty,” a term that is poorly understood by most physicians. Chadwick (35) offered a definition of reasonable medical certainty as “certain as a physician should be in order to recommend and carry out treatment for a given medical condition.” He offered an example that the certainty for the diagnosis and treatment of leukemia must be much higher than that for diagnosis and treatment of a viral upper respiratory infection.

During testimony, the orthopaedist's words should be carefully chosen and should be understandable by a lay jury. Testimony should be objective, honest, and thorough (64). Attorneys may frame questions in ways that are difficult to understand, and the orthopaedist should not hesitate to ask the attorney to clarify a question (35). Answers should be brief, without volunteering extra information, but the perception listeners will have of the answers should be carefully considered by the orthopaedist. In particular, attorneys may phrase yes or no questions that could place misleading words in the mouth of the orthopaedist. In such situations, when neither response is appropriate, the orthopaedist should answer in a sentence that provides an accurate answer (64). Physicians are considered expert to the court because they have more information than is usual and customary, and they are to provide the judge and jury with an unbiased expert opinion (64). Language should be straightforward, and visual aids may be used in providing clear testimony. The expert should use testimony as an educational process for the court, in which the common experience and knowledge of the jury is used to build understanding with common sense explanations of medical findings (35).

Cross-examination by the opposing attorney follows direct examination. The opposing attorney's role is to challenge the material presented by the physician witness to protect the defendant (64). This may involve an attempt to bring into question the physician's credibility, the medical record, the physician's training or expertise, or the physician's objectivity or composure and clarity of thought before the jury (64). Attorneys may accomplish this by finding inconsistencies with prior statements, asking leading questions as well as questions that allow only certain desired answers, and minimizing physician qualifications (35). The attorney may frame a question that contains certain elements that the physician agrees with and others that are misleading, and the question will often end with “Isn't that so, doctor?” The physician witness should be firm in answering such questions, clearly stating what in the question they agree with and what they do not. It is also common to encounter questions from attorneys based on hypotheses that are extremely unlikely, and the physician needs to point out that unlikelihood (35). Part of the strategy of aggressive cross-examination is to provoke the physician into arguments or unprofessional behavior that could discredit the physician or his or her testimony before the court. In particular, juries will allow aggression on the part of the attorney, but they expect physician witnesses to respond professionally, even under extreme duress (64). Inexperienced potential physician witnesses can prepare themselves by either watching trials or participating in mock trials (35). Brent (24) assembled an excellent series of vignettes of expert medical witness case studies in court and provided detailed instructions with regard to the responsibilities of such experts. Both

redirect examination and recross-examination may follow cross-examination at the discretion of attorneys, but usually these procedures are very short (35).

Disposition Following Custody Hearings

After a hearing or trial, the child historically either remained in the protective custody of the state or was returned to the home, but the danger of further abuse exists in both situations. In a study of 206 care and protection petitions brought to the Boston juvenile courts (114), 31% were dismissed with return of the child to the parents. During a 2-year follow-up of these dismissed cases, 29% had reports of further mistreatment and 16% were returned to court under another care and protection petition. One risk factor identified by the study was a previous appearance in court. Half of dismissed cases with this risk factor returned to court again. Of the children ordered permanently removed from parental custody by the court, 6% returned to court with evidence of further abuse by another caretaker. Another alternative pathway of custody is gaining popularity with the court systems in which the abused child is released to the custody of a relative of the family with consideration given to the wishes of the parents or other prior custodians of the child. Although in theory this approach may help preserve the integrity of the family unit, the child may still be in danger in this sort of arrangement. Handy et al. (65) of the Pediatric Forensic Medicine Program of the Kentucky State Medical Examiner's Office noted evidence of recurrent abuse 2 to 9 months after the original injury in six patients out of 316 referrals to the program. They emphasized that in two of these cases, the child was in protective custody of a family relative when the original perpetrator was allowed unsupervised access to the child in violation of court order. One 6-month-old infant placed in the custody of a grandmother was bent backwards by the original perpetrator until his head touched his feet, sustaining a thoracic spinal fracture with fatal outcome. Another 4-year-old was in the custody of her grandmother when the child's mother gained unauthorized access to her and the child was reinjured with a burn on the face with an iron. It is possible that such reinjuries occur because either the close relatives of child abuser may not believe that the caretaker committed the original abuse or the relatives are under emotional pressure to allow the caretaker to have access to the child in spite of court order. It is hoped that the court systems can strike a balance between the need to preserve the family unit and the need to protect the child from further abuse.

PREVENTION OF CHILD ABUSE

Prevention of child abuse lies in early intervention. Home visitor programs can contact a mother immediately after the birth of her child and arrange for a visit in which the mother's parenting strengths are assessed. Parents requiring additional support are linked to community agencies and family resources (134,142). Such support seems to enhance parent and child interactions, and mothers report a diminished need to punish or restrict their children. Antivictimization programs teach children certain concepts believed to facilitate self-protection, such as identification of strangers, types of touching, saying “no” to inappropriate advances, and telling someone about inappropriate behavior. Parenting education offers instruction in specific parenting skills such as discipline methods, basic child care, infant stimulation, child development, education, and familiarity with local support services and introduction to other new parents in the community (156). Continuing abuse can be prevented by the orthopaedist's prompt recognition of child abuse in the emergency department and appropriate intervention.

The most important issue in dealing with child abuse is to help both the child and the family through early recognition of the problem and appropriate therapeutic measures by all health personnel. The failure to diagnose child abuse may result in serious injury to or death of the child.

FRACTURES AND DISLOCATIONS OF THE HAND AND CARPUS IN CHILDREN

THOMAS J. GRAHAM
PETER M. WATERS

OVERVIEW OF PEDIATRIC HAND INJURIES

For the growing child, the hand is the primary instrument of protection, social interaction, and discovery. Therefore, it is not surprising that it remains one of the most frequently injured parts of the body in children. The recognition and appropriate treatment of these injuries have immediate and long-ranging effects on the child's ability to participate in society.

Epidemiology

Overall Incidence

Several factors combine to make the pediatric hand vulnerable to injury. Among these are the usage pattern of this relatively exposed appendage and the child's curiosity about the surrounding world. Youngsters are often profoundly ignorant of the dangers in their environment, even at home, where most injuries occur (18,104,234,235). This is why injuries of the hand and wrist are among the most common in the skeletally immature population (88,104,232). They account for up to 25% of fractures recorded in pediatric populations (Table 8-1).

Peak age: 13 years
Annual incidence: 26.4 per 10,000 children
Percentage of all pediatric emergency patients: 1.7%
Right side incidence equals left
Male incidence is greater than female incidence
Most common areas
  Nonphyseal: distal phalanx (crush)
  Physeal: proximal phalanx
the index and small fingers are more commonly fractured

TABLE 8-1. INCIDENCE OF PEDIATRIC HAND INJURIES

Biphasic Distribution of Pediatric Hand Fractures

Fractures of the hand have a peak incidence in the adolescent age group. The most common mechanism of injury in this age group is from participation in sports. The second peak is in the toddler age group secondary to crush injuries (12,70,104,127,234,235).

The prevalence of these injuries increases sharply after the eighth year 104,234,235). This may be due to the changing balance between injury-resistant cartilage and bone in the maturing hand, and the fact that children participate more aggressively in contact sports around this age. The number of hand fractures in children peaks around age 13, which coincides with adolescents in organized contact sports (Fig. 8-1).

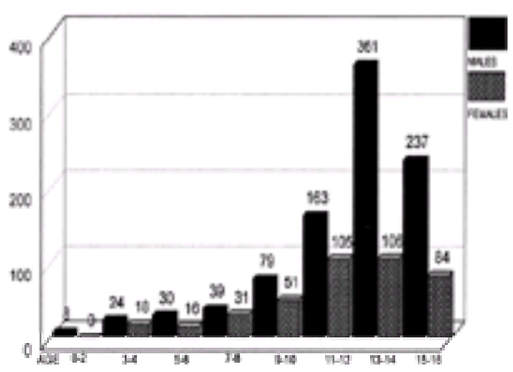

FIGURE 8-1. Total number of fractures of the hand, 1970–1975, Malmo, Sweden. (Reprinted from Landin LA. Fracture patterns in children. *Acta Orthop Scand Suppl* 1983;202:54; with permission.)

At-Risk Population

Worlock and Stower (235) conducted a true incidence study of pediatric hand fractures in Nottingham, England, by carefully defining the at-risk population. They projected an annual incidence of 26.4 fractures per 10,000 children. Bhende et al. (18) reported their experience in a busy pediatric emergency department in Pittsburgh, Pennsylvania. A total of 27,294 patients were seen in a 6-month period at their center, of which 464 (1.7%) had a final diagnosis of “hand injury.” Eighty-seven patients sustained 92 fractures. Those sustaining skeletal trauma were significantly older than the rest (11.5 years vs. 8.25 years).

Incidence of Specific Fractures

There is disagreement about which is the most common fracture in the child's hand. Some researchers cite the distal phalanx crush injury as the most frequent (88); others recognize the Salter-Harris (S-H) II fracture of the proximal phalanx base (104,234,235). Many pediatric hand injuries occur about the metacarpophalangeal (MCP) joint (50,214). Dislocations of the pediatric hand are relatively uncommon injuries. The MCP joint is the most commonly dislocated joint in the immature hand (84,130).

Fractures of the phalanges outnumber metacarpal fractures. The right and left hands are equally affected by skeletal trauma. The border digits (index and small fingers) are the most commonly injured rays (18,104,234,235). More boys than girls present with hand fractures.

Incidence of Physeal Fractures

Pathologic forces may be transmitted through the physis in a child's hand, because this often is the path of least resistance. Injuries involving the physis are less common than extraphyseal fractures. The prevalence of physeal injuries in the hand varies from 10% to almost 40% in the reported series (104,127,138,198,234,235). S-H II fractures predominate in all reports. The proximal phalanx is the most commonly injured single bone, involved in about 70% of patients. The small and thumb rays are the most commonly injured (roughly 40% and 30%, respectively) (104).

Athletic Injuries

Second to the home, playing fields and school settings are the most common sites of injuries for children. American football is the predominant contributor to athletic hand injuries. Skiing is well known for causing ulnar collateral ligament (UCL) injuries, or the bony equivalent, at the thumb MCP joint (21,37,76). Pediatric hand injuries have been reported in almost every sport, including boxing, swimming, soccer, and gymnastics (40,76,85,104,138,182,226,240).

Practical Anatomy of the Immature Hand

Adults and children have different patterns of hand injury because of different usage patterns and the unique character of the child's skeleton and soft tissues. Knowledge of physeal architecture, soft tissue origins and insertions, and the influence of the strong ligaments and the periosteum is helpful in recognizing and treating children's hand fractures. In this section, the skeletal articular anatomy of the immature hand is described, with special emphasis on structural relationships and their influence on mechanics. In later parts of this chapter, the relevant pathologic anatomy is covered as specific injuries are discussed.

Osseous Anatomy

Phylogenetically, there are potential epiphyses at both the proximal and distal ends of all the tubular hand bones. However, secondary ossification centers develop only at the distal ends of the metacarpals of the index, long, ring, and small rays, and proximally in the thumb. Conversely, the secondary centers of ossification are manifested only at the proximal ends in all digits (95,211).

Secondary Ossification Centers

In boys, the proximal phalangeal secondary ossification center appears at 15 to 24 months and fuses at 16 years (Fig. 8-2) (95,211). In girls, the appearance and fusion occur earlier, at 10 to 15 months and 14 years, respectively. The appearance of the secondary ossification centers of the middle and distal phalanges lags behind by 6 to 8 months, but fusion occurs at the same time as that of the proximal phalanx. The epiphyses of the small finger phalanges appear later than those of the other triphalangeal digits (index, long, and ring fingers).

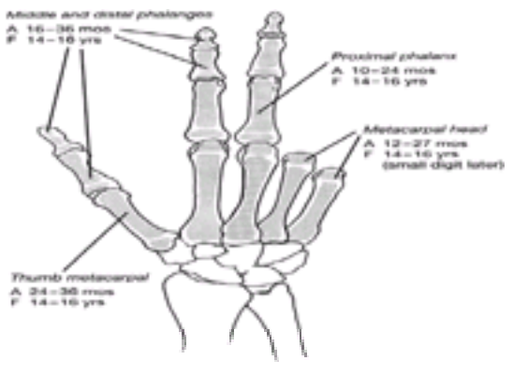

FIGURE 8-2. Appearance of secondary ossification centers *(A)*. Fusion of secondary centers to the primary centers *(F)*.

At the metacarpal level, the secondary ossification centers appear distally in the index, long, ring, and small rays at 18 to 27 months in boys and at 12 to 17 months in girls. The proximally located thumb metacarpal secondary ossification center appears 6 to 12 months after its counterparts in the fingers. These secondary centers fuse at the metacarpal and phalangeal levels at the same time, about 14 to 16 years.

Physeal Anatomy

The microscopic anatomy of the physis and its influence on fracture geometry have been the focus of intense study. The zones of the physis have distinct morphology and molecular/chemical composition that contribute to the unique biomechanics of fracture propagation in the skeletally immature patient (31). Although there is an expanded discussion in Chapter 5, some characteristics of physeal injury specific to the hand are presented here.

The zone of chondrocyte hypertrophy (zone III) is the least resistant to mechanical stresses. It is devoid of the inherent stabilizing properties of collagen maintained in juxtametaphyseal zones I and II or the calcium present in zone IV (88,215). Therefore, the fracture often involves zone III as the path of least resistance.

Near skeletal maturity, the irregularity of the physeal zones increases (31). Thus, a fracture line may actually be transmitted through several zones. This variable path through irregular topography may contribute to the phenomenon of partial growth arrest seen with fractures involving the physis.

Furthermore, the pattern of physeal injuries appears to be somewhat age dependent. Intraarticular epiphyseal fractures (S-H III or IV) are more prevalent as the child nears skeletal maturity; S-H I and II fractures that leave the epiphysis intact are more likely to occur in younger patients (90,232).

The high level of metabolic activity about the physis is fueled by a rich blood supply that is particularly well suited to resist injury and combat future growth disturbance. The generous perfusion of the physis and epiphysis from both periosteal and endochondral vessels probably contributes to the maintenance of normal growth patterns after fracture. The ability of these vessels to maintain blood supply even after significant displacement of fractures has been consistently demonstrated.

Pseudoepiphyses and Double Epiphyses

A persistent expression of the distal epiphysis of the thumb metacarpal is called a pseudoepiphysis (97). The pseudoepiphysis appears earlier than its standard counterparts, then fuses rapidly. By the sixth or seventh year, it has been incorporated and is inconspicuous. Pseudoepiphyses also have been noted at the proximal ends of the finger metacarpals, usually of the index ray. Its only clinical significance is that it must be differentiated from an acute fracture (Fig. 8-3).

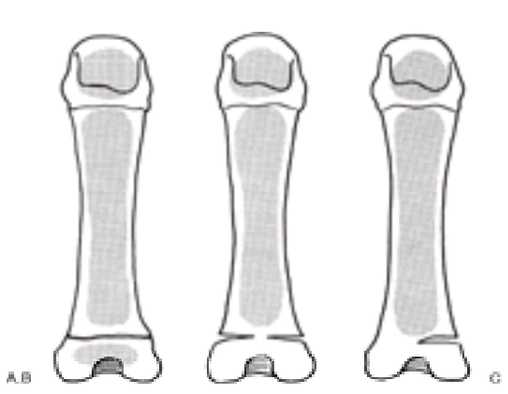

FIGURE 8-3. Abnormal epiphyseal appearance. **A:** Double epiphysis. **B:** Pseudoepiphysis. **C:** Notched epiphysis.

A “double epiphysis” can be seen in any bone of the hand, but these anomalies are more common in the metacarpals of the index finger and thumb. There are variable expressions of the double epiphysis, but the true entity must be considered only when a fully developed growth mechanism is present on both ends of a tubular bone. The double epiphysis must be delineated from the pseudoepiphysis or metaphyseal “notching” (57,97,221,233).

The double epiphysis is usually seen in children with other congenital anomalies, but its presence does not appear to influence bone growth appreciably. When fractures occur in bones with a double epiphysis, growth of the involved bone appears to be accelerated (233). Periphyseal notching can be confused with trauma or the double epiphysis. The location of the notches can coincide with the physis or may be slightly more distant from the epiphysis. Notching is a benign condition that should not influence the structural properties of the bone to a clinically significant level (233).

Soft Tissue Anatomy

The material strength of the child's soft tissues to withstand tensile forces often exceeds that of the adjacent physis and epiphysis (156). For this reason, ligament ruptures and tendon avulsions occur less often in children than physeal or epiphyseal fractures.

Knowledge of the relationships between the bony elements and supporting soft tissues in the pediatric hand has been enhanced by cadaver dissections of skeletally immature specimens (24,102). The collateral ligaments, volar plate, and mechanically weak extensors provide little protection for the physis, because of the relative paucity of supporting structures aligned to resist these forces. The physes are unprotected by the collateral ligaments, volar plate, and mechanically weak extensors. The flexor tendons provide only a modicum of protection, and also may propagate the fracture through the physis, especially in the terminal phalanx (196).

Tendons

As a rule, extensor tendons insert onto epiphyses. The terminal tendon of the digital extensor mechanism and the extensor pollicis longus both insert on the terminal phalangeal epiphyses of their respective rays. The central slip of the extensor digitorum communis terminates onto the dorsal aspect of the epiphysis of the middle phalanx. Likewise, the extensor pollicis brevis inserts onto the epiphysis of the proximal phalanx of the thumb.

The thumb abductors—the abductor pollicis longus and brevis—have more broad-based insertions onto the epiphysis and metaphysis of the first metacarpal. The multiple slips of the abductor pollicis longus vary in number and have insertions onto the bone, capsule, and fascia of the thenar eminence.

The digital flexor tendons—the flexor digitorum profundus and the flexor pollicis longus—insert at the metadiaphyseal region of their respective terminal phalanges. The flexor digitorum superficialis inserts onto the central three fifths of the middle phalanx.

Collateral Ligaments

Interphalangeal

At the interphalangeal joint level, the collateral ligaments originate from the collateral recesses of the phalangeal head, span the physis, and insert onto both the metaphysis and epiphysis of the middle and distal phalanges (Fig. 8-4). This accounts for the rarity of lateral S-H III injuries at the interphalangeal joints. The collaterals also insert onto the volar plate, which also spans the interphalangeal joints. This three-sided box protects the physes and epiphyses of the interphalangeal joints from laterally directed forces (50).

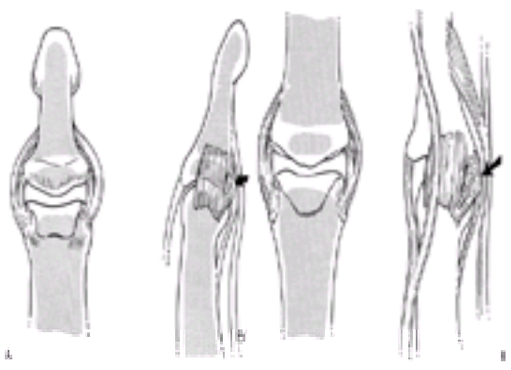

FIGURE 8-4. The anatomy of the collateral ligaments at the distal **(A)** and proximal **(B)** interphalangeal joints. The collateral ligaments at the interphalangeal joints originate in the collateral recesses of the juxtaepiphyseal region and insert into both the metaphyses and epiphyses of their respective middle and distal phalanges. Additional insertion into the volar plane (*arrows*) is seen at these levels.

Metacarpophalangeal Joint

At the MCP joint of the fingers, the collateral ligaments originate from the metacarpal epiphysis and insert almost exclusively onto the epiphysis of the proximal phalanx (Fig. 8-5). This anatomic arrangement accounts for the frequency of lateral S-H III injuries at the MCP level. Some fibers may originate from the distal metaphysis of the metacarpal, but this represents only a minor and variable component of the ligament's substance. The ligamentous anatomy about the thumb MCP joint most closely resembles that of the interphalangeal joints because of its growth center arrangement.

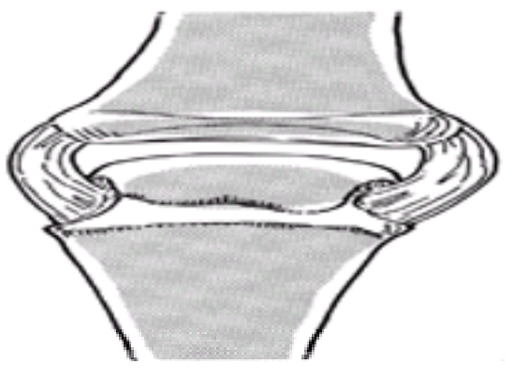

FIGURE 8-5. The collateral ligaments at the metacarpophalangeal joint both originate and insert almost exclusively on the epiphyseal regions of the metacarpal and the proximal phalanx.

The anatomy of the supporting structures at the MCP level accounts for the high percentage of S-H II and III fractures at this level. The physis is relatively unprotected by soft tissue restraints, and therefore must rely almost solely on the inherent stability of the physis to resist fracture forces.

Other Soft Tissues

Volar Plate

The volar plate, a stout stabilizer of the interphalangeal joint and MCP joint, is particularly well suited to resist hyperextension forces. Its origin is from the volar metaphysis of the respective proximal digital segment (Fig. 8-4B). The volar plate inserts onto the epiphysis of the distal segment. The plate itself receives insertional fibers from the accessory collateral ligaments, which are best developed at the proximal interphalangeal (PIP) joint.

Periosteum

Little had been written about the specific role of the periosteum in the stabilization of fractures in the tubular bones of the hand. Because it is so well developed in the child's hand, it can be a significant asset or liability in fracture management. It can minimize displacement of torsional fractures of the diaphysis and may aid in maintaining the stability of other reduced fractures. Conversely, the thick periosteum can become interposed between displaced fracture fragments, thus preventing an effective closed reduction.

Evaluation of Pediatric Hand Injuries

Unique Challenges

Many factors make the injured child uncomfortable, including pain, the novel surroundings, and “white coat” fear. He or she may temporarily refuse to offer either the injured or uninjured hand for examination. Patience and minimizing the contributors to anxiety are essential. The child's hand posture and movements can be observed to gain clues about the location and severity of the injuries by watching the child interact with the environment. In addition to performing a standard, comprehensive examination of the upper extremity, nontraditional methods of assessment may be needed in children, such as an assessment of tendon function by having the child grasp the examiner's pen. It often is helpful to examine the uninjured hand first to familiarize the child with the techniques of examination.

Many factors may be at work to make interaction with the involved adults another obstacle to effective examination. These range from guilt over the injury to the rare child abuse issues. Calming the adults pays dividends: more information can be gained, and a cooperative parent can help the physician communicate with the child.

Tissues Are Unique

Small Structures

The hands of the child are much smaller than those of the examiner, making precise palpation and some diagnostic maneuvers difficult.

Loose Areolar Tissue

The loose areolar tissues and generous fat of the child's hand, especially on the dorsal aspect, can hide significant deformity and swelling.

Physiologic Hyperelasticity

Many children maintain a physiologic hyperelasticity that would be judged pathologic in most adults. However, joint stability and proper tracking of congruous articulations should not be affected by this. Therefore, it is important to conduct a comparison examination of the contralateral side when injury to a stabilizing structure is being considered.

P>***Clinical Examination***

The examination begins immediately on entering the room, when the child's level of comfort, hand posture, and extremity use pattern has not been altered by examination.

Basic Examination

The physician should look for swelling, ecchymosis, deformity, and obvious open injuries. The uninjured hand has a normal cascade of semi-flexed digits; deviation from this posture may indicate injury. For examples, digital flexor tendon lacerations or malrotated fractures interrupt the cascade.

Palpation for tenderness should be anatomically specific to increase diagnostic accuracy. Another valuable diagnostic tool is osseous percussion to assess for fractures. However, it is best to defer these potentially painful maneuvers to the later stages of the examination.

Dynamic Evaluation

Range of Motion. Range of motion should be measured and recorded. The integrity of extrinsic flexor and extensor musculotendinous units can be assessed by

observing the excursion of the digits with wrist flexion and extension (the tenodesis effect). The digits should extend with wrist flexion and flex as the wrist is extended.

Persistent limitation of active motion in a child usually means that significant bony or soft tissue injury is present. Stability of each joint in question should be assessed in a systematic fashion. Collateral ligament integrity should be checked by stressing the MCP and interphalangeal joints in both 30 degrees of flexion and full extension. If the amount of deviation resulting from stress on a particular joint is markedly different from the adjacent digit or the same digit on the contralateral side, the stabilizing structures may be injured. Likewise, the quality of the end point determined on stress examination can be an important clue to the degree of tissue disruption.

Volar Plate Integrity. Integrity of the volar plate is assessed by hyperextension of the joint. A significant increase in passive extension compared with an adjacent or the contralateral digit usually indicates a volar plate injury that requires immobilization in flexion.

Stress Testing of a Dislocated Joint. Stress testing of the relocated joint also is important in determining further treatment. A functional relocation test can be performed to determine the range of motion through which a relocated joint is stable. Active range of motion of the digit is performed by the patient, and the congruence of the reduction can be assessed clinically and radiographically. Motion of the joint should be painless if the anesthetic block has been successful. If the digit is prone to subluxation or redislocation in a narrow range of active motion, the need for operative intervention or long-term immobilization must be considered.

Neurovascular Injury. One clue to possible nerve injury is excessive bleeding at the time of the original injury or during evaluation in the emergency department. Because of the proximity of the digital artery to the digital nerve, there is a high concordance between extensive pulsatile bleeding and laceration of the digital nerve.

Neurologic Evaluation. It is particularly difficult to determine sensory function in a young child. Meaningful objective data are difficult to obtain, and gross observations, such as withdrawal to stimuli, are inadequate grounds on which to base therapeutic decisions. A helpful examination maneuver to assess nerve integrity is the wrinkle test. Immersion of a normally innervated digit in warm water for up to 5 minutes results in corrugation or wrinkling of the volar skin of the tuft. This finding is absent in a denervated digit. The wrinkle test also can be performed simply by observing the digit as it soaks in the solution as part of the preoperative preparation.

Objective sensibility testing requires patient cooperation and maturity. For example, two-point discrimination is a learned test. Techniques to increase its validity would be performance of repeated trials, testing of multiple uninjured digits, and use of the test only in children over 5 years of age. There is no role for pin-prick or sharp sensation testing in a young child.

Sedation and Anesthesia. After nerve function has been adequately assessed and documented, conscious sedation or local anesthesia may be worthwhile to perform reduction maneuvers, assess joint laxity or tendon integrity, explore wounds, and apply splints. If the patient is relaxed and pain free, the opportunity to effect good fracture care is enhanced. The specific protocols for using analgesic agents, conscious sedation, and local or regional anesthesia are discussed in Chapter 3.

Radiographic Examination

Special Considerations

A careful clinical evaluation is the prerequisite for conducting proper radiographic examination. This is especially true in the multiply injured hand, in which careful localization of areas of tenderness or deformity can direct a thorough radiographic assessment. Several imaging factors can make it difficult to obtain information necessary for a correct diagnosis and effective treatment.

Lack of Osseous Detail

Knowledge of the age-specific morphology of the hand and wrist bones is essential. In addition, an appreciation of the relationships of the ossific nuclei to each other can allow recognition of physeal fractures or soft tissue injuries that may produce only subtle widening of the interosseous spaces or small angular variations.

Normal Variants

Irregularities and normal variants are relatively common in the young hand. Imaging of the contralateral, presumably uninjured, side usually is the most effective way to resolve many of the questions that arise in interpretation of the radiographs of a traumatic injury. A familiarity with some of the better recognized variations also helps to determine whether skeletal injury is present. The examiner should not hesitate to consult an atlas of child development and normal radiographic variants (95,211).

Plain Radiographs

Anteroposterior (AP), lateral, and oblique radiographs usually are needed to evaluate the injured hand or digit completely. Oblique views are particularly useful in assessing intraarticular fractures. Specialized views for detailing particular anatomic areas can compliment the standard hand and wrist series.

A common pitfall in treating children's finger fractures is failing to obtain a true lateral film of the injured digit. Overlap of the adjacent fingers must be overcome by isolating the digit or splaying the fingers.

Stress views are now rarely used for evaluation of fractures. With the advent of low-radiation mini-fluoroscopy units, real-time assessment of articular congruity and joint stability throughout a motion arc can be conducted.

Differential Diagnosis

Nontraumatic entities are often interpreted as acute injuries. These entities are rare but may cause swelling, deformity, and limited range of motion.

Congenital

In 1927, Kirner (116) described palmar and radial curving of the terminal phalanx of the small digit distal phalanx that occurred spontaneously between 8 and 14 years of age (Fig. 8-6). This entity can be confused with an acute fracture or epiphyseal separation, but the history, the clubbed appearance of the affected digit, and bilaterality would argue against an acute cause (63). Trigger thumbs in young children are sometimes mistaken for interphalangeal joint dislocations because of the fixed flexion posture of the interphalangeal joint. Attempted reductions are painful and do not resolve the problem. The key diagnostic feature of the trigger thumb is the palpable nodule at the A1 pulley region.

FIGURE 8-6. A and B: A 12-year-old boy presented with incurving of the tip of the right small finger. The anteroposterior and lateral radiographs show radial and palmar incurving of the distal phalanx, characteristic of Kirner's deformity. **C:** Two years later, healing has occurred, but the deformity has persisted.

Thermal Injury

Thermal injury to the growing hand (frostbite, burns from flame or radiation) can cause bizarre deformities from altered appositional and interstitial bone growth. An ischemic necrosis of the physes and epiphyses can result (Fig. 8-7). The clinical result can be manifested by bone width, length, or angulatory growth disturbance due to the unpredictable effect on the growing elements (98,159).

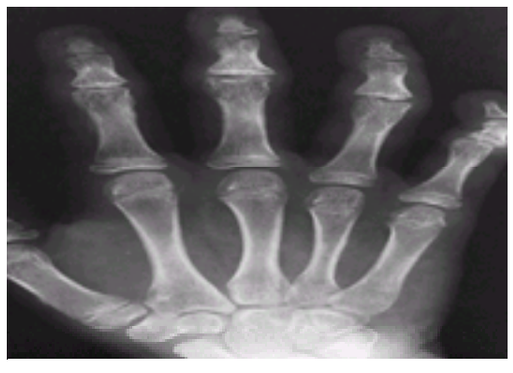

FIGURE 8-7. An 11-year-old girl sustained a frostbite injury to the right hand at age 5 when she lost her mitten. There has been premature fusion of the physis of the middle and proximal phalanges and widening and irregularity of the bases of the shortened phalanges. Although not demonstrated in this photograph, the thumb has been spared, because it is usually enclosed in the hand while the child is exposed to the elements.

Osteochondrosis (Thiemann's Disease)

Epiphyseal narrowing and fragmentation can be a characteristic of Thiemann's disease, thought to be an osteochondrosis of the phalangeal epiphyses. This hereditary entity usually involves the middle and distal phalanges and typically resolves without aggressive treatment, although some permanent joint deformity has been reported in some patients (52,191).

Tumors

Benign ganglia of the wrist and hand may cause limited motion, pain, and obvious swelling. Generally, clinical examination of the ganglion of the affected joint or cyst of tendon sheath is diagnostic. Radiographs are typically normal except for the soft tissue changes.

The rare bone, cartilage, or muscle malignancies of the hand have a much firmer consistency to palpation. Radiographs reveal the bony changes in an osteogenic sarcoma and may demonstrate periosteal reaction in an adjacent rhabdomyosarcoma.

Inflammatory and Infectious Processes

Dactylitis from sickle cell anemia can masquerade as either an infectious or traumatic process. Historical evidence of sickle cell disease in the patient or family and the characteristic fusiform digital swelling indicate this pathology.

The inflammatory arthropathies (juvenile rheumatoid arthritis, scleroderma, systemic lupus) may cause joint effusion or tenosynovitis that can be confused with trauma.

An infectious process often can be mistaken for a traumatic one, but local and systemic evaluation usually makes this distinction evident.

General Principles of Treatment

Nonoperative Management

Most children's hand fractures heal without complications. Many do not require reduction, and brief immobilization is sufficient. Minimally displaced fractures without malrotation can be treated with closed reduction and immobilization for 3 to 4 weeks.

Pain Control

Conscious sedation, careful regional anesthesia, or even general anesthesia should be considered to facilitate reduction and application of immobilization. The choice of anesthestic technique is age dependent. Digital block administered at the level of the metacarpal head frequently is used for fracture reduction in children and adolescents. Axillary blocks, hematoma blocks, and rapid fracture manipulation without anesthesia should be avoided in young children.

Traction

Skin or skeletal traction has little role in the treatment of children's hand fractures. Application of external devices such as finger traps is poorly tolerated in children. Furthermore, it is difficult to find a size match that permits adequate distraction. Skeletal traction is rarely useful in treating fractures of the hand in a child.

Gentle and Prompt Manipulation

The likelihood of iatrogenic physeal injury substantially increases with repeated, forceful manipulations. Likewise, late (more than 5–7 days) manipulation of a periphyseal fracture should be avoided. Prompt reduction is advisable unless anesthesia is contraindicated. In the acute period, swelling is at its minimum, reduction is more easily performed, and immobilization can be more effectively applied. Swelling itself is not an indication to postpone fracture care; fracture reduction is typically the best way to control swelling and deformity.

Postreduction Management

Types of Immobilization

Immobilization is best applied when the child is under the influence of the sedative or anesthetic used for fracture reduction. An appropriate amount of cast padding material should be applied. Too much padding renders the splint or cast ineffective in controlling the reduction, but too little may lead to skin compromise from thermal injury or pressure. The risk of compartment syndrome may be decreased by the use of splints rather than circumferential casts.

For fractures of the phalanges and metacarpals, immobilization of the injured digit with at least one of the adjacent digits is advocated. The axiom “Never immobilize a single digit” should be followed. Below-elbow (short arm) immobilization is acceptable, provided cooperation is reasonable. For more proximal fractures or fractures in very young children (under age 3–5), long arm immobilization is necessary. Children will attempt to “escape,” so long arm immobilization in a “boxing glove” or “mitten” cast is important to prevent loss of immobilization. The use of rigid materials other than accepted casting materials (e.g., tongue blades, aluminum splints,

arm boards) or wrapping the hand and digits around rolls of tape or gauze should be discouraged.

The Safe Position

Like the adult hand, the child's hand should be placed in the correct position for immobilization, the “safe position.” Maximal MCP flexion with extension of the interphalangeal joints places the collateral ligaments at their maximal length and helps prevent contracture. However, the likelihood of MCP joint contracture is small in children.

Follow-up Frequency

Nondisplaced fractures that were simply immobilized can be reevaluated at 3 to 4 weeks when the cast or splint is discontinued. Fractures that required reduction or specialized immobilization should be evaluated weekly to ensure that reduction has not been lost. Because children's hand fractures heal rapidly, close follow-up, especially in the first 7 to 14 days, is necessary to detect displacement before it is too late for closed correction.

Surgical Management

Meticulous Soft Tissue Handling

As in all hand surgery, gentle tissue handling is mandatory. Careful handling of the thick periosteal layer is important, because creation of periosteal flaps, later sutured back anatomically, enhances healing and remodeling. The periosteal layer also provides an excellent cover for implants and is a good sliding surface, allowing smooth tendon excursion.

Preservation of Growth Potential

Careful manipulation of and around the physis is of obvious importance. Excessive tissue stripping at this level should be avoided. Thoughtful consideration of whether the physis needs to be exposed to effect fracture reduction, and whether it should be crossed by an implant, is warranted. The smallest diameter nonthreaded wire that effectively holds the fragments should be used. Wires are left in only 3 to 4 weeks, so they should be left protruding (but protected) for easy removal.

Implant choices must be individualized to the fracture pattern and to the patient's size. Smooth wires, tension bands, and mini-screws are preferred over larger implants in children. For most fractures requiring fixation, smooth wires are the implant of choice.

Postfracture Care

Formalized therapy rarely is necessary in children. Simple liberation from immobilization and instructions to the patient and parents regarding range of motion, strengthening, and activity return usually are sufficient. In rare circumstances (complicated fractures, multiple trauma, or failure to achieve desired functional results in an appropriate time period), formal hand therapy may be indicated. If corrective splinting is to be used, the child and caregivers must be comfortable with its application and use. Serial static splinting may be preferred to patient-adjustable dynamic splints.

Complications

The clinician should not be nonchalant about any aspect of the child's treatment simply because the pediatric hand is so forgiving in its ability to remodel and regain motion. Recognition of the potential pitfalls is important, as is the development of a systematic plan for rectifying complications if they occur.

Pitfalls to Avoid

Failure to Appreciate the Severity of Injury

A complete set of high-quality radiographs should be obtained; with the surgeon accompanying the child to the radiographic suite if necessary. Contralateral views should be obtained as needed, and normal variants identified.

Specific problem fracture patterns (phalangeal neck, intercondylar, osteochondral “slice,” or any malrotated fracture of the tubular bones) need to be recognized to select appropriate treatment.

Inadequate Postreduction Alignment

Radiographs after reduction must be scrutinized for subtle hints of malalignment or associated injuries. The reduced digits should be checked for malrotation by evaluating the plane of the fingernails with the fingers semiflexed or with the tenodesis maneuvers previously described. Restoration of length, particularly in fractures of the metacarpals, is best evaluated with radiographs, but clinical foreshortening of the ray may be the first clue to malreduction.

Overdependence on Remodeling

Although remodeling in the immature skeleton is extensive, it is not a substitute for inadequate treatment (162). Bony remodeling occurs in the AP plane, especially in younger patients and injuries close to the physis. Correction of medial-lateral malalignment is much more limited, except at the MCP and carpometacarpal (CMC) joints, where multiplanar motion exists. Little, if any, rotational remodeling should be performed.

SPECIFIC FRACTURES OF THE PEDIATRIC HAND

Fractures of the Phalanges

Injuries of the Distal Phalanx

The terminal aspect of the digit is among the most frequent sites of injury in children. The distal phalanx and its accompanying soft tissues are relatively unprotected and are offered by the curious child as a first contact with the environment.

Surgical Anatomy

The skin, nail elements, soft tissues, and bone of the distal digit are closely related (Fig. 8-8). The dorsal periosteum of the distal phalanx is the underlying nutritional and structural support for the sterile matrix or ventral nail. The germinal matrix, made up of the dorsal and intermediate nail, is responsible for generating the nail plate. The volar aspect of the distal phalanx anchors the pulp through tough, fibrous septae that stabilize the skin against shear forces. The terminal extensor tendon inserts onto the epiphysis of the distal phalanx. The flexor digitorum profundus bypasses the physis to insert onto the metadiaphysis of the distal phalanx.

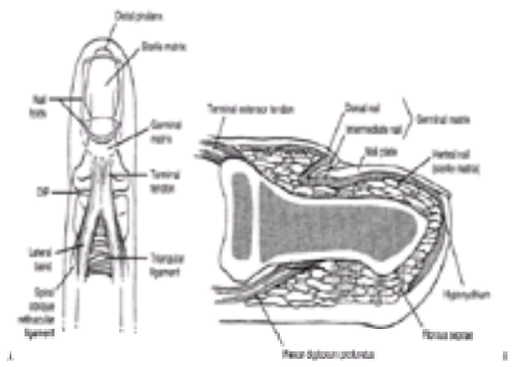

FIGURE 8-8. Anatomy about the distal phalanx. **A:** The skin, nail, and extensor apparatus share a close relationship with the bone of the distal phalanx. Specific anatomic structures at the terminal aspect of the digit are labeled. **B:** This lateral view of the nail demonstrates the tendon insertions and the specific anatomy of the specialized nail tissues.

Mechanism of Injury

The two primary mechanisms of injury about the distal phalanx are crush trauma and hyperflexion force.In a crushed fingertip, the soft tissues are injured and the bone is fractured. Conversely, if violent forced flexion is exerted on the extended distal phalanx, there is a greater potential for bony injury of the dorsal epiphysis.

The spectrum of injury produced by both these mechanisms varies. Many crush injuries result only in minor tissue disruption and need little or no intervention (Fig. 8-9), whereas other injuries may require bony fixation, meticulous nail bed repair, and skin coverage.

FIGURE 8-9. A and B: Crush injury to the fingers of a 4-year-old in which the lacerations were closed by primary repair; only minimal nail bed repair was necessary. Of concern is the depth of the laceration about the germinal matrix tissue. Meticulous repair must be undertaken in this area, as well as at the sterile matrix level.

Mallet injuries result from an axial loading or flexion force applied to the extended tip of the finger. Although the underlying pathology can be variable, the digit usually is flexed at the distal interphalangeal (DIP) joint and active extension is impossible.

Fracture Patterns

Fractures of the distal phalanx can be divided into those that are extraphyseal and those that are physeal (Table 8-2).

Extraphyseal (see Fig. 8-10)
Transverse diaphysis
Longitudinal splitting
Comminuted separations
Physeal
Dorsal mallet injuries (see Fig. 8-13)
Salter-Harris I or II
Salter-Harris III or IV
Salter-Harris I or II joint dislocation
Avulsion of extensor + Salter-Harris fracture
Reverse mallet injuries (see Fig. 8-14)
Avulsion of flexor with bone (jersey finger)

TABLE 8-2. CLASSIFICATION OF FRACTURES OF THE DISTAL PHALANX

Extraphyseal Fractures

Extraphyseal fractures of the distal phalanx are common and can take the form of a simple distal tuft fracture or an unstable diaphyseal fracture underlying a nail bed laceration. They can be divided into three types (Fig. 8-10).

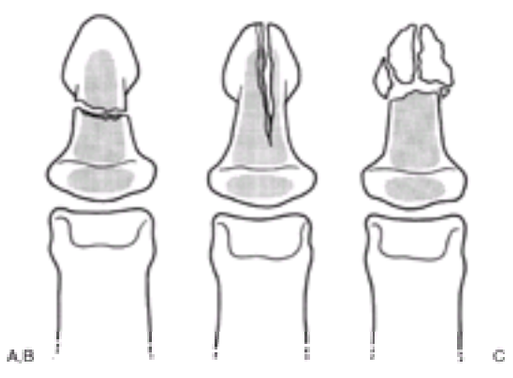

FIGURE 8-10. Three types of extraepiphyseal fractures of the distal phalanx. **A:** Transverse diaphyseal fracture. **B:** Cloven-hoof longitudinal splitting fracture. **C:** Comminuted distal tuft fracture with radial fracture lines.

A transverse fracture (Fig. 8-10A) may occur either at the distal extent of the terminal phalanx or through the diaphysis. Distal fractures are separations between the diaphysis and the most distal extent of the phalanx and also can include a series of radial fracture lines propagating through the distal tuft. Transverse fractures through the diaphysis are almost always associated with a significant nail bed injury.

A longitudinal splitting of the nail tissues and bone (Fig. 8-10B) is much less common. This pattern is the result of excessive hoop stress when the tubular distal phalanx is subjected to crushing forces. The “cloven-hoof” appearance of the fracture is characteristic (Fig. 8-11). The fracture can be completely contained within the shaft or can continue to be propagated through the physis and even into the joint (12).

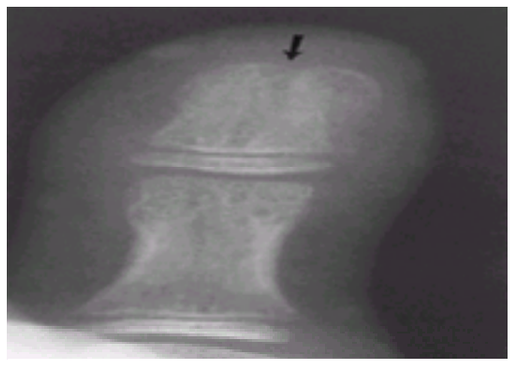

FIGURE 8-11. Extraepiphyseal fracture of the distal phalanx, the cloven-hoof longitudinal splitting fracture. In this patient, the fracture line (*arrow*) does not appear to extend across the physis.

Comminuted fractures take the form of semilunar separations at the distal tuft, or multifragment fractures of the distal diaphysis (Fig. 8-10C and Fig. 8-12). Usually sustained as a result of a crush injury, these fractures are often accompanied by significant injury to surrounding soft tissues of the distal tip.

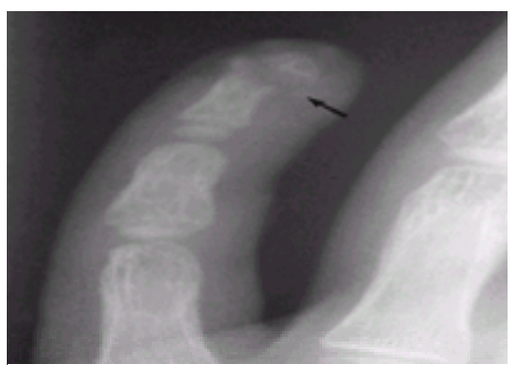

FIGURE 8-12. Extraepiphyseal distal phalanx fracture. The fracture line is slightly distal to the insertion of the flexor digitorum profundus tendon. The accompanying soft tissue disruption (*arrow*) can be appreciated on the radiograph.

A rare but clinically important fracture, sometimes called a reverse mallet injury, can occur in the distal phalanx. This is an avulsion fracture of the volar metaphysis caused by traction on the flexor digitorum profundus tendon. These fractures occasionally extend into the physis. The DIP joint usually is held in neutral or slight dorsiflexion.

Physeal Fractures

The clinical appearance of a physeal fracture resembles that of an adult mallet finger. Four basic fracture patterns involve the physis, and all result in the characteristic flexed posture of the DIP joint.

Fractures often cause the flexed posture of a mallet finger in the child. However, a “typical” mallet injury, avulsion or laceration of the terminal tendon at the DIP or distal phalanx level, can occur in a patient of any age. The mallet equivalent fractures are of four types (Fig. 8-13). An open S-H I or II fracture with flexion of the distal fragment occurs predominantly in young patients (under 12 years of age). The characteristic flexed posture is adopted because of the unapposed flexor digitorum profundus force acting on the distal fragment. Because this fracture is almost always accompanied by nail bed laceration, there is a high risk for infolding or incarceration of the germinal or sterile matrix in the fracture site. This constellation of clinical findings has been labeled a Seymour fracture (195).

FIGURE 8-13. The mallet-equivalent fractures.

In teenagers, a true bony mallet can occur with a displaced S-H III or IV fracture. Instead of an avulsion of the terminal tendon from its distal phalanx insertion, a fracture results in inability to actively extend the DIP joint.

Rarely, an S-H I or II fracture causes extrusion of the epiphyseal fragment (146). This “epiphyseal dislocation” is clinically challenging to diagnose because the distal fragment can remain relatively colinear with the axis of the digit, whereas the displaced epiphysis is dorsally dislocated by the traction of the extensor mechanism.

Even more rarely, the epiphysis separates or is fractured simultaneously, with an avulsion of the terminal extensor from the fragment. This variant may leave the DIP joint unreduced, or the free epiphysis may settle into a reasonable articular relationship at the DIP joint (190). These injuries may be unrecognized initially when they occur before the secondary ossification center appears.

Jersey Finger

This rare injury causes an inability to actively flex the DIP joint. Forced extension of the flexed DIP joint can result in either a bony injury or a soft tissue disruption involving the insertion of the flexor digitorum profundus (Fig. 8-14) (125,227). If a fracture occurs at the tendon insertion, the flexor digitorum profundus is sometimes prevented from retraction by tethering on the A5 or A4 pulley. The location of the bony fragment on radiography will identify the level of tendon retraction. Soft tissue avulsion of the flexor digitorum profundus usually retracts to the level of the palm.

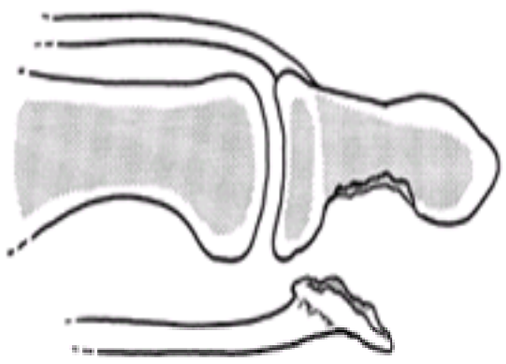

FIGURE 8-14. A flexor digitorum profundus avulsion fracture of the distal phalanx, the jersey finger.

Diagnosis

Signs and Symptoms.

Status of the Nail and Nail Bed. Because almost half of patients with nail bed injuries seen in an emergency department have a concomitant fracture of the distal phalanx, a high index of suspicion for bony injury must be maintained when an obvious open nail bed injury or a subungual hematoma is present (Fig. 8-15) (241). A subungual hematoma that involves more than 50% of the nail plate often indicates a distal phalangeal fracture.

FIGURE 8-15. A: A crush injury to the thumb of a 4-year-old with a stellate nail bed laceration and fracture of the tuft. **B:** Avulsion of the nail plate after crushing trauma is accompanied by a distal phalanx fracture. This must be treated as an open fracture.

Occasionally, smaller matrix lacerations can bleed enough to cause pain simply from the pressure developed under the nail plate. More often, the nail plate is lifted from under the folds, which may decompress any underlying hematoma. Rarely, the nail is completely avulsed without an accompanying soft tissue injury to the sterile or germinal matrix.

Tissue Loss. The distal aspect of the fingers and thumb are at risk for significant trauma. Partial or complete terminal amputations occur in patients of all ages. Most of these injuries are incomplete amputations, through a level that includes variable amounts of the specialized nail tissues. Complete amputations at the distal phalangeal level generally are distal to the physis.

Radiographic Findings. A thorough series of films focusing on the distal phalanx and DIP joint is necessary to evaluate the injury completely. Specialized imaging, such as computed tomography (CT) scanning or magnetic resonance imaging (MRI), is not needed to evaluate this region.

Treatment Options

The fractures associated with nail bed lacerations are true open injuries and require attention to both the osseous and soft tissue elements. Any open fracture requires mechanical debridement, irrigation, and appropriate antibiotics. Most of these injuries occur in children under 5 years of age and do not require treatment beyond initial repair. The stability of the phalangeal fracture is evaluated, and if the phalanx is not stable enough to act as a foundation for nail bed repair, pinning is performed.

The repair or reconstruction of the soft tissues surrounding the distal phalanx is just as critical as the osseous repair. When indicated, meticulous nail bed repair, neurorrhaphy, tenorrhaphy, and skin coverage must be performed.

Extraphyseal Fractures.

Stabilization. Options for stabilizing extraphyseal fractures include closed splinting, percutaneous fixation, or open reduction. Most fractures are stable, and require only simple splinting. However, a smooth Kirschner wire may be inserted either into the phalanx from the tip or occasionally across the DIP joint in fractures with marked comminution or very proximal fractures. A hypodermic needle is a good substitute for the standard smooth wires (145).

Hematoma Evacuation. If a hematoma is the only outward manifestation of underlying injury, observation or simple evacuation may be sufficient. Indications for a hematoma evacuation include significant subungual hematoma (>50% of the nail plate), painful pressure under the nail, or evidence of infection. The decompression can be performed with a hypodermic needle used as a drill. A heated paper clip or cautery tip can be effective, but a margin of safety is necessary to avoid further tissue injury. DaCruz et al. (53) reported a high incidence of late nail deformity if the hematoma was not decompressed.

Nail Bed Repair. If nail bed repair is required, the nail is removed with a blunt septal or Freer elevator. Partial nail removal is seldom appropriate, because the extent of the injury may not be appreciated. Further exposure of the proximal nail tissue (germinal matrix or dorsal/intermediate nail) by incisions in the eponychial fold may be necessary. The nail bed is repaired with interrupted absorbable 6-0 or 7-0 sutures under loupe magnification. The likelihood of nail deformity is minimized by this surgical intervention.

After careful approximation, the nail bed is stented to avoid scarring that could hinder subsequent nail growth. If the nail has not been too badly damaged, it can be used to stent the nail folds after it has been denuded of all soft tissue remnants and has been perforated centrally to allow free drainage of subungual fluids. Other

substitutes, such as a plastic stent fashioned from a culturette tube, a foil suture pack, or a commercially available stent, also can be used. The use of the nail itself or some inert foreign material has been controversial (68,189,241). The nail itself is thought to be more stable and may assist in “molding” the repair, but the risk of infection must be considered if the preparation before insertion is inadequate. Sandzen and Oakey (184) argued that this risk is lower in children than in adults. Suturing of the replaced nail may help prevent migration from underneath the nail folds. Anchoring the stent with a suture has been described, but this may cause incidental injury to the sterile or germinal matrices.

Physeal Fractures.

Nonoperative Management. Nonoperative treatment of a mallet finger in a child, as in an adult, is overwhelmingly favored. When the injury is closed, there is seldom an indication for operative intervention in a typical bony mallet. Even when there is some displacement of the dorsal epiphyseal fragment, good results can be obtained with splinting (Fig. 8-16).

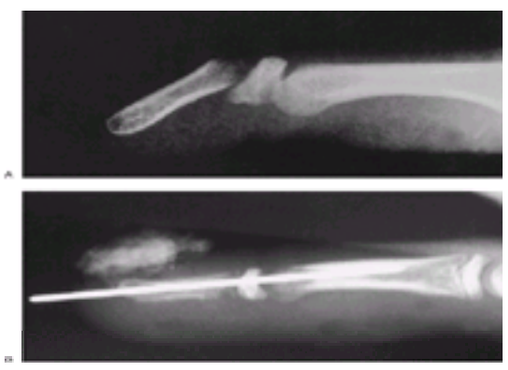

FIGURE 8-16. A: A very unstable fracture that necessitated extrication of the nail bed with subsequent repair. **B:** Stabilization of the bony elements with a longitudinal smooth pin.

Amputation at the distal tip can involve skin, nail tissue, and bone. These injuries are often worrisome to parents of a young child because of the potential loss of digital length. However, it is important to remember that the growth for the distal phalanx comes from the physis that often is proximal to the level of the amputation, and long-term digital shortening is rare.

Support for nail growth is a primary consideration. When less than 50% to 60% of the distal phalanx remains, the likelihood of nail deformity in the form of a hooked or “parrot's beak” nail is high. Often, lesser injuries can be treated with simple dressing changes or allowed to heal by secondary intention. Skin grafting at the distal tip often is unsatisfying because the durability, sensibility, and appearance are suboptimal.

If most of the distal phalanx is spared, only a relatively transverse nail bed and soft tissue laceration exists. Simply allowing the tissue to heal, with or without a small amount of bony resection, is an option. In addition, results are often surprisingly good with healing by secondary intention over a small amount of exposed bone.

The spectrum of injury can range from a minimal nail bed laceration, manifesting as a minor subungual hematoma, to the significant laceration and unstable periphyseal injury (Fig. 8-17). Campbell (36) advocates an aggressive approach for open bony mallet fingers, even with minimally displaced fractures. Late complications such as tendon imbalance, nail growth or adherence problems, premature physeal closure, and even chronic osteomyelitis can occur with relatively innocuous trauma.

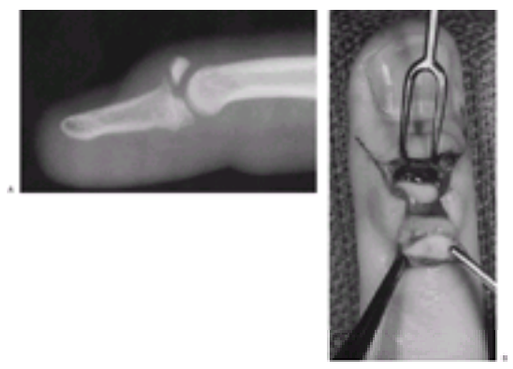

FIGURE 8-17. A: Although mallet fractures of this pattern and amount of displacement often can be treated by closed methods, the extreme deformity and dorsal prominence was of concern to the patient and his parents. It was therefore elected to open the fracture to reduce and stabilize the fragment. **B:** This intraoperative photograph demonstrates the amount of articular surface involved and the attachment of the terminal tendon.

Operative Management. When an S-H IV bony mallet fracture is displaced and adequate reduction cannot be obtained by closed means, operative stabilization should be considered. Although most of these fractures can be treated closed, a large dorsal fragment (typically >50%) or significant DIP joint subluxation may require operative intervention (50,198). Closed manipulation and percutaneous pin stabilization of the reduced joint are generally used.

The Seymour fracture is an absolute indication for open reduction and stabilization. The sterile matrix must be extricated from the fracture at the physeal level. Not until the soft tissue is removed will the fracture reduce appropriately. Those rare fractures with epiphyseal dislocation require operative intervention to restore joint congruity and to reestablish continuity of the extensor apparatus.

Surgical Procedures. When a complex injury cannot be reduced or stabilized using a closed technique, a dorsal approach is necessary to expose the fragment and reduce the fracture (Fig. 8-18). It may be necessary to take down the collateral ligament to obtain reduction. Although we prefer to avoid it, fixation of the fragment itself is advocated by some clinicians (88,92,104,117,162,175). When the epiphysis is completely displaced from its articular contact and its relationship with the remaining distal phalanx, open reduction through a dorsal approach is necessary. Several different approaches for exposure of the DIP joint have been described, primarily for use in the treatment of arthrosis and mucous cyst excision (48,65), for example, an H- or S-shaped incision or an extended Y flap (Fig. 8-19).

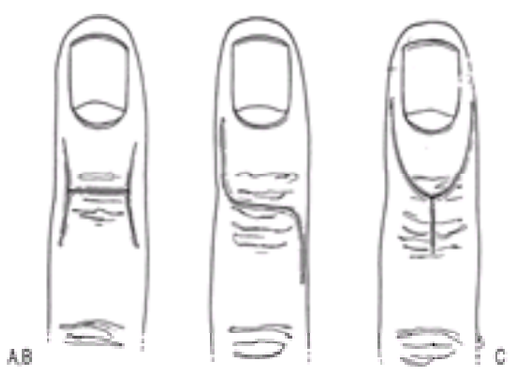

FIGURE 8-18. Three exposures of the distal interphalangeal joint. **A:** H-type flap with the transverse limb over the distal interphalangeal joint. **B:** S-shaped exposure of the distal interphalangeal joint. **C:** An extended Y exposure of the DIP joint; the apex of the V part of the incision is at the distal interphalangeal joint. In all these exposures, care is taken not to injure the germinal matrix or its blood supply, which is located in the sulcus just proximal to the nail fold.

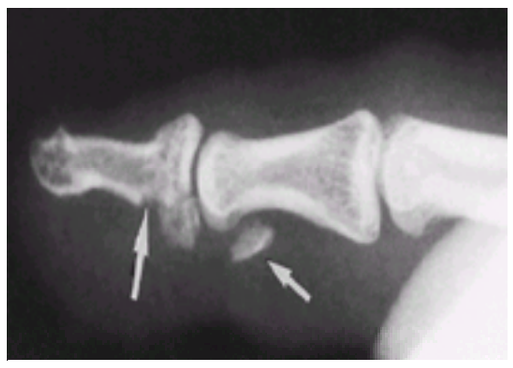

FIGURE 8-19. In this volar fracture in a 17-year-old athlete, a fracture through the epiphysis extends into the joint (*large arrow*). The flexor digitorum profundus with an attached fragment of the metadiaphysis has retracted to the level of the A4 pulley (*small arrow*).

Once the joint is exposed and the fragment with its attached terminal tendon is retrieved (or the free fragment and avulsed tendon), repair can be performed with a smooth wire, pullout wire, tension band, or heavy suture (99). Pinning of the DIP joint is necessary to maintain joint and physeal congruity.

A jersey finger avulsion of the flexor digitorum profundus requires open repair. The profundus tendon needs to be identified surgically at the level of retraction. This may be at the A2 or A4 pulley of the flexor tendon sheath (Fig. 8-20), or it may have retracted to the lumbrical origin off the flexor digitorum profundus in the palm. If the vincular blood supply and synovial bathing from the fibroosseous sheath are both lost, the repair should be immediate. Ideally, a primary repair under little or no tension should be performed within a week. Treatment of chronic flexor digitorum profundus avulsions may include no repair, flexor digitorum profundus tenodesis, DIP joint fusion, and delayed repair.

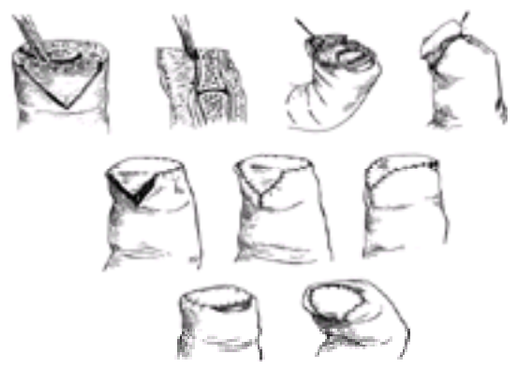

FIGURE 8-20. The reversed cross-finger subcutaneous flap. A full-thickness skin flap is elevated from the donor digit based on the side opposite the injured digit. The subcutaneous tissues are then elevated from the epitenon, based on the side of the injured digit. The subcutaneous tissues are reflected in a reversed fashion into the defect, and a thin full-thickness skin graft is applied to the recipient. The full-thickness skin flap from the donor is then replaced over the vascular epitenon. Division of the flap can take place at 2 weeks. (Reprinted from Atasoy E. Reversed cross-finger subcutaneous flap. *J Hand Surg* 1982;7:481–483; with permission.)

Soft Tissue Coverage of Amputations. Soft tissue coverage over the dorsal aspect of the distal phalanx and reconstruction of the nail folds are among the most difficult challenges in hand surgery. The surgical approach for the dorsal injury must be tissue specific. Simple healing by primary closure is preferred. In the rare complete avulsion of the nail bed with exposed distal phalanx dorsally in a young child (under 5 years), the amputated nail bed and pulp can be replaced with minimal defatting. In addition to simple nail bed repair or nonvascular replacement of the amputated part, composite grafts of skin and subcutaneous tissue from local or distant sites (e.g., the adjacent digits, the toes) have been used (42,196,242).

The simplicity and predictability of bony recession, traction neurectomy, and primary closure must not be forgotten in the midst of more elaborate techniques. A well-performed primary closure of a traumatic amputation can hasten a return to high-level function with minimal discomfort and disability. Ablation of the germinal matrix, when indicated for significant nail loss, and neurectomy minimize the need for future revision surgeries. Of course, amputation in a child's hand should be reserved for only the most significant tissue disturbances that are not reconstructable in other ways.

Reconstruction Options. Options for reconstructing the distal tip injury include V-Y volar advancement, a thenar flap, a cross-finger flap, a pedicled flap, and a neurovascular island flap.

The triangular V-Y volar advancement flap was described in 1970 by Atasoy et al. (8). Adequate skin on the volar and lateral sides is needed. The flap is designed so that the apex of the triangle proximally is at the DIP crease, and the base of the triangle is the amputation margin. The triangle of skin is liberated carefully with sharp dissection of the fibrous septae that tether it proximally, thus allowing it to advance distally to cover the defect. The void left behind is closed, converting the Vinto a Y (Fig. 8-21).

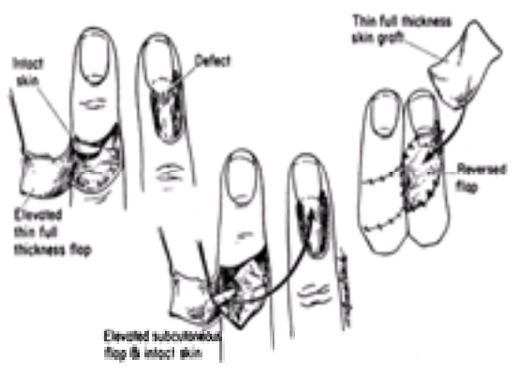

FIGURE 8-21. V advancement flap. This triangular volar flap is elevated to cover a distal defect in the author's original description. A V is formed with its apex at the distal interphalangeal joint flexion crease. The base of the triangular flap is the margin of the amputation. The fiber septae are elevated from the distal phalanx. Care is taken to advance the volar skin by sequential division of small fibrous tethers to the volar side. When adequate immobilization of the flap is realized, it can be sutured in place over the tip. (Reprinted from Atasoy E, Ioakimidis E, Kasdan ML, et al. Reconstruction of the amputated finger tip with a triangular volar flap. *J Bone Joint Surg [Am]* 1970;52:921–926; with permission.)

The thenar flap was first described by Gatewood in 1926 (78). This innovative procedure buries the amputated tip into the tissue about the thenar eminence. The disadvantage of this flap is the extreme flexion that must be maintained for the duration of the attachment. Other clinicians (145) have described flexion contractures with this flap, and they have suggested that the candidates for this seldom-needed procedure be young. I also advocate the thenar flap only in patients under 20 years of age. If it is selected for coverage, the U- or H-shaped flap of skin and subcutaneous tissue must be located as close to the thumb MCP flexion crease as possible to minimizes PIP joint flexion.

The cross-finger flap is one of the most versatile reconstructive procedures used about the distal tip (113). If tissue is inadequate for primary closure or local advancement, a cross-finger flap permits coverage without the need for a distant flap (e.g., groin, cross-chest). This flap requires a nontraumatized adjacent donor. Like the reverse cross-finger flap (Fig. 8-22), the donor flap is based on the side of the injured digit, but instead of using only the subcutaneous fat as a flap applied to the dorsum, the cross-finger flap brings skin and subcutaneous tissue to the volar side (Fig. 8-23).

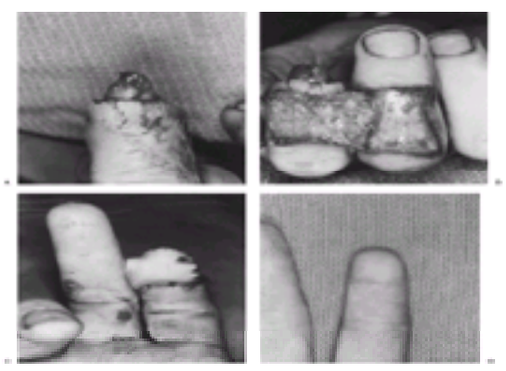

FIGURE 8-22. The cross-finger flap. This 17-year-old boy was working on his car when his distal tip was caught in the area of the fanbelt. **A:** Extensive volar and distal loss was appreciated, but there is only minimal injury to the bony elements and laceration of the nail bed. The patient and parents were strongly against amputation and therefore were offered the option of a cross-finger flap. The most proximal level of injury is at the distal interphalangeal joint flexion crease. **B:** A flap of skin and subcutaneous tissue is elevated from the dorsal aspect of the adjacent donor digit based on the side of the index finger. The vascular epitenon is left behind to nourish the donor digit and support a graft. The flap is then brought to the volar aspect and sewn into the recipient. Care is taken to contour the flap to recapitulate the appearance of a normal digital tip. **C:** An excellent functional and cosmetic result was realized in this case. **D:** More than 50% of the nail was supported by the distal phalanx, and this can be maintained by performing good nail hygiene to avoid any type of hooked-nail deformity.

FIGURE 8-23. A pedicle neurovascular island flap for distal thumb coverage. **A and B:** This 16-year-old guitarist sustained a sharp distal tip amputation of the thumb. Because of the importance of this digit to his musical abilities, he strongly wanted this to be resurfaced with a durable, sensible, and contoured flap. A neurovascular island flap was based on the radial digital nerve and large accompanying vessel. The flap was designed in a V-Y fashion. **C:** After the flap was mobilized, it was brought up to cover the distal tip, and care was taken to contour the flap. **D:** Excellent contour of the distal thumb was realized with intact sensibility. The patient was able to play the guitar without decrement in his skills. (Courtesy of Richard S. Idler, M.D.)

A pedicled neurovascular island flap is an appropriate alternative when durable sensible tissue is needed. This flap can be designed and advanced on a local neurovascular bundle or transferred from a remote location, and it is particularly useful in the thumb for unilateral volar tissue loss (Fig. 8-24).

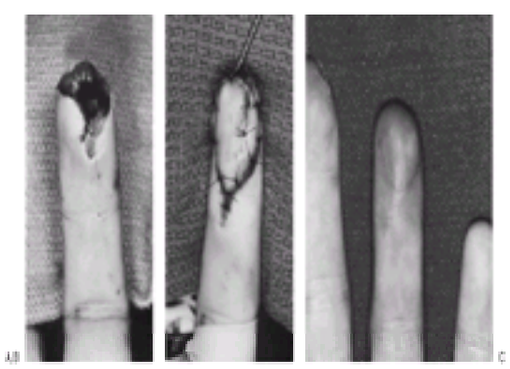

FIGURE 8-24. Volar V-Y advancement flap for coverage of volar tissue loss. **A:** A volar oblique tissue loss is a particularly good indication for an advancement flap when there is adequate tissue remaining between the distal interphalangeal joint crease and the level of the injury. In this case, the nail tissues were uninjured. **B:** The flap is fashioned with its apex at the distal interphalangeal joint and mobilized to cover the tip. The defect is closed behind the flap, thus creating the Y. **C:** The result is a very cosmetic-appearing digit that has good durability and sensibility.

The more autonomous volar and dorsal blood supply of the thumb is the basis of Moberg's volar advancement flap for coverage of tissue loss at the distal thumb (Fig. 8-25) (155). Bilateral mid-lateral incisions permit advancement of the volar skin to cover an acral defect. Coverage is made easier by flexing the interphalangeal joint of the thumb. Transverse division of the more proximal skin can sometimes be performed, with skin grafting into the defect. In a child, the skin usually is more pliable and permits primary closure.

FIGURE 8-25. A thenar flap was chosen in this case. An H-flap technique was used. Another common technique is use of a composite graft from the toe pulp.

AUTHORS' PREFERRED METHOD OF TREATING DISTAL PHALANGEAL INJURIES

Extraphyseal Fractures

For distal phalangeal fractures that do not involve the physis, the decision concerning treatment is based on the stability of the fracture and the status of the nail bed. Most simple closed fractures are treated with immobilization. In a young child, this may involve a mitten cast; in an adolescent, splinting of the tip and DIP joint, leaving the PIP free for motion, may be all that is necessary. Gentle manipulation of some fractures may improve slight angulation. Immobilization is worn for 3 to 4 weeks at most, until clinical union has brought comfort. Protection during contact activity can be continued if the digit is at risk.

For fractures accompanied by a nail bed laceration, adequate local anesthesia (a metacarpal block) is instilled with or without conscious sedation. A Penrose drain is inserted at the base of the digit, the nail plate is completely removed with a Freer elevator, and meticulous mechanical debridement and copious irrigation are performed. In the rare unstable distal phalangeal bony injury, the fracture is pinned.

Pinning of the phalanx is best performed with image intensification with a low-radiation fluoroscopy unit. We use 0.028- or 0.035-inch smooth wire, depending on the patient's size. A 22-gauge hypodermic needle can be used if other resources are unavailable. The wire or needle is left protruding from the distal end of the phalanx, to make later removal easier. The DIP joint is crossed if sufficient stability is not achieved by pinning the fragments of the terminal phalanx, but this is avoided if possible. The pin is maintained for about 3 to 4 weeks.

With a stable platform established, sterile germinal matrix repair proceeds. Using 6-0 or 7-0 absorbable on a spatulated needle minimizes damage to the friable tissues of the nail bed. The injured nail is discarded, and petroleum- or antibiotic-impregnated gauze is placed under the nail folds. This covering of the repaired matrix simply falls off in several weeks.

A bandage that protects the distal phalanx usually is all that is necessary after nail bed repair. Leaving the PIP free is appropriate in older, cooperative patients, but younger patients may need immobilization up to and including a long arm dressing for this very distal injury. The parents and patient are told that it may take several cycles of nail growth (3–6 months) before the final morphology of the nail is known.

Physeal Fractures

Dorsal Mallet Injuries

We attempt to reduce the fracture in almost all closed mallet injuries. The reduction maneuver recreates the deformity by gentle flexion. The distal fragment is then extended to restore the anatomy. Reduction is held while the splint is carefully applied. We apply a splint (either volar or dorsal) then obtain radiographs to evaluate the reduction in the immobilized state (Fig. 8-26).

FIGURE 8-26. A: A 13-year-old boy sustained an open type II fracture when a fellow football player stepped on his hand. **B:** After the wound was cleansed, a closed reduction was performed, preserving the nail. Normal function resulted.

Our normal splinting regimen is 24-hour wear for no less than 4 weeks, and typically for 6 weeks. This time frame can be adjusted depending on the amount of bony apposition and age of the patient. A cooperative patient can be furnished with both volar and dorsal splints, if it is understood that any flexion of the DIP during changing of the splint will prolong the immobilization period. The two-splint regimen has almost eliminated the infrequent skin problems seen with dorsal splinting alone and the transient sensory disturbance with prolonged volar protection. The finger is held in neutral to 15 degrees of extension; extreme hyperextension is contraindicated, because it may cause skin hypoperfusion and necrosis (178). Loss of flexion can occur with prolonged hyperextension but is rare with closed treatment.

The patient and parent should check the skin at least daily to prevent skin necrosis from splint pressure. A follow-up visit at 5 to 7 days will reveal problems if the patient does not understand the instructions. Radiographs are taken weekly for the first 2 weeks, then every 2 weeks to monitor for loss of reduction and volar subluxation (188).

The presence or absence of an open injury and the fracture configuration dictate the need for operative intervention. If unacceptable reduction of the fracture fragments or subluxation or dislocation of the DIP joint remains after closed manipulation, then surgery is performed to reduce the fragment and DIP joint. We prefer to perform this percutaneously. The dorsal fragment can be pinned with a 0.028-inch smooth Kirschner wire driven into the epiphysis in a parallel direction (Fig. 8-27). The wire is left protruding from the skin for later removal. Pinning of the DIP joint also often is necessary. If this is not feasible, a dorsal approach is used to expose the dorsal fragment in these mallet equivalent injuries (Fig. 8-19). Care is taken to avoid the vessels that nourish the germinal matrix, which are located in the shallow sulcus proximal to the nail fold. This area can be appreciated by viewing the distal digit from the lateral side. This averts interruption of tissue perfusion and prevents the major complication of hematoma.

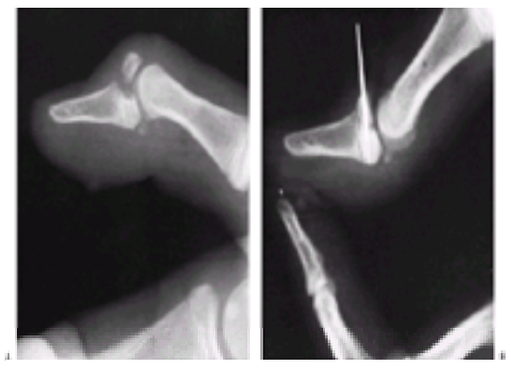

FIGURE 8-27. A: A 14-year-old boy sustained a displaced type III fracture of the distal phalanx when he was struck on the end of the thumb with a ball. **B:** Open reduction and Kirschner wire fixation were required when manipulation failed to reduce the fracture because of the displacement caused by the action of the extensor pollicis longus tendon on the fracture fragment.

If the patient is near skeletal maturity, a tension band, pullout wire, or suture anchor can be used for fixation. Although a neutral position or slight (10 degrees or more) hyperextension is preferred for closed treatment, the joint should not be repaired open in hyperextension because this position tends to persist. Neutral alignment of the DIP joint is favored if the fracture is open.

Reverse Mallet Injuries

For reverse mallet, flexor digitorum profundus avulsion injuries, we prefer bone-to-bone fixation whenever possible. If the fragment is too small or comminuted, repair of the tendon to the fracture bed is adequate. Pinning of the joint is avoided so that passive motion can be started early. In patients under15 years of age, 4 weeks of immobilization yields results equivalent to those of protected motion protocols in adults.

Soft Tissue Management

For terminal loss of skin and subcutaneous tissue only, we again stress the necessity of wound cleansing and dressing changes to all injuries left to heal by secondary intention. This method of treatment is not benign neglect, but rather a reasonable approach that usually results in superior functional and cosmetic results. Skin grafts from the groin, antecubital fossa, or hypothenar glabrous border rarely are used for coverage. Donor morbidity, hyperpigmentation, lack of sensitivity, and appearance are potential drawbacks of skin-grafting procedures.

Dorsal loss is the most difficult to reconstruct. We attempt tension-free closure first, then consider local tissue relaxation and advancement before opting for a reverse cross-finger flap or distant flap. Distal tip and volar loss on the remaining bone, the status of the nail tissues, and the availability of sufficient volar skin distal to the DIP flexion crease must be considered. We have found the volar V-Y advancement, cross-finger flap, and thenar flaps to be good options.

We have not detailed microsurgical reconstruction methods or many of the innovative but arduous flaps reported frequently in the literature. Instead, we have provided a basic list of options that will suffice in most patients. Knowledge of the indications for and the technical aspects of these procedures permits the surgeon to approach most distal tip reconstructive challenges in a logical fashion.

Postoperative Care and Rehabilitation

The immobilization used for an extraphyseal fracture depends on the stability of the fracture and the age of the patient. Young children with fractures that require reduction are immobilized with long arm mitten casts. As the child ages, or with stable injuries, the degree of immobilization is decreased. For an adolescent, this may mean that only the digital tip is splinted to the mid-middle phalangeal level, thus allowing PIP motion.

Treatment of physeal fractures is similar to that described for extraphyseal fractures. If there is a persistent extensor lag, continued splinting even after pin removal can effect improvement. Removal of the pin at 3 weeks and full-time splinting for an additional 2 to 3 weeks is reasonable. This is particularly useful when a pin was placed across the DIP joint to gain stability.

Antibiotic use is advocated with open fractures, but in only the most complex, contaminated injuries should a patient be admitted for intravenous antibiotic administration. A seven-day course of oral agents usually suffices. Antibiotics do not replace the need for thorough mechanical debridement.

If the distal phalangeal fracture was pinned with a smooth wire or hypodermic needle, the implant can be removed at 3 or 4 weeks, usually in the office setting. There is no need for sedation or local anesthesia.

The covering of the nail bed, whether native nail plate or foreign material, falls off with dressing changes or activities of daily living. Monitoring of the soft tissue healing often is monitored for several weeks after injury. Waiting several months to evaluate the status of nail growth and adherence is imperative.

No formal hand therapy is required, because the child's own use pattern returns the DIP joint to good function in a matter of weeks. In some patients, DIP joint motion is more limited, especially when there has been an arthrotomy for articular restoration. The patient can be taught an exercise program that specifically includes middle phalanx blocking exercises to restore DIP flexion.

Prognosis

Functional and cosmetic results are generally favorable. Even a small amount of extensor lag or a minor longitudinal nail ridge are well tolerated by most patients. During the early dialogue with parents, the potential for long-term impact of the injury should be emphasized. They must understand that any injury in a skeletally immature patient may interfere with longitudinal or angular growth, and that articular injury may accelerate the degenerative process later in life. However, these problems are rare. The appearance of the nail is important to most parents, and the possibility of growth failure, plate deformity, and nonadherence should be described. Although DeCruz cited a high rate of nail deformity with subungual hematomas and distal phalanx fractures, this has not been the norm in our institutions.

Complications

Inability to Maintain a Stable Bony Foundation. Pinning the distal phalanx, with or without crossing the DIP joint, provides stability and improves the chances for healing of the dorsal aspect of the distal phalanx.

Osteomyelitis. Osteomyelitis is best prevented by meticulous debridement and irrigation of the fracture and soft tissue injury at the initial evaluation. If infection appears later in the treatment course, the usual principles for skeletal infection must be followed. The infected tissue must be thoroughly debrided, weighing the options of skin coverage or shortening amputation. The amount of bony support of the nail is a key issue in the retention of the germinal matrix, because a hook-nail may result when a significant amount (>50%) of the distal phalanx is lost.

Impaired Nail Growth. The problem can be one of poor growth or adherence. If it is a growth problem, the germinal matrix has been injured, and the absence can be complete or partial. One option for treatment is to resect the area of a “normal nail” and replace it with a full-thickness or split-thickness skin graft (42); nail bed grafting from the adjacent bed, another digit, or toe is a sound alternative. These grafts can be vascularized or nonvascularized. The results in children have been superior to those in adults (119,196,197,242).

If the problem is nail lift-off or lack of adherence, then similar resection and grafting techniques can be used to contour the sterile matrix. Partial-thickness grafting

from the adjacent sterile matrix of the injured digit can be used. In the rare instance that an underlying deformity of the distal phalanx is causing the problem, splitting the sterile matrix for exposure and smoothing the dorsal aspect of the phalanx can help.

One specific complication of lost nail support is a hook-nail or “parrot's beak” nail, in which the nail plate takes a significant volar curve over the end of an abbreviated distal phalanx (Fig. 8-28). This is a potential hygiene and cosmetic problem and may prevent the tip from being functional. Atasoy et al. (9) described an “antenna” procedure for reconstructing the hook-nail. Elevating the sterile matrix and supporting the nail tissue with a volar advancement flap, thenar flap, composite graft from the toe, or a cross-finger flap can significantly improve the appearance and eliminate marginal and distal skin compromise. The name *antenna* comes from the multiple (usually three) small wires used to support the matrix postoperatively (Fig. 8-29).

FIGURE 8-28. A patient with a distal fingertip amputation that has gone on to develop a hook-nail deformity.

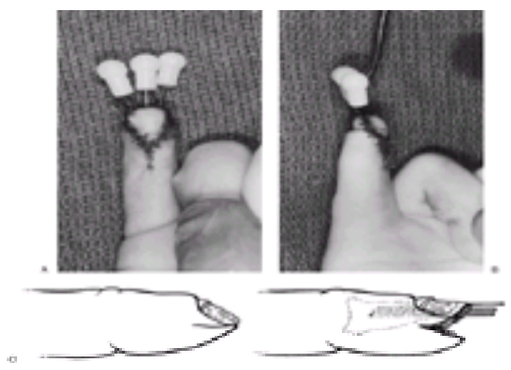

FIGURE 8-29. A and B: Postoperative photograph views of the patient shown in Fig. 8-28 who had the antenna procedure. This involved a volar V-Y advancement flap chosen to cover the distal tip. The sterile matrix of the nail was elevated and is supported by the three smooth wires and transferred flap tissue. **C:** Line drawings demonstrating technique of elevation and support of the sterile matrix with wires. (A and B Courtesy of William B. Kleinman, M.D. C reprinted from Atasoy E, Godfrey A, Kalisman M. “Antenna” procedure for the “hook-nail” deformity. *J Hand Surg* 1983;8:55; with permission.)

Extensor Lag. Some extensor lag (10 degrees or less) is not uncommon after appropriate treatment of a mallet injury. Continued extension splinting can be tried but loses efficacy after the third or fourth month. A digital cast may be an excellent way to avoid a potential lapse in splint wear that is required over a long period. Terminal tendon reconstruction with a dermodesis procedure has been described for this situation. A spiral oblique retinacular ligament reconstruction has been used to correct “chronic mallet,” but the procedure is technically demanding (214). Release of the central slip insertion into the middle phalanx (Fowler procedure) can lessen the DIP extensor lag and the PIP secondary swan neck deformity. If the amount of lag is unacceptable and is accompanied by the rare occurrence of arthrosis at the DIP joint due to premature physeal closure, the only realistic options may be DIP fusion or interposition arthroplasty. These are radical steps in children, and we have not used them. If the impairment does not severely compromise function or limit future vocational avenues (e.g., musician), then the patient can make the decision later in life.

Proximal and Middle Phalanges

The proximal and middle phalanges have similar characteristics with respect to their osteology and soft tissue anatomy. Other factors, such as the tendon balance around each segment, contribute to the unique fracture characteristics seen at the individual members of the osteoarticular column.

Surgical Anatomy

Some pertinent aspects of the unique anatomy of the child's hand affect the pattern of fractures about the phalanges. These concepts are integral to understanding the radiograph and the clinical manifestations of skeletal trauma children.

The physes are located proximally in the phalanges. The physis of the thumb metacarpal also is located proximally; those of the other four metacarpals are distal (Fig. 8-2). The collateral ligaments at the PIP and DIP joints originate from the collateral recesses of the proximal bone and insert onto both the epiphysis and metaphysis of the distal bone. The ligament also inserts on the volar plate (Fig. 8-4). The collateral ligaments at the MCP joints of the fingers originate and insert almost exclusively onto the epiphyses of the opposing bones. The thumb MCP collateral ligaments most closely resemble those of the interphalangeal joints, having epiphyseal and metaphyseal insertions distally (Fig. 8-5).

The volar plate has a metaphyseal origin from a recessed part of the phalangeal neck and inserts distally onto the epiphysis. It receives fibers from the collateral ligaments (Fig. 8-4).

The extensor tendons insert onto the dorsal aspect of the epiphysis of the middle and distal phalanges. At the middle phalanx, the flexor digitorum superficialis inserts over about two thirds of the central portion of the middle phalanx onto the sublimis ridge. The flexor digitorum profundus has a metaphyseal insertion onto the distal phalanx.

The periosteum is important in fracture stability, reduction maneuvers, and potential remodeling capability. It is a well-developed structure that may occasionally block reduction when it is interposed in the fracture. The periosteal hinge may be a useful adjunct in fracture reduction.

Diagnosis

Anatomic Considerations. The epiphysis and physis at the MCP level are relatively unprotected for two reasons: the collateral ligaments and volar plate insert exclusively proximal to the physis, and there are two epiphyses opposed at this joint. Conversely, the periphyseal bone of the middle phalanx is stabilized by the insertion of the collaterals onto both sides of the physis.

Fracture Forces. Pure torsion or lateral bending forces are rare: a combination is typically responsible for fractures of the phalanges. These fractures can affect the periarticular areas or the shaft. Forces resulting from a violent lateral bending moment or a significant injury directed in the AP (flexion/extension) plane can cause a phalangeal neck fracture. This fracture propagates through the subcondylar fossa and the distal diaphysis. Fractures caused by hyperextension forces are found predominately about the PIP joint and, to a lesser extent, at the MCP joint.

Injury Mechanisms. Most fractures of the proximal and middle phalanges result from axial loads, torsional or angular forces, such as catching balls or collisions in sports. Crush injuries include direct injuries from implements such as hammers or closing doors.

Classification

Four patterns of phalangeal fractures can be recognized: fractures involving the physis, the shaft of the phalanx, the unique fracture anatomy about the phalangeal neck, and the condylar area (Table 8-3).

Physeal
Shaft
Phalangeal neck
Intraarticular (condylar)

TABLE 8-3. CLASSIFICATION OF PROXIMAL AND MIDDLE PHALANX FRACTURES

Physeal Fractures. Hastings and Simmons (104) reported that the proximal phalanx was the most commonly injured bone in their series of 354 pediatric hand fractures, and this has been corroborated by other clinicians (12,90,127,215). This was due in part to the large number of S-H II fractures of the base of the proximal phalanx. They also observed that physeal fractures occurred in the hand 34% more often than elsewhere in the appendicular skeleton. Leonard and Dubravcik (127) cited a 41% incidence of physeal fractures among their 276 pediatric hand fractures.

Two Variations. Physeal fractures of the proximal phalanx are of two varieties: S-H type II extraarticular fractures and S-H types III and IV intraarticular fractures (Fig. 8-30). Both of these patterns can be caused by lateral bending moments, but the more prevalent S-H II results from additional rotational forces.

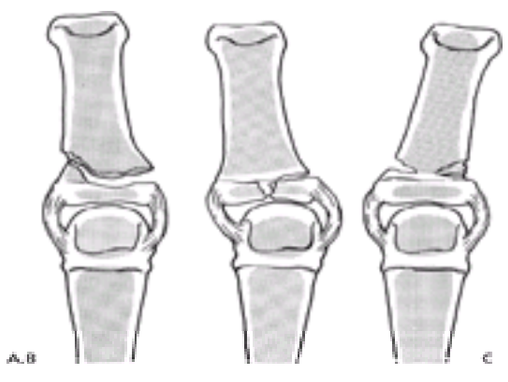

FIGURE 8-30. Type A fractures of the proximal phalanx. **A:** Classic Salter-Harris type II fracture with the Thurston-Holland fragment. **B:** The intraarticular Salter-Harris type III or type IV fracture pattern. **C:** The extra-octave Salter-Harris II type of fracture with metaphyseal buckling.

Physeal fractures about the middle phalanx are rare. A lateral avulsion mechanism can cause an S-H III or IV fracture, but the entire epiphysis rarely separates through the physis, or in an S-H II pattern. A dorsal avulsion of bone by the central slip can be caused by forced flexion against an extended digit, producing a dorsal S-H III fracture. Furthermore, the lateral band can subluxate volar to the axis of rotation of the PIP joint, creating a boutonniere deformity.

Children rarely sustain comminuted intraarticular fractures of the PIP joint, considered “pilon” fractures or fracture–dislocations (207). These injuries usually involve the proximal aspect of the middle phalanx. They often occur in adolescent athletes and usually result from an axial load sustained while catching a ball or contacting an opponent. Fracture fragments from the volar side may have attached volar plate; the dorsal fragment is likely to have the central slip attached. The central aspect of the joint may be depressed, and comminution is frequent (Fig. 8-31).

FIGURE 8-31. Pilon fracture of the middle phalanx, in which there is comminution or central joint depression of the epiphysis.

Gamekeeper's Injuries. A UCL avulsion injury at the base of the thumb proximal phalanx is similar to the adult gamekeeper's or skier's thumb. The fracture itself usually is an S-H III injury (Fig. 8-32). Despite the obvious fracture deformity, the focus is on the ligament that may be attached to the small fragment. Rarely, the ligament tears away from the bone, in addition to the fracture of the epiphysis. If the UCL (with or without a bony attachment) is excluded from its bed by the adductor aponeurosis, then open repair is necessary. This injury is called a Stener lesion after the clinician who described the exclusion of the UCL from its proximal phalangeal insertion by the adductor aponeurosis (206). In his 1962 account, Stener described this lesion in 25 of 39 patients with complete ruptures of the thumb MCP joint UCL. This derangement is significant because healing of the ruptured collateral ligament back to its original bed cannot occur owing to adductor interposition. The purely ligamentous injury is discussed in the later section of this chapter on Dislocations of the Hand and Carpus.

FIGURE 8-32. The spectrum of presentation of ulnar collateral ligament injury of the thumb. **A and B:** On stress examination, a widening of the physis is seen. No true intraarticular fracture can be appreciated, yet instability at this level is inferred by this radiographic finding. The arrow demonstrates the direction of force and location of the pathology. Varying sizes of fragments **(B and C)** can be associated with ulnar collateral ligament avulsion fractures (*arrows*). The size of the fragment is important with respect to the congruity of the metacarpophalangeal joint.

Shaft Fractures. Fractures of the phalangeal shaft are not as common as those around the joints, perhaps because of the stabilizing influences of the flexor sheath and thick periosteum, and the relatively short lever arm of the digit.

Phalangeal fractures may be transverse, spiral, or spiral-oblique (Fig. 8-33). Any of these types can be comminuted. The characteristic displacement is an apex volar pattern. The proximal fragment is pulled into flexion by the intrinsic influence, and the distal fragment is extended by the force of the central slip and lateral band insertions (Fig. 8-34).

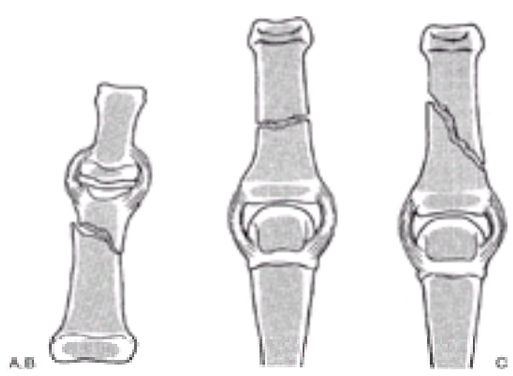

FIGURE 8-33. Metacarpal shaft fractures. Fracture in the distal shaft **(A)**. Transverse **(B)** or spiral oblique **(C)** fractures.

FIGURE 8-34. A and B: Two views of a transverse mid-diaphyseal fracture of the proximal phalanx that demonstrates the characteristic apex volar deformity. The volar flexion of the proximal fragment and dorsiflexion of the distal fragment are secondary to the tendon forces acting across the fracture site. The arrows demonstrate the actual direction of displacement.

With an oblique fracture, the deformity involves shortening and rotation. The displacement seen on radiography usually is minimal, but careful clinical evaluation of rotational alignment is critical. If a spiral-oblique fracture appears widely displaced, soft tissue interposition (extensor mechanism or periosteum) may be an impediment to reduction. Direct trauma to the phalanx, or a high-energy bending or torsional injury, can result in comminution (Fig. 8-35).

FIGURE 8-35. A: A crushing mechanism resulted in a complex comminuted fracture of the proximal phalanx in this child. Longitudinal splitting elements seemed to involve the proximal phalangeal growth mechanism. Excellent alignment was maintained and healing progressed. **B:** There was little disturbance of growth, but the subcondylar fossa (*arrow*) was somewhat obliterated by callus. There was only minor loss of flexion in this digit, and this will be allowed to mature before decisions are made concerning subcondylar fossa reconstruction.

Neck Fractures. Extraarticular fractures of the distal aspect of the phalanges are often located at the phalangeal neck. Displaced neck fractures, also referred to as subcondylar fractures, can occur in young children as a result of getting a finger trapped in a closing door with a subsequent attempt to withdraw it. In fractures of the phalangeal neck, the head fragment remains attached to the collateral ligaments and tends to rotate into extension (59). This displacement through the phalangeal neck disrupts the architecture of the subcondylar fossa. Because this region accommodates the infolded volar plate and volar phalangeal lip during interphalangeal flexion, malunited neck fractures result in a mechanical block to interphalangeal flexion.

Intraarticular (Condylar) Fractures. Phalangeal fractures that involve the joint can result from combined longitudinal and angulatory forces, and osteochondral fractures may result from shearing stress. Fractures can be associated with subluxations or dislocations of the joint. Despite heightened awareness of these fractures, they are difficult to identify and hard to treat (104,127).

Fracture patterns include small lateral avulsion fractures, unicondylar or intracondylar fractures, bicondylar or transcondylar fractures, and a rare shearing injury in which nearly the entire articular surface and its underlying subchondral bone are separated from the distal aspect of the phalanx. A T or Y condylar pattern can be caused at the interphalangeal joints by an axial loading injury but is uncommon in children.

Signs and Symptoms

Aside from swelling and minor ecchymosis, many of these deformities are not clinically obvious. The child generally refuses to actively move the digit, and attempts at passive motion are resisted. Rarely, there is a subtle deviation of the phalangeal segment that reflects the depression of the condylar support.

Every fracture of the proximal and middle phalanges must be carefully examined for clinical malrotation. Malrotation of the digit can be detected by deviation of the plane of the nails with the fingers semiflexed or by an abnormal cascade with wrist tenodesis. This may result from deformity at any level in the osteoarticular column. Fracture at the middle or proximal phalanx can result in significant rotational deformity.

Radiographic Findings

True AP and lateral radiographic views are mandatory in the assessment of phalangeal fractures, and oblique radiographs of the digits in question should be obtained.

One of the most significant factors influencing the long-term results in many phalangeal fractures is failure to recognize the extent of injury on the original radiographs. This is especially true in unicondylar and bicondylar fractures. The presence of the physes proximally and the complex periarticular architecture distally add to the difficulty of diagnosing subtle injuries.

Physeal and diaphyseal fractures usually can be detected by clinical and radiographic examination. However, a proximal shaft fracture of the proximal phalanx with volar angulation can be obscured by overlap of the digits on radiography. If there is a questionable finding on standard radiographs, special views or tomograms may assist in making a definitive diagnosis (130). Examination under fluoroscopy can be especially helpful when trying to characterize proximal phalangeal shaft fractures near the physis.

Straight-Line Method. Injuries about the MCP joint are common, but sometimes the relationships in this region where two epiphyses meet can be confusing. One radiographic technique particularly helpful in assessing alignment about the MCP joint is Campbell's straight-line method (Fig. 8-36) (36). Although best for discovering MCP dislocations, it also can assist in evaluation of fractures about this joint that may be associated with displacement or joint subluxation. The phalangeal line is drawn down the centers of the phalanges and metacarpals. In the uninjured digit, these lines are colinear, but fracture deformity or dislocation about the MCP joint can skew this relationship.

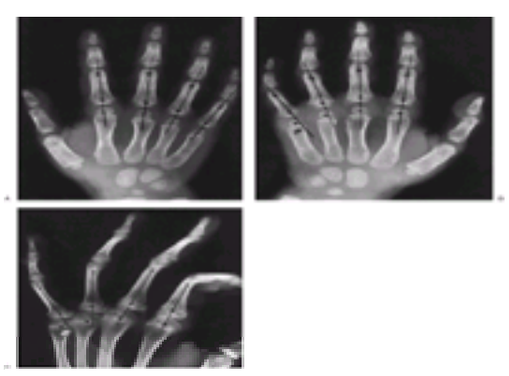

FIGURE 8-36. The straight-line method of assessing alignment about the metacarpophalangeal joint. The long axes of the metacarpal and proximal phalanx should align, as they do in this normal hand **(A)**. If there is a fracture in the proximal phalanx, as in this patient's opposite or injured hand **(B and C)**, the axes will not be colinear (*arrows*). (Courtesy of Robert M. Campbell, Jr., M.D.)

Double Density Sign. The most difficult fracture to recognize on radiography is the partial condylar or unicondylar pattern. The AP films may look completely normal, and there is only a slight overlap of the subchondral surfaces on the true lateral projection. This small inconsistency is often overlooked as poor technique, but the “double density” shadow is made by the offset of the displaced condyle (Fig. 8-37). A rotated unicondylar fracture is best identified on the oblique view.

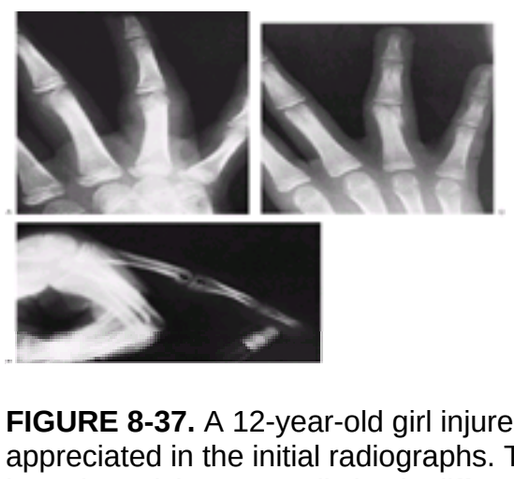

FIGURE 8-37. A 12-year-old girl injured her left proximal interphalangeal joint playing volleyball. She was treated for a sprained finger because no fracture was appreciated in the initial radiographs. The first film **(A)** that was accepted as an anteroposterior view was actually rotated. On the lateral projection **(B)**, the medial and lateral condyles are at distinctly different levels (*arrows*). This represents the double density shadow made by the offset of the displaced condyle. Six weeks later, the patient had a significant angular deformity secondary to a malunited single condyle fracture **(C)**. (Reprinted from O'Brien ET. Fractures of the hand. In: Green DP, ed. *Operative hand surgery,* 2nd ed. New York: Churchill Livingstone, 1988:737; with permission.)

“Distal Epiphysis” Means Fracture. In phalangeal neck fractures, the rotated head can be confused with an epiphysis. However, there is no epiphysis at the distal end of the phalanx; this represents a pathologic condition. The adequacy of the subcondylar fossa must be evaluated on the lateral view.

Treatment

Most phalangeal fractures can be treated nonoperatively. Outcomes are uniformly good for most of these fractures. Despite the favorable biology of youth, certain fractures require a more aggressive approach.

Physeal Fractures. Most phalangeal fractures are fractures of the proximal phalangeal base. One of the most common fractures has a readily recognizable name that is both descriptive and memorable. Rang (175) coined the term *extra-octave fracture* to describe the S-H II fracture of the ulnar aspect of the proximal phalangeal base. The digit has the clinical appearance of supraphysiologic deviation in an ulnar direction. Such an arrangement may be beneficial to the span of a pianist (Fig. 8-38). Most of these fractures can be treated with closed reduction and immobilization for about 3 weeks.

FIGURE 8-38. A: An extra-octave fracture in a 12-year-old girl. **B:** The deformity was corrected with the metacarpophalangeal joint in full flexion.

Closed Methods. If displacement is minimal, simple splinting in the safe position for 3 weeks is indicated. If the fracture is displaced, manipulation can be performed with local anesthesia or conscious sedation. Placing a hard object (such as a pencil) in the web space and using it as a fulcrum to assist reduction has been perpetuated in orthopaedic training (232), but this manipulation technique may create a transient nerve injury from a focal crush.

The reduction maneuver requires maximal MCP joint flexion, which relaxes the skin of the web space and the intrinsic muscles. Then the digit is manipulated into the opposite direction of the deformity. Temporary immobilization (light plaster or loose “buddy taping”) should be used while radiographs are obtained after reduction to minimize the chance of redisplacement during positioning for the radiographs.

Operative Indications. Despite the high rate of success with closed treatment of phalangeal base fractures, irreducible fractures have been reported (12,47,103,127). Reduction was prevented by various tissues, including periosteum and flexor or extensor tendons. In significantly displaced fractures, the distal fragment can herniate through the extensor apparatus (Fig. 8-39).

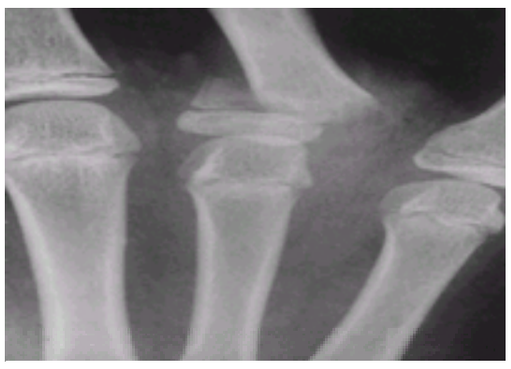

FIGURE 8-39. This displaced type I phalangeal base fracture was irreducible by closed means. The distal fragment can herniate through a rent in the sagittal band, periosteum, or extensor mechanism to become incarcerated in the fracture.

Some S-H II fractures may be reducible but unstable after reduction. These tend to be higher energy injuries with more internal disruption of the supporting soft tissues. Insertion of a smooth percutaneous pin after reduction may be warranted. Rarely is there any long-term functional compromise or growth disturbance (Fig. 8-40) (103,193).

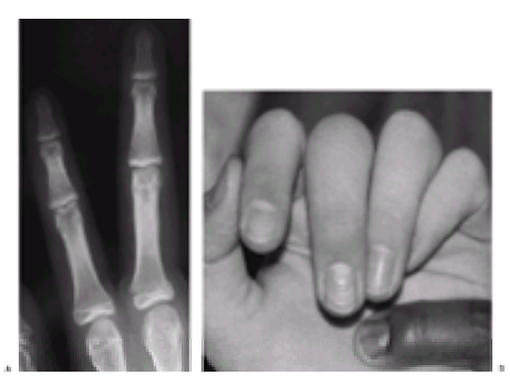

FIGURE 8-40. A: Anteroposterior radiograph of a Salter-Harris II fracture at the base of the middle finger. The radiograph reveals slight angulation and can look relatively benign. However, it is imperative that a clinical examination be performed with assessment of the digital cascade for malrotation. **B:** Tenodesis of the wrist with passive extension results in relatively painless digital flexion. In this case, the unacceptable malrotation is evident by the degree of overlap of the middle finger on the ring finger and the widening of the interspace between the index and middle fingers.

A displaced S-H III fracture of the proximal phalangeal base is particularly difficult to treat. The fracture fragments can be sizable and may involve more than one fourth of the joint surface, affecting the stability of the articulation. If a significant amount (>25%) of the articular surface is involved, or if residual displacement exceeds 1.5 mm, most clinicians advocate open reduction and internal fixation (104,193).

If open reduction and internal fixation are required, the alternatives are intraepiphyseal Kirschner wires or small screws that are inserted parallel to the joint surface (35,73). The latter have little use in the small phalanges of children.

Comminuted fracture–dislocations of the middle phalangeal epiphysis are rare in children, so the recommendations for treatment are extrapolated from experience in adults. Displacement of the fragments, compression of the central aspect, and instability of the joint all complicate this injury. The alternatives for treatment are open reduction with internal fixation and closed dynamic traction.

Anatomic restoration of these pilon fractures (209) is desirable, but the morbidity of opening the PIP joint is well known. If the fragments are large, then open reduction and smooth wire fixation may be possible. This can be accomplished by elevating the lateral bands, taking care to protect the central slip insertion on the dorsal

fracture fragment. A central depression of the epiphysis may require elevation. The implications for potential future growth are ominous.

The other alternative, dynamic traction, avoids open manipulation of the PIP joint (1,192). This may take one of several forms, but the concepts of ligamentotaxis and early motion for articular remodeling are the basis for this treatment. Agee's force-couple concept is innovative but somewhat arduous to apply and wear (1). Likewise, Schenck's large outrigger device has demonstrated remarkable results but is cumbersome (192). The use of distraction devices is evolving, and development of new external fixators and lower profile distractors with articulating elements may provide better options.

Primary arthrodesis and volar plate arthroplasty have no role in children's phalangeal fractures.These are salvage procedures that should be contemplated only after skeletal maturity.

Shaft Fractures. Nondisplaced and stable fractures can be treated successfully with simple immobilization. Fractures that are unstable after reduction or cannot be reduced by closed methods require operative intervention. The fracture orientation, amount of comminution, success of closed manipulation, and stability all influence the treatment decisions for phalangeal shaft fractures. The stabilizing influence of the flexor sheath and periosteum help keep reduced fractures in place. Safe position splinting for 3 to 4 weeks should be adequate for clinical union (46).

Phalangeal fractures in the proximal third of the shaft can have significant volar angulation because of tendon forces. They can be difficult to see on radiography, and malunion may result from inadequate treatment. If significant remodeling does not occur, a claw hand can be caused by imbalance of the extensor mechanism (13).

Limits of Remodeling. Failure of closed reduction also can cause persistent malrotation, instability of a transverse mid-shaft fracture, or unacceptable angulation (Fig. 8-41). Simmons and Lovallo (198) reported that angulation of up to 20 to 25 degrees in the plane of motion may be acceptable in children under 10 years of age, but older children have difficulty tolerating more than 10 to 15 degrees of deformity. Coonrad and Pohlman (46) concluded that angulations of 30 and 20 degrees respectively will be remodeled in these groups. Favorable factors for remodeling are young age, juxtaphyseal location, and deformity within the plane of motion of the involved joint.

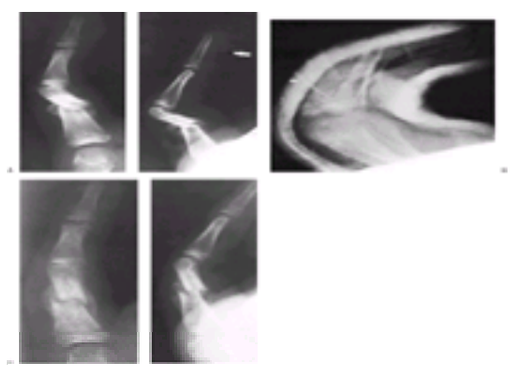

FIGURE 8-41. A: A 12-year-old boy presented with this healing angulated fracture of the shaft of the proximal phalanx of the little finger 2½ weeks after injury. **B:** Closed osteoclasis corrected the deformity, and the finger was immobilized in flexion in an ulnar gutter splint. **C:** The splint was discontinued 4 weeks later when these radiographs were made. Nearly normal function had returned when the patient was seen 3 months after injury.

Late clinical malunion is a frequent problem. Prompt referral, accurate clinical and radiographic assessment, and appropriate fracture stabilization will prevent this problem.

Surgical Management. Stein (205) advised closed reduction and crossed Kirschner wire fixation of transverse phalangeal shaft fractures that could not be maintained in less than 20 degrees of angulation in a well-molded splint (Fig. 8-42). Closed pinning also is an option for spiral and oblique fracture patterns. If comminution is significant or reduction cannot be obtained or maintained, open treatment is indicated.

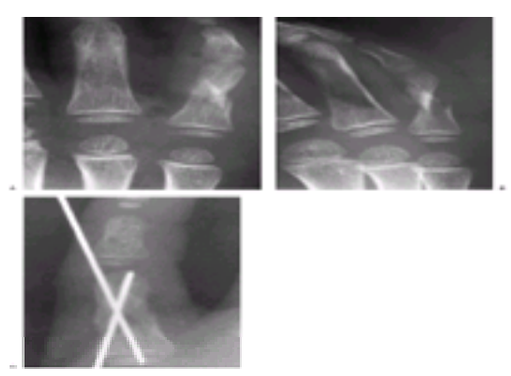

FIGURE 8-42. A and B: A minimally comminuted transverse fracture of the proximal phalanx with a short oblique component was difficult to control by closed methods. **C:** Crossed Kirschner wires were used to stabilize the fracture. The distal-to-proximal wire exits dorsal to the physis and therefore does not jeopardize the growth potential.

Open reduction can be performed through a dorsal incision. Splitting of the extensor tendon provides excellent exposure of fractures of the proximal phalanx, and the lateral bands can be elevated to gain access to the fracture. The choice of implant is smooth wires or screws. In adolescent athletes, the goal of early motion and protected return to activity may influence implant choice.

For fractures of the distal third of the proximal and middle phalanges, the extensor tendon should not be split, but instead deviated to the radioulnar side for access to the fracture. To permit this, part of the distal aspect of the transverse retinacular ligament must sometimes be incised at its insertion onto the dorsal apparatus.

Phalangeal Neck Fractures. Some clinicians have reported successful closed treatment of fractures of the phalangeal neck. However, this is difficult because these fractures tend to be unstable and displace due to the persistent attachment of the distal fragment on the collateral ligaments (Fig. 8-43).

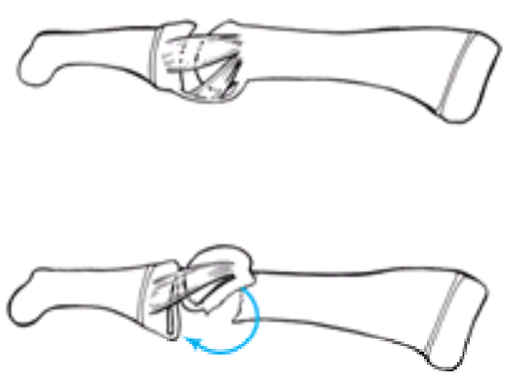

FIGURE 8-43. Pericondylar or subcondylar phalangeal fractures tend to rotate due to their ligamentous attachments. These fractures are difficult to reduce and control by closed means because of the interposition of the volar plate and ligamentous forces. (Reprinted from Wood BE. Fractures of the hand in children. *Orthop Clin North Am* 1976;7:527–534; with permission.)

Closed manipulation is by digital distraction and volar-directed pressure on the distal fragment with hyperflexion of the PIP joint. Percutaneous pinning usually is necessary to maintain the reduced position (Fig. 8-44) (59). This is difficult because of the small size of the fragment. Under fluoroscopy, one or two small Kirschner wires are inserted through the collateral recess and across the fracture. These wires should engage the contralateral cortex proximal to the fracture site. An alternative is to insert the pins through the articular surface of the proximal phalanx in a longitudinal fashion, crossing the fracture to engage the proximal fragment. This carries the risk of growth disturbance, because the pins cross the physis of the proximal phalanx.

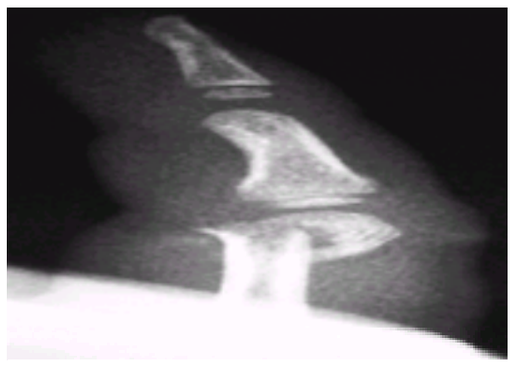

FIGURE 8-44. Displaced phalangeal neck fracture of the proximal phalanx revealing loss of subchondral fossa at the proximal interphalangeal joint joint. If this is not corrected to anatomic alignment, there will be a mechanical block to flexion.

Intraarticular Fractures. The treatment options for displaced intraarticular fractures of the phalanges are closed reduction with percutaneous pinning and open reduction with internal fixation (20,104,193). The percutaneous technique involves the use of a towel clip or reduction clamp to effect and maintain reduction while percutaneous pins are inserted. If this is not feasible, open reduction and internal fixation is indicated through a dorsal or lateral incision with reduction of the fragment under direct vision. Care should be taken to preserve the blood supply of the fracture fragments entering through the collateral ligaments. Fracture stabilization is by either Kirschner wires or mini-screws (Fig. 8-45).

FIGURE 8-45. A: A 10-year-old boy sustained a displaced radial condylar fracture of the proximal phalanx when he injured his ring finger playing football. **B:** The oblique view is most helpful in determining the extent of displacement. **C:** Open reduction and internal fixation the day after injury resulted in normal function.

Rarely, severe metaphyseal comminution leaves a void after anatomic alignment of the articular fragments. This may require supplemental bone grafting and more extensive fracture stabilization with a condylar blade plate.

AUTHORS' PREFERRED METHOD OF TREATING PROXIMAL AND MIDDLE PHALANGEAL FRACTURES

Physeal Fractures

All nondisplaced fractures are treated with simple immobilization until pain free. Most displaced S-H I and II fractures about the hand can be treated with closed reduction (Fig. 8-46). This should be performed under comfortable conditions for the patient, including local anesthesia and conscious sedation. Simply flexing the digit maximally at the MCP joint and applying the appropriate maneuver (e.g., radial deviation for extra-octave fractures) successfully reduce the fracture. Checking the clinical alignment and rotation, as well as the radiographs, is imperative. We place the patient in a safe position splint for 3 to 4 weeks. One interval radiograph is obtained at 5 to 7 days to ensure that the reduction is being held. The rapidity of healing limits the ability to remanipulate the fracture if reduction has been lost. The remodeling potential of fractures angulated in the flexion-extension plane is significant because of their proximity to the active physis. Remodeling in the medial-lateral plane is more limited because of the minor adduction-abduction range of motion at the MCP joint.

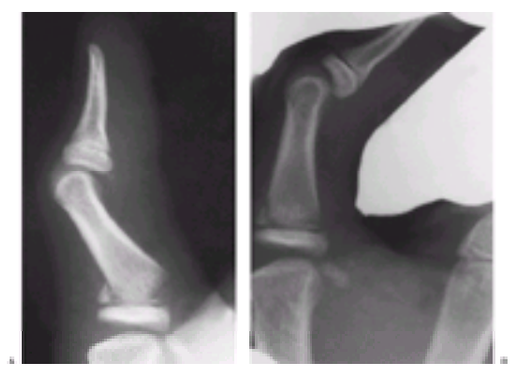

FIGURE 8-46. A: Salter-Harris II fracture of the proximal phalanx of the thumb. **B:** Gentle closed reduction, performed under fluoroscopic control, yielded an anatomic reduction. The large surface area contact about the physis helped stabilize the fracture without the use of implants. Rapid healing and excellent function resulted.

Operative Indications

Unstable fractures can be percutaneously pinned after reduction. Small (0.028-inch) smooth wires that hold the epiphysis reduced can be placed through the metaphyseal flag or the Thurston-Holland fragment, or the physis can be crossed if necessary.

If closed reduction is not possible, a dorsal exposure of the fracture allows extrication of the impediment and fixation with smooth wires. This is rarely necessary.

Salter-Harris III fractures of both the middle and proximal phalanges are difficult to reduce and maintain by closed methods. The rare dorsal S-H III fracture of the middle phalanx base can sometimes be treated by closed reduction and splinting in extension. If the fragment does not reduce, open reduction and fixation are warranted to avoid the later development of a boutonniere deformity. A dorsal approach, with an incision between the central tendon and the lateral band, is preferred. The dorsal fragment can be excised if it is small and the patient is near skeletal maturity, and the central slip can be repaired back to bone. The fragment usually should be pinned so the epiphysis is restored. The PIP joint may need to be pinned for up to 3 weeks to permit healing.

If the epiphyseal fragment is displaced more than 1.5 mm or involves more than 25% of the articular surface, or if joint stability is compromised, then open reduction and internal fixation are indicated. This is more common in the proximal phalanx at the MCP joint. The fracture is exposed through a dorsal incision between the sagittal band and the extensor tendon. The joint capsule is incised dorsally while preserving the collateral ligaments. If there is an associated collateral ligament or soft tissue disruption, this should be repaired simultaneously. Smooth wires are driven parallel to the joint to reduce and stabilize the epiphysis. It rarely is necessary to pin the fragment to the shaft. Mini-screws can be used in larger patients and larger fragments but add little stability. Motion can be started at 7 to 10 days, and the pins are removed at 4 to 6 weeks. However, intraarticular fractures typically take longer to heal.

Rare Intraarticular Fracture–Dislocations

The very rare pilon fracture or intraarticular fracture–dislocation at the proximal phalanx base presents a management dilemma in children and adults (209). The treatment alternatives are open reduction with anatomic restoration and dynamic traction (1,192). Opening the PIP joint is worthwhile when a large enough fragment exists and the epiphysis has not been too distorted. If the child is in later adolescence, treating the complex fracture–dislocation with elevation of the epiphyseal bone (with bone grafting) is reasonable.

Outstanding results with the use of the traction method in adults have been reported, and the benefits of early motion to both the bone and soft tissue present a strong argument against open reduction. If the child is not within 1 to 2 years of maturity, a significant physeal injury at this level has growth consequences. Open reduction may increase that risk. Although the utility of dynamic traction methods in skeletally immature patients is unproven, the healing and remodeling potential of children makes them particularly good candidates for minimal intervention in these complex injuries.

Shaft Fractures

Closed Reduction Technique

After satisfactory anesthesia is obtained, displaced shaft fractures are reduced by longitudinal traction followed by correction of the angular deformity with flexion or the rotatory deformity with appropriate pronation or supination. For reduction of a proximal phalangeal fracture, the MCP joint is maximally flexed to relax the intrinsic muscle pull and to stabilize the proximal fragment. Recreation of the deformity with exaggerated dorsiflexion of the distal fragment disengages the fracture fragments and allows the periosteum to assist in guiding fracture alignment.

Checking the reduction with respect to length and displacement in the coronal, sagittal, and rotatory planes is essential. Three or four plaster strips are carefully applied anteriorly and posteriorly while molding the fractured digit and one adjacent digit into the safe position. Despite best efforts, it is difficult to obtain more than 75 to 80 degrees of MCP flexion. The lighter plaster dressing is stable enough to permit radiographs to be taken; if alignment is adequate, the splint is reinforced.

Postreduction Care

Fractures of the middle phalanx should be immobilized in more of a functional position, with moderate flexion of the PIP and DIP joints added to maximal MCP flexion. For fractures of both segments, immobilization should be for 3 to 4 weeks. Tenderness usually has abated at this time, and many children show evidence of bony healing at this interval. Buddy taping can be used for an additional 2 weeks. Formal therapy or dynamic splinting usually is not required to regain motion. Protection during sporting activities should be continued until motion and strength are fully restored.

Percutaneous Pinning

Unstable spiral-oblique fractures of the proximal and middle phalanges require closed reduction with pinning (91). The fracture orientation dictates the angle of pin insertion. Ideally the pins should be placed at 90 degrees to the fracture line. Traction through fingertraps or an assistant and the aid of image intensification are indispensable. Placement of the pins in the mid-axial line prevents iatrogenic injury of the more volar neurovascular structures in the mid-lateral line.

Open Reduction

Open reduction rarely is required except in older adolescents or for irreducible fractures in younger children. The surgical approach for phalangeal shaft fractures can be dorsal or mid-lateral. The dorsal approach with tendon splitting is better for fractures of the proximal two thirds of the phalanx. The extensor tendon is split longitudinally in the center, with care to avoid injuring the underlying periosteum. The periosteum can be incised to one side of the phalanx so that the tendon and periosteal incisions do not coincide. Repair of the two layers after anatomic reduction should keep knots away from the sliding surface between them; thus, the knots in the periosteum should be buried close to the bone, and the tendon sutures should be tied so the knots face the subcutaneous tissue.

Fractures of the distal third of the proximal and middle phalanges are best approached through elevation of the lateral bands or deviation of the extensor apparatus. Access can be gained through a dorsal skin incision or a mid-lateral incision; however, the latter might be preferable to keep the skin incision away from the tendon. The insertion of the central slip on the epiphysis of the middle phalanx should not be detached, because this could result in a late boutonniere deformity.

Complex Injuries

Combined injuries that affect several tissue systems are common in the digits. Because of their curiosity and desire to explore, children are vulnerable to injury from machinery and household equipment. Skin, tendon, neurovascular structures, and bone can all be injured in the same digit (Fig. 8-47). Anatomic reduction and stable fixation are the goals in older children with these complex injuries so that early motion can be achieved.

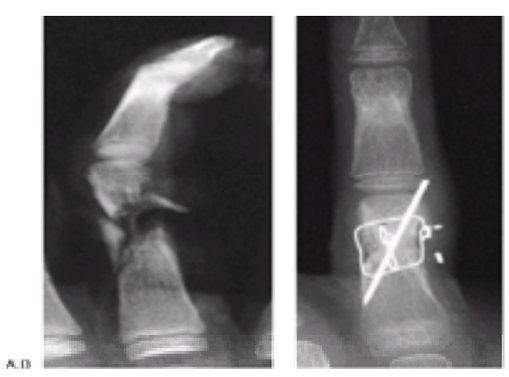

FIGURE 8-47. A: 14-year-old boy sustained a near-amputation of his ring digit while using a bandsaw. **B:** 90-90 intraosseous wiring was supplemented with Kirschner

wire fixation to provide a stable base for soft tissue repair. Good healing was achieved in the 2 intervening months since the original operation.

Open fracture care is of paramount importance, followed by establishment of a stable bony foundation. Markedly comminuted fractures or injuries with bone loss may require staged bony reconstruction, with stabilization in the acute setting by minimal internal or external means. Again, stable fixation is the absolute goal so that early motion can be achieved. Bone grafting of defects can be performed at the time of secondary closure or skin coverage.

Vascular reconstruction, as necessary, is performed next, then the nerve status is assessed. Primary neurorrhaphy usually is favored, but later nerve grafting may be considered for large segmental nerve defects in untidy wounds. Tendon surgery principles are the same for children and adults. A viable bed must be established, and the status of the tendon and the fibroosseous theca must be assessed. Repair of the tendon by an experienced surgeon usually is best. Tendon grafting or other salvage procedures have a very limited role in children. Flexor tendon rehabilitation in a child sometimes can be complicated due to lack of cooperation, so individualizing the protocol may be necessary. In patients under 15 years of age, cast immobilization and protected motion protocols yield the same end results.

Neck Fractures

Pin Fixation

If recognized early, minimally displaced subcondylar fractures can be treated with gentle manipulation and immobilization (Fig. 8-48). Because the distal fragment is dorsally displaced, flexion of the fragment with thumb pressure may reestablish the anatomic relationships, and immobilization in flexion can maintain reduction. However, most of these fractures are more displaced and unstable. If the fracture is reducible but unstable, cross-pinning can be performed. This is best performed by flexing the PIP or DIP joint and placing small (0.028-inch) wires through the collateral recesses to engage the proximal fragment in a crossed fashion. Wires can be removed at 4 weeks and motion started soon thereafter. If an acute subcondylar fracture cannot be reduced by closed manipulation, open reduction and similar percutaneous pinning are indicated. Elevating the lateral bands to gain access would be the choice of approach to the proximal phalanx; deviating the extensor mechanism to the radial or ulnar side for middle phalangeal subcondylar fractures would yield the best access. Care is taken to maintain the blood supply to the small distal fragment to lessen the risk of avascular necrosis.

FIGURE 8-48. This minimally displaced type III fracture was amenable to closed reduction. Although the anatomy of the subcondylar fossa was altered by the fracture, excellent active and passive motion of the PIP joint was maintained. Excellent function was realized after 3 weeks of splinting and an early aggressive motion program.

Limited Remodeling Potential

If the fracture is unrecognized or neglected, significant loss of flexion may result. Rarely younger children may remodel at this end of the bone even through it is distant from the physis. Usually the residual deformity is functionally limiting. If the patient presents when there is still a slight fracture line present in the healing, malaligned bone, percutaneous pin osteoclasis can be performed. Using fluoroscopy, one or two smooth pins are inserted into the fracture and used to “joystick” the distal fragment into a reduced position. The fracture is then stabilized with percutaneous pins. This approach may lessen the risk of avascular necrosis with late open reduction. Rarely these fractures can be opened as late as 2 to 3 weeks by taking down the early callus with a combination of sharp dissection and blunt dissection with a Freer elevator. Again, fixation with crossed pins is the best way to stabilize the injury.

Intraarticular Fractures

Open Reduction Usually Necessary

Intraarticular fractures of the phalanges are likely to require either percutaneous reduction and pin stabilization or open reduction and internal fixation. Figure 8-49 illustrates an intraarticular fracture of the proximal phalanx treated by open reduction through a dorsal incision. A mid-lateral incision can be used to approach an intraarticular fracture at the DIP joint, and a volar incision can be used to expose the PIP joint. The same concepts of careful tendon and periosteal handling described above hold true. Longitudinal division of the transverse retinacular band on the side of a single condyle fracture is preferred. Rarely, the extensor tendon/lateral band interval must be exploited on both sides of the digit to inspect and manipulate the fragment. Exposure of the fragment with minimal soft tissue stripping is important. This may be difficult, because an abundant amount of early callus forms in these fractures, and clearing this tissue can be arduous. Flexion of the PIP or DIP joint provides better access to the fracture.

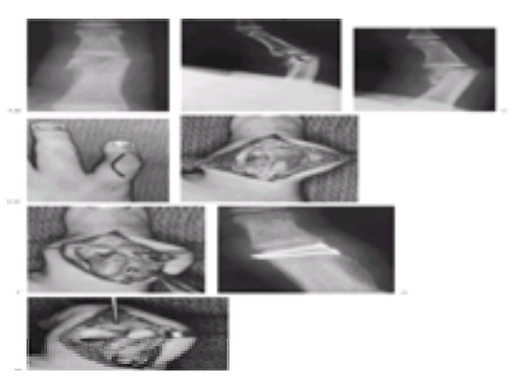

FIGURE 8-49. Authors' treatment of a complex unicondylar fracture of the proximal phalanx. **A:** Anteroposterior film demonstrating the intraarticular component of fracture and comminution on the radial aspect. **B:** The double density sign (*arrows*). **C:** Oblique film better characterizes the displaced rotated condylar fracture fragment. The step-by-step operative approach follows. **D:** Dorsal approach to the fracture fragment. **E:** Incision between the central tendon and lateral band. **F:** Careful handling of the periosteal flap (*open triangle*). The fracture fragment is exposed and debrided of the early callus. **G:** Flexion of the digit shows how the displacement is exacerbated (*arrows*) because of the pull of the collateral ligaments. **H:** A mini-screw is applied after reduction of the fragments. This can be preceded by provisional smooth wire fixation. The reduction must be judged by the articular surface and not the area in the metaphysis, because part of this may have been reabsorbed or debrided. Two screws were selected because of comminution of the fracture, but care was taken not to hinder motion by incarcerating the collateral ligament. Great care must be taken not to tether the ligament when placing definitive fixation. By 6 weeks' follow-up, excellent motion had been obtained.

Sometimes the fragment has been slightly comminuted or plastic deformation has occurred, making a perfect fit all around the fragment impossible. Therefore, reduction must be judged at the articular surface. Often the subcondylar fossa must be cleared of bone, and failure to perform this step results in a flexion block despite anatomic joint reduction. Provisional or permanent fixation can be obtained with one or two smooth wires. The direction of these wires is dictated by the fracture configuration. Oblique cross-pinning is best for subcondylar and some transcondylar fractures, but small avulsions and unicondylar fractures may be stabilized better by pinning parallel to the joint. Rotational control of the fragment may require multiple implants. Pinning or screw placement through the collateral ligament should be avoided so that there is no tethering of the soft tissues.

Full motion should be verified before closing the wound. The decision to leave the pins as retained implants or to bring them out of the skin for later removal must be individualized. In younger children, the pins are left out of the skin, and a sterile dressing and cast are left intact until removal. In cooperative adolescents, treatment is more adultlike, with early motion protocols. In this case, the pins are buried to lessen the risk of skin irritation and superficial or deep infection. Countersunk 1.5- or 2-mm mini-screws are not too prominent to become troublesome later. Late removal of these implants at this level rarely is necessary.

For a simple collateral ligament avulsion fracture, protected early motion usually is satisfactory treatment. The digit should be buddy taped to the adjacent digit to prevent recurrent angulatory or rotatory stress on the healing ligament avulsion. Rarely, interphalangeal or metacarpophalangeal joint instability requires open repair. The surgical approach can be through a mid-axial incision, and arthrotomy can be avoided. Secure fixation allows early motion and less risk of long-term contracture (Fig. 8-50).

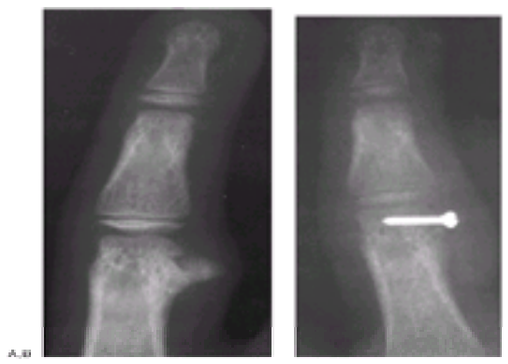

FIGURE 8-50. A: An avulsion fracture of the proximal phalanx with its attached collateral ligament destabilized the digit. **B:** It was approached extraarticularly through a mid-axial incision and secured with a mini-screw, permitting early motion.

Certain intraarticular fractures present even greater challenges because of their pattern or orientation (Fig. 8-51). Intraarticular shear fractures can be treated with arthrotomy and small Kirschner wire fixation. Supplemental bone graft may be necessary. This osteochondral slice fracture can be problematic despite appropriate treatment. It is even more complicated when it is missed or its severity underappreciated in the acute setting. When multiple injuries about the interphalangeal joints occur (Fig. 8-52), the treatment approach must maximize fixation of all injuries.

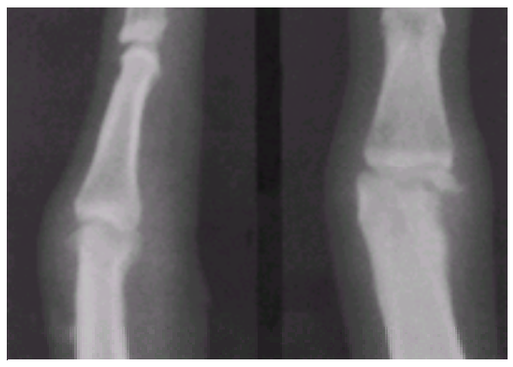

FIGURE 8-51. This intraarticular shearing fracture of the proximal phalanx is one of the more difficult ones to treat. There is little bony support for the articular cartilage, which makes fixation difficult.

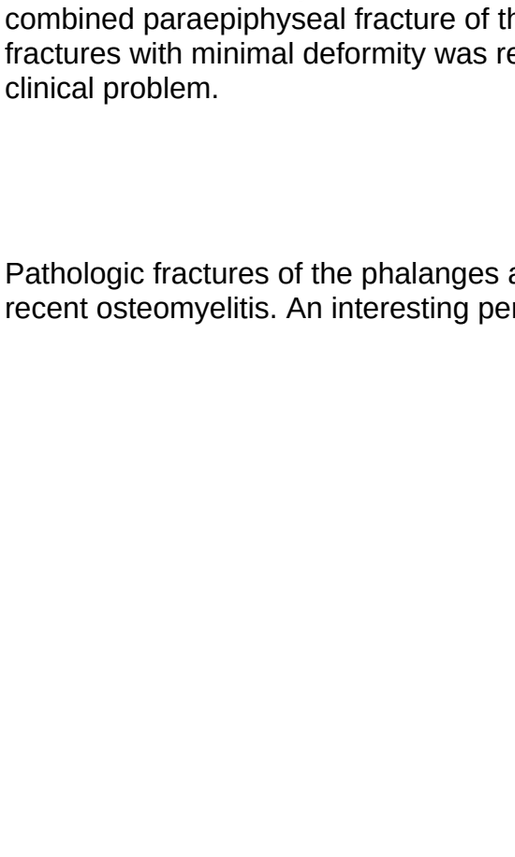

FIGURE 8-52. A: A 4-year-old with a significant crush injury to the long digit resulting in a metadiaphyseal and subcondylar fracture of the proximal phalanx with a combined paraepiphyseal fracture of the middle phalanx. The PIP joint appears reduced. **B:** Reduction was followed by longitudinal wire fixation. Healing of the fractures with minimal deformity was realized. **C:** There appears to be a possibility of partial growth arrest (*arrows*) of the middle phalanx physis, which presented little clinical problem.

Pathologic fractures of the phalanges are rare. The most common is secondary to enchondromas and other benign tumors of bone. Rarely, they occur with remote or recent osteomyelitis. An interesting pericondylar fracture in a child with a congenital deformity is shown in Fig. 8-53.

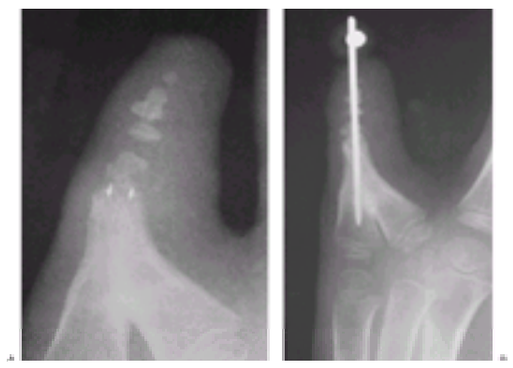

FIGURE 8-53. A: A subcondylar fracture (*arrows*) in an 8-year-old boy with complete complex syndactyly of the two ulnar digits. **B:** Because closed reduction and splinting failed to control it adequately, it was stabilized with a single longitudinal pin. Recovery was complete.

Postoperative Care and Rehabilitation

The duration of immobilization after surgical intervention for phalangeal fractures is usually 3 to 4 weeks. Percutaneous pins are removed at the same time as the immobilization. For periarticular fractures in an older child, an interval of protected motion or further immobilization may be considered. For example, pins can be removed at 3 weeks and motion started at 4 weeks. Periarticular fractures must be monitored more closely than others for the progress of motion recovery. Although little formal hand therapy is needed, the child must reestablish a usage pattern of the digit for the soft tissues and joints to improve their flexibility. The border digits, index and small, seem to be the most difficult to activate after fracture surgery. If full motion and strength are not achieved at home, then formal hand therapy may be necessary.

Patients who have more extensive surgery, such as for complex fractures or replantations, are more prone to develop motion limitations. Flexion can be lost from the mechanical block of scar or bone in the subcondylar fossa. Extension can be limited after surgical manipulation of the extensor apparatus. Attention must be directed to both flexion and extension in the postoperative regimen. Static or dynamic splinting may be instituted if progress is slow.

Prognosis

Considering the frequency with which most surgeons care for these injuries, the number of true complications and functional impairments is low. Despite appropriate treatment, however, some patients have motion loss, malunion, and growth disturbance.

Factors Affecting Remodeling

The factors that influence the remodeling of fractures are the patient's age at the time of injury and the amount of growth remaining, the location of the fracture with respect to the physis, and the magnitude and the plane of malalignment (23).

Age. The younger the patient, the more time and potential exist for remodeling. However, several clinicians argue that significant remodeling can still occur when as little as 2 years of growth remains (88,175).

Fracture Location. Fractures near an open physis have a greater potential to remodel. This is why so few of the prevalent proximal phalanx base fractures cause later deformity, and why there is even greater emphasis on anatomic restoration of pericondylar injuries, which are so distant from the physis.

Malalignment. Angular deformity usually is not strictly limited to the coronal or sagittal plane, but most of the displacement may be present in one of these directions. Deformity in the flexion-extension plane is thought to remodel reliably. Several clinicians have observed remodeling in the range of 20 to 30 degrees in the sagittal plane in children under 10 years of age and about 10 to 20 degrees of remodeling in older children (46,198).

Limits of Remodeling. Deformity in the coronal or adduction-abduction plane is considerably less. This is rarely quantified but is probably 50% or less than remodeling in the sagittal plane. The ability of border digits to withstand more coronal plane angulation before overlap occurs may dictate different recommendations for acceptable residual angulation. Likewise, the potential of the second and fifth rays to remodel is higher due to their relative freedom of motion in abduction. Radial abduction deformity of the index finger and ulnar abduction deformity of the small digit at the proximal phalanx level may be tolerated up to 20 degrees. It is likely that only 10 degrees will remodel to an acceptable amount in the other digits. No significant amount of coronal remodeling (5 degrees or more) occurs at the middle phalanx.

We agree with Green that little remodeling occurs at the distal aspect of the phalanges (90). However, in one report a displaced phalangeal neck fracture demonstrated striking remodeling in a 7-year-old boy. Dramatic improvement in the radiographic appearance and the motion of the digit occurred 14 months after the injury without surgical intervention (151). Perhaps very young children can reconstitute their anatomy, but early anatomic reduction remains the treatment of choice for displaced phalangeal neck (subcondylar) fractures.

Late Deformities

Posttraumatic degenerative joint disease is rare in children, but intraarticular injury and sepsis are two factors that may predispose to these changes. As Rank and Wakefield stated, “Unless the joint itself has been the subject of direct injury, we need never fear secondary joint changes in children to the extent that we do in adults” (176). In the rare occurrence of traumatic arthrosis, emphasis should be on the patient, not on the radiographs: minimal pain and excellent function often accompany a significant architectural disturbance. Nonsurgical treatment options are few, so the timing of intervention is likely to be the most important factor. Only when pain and functional limitation compromise the patient's daily activities or when the deformity threatens to affect future vocational choices should reconstruction be considered.

Reconstruction options include osteotomy, vascularized joint transfer, interposition or distraction arthroplasty, prosthetic joint replacement, and arthrodesis (199). Amputation may be appropriate for a completely dysfunctional digit. All these interventions are considered salvage surgery.

Complications

Failure to Recognize a Displaced Fracture. Recognition of a displaced intraarticular fracture is difficult, and the impact of an unrecognized injury is functionally significant (Fig. 8-54). There usually is a suggestion of pathology on the lateral film, but it is subtle. The AP film is notorious for concealing the true nature of this injury. The oblique film most effectively shows the fracture configuration. Fluoroscopy can be useful in examining the small joints.

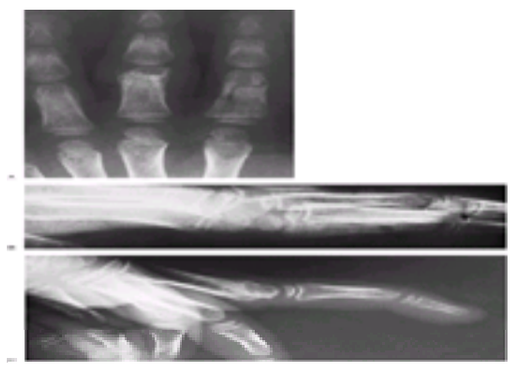

FIGURE 8-54. A: A 3-year-old girl sustained a fracture of the neck of the proximal phalanx of the index and middle fingers when they were caught in a door. The displaced fracture in the middle finger gives the appearance of an epiphysis at the distal end of the phalanx. **B:** Unfortunately, no true lateral radiograph of the injured finger was obtained. Close scrutiny of this lateral hand radiograph shows a dorsally displaced neck fracture, rotated almost 90 degrees (*arrow*). No reduction was performed because the displacement was not appreciated. **C:** Eighteen months later, remodeling is not correcting the deformity. The proximal interphalangeal joint is hyperextended, and the patient had a significant loss of flexion.

Unfortunately, too often displaced phalangeal neck fractures are not recognized. The fracture may be confused with an epiphysis, or a minor avulsion fracture, or it may be believed to be nondisplaced. Unfortunately, many children with these fractures present late with a malunion and loss of interphalangeal flexion.

Malrotated fractures also are often missed until healed. The radiographs can be benign in appearance but the clinical appearance profound. Every patient with an acute phalangeal shaft or physeal fracture should be examined for malrotation.

Redisplacement. Although most phalangeal fractures are successfully treated by closed means, some fractures are difficult to control (Fig. 8-55). In general, the closer the patient is to skeletal maturity, the more likely it is that reduction will be lost, especially with transverse or short oblique fractures of the proximal phalanx. Because of surrounding tendon forces, the fracture tends to angulate with the apex volar. The physician must guard against this when applying immobilization, and frequent follow-up is suggested.

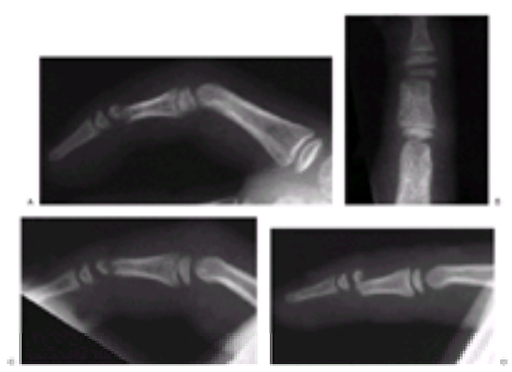

FIGURE 8-55. A and B: An 8½-year-old girl with a mildly displaced fracture of the neck of the middle phalanx. **C:** Closed reduction was successful on the day of injury. A plaster splint was applied. **D:** Two weeks later, the fracture had redisplaced and the deformity was worse than it was originally. Closed pin fixation could have prevented this problem.

If the fracture is unstable in the first 7 to 10 days after injury, closed reduction with percutaneous smooth wire fixation is an excellent option. The reduction must be carefully assessed and ensured before proceeding with fixation. If the fracture cannot be reduced, then soft tissue or bony interposition may necessitate open reduction. Percutaneous pinning is still favored, but mini-screw fixation in patients close to maturity can be considered for some fracture patterns.

Malunion. Because children's fractures heal so quickly, a significant amount of callus is sometimes encountered in patients who were not referred in a timely manner, or in those who lost reduction in the interval since the last assessment (Fig. 8-56). This complication can be prevented by examining the child within 24 to 48 hours of the injury, and frequent clinical and radiographic examinations should be performed in the first 7 to 10 days. Rereduction and pinning or internal fixation is always easier than reconstructing a complex malunion.

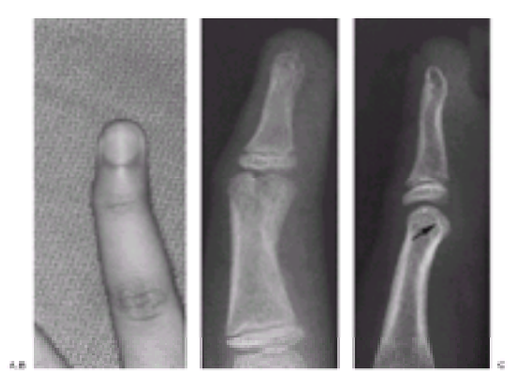

FIGURE 8-56. A: Deformity in the ring finger of a 13-year-old. **B and C:** Radiographs revealed a malunion of the radial condyle with intraarticular incongruity. It is difficult to appreciate this from the lateral film, but the hint of a double density shadow is seen (*arrow*). The lateral alignment and flexor function in the digit was essentially normal. Accelerated arthrosis is possible, but no reconstructive options should be offered because of normal function.

Late Osteotomies. If the deformity is significant, the malunion should be allowed to mature biologically, while regaining maximal motion, strength, and tissue elasticity. Osteotomy should be performed through the site of deformity or, if feasible, at a site where good fixation can be obtained and the bone has a realistic chance of proceeding to union. For malunions of the diaphysis of the phalanges, osteotomy usually is performed at the basilar metaphysis. It is easier to make the correction at this level because the tissues are more substantial and the bones are larger for holding fixation.

If the malunion is at the subcondylar or intraarticular level, the osteotomy needs to be at the site of deformity. If the fracture is mature, then realistic reconstructive goals must be established. Imaging studies such as CT scanning, tomography, or dynamic fluoroscopy can be used to assess the effect of the articular incongruity and the “extra” bone in the subcondylar fossa that may be impinging on the volar lip of the flexing phalanx. Motion can be restored by simply removing the mature bone from the subcondylar fossa, but this does little to improve joint congruity. When the child is still young, it may be more reasonable to accept the intraarticular deformity and perform the osteotomy of the fossa only for motion recovery.

Intercondylar osteotomy is exceedingly difficult, but it is the only way to improve or restore articular anatomy. This procedure is seldom performed, and there is little information about it in the literature. It may be best to follow the child and consider a salvage procedure, such as fusion or arthroplasty, only if significant symptoms

persist.

Fracture Take-Down. Juxtaarticular malunions are among the most challenging problems facing the reconstructive surgeon. If the child is under 10 years of age and the problem is recognized in the first 2 weeks after injury, callus take-down and anatomic restoration either by percutaneous osteoclasis or open repair can be successful. The status of the joint must be evaluated and any fracture callus in the subcondylar fossa that may inhibit flexion must be removed. The interval of time from injury to reconstruction can be extended to 3 weeks in children up to their mid-teens. There are no physes on the distal ends of the phalanges that would permit significant remodeling.

Growth Disturbance. If the original injury involved the physis, growth disturbance can occur, resulting in stunted longitudinal growth or angulatory deformity (Fig. 8-57). Fortunately, this is rare. It is more likely when there is a vascular injury or infection.

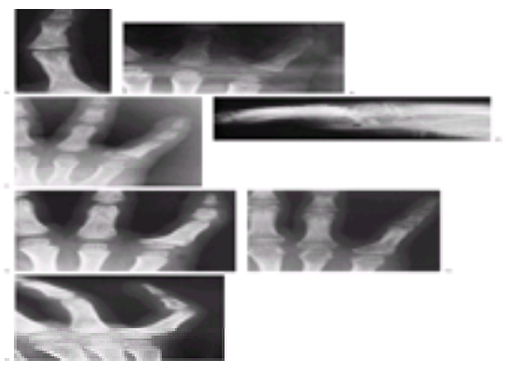

FIGURE 8-57. Types of growth disturbances after fracture in the skeletally immature patient. **A:** Partial growth arrest. Seven months after a Salter-Harris type IV fracture of the middle phalanx, there is mild angular deformity and a bony bar crossing the physis. **B:** Recovery and remodeling. In this 3-year-old boy, the true extent of the cause of his swelling little finger was not appreciated. Anteroposterior view shows a rounded appearance of the epiphysis of the proximal phalanx. **C and D:** Six weeks later, the anteroposterior view reveals some bone formation adjacent to the displaced epiphysis, and a true lateral view shows the epiphysis as rotated 90 degrees (*arrow*). **E and F:** Twelve months later, anteroposterior and oblique views show a persistently distorted epiphysis. **G:** Appearance at age 18 (15 years after injury) shows complete correction. He also had normal clinical appearance and function.

Fractures of the Metacarpals

Fractures of the Finger Metacarpals

Unlike the phalanges, the metacarpals are relatively protected by their position within the hand and the stout soft tissues that surround them. There is significant variation in the relative mobility of the metacarpals. The stability of the second and third rays at the CMC joint is in contrast to the significant motion of the thumb and medial two rays.

Surgical Anatomy

Fractures of the metacarpals occur at the epiphyseal or periphyseal region, the neck, the shaft, or the base. Because the collateral ligaments at the MCP joint level originate and insert almost exclusively on the epiphyses, the physes are relatively unprotected from injury (Fig. 8-5). This is especially true when the forces have a combined axial load with a rotational component. Failure at the physis or an intraarticular fracture can be caused by any combination of forces. S-H II, III, and IV fractures of the metacarpals have all been reported (131,142,162,188).

The metacarpal neck is the most common site of fracture in this bone. The geometry of the metacarpal and the way the hand is used in a punching motion make the metacarpal neck susceptible to fracture. The cortical bone of the subcondylar fossa is relatively thin and supports a broad metaphyseal area. The angulation of the metacarpal as it approaches the articular region also may play a role.

Fracture patterns of the metacarpal diaphysis are similar to those in the phalanges. Transverse fractures, resulting from a direct blow to the hand, are relatively uncommon. Most metacarpal fractures resulting from torsion have a spiral or oblique pattern. Fractures of the central rays are stabilized by the transverse metacarpal and intervolar plate ligaments, making significant displacement uncommon. Diaphyseal fractures of the border digits (index and small) displace more readily.

Role of Periosteum

Each metacarpal has a thick periosteal layer that provides an excellent gliding surface between it and the undersurface of the extensor tendons. This layer can either aid or hinder the closed management of fractures in this area. The periosteum can serve as a hinge for reduction (particularly in neck fractures) or can prevent significant displacement. Conversely, the periosteum can become interposed between fracture fragments (especially in spiral fractures) and prevent reduction. If open treatment is necessary, the periosteal layer must be respected, and careful handling improves healing and motion potential.

Avascular Necrosis

McElfresh and Dobyns (142) and others (174) recognized that a tense effusion can develop after intraarticular fracture of the metacarpal epiphysis. The pressure can tamponade the vessels that enter the epiphysis circumferentially adjacent to the physis (51). Synovial vessels also may be disrupted by trauma. These vascular injuries can leave the physis devoid of blood supply and susceptible to necrosis and growth arrest.

Mechanism of Injury

Direct trauma, rotational forces, and axial loading may all cause fractures at the metacarpal level. All these forces can be generated by striking an object or participating in contact sports, the two etiologies that produce most metacarpal fractures in children.

Physeal Injuries

Epiphyseal and physeal fractures of the metacarpal head are common in the fifth ray but are rare in the index, long, and ring digits (13,36,104). Light and Ogden (131) reported five patients who sustained metacarpal epiphyseal fractures of the central three rays. Longitudinal growth disturbance resulted after axial loading mechanisms in these patients, but the prevalence of growth disturbance after metacarpal fracture is probably minimized because most of these injuries to the physis occur in older children (12–16 years of age). Fractures of the metacarpal neck are more common than physeal injuries.

Pediatric Boxer Fracture

The mechanism of metacarpal neck fracture in the child is the same as that seen in the adult “boxer's fracture.” Bending moments concentrated at the metacarpal neck can be generated by a force concentrated more dorsally on the epiphysis. These fractures have a component of axial loading and an element of tangential force, and the inherently weaker architecture of the neck fails under these combined forces.

Direct and Torsional Forces

Torsional forces that cause oblique and spiral fractures in other tubular bones also may act on the metacarpals. Although the border digits are more susceptible to this

injury, the interior rays can just as easily be grasped and torqued in a wrestling match or bicycle accident. The other way in which the diaphysis can fail is by exposure to direct trauma. A transverse fracture can result by three-point bending when the bone is stabilized on its proximal and distal end and force is directed to the mid-diaphysis. A classic example of this mode of failure would be when the hand is stabilized on the ground and is stepped on, as in a football pile-up.

Patterns of Fracture in the Finger Metacarpals

Table 8-4 lists the types of finger metacarpal fractures.

Epiphyseal and physeal fractures
Neck fractures
Shaft fractures
Metacarpal base fractures

TABLE 8-4. CLASSIFICATION OF FINGER METACARPAL FRACTURES

Epiphyseal and Physeal Fractures. Although S-H II fractures of the fifth metacarpal are common among patients 12 to 16 years of age, fractures that involve the epiphyseal and physeal regions of the other digits are rare (13,36,104). Intraarticular, head-splitting fractures at the metacarpal epiphysis and physis consistent with S-H II, III, and IV patterns seldom occur at the metacarpal level (Fig. 8-58).

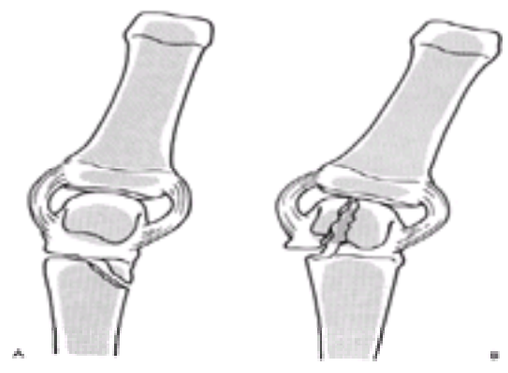

FIGURE 8-58. A: A Salter-Harris type II fracture of the metacarpal head. **B:** A head-splitting fracture of the metacarpal epiphysis.

In their report of five head-splitting fractures in the central three digits (131), Light and Ogden emphasized the role of open reduction and internal fixation. They postulated that fractures resulting from an axial loading injury were more likely to develop longitudinal growth disturbance.

The rich blood supply of the epiphyseal and periphyseal areas has already been described, but special consideration of intracapsular bleeding in metacarpal fractures is warranted. McElfresh and Dobyns (142) and Prosser and Irvine (174) emphasized the possible pathogenesis of avascular necrosis: it may be caused by vascular tamponade resulting from intracapsular bleeding associated with distal metacarpal fractures. Although the influence of the fracture itself on the development of avascular necrosis cannot be ruled out, these clinicians advocated joint aspiration as a preventive measure in the management of these complex injuries.

Metacarpal Neck Fractures. The metacarpal neck is the most frequent site of metacarpal fracture in children. It is unknown why neck fractures are so much more common than physeal fractures. Neck fractures in children are analogous to boxer's fractures in adults (Fig. 8-59). They are more common in the fifth and fourth rays than in the radial triphalangeal digits. This is why the term *boxer's fracture* is a misnomer, because trained pugilists take the punching impact on the second and third rays (those with a stable CMC joint), not the medial two rays.

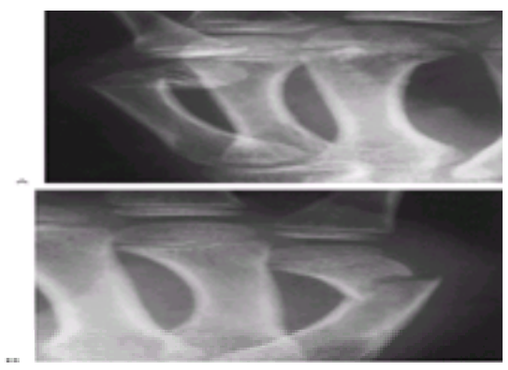

FIGURE 8-59. A: A true boxer's fracture of the metacarpal neck of the fifth ray. **B:** This fracture occurs more in the diaphysis and should not be considered a boxer's fracture.

Metacarpal Shaft Fractures. Patterns of metacarpal shaft fractures are transverse, oblique, or spiral. These injuries tend to occur in older children. Like fractures in other tubular bones, the pattern of shaft fracture yields clues to the pathologic forces that caused the fracture, and indicates the mechanism of reduction. Aside from recognition of the pattern, the amount of shortening, angular displacement, and rotation is critical to making treatment decisions.

Metacarpal Base Fractures. The CMC joint is protected from injury by its proximal location in the hand and the stability afforded by the bony congruence and soft tissue restraints. The fourth and fifth CMC joints are more mobile than the second and third rays. Injury at this level is uncommon in children and usually results from high-energy trauma.

Fracture through the metaphyseal region of the base can occur as the result of a direct blow or an axial load (often delivered while punching). These are typically small compression injuries that usually are stable. Significant injury at this level often results from a fall from a height or a crushing mechanism, and is associated with fracture–dislocation at the CMC level.

Signs and Symptoms

Deformity and significant swelling accompanying a metacarpal fracture can be hidden in the dorsal hand. In young children, the capacious areolar tissue can accommodate a large amount of blood and edema.

Any fractured element of the osteoarticular column can cause rotational and length deformity of the entire ray. In metacarpal fractures, the border digits (index and small) are more prone to displace significantly because they have only minimal stabilizing influence from the transverse metacarpal ligaments (88). A small amount of displacement at the metacarpal level can translate into significant clinical malrotation at the more distal digit.

Radiographic Findings. Metacarpal fractures usually are not difficult to identify on radiography. A metacarpal head-splitting fracture or some periepiphyseal fractures can be occult, however, and these may have the greatest impact on long-term outcome.

The Brewerton view is helpful in evaluating the metacarpal head and is taken with the dorsum of the hand against the cassette and the MCP joints flexed about 65 degrees. The central beam is angled 15 degrees to the ulnar side of the hand (122). This projection focuses on the metacarpal heads of the supinated and slightly dorsiflexed hand and may highlight subtle bony detail in this area. It demonstrates better the relationship at the MCP joint. An oblique film also may disclose a coronal fracture pattern.

It is sometimes difficult to measure the amount of displacement or angulation of a metacarpal neck fracture on a standard lateral radiograph. Therefore, it is helpful to mentally subtract superimposed images of the adjacent metacarpals to appreciate the position of the fragments. Oblique films also can help in this evaluation.

If a fracture involves the base of the metacarpal, the standard radiographic series should be supplemented with a 30 degree pronated or supinated oblique view. These show the extent of joint involvement and demonstrate any associated joint subluxation or dislocation.

The most gracile of the metacarpals is the ring or fourth ray; this is a consistent finding in children and adults. Oblique nutrient arteries that can be confused with fractures usually are seen on the volar radial aspect of the metacarpals. These lucent lines usually appear to affect only one cortex, and there is no interruption in the outer contour of the cortex.

Treatment

Epiphyseal and Physeal Fractures.

Closed Reduction. If the fracture pattern is consistent with a collateral ligament avulsion fracture, management can be based on the amount of displacement and fracture stability (Fig. 8-60). Many of these fractures can be treated by closed methods. Gentle reduction under metacarpal or wrist block should be followed by careful application of a safe position splint (Fig. 8-61).

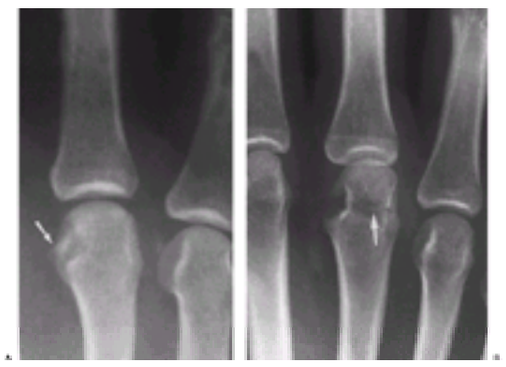

FIGURE 8-60. A: A small avulsion fracture from the collateral recess in a child near skeletal maturity can be treated by closed means (*arrow*). **B:** In another child, close to growth plate fusion, this fracture propagated through the vestige of the physis (*arrow*). Likewise, this can be treated by closed means. In both of these fractures, aspiration should be contemplated.

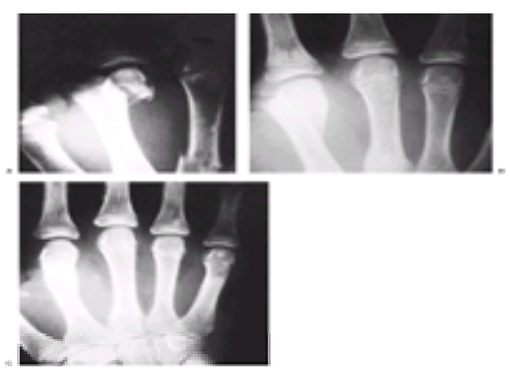

FIGURE 8-61. A: A 12-year-old boy with a displaced Salter-Harris type II fracture of the second metacarpal and an undisplaced fracture of the proximal shaft of the third metacarpal. **B:** Reduction was incomplete, but good remodeling is noted in this radiograph made 4 months later. **C:** Eighteen months later, remodeling is complete and there is a full range of motion in the index metacarpophalangeal joint. (Courtesy of Sigurd C. Sandzen, Jr., M.D.)

Pin Fixation. If the fracture is reducible but unstable, percutaneous pin fixation is recommended. If the metaphyseal flag (the Thurston-Holland fragment) is large enough, the wire can gain purchase through it, but usually the pin must cross the physis. If this is the case, the use of small-diameter smooth wires is advocated. Care must be taken to minimize the number of passes that may further damage the physis.

Open Reduction. Displaced intraarticular head-splitting fractures require open reduction and internal fixation. Immediate aspiration of intraarticular hematoma, which may compromise the physeal and epiphyseal blood supply, also should be considered (142,174).

Mini-screw fixation may be preferred over smooth wire fixation for greater stability, although either implant is acceptable. The goals of surgical treatment are anatomic reduction and stable fixation, permitting early motion.

Neck Fractures.

Nonoperative Procedures. Metacarpal neck fractures are most often treated successfully by closed methods. Adequate anesthesia, closed reduction with the Jahss maneuver, and application of a safe position splint are normally the definitive treatment.

The Jahss maneuver is performed by flexing the MCP joint to 90 degrees, to relax the deforming force of the intrinsic muscles and the tightened collateral ligaments (110a). The proximal phalanx exerts upward pressure on the metacarpal head as the physician applies pressure on the dorsal aspect of the proximal metacarpal

fracture, forcing it toward the volar side to place upward pressure on the proximal phalanx. Jahss suggested immobilization in a position of MCP and PIP flexion, but we do not advocate this type of immobilization because of central stiffness and skin compromise. Immobilization in the intrinsic plus or safe position in the appropriate splint, with the PIP joints free, usually suffices. Recently, we have been limiting the immobilization to a level just distal to the MCP flexion crease and encouraging early motion of the liberated segments.

Operative Procedures. A few children near skeletal maturity have metacarpal neck fractures that are difficult to reduce or maintain. Options for treatment are percutaneous pinning and open reduction. As the child matures, less angulation can be accepted at the metacarpal neck. For fractures at the index and long metacarpal neck, closed reduction may be successful in reestablishing anatomic relationships, but continued instability may necessitate percutaneous pinning to maintain the reduction. Open reduction may guarantee anatomic restoration, but the dissection and manipulation may further compromise the physeal blood supply (Fig. 8-62). Stabilization with percutaneous pins is typically elected. Minifragment screws are seldom used in this region.

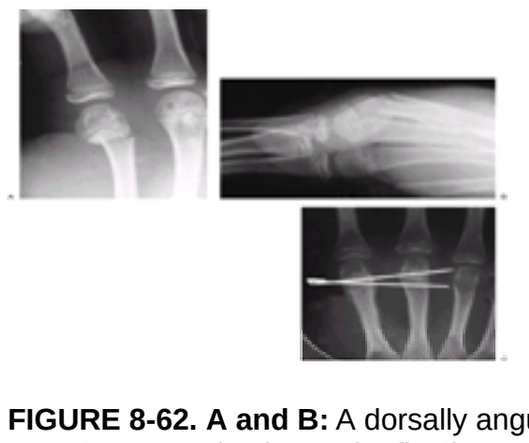

FIGURE 8-62. A and B: A dorsally angulated fracture of the second metacarpal in a 14-year-old boy. Closed reduction was unstable. **C:** Closed reduction and percutaneous Kirschner wire fixation was performed. Because of the lack of mobility of the second carpometacarpal joint, a proximal transfixation pin is usually unnecessary when the fracture involves the second metacarpal. (Reprinted from O'Brien ET. Fractures of the hand. In: Green DP, ed. *Operative hand surgery,* 2nd ed. New York: Churchill Livingstone, 1988:715–716; with permission.)

Intramedullary (bouquet) pinning has been used for metacarpal shaft and neck fractures in adults and adolescents (72,87). This technique should be reserved only for patients at or near physeal closure. Through a small incision near the metacarpal base, access to the intramedullary canal is made with a drill or awl. Prebent Kirschner wires, with the sharp tip removed, are introduced in an antegrade fashion. The wires assist in fracture reduction and stabilization. Several wires are stacked in the canal for immediate stability. The wires are cut flush with the proximal cortex. This technique is particularly well suited for the small and index metacarpals, but fractures in all the triphalangeal rays can be treated in this fashion. Because intramedullary wires are likely to cause growth disturbance in an active physis, this technique should be reserved for special situations in which immediate stability and early motion are needed for patients at or near skeletal maturity.

Shaft Fractures.

Closed Reduction Usually Adequate. Treatment of fractures of the metacarpal shafts is similar to that of phalangeal fractures. Closed reduction and splint immobilization suffice for most metacarpal fractures. An unstable shaft fracture can be managed by closed reduction and percutaneous pinning. Open reduction and internal fixation of a metacarpal shaft fracture are rarely indicated in children; one exception may be multiple adjacent displaced metacarpal fractures.

Pin Fixation Options. Some transverse or spiral oblique fractures may be difficult to control by closed methods. Pinning of the fracture fragments to the adjacent stable metacarpal or percutaneous pin fixation of the fracture itself may hold fragments in a favorable position (Fig. 8-63). If a long spiral-oblique fracture is associated with significant malrotation, percutaneous pinning or mini-screw fixation may be considered. The latter may permit early motion, which may minimize tendon adhesions. Another option for stabilization of transverse and some oblique fractures is intraosseous wires combined with smooth Kirschner wire fixation, but the magnitude of the dissection and volume of hardware argue against this option.

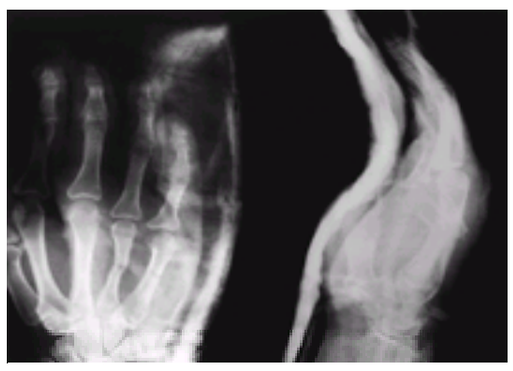

FIGURE 8-63. Radiographs of ring and small finger diaphyseal metacarpal fractures initially treated with closed reduction and splinting. The malalignment with a flexion deformity is evident on the lateral view. Multiple diaphyseal level metacarpal fractures are usually unstable with a high rate of loss of reduction with closed treatment. Percutaneous pin treatment is preferred.

Open Reduction. Although this procedure is rarely indicated in children, the capacity of the dorsal metacarpal area to accommodate a screw or a plate is greater than that in the digit. For long spiral oblique fractures, interfragmentary screws can be an excellent option. Anatomic reduction can be obtained, the screws can be countersunk so as not to interfere with tendon gliding, and the excellent stability can permit early motion.

For a severely comminuted fracture, especially if there is bone loss, plate fixation can be used. Bone grafting should be considered if there has been bone loss. Plating requires more extensive soft tissue dissection and occupies more space than wires or screws. Tendon adhesions are a significant concern with plate fixation. If plating is used, rigid fixation must be ensured so that early motion can combat these potential complications.

Metacarpal Base Fractures.

Associated Injuries. Fractures of the metacarpal base or fracture–dislocations at the CMC joint are high-energy injuries with significant tissue disruption. Palpation of the muscle compartments for signs of evolving compartment syndrome and careful neurovascular assessment are always indicated.

Pin Fixation Techniques. Sandzen (187) advocated closed reduction and percutaneous pinning for isolated dislocations of the small ray CMC joint. Closed treatment is aided by longitudinal traction and careful manipulation. A palpable and audible reduction may accompany successful manipulation. If the reduction is unstable (which is the rule rather than the exception), consideration can be given to percutaneous pinning. The pins can be placed transversely between the metacarpals and through the base of the fractured or dislocated metacarpal, or they can be placed through the collateral recess, across the medullary canal, and across the CMC joint. The latter pattern is more technically difficult, and care must be taken to avoid the physis. If the medullary canal can be accessed through the collateral recess, the pin can be driven from distal to proximal, crossing the reduced CMC joint.

Open Reduction. Open reduction may be necessary to effect reduction and ensure stable fixation (Fig. 8-64) (118,230). Various incisions can be used to gain access to the CMC joint. Longitudinal incisions adjacent to the affected ray permit investigation of the fracture–dislocation and allow fasciotomies if necessary. Percutaneous

pinning can be performed in any of the ways described previously. Regardless of the pinning method chosen, the physes should be avoided.

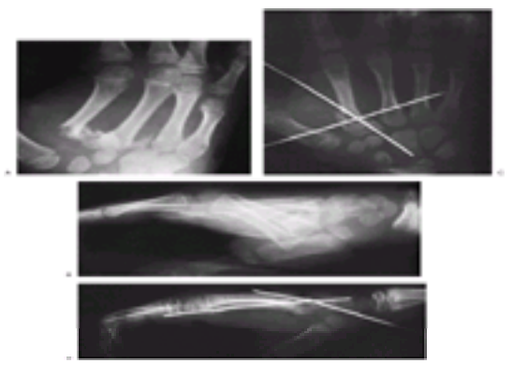

FIGURE 8-64. A and B: An 11-year-old boy sustained a fracture of the proximal shaft of the second metacarpal and a fracture–dislocation of the third carpometacarpal joint when his hand was caught in a cyclone fence he was attempting to climb. **C and D:** Closed manipulation reduced the third metacarpal joint, but buttonholing of the second metacarpal in the volar soft tissues necessitated open reduction and Kirschner wire fixation. Normal function resulted.

AUTHORS' PREFERRED TREATMENT OF FINGER METACARPAL FRACTURES

Role of Closed Manipulation

There is a limited role for closed manipulation and immobilization in the treatment of displaced physeal and epiphyseal fractures. It is difficult to gain access to the head-splitting variant and very difficult to control these highly unstable intraarticular fractures. When the patient is seen soon after the injury, the likelihood of successful closed manipulation may be greater. Aspirating the hematoma from the joint is a prerequisite to successful fracture manipulation.

Fractures of the metacarpal neck are particularly suited to closed treatment. Again, it is best to perform these reduction maneuvers early after the injury so that swelling is at a minimum. The Jahss maneuver (previously described) is our treatment of choice for closed reduction of metacarpal neck fractures. Under wrist block and conscious sedation as necessary, an appropriate reduction maneuver often aligns the fracture, improves comfort, and provides information about the “personality” of the fracture. We can then determine the difficulty of the reduction, the presence of interposed tissue, and the instability of the fracture. We advocate the more low-profile splint that permits motion with most of these fractures that have been reduced and are believed to be stable.

The fracture pattern and amount of comminution usually determine if closed reduction of metacarpal shaft fractures is possible. Some long spiral-oblique fractures can be successfully treated with closed methods because their fracture surfaces can be readily approximated, and the large surface area can help stabilize the fracture and promote healing. Other oblique fractures demonstrate a tendency to shorten and rotate, and may require stabilization with pins (younger patient) or screws (adolescent).

It is sometimes difficult to effect or maintain reduction in transverse fractures of the mid-shaft, but we attempt closed treatment of single metacarpal fractures. We have more success in reducing and holding fractures of the central rays (long and ring digits) than with fractures of the border digits. If the transverse fracture can be reduced, but is unstable, percutaneous intramedullary pining through the collateral recess or tangentially from the base is used. We try to cross the fracture with a pin that is as close to perpendicular to the transverse fracture as possible.

Fractures and fracture–dislocations of the CMC joint can be reduced closed as described previously. We attempt to perform a closed reduction, but recognize the tendency of these injuries to redislocate if they are not stabilized. Our assessment of stability after the reduction dictates the need for fixation, but pinning across the CMC joint is almost always required. Additional pins to adjacent metacarpals can be used to add stability.

Techniques for Operative Management

Despite early treatment, expert reduction maneuvers, and careful application of immobilization, some fracture patterns cannot be adequately closed.

Epiphyseal and Physeal Fractures

For epiphyseal and physeal fractures, the joint is approached through a gently curved or longitudinal incision just to the side of the metacarpal head. The arthrotomy can be made in a tendon-splitting and tendon-sparing manner; both choices are reasonable and typically do not affect later extensor function. The tendon-splitting approach is performed by incising in the mid-portion of the tendon without disturbing the underlying periosteal layer. We prefer the tendon-sparing approach. A longitudinal incision 2 or 3 mm lateral to the extensor tendon, through the sagittal band, permits elevation. Another option is to create a T-shaped incision in which the longitudinal peritendinous aspect is joined by a perpendicular incision in line with the fibers of the sagittal band. In either approach, the extensor mechanism is then elevated to a limited extent by dorsal retraction on the hood. The periosteum is carefully handled, although very little of it needs to be reflected when approaching intraarticular fractures. The capsule itself can be incised either transversely or in a T-shaped fashion, depending on the intraarticular fracture pattern. This is the least traumatic and most easily reconstructable approach into the MCP joint.

The joint capsule can be entered with a T- or L-shaped incision to expose a head-splitting fracture. The arthrotomy decompresses any hematoma in the joint. Direct manipulation of the fragments with a dental pick (respecting the hyaline cartilage) aligns the fracture. The use of reduction clamps or a transverse smooth wire can provide provisional stabilization while mini-screws are placed. We prefer mini-screw fixation, but 0.035-inch wires can be used if the fragments are too small or if multiple fractures are present.

Salter-Harris II fractures seldom require open reduction. They typically occur in adolescents, but enough remodeling is left about the physis that up to 30 to 35 degrees of angulation probably can be accepted. If the reduction can keep the angulation in the AP plane within 25 or 30 degrees and there is no rotational deformity, casting for 3 to 4 weeks is usually adequate, with functional bracing and guarded motion started at that time.

If the fracture is unstable, percutaneous pinning with a single smooth Kirschner wire is best (Fig. 8-65). Engaging a large metaphyseal fragment is difficult but feasible. Avoiding the extensor mechanism with the pin is important and is best done with a lateral approach of the pin. The pin can cross the physis near its center and rest in the head. Penetration into the joint must be avoided.

FIGURE 8-65. A and B: This markedly comminuted and displaced transphyseal fracture of the fourth metacarpal ray presented in this 7-year-old boy. **C:** Effective

closed reduction, followed by percutaneous pinning, stabilized the metaphyseal aspect of the fracture and resulted in near-anatomic reduction and an excellent final result. The Salter-Harris type II fracture of the small finger metacarpal required no additional treatment aside from the splint used for the pinned ring finger ray. This secondary injury healed uneventfully.

Metacarpal Neck Fractures

Reduction Techniques

Fractures at the metacarpal neck are treated with closed reduction and safe position splinting. Rarely, a fracture is quite unstable and difficult to control by closed means. After careful assessment of sensation, anesthesia in the form of a wrist block (with the possible addition of conscious sedation) can be used. If the metacarpal neck of the small or ring digit is fractured, an ulnar nerve block usually suffices. A median nerve block is necessary for comfortable reduction of fractures in the index and long metacarpals.

We advocate the Jahss maneuver described previously for reduction of these fractures. Sometimes, additional manipulation with palmar pressure to the metacarpal head can effect further reduction of the neck fracture. The reduction can be checked with fluoroscopy before applying the splint, or careful splinting can be performed and plain radiographs obtained.

Postreduction Immobilization

We recommend the following measures for the application of immobilization:

1. An adequate but not excessive amount of cast padding should be applied. Skin integrity is important, but too much cast padding diminishes the ability of the plaster to hold the fracture reduction.
2. Using plaster strips in the anterior and posterior aspects of the hand and wrist permits good molding. Applying two or three thicknesses of splints on the anterior and posterior sides, followed by careful molding of the fractured rays into a safe position, can temporarily hold the reduction. Repeating this sequence two or three times over already hardened underlayers offers the best chance to stabilize fractures that are difficult to maintain.
3. Before applying too many thicknesses of plaster, it is prudent to wrap a single layer of cast padding around five or six thicknesses (on each of the volar and dorsal sides) and check the radiographs. This permits evaluation of the reduction without obscuring by plaster.
4. Careful molding with application of the splints is performed by using palmar pressure at the metacarpal head level and continued dorsal pressure on the proximal metacarpal. To avoid leaving finger impressions that could cause areas of skin damage, continuous smoothing of the plaster to eliminate areas of depression and air bubbles is advisable.
5. If the reduction is adequate, more plaster can be applied to make the splint as rigid as possible.
6. For immobilization, the safe position at the MCP and PIP joints could be used, but we have had success with a more extended MCP joint and a free PIP joint in most of our patients. If the safe position is elected, the wrist should be extended about 10 to 15 degrees and the MCP joint flexed maximally. Because children rarely develop significant stiffness, it may be advisable to extend the splint past the PIP.
7. The typical period of immobilization for metacarpal neck fractures is 3 to 4 weeks for most children.
8. We change the initial splint to a cast of similar nature at 2 weeks if needed, depending on the integrity of the cast. We typically assess the fracture reduction at 5 to 7 days to ensure that rare remanipulation is not necessary. If the integrity of the original splint is good and the reduction is being maintained, we continue the original immobilization for the entire treatment course.

Unstable Fractures

If the fracture of the metacarpal neck is reducible but unstable, we consider percutaneous pinning. This is important in unstable neck fractures in the index and long metacarpals. We have a fluoroscopy unit available so that the adequacy of the reduction and the location of the pinning can be determined intraoperatively. One limiting factor to the use of percutaneous pinning is the amount of bony purchase that can be achieved. We avoid tethering the collateral ligaments with the pin, which is why we pin in maximal MCP flexion. We seek the collateral recess as the entry site for the pin and often perform cross-pinning, meaning two collateral recess pins from opposite sides that cross near mid-shaft. Sometimes the pin simply slides down the intramedullary canal and has good purchase; this is perfectly acceptable. This method also requires 3 to 4 weeks of immobilization.

We make sure that the pins that penetrate the skin do not have any direct contact with the cast padding or plaster, because motion of the splint could cause pin track problems. This is why we pad the pins adequately. We also bend the pins to prevent migration.

Shaft Fractures

Uncomplicated Fractures

We usually are successful in treating most metacarpal shaft fractures with closed reduction and immobilization for 3 to 4 weeks. We mold the splint to provide adequate three-point bending. Downward pressure at the apex-dorsal fracture site should be balanced with upward pressure at the head and the proximal shaft. Correct rotation and acceptable length must be verified before applying the splint to keep the MCP joint flexed about 70 degrees. The PIP joint can be free, thus avoiding even transient stiffness. Because the ability of the metacarpal shaft to remodel is small compared with that of the metacarpal neck, rotation and angulation must be carefully assessed. Careful assessment of the appearance of the hand and angulation in the AP and lateral planes on radiography ensures the success of reduction.

Multiple or Unstable Fractures

Occasionally, shaft fractures are unstable or accompanied by adjacent shaft fractures. Options for stabilizing these fractures include percutaneous pinning and open reduction and internal fixation. Some of these fractures can be stabilized with cross-pinning technique or other pinning constructs that traverse the intramedullary canal. Checking the rotation of each ray after stabilization is key.

Another option is to pin the reduced distal fragment to the adjacent metacarpal with two parallel transverse wires (0.035- or 0.045-inch). An additional proximal pin placed parallel to the distal pins helps stabilize the construct. We avoid flattening of the hand: attempts to recreate the longitudinal and transverse arches of the hand are important when dealing with adjacent metacarpal fractures.

If the metacarpal shafts of the ring and small digits are involved, additional stabilization of the proximal fragment to the adjacent metacarpal is required. If the fracture is quite proximal, we consider pinning the CMC joint to avoid further influence of CMC motion.

The pins are bent and cut off, and the sharp ends of the pins are covered with a prefabricated cover for cast padding. An additional safe position splint is then applied. Fracture healing in the shaft of the metacarpal may be slower than in the areas about the physis, so we usually keep these pins in for 5 to 6 weeks. Careful assessment of clinical union is important because with excellent reduction, very little fracture callus may be seen on radiographs. When the patient is nontender to palpation about the fracture site and radiographs show evidence of fracture union after the fourth or fifth week, the splinting is discontinued.

Open Reduction

Open reduction and internal fixation of metacarpal shaft fractures are rarely indicated. Multiple adjacent fractures, fractures with interposed soft tissue blocking reduction, or open comminuted fractures may be exceptions. Most of these patients are pre- or true adolescents. We occasionally use interfragmentary screw fixation for long spiral-oblique fractures with good bony apposition. After careful reduction and stabilization of the fracture in anatomic position, screws can be inserted, typically 1.1, 1.5, or 2.0 mm in diameter. We overdrill the proximal cortex to effect compression with interfragmentary screw fixation. Countersinking the heads of the

screws is advisable to minimize prominence and potential adhesions.

Surgical Approach

Whichever method of internal fixation is chosen, the approach is similar. The metacarpal shaft is approached through an incision centered over the dorsum of the web spaces adjacent to the fracture. To minimize potential extensor adhesions, we prefer to use this interval rather than a direct incision over the bone. The incision can be extended proximally if necessary. The extensor tendon is retracted to gain access to the shaft. The thick periosteum should be meticulously respected and repaired if possible. The periosteum usually cannot be repaired after plate fixation. The interfragmentary screws often can be covered by the periosteal layer, especially if countersunk. Because the fractures should be crossed at 90 degrees with the interfragmentary screws, some of the screw heads could be in the plane of the metacarpals and would not be problematic on the dorsum.

With multiple metacarpal fractures, an approach through an incision in the intermetacarpal space is particularly helpful. We usually can reach adjacent metacarpals easily through a single incision between them. If all four metacarpals are fractured, making one incision in the intermetacarpal space on the dorsum between the index and long finger and a second between the ring and small digits permits access. If needed for developing compartment syndrome, fasciotomies of the interosseous muscles also can be performed through these incisions.

Plate Fixation

If mini-plate fixation is chosen, options are a flat plate or a semitubular plate. The plate that conforms to the bone architecture and offers the best stability should be chosen. Usually, a five-hole or seven-hole plate is selected, and the hole directly over the fracture site often is left unfilled. The engagement of at least four cortices proximal and distal to the fracture is advisable.

Metacarpal Base Fractures: Closed Procedures

We usually gently manipulate basilar fractures of the metacarpal after a regional block of the ulnar nerve and its dorsal sensory branch, or a Bier block. The fracture can then be immobilized in a short arm ulnar gutter splint, leaving the PIP joint free to move for about 3 to 4 weeks, or until nontender.

Complex Fracture–Dislocations

Fracture–dislocations at the CMC base are more challenging. Few reports in the literature address this subject, and the patterns of presentation and treatments vary. Researchers have reported isolated (187), multiple (118,230), dorsal (187,230), and volar (118) dislocations. The treatments have varied from closed manipulation and immobilization to open treatment (118,187). Initial closed treatment failed in a complex case of fracture–dislocation of the medial four CMC joints, and later operative treatment was necessary (230). We advocate an initial attempt at closed reduction to diminish the pain and deformity in the area of the injury. Regional (wrist) or Bier block and conscious sedation usually provide adequate anesthesia. We use fingertraps for distraction. An audible and palpable “clunk” accompanies a successful reduction, but we remain concerned about instability. We question the adequacy of simple closed treatment for this injury. An isolated fifth ray fracture–dislocation can be stabilized with a well-padded splint, but this is not our choice; stability must be ensured by pinning.

Percutaneous Pinning

Percutaneous pinning of the reduced fracture–dislocation can be performed with oblique and transverse pins between the metacarpals and across the CMC joint in single- or double-ray injuries. We also use longitudinal Kirschner wires inserted through the collateral recesses and down the canal to eventually cross the CMC joint (118). However, inserting these pins can be difficult, and the physis is at greater risk for pin penetration. An easier arrangement is to place oblique and transverse pins through the bases of the metacarpals, then perform intermetacarpal transverse pinning, respecting the transverse arches of the hand.

Radiographs (including appropriate oblique views) are needed to verify the reduction and pin placement. Very unstable ulnar-sided dislocations tend to slip if not pinned after reduction. Furthermore, fragments can rotate (up to 180 degrees) and block reduction. If the surgeon is not completely comfortable with the reduction, then proceeding to open reduction is advocated.

Open Reduction

If reduction cannot be achieved by closed means, or if there are multiple irreducible CMC dislocations (especially if the CMC dislocation is volar), two dorsal incisions in the II-III and IV-V web areas at the CMC level are necessary. These incisions allow access to the bony injuries at the two adjacent rays and permit volar and dorsal fasciotomies if needed for developing compartment syndrome. Bony reduction is performed, ensuring that the articular fragments are not rotated or blocking reduction at the CMC joint. Either pinning method described can be used.

Postoperative Care and Rehabilitation

For fractures treated by closed methods, no formal therapy is needed after casting. In very active children and young athletes, a light splint can be worn for protection from direct trauma and as a signal to the patient and his or her peers that the hand is not quite back to normal. Free motion of the digits and wrist is permitted while the patient is in a controlled environment, and the splint is weaned off by 7 or 10 days.

Epiphyseal and physeal fractures successfully stabilized by mini-screw fixation should be aggressively rehabilitated. After 3 to 5 days, a removable splint is applied. Active-assisted motion is performed six to eight times a day. Interval splinting is discontinued after 3 to 4 weeks. Dynamic splinting rarely is required.

Neck fractures treated with percutaneous pinning are maintained in a safe position splint with the PIP joint free for 3 to 4 weeks. The pins are removed at the end of this period, and more aggressive mobilization of the MCP joint with active and active-assisted motion is begun. If the intramedullary technique was used, unrestricted active motion is started after 3 to 5 days of hand rest. A removable splint can be furnished for interval wear. The intramedullary pins need not be removed.

For shaft fractures, the postoperative care is determined by the method of fixation used. Percutaneous pin fixation should be protected for 4 to 6 weeks in a splint. Because dorsally angulated shaft fractures may redisplace if fixation is removed too soon, pins should be removed after radiographs demonstrate bridging callus. After pin removal, a motion program can commence. If a spiral-oblique fracture was fixed with screws, motion can safely start within a week of surgery, depending on the status of the wound.

Percutaneous pins stabilizing fracture–dislocations of the metacarpal base should be left in place for at least 5 or 6 weeks. It is important to assess the patient clinically and with a complete radiographic series to determine the progress of healing. When the pins are removed, active and active-assisted motion of the adjacent joints can begin.

Prognosis

Most metacarpal fractures of all types heal well and leave little residual deformity or functional limitation. The factors that may hinder the eventual outcome are summarized for each type of fracture in Table 8-5.

Epiphyseal and physeal fractures	
Avascular necrosis, malreduction/malunion	
Neck Fractures	
Excessive apex dorsal angulation, malrotation	
Shaft fractures	
Malrotation, soft tissue interposition, nonunion	
Metacarpal base fractures	
Loss of reduction, malreduction of articular fragments, late instability	

TABLE 8-5. ADVERSE FACTORS FOR FINGER METACARPAL FRACTURES

Complications

Avascular Necrosis of the Metacarpal Head. Avascular necrosis of part or all of the intraarticular metacarpal head can occur after fracture and may be influenced by the direct injury and also by the intracapsular pressure caused by the contained hematoma (Fig. 8-66). Avascular necrosis may result in significant irregularity of the articular surface, but symptoms rarely are significant enough to warrant surgical intervention.

FIGURE 8-66. A: A 12-year-old boy sustained a minimally displaced Salter-Harris type II fracture of the proximal phalanx in a fall. **B:** One year later, the patient presented with mild pain in the metacarpophalangeal joint. The metacarpal head shows considerable deformity secondary to avascular necrosis. (Courtesy of James H. Dobyns, M.D.)

If the insult occurs in a growing child, remarkable remodeling of the adjacent articular surface may still result in a functional joint. Part-time splint protection while the joint is symptomatic is all that is needed in most patients. Rarely, significant joint incongruity as a residual of avascular necrosis may require reconstructive surgery. There are several reconstructive options for incongruous joints with early arthrosis, but none are very satisfactory. The most predictable treatment is arthrodesis; arthroplasty (interposition, perichondral resurfacing, distraction, or implant) and vascularized joint transfer rarely are appropriate in children (199).

Rotational Malalignment. Even a small amount (<10 degrees) of rotational malalignment of the metacarpals can cause overlap of the digits in flexion and functional disturbance (Fig. 8-67). If rotation was not corrected and maintained by closed reduction and percutaneous pinning, decisions about the timing and type of treatment are important. The correction can be performed electively several months after the original injury. This permits the fracture to mature and allows the tissues to stabilize.

FIGURE 8-67. A and B: A 15-year-old boy presented with severe overlapping of the ring finger on the little finger when he made a fist. Four months earlier, he had a spiral fracture of the metacarpal that had healed with a severe rotatory malunion. **C:** Distal osteotomy through the deformity stabilized with pin fixation corrected the malrotation. Basilar rotational osteotomy is another treatment alternative. (Reprinted from O'Brien ET. Fractures of the hand. In: Green DP, ed. *Operative hand surgery,* 2nd ed. New York: Churchill Livingstone, 1988:731; with permission.)

We advocate proximal shaft or basilar osteotomy to correct malrotation of even a distal deformity (in contrast to performing an osteotomy at the site of the deformity to correct angulation). Performing the correction away from the site of original fracture has many advantages. The bone in this area heals well, and the relatively large cancellous surfaces permit correction of rotational malalignment. Kirschner wire fixation usually is satisfactory, but a small T plate applied to the tension side of the bone is an acceptable alternative.

Nonunion. Experience with metacarpal nonunion is limited. Although treatment approaches have varied, the results have all been satisfactory. Ireland and Taleisnik (110) reported on two patients, noting that their report of this entity was the first in the literature. A 10-year-old girl underwent bone grafting and pinning of painless but clinically deformed second and third metacarpal nonunions 7 months after injury. She healed uneventfully. A second metacarpal nonunion in a 3-year-old boy healed spontaneously after 2 years of follow-up. Ogden (162) successfully treated nonunions of the second and third metacarpals of a child by reduction and pinning without bone grafting. These patients all appeared to be relatively asymptomatic. Unless clinical deformity is present, following these “nonunions”' (perhaps until maturity) may be a reasonable alternative. When reconstruction is performed, open reduction and bone grafting are the standard. Fixation choices are percutaneous pins or small plates.

Fractures of the Thumb Metacarpal

Fractures of the thumb metacarpal neck and head are uncommon and usually result from direct injury. Fractures of the metacarpal shaft are common, and typically closed reduction is adequate. Metaphyseal and physeal fractures of the thumb metacarpal have received most of the attention in the literature because of their frequency and potential impact on function.

Anatomic Considerations

Muscle Forces. The muscles that originate or insert on or distal to the metacarpal may influence fracture geometry. Depending on the vector of pull, these musculotendinous units act as stabilizers or deformers of particular fracture patterns. The other soft tissues (collateral ligaments, volar plate, periosteum) also influence the pathoanatomy. Their relative positions in the thumb ray were described earlier in this chapter.

Musculotendinous Units Inserting Distal to the Thumb Metacarpal. Like the tendon insertions on the terminal phalanges of the fingers, the flexor pollicis longus inserts on the metaphysis and the extensor pollicis longus on the epiphysis, on their respective palmar and dorsal surfaces. The distal two thirds of the proximal phalanx is devoid of tendinous insertion. The base of the proximal phalanx and its intimate structures (the volar plate and sesamoid bones) are the site of multiple attachments that play a role in fracture mechanics. The adductor pollicis has insertion into the extensor apparatus and onto the medial aspect of the proximal phalanx. The aponeurotic expansion plays a role in the pathologic anatomy of thumb UCL ruptures by excluding the torn UCL from its original bed (the Stener lesion) (206). The flexor pollicis brevis has two insertions: the fibers insert onto the volar medial aspect of the proximal phalangeal base and into the medial sesamoid and volar plate tissues. Most of the abductor pollicis brevis insertion is onto the sesamoids and volar plate.

All three of these structures (adductor pollicis, abductor pollicis brevis, flexor pollicis brevis) can deform fractures occurring at the metacarpal level. Their direction of displacement or activity in fracture stabilization is dictated by their relative positions and directions of pull. The fiber orientation and the point of insertion determine the degree and pattern of fracture deformity.

Musculoskeletal Units Inserting on the Thumb Metacarpal. The opponens pollicis has a very broad insertion over the central metacarpal shaft and base. It plays an integral role in the concerted motions that allow thumb opposition. The opponens pollicis also may participate in fracture situations by pulling the distal fragment into relative adduction and flexion, along with the units that insert distally on the flexor surface.

At the metacarpal base, the abductor pollicis longus has one of its multiple potential insertion sites. The abductor pollicis longus can have insertional slips to the fascia of the thenar eminence, the trapezium, and the CMC capsule. It also is the prime deforming force in some fracture–dislocations or subluxations (15) about the thumb CMC joint. In addition, the flexor pollicis brevis can have part of its origin from the more medial aspect of the metacarpal base. This may add to the flexion force and apex-dorsal angulation in some fractures of the metacarpal shaft.

Bony Architecture at the MCP joint. The “double saddle” architecture of the articular surfaces of the thumb metacarpal and distal trapezium is uniquely well suited to provide mobility for positioning the thumb in space. It also locks into a stable arrangement when pinch force is initiated. When the metacarpal is fractured, the mobility present at the CMC joint can make reduction difficult. There is no volar plate or well-developed collateral ligament system to provide reinforcement. When the base becomes untethered from the rest of the column, it can be difficult to balance the remaining distal metacarpal fragment onto this moving target.

Classification

Head and Shaft Fractures. Fractures of the thumb metacarpal head and shaft are similar to those of the triphalangeal digits (Table 8-6). There is little need to subclassify these injuries, because of this similarity and because they are treated in a similar manner to their medial counterparts. The focus of this section is on the variable patterns of metacarpal base fractures, including fractures that involve the physis and epiphysis (Fig. 8-68).

Fractures of the head
Fractures of the shaft
Fractures of the thumb metacarpal base
Fractures distal to the physis
Salter-Harris II fractures—metaphyseal medial
Salter-Harris II fractures—metaphyseal lateral
Intraarticular Salter-Harris III or IV fractures

TABLE 8-6. CLASSIFICATION OF THUMB METACARPAL FRACTURES

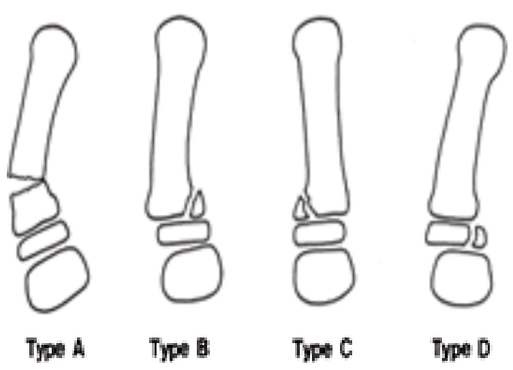

FIGURE 8-68. Classification of thumb metacarpal fractures. **A:** Metaphyseal fracture. **B and C:** Salter-Harris type II physeal fractures with lateral or medial angulation. **D:** Salter-Harris type III fracture (pediatric Bennett's fracture).

Thumb Metacarpal Base Fractures. Type A fractures occur between the physis and the junction of the proximal and middle thirds of the bone. They often are transverse or slightly oblique and angulated apex-lateral, with an element of medial impaction (Fig. 8-69).

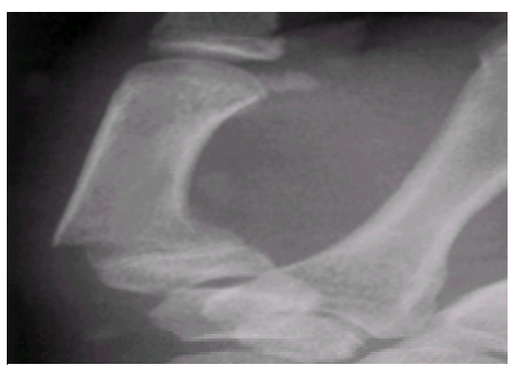

FIGURE 8-69. Thumb metacarpal fracture. This transverse fracture does not involve the growth plate. It was successfully reduced and went on to heal nicely.

Salter-Harris II fractures are prevalent at the thumb metacarpal base. Most of the patterns have the metaphyseal flag on the medial side (type B) and the shaft fragment angulated laterally and slightly proximally from the pull of the abductor pollicis longus. In addition, the adductor pollicis may adduct the shaft. Although this common pattern resembles Bennett's fracture with respect to the deforming forces, it does not have an intraarticular extension.

The less common type C thumb metacarpal base fracture has the reverse pattern, with the metaphyseal fragment on the lateral side and the shaft displacement medial. This may result from more significant trauma and usually is more difficult to treat by closed methods.

The type D fracture is an S-H III or IV fracture of the thumb base that most closely resembles the adult Bennett's fracture. Several clinicians have related anecdotal experience with this injury (23,79,88,193) and have underscored the rarity of this pattern. The deforming forces are similar to those for type B injuries, but the intraarticular component of the fracture permits the base-shaft fragment to subluxate laterally at the CMC joint.

Signs and Symptoms

Swelling and ecchymosis are obvious signs of significant injury to the metacarpal. Most of the swelling appears to be in the thenar eminence. Depending on the level of injury, the thumb can be malrotated or angulated. Active thumb motion usually is limited.

The planes of motion for the thumb are different from those of the rest of the hand. When conducting the physical examination, motion of the thumb in radial and palmar abduction should be assessed carefully. The integrated motion of opposition also should be scrutinized. Malrotation is more challenging to judge, but the perpendicular relationship of the thumb's nail plate to those of the other digits provides a good guide.

Radiographic Findings

A standard set of hand films can be supplemented by a hyperpronated view of the thumb that accentuates the detail at the CMC joint. Biplanar images of the thumb are a must. Type B fractures often appear well reduced on one view (the lateral view of the thumb) but are significantly displaced on the AP radiograph.

Fracture Eponyms

We avoid the use of eponyms to describe fracture patterns about the metacarpal base. The use of terms such as *children's Bennett's fracture* or *baby Bennett's* do little to assist the evaluator in developing a plan of treatment. This is why we discourage the use of the terms *Bennett's fracture* (15) and *Rolando's fracture*. Terms to characterize the size, location, intraarticular or physeal extension, degree of comminution, and displacement of this complex set of fractures are more descriptive.

Treatment

Head and Shaft Fractures

The need for anatomic restoration of intraarticular or peri-articular fractures of the distal metacarpal has already been emphasized in other sections. Fractures of the thumb metacarpal shaft can be treated much the same as those of the medial four rays.

Thumb Metacarpal Base Fractures

Type A.

Closed Reduction. Type A fractures usually can be treated by closed methods. Although swelling about the thenar eminence limits manipulation of the fracture and diminishes the effectiveness of immobilization, most fractures can still be treated successfully by closed reduction and immobilization.

The maneuver is performed with local anesthesia and is accomplished by exerting an extension force on the metacarpal head; hyperextension of the MCP joint should be avoided. Pressure is applied to the apex of the fracture to effect reduction. With the proximity of the fracture to the physis, exact reduction may not be required, because remodeling is rapid in this region of the bone (Fig. 8-70). Ogden (162) and others (104,117) have shown that lateral angulation of up to 30 degrees can adequately remodel.

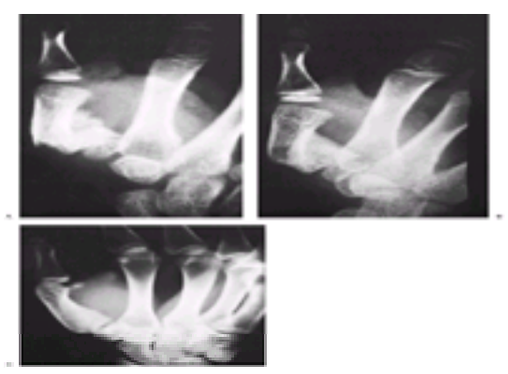

FIGURE 8-70. A: A 10-year-old boy with a severe head injury was first noted to have this markedly displaced type A fracture of the first metacarpal 3 weeks after injury. **B:** One month later, the radiograph shows union of the unreduced fracture with some early remodeling. **C:** Seven years later, the radiograph shows that complete remodeling has occurred. Functioning was normal. (Remodeling around this multiaxial joint can be compared with that seen in fractures around the proximal humerus.) (Courtesy of Sigurd C. Sandzen, Jr., M.D.)

Percutaneous Pins. If there is interposed tissue or if the reduction is too unstable to maintain in a splint, percutaneous pinning can be used. Because of the fracture pattern, it is highly likely that the physis will need to be crossed by the smooth wires. Pinning across the CMC joint can even be performed, but it is usually reserved for more proximal fracture patterns.

Types B and C.

Closed Reduction. Type B and C fractures deserve an attempt at closed reduction, but the mobility of the metacarpal base and the swelling about the ray make this difficult. Comminution and soft tissue interposition (or transperiosteal “buttonholing” in type C fractures) (123,232) may further complicate the situation. Regardless of the method used to obtain reduction, anatomic restoration of this injury, which involves the physis, is important and has been emphasized by Smith and Peimer (201). Other clinicians have documented significant remodeling in S-H II fractures in this area (13,117). If closed reduction is accomplished and maintained in a short arm thumb spica splint, radiographs should be obtained after splint application and again in the first 5 to 7 days to reassess the status of the reduction.

Percutaneous Pins. If closed reduction is possible but the resulting relationship is unstable, percutaneous pinning is an excellent alternative (Fig. 8-71). Three options for pin configuration are direct fixation of the reduced fragments (however, this is prohibitively difficult because of the small size of the metaphyseal flag); pinning across the CMC joint in a position where the fragments are reduced; and pinning from the first to the second metacarpal to stabilize the larger shaft-base fragment. Combinations of these configurations may need to be used for more complicated or unstable fractures.

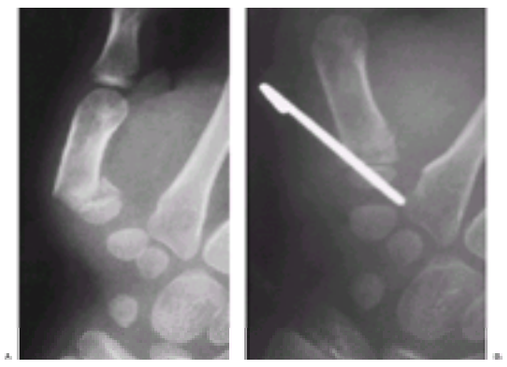

FIGURE 8-71. A: The reduction of this type B fracture was unstable. **B:** A single percutaneous pin was necessary to maintain alignment. An excellent functional result followed.

Open Reduction. Open reduction must be performed if the epiphyseal fragments cannot be aligned and maintained by closed means. Butt (35) observed that medially displaced type C fractures require open reduction (Fig. 8-72). This often is due to the interposed periosteum blocking the reduction (232).

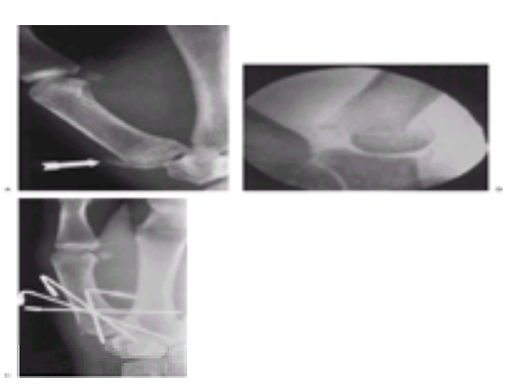

FIGURE 8-72. A: The small metaphyseal flag on the lateral aspect of the thumb base looks fairly innocuous in one projection (*arrow*). However, it was a herald of more marked displacement of the distal fragment in a medial direction. **B:** This was well imaged with the aid of fluoroscopy when closed reduction was attempted. Closed reduction maneuvers were unsuccessful, because the physeal fracture appeared to have interposed tissue and was difficult to manipulate. **C:** Open reduction was performed through a curvilinear incision over the carpometacarpal joint. The fracture was stabilized by Kirschner wires that crossed the fracture site, the physis, and the carpometacarpal joint. An additional pin was placed between the first and second metacarpals to keep the thumb in good position. Near-anatomic reduction was realized with rapid healing and excellent function.

Type D Fractures.

Nonoperative Treatment. Most of the experience with treating type D injuries has been in adults. Numerous treatment methods have been described, including splinting, traction devices, pinning, and special screw fixation (208). For type D fractures in children, closed reduction has been tried with variable results by Gedda (79). He reported 105 patients with fracture–dislocations of the thumb trapeziometacarpal joint, only two of whom had open physes. One patient did well with 4 weeks of immobilization; the other, who required repeated reduction attempts, had significant loss of mobility, early physeal closure, and persistent subluxation at a 4-year follow-up. Griffiths (96) reported two childhood Bennett's fractures, both treated by closed means. Healing of the fracture was delayed in the first patient, but the outcome was good at 1 year. In the second patient, significant clinical and radiographic deformity was present at follow-up, but no pain or motion loss resulted.

Open Reduction. The best results have been reported with operative means to restore anatomy. Blount (23) used skeletal traction through the head or shaft of the proximal phalanx to treat this injury in an adolescent. Percutaneous pinning of the reduced fracture, including trans-CMC pinning, was successful in a report by Rang (175). Segmüller and Schönenberger (193) recommended open treatment as a way to ensure anatomic reduction and fracture stability. The implant choice can be individualized, but smooth wires are favored to minimize potential injury to the physis and articular cartilage (Fig. 8-73) (88,193).

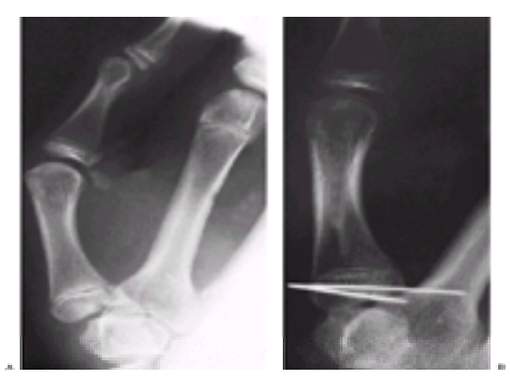

FIGURE 8-73. A: A 14-year-old boy sustained this Salter-Harris type III fracture of the proximal thumb metacarpal when he fell out of a pickup truck. There is slight lateral subluxation of the carpometacarpal joint. **B:** Uneventful healing and normal function followed open reduction and Kirschner wire fixation. (Reprinted from O'Brien ET. Fractures of the hand. In: Green DP, ed. *Operative hand surgery,* 2nd ed. New York: Churchill Livingstone, 1988:769; with permission.)

Traction. Although not an initial choice for the treatment of intraarticular metacarpal base fractures, oblique skeletal traction is an alternative treatment that may have a role in some complex injuries. Spanberg and Thoren (203) described this method, which has the advantage of minimal tissue dissection but offers no direct control of the fragments. More severe comminution or skin compromise overlying the thenar area are possible indications for this method.

External Fixation. In a severe open injury with potential bone loss, there is another alternative that we have used extensively in our adult patients with crush injuries to the hand from farming or industrial accidents. Büchler et al. described a quadrilateral external fixator system between the first and second rays that keeps the column out to length, permits soft tissue management, and maintains the first web space span (32). Staged reconstruction can then be performed, including bone grafting and skin coverage.

AUTHORS' PREFERRED TREATMENT OF THUMB METACARPAL FRACTURES

Closed Reduction

For most thumb metacarpal fractures, closed manipulation and splinting is the appropriate and definitive treatment. Intraarticular fractures of the head and complex

shaft fractures in the distal aspect of the bone with soft tissue interposition may be the exceptions to this rule.

Base fractures usually can be managed by closed methods. Type A and B fractures can be reduced under adequate conscious sedation supplemented by radial and median nerve blocks. The maneuver for reduction consists of palmar-directed pressure exerted over the apex of the fracture, with counterpressure applied to the metacarpal head. Pressure applied distal to the head will only extend the MCP joint and affects the fracture minimally. A well-molded splint can then be applied and postreduction radiographs obtained.

Acceptable Angulation

The amount of residual angulation considered acceptable in basilar metacarpal fractures is based on our experience and the reports in the literature (104,118,162). Because the motion at the adjacent CMC joint is multiplanar and the fractures are near (or involve) the physis, the remodeling potential is great. Malangulation of about 20 degrees or less remodels quite predictably; even angulation of 30 degrees appears to exhibit significant remodeling, but the improvement in radiographic appearance is less predictable. Clinical deformity and functional loss are still unlikely, even at that degree.

Pin Fixation

If closed methods are successful but the fracture remains unstable, it should be pinned with smooth wires (0.028- or 0.035-inch). Driving the pins in a lateral-to-medial direction is usually a reliable way to secure the larger fragments. Pinning across the CMC joint or to the adjacent metacarpal can be performed to increase stability. We have not encountered growth disturbance when the physis and joint have been crossed by a single smooth wire.

Open Reduction

Displaced S-H III and IV fractures require open reduction and internal fixation. We prefer to perform an open reduction through an L-shaped incision overlying the CMC joint at the glabrous border of the skin. We carefully avoid injury to the small terminal branches of the dorsal sensory branch of the radial nerve, the palmar cutaneous branch of the median nerve, and the lateral antebrachial cutaneous nerve. All these branches may innervate this area. The origins of the thenar eminence muscles can be reflected medially and the capsule entered. The joint is inspected for loose fragments and cartilage damage, and the fracture is reduced and pinned.

We prefer to avoid multiple pins (or attempts) and minimize the number of pins crossing the physis. In some larger fragment fractures, parallel pinning can minimize the potential injury to the physis. Pinning of the first metacarpal to the second is a sound practice that stabilizes the entire construct and avoids transarticular or transphyseal pinning.

Type C fractures can be particularly difficult to manage. They are often more widely displaced, and the distal fragment may be buttonholed through the thick periosteum. We still attempt closed reduction, but the threshold to progress to open reduction is low. The same concepts for the open treatment of type A and B fractures hold true in the treatment of this variant.

Type D fractures require open reduction and internal fixation. Pinning across the CMC joint sometimes is needed to maintain the congruity of the joint that has been subluxated. This added stability allows the pericapsular structures time to heal. Pinning across to the second metacarpal sometimes can accomplish the same stability.

Postoperative Care and Rehabilitation

Immobilization of 4 to 6 weeks usually is adequate, depending on the fracture severity and rate of healing. Pins usually are removed before 6 weeks. Original stiffness usually subsides quickly. Attention should be focused on the interphalangeal joint of the thumb in all phases of rehabilitation. If there is some limitation of motion at the CMC joint due to the primary pathology, additional motion may be required from the adjacent articulations.

Return to Sports. Return to contact sports and hand-intensive activities is a complex issue that involves the patient, parents, and coach, as well as the physician. The decision is based on multiple factors such as the nature of the injury, the temporal relationship to the season of play, and the level of participation required. Many patients with less severe injuries who are involved in minimally hand-intensive aspects of sports may be candidates for early return (within 1 or 2 weeks to permit wound healing). Protective orthoses can be worn, and a removable splint and systematic motion program can be conducted when not participating. For example, a football lineman with a central metacarpal fracture may receive a “playing cast” for practice and games and can be protected with a thermoplastic safe position splint between games (17). If the injury was more severe or if greater dexterity is needed for adequate participation, the player must regain a full range of painless motion before returning to the sport. The interval between clinical union and regaining the proper dexterity for athletic endeavors usually is 2 to 4 weeks.

There are no stock answers to these questions, which are being faced with increasing frequency in a society that places such emphasis on athletic achievement. Recommendations must be based on the surgeon's preference and experience. Recalling the admonition to “do no harm” is an excellent guiding principle when trying to reach an important decision. However, it is sometimes difficult to convince the patient, parents, and coach of the relative importance of present sporting involvement versus long-term hand function.

Prognosis

The remodeling capabilities of fractures near or involving the physis are extensive. This is especially true about the basilar thumb joint, where multiple planes of motion encourage remodeling. Even residual deformity that exists in the metacarpal of the thumb can be concealed by excellent function. The other elements of the osteoarticular column adapt positively to limitation at one link. Even malrotation is tolerated better by the thumb than any of the triphalangeal digits. Malreduction predictably hinders long-term function only when the fracture involves a significant portion of the joint. Arthrosis is accelerated if the joint remains significantly incongruous.

Complications

The complications described for the other tubular bones of the hand—particularly those involving the finger metacarpals—can be seen in the thumb ray. Nonunion, malunion, and aseptic necrosis can all complicate the treatment course of thumb metacarpal fractures.

For the rare nonunion, extended immobilization may result in late consolidation (96), but bone grafting and rigid fixation can be performed if the nonunion is recalcitrant. Symptomatic malunion is uncommon, but basilar osteotomy and fixation can restore the relationships needed for improved function.

Intraarticular incongruity is a potential short- and long-term problem: pain, motion limitation, and accelerated arthrosis may all be sequelae. Surgical intervention should be delayed as long as possible, and the available options discussed with the patient and parents. Salvage procedures (e.g., fusion, interposition, or implant arthroplasty) have already been described. Surprisingly good function can accompany a poor radiographic appearance, so the surgeon must remember to treat the patient, not simply the radiographs, in a child with degenerative arthrosis.

CARPAL INJURIES IN CHILDREN

General Principles

Epidemiology

Fractures and dislocations about the child's wrist are rare, and injuries to the immature carpus often present diagnostic and therapeutic dilemmas because of the difficulties in examining an injured child and the limited ability of radiographs to detail the immature skeleton (13,158).

The neighboring physis of the distal radius is among the body's most frequently injured (49). When the typical history of a fall on an outstretched hand is elicited and wrist pain is the presenting complaint, it is likely that the forces were transmitted through the distal radial physis, not the carpus (218). Nonetheless, the impact of a

highly mechanized society and the increased level of participation in athletics has made the wrist a focus of both acute and chronic injury in the child (183).

Anatomy

The unique chondroosseous composition of the bones of the maturing carpus make them relatively immune to fracture throughout early development. Likewise, the inherent hyperelasticity of young tissue protects the ligamentous anatomy about the carpus.

Ossification of the Carpus

The human wrist begins as a single cartilaginous mass, but by the 10th week the carpus transforms into eight distinct entities with definable intercarpal separations. Although there are some minor changes in contour, these precursors greatly resemble the individual carpal bones in their mature form (129). It is distinctly unusual for the capitate not to demonstrate an ossification center by the sixth month, and failure to ossify by the first year may indicate a congenital anomaly.

The carpal bones ossify in a predictable pattern, with only slight variations (Fig. 8-74) (95,211). The appearance of the hamate on radiography closely follows that of the capitate at about 4 months. The ossification center for the triquetrum appears during the second year and is almost always present by 3 years of age. The lunate begins ossification around the fourth year. The scaphoid begins to ossify in the fifth year, usually slightly predating the appearance of the trapezium. Scaphoid ossification begins distally and progresses proximally; this factor affects certain pathologic processes that are discussed later (162). The trapezium and trapezoid demonstrate ossification centers on radiography in the fifth year, with the trapezoid lagging slightly behind. The pattern of ossification usually concludes with the bony development of the pisiform at the ninth or tenth year.

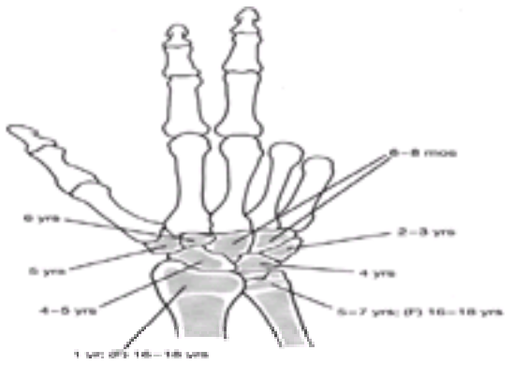

FIGURE 8-74. The age at the time of appearance of the ossific nucleus of the carpal bones and distal radius and ulna are shown. The ossific nucleus of the pisiform (not shown) appears at about 6 to 8 years of age.

Within each chondral mass, ossification occurs around a defined centrum in an eccentric, centrifugal fashion (170). The scaphoid, trapezoid, lunate, trapezium, and pisiform may demonstrate multiple centers of ossification (136,162). Although these variations are well recognized, they may be confusing in the setting of acute trauma to the wrist region.

Anatomic Relationships to Carpal Fracture Patterns

The ossific nucleus remains cloaked in its cartilaginous cover during development. This is thought to provide a unique protection that makes fracture in the immature carpus extremely rare (13,88). This observation is supported by epidemiologic studies of fractures of the scaphoid that show them to be infrequent in children under 7 years of age but more common through the teenage years (93,124). A critical ratio of cartilage to bone at which fractures become more prevalent has never been determined. In addition, biomechanical studies of fracture propagation in the immature carpus are lacking.

Although this section focuses on injuries to the wrist, the surgeon must appreciate the frequency and mechanics of fracture about the distal radius, because this provides the platform for surgery on the carpal bones. An in-depth discussion of fractures about the distal radius in children appears in Chapter 9.

Fractures about the radial platform account for almost half of the pediatric fractures in some series (23,49,58,234). A significant number of these fractures involve the distal radial physis, placing it at or near the top in frequency of physeal injuries (126,154). Concomitant injury of the radius and carpus should always be suspected in children, as in adults.

Force Transmission During Carpal Injury

It is important to understand the force transmission characteristics about the distal radius and wrist, because simultaneous fractures of the radial platform and carpus have been reported in children (3,45,94,158,216). Examples of these combined injuries are given here and in Chapter 9. Although these combined injuries are rare, they must be recognized and treated appropriately to maximize functional outcome.

Specific Carpal Fractures

Scaphoid Fractures: Epidemiology

The scaphoid is the most frequently injured carpal bone in children (13,41,93). This is also true in adults, one of the few similarities between wrist injuries in skeletally mature and immature patients. The incidence of scaphoid fracture in the entire population peaks in the late teens to mid-twenties (62,88). In skeletally immature patients, the peak is at about age 15 (198). This peak comes after a steady increase, paralleling the evolving ossification of the scaphoid from its cartilaginous precursor.

During the first decade of life, fractures to the scaphoid are extremely rare but have been reported (22,93,124,182,198,202,216). The rarity of scaphoid fractures in very young children is somewhat comforting because of the difficulties in evaluating them. However, fractures have been reported in children as young as 4 years (22), and there has even been a report of bilateral scaphoid fractures in an 8-year-old child (75).

Mechanism of Injury: Differences in Children

The mechanisms and pathoanatomy of scaphoid fractures vary considerably between adults and children (Fig. 8-75). The familiar mid-waist fracture in adults who fall on an outstretched hand is uncommon in childhood (135,223).

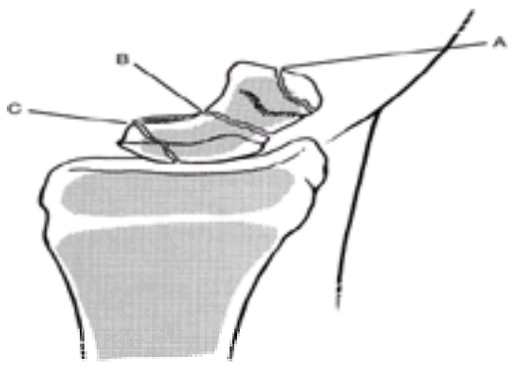

FIGURE 8-75. The three types of scaphoid fractures. (*A*) Distal third. (*B*) Middle third. (*C*) Proximal pole.

Fracture of the distal third of the scaphoid, often an extraarticular injury, is the most common injury (216). Many scaphoid fractures that occur in teenagers and younger children result from direct trauma to the bone itself, not from the usual hyperdorsiflexion injury (22,124).

Fractures at the scaphoid waist are becoming more common in older adolescents as rigorous participation in contact athletics increases. These adult-like injuries carry with them the same risks of nonunion and avascular necrosis as their counterparts in skeletally mature patients (153).

Proximal pole fractures are distinctly rare in children and often represent a ligament avulsion fracture of the scapholunate ligament. The scaphoid also can be fractured as a component of a greater arc injury (140).

Regional Mechanisms Vary

Distal Scaphoid

Distal pole fractures usually have a dorsoradial or dorsovolar fragment resulting from an avulsion injury. The strong scaphotrapezial ligaments can direct force through the distal scaphoid, and the capsular attachments on both sides may contribute additional force. The ligament/bone interface typically remains intact, with mechanical failure through the bone substance. The fracture line can skirt the periphery of the ossific nucleus, resulting in a chondral injury alone or a small osteochondral fragment that may be discernible on radiography.

A systematic study of fracture patterns of maturing bones is needed, but the observation that immature bones fail before their surrounding soft tissue structures is well accepted. There is speculation that recently ossified areas are weaker than more mature ones (46).

The different fracture patterns in the distal scaphoid may indicate a vulnerability of the bone to tension forces from several surrounding soft tissues, including the radioscaphoid ligament, radioscaphocapitate ligament, scaphotrapezial ligaments, and capsular attachments, as well as the dorsal radiocarpal or intercarpal ligaments (Fig. 8-76) (44,216).

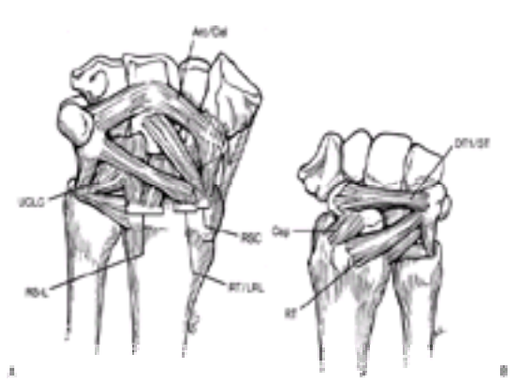

FIGURE 8-76. The volar and dorsal extrinsic and intrinsic carpal ligaments. **A:** Selected volar ligaments about the wrist. *RS-L,* radioscaphoid-lunate; *RT/LRL,* radiotriquetral/long radiolunate; *RSC,* radioscaphocapitate ligament; *Arc/Del,* arcuate or deltoid ligament; *UCLC,* ulnocarpal ligament complex, including ulnocarpal volar ligament, disc-triquetral and disc-lunate ligaments. **B:** Dorsal ligaments about the wrist. *Cap,* capsular attachments; *RT,* radiotriquetral ligament; *DTI/ST,* dorsal transverse intercarpal ligament or scaphotrapezial ligament.

Middle Third

Fractures at the middle third of the scaphoid account for about a third of those in immature patients. These fractures occur closer to the mid-teenage years and usually are more recognizable on radiography. Because they are encountered with advancing maturity and in situations where trauma has been significant, it is advisable to keep a high index of suspicion for other injuries about the carpus (2,41,75,205).

Despite the frequency with which these injuries are seen in both children and adults, there is still debate about the mechanism of fracture. The direction of force, its magnitude, and the position of the intercalated segments of the hand-forearm unit all exert influence.

Influence of Dorsiflexion

Cadaver studies by Frykman demonstrated that greater degrees of wrist dorsiflexion correlate with increasingly more distal fractures in the upper extremity (74). This work was reproduced by Weber and Chao (223), and it is generally agreed that extreme dorsiflexion (more than 90 to 95 degrees) is necessary to cause volar, tension-side scaphoid fractures at the mid-waist. Whether the fracture occurs in the proximal or distal part of the middle third is determined by the extent of radial or ulnar deviation at the time of impact.

Tension Versus Compression Forces

Some clinicians argue that the fracture is caused by tension or bending loads concentrated on the volar side at the distal pole (74,223). In this scenario, the proximal pole is stabilized and protected by the concavity of the radius and the radiocarpal ligaments while the exposed distal pole is subjected to force applied on the radial half of the palm. Other clinicians postulate a compression mechanism for midwaist fractures (43). The compressive forces may be exerted from the capitate onto the concave acetabulum of the scaphoid, or possibly from the dorsal lip of the distal radius. This may explain some of the volar radial comminution in a pattern resembling “butterfly” fragments (Fig. 8-77).

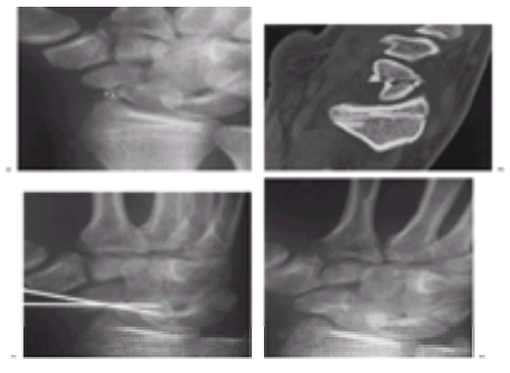

FIGURE 8-77. A: A displaced mid-waist scaphoid fracture with comminution, including a butterfly fragment (*arrow*) from the volar radial aspect. **B:** Computed tomographic scan demonstrates the comminution. **C:** Open reduction with internal fixation was performed with two smooth wires and bone graft from the distal radius. **D:** Normal healing and function resulted.

Strict deviation in the sagittal or coronal plane is not commonly encountered outside the laboratory. Torsional forces also influence the types of fractures seen (71). The unique shape of the scaphoid at its mid-section also may play a role in the pattern of fracture propagation through this region.

Proximal Pole

Fractures at the proximal pole of the scaphoid are rare in children. Because the pattern of ossification follows the distally derived blood supply (124), a fracture at the proximal end of the scaphoid may propagate through the interface between newly ossified tissue and the cartilaginous anlagen, or the injury may be strictly transchondral. Proximal pole fractures can occur at the margin of the radioscaphocapitate ligament or slightly proximal to that area. More proximal fractures may represent destabilization of the scapholunate joint, because the interosseous ligament may avulse a small fragment of bone from the proximal pole rather than a mid-substance rupture (Fig. 8-78).

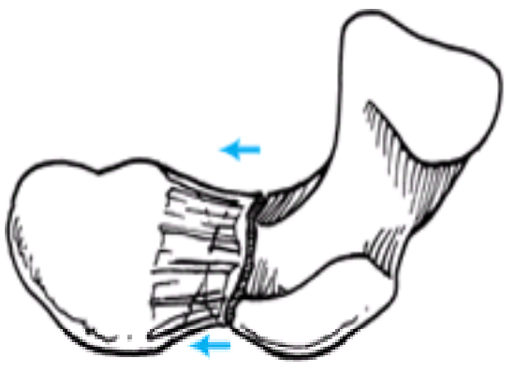

FIGURE 8-78. A proximal pole scaphoid fracture can destabilize the scapholunate articulation. The scapholunate interosseous ligament can avulse a fragment of bone from the proximal pole (*arrows*). Small proximal pole fractures, therefore, are not innocuous and may herald significant disturbance in wrist mechanics.

Classification

Table 8-7 lists the types of scaphoid fractures.

Fractures of the distal pole
- Extraarticular distal pole fractures
- Intraarticular distal pole fractures

Fractures of the mid-waist

Fractures of the proximal pole

TABLE 8-7. CLASSIFICATION OF SCAPHOID FRACTURES

Type A: Fractures of the Distal Pole

Fractures of the distal pole are the most frequent scaphoid fractures in children. The multiple soft tissue attachments in this area can lead to variations in fracture pattern, but the most important factor affecting prognosis is whether the fracture involves the articulations of the scaphoid with adjacent bones (Fig. 8-79).

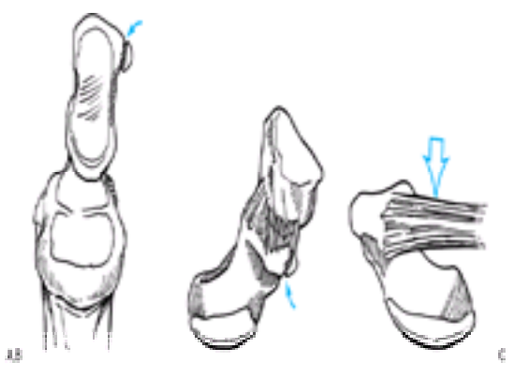

FIGURE 8-79. A and B: Small extraarticular distal fractures of the scaphoid (*arrows*) are likely to be the result of traction forces by the capsular condensations on the volar aspect, or the radial leaf of the scaphotrapezial ligament. **C:** Extraarticular dorsal fractures can likewise be the result of capsular attachment, but the dorsal transverse intercarpal ligament (*open arrow*) also may play a role in their propagation.

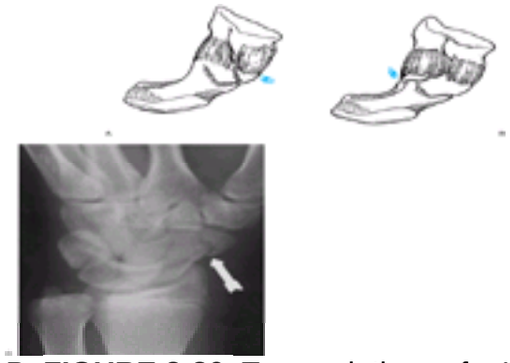
Type A1: Extraarticular Distal Pole Fractures

Fractures of the distal pole can be either volar or dorsal avulsions; rarely, a direct volar impaction injury occurs. The stout scaphotrapezial ligaments can contribute the tensile force that accounts for most of the fractures. The volar and dorsal capsules also can be a factor. Most extraarticular fractures are volar fractures that probably result from the combined influence of the radial leaf of the scaphotrapezial ligament and the volar capsule acting in tension. The fragments vary in size, and their radiographic appearance is age dependent. The dorsal transverse intercarpal ligament attaches to the distal scaphoid and may contribute tensile forces with wrist hyperflexion. This ligament, usually implicated in dorsal triquetral avulsion fractures, also can cause a fracture of the distal scaphoid.

The tissue condensation on the radial side that has been considered the “radial collateral ligament” may be implicated in more radial distal pole fractures. These tissues are taut in wrist extension and ulnar deviation and may provide an additional force in the development of the volar extraarticular fracture.

Type A2: Intraarticular Distal Pole Fractures

These fractures may be simply larger fragment counterparts to type IA fractures with an intraarticular component (Fig. 8-80). The ulnar leaf of the scaphotrapezial ligament is typically more stout than the radial. It is more difficult to generate the pure tensile forces in this ligament because of its location and the orientation of the insertion to the more sloping articular surface of the distal ulnar scaphoid. If there is more of an element of straight dorsiflexion, or a radial-directed vector force on the thenar area, this complex can be put on tension.



P>**FIGURE 8-80.** Two variations of a IB intraarticular fracture of the distal pole of the scaphoid. **A:** The more prevalent type is on the radial aspect of the volar distal scaphoid. This fragment has attached to it the radial leaf of the scaphotrapezial ligament (*arrow*). **B:** It is rare to have an intraarticular fracture slated to the ulnar aspect of the scaphoid, but the stout ulnar leaf of the scaphotrapezial ligament may be attached to a fracture fragment (*arrow*). **C:** Radiograph of an intraarticular distal pole scaphoid fracture. Closed reduction produced an excellent result.

Type B: Mid-waist Fractures

The waist of the scaphoid can be defined either by dividing the bone into thirds or considering the area bounded by the radioscaphocapitate ligament. In any case, fractures of the midwaist can take many forms in children (Fig. 8-81). Many of these fractures appear incomplete or at a minimum nondisplaced. Comminuted fractures are rare but can occur with higher energy (Fig. 8-77).

FIGURE 8-81. Mid-waist scaphoid fractures can differ in their location, orientation, and amount of comminution. All these factors influence the stability and potential healing of these injuries.

Displacement and comminution are other important factors to consider. Significant fracture fragment displacement is rare in isolated scaphoid trauma. When a scaphoid fracture is associated with more extensive carpal injury, such as a fracture–dislocation, displacement is more likely.

Not all mid-waist fractures can be lumped into the same category. An appreciation for the location of the fracture as it relates to the radial and capitate articular surfaces is important in treatment planning (Fig. 8-82).

FIGURE 8-82. A: A barely detectable fracture line is located in the mid-waist of the scaphoid (*arrow*). **B:** In contrast, this mid-waist scaphoid fracture has occurred at the junction of the middle and distal thirds. Articulation between the scaphoid and capitate has been rendered incongruous by displacement of the distal pole (*open arrow*). There is mild comminution in the radial aspect (*closed arrow*).

Type C: Proximal Fractures

Fractures of the proximal third of the scaphoid and proximal pole present diagnostic and therapeutic dilemmas. Because this area is the last to ossify, radiographs may be difficult to interpret. The tenuous blood supply of this region presents the same problems in children as it does in adults.

Bipartate Scaphoid Controversy: Traumatic versus Developmental

Louis et al. (136) argue that the concept of the bipartite scaphoid should be dismissed in favor of a traumatic etiology for the radiographic appearance of a dissociated proximal pole (Fig. 8-83). In contrast, Doman and Marcus (60) demonstrated bilateral bipartite scaphoids by MRI in a child with no history of antecedent trauma. These clinicians argued that congenital bipartite scaphoids can exist apart from syndromic conditions, but are less prevalent than Pfitzner's estimate of 0.5% (168). There is also speculation that the abnormal morphology associated with many of the preaxial dysplasias may predispose the usually gracile scaphoid to fracture and possible avascular necrosis (129). The debate continues concerning the existence of a congenital bipartite scaphoid. Bunnell (30) enumerated five criteria that must be met to classify such a variant as a congenital bipartite scaphoid: (a) similar appearance of a bipartite scaphoid bilaterally, (b) absence of historical or clinical evidence of antecedent trauma, (c) equal size and uniform density of each component, (d) absence of degenerative change between the scaphoid components or elsewhere in the carpus, and (e) smooth, rounded architecture of each scaphoid component.

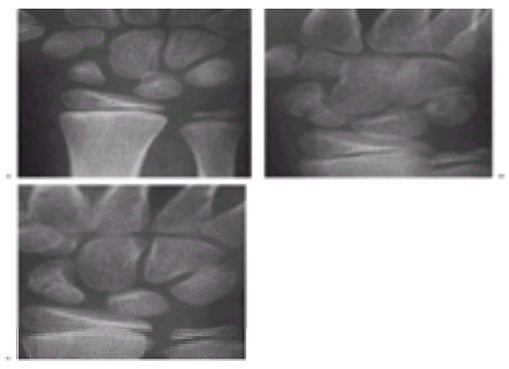


FIGURE 8-83. A: This 9-year-old boy fell on an outstretched hand and had significant radial-sided pain and tenderness, but original radiographs failed to reveal any bony abnormalities. It is difficult to judge the scapholunate relationship in the immature carpus. **B:** About 1.5 years later, the patient still had radial-sided wrist pain, and radiographs demonstrated a mid-waist scaphoid nonunion. This would not be considered a bipartite scaphoid, but instead an injury that was sustained while the cartilaginous anlagen persisted. Later ossification demonstrated the bony injury. **C:** After 2 months of casting, the fracture appears to be on its way to union.

Signs and Symptoms

Snuff Box Tenderness

As in adult scaphoid fractures, the primary cause of delayed union or nonunion in a child is delayed diagnosis. Recognition of this fracture is even more challenging in children. Swelling commonly obliterates the anatomic snuff box when the scaphoid is fractured. Tenderness to palpation in this area has long been recognized as a sign of scaphoid fracture. Painful, limited wrist motion accompanies this injury.

Trapping the Scaphoid

Another diagnostic maneuver that may prove helpful in isolating injury to the scaphoid is “trapping” the scaphoid between the examiner's thumbs. By placing one thumb in the anatomic snuff box and the other on the distal tubercle of the scaphoid, pain with scaphoid motion can be better assessed. Because many scaphoid fractures occur in the distal region in children, palpation of the volar radial tubercle is especially important.

Radiographic Findings

Study of radiographs must be complete and meticulous. Malformations of the maturing carpus have been described with certain congenital anomalies (173), and often the scaphoid has more than one potential center of ossification (202). AP, lateral, oblique, and dedicated scaphoid views make up the standard series. Fractures of the mid-waist may be appreciated on all views. Distal pole fractures are typically best imaged on the lateral or pronated oblique view. CT scanning of acute fractures or potential nonunions or malunions of the scaphoid furnishes detailed information about scaphoid morphology (186). The scans are made in the longitudinal axial plane of the scaphoid, and three-dimensional reconstructions can be made if necessary.

Treatment

Presumed Fracture

Even if radiographs of the acutely injured wrist appear normal, application of a thumb spica cast is advocated if the mechanism of injury and clinical examination raise the suspicion of a scaphoid fracture. Occult fractures of the scaphoid occurred in 12% of patients in one series (41).

A long arm thumb spica cast in the initial 2 weeks after wrist injury optimally immobilizes the area and prevents cast slippage or damage in children, known for their propensity to escape immobilization. At clinical follow-up in about 2 weeks, radiographs are obtained out of plaster to assess the presence of a fracture line or the position of fracture fragments. If pain is markedly diminished and there remains no radiographic evidence for a scaphoid fracture, immobilization may be discontinued or changed to a removable orthosis. Gradual motion programs need not be formalized for most children.

If there is persistent pain with normal radiographs, replacement in a cast and repeat examination and radiography can be performed 2 weeks later. A bone scan can be considered; it is a sensitive test but lacks specificity. Bone scans are particularly difficult to interpret in growing children because of the increased uptake about the physes. Furthermore, the invasive nature of the test and the prolonged periods of scanning may be difficult for the child to endure. MRI provides a noninvasive alternative, but motion artifact is again a problem.

Confirmed Fracture

If a scaphoid fracture is appreciated at the first clinical follow-up, immobilization can be continued. The debate over whether long arm or short arm immobilization is best continues. Considering a child's activity level and potential lack of cooperation, long arm immobilization may be best. However, if treatment is begun promptly, most scaphoid fractures in children heal within 6 to 8 weeks (41) if immobilized in a short arm cast. Longer periods of immobilization—8 weeks to 4 months—should be considered for fractures that occur in later adolescence or fractures that were initially unrecognized.

Recommended casting positions have included radial deviation with or without flexion (6,223,236). Conversely, ulnar deviation opens the fracture gap in mid-waist fractures. The position of the cast and the joints immobilized are a matter of individual preference and experience with particular techniques. Because most of these different casts furnish roughly the same union rates (around 90%), the importance of the final casted position is probably not paramount. We recommend a thumb spica cast that permits interphalangeal joint motion. Positioning the wrist in slight flexion and radial deviation maximally coapts the fragments.

Including other joints in the scaphoid cast has been suggested. Inclusion of the elbow is controversial. Eliminating forearm rotation is thought by some to neutralize the forces that displace scaphoid fractures (212). However, other investigators considered long arm immobilization unnecessary (4). This issue was largely resolved with the prospective, randomized work of Gellman et al. on the treatment of nondisplaced scaphoid waist fractures in adults (80). This group randomized stable fractures to either long or short arm casting, then changed the cast to a short arm cast at 6 weeks. The long arm group had 100% union, but two of the 23 fractures treated with short arm immobilization failed to heal. The healing time was protracted in patients with short arm casts (9.5 vs. 12.7 weeks).

In children, long arm immobilization is unlikely to cause significant functional debility (or impose restraints that may affect occupation, thus causing economic

hardship), so long arm thumb spica immobilization is a sound initial treatment for these fractures. It is also a much more secure construct.

Inclusion of the thumb interphalangeal joint or other digits (namely the index and long fingers in the three-fingered chuck cast) is seldom practiced today. This is an effective method for eliminating forces about the scaphoid but is cumbersome and difficult to apply.

In one study of adult scaphoid fractures, good results were recorded with dynamic splinting (26), but there would be little if any indication for this flexible splint in children.

Fractures Presenting Late

Vahvanen and Westerlund (216) reported three children with scaphoid fractures recognized late. At the time, these children had bone resorption at the fracture site, although all achieved union after lengthy immobilization (7, 12, and 14 weeks). Segmuller and Schonenberger (193) reported three children with delayed union of the scaphoid and significant bone cyst formation, in whom union was obtained with immobilization for several months. Healing of delayed unions in the pediatric scaphoid with lengthy immobilization has been verified by other clinicians and should be the first alternative used for a pediatric scaphoid fracture that is recognized late (93).

The favorable biology for bone healing in children is probably the reason for the success of closed treatment of scaphoid fractures, whether initiated in acute fractures or in those that present late. The fact that most scaphoid fractures in children are minimally displaced or nondisplaced enhances the ability to treat these fractures by closed means.

Displaced Scaphoid Fracture

Closed Reduction and Casting.

There are no reports detailing specific experience with closed treatment of significantly displaced fractures of the scaphoid in children. In the rare displaced pediatric scaphoid fracture, closed reduction should be attempted. Several researchers have described maneuvers to reduce the displaced scaphoid fracture (115,132). Traction and ulnar deviation usually extend the distal pole that is probably displaced into a flexed posture, but holding the reduction when the wrist is returned to a more anatomic position with a molded cast is difficult, and there is some risk of skin compromise over the distal pole. McLaughlin (144) emphasized the difficulty in obtaining anatomic reduction in his observations of intraoperative fragment relationships with different wrist positions.

Placing percutaneous smooth wires under fluoroscopy may be a more realistic method for closed treatment if reduction is to be effected. The possible collapse pattern of the lunate must be corrected to achieve maximal results.

Open Reduction and Internal Fixation

If displacement exceeds 1 mm or if there is significant angulation (10 degrees or more) on any of the images during a treatment course for fracture of the scaphoid, open reduction and internal fixation should be considered. There is no role for open reduction without internal fixation (144). The implant choice must be individualized, and size is a significant consideration. Smooth wires are very effective in the treatment of scaphoid fractures, including those in children. Smooth Kirschner wires of 0.035 or 0.045 inch are relatively easy to insert and provide good stability. Inserting a Herbert screw or a similar implant is more technically demanding. The ability to use such an implant is based on the size of the fragments and the surgeon's experience.

Mintzer and Waters (152) reported open reduction and internal fixation of an acute displaced scaphoid fracture in a 9-year-old girl. They elected to operate because of the initial displacement at the fracture site and the flexion (humpback) deformity of the distal fragment. Through the usual volar approach, a Herbert screw was used to stabilize the fracture, which went on to uneventful union; good wrist function resulted.

AUTHORS' PREFERRED METHOD OF TREATMENT OF SCAPHOID FRACTURES

We treat almost all nondisplaced or minimally displaced scaphoid fractures with cast immobilization when there is no associated injury. The indications for open reduction in adults include any fracture displaced more than 1 mm or 10 degrees, and some minimally displaced fractures in special circumstances (e.g., professional athletes, surgeons) (152). We are not as aggressive in children, preferring instead to treat nondisplaced and minimally displaced complete fractures with casting.

Fractures with more than 1 mm of displacement or angular deformity of more than 10 degrees are considered for more aggressive treatment. Acceptable displacement depends on the level of the fracture and the maturity of the child's bones. The most accepted indications for open reduction and internal fixation of acute fractures of the scaphoid are significant displacement and association with additional carpal injury.

Role of Closed Treatment

For scaphoid fracture treatment, we favor long arm thumb spica immobilization for the initial 4 to 6 weeks, followed by short arm immobilization until clinical and radiographic union occurs. We use long arm immobilization even in presumed scaphoid fractures as an initial treatment: it protects the patient and underscores the potential gravity of the injury.

Radiographs should be obtained in the first 7 to 10 days, then monthly. Clinical examination yields similarly important information about the progress toward union. We have rarely needed tomograms or CT scanning to assess the relative position of fragments, but they may be considered when loss of reduction is questioned.

Open Reduction and Internal Fixation

If we opt to proceed with surgical treatment, fractures of the middle and distal thirds are exposed through a volar approach. The tendon sheath of the flexor carpi radialis is divided on its radial side to protect the palmar cutaneous branch of the median nerve. The tendon is retracted ulnarward as the incision is taken down to the scaphoid through the floor of the sheath. The radioscaphocapitate ligament and part of the long radiolunate ligaments are carefully divided and tagged for later repair. The scaphoid fracture is assessed for fragment position, reducibility, and stability after reduction. Bone grafting may be considered if there is extensive comminution. We prefer to obtain this graft from the volar or dorsal distal radius, avoiding the morbidity of iliac surgery.

Once the scaphoid is reduced, the method of fixation can be chosen. Smooth wires (0.035-, 0.045-, or 0.062-inch) are preferred in pediatric scaphoid fractures. At least two wires should be placed to stabilize the fracture and minimize rotational displacement. If the patient is near skeletal maturity, a Herbert screw can be inserted as described by its originator (106,107). Pins, if used, can be left under the skin of the thenar eminence or allowed to penetrate the skin. A short arm thumb spica splint is used if the patient is cooperative and the fracture was well stabilized. If a bone screw was used, early motion can be started at the second to fourth week, with interval splinting for protection. When smooth wires stabilize the fracture, rigid immobilization is continued until healing is demonstrated on radiography.

Rare proximal pole fractures can be approached through the same volar approach or a dorsal incision based over the anatomic snuff box. The scaphoid can be delivered into the interval between the first and third dorsal compartments by ulnar deviation of the wrist. The radial artery and its branches are vulnerable on this approach and must be protected (Fig. 8-84).

FIGURE 8-84. A: A 15-year-old male athlete sustained a proximal pole scaphoid fracture that was minimally displaced. **B:** After long discussion with the family, it was decided to perform open reduction and internal fixation. This was performed through a dorsal approach with Herbert screw fixation. Excellent results were obtained. (Courtesy of James E. Culver, Jr., M.D.)

The dorsal approach is particularly useful in surgery for proximal pole fractures and nonunions. We have expanded the use of this approach to include selected patients with more distal fractures that are minimally displaced. The morbidity from the dorsal exposure can sometimes be less than that of the volar route; experience with patient selection and the geometry of the scaphoid are prerequisites for using this approach.

Follow-up Care and Rehabilitation

The protocols for immobilization with closed and open treatment have already been detailed. After the cast is removed, a program may be started that emphasizes recovery of a full range of painless motion before embarking on any strengthening. For young patients immobilized less than 2 months, it usually is unnecessary to use formal therapy modalities. For some adolescents, and if an operatively treated fracture was accompanied by other injuries about the carpus, some formal rehabilitation may be needed. There is little role for dynamic splinting.

Continued follow-up with radiographs and clinical examinations ensures that no carpal collapse pattern is present and that avascular necrosis of the scaphoid has not complicated the fracture course.

If the child or adolescent is amenable, we remove the smooth wires in the office under local anesthesia. We have not found it necessary to remove a Herbert screw in any patient who has a united fracture, but the implication of long-term indwelling metal is unknown.

Complications

Nonunion

Nonoperative Treatment. Scaphoid nonunion is distinctly rare in children, but reports of this complex entity do exist (41,55,134,139,163,170,202). About 20 nonunions have been reported in the world literature, with the largest series detailing eight cases. This paucity of material emphasizes the rarity of this complication and also limits our understanding of treatment methods. There is convincing evidence that immobilization, lengthy if necessary, is the cornerstone of treatment of scaphoid nonunions in children (Fig. 8-85). The evaluation of serial clinical and radiographic parameters must be thorough, and tenderness about the scaphoid and continued radiolucency may persist even after union has been achieved (124).

FIGURE 8-85. A: A 10-year-old boy was first seen after a fall on the outstretched hand. The radiograph shows an old fracture of the waist of the scaphoid. There was no definite history of an old injury. **B:** The fracture went on to solid healing after 9 months of immobilization. Motion and strength of the wrist were normal. (Courtesy of Norman H. Higgins, M.D.)

Operative Treatment. Open reduction, bone grafting, and internal fixation are the standard procedures for treatment of scaphoid nonunions in adults and also have been used in children (134,139,170,202). The volar approach is typically used, along with autogenous bone graft and internal fixation (Fig. 8-77). The concepts of operative scaphoid nonunion treatment in children are similar to those in adults and are familiar to practitioners who do scaphoid surgery (Fig. 8-86). However, the technical demands of the procedure may be amplified because of the patient's small bone size. This may be a factor in the choice of implant, and smooth wires usually are better suited than a scaphoid screw.

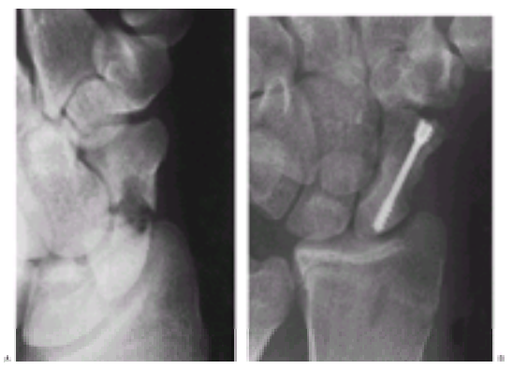

FIGURE 8-86. A: A 15-year-old boy developed a nonunion of the scaphoid. A thumb spica cast for a period of months failed to bring about union. The cyst at the mid-waist grew. **B:** Formal takedown of the nonunion via a volar approach plus intercalary bone grafting with Herbert screw fixation permitted union and had excellent function.

Sequelae. The altered kinematics that predispose the adult wrist to accelerated degenerative change after scaphoid nonunion, scapholunate ligament injury, or scapholunate advanced collapse (the SLAC wrist) (137,222) have never been demonstrated in the pediatric wrist. Studies detailing bipartite scaphoid when

radiographic union was not demonstrated after fracture suggest that only minimal clinical symptoms have been present at long-term follow-up (124,136). Therefore, it is unknown how aggressively scaphoid nonunion should be treated in children.

Most patients have tenderness to palpation about the scaphoid in the snuff box or over the volar tubercle. Motion between the fragments is likely to be demonstrated on fluoroscopy. However, sometimes there is a strong cartilaginous bridge between two ossification centers that were separated by a traumatic injury. This may permit normal motion of the scaphoid in daily activities and possibly with even higher demand occupations. If this is true, the morbidity of bone grafting and open reduction must be balanced against the potential for improved results. Our bias is decidedly against leaving the child with an established nonunion.

We probably will never have sufficient data to provide meaningful conclusions. Natural history studies would be necessary to resolve this issue, and the rarity of scaphoid nonunion probably makes this unfeasible. With the refinement of MRI as a diagnostic tool, fractures in the immature carpus may be better diagnosed (124), and we may see a greater number of defined chondral injuries that can be studied.

Pathologic Fracture

Nonunion of a pathologic fracture has been reported in an adolescent girl. As a 7-year-old, she had osteomyelitis of the scaphoid that was treated by operative drainage and intravenous antibiotics. She was asymptomatic for 6 years, and then wrist pain recurred with activity. Nine years after the original episode, she presented with a frank nonunion of the scaphoid. After two operations to gain union, without the complication of infection in either, the patient went on to have a good result. In retrospect, evaluation of the initial radiographs demonstrated a loss of normal density of the scaphoid with disturbance of the normal trabeculation.

Avascular Necrosis

Idiopathic avascular necrosis of the scaphoid, similar to Preiser's disease of the adult carpus, appears to have no counterpart in children. One child with radial hypoplasia demonstrated changes consistent with avascular necrosis in a very gracile scaphoid that was thought to fail under normal compressive loads (129). The patient had significant pain and was treated with scaphoid excision and interposition arthroplasty.

Capitate Fractures

Impaction or compression fractures of the capitate have been reported by several researchers (129,217). A hyperdorsiflexion type of mechanism causes abutment of the capitate waist against the lunate or dorsal aspect of the radius. Isolated fractures of the capitate are rare and usually result from high-energy trauma (82,239). They can be diagnostic challenges: the proximal fragment of the capitate can rotate 180 degrees, thus presenting a confusing radiographic picture in the immature wrist. In an adult, it usually is easier to determine that such a displacement has occurred, but in a child whose ossification is incomplete, the malposition may be more difficult to ascertain. Radiographs of the contralateral side are needed when attempting to evaluate some of the more complex injury patterns about the pediatric wrist.

Naviculocapitate Syndrome

The naviculocapitate syndrome is well described in adults (217), and this same combination, originally described by Gouldesbrough (86), also has been seen in children. Anderson treated two 13-year-old patients with scaphoid-capitate fractures in combination with distal radial fractures (7).

Associated Fractures Common

More commonly, fracture of the capitate occurs with fractures of other carpal bones (Fig. 8-87). Typically, the scaphoid is injured by forces transmitted in a dorsiflexion, ulnar deviation, intercarpal direction through the radial column (7,86).

FIGURE 8-87. A 12-year-old boy sustained multiple carpal fractures when a heavy weight crushed his wrist. Sixteen months later, he had an established nonunion of the capitate that required bone grafting to obtain union. (Courtesy of James H. Dobyns, M.D.)

Treatment

Treatment of a capitate fracture depends on the character of the particular injury, as well as the trauma sustained by surrounding tissues. Obtaining a film of the wrist in distraction might be one of the most valuable methods for determining whether an injury to the intercarpus has occurred. Before full ossification has been completed, small osteochondral fragments in the mid-carpal region may indicate a greater arc injury or isolated capitate fracture. MRI may be a useful adjunct in these complex injuries.

Nonoperative Treatment

If the displacement of the capitate, or even the capitate and the scaphoid, is minimal, 6 to 8 weeks of immobilization is an effective means of treatment (7). In one report of simultaneous scaphoid and capitate fracture, closed reduction and immobilization proved to be acceptable treatment for the bony injuries, but the position of radial deviation and extreme flexion necessary to maintain this reduction caused a compression neuropathy of the median nerve in a child, requiring decompression (45).

Operative Treatment

If displacement of the proximal pole of the capitate is significant, open reduction with or without internal fixation should be considered. These anatomic relationships must be restored for the mechanics of the carpus and to avoid future problems of ischemic necrosis of the proximal pole. Nonunion of the capitate has been reported in a significant crush injury to the hand of a 13-year-old girl. Bone grafting was performed about 1.5 years later with good success (149). We are aware of no literature detailing avascular necrosis after capitate fracture in children.

Triquetral Fractures

Small triquetral avulsion fractures are common in adults. It is likely that they are so commonly seen by practitioners dealing with hand injuries that a true incidence or prevalence could never be determined. This injury can happen in the maturing carpus, especially as ossification nears completion. The probable mechanism is an avulsion force from the dorsal ligament structures (Fig. 8-88).

FIGURE 8-88. A minimally displaced dorsal triquetral avulsion fracture (*arrow*). These can be treated with short-term immobilization.

Extremely Rare Injury

Although there are no published papers specifically reporting this injury in children, its treatment should be conservative, as in the adult wrist. A short period of immobilization with icing is likely to be enough symptomatic treatment to permit early motion. O'Brien (E.T. O'Brien, personal communication) observed a triquetral body fracture in a child that required open reduction and internal fixation.

Associated with Global Injuries

A significant fracture to the triquetral body also can occur with a more global carpal disruption. The path of the greater arc (140) can go through the triquetrum (Fig. 8-89) (45,124). If a transtriquetral fracture is seen, attention must be directed toward the radial styloid, scaphoid, and mid-carpal joint as well. Again, distraction films may be helpful. Closed treatment for some of these complex disruptions, including the triquetrum, is effective.

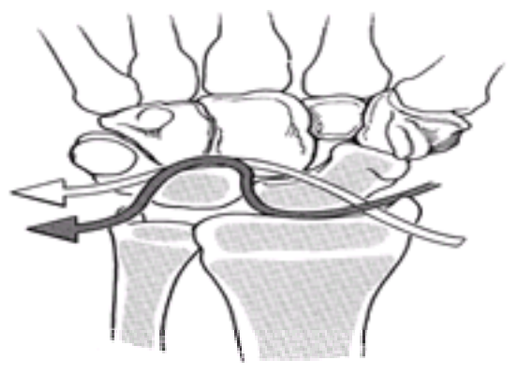

FIGURE 8-89. The greater arc (*white arrow*) is associated with fractures of the carpal bones, which may include the scaphoid, lunate, capitate, hamate, and triquetrum. In this depiction, the radial styloid also has been fractured, creating a trans-styloid pattern. The dark arrow depicts the lesser arc, in which forces are transmitted through soft tissue structures only, resulting in progressive perilunar instability. Numerous varieties of injuries associated with these patterns of forced transmission can be seen. (Reprinted from Mayfield JK, Johnson RP, Kilcoyn RK. Carpal dislocations: pathomechanics and progressive perilunar instability. *J Bone Joint Surg [Am]* 1980;5:226–241; with permission.)

Hamate Fractures

Ali (5) reported on a 16-year-old boy with a fracture of the hamate body and a pisotriquetral dislocation. The patient also had an evolving compartment syndrome of the volar forearm from the significant crush injury. The patient underwent open reduction and internal fixation for the bony lesions, but an ulnar nerve palsy persisted 3 months after the surgery.

There are no specific articles detailing fractures of the hamulus in children, but such fractures can occur in someone nearing skeletal maturity. Those who play racquet sports or golf would be specifically susceptible. The evaluation and treatment of this entity in children may differ from those in adults. Early excision may be too aggressive in a skeletally immature patient, and closed treatment should be favored initially.

Pisiform Fractures

There are no specific discussions of pisiform fractures in children in the literature. Direct trauma causing a comminuted fracture or a flexor carpi ulnaris avulsion injury may occur in late adolescence. Most of these fractures can be treated symptomatically, as in adults.

Lunate Fractures

Blount described a fracture–dislocation of the lunate in association with a crushing type of physeal fracture of the distal radius in a 12-year-old boy (23). Open reduction of the lunate through a volar approach (without internal 7 necessary), as a growth arrest of the radial physis resulted from this complex fracture mechanism.

Perilunar Injuries

Perilunar injuries with or without fractures of the carpal bones have been reported by several researchers (Fig. 8-90) (41,45,166). Because of the unique chondroosseous nature of the maturing lunate, a small osteocartilaginous fracture may go unrecognized on radiography and heal uneventfully. Otherwise, lunate fractures in children are decidedly rare.

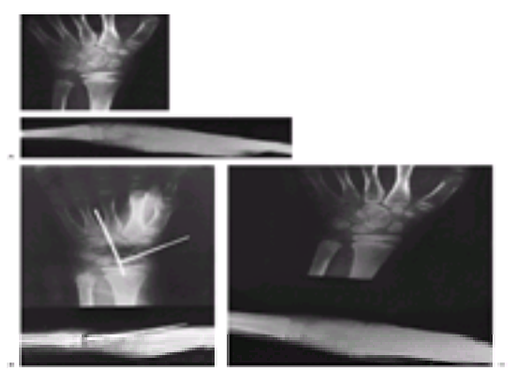

FIGURE 8-90. A: This 6-year-old boy was first seen with a dorsal perilunar dislocation 6 months after falling downstairs. He had been treated with steroids by a pediatrician because of a presumptive diagnosis of juvenile rheumatoid arthritis. **B:** Open reduction and pin fixation was performed through a dorsal incision 6 months after injury. **C:** Seven months later, most of the displacement had recurred, but motion was quite good and the patient had no pain. (Courtesy of William F. Benson,

M.D.)

The pattern of progressive perilunar instability can occur in a child (140). In some of these patients, a scaphoid fracture is the focus, and an appreciation for the force transmission through the wrist will be lost. In these trans-scaphoid injuries, soft tissue injury to the intrinsic ligaments must be suspected and appropriate diagnostic and therapeutic interventions instituted (Fig. 8-91). Transcarpal dislocations are discussed later in this chapter.

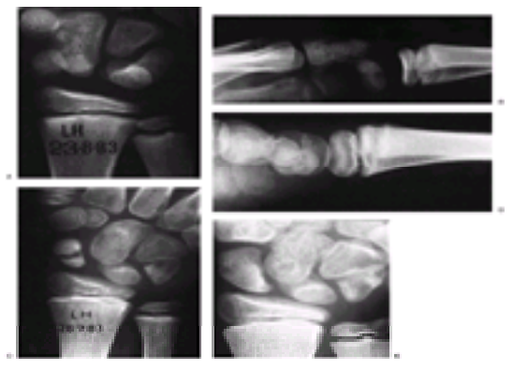

FIGURE 8-91. A and B: A 9½-year-old boy sustained a trans-scaphoid perilunate dislocation of the wrist when he fell 60 feet off a viaduct. **C and D:** Closed reduction was performed 8 days after injury because the correct diagnosis had initially been unrecognized. Plaster immobilization was maintained for 4½ months because of transient avascular necrosis of the proximal pole and delayed healing. **E:** Three years after injury, there was slight irregularity of the proximal pole, but the patient had normal function. (Case courtesy of C.L. Colton.)

Lunatomalacia or Kienböck's Disease

An analogue to the adult Kienböck's disease or lunatomalacia has been observed in children under 10 years of age (Fig. 8-92) (16,177). It was unclear in these reports whether a history of trauma preceded the clinical picture. The symptoms were vague and of low grade, and radiographs revealed only mildly increased density of the lunate with no change in external morphology. Advanced imaging studies such as tomography, MRI, or scintigraphy were not used to evaluate these patients. Immobilization for up to 1 year has been used with success to treat this Kienböck's variant in children. The lunate itself has remodeled in satisfactory fashion; furthermore, if there is altered lunate architecture, usually there are few symptoms, and good motion recovery is expected.

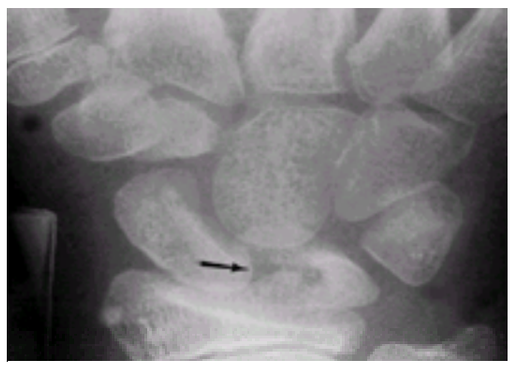

FIGURE 8-92. A 12-year-old boy sustained a wrist injury and developed a small area of segmental rarefaction in the lunate, consistent with avascular necrosis (*arrow*). This may represent a pediatric form of adult Kienböck's lunatomalacia. (Courtesy of Greg Goldsmith, M.D.)

Trapezium Fractures

A fracture of the trapezium is extraordinarily rare in adults or children. Direct palmar trauma may cause a trapezial ridge fracture. A dorsal impaction fracture may result from a hyperextension injury (Fig. 8-93), or a small ligament avulsion can be seen. In general, immobilization and symptomatic treatment are adequate.

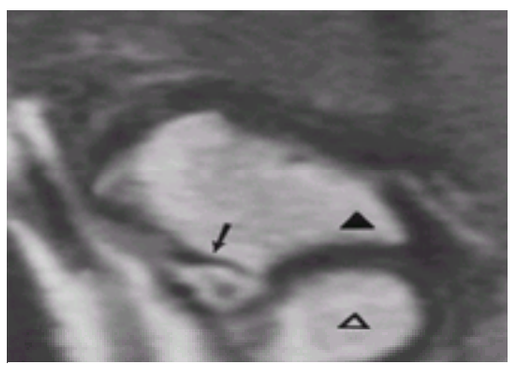

FIGURE 8-93. A 15-year-old girl sustained a nondisplaced scaphoid fracture that healed uneventfully with closed treatment. She continued to complain of dorsal wrist pain 10 months after the injury. Bone scan revealed increased uptake in the area of the distal scaphoid and proximal triquetrum. No plain radiograph abnormalities could be appreciated. A limited magnetic resonance imaging scan demonstrated a nonunion of an intraarticular fracture of the trapezium (*arrow*). The scaphoid is identified by an open triangle, the triquetrum by a closed triangle. Excision of the fragment brought pain relief, and normal function returned.

Soft Tissue Injuries About the Carpus

Ligamentous Injuries

Ligamentous injuries about the pediatric wrist are even more uncommon than osseous injuries. The special viscoelastic properties of the carpal structures probably provide protection from catastrophic ligament injuries in the immature wrist. Also, the difficulties with physical examination and radiographic interpretation may disguise some injuries.

Fracture–dislocations of the pediatric wrist have been described (2,166). These were not subtle injuries: they were easily detectable and resulted from high-force mechanisms. These children, 10 and 12 years old, probably had bony and soft tissue makeup approximating that of an adult wrist and also sustained enough trauma to manifest this combined injury. Another combined injury about the wrist was reported by Giddins and Shaw (83). In this case, lunate subluxation was associated with

a distal radius physeal fracture. Instability of the lunate was initially recognized and treated surgically 6 weeks after the injury by repair of the dorsal ligament and pin fixation of the lunate.

There are a few reports of isolated ligamentous injuries of a child's wrist. Gerard (81) reported a 7-year-old girl who sustained only low-energy injuries from a fall from a standing posture at 3 months of age. The parents related that the child excluded the affected hand from normal activity, and a painful limitation and clinical deformity of the wrist were present at the time of evaluation at 7 years. A volar intercalated type of instability with carpal collapse was present when the radiographs were reviewed. The distinct pattern was absent on the contralateral uninjured side. Operative reconstruction was chosen, using an extensor carpi radialis graft and pinning. Although follow-up was brief, clinical and radiographic results were considered excellent.

Hyperelasticity syndromes may predispose patients to aberrant carpal mechanics. Atraumatic bilateral perilunar dislocation patterns have been observed in association with Marfan's syndrome (167). A complete examination of the patient to determine whether global hyperlaxity is present would be useful in evaluating wrist findings that seem out of the ordinary. Films of the contralateral extremity also can provide vital information. True intercarpal and radiocarpal ligamentous injuries are rare in children, but the diagnosis should still be considered if clinical findings suggest it. Despite the infrequency of these injuries, clinicians may find themselves questioning an apparent subtle widening or malalignment in the carpus. An appropriate index of suspicion, experience, and judicious use of ancillary studies (e.g., arthrography, stress radiography, and real-time fluoroscopic evaluation) are advocated.

If several factors in the history and examination point to potential ligamentous injury, short-term immobilization and reexamination are appropriate. Often there is a marked diminution in clinical symptoms, and uncomfortable intervention is avoided.

The goals of a mobile, painless wrist and the prevention of accelerated degeneration within the carpus are most often met by a systematic evaluation and treatment process. If aggressive intervention is necessary, the timing may have to be considered.

It is difficult to make a general recommendation about treatment for these extremely rare injuries. Some difficult decisions would have to be made in, for instance, a late adolescent athlete with an acute scapholunate injury. We would probably treat these patients as adults, with anatomic reduction, repair of soft tissues, and internal and external immobilization as necessary until healing occurs. Some formal rehabilitation may be needed to recover motion and strength. If ligamentous disruptions occur in an extremely young patient, it is not unreasonable to permit the remodeling potential of the immature carpus and the innate ability of children to regain useful and painless range of motion to work in the child's favor.

Distal Radioulnar Joint Disruption

Dislocation of the distal radioulnar joint also is rare in children, although with higher levels of athletic participation, we may start to see more open soft tissue destabilizing injuries (100). Fracture through the ulnar physis occurs with some frequency, and this route of force transmission may be somewhat protective to the distal radioulnar joint and triangular fibrocartilage complex (120,128). The pediatric Galeazzi equivalent is a fracture of the radius accompanied by a fracture of the distal ulnar physis that destabilizes the distal radioulnar joint. Galeazzi fractures and their equivalents are discussed in Chapter 9.

Acute lesions of the triangular fibrocartilage complex are rare in childhood. If there is a high index of clinical suspicion for such an injury in a child, arthrography may be used to confirm the diagnosis. Cadaver dissections by Mikic (147) failed to demonstrate triangular fibrocartilage changes of a degenerative nature in any specimen under 27 years of age. Although this information may not be directly applicable, it does lower the likelihood of a significant triangular fibrocartilage complex injury, with or without distal radioulnar joint disruption.

A radiocarpal dissociation from the distal ulna usually is a catastrophic injury that results from high-energy mechanisms. Subtle injuries also can occur; comparison radiographs and clinical examination are important steps in evaluation. Many of these less significant injuries can be treated with immobilization in full supination, which reduces the distal radioulnar joint.

Athletic Injuries of the Immature Wrist

Injuries to the upper extremity have been largely neglected in sports medicine because of the focus on catastrophic, high-profile lower extremity injuries. However, as our young patients participate with greater sophistication at earlier ages, the number of wrist injuries is increasing. This is especially true in high-velocity, hand-intensive sports, where the demands on the hand and wrist are the greatest (17,56).

Significant injuries to the wrist are underrecognized and can be undertreated unless the physician is familiar with these pathologies. In addition, the health-care professional attending athletic contests or evaluating the injured player in the early period must temper the athlete's and coaches' desire for him or her to continue play if the extent of the injuries may make this unfeasible. Acute injuries to the wrist can occur as a result of direct contact from a ball, high-energy collisions, and attempts to brace against opponents or falls onto the turf. Fractures of the carpal bones, ligamentous injuries, or a combination injury may result.

Conversely, there is increasing recognition of the effect of long-term, repetitive exposure to particular activities specifically involving the wrist. The stresses that high-performance gymnastic maneuvers place on the radial physis have been discussed and characterized in the literature (38,179,183,184). Similar physeal injuries have been reported at the distal ulna as a result of gymnastics (238). The clinical and radiographic manifestation is not unlike an “acquired Madelung deformity,” as reported in one patient by Vender and Watson (219). Management is described in Chapter 9.

Whether a sports injury to the wrist is acute or secondary to repetitive loading, a sensible approach that includes input from the patient, parents, and coaches is advocated. We strongly recommend using the traditional and tested methods of treating injuries and try to disregard any outside influences that may be at work forcing a more aggressive approach to these young athletes. The definitions of *aggressive* and *conservative* are sometimes clouded in this population. Some argue that internal fixation of a minimally displaced scaphoid fracture in a high-performance athlete is a safe and predictable method that brings about rapid union and returns the patient to the previous level of athletic involvement. However, we do not advocate such an approach in children.

There may be some debate about scholarship candidates who have little growth remaining before their final season of high school sports. These decisions must be individualized, and the patient's desires and the particular aspects of the sport are important factors to be considered.

Physicians, parents, and coaches can work together to effect significant change in the realm of education and safety. It is important to have proper coaching, conditioning, and equipment when teaching young athletes. This applies to both team activities and individual sports. Proper use of safety equipment is necessary and beneficial. Such equipment includes materials for preventing injury to the upper extremity, such as the wrist guards used in in-line skating or the hand and wrist protectors used in gymnastics (Fig. 8-94). Innovative types of immobilization and protection that are approved by rules committees of the particular level of play, whether it be the local school board all the way up to the NCAA or NFL, are used. The concept of the playing cast has been well studied and is an excellent adjunct to return athletes safely to the field or court while minimizing the danger to themselves and other participants.

AUTHORS' PREFERRED METHOD OF TREATMENT

Distal pole fractures occurring in preadolescents are treated symptomatically. Short-term (2–3 weeks) splinting or casting is usually adequate.

Our experience with teenaged athletes has forced us to contemplate an emerging subset of carpal injuries—the “typical” scaphoid waist fracture in a skeletally immature patient. If displaced (1 mm or more of fracture gap or 10 degrees of angulation), open reduction and internal fixation are indicated. We favor a variable pitch screw inserted through a volar approach, after anatomic reduction. For some fractures in the proximal third, a dorsal approach for insertion can be used.

If there is a mismatch between the size of the scaphoid, or the fracture fragment, and the prospective implant, then smooth wires can be used for stabilization. The same concepts of approach and implant insertion hold.

DISLOCATIONS OF THE HAND AND CARPUS

Dislocations of the Interphalangeal Joints

In children, the soft tissue stabilizers of the interphalangeal joints (the collateral ligaments, the inserting tendons, and volar plate) exceed the physeal tissue in strength and ability to withstand pathologic forces. It is for this reason that failure through the bony elements is much more common in this age group. Occasionally, dislocations do occur, as do fracture–dislocations (Fig. 8-95).

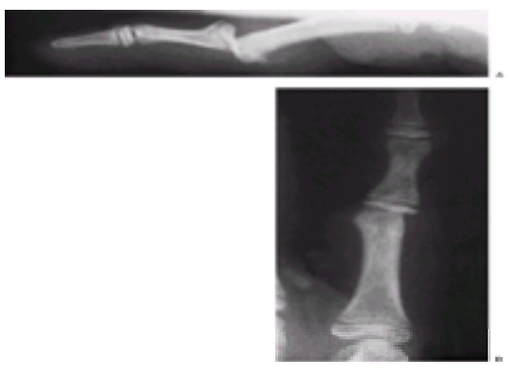

FIGURE 8-95. A: A 15-year-old boy sustained a dorsal dislocation of the proximal interphalangeal joint with a Salter-Harris type II fracture of the middle phalanx when he jammed his little finger playing baseball. **B:** Closed manipulation successfully reduced the dislocation and the fracture.

The specific anatomy and interrelationships of the bones and soft tissues in the pediatric hand have been extensively discussed earlier in this chapter. We refer the reader to these sections for a thorough description of the insertions of the volar plate, collateral ligaments, and musculotendinous units about the interphalangeal joints.

Interphalangeal Joint Dislocations

The Distal Interphalangeal Joint

A hyperextension force or axial load on a slightly flexed terminal phalanx can result in dislocation of the DIP joint without fracture. Most soft tissue disruption is volar and lateral, resulting in the distal phalanx coming to rest in a position dorsal to the middle phalanx. The collateral ligaments and volar plate typically fail at their middle phalangeal origin.

Most of these pure dislocations can be easily relocated by longitudinal traction and recreation of the hyperextension force, followed by the terminal reduction maneuver. The DIP joint congruity is assessed clinically and with radiographs. Two to three weeks of splinting, similar to the splinting used for mallet injuries, will allow the ligaments to heal. Motion recovery usually is full, and late instability is rare.

Irreducible or complex dislocations of the DIP occur almost exclusively in adults, but some clinicians have included immature patients in their series (164,171,185,194). The reports that have included younger patients have lacked specific details of operative findings, and have mixed pure soft tissue injuries with fracture–dislocations (210). However, some important facts have been common to most reports:

1. The distal phalanx is dorsal and blocked from reduction by the interposed volar plate, having been avulsed from the middle phalanx. Other tissues that may be interposed are the collateral ligaments and the flexor digitorum profundus (211).
2. Relocation of the complex dislocation, performed through a dorsal approach, usually requires division of at least one collateral ligament, removal of the interposed volar plate, and relocation of the flexor digitorum profundus.
3. Pinning of the joint is an option for a period of 3 weeks until soft tissue healing is adequate to start early motion. No late instability was reported, and motion recovery was uniformly satisfactory.

The Proximal Interphalangeal Joint

Injuries of the PIP joint are relatively rare in children, in comparison with their occurrence in adults. Bony injuries about the PIP joint garner the most attention because of their potentially disastrous results, but injuries to the soft tissues often lead to persistent swelling, instability or stiffness, and tendon imbalance.

The Jammed Finger. The jammed finger or “coach's finger” is a popular term in the lay community used to describe the swollen digit resulting from an axial loading injury with variable angulatory and rotational forces. The pain and deformity usually are localized to the PIP joint, and flexion is difficult. The pediatric patient often has trouble localizing the discomfort to the volar, lateral, or dorsal aspect of the joint. By the time the physician has seen the patient, several coaches or parents have already tried to “pull it back in place.”

At first evaluation, little more is known about the pathoanatomy than it is primarily focused at the PIP joint. The history should include questions about the mechanism of injury, and whether there was a perceived deformity of the digit that was reduced by manipulation.

Radiographs will reveal a fracture, if present, but often are unclear with respect to the skeleton. Diffuse soft tissue swelling is appreciated. Care must be taken to study the congruity of the reduction at the PIP joint. A loss of concentricity can be quite subtle, evidenced by a dorsal V space instead of a smooth articular mating.

Evaluation under metacarpal block anesthesia is helpful in determining the integrity of the soft tissue structures about the PIP joint. A stress examination of the collateral ligaments can be conducted. Passive range of motion can be recorded painlessly, and active motion can be assessed.

A closed boutonniere deformity is inferred when active extension from a flexed posture is impossible, but extension can be maintained if the digit is passively placed at neutral. Other provocative maneuvers for diagnosis of an extensor mechanism injury include a test of central slip continuity described by Elson (66). With the patient's digit flexed 90 degrees at the PIP joint over a table edge, inability to extend the PIP joint coupled with fixed extension of the DIP joint indicates a central slip

rupture.

For many of these presentations, no specific pathologic entity is defined. The soft tissue swelling and vague pain can persist for nearly a year, and the affected PIP joint may always be slightly more voluminous. Radiographs typically show no bony sequelae or accelerated degeneration, although cartilage or bone bruise is a likely part of the injury.

Treatment of the “jammed finger” consists of initial icing and elevation for 72 hours, with immobilization in a hand-based splint to permit rest. Edema reduction and motion should then follow, and warm soaks may bring some relief. Buddy taping to the adjacent digit protects the injured member and promotes earlier motion recovery.

A documented central slip rupture is treated with extension splinting for four weeks, followed by dynamic extension splinting for 2 to 4 weeks. The splint permits motion, while preventing volar subluxation of the lateral bands. Rarely, operative intervention is required for closed extensor mechanism injuries. Primary tendon repair, with or without joint pinning, usually is reserved for special circumstances. The greater strength of the flexor surface muscles usually allows recovery of flexion, even after several weeks of extension splinting.

True Pip Dislocations. PIP dislocations can be dorsal, volar, or lateral. Although a significant number of these injuries are incomplete ligament avulsions or intrasubstance tears, combined with a spectrum of injuries to the volar plate, some may present as irreducible joint dislocations.

Dorsal PIP Dislocations. Dislocations about the PIP joint in which the middle phalanx is displaced dorsal to the proximal phalanx are the most common (Fig. 8-96). Failure of the collateral ligaments and the volar plate are all a part of the pathogenesis of the dislocation. These structures may even block attempts at reduction, creating a rare irreducible dorsal dislocation.

FIGURE 8-96. A: Lateral radiograph of a volar plate avulsion injury. There is a small fracture fragment volarly from the epiphysis of the middle phalanx. Note the associated soft tissue swelling. These fractures should not be treated with prolonged immobilization. Early buddy taping and motion lessen the risk of a flexion contracture. **B:** Dorsal dislocation of the proximal interphalangeal joint in a 10-year-old girl.

Many dorsal dislocations are better termed subluxations or sprains, because the injury to the fibers of the collateral ligaments does not result in frank loss of joint congruity or cause instability of the articulation through a normal arc of motion. In fact, many of these injuries either go unseen by the physician or are seen after they are reduced by the patient or other attendant. Many of these reductions take place on the playing field or gymnasium, and the patient returns to an athletic contest.

With a dorsal dislocation, neurovascular status typically is normal, but pain and deformity are obvious. Fracture is ruled out with standard radiographs, with the addition of an oblique film to better assess the condylar area. After adequate anesthesia, the dislocation is reduced with longitudinal traction and hyperextension, followed by gentle flexion of the middle phalanx back onto the proximal phalanx articular surface.

The quality of the reduction and the stability of the joint must be assessed. Radiographs should demonstrate a concentric reduction. Most dislocations are stable throughout the normal range of motion, but others may redislocate as the PIP joint is brought into more extension. Eaton (65) described the active stability test to determine the adequacy of reduction and the need to potentially treat by operative means. Simply asking the blocked and reduced patient to perform active flexion and extension to determine stability is the cornerstone. If the joint remains stable in this arc, then 2 to 3 weeks of buddy taping are adequate.

Extension-block splinting, as advocated by McElfresh et al. (142), may be needed for fracture–dislocations. Our regimen for splinting of injuries that are reducible and stable in at least some range is detailed below:

1. For a completely stable joint with no lateral instability or volar plate laxity, we allow early motion with buddy taping to the side of the greatest lateral tenderness.
2. For a closed reduction that is stable, yet associated with a degree of lateral instability (<20 degrees) or volar plate laxity (<20 degrees hyperextension), splinting of the PIP joint for 2 to 3 weeks in about 30 degrees of flexion is the initial treatment. Buddy taping can continue for 2 to 3 additional weeks.
3. For significant volar plate injury without lateral instability, a greater degree of PIP joint flexion is used for about 3 weeks. We typically splint at 5 degrees less than the maximal extension at which the joint starts to dislocate; this is usually between 45 and 60 degrees. The joint is extended slowly every 7 to 10 days until full extension is realized at the third or fourth week. The joint has been left free to flex throughout this treatment course. Bowers (29) has reported development of a swan neck pattern in two children with volar plate rupture after dorsal dislocation, and both needed volar plate repair. More aggressive early dorsal block splinting may permit healing of the injured plate and prevent such a deformity.

There is considerable disagreement concerning primary repair of torn collateral ligaments associated with PIP joint dislocations in adults (135,141,180,188). With the paucity of experience or reports of this pure ligamentous injury in children, even less of a consensus exists. Redler and Williams (180) did include four skeletally immature patients in their series of 14 complete collateral ligament ruptures. They reported complete functional recovery. Blount (23) and Vicar (220) described a patient in whom the collateral ligament was interposed in the PIP joint and had to be extracted to permit reduction. In Vicar's patient, the injury was several weeks old, but the open repair was successful.

Other researchers (28,232) described a tumescence at the site of the collateral ligament avulsion (from its proximal phalangeal origin) that has been bothersome to patients and may cause functional limitation. These fibrocartilagenous or fibroosseous masses have been excised with uniform success. Another peculiar injury was reported by Whipple et al. (228) in which the volar cartilage surface of the middle phalanx was folded into the joint, in a dorsal fracture–dislocation. The cartilage flap was easily restored, and excellent function was realized within a month.

We have been very pleased with simple closed reduction, coupled with either short-term immobilization in an extension block splint or simple buddy taping. If the dorsal dislocation cannot be reduced, evacuation of interposed tissue is necessary. When the joint is to be opened for reduction, we primarily repair the collateral ligament(s) with nonabsorbable suture. However, we reserve this treatment for unstable joints, because we have found that postreduction instability is rare, because most of these patients tend toward stiffness.

The “gray area” between open and closed treatment of these injuries is when reduction can be accomplished, but significant instability is present. In this young population, we still make an attempt at closed treatment if the joint can be reduced. If the joint needs to be splinted in more than 60 degrees of flexion to remain stable, we advocate primary ligament repair. We approach the digit through a mid-axial incision on the side of the collateral ligament rupture. Secure primary repair or suture to bone is accomplished. Pinning of the joint is avoided if possible. Motion is begun at the second week.

Dynamic splinting may be necessary for terminal motion recovery. The fibrous masses that have been described above usually present little impediment to motion recovery. If the mass is troublesome, it can be excised after the other tissues have stabilized. Waiting about 6 months may allow the surgeon to combine a capsulotomy or tenolysis, if needed, with the excision.

Volar PIP Dislocations. Although volar PIP dislocations are uncommon in the pediatric population, there are common themes that can be appreciated from the few reports (111,160,165):

1. These injuries often go undetected. The delay in diagnosis ranged from 1 to 52 months in one series (165), and the single patient reported in another series was 3 weeks old (160).
2. Interposition of soft tissues (the volar plate, lateral band) can hamper attempts at closed reduction. Likewise, fracture fragments can render the dislocation irreducible by closed means (111).
3. Long-term results are often suboptimal. It is difficult to ascertain whether the late treatment is the ultimate cause, or contributing factors like the violence of the initial trauma or extent of tissue involvement also may play a role.

Volar dislocation is an extensor-side injury. The interval between the lateral band and the central tendon may be the site for herniation of the proximal phalangeal head, or the central slip may rupture from its middle phalangeal insertion. Thompson and Eaton (213) recommend 3 weeks of extension splinting followed by intermittent dynamic splinting for patients in whom a congruous reduction is obtained. If the reduction is blocked by soft tissue, exploration may be necessary. We approach the digit from the dorsum, and exploit the injury interval to evacuate the joint. Careful reconstruction of the extensor tendon is performed, and splinting in extension is continuous for 3 to 4 weeks. The flexion typically is regained without too much difficulty over the course of the next 6 weeks. Some dynamic splinting can be used to assist or accelerate motion recovery.

Lateral PIP Dislocation. Garroway et al. (77) emphasized the role of torsional forces in the development of complex dislocations about the PIP joint. Although his five classes spanned volar and dorsal dislocations, and no specific mention of these injuries in children was made, the concept of multiaxial force in the pathogenesis of PIP dislocations was underscored. It is rare to have forces directed purely in one plane, and simply labeling the injury as a dorsal or volar tissue disruption is practical but incomplete. The tissue that is likely damaged in all these injuries, to an extent, is the collateral ligament.

Kiefhaber and co-workers (114) focused attention on the collateral ligament system and related displacement of the digit in the coronal plane to tissue pathology. More than 20 degrees of lateral deviation to gentle stress reliably indicated complete ligamentous disruption. The order of failure was also elucidated in this study: first, the collateral ligament is detached from the proximal phalangeal origin; then the accessory and proper collaterals are separated as forces move distally; the final area of failure is the distal volar plate insertion from the middle phalanx.

Treatment of the collateral ligament in the setting of a volar and dorsal dislocation has already been described. Protection of the collateral ligament can be accomplished with rigid splinting or buddy taping. The extent of the injury, evidenced by the amount of lateral deviation to stress and the quality of the end point, may mitigate for more aggressive treatment in some patients. If the joint can be dislocated by applying lateral stress, then consideration should be given to collateral repair. If a fracture is present in conjunction with the lateral stress injury, consideration could be stronger for opening the injury through a mid-axial approach and stabilizing the bone and repairing the soft tissues (47).

AUTHORS' PREFERRED METHOD OF TREATMENT

The variables that must be considered when planning a treatment course for PIP level injuries in a child include extent and anatomic location of soft tissue disruption, presence or absence of fracture, reducibility, and stability after reduction. Almost all PIP dislocations deserve an attempt at closed reduction and stability assessment. Indeed, the standard protocol of anesthetic block, reduction, active and passive motion testing, and radiographic assessment suffice in most circumstances.

Dorsal Dislocation

If the reduction was easily obtained and good motion arc and stability are present, we prescribe a short period (less than a week) of dorsal blocking protection. This can be followed by active motion with buddy taping.

If there is a proclivity for the joint to redislocate at 30 degrees of flexion or more, we exercise more of a standard dorsal blocking splint regimen: 45 to 60 degrees for 5 to 7 days, followed by 30 to 45 degrees for 5 to 7 days, followed by 15 to 30 degrees or buddy taping until swelling is decreased and stable motion is realized. The entire course usually lasts 2 to 3 weeks.

If surgical intervention is indicated in the rare severe intraarticular fracture, irreducible dislocation, or a combination, the ultimate goal of stable fixation to permit early motion must be observed. These problem fractures typically occur in adolescents, so “adult principles” govern.

Volar Dislocation

This is a rare injury, but can occur in children. One of the classic mechanisms seems to be catching the digit in the spokes of a bicycle or exercise equipment. This injury reflects a disruption of the dorsal apparatus, and this must be respected. Therefore, splinting is in extension for up to 4 weeks, followed by a spring-loaded extension splint.

A dorsal epiphyseal fracture may indicate a central slip avulsion fracture that may require open treatment.

Lateral Dislocations

Injury to the collateral ligaments is a likely component of all these dislocations, regardless of true “direction.” Conversely, isolated rupture, or pure lateral dislocation, is probably rare. An incompetent collateral ligament is best treated by closed means. The exception to this is when there has been an incarceration of a lateral band in the dislocated joint.

Metacarpophalangeal Joint Dislocations

The most common site for dislocation in the child's hand is the MCP joint (84,130,200). The thumb MCP joint dislocates most often as a result of a hyperextension force. The gamekeeper's or skier's thumb can be thought of as a momentary dislocation or subluxation. A small epiphyseal fragment may accompany the UCL, or a pure soft tissue injury can result. The most common complex or irreducible dislocation is at the index MCP joint.

Dorsal Dislocations of the Triphalangeal Digits

The most common dislocation of the MCP joint is dorsal dislocation of the index digit (Fig. 8-97). The injury results from a hyperextension force that causes a rupture or avulsion of the volar plate (33). When the proximal phalanx becomes situated dorsal to the metacarpal, there is little question of the diagnosis. The digit is supinated, ulnarly deviated, and shortened. The interphalangeal joints are slightly flexed. Most patients have volar skin dimpling over the metacarpal head.

FIGURE 8-97. A: A 3-year-old boy with a complete complex dislocation of the index finger metacarpal joint. **B:** Note the parallelism in this lateral view. Open reduction was performed through a volar approach, and normal function resulted.

Radiographs can confirm the diagnosis, especially when there is gross malalignment of the bony elements or the sesamoids are seen in the joint. The position of the volar plate in children over 10 years of age can be inferred by sesamoid position in the index and thumb rays (211). Rarely, other digits have visible sesamoids, and this same diagnostic technique can be used. It is often suggested that the presence of the sesamoids in the joint connotes a complex dislocation, but this finding is not absolute.

Other clues to dislocation at the MCP joint can be gleaned from radiographs. Robins (181) observed simple narrowing of the MCP joint space in MCP dislocation. Campbell (36) described the concept of the “phalangeal line” as a guide to determining the presence of fracture or dislocation at the MCP joint. He showed that a line drawn down the axis of the proximal phalanx should pass through the axis of rotation of the metacarpal head in the uninjured digit. When a fracture or dislocation was present, the phalangeal line became skewed (36). The concept of “parallelism” of the metacarpal and the phalanx is another expression of Campbell's concept. This finding is not universally seen in the complex dislocation. The surgeon should be especially cognizant of the infrequent occurrence of adjacent MCP dislocations. These most often occur with more violent trauma and can be difficult to diagnose clinically because of hand swelling. Radiographs may be difficult to interpret, because projections may obscure adjacent MCP joints.

To explain the pathoanatomy of an irreducible or complex dislocation, Kaplan (112) described the position of the metacarpal head with respect to the surrounding soft tissues. The metacarpal head becomes “picture-framed” by the flexor tendon to the ulnar side and the lumbrical to the radial side. The superficial transverse metacarpal ligament and the natatory ligaments can settle dorsally around the metacarpal neck, and the palmar aponeurosis captures the metacarpal on the volar side. The collar is tightened by longitudinal traction, and this common reduction maneuver can actually convert a reducible dislocation to an irreducible one. The volar plate can become interposed between the dorsal metacarpal head and the dislocated proximal phalanx, further blocking reduction.

Reduction is effected by further hyperextending the joint, then attempting to capture the volar plate with the dorsal lip of the proximal phalanx. Intraarticular infiltration of anesthetic fluid can assist reduction by “floating” the volar plate out of its displaced position. The success rate for closed reduction of complex dislocation is low. Operative reduction and clearing of the joint usually are required. If a reasonable attempt at closed reduction has failed, open reduction is warranted.

Volar Approach. When closed reduction is unsuccessful, open methods are needed. Many surgeons prefer the volar approach for reduction of the MCP dislocation (Fig. 8-97). The volar approach affords excellent exposure of the metacarpal head and the structures that incarcerate it (11,14,23,84,92,112,130,143). The authors that prefer this approach accept the risk of potential injury to the digital nerves that are draped over the articular surface of the metacarpal head. Kaplan and others advocate division of multiple structures, including the A1 pulley, the distal edge of the palmar aponeurosis, the superficial transverse metacarpal ligament, and the natatory ligaments. Other clinicians believe that division of the A1 pulley alone (130) or the transverse metacarpal ligament alone (104) is sufficient.

McLaughlin modified the volar approach to the MCP joint by incorporating it with a mid-lateral incision into the digit, choosing to extend the incision along the radial mid-lateral line (143). He used a skin hook to extract the volar plate from its position in the dislocated joint. Reduction was accomplished without the need for additional soft tissue releases.

Metacarpophalangeal dislocations in the other triphalangeal joints are uncommon (Fig. 8-98). Baldwin et al. (10) described an irreducible fifth ray MCP dislocation in which the metacarpal head was entrapped by the abductor digiti quinti and flexor digiti minimi on the medial side and the long flexor tendons to the lateral side. Open reduction with incision of the volar plate was necessary to correct the deformity.

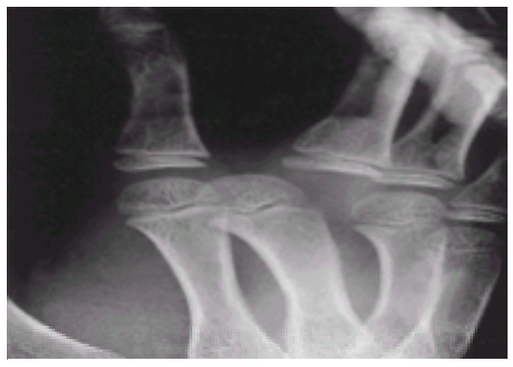

FIGURE 8-98. A relatively rare dorsal dislocation of the long finger was irreducible by closed means. A dorsal approach permitted visualization of the joint and extrication of the volar plate. Excellent function ensued after early motion was started.

Metacarpophalangeal dislocations in the central rays are rare (Fig. 8-99) (161). Lateral fracture–dislocations at the MCP joint sometimes occur, and are often S-H III fractures of the phalangeal base. Open reduction usually is necessary to treat the fracture.

FIGURE 8-99. A: A 9-year-old girl sustained this radial fracture–dislocation of the middle finger in a fall on the stairs. **B:** Six weeks after closed reduction and immobilization in a radial gutter splint for 3 weeks, there was full motion and normal stability.

The optimal treatment is prompt recognition and reduction of the MCP dislocation. The window of opportunity for successful reduction is difficult to define. Although reasonable results have been obtained when the dislocation is reduced within the first 3 to 4 months, this is still suboptimal treatment. After 6 months, results are less predictable, and accelerated arthrosis may necessitate an early salvage procedure.

Dorsal Approach. Most surgeons use a dorsal exposure for reduction of complex MCP joint dislocations. Described by Becton et al. (14), this simplified technique avoids the catastrophic complication of digital nerve transection, while still permitting adequate joint access.

By relaxing the flexor pull by simply flexing the wrist and digits, the joint can be approached through a tendon-splitting incision. Either a transverse or hockey stick

capsulotomy can be used, but the injury may have stripped the capsule to an extensive degree. Use of a Freer or septal elevator defines the joint, and may sweep away the soft tissue that was interposed. Throughout the procedure, protection of the metacarpal head articular surface is paramount.

Pushing the volar plate back into position may be the only treatment needed for the joint. At times, a flexor tendon is wrapped around the condyle. If the volar plate is difficult to reduce, it can be split from the dorsum in a longitudinal fashion. This maneuver relaxes the plate, and permits it to slip back to anatomic position. The volar plate need not be repaired or sutured back to surrounding tissues after its reduction.

Postoperative Therapy. Regardless of the approach used, there is universal agreement that early motion is necessary. The minimal amount of tissue dissection facilitates this, and a minimal soft dressing is all that is needed in the acute postoperative period. Rarely, a dorsal blocking splint may be needed to prevent hyperextension that may lead to redislocation. There exists no report of redislocation at the MCP level after open reduction.

Missed MCP Dislocations. Early reduction of the MCP dislocation has been stressed by Hunt et al. (109). It is universally agreed that early reduction and an early motion program should be accomplished within the first 7 days (112,143). Despite appropriate radiographs and clinical examination, inexperience with these injuries can lead to a missed dislocation.

Significant motion limitation and deformity characterize this entity, although pain is typically minimal. Operative intervention is the only reasonable alternative, thus we caution against vigorous attempts at closed reduction when a dislocation has been present more than 2 or 3 weeks.

Murphy and Stark (157) discussed the treatment of missed dislocations. They performed open reduction of MCP dislocations that had been neglected for 3 weeks to 3 months. Both volar and dorsal approaches were used, and the UCL had to be resected in some patients. Transarticular pinning was maintained for 3 weeks. There was decreased motion at the MCP joint, but it was still thought to be in the useful range. Late complications included partial growth arrest. Barenfeld (11) achieved normal motion in a patient whose dislocation was reduced 3½ months after injury. Lipscomb and Janes (133) reported a 20-year follow-up of an unreduced thumb MCP dislocation. They related that a “new metacarpal head, joint, and ligament apparently formed spontaneously.” It is likely that the exceptional remodeling about the adjacent epiphyses adapted to the new forces contributed by the bones in their new position.

We agree that surgical reduction will likely require both volar and dorsal approaches. The multiple structures that can incarcerate the metacarpal head have contracted, and release of any tight structure is indicated. Dorsal clearing of the joint often is needed to remove the fibrous tissue that has occupied the void left by the dislocation.

Dorsal Dislocation of the Thumb Ray

In many ways, MCP joint dislocations of the thumb are similar to those of the triphalangeal digits. The hyperextension mechanism is the same, as is the proclivity of the dislocation to be irreducible. Because of the thumb's differing anatomy and functional importance, it is considered separately.

The pathophysiology was elucidated by Farabeuf in 1876 (69). His classification system is complete and quite useful. It describes tissue injury and explains the implications for and likelihood of reduction. The focus of the system is the integrity and position of the volar plate, the status of the collateral ligaments, and the relative position of the metacarpal and proximal phalanx. The components of the classification are incomplete dislocation, simple complete dislocation, and complete complex dislocation (Fig. 8-100).

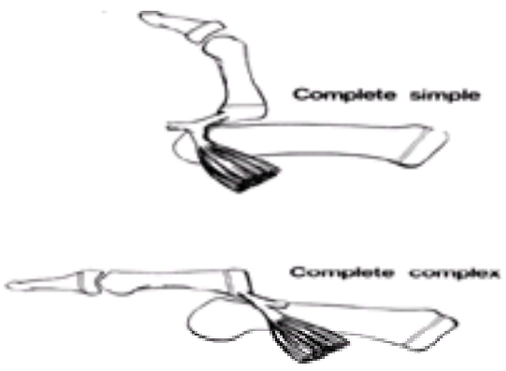

FIGURE 8-100. Simple and complex dorsal dislocation of the thumb metacarpophalangeal joint.

Incomplete Thumb MCP Dislocations. Incomplete dislocations occur when the volar plate ruptures, but the collateral ligaments remain intact. In its most benign form, an intrasubstance injury or partial avulsion of the volar plate occurs, which may result in supraphysiologic extension at the MCP joint. Often, the volar plate rupture is complete, and the MCP joint subluxates as the proximal phalanx perches on the dorsum of the metacarpal.

A period of immobilization usually is adequate treatment. Three weeks is sufficient for more significant injuries, and discontinuation of the splint when tenderness subsides is reasonable for low-level trauma. If a child desires to return to athletic participation, protection with a hand-based thumb spica orthosis is recommended. A pure ligamentous injury at the ulnar collateral can be classified as an incomplete dislocation. This is best shown by stress radiographs and examination.

Simple Complete Thumb MCP Dislocation. The simple complete dislocation of the thumb MCP is the most clinically obvious. The proximal phalanx is dorsally displaced, and its long axis is 90 degrees to that of the metacarpal.

Many of these dislocations can be reduced by closed means (Fig. 8-101). The reduction maneuver previously described for interphalangeal joint reduction is particularly useful, including insufflation of the joint with lidocaine. This maneuver resembles that described by Burton and Eaton (34), who recommended extension of the thumb interphalangeal joint to lift the flexor pollicis longus and volar plate away from their position potentially blocking the reduction. Many clinicians have warned against excessive longitudinal traction when attempting reduction. The resulting force may convert a reducible injury into a complex dislocation (92,143).

FIGURE 8-101. Complete simple dislocation. A 9-year-old boy with a dorsal dislocation of the thumb metacarpophalangeal joint. The dislocation lacks parallelism, and closed reduction was successful.

If reduction is successful, thumb spica casting for 3 weeks usually is sufficient to permit healing of the volar plate and collateral ligaments. Care must be taken during cast application so as not to deviate the thumb in a radial or ulnar direction, because of the potential of concomitant collateral ligament rupture.

Complete Complex Thumb MCP Dislocation. The dislocation that represents the most tissue disturbance, and the one that normally requires open reduction, appears as the most clinically inconspicuous. In a complete complex dislocation, the long axes of the proximal phalanx and metacarpal can be parallel. The thumb is shortened and swollen about the MCP joint.

It is difficult to obtain closed reduction of a complete complex dislocation, although occasionally closed manipulation can reduce the joint (200). Even if closed reduction is successful, some surgeons advocate open ligament repair if significant lateral instability is present.

As a rule, this injury must be treated by open reduction (Fig. 8-102). Farabeuf (69), Weeks (225), and Bohart (25) recommended a dorsal approach to the joint, but a volar approach usually is advocated to reliably extricate the volar plate.

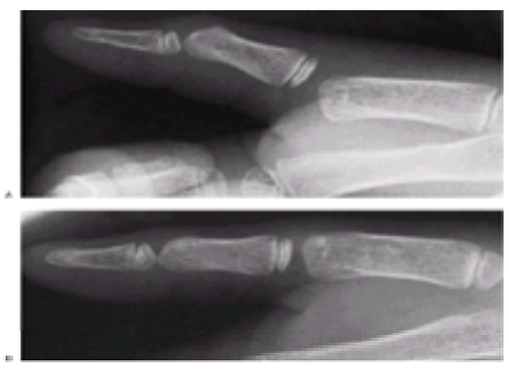

FIGURE 8-102. Complete complex dislocation. **A:** Closed reduction attempts failed to reduce this dorsal metacarpophalangeal dislocation in a 7-year-old boy. Note the relative parallelism between the dislocated thumb and metacarpal. **B:** After open reduction through a volar incision. Normal function resulted.

The volar approach is made through a Brunner incision. The digital nerves of the thumb are central in an uninjured thumb, and become dangerously tented over the metacarpal head in a complete dislocation. Great care must be exercised to avoid their injury. The flexor pollicis brevis muscle is followed down to the volar plate, then the plate can be removed from the displaced position. Repair of the volar plate back to the metacarpal neck restores anatomy (92,207), but the value of this procedure must be weighed against the potential of undue stiffness. It seldom is necessary to repair or reconstruct the collateral ligaments.

Three weeks of immobilization in a thumb spica cast is followed by a gradual range-of-motion program. Protection during athletics is also recommended for complete complex dislocations.

Fracture–Dislocation

Dorsal fracture–dislocation of the thumb MCP joint is a rare injury that also usually requires treatment (Fig. 8-103).

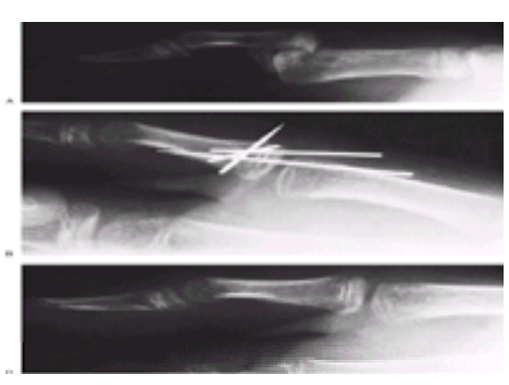

FIGURE 8-103. A: A 12-year-old boy sustained a dorsal fracture–dislocation of the metacarpophalangeal joint when his thumb was struck by a shotgun bolt. Note that a posteroanterior view of the thumb metacarpal appears on the same image as a lateral view of the phalanges. **B:** Closed attempts to reduce the fracture–dislocation were unsuccessful, and open reduction and internal fixation with Kirschner wires were performed. **C:** Four months after surgery, he had only a 10 degree loss of joint motion.

Thumb MCP UCL Injury (Gamekeeper's Thumb)

Four Types in Children Ulnar collateral ligament injury of the child's thumb MCP is not given much attention in the voluminous literature on gamekeeper's thumb. Forced abduction stress at the child's thumb MCP joint results in four types of injury: (a) a simple sprain of the UCL; (b) a rupture or avulsion of the insertion or origin (229) of the ligament; (c) a simple S-H I or II fracture of the proximal physis; or (d) an avulsion fracture (S-H III) of the ulnar one fourth to one third of the epiphysis of the proximal phalanx (Fig. 8-104).

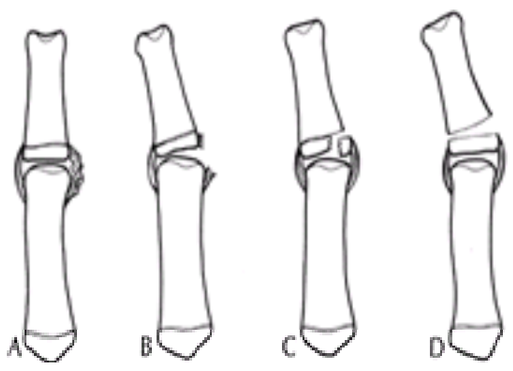

FIGURE 8-104. Ulnar instability of the thumb metacarpal joint. **A:** Simple sprain. **B:** Rupture of the ligament. **C:** Avulsion fracture (Salter-Harris type III). **D:** Pseudo-gamekeeper's injury resulting from a Salter-Harris type I or II fracture of the proximal phalanx.

An Adolescent Injury. The injury is usually encountered in the preadolescent or adolescent. Clinically, the thumb is quite swollen, particularly in the area of the MCP

joint, and ecchymosis often extends out into the skin of the first web. If routine radiographs show no bony injury, the joint must be stressed by applying lateral force with the joint in full extension first, then in full flexion. Preliminary infiltration of the joint with lidocaine or blocking of the median and superficial radial nerves is usually necessary. If the ligament is completely torn, there will be no exact end point on stressing the ligament, particularly in flexion.

Breakdancer's Thumb. Winslet and associates (231) reported on three teenagers with a displaced fracture of the ulnar corner of the base of the proximal phalanx of the thumb with ulnar instability after breakdancing. All three had open reduction and internal fixation. They coined the name *breakdancer's thumb* for the injury.

Treatment.

Cast Immobilization. Healing in a cast is unlikely because the ligament, which is usually avulsed from its distal insertion, is often caught over the edge of the extensor aponeurosis when the joint reduces spontaneously (206,207). The ligament cannot heal, and chronic lateral instability with a weakened pinch is likely. A false impression of instability can result from an S-H I or II fracture of the proximal phalanx that is undisplaced on the original radiograph and becomes obvious only on the stress radiograph (Fig. 8-104D and Fig. 8-105). Cast immobilization is all that is required for this injury. Incomplete tears (<45 degrees difference on stress testing) heal in a thumb spica cast worn for 4 weeks.

FIGURE 8-105. A: Even with gentle stress, a complete ulnar collateral ligament incompetence is easily detected. This 8-year-old girl was treated with early ligament repair, and normal stability resulted. **B:** In this 10-year-old boy, a pseudo-gamekeeper's thumb is the result of a Salter-Harris type II fracture of the proximal phalanx. (B courtesy of James H. Dobyns, M.D.)

Operative Indications. If the stress radiograph, made with the thumb extended, shows that the joint opens 45 degrees more than the normal side, a complete tear has occurred, and open repair is indicated (Fig. 8-105) (200). An S-H III fracture of the ulnar corner of the epiphysis of the proximal phalanx is by far the most common childhood gamekeeper's injury. The significantly displaced fracture (fragment rotated and displaced >1.5 mm) requires open reduction and internal fixation to restore the integrity of the UCL and to obtain a congruous joint surface (Fig. 8-106).

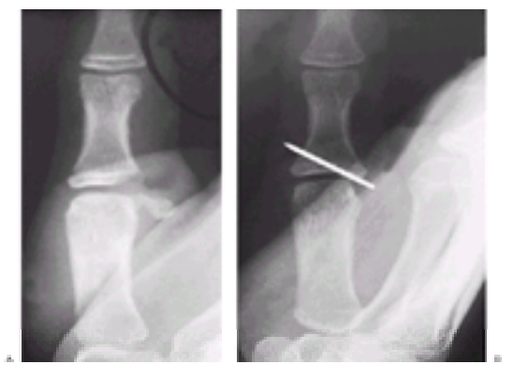

FIGURE 8-106. A: An ulnar collateral ligament Salter-Harris type III avulsion fracture in a 12-year-old girl. **B:** After open reduction and internal fixation.

Missed Thumb MCP Dislocations. Like some MCP dislocations in the triphalangeal digits, thumb MCP dislocations also can go undetected or neglected (133). Depending on many factors (length of time since original injury, age of the patient, current level of function), the surgeon must decide how aggressively to treat the problem once recognized.

If detected in the first 6 to 8 weeks, we recommend an attempt at reduction through a volar or combined approach. Transarticular pinning can be considered. Depending on the tissue quality, amount of symptoms, and functional status, it is not unreasonable to attempt reduction up to 4 to 6 months after injury.

Some late injuries may be best left to remodel to their maximal function, then a salvage procedure such as soft tissue arthroplasty or fusion (199) can be performed.

AUTHORS' PREFERRED METHOD OF TREATMENT

Management of MCP level dislocations should be stepwise and logical. We believe that essentially every MCP dislocation deserves an attempt at closed reduction. After insufflating the joint with anesthetic, recreation of the deformity with hyperextension and performing a reduction maneuver can result in reestablishment of the articular relationship. This should be performed under optimized conditions, which may include conscious sedation and even an operating room setting. The latter is advocated in case the surgeon must proceed to open reduction.

We advocate the dorsal approach for most MCP dislocations requiring open treatment. The volar plate is the typical tissue blocking reduction, and it usually can be removed by sweeping the joint with a septal elevator in most cases. In some patients, the interposed volar plate needs to be incised in a longitudinal fashion to promote its exit from the joint. There is no indication for volar plate repair.

If the surgeon is more experienced or more confident with the volar approach, it cannot be overemphasized that the digital nerve is draped over the prominent metacarpal head. Utmost care must be exercised in liberating the incarcerated metacarpal from the surrounding soft tissues and reducing the joint.

Dislocations of the Carpometacarpal Joints

Dislocations of the CMC joint, with or without small fracture fragments from the metacarpal base, are rare injuries. The decision whether to open the dislocation sight is based primarily on the stability after closed reduction. We suggest stabilization with percutaneous pins in almost all these injuries because of the proclivity to redislocate.

The fractures that accompany the dislocations can range from small avulsions that accompany the ligament disruption to large fragments comprising a significant percentage of the articular surface (Fig. 8-64). Often these fragments are displaced and rotated. Some large articular fractures can rotate 180 degrees while the fracture dislocation is in its maximum displacement. It is important to recognize that fracture fragments can block reduction and be the source of continued pain and

potential nonunion.

Although isolated dislocations at the CMC level do occur, their pathogenesis and treatment are the same as disruptions in which fractures occur. (See previous section on metacarpal fractures.)

Dislocations of the Carpus

Rare and Often Unrecognized

Intercarpal dislocations are uncommon in children. Due to the rarity of the injury and the relative smallness of the child's carpal bone, this injury is likely to go unrecognized (Fig. 8-90 and Fig. 8-91). A 10-year-old child with an acute dorsal trans-scaphoid perilunate dislocation was reported by Peiro et al. (166). Sixteen weeks after closed reduction and cast immobilization, he had a normal wrist. Ogden (162) published the radiograph of a young child with a trans-scaphoid perilunar dislocation but gave no details. Christodoulou and Colton (41) mentioned a 9-year-old boy who had a trans-scaphoid perilunar dislocation, but no details were given. Light (129) described an 11-year-old child who had open reduction and Kirschner wire fixation of a trans-scaphoid perilunar dislocation with a fracture through the lunate. Pennes et al. (167) reported a 14-year-old girl with Marfan's syndrome who had bilateral dorsal perilunate dislocations, unrelated to trauma, secondary to ligamentous laxity.

Salvage Treatment Needed

The principles of treatment do not differ from those for adults with dislocations of the carpus. Reconstructive surgery may be required for a chronic dislocation that has gone unrecognized (Fig. 8-107). Gerard (81) reported the only child in the literature with a chronic posttraumatic carpal instability. The 7-year-old girl had pain and limitation of wrist motion secondary to a scapholunate dissociation with a palmar flexion collapse deformity of the lunocapitate joint. Open reduction and pin fixation, with reconstruction of the scapholunate ligament with a portion of extensor carpi radialis longus tendon, corrected the instability. Light (129) recommended the use of arthrography and MRI to demonstrate scapholunate dissociation in the immature carpus.

FIGURE 8-107. A and B: An 11-year-old girl sustained this injury 7 months previously. She had been radiographed several times, but the correct diagnosis of volar trans-scaphoid perilunate dislocation was not made. **C:** Intercarpal fusion was performed, and 1 year after injury the range of motion was as follows: dorsiflexion 30 degrees, palmar flexion 30 degrees, radial deviation 10 degrees, and ulnar deviation 25 degrees. She had minimal discomfort with strenuous use.

One of us (T.J.G.) has reported a skeletally immature teenage girl with hemiatrophy who presented with the extremely rare pattern of a palmar mid-carpal dislocation (89). Although the patient recalled no antecedent trauma, the wrist had apparently been dislocated for a lengthy period, judging from the radiographic and clinical appearance. Symptoms and function improved after reduction and mid-carpal fusion.

Dislocation of the Distal Radioulnar Joint

More Common in the Older Child

Dislocation of the distal radioulnar joint may occur with (148) or without a fracture of the radius. An isolated dislocation is uncommon in young children, but may occur near the end of the growth period. The dislocation may be in a dorsal or volar direction and is likely to go unrecognized.

Computed Tomographic Imaging Most Useful

Computed tomographic scanning has proved superior to plain radiographs in diagnosing a dislocation or subluxation of the distal radioulnar joint (61,150,224). The scan is especially useful in determining through a cast whether the dislocation is reduced.

Anatomic Considerations

Many clinicians (54,105) have correctly pointed out that the radiocarpal complex dislocates from the ulna, which, because of its fixed proximal articulation with the humerus, cannot dislocate. Common terminology, however, still refers to the ulna as being dislocated.

The head of the ulna articulates with the sigmoid notch of the radius. The stability of the distal radioulnar joint is maintained by the triangular fibrocartilage and the dorsal and volar radioulnar ligaments. The triangular fibrocartilage, extending from the distal margin of the radial sigmoid notch to the base of the styloid process of the ulna, acts primarily to prevent lateral displacement of the ulna (100,105). The dorsal and volar radioulnar ligaments are the prime stabilizers of the distal radioulnar joint. The dorsal radioulnar ligament becomes taut on pronation, and the volar radioulnar ligament becomes taut on supination.

Mechanisms Vary

Hyperpronation results in a tear of the dorsal ligament and triangular fibrocartilage and a dorsal dislocation of the distal ulna. Hypersupination tears the volar radioulnar ligament and triangular fibrocartilage, producing a volar dislocation of the distal ulna.

Clinical and Radiographic Findings

If the dislocation is dorsal, there is a marked dorsal prominence of the distal end of the ulna, and any attempt to supinate the pronated forearm is resisted. The AP view shows an abnormal separation at the distal radioulnar joint, and the ulna is dorsally displaced on the true lateral view. If the dislocation is volar, the wrist appears narrower than normal because the normal dorsal prominence of the distal ulna is missing. The forearm is fixed in supination. The ulna and radius are overlapped on the AP view, and the ulna is volarly displaced on the true lateral view.

Treatment

Nonoperative Usually Satisfactory

If the diagnosis is made acutely, closed reduction usually is successful. A volarly displaced ulna is reduced in full pronation, and a dorsal displacement is corrected by direct pressure over the ulna and full supination. A long arm cast in the corrected position is worn for 4 to 6 weeks. A 4-year-old girl with a dorsal dislocation of the distal ulna, successfully treated with a long arm cast in supination for 4 weeks, was reported by Heiple and Freehafer (105). Birch-Jensen (19) reported a successful

result in a 14-year-old boy with a volar dislocation of the distal ulna reduced by slight pressure and immobilized for only a week with a dorsal splint.

Operative Indications

The dislocation is occasionally irreducible because of an interposed extensor carpi ulnaris tendon (10,39). Chronic or recurrent dislocation is likely to follow an undiagnosed or inadequately treated acute dislocation. Attempts to restabilize the distal radioulnar joint in children using soft tissue procedures have met with some success. Dameron (54) advised excision of the distal end of the ulna if the dislocation was untreated for 2 months or longer. Excision of the distal ulna, if indicated, should of course be postponed until growth is complete. Dislocation of the distal ulna secondary to premature cessation of radial growth is best treated by ulnar shortening.

Association with Fractures of the Radius

Dislocation or disruption of the distal radioulnar joint with a fracture of the shaft or distal radius is referred to as a Galeazzi fracture (actually a fracture–dislocation complex). This entity is discussed in more detail in Chapter 9.

ACKNOWLEDGMENT

We would like to recognize the unparalleled contribution of Eugene T. “Tom” O'Brien, M.D., to the clinical understanding and surgical science of treating children's hand and wrist injuries. His experience and insight was brought to us through the first four editions of this text, and the influence of his dedication to this topic guides this and future writings.

9
DISTAL RADIUS AND ULNA FRACTURES

PETER M. WATERS

Forearm fractures in children are the most common long bone fractures, comprising about 40% of all pediatric fractures (19,20,32). The distal aspect of the radius and ulna is the most common site of fracture in the forearm (5,18,19,26,36) . These fractures have been reported to be three times more common in boys; however, the increased participation in athletics by girls at a young age may be changing this ratio. Although these fractures occur at any age, they are most frequent during the adolescent growth spurt (2). A direct fall is the usual mechanism of injury. With the wrist and hand extended to protect the child, a fracture occurs if the mechanical force is sufficient. Regardless of the type, these fractures cause pain in the distal forearm, tenderness directly over the fracture site, and limited motion of the wrist and hand. Deformity depends on the degree of fracture displacement. Standard radiographs are diagnostic of fracture type and displacement. Metaphyseal fractures are most common, followed by physeal fractures (13,23,32); the distal fragment in either usually is extended. Associated fractures of the hand and elbow regions are rare. Occasionally a direct blow or a fall onto a flexed wrist and hand causes volar displacement or angulation of the distal fragment.

Repetitive loading of the wrist can lead to physeal stress injuries of the distal radius and, less commonly, the ulna. These injuries are rare, and occur most frequently in gymnasts (1,4,6,9,21,27,33). Any patient with chronic physeal region wrist pain who participates in an activity with repetitive axial loading of the wrist, such as gymnastics or break dancing (15), should be examined for a stress injury.

The pediatric Galeazzi injury usually involves a distal radial metaphyseal fracture and a distal ulnar physeal fracture. These injuries are rare, but need to be identified acutely for proper management. The specifics of injury mechanisms and fracture patterns for individual fracture types are discussed in separate sections of this chapter.

CLASSIFICATION

Distal radial and ulnar fractures are defined by their anatomic relationship to the physis. Transphyseal injuries are classified by the widely accepted Salter-Harris system (88). Metaphyseal injuries may be torus or buckle fractures, greenstick or incomplete fractures, or complete injuries. Pediatric equivalents of adult Galeazzi fracture–dislocations involve a distal radial fracture and either a soft tissue disruption of the distal radioulnar joint (DRUJ) or a transphyseal fracture of the ulna (Table 9-1). In contrast to adults, skeletally immature patients rarely sustain intraarticular fractures of the distal radius. On occasion, a Salter-Harris type III fracture, a triplane fracture (42), or an adolescent intraarticular Colles' fracture occurs.

Physeal fractures
Distal radius
Distal ulna
Distal metaphyseal (radius or ulna)
Torus
Greenstick
Complete fractures
Galbazzi fracture–dislocations
Dorsal displaced
Volar displaced

TABLE 9-1. DISTAL FOREARM FRACTURES: GENERAL CLASSIFICATION

Distal radial fracture stability has been more clearly defined in adults (35) than in children. At present, an unstable fracture in a child is often defined as one that cannot be reduced closed. Pediatric classification systems have yet to more precisely define fracture stability, but this issue is critical in determining proper treatment

management.

Fractures also are defined by the degree of displacement and angulation. Static anteroposterior (AP) and lateral radiographs can be diagnostic of the fracture type and degree of deformity (Fig. 9-1). In adults, the distal radial articular alignment averages 22 degrees on the AP view and 11 degrees on the lateral view (17,22,24,28,34). Radial inclination is a goniometric measurement of the angle between the distal radial articular surface and a line perpendicular to the radial shaft on the AP radiograph. Palmar tilt is measured by a line across the distal articular surface and a line perpendicular to the radial shaft on the lateral view. Pediatric values for radial inclination tend to be less, depending on the degree of skeletal maturity of the patient. Palmar tilt tends to be more consistent regardless of the age of the patient.

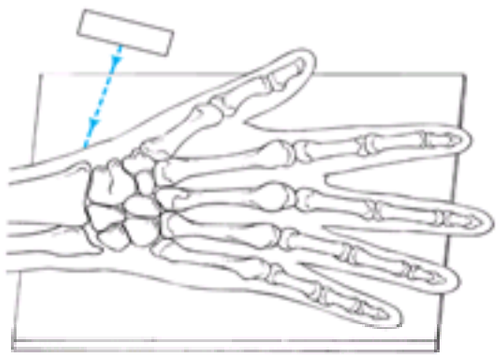

FIGURE 9-1. Radiographic angulation of the distal radius. The correct position for a lateral view of the distal radius. The wrist is positioned as for the standard lateral radiograph, but the x-ray beam is directed 15 degrees cephalad. (Redrawn from Johnson PG, Szabo RM. Angle measurements of the distal radius: a cadaver study. *Skel Radiol* 1993;22:243; with permission.)

Rarely, tomographic views are necessary to assess intraarticular involvement or displacement (Fig. 9-2). This can be by AP and lateral tomograms, computerized tomographic (CT) scans, or magnetic resonance imaging (MRI). Dynamic motion studies with fluoroscopy can provide important information on fracture stability and the success of various treatment options (31). Dynamic fluoroscopy requires adequate pain relief and has been used more often in adult patients with distal radial fractures.

FIGURE 9-2. A: Computed tomography scan of displaced Salter-Harris type IV fracture. **B:** Surgical correction included external fixation distraction, arthroscopically assisted reduction, and smooth pin fixation.

ANATOMY

The distal radial epiphysis normally appears between 0.5 and 2.3 years in boys and 0.4 and 1.7 years in girls (12). Initially transverse in appearance, it rapidly becomes more adultlike with its triangular shape. The contour of the radial styloid progressively elongates with advancing skeletal maturity. The secondary center of ossification for the distal ulna appears at around age 7. Similar to the radius, the ulnar styloid appears with the adolescent growth spurt. It also becomes more elongated and adultlike until physeal closure. On average, the ulnar physis closes at age 16 in girls and age 17 in boys, whereas the radial physis closes on average 6 months later than the ulnar physis (16,30). The distal radial and ulnar physes contribute approximately 75% to 80% of the growth of the forearm and 40% of the growth of the upper extremity (75) (Fig. 9-3).

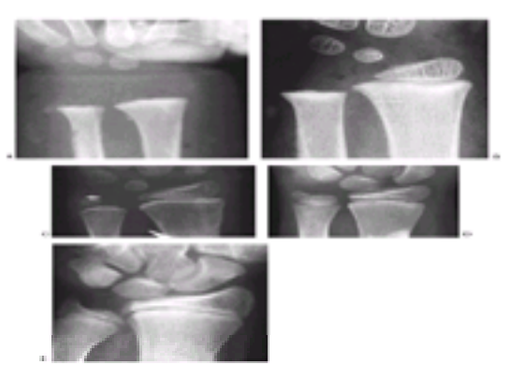

FIGURE 9-3. Ossification of the distal radius. **A:** Preossification distal radius with transverse ossification front in a 15-month-old boy. **B:** The triangular secondary ossification center of the distal radius in a 2-year-old girl. The initial ossification center of the styloid in this 7-year-old girl progresses radially (*arrow*). **D:** Extension of the ulnar ossification center into the styloid process of an 11-year-old. **E:** The styloid is fully ossified and the epiphyses have capped their relative metaphyses in this 13-year-old boy.

The distal radius articulates with the distal ulna at the DRUJ. Both the radius and ulna articulate with the carpus, serving as the support for the hand. The radial joint surface has three concavities for its articulations: the scaphoid and lunate fossi for the carpus and the sigmoid notch for the ulnar head. These joints are stabilized by a complex series of volar and dorsal radiocarpal, ulnocarpal, and radioulnar ligaments. The volar ligaments are the major stabilizers. Starting radially at the radial styloid, the radial collateral, radioscaphocapitate, radiolunotriquetral, and radioscapholunate ligaments volarly stabilize the radiocarpal joint. The dorsal radioscaphoid and radial triquetral ligaments are less important stabilizers.

The triangular fibrocartilage complex (TFCC) is the primary stabilizer of the ulnocarpal and radioulnar articulations. It extends from the sigmoid notch of the radius across the DRUJ and inserts into the base of the ulnar styloid. It also extends distally as the ulnolunate, ulnotriquetral, and ulnar collateral ligaments and inserts into the ulnar carpus and base of the fifth metacarpal (10). The interosseous ligament helps stabilize the radius and ulna more proximally in the diaphysis of the forearm. The ulna remains relatively immobile as the radius rotates around it. The complex structure of ligaments stabilize the radius, ulna, and carpus through the normal wrist

motion of 120 degrees of flexion and extension, 50 degrees of radial and ulnar deviation, and 150 degrees of forearm rotation (10).

The length relationship between the distal radius and ulna is defined as ulnar variance. In adults, this is measured by the relationship of the radial corner of the distal ulnar articular surface to the ulnar corner of the radial articular surface (56). However, measurement of ulnar variance in children requires modifications of this technique. Hafner (53) described measuring from the ulnar metaphysis to the radial metaphysis to lessen the measurement inaccuracies related to epiphyseal size and shape (Fig. 9-4). If the ulna and radius are of equal lengths, there is a neutral variance. If the ulna is longer, there is a positive variance, and if the ulna is shorter, there is a negative variance.

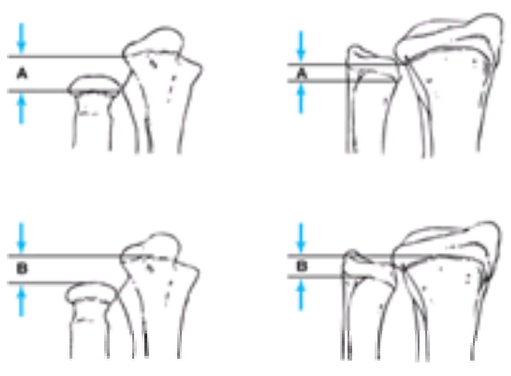

FIGURE 9-4. Hafner's technique to measure ulnar variance. **A:** The distance from the most proximal point of the ulnar metaphysis to the most proximal point of the radial metaphysis. **B:** The distance from the most distal point of the ulnar metaphysis to the most distal point of the radial metaphysis. (From Hafner R, Poznanski AK, Donovan JM. Ulnar variance in children. Standard measurements for evaluation of ulnar shortening in childhood. *Skel Radiol* 1989;18:514; with permission.)

Variance is not dependent on the length of the ulnar styloid (3), but the measurement is dependent on forearm positioning and radiographic technique (8,11,29). Radiographs of the wrist to determine ulnar variance should be standardized with the hand and wrist pronated on the cassette, the elbow flexed 90 degrees, and the shoulder abducted 90 degrees. The importance of ulnar variance relates to the force transmission across the wrist with axial loading. Normally the radiocarpal joint bears approximately 80% of the axial load and the ulnocarpal joint bears 20%. Changes in the length relationship of the radius and ulna alter respective load bearing. Biomechanical and clinical studies have shown that this load distribution is important in fractures, TFCC tears, and Kienbock's disease (9,14,25).

PHYSEAL INJURIES

Distal radial physeal injuries were described more than 100 years ago (43,85), and these early descriptions raised concerns regarding permanent deformity from this injury. In the 1930s, however, Aitken (37,38) concluded from his observations at the Boston City Hospital outpatient clinic that permanent deformity was rare. Instead, he emphasized the remodeling potential of distal radial physeal fractures, even when not reduced. The observations of Aitken have been confirmed throughout the twentieth century (Fig. 9-5). Most researchers agree that as long as there is sufficient growth remaining, a distal radial extension deformity from a malunited fracture has the potential to remodel. Permanent deformity can occur in malunited fractures near the end of growth or fractures that cause distal radial growth arrest.

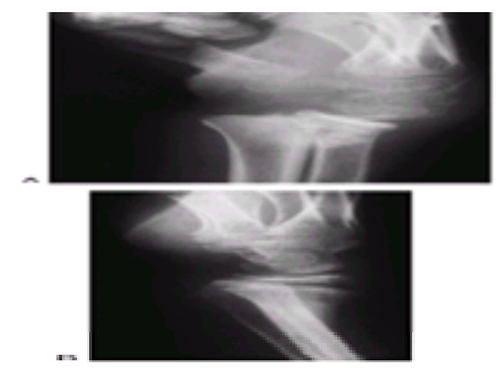

FIGURE 9-5. A: A 13-year-old boy presented 1 month after injury with a displaced and healed Salter-Harris type II distal radius fracture with obvious clinical deformity. **B:** Over the next 6 months the patient grew 4 inches and the deformity remodeled without intervention.

Diagnosis

Distal radial physeal fractures are far more common than distal ulnar physeal fractures (61,71,79,84,91). The nondominant arm in boys is most commonly injured. The peak incidence is in the preadolescent growth spurt (36,61). More than 50% of distal radial physeal fractures have an associated ulnar fracture. This usually is an ulnar styloid fracture but can be a distal ulnar plastic deformation, greenstick, or complete fracture (40,65,67). The mechanism of injury generally is a fall on an outstretched hand and wrist. The distal fragment usually displaces dorsally, creating an extension deformity that is usually clinically apparent. Patients have pain and tenderness at the fracture site, and the range of motion at the wrist and hand usually is limited by pain. Neurovascular compromise is uncommon but can occur (95). When present, it usually consists of median nerve irritability or dysfunction caused by direct trauma to the nerve at the time of injury or ongoing ischemic compression from the displaced fracture. Thenar muscle function and discriminatory sensibility (two-point discrimination) should be tested before reduction in the emergency setting. Acute carpal tunnel syndrome or forearm compartment syndrome can occur, but more often is caused by marked volar forearm and wrist swelling that occurs after reduction and application of a well-molded, tight cast (46,89,95). Open physeal fractures are rare, but the local skin should be examined closely for penetration.

Plain AP and lateral radiographs are diagnostic of the fracture type and deformity. Classification is by the Salter-Harris system for physeal fractures (88). Most are Salter-Harris type II fractures. The dorsal displacement of the distal fragment of the epiphysis and dorsal Thurstond-Holland metaphyseal fragment is evident on the lateral view (Fig. 9-6). Salter-Harris type I fractures also usually displace dorsally. Volar displacement of either a Salter-Harris type I or II fracture is less common (Fig. 9-7). Nondisplaced Salter-Harris type I fractures may be indi- cated only by a displaced pronator fat pad sign (Fig. 9-8 and Fig. 9-9) (90,100) or tenderness over the involved physis (40,86). A scaphoid fat pad sign may indicate a scaphoid fracture (Fig. 9-10). If the acute fracture is unrecognized, a late-appearing periosteal reaction may indicate the fracture.

FIGURE 9-6. Dorsally displaced physeal fracture (type A). The distal epiphysis with a small metaphyseal fragment is displaced dorsally (*curved arrow*) in relation to

the proximal metaphyseal fragment.

(Reprinted from Terry DW, Ramen JE. The navicular fat stripe. *Ham J Roent Rad Ther Nucl Med* 1975;124:25; with permission.)

Salter-Harris type III fractures are rare and may be caused by a compression injury or an avulsion of the radial origin of the volar radiocarpal ligaments (39,65) (Fig. 9-11). Triplane equivalent fractures (81,–83), a combination of Salter-Harris type II and III fractures in different planes, are rare. CT scans may be necessary to define the fracture pattern and degree of intraarticular displacement (Fig. 9-2). Stress injuries to the physis occur most commonly in competitive gymnasts (Fig. 9-12).

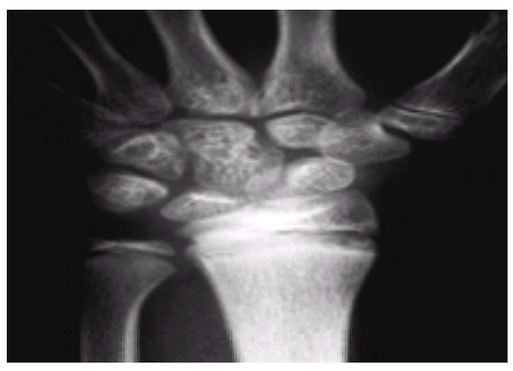

FIGURE 9-12. Stress changes in a female gymnast with widening of the distal radial physis from long-standing high-level performance.

Treatment Options

As for most fractures, treatment options include no reduction, closed reduction and cast immobilization, closed reduction and pin fixation, and open reduction. Nondisplaced fractures are immobilized until appropriate healing and pain resolution have been achieved (40,86). If there is a question of fracture stability, these fractures should be treated with a long arm cast and monitored closely during the first 3 weeks of healing to be certain that there is no loss of alignment. Most displaced Salter-Harris type I and II fractures can be treated successfully in the acute care setting with gentle closed reduction and cast immobilization. Closed reduction and percutaneous pin fixation are performed in patients with neurovascular compromise and displaced physeal fractures (95) to lessen the risk of development of a compartment syndrome in the carpal tunnel or forearm. Open reduction is indicated for irreducible fractures, open fractures, displaced Salter-Harris type III and IV fractures, and triplane equivalent fractures. Irreducible fractures are usually due to an entrapped periosteum or pronator quadratus (70). Internal fixation usually is with smooth pins to lessen the risk of growth arrest. Plates and screws are rarely used unless the patient is near skeletal maturity because of concerns about further physeal injury. In the rare displaced intraarticular Salter-Harris type III or IV fracture, internal fixation can be intraepiphyseal without violating the physis. If it is necessary to cross the physis, then smooth pins should be used to lessen the risk of iatrogenic physeal injury. Extraarticular external fixation also can be used to stabilize and align the fracture.

Closed Reduction

Most displaced Salter-Harris I and II fractures are treated with closed reduction and cast stabilization. Closed manipulation of the displaced fracture is performed with appropriate sedation, analgesia, or anesthesia to achieve pain relief and an atraumatic reduction (40,58,86). Most of these fractures involve dorsal and proximal displacement of the epiphysis with an apex–volar extension deformity. Manipulative reduction is by gentle distraction and flexion of the distal epiphysis, carpus, and hand over the proximal metaphysis (Fig. 9-13 and Fig. 9-14). The intact dorsal periosteum is used as a tension band to aid in reduction and stabilization of the fracture. Unlike similar fractures in adults, finger trap distraction with pulley weights is often counterproductive. However, finger traps can help stabilize the hand, wrist, and arm for manipulative reduction and casting by applying a few pounds of weight for balance. Otherwise an assistant is helpful to support the extremity in the proper position for casting.

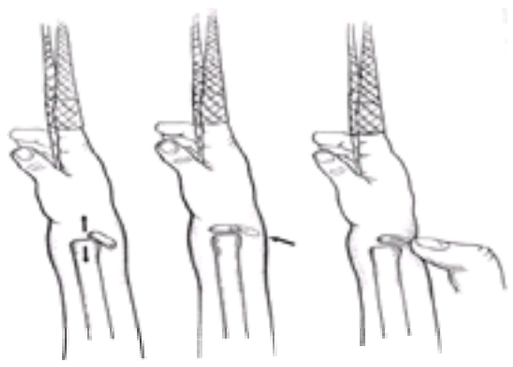

FIGURE 9-13. Acceptable method of closed reduction of distal physeal fractures of the radius. **A:** Position of the fracture fragments as finger trap traction with countertraction is applied (*arrows*). **B:** Often with traction alone the fracture will reduce without external pressure (*arrows*). **C:** If the reduction is incomplete, simply applying direct pressure over the fracture site in a distal and volar direction with the thumb often completes the reduction while maintaining traction. This technique theoretically decreases the shear forces across the physis during the reduction process.

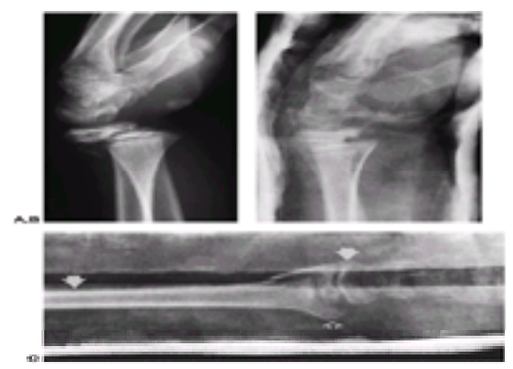

FIGURE 9-14. A: Lateral radiograph of dorsally displaced Salter-Harris type II fracture. **B:** Lateral radiograph after closed reduction and cast application. **C:** Reduction of the volar displaced fracture shown in Fig. 9-5. The forearm was in supination with three-point molding anterior over the distal epiphysis and proximal shaft (*white arrows*). The third point is placed dorsally over the distal metaphysis (*open arrow*). (The dorsal surface of the cast is oriented toward the bottom of this figure.) (Reprinted from Wilkins KE, ed. *Operative management of upper extremity fractures in children.* Rosemont, IL: American Academy of Orthopaedic Surgeons, 1994:17; with permission.)

If portable fluoroscopy is available, immediate radiographic assessment of the reduction is obtained. Otherwise, a long arm cast is applied and appropriate AP and lateral radiographs are obtained to assess the reduction. The cast should provide three-point molding over the distal radius to lessen the risk of fracture displacement (Fig. 9-13 and Fig. 9-14). The distal dorsal mold should not impair venous outflow from the hand, which can occur if the mold is placed too distal and too deep so as to obstruct the dorsal veins. Postcasting instructions for elevation and close monitoring of swelling and the neurovascular status of the extremity are critical.

The fracture also should be monitored closely with serial radiographs for the first 3 weeks to be certain that there is no loss of anatomic alignment (Fig. 9-15). Generally these fractures are stable after closed reduction and cast immobilization. If there is loss of reduction after 7 days, the surgeon should be wary of repeat reduction because of the risk of physeal arrest (40,88). Fortunately, remodeling of an extension deformity with growth is common if the patient has greater than 2 years of growth remaining and the deformity is less than 20 degrees (Fig. 9-5).

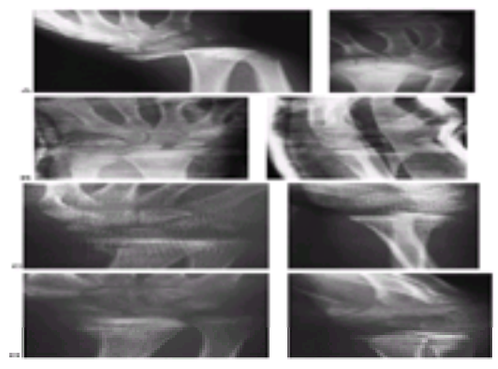

FIGURE 9-15. A: Anteroposterior and lateral radiographs of severely displaced Salter-Harris type II fracture of the distal radius. **B:** Closed reduction shows marked improvement but not anatomic reduction. The cast had to be bivalved due to excessive swelling. **C:** Unfortunately, the patient lost reduction after a new fiberglass cast was applied. **D:** Out of cast radiographs show a healed malunion in a similar position to the prereduction radiographs.

Closed Reduction and Percutaneous Pinning

The indications for percutaneous pinning of distal radial physeal fractures are controversial. The best indication is a displaced radial physeal fracture with median neuropathy and significant volar soft tissue swelling (95) (Fig. 9-16). These patients are at risk for development of an acute carpal tunnel syndrome or forearm compartment syndrome with closed reduction and cast immobilization (46,54,89,95). The torn periosteum volarly allows the fracture bleeding to dissect into the volar forearm compartments and carpal tunnel. If a tight cast is applied with a volar mold over that area, compartment pressures can increase dangerously. Percutaneous pin fixation allows the application of a loose dressing, splint, or cast without the risk of loss of fracture reduction (Fig. 9-16).

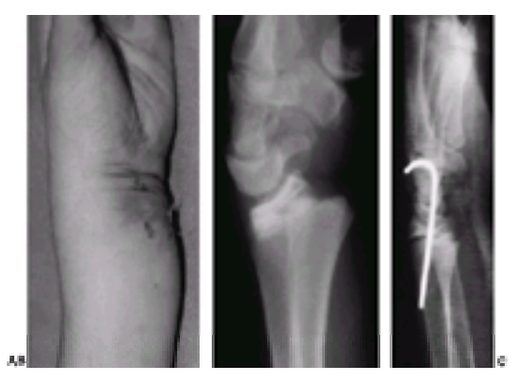

FIGURE 9-16. A: Clinical photograph of patient with a displaced Salter-Harris type II fracture of the distal radius. The patient has marked swelling volarly with hematoma and fracture displacement. The patient had a median neuropathy upon presentation. **B:** Lateral radiograph of the displaced fracture. **C:** Lateral radiograph in postoperative splint after percutaneous pinning to lessen the risk of neurovascular compromise in a cast.

Pin fixation can either be single or double (Fig. 9-17). Fluoroscopy is used to guide proper fracture reduction and pin placement. Anesthesia is used for adequate pain relief and to lessen the risk of further physeal injury. The fracture is manipulated into anatomic alignment and the initial, and often only, pin is placed from the distal epiphysis of the radial styloid obliquely across the physis into the more proximal ulnar aspect of the radial metaphysis (Fig. 9-17). A sufficient skin incision should be made with pin placement to be certain there is no iatrogenic injury to the radial sensory nerve or extensor tendons. Stability of the fracture should be evaluated with flexion/extension and rotatory stress under fluoroscopy. Often in children and adolescents a single pin and the reduced periosteum provide sufficient stability to prevent redisplacement of the fracture. If fracture stability is questionable with a single pin, a second pin should be placed. The second pin can either parallel the first pin or, to create cross-pin stability, can be placed distally from the ulnar corner of the radial epiphysis between the fourth and fifth dorsal compartments and passed obliquely to the proximal radial portion of the metaphysis (10,66,92). Again, the skin incisions for pin placement should be sufficient to avoid iatrogenic injury to the extensor tendons.

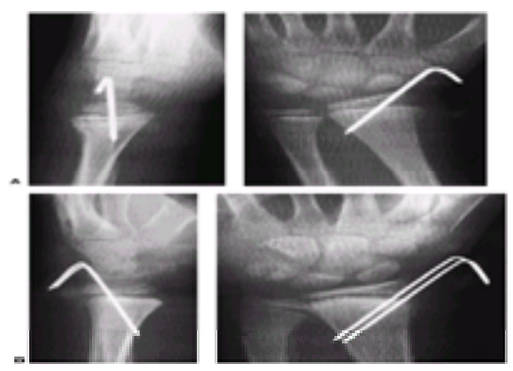

FIGURE 9-17. A: Anteroposterior and lateral radiographs of displaced Salter-Harris type II fracture pinned with a single pin. **B:** After reduction and pinning with parallel pins.

The pins are bent, left out of the skin, and covered with a sterile dressing. Splint or cast immobilization is used but does not need to be tight because fracture stability is provided by the pins. The pins are left in until there is adequate fracture healing, usually 4 weeks. The pins can be removed in the office without sedation or anesthesia.

One of the arguments against pin fixation is the risk of additional injury to the physis by a pin (42), but this has not been documented. The risk of physeal arrest is more from the displaced fracture than from a short-term, smooth pin. As a precaution, smooth, small-diameter pins should be used, insertion should be as atraumatic as possible, and removal should be executed as soon as there is sufficient fracture healing for fracture stability in a cast or splint alone.

Open Reduction

The main indication for open reduction of a displaced distal radial Salter-Harris type II physeal fracture is irreducibility (Fig. 9-18). Most often this is caused by

interposed periosteum or, less likely, pronator quadratus (57,70,99). Open reduction is performed via a volar approach to the distal radial physis. The interval between the radial artery and the flexor carpi radialis is used. This dissection also can proceed directly through the flexor carpi radialis sheath to protect the artery. The pronator quadratus is isolated and elevated from radial to ulnar. Although this muscle can be interposed in the fracture site, the volar periosteum is more commonly interposed. This is evident with elevation of the pronator quadratus. The periosteum is extracted from the physis with care to minimize further injury to the physis. The fracture can then be easily reduced. Cast immobilization is possible, but usually a percutaneous smooth pin is used for stabilization of the reduction. The method of pin insertion is the same as after closed reduction.

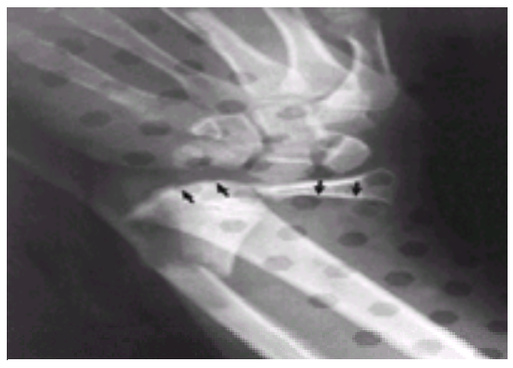

FIGURE 9-18. Irreducible fracture. This 13-year-old sustained severe trauma producing widely displaced fracture fragments (*arrows*). Closed reduction could not be performed because of interposed median nerve and deep flexor tendons: open reduction was required. (Courtesy of Earl A. Stanley, M.D.)

Open physeal fractures are rare but do require open reduction. The open wound and fracture site require irrigation and debridement. Care should be taken with mechanical debridement of the physeal cartilage to avoid further risk of growth arrest. Cultures should be taken at the time of operative debridement, and appropriate antibiotics are used to lessen the risk of deep space infection.

The rare Salter-Harris type III or IV fracture or triplane fracture (83) may require open reduction if the joint or physis cannot be anatomically reduced closed. The articular and physeal alignment can be evaluated by radiographic tomograms (trispiral or CT), MRI scans, or wrist arthroscopy (Fig. 9-2). If anatomic alignment of the physis and articular surface is not present, the risk of growth arrest, long-term deformity, or limited function is great (Fig. 9-15). Even minimal displacement (>1 mm) should not be accepted in this situation. Arthroscopically assisted reduction is helpful to align and stabilize these rare physeal fractures (47,50).

AUTHOR'S PREFERRED METHOD OF TREATMENT

Most Salter-Harris type I and II fractures are reduced closed under conscious sedation with the assistance of portable fluoroscopy. A long arm cast with appropriate three-point molding is applied. This is changed to a short arm cast when there is sufficient healing for fracture stability, usually after 3 to 4 weeks. Cast immobilization is discontinued when there is clinical and radiographic evidence of fracture healing, generally 4 and 6 weeks after fracture. Range-of-motion and strengthening exercises are begun with a home program. When the child achieves full motion and strength, he or she can return to full activity, including competitive sports. Follow-up radiographs are obtained at 6 to12 months after fracture to be certain there is no growth arrest.

A patient with a displaced Salter-Harris type I or II physeal fracture, significant soft tissue swelling volarly, and median neuropathy (Fig. 9-16) with ipsilateral elbow and radial fractures (Fig. 9-19) is treated with closed reduction and percutaneous pinning. This avoids the increased risk of compartment syndrome in the carpal canal or volar forearm that is present if a well-molded, tight cast is applied. In addition, acute percutaneous pinning of the fracture prevents increased swelling, cast splitting, loss of reduction, and concerns about malunion or growth arrest with repeat reduction (Fig. 9-17). Acute pinning of the fracture with one or two smooth pins through the radial epiphysis provides fracture stability without a compressive cast. The risk of growth arrest from a narrow-diameter, smooth pin left in place for 3 to 4 weeks is exceedingly small.

FIGURE 9-19. A: Ipsilateral distal radial physeal and supracondylar fractures. This 6-year-old sustained both a dorsally displaced distal radial physeal fracture (*closed arrow*) and a type II displaced supracondylar fracture of the humerus (*open arrows*). **B:** Similar case treated with percutaneous pinning of radial physeal fracture and supracondylar humeral fracture.

Open reduction is reserved for irreducible Salter-Harris type I and II fractures, open fractures, fractures with associated acute carpal tunnel or forearm compartment syndrome, displaced (>1 mm) Salter-Harris type III or IV fractures, or triplane equivalent fractures. For an irreducible Salter-Harris type I or II fracture, exposure is from the side of the torn periosteum. Because these fractures usually are displaced dorsally, a volar exposure is used. Smooth pins are used for stabilization and are left in for 3 to 4 weeks. Open fractures are exposed through the open wound with proximal and distal extension for adequate debridement. All open debridements are performed in the operating room under general anesthesia. Acute compartment syndromes are treated with immediate appropriate release of the transverse carpal ligament or forearm fascia. The transverse carpal ligament is released in a Z-plasty fashion to lengthen the ligament and prevent volar bow-stringing and scarring of the median nerve against the palmar skin. Displaced intraarticular fractures are best treated with arthroscopically assisted reduction and fixation, but this is an equipment-intensive operation requiring arthroscopic instruments, camera, and monitor, along with fluoroscopy. Distraction across the joint can be achieved with application of an external fixator or finger traps. Standard dorsal portals (3/4 and 4/5) are used for viewing the intraarticular aspect of the fracture and alignment of the reduction (Geisling). In addition, direct observation through the arthroscope can aid in safe placement of the intraepiphyseal pins. Fluoroscopy is used to evaluate the extraarticular aspects of the fracture (triplane equivalent and type IV fractures), the reduction, and placement of fixation pins (Fig. 9-2).

Complications

Malunion

Complications from physeal fractures are relatively rare. The most frequent problem is malunion. Fortunately, these fractures often occur in children with significant growth remaining. The deformity from a Salter-Harris type I or II fracture is within the plane of motion of the wrist joint and, therefore, will remodel with ensuing growth (40,58,86) (Fig. 9-5). Repeat reduction should not be performed more than 7 days after fracture because of the risk of growth arrest. The malunited fracture should be monitored over the next 6 to 12 months for remodeling. If the fracture does not remodel, persistent extension deformity of the distal radial articular surface puts the patient at risk for developing mid-carpal instability (96) or degenerative arthritis of the wrist. Corrective osteotomy with bone grafting and internal fixation is required (49) (Fig. 9-20). An opening-wedge dorsal osteotomy is made, iliac crest bone of appropriate trapezoidal shape to correct the deformity is inserted, and either plate or

external fixator is used to maintain correction until healing.

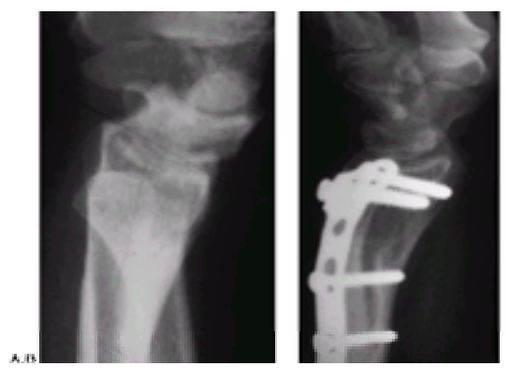

FIGURE 9-20. A: Radial metaphyseal fracture that did not remodel in a now 16-year-old skeletally mature boy. **B:** Corrective osteotomy with iliac crest bone graft and internal fixation was performed.

Intraarticular malunion is more worrisome (Fig. 9-21 and Fig. 9-22) because of the risk of development of degenerative arthritis if the articular step-off is more than 2 mm (59). MRI or CT scans can be useful in preoperative evaluations. Arthroscopy allows direct examination of the deformity and areas of impingement or potential degeneration. Intraarticular osteotomy with bone grafting in the metaphysis to support the reconstructed articular surface is controversial and risky. However, it has the potential of restoring anatomic alignment to the joint and preventing serious long-term complications. This problem fortunately is uncommon in children because of the rarity of the injury and this type of malunion.

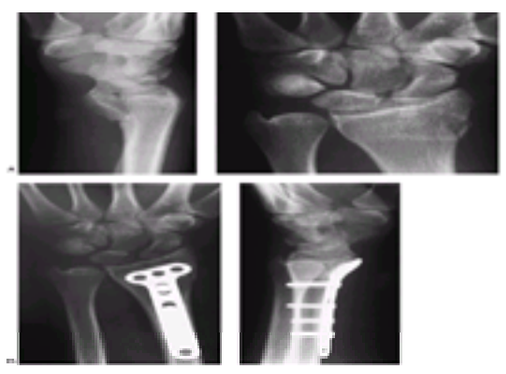

FIGURE 9-21. A: Anteroposterior and lateral radiographs of a 15-year-old skeletally mature boy with a displaced intraarticular fracture. **B:** This fracture needs to be treated like an adult's, with open reduction and internal fixation with a volar buttress plate.

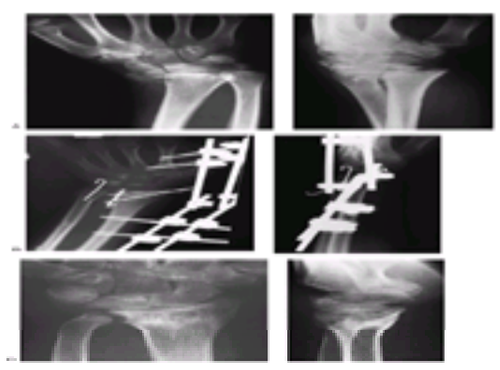

FIGURE 9-22. A: Anteroposterior and lateral radiographs of a 14-year-old girl who fell from a height. There is extensive intraarticular comminution. **B:** Open reduction, internal fixation, and external fixation was performed. **C:** One year follow-up radiographs reveal early arthosis. The patient has mild pain and near full range of motion.

Physeal Arrest

Distal radial physeal arrest can occur from either the trauma of the original injury (Fig. 9-23) (55,65,94) or late (>7 days) reduction of a displaced fracture. The exact incidence of radial growth arrest is unknown, but has been estimated to be 7% of all displaced radial physeal fractures. (65). The trauma to the physeal cartilage from displacement and compression is a significant risk factor for growth arrest. However, a correlation between the risk of growth arrest and the degree of displacement, type of fracture, or type of reduction has yet to be defined. Similarly, the risk of further compromising the physis with late reduction at various time intervals is still unclear. The current recommendation is for an atraumatic reduction of a displaced physeal fracture less than 7 days after injury.

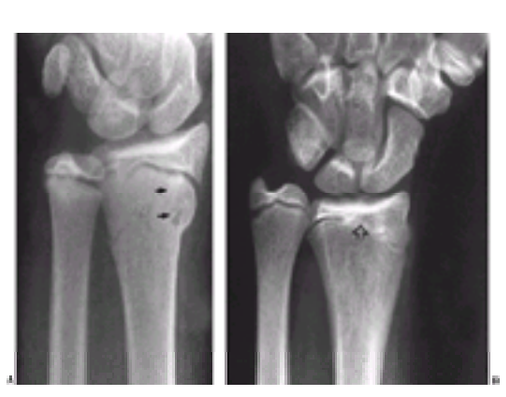

FIGURE 9-23. Physeal arrest in a Peterson type I fracture. **A:** Injury film showing what appears to be a benign metaphyseal fracture. Fracture line extends into the physis (*arrows*). **B:** Two years postinjury, a central arrest (*open arrow*) has developed, with resultant shortening of the radius. (Reprinted from Wilkins KE, ed. *Operative management of upper extremity fractures in children.* Rosemont, IL: American Academy of Orthopaedic Surgeons, 1994:21; with permission.)

When a growth arrest develops, the consequences depend on the severity of the arrest and the amount of growth remaining. A complete arrest of the distal radial physis in a skeletally immature patient can be a serious problem. The continued growth of the ulna with cessation of radial growth can lead to incongruity of the DRUJ, ulnocarpal impaction, and development of a TFCC tear (Fig. 9-24). The radial deviation deformity at the wrist can be severe enough to cause limitation of wrist and

forearm motion (Fig. 9-25). Pain and clicking can develop at the ulnocarpal or radioulnar joints, indicative of ulnocarpal impaction or a TFCC tear. The deformity will progress until the end of growth. Pain and limited motion and function will be present until forearm length is rebalanced; until the radiocarpal, ulnocarpal, and radioulnar joints are restored; and until the TFCC tear and areas of chondromalacia are repaired or debrided (72,77,93).

FIGURE 9-24. A: Anteroposterior radiograph of ulnar carpal impaction secondary to growth arrest in the distal radius. **B:** Anteroposterior and lateral radiographs after Z-shortening of the ulna to a negative ulnar variance.

FIGURE 9-25. A: Anteroposterior radiograph of radial growth arrest and ulnar overgrowth after physeal fracture. Patient complained of ulnar-sided wrist pain and clicking. **B:** Clinical photograph of ulnar overgrowth and radial deviation deformity.

Ideally, physeal arrest of the distal radius will be discovered early before the consequences of unbalanced growth develop. Radiographic screening 6 to 12 months after injury can identify the early arrest. A small area of growth arrest in a patient near skeletal maturity may be clinically inconsequential. However, a large area of arrest in a patient with marked growth remaining can lead to ulnocarpal impaction and forearm deformity if intervention is not performed early. An MRI scan can map the area of arrest (80) (Fig. 9-26). If it is less than 45% of the physis, a bar resection can be attempted (63,64). This may restore radial growth and prevent future problems (Fig. 9-27). If the bar is larger than 45% of the physis, an ulnar epiphysiodesis will prevent growth imbalance of the forearm (72). The growth discrepancy between forearms in most patients with fractures is minor and does not require treatment.

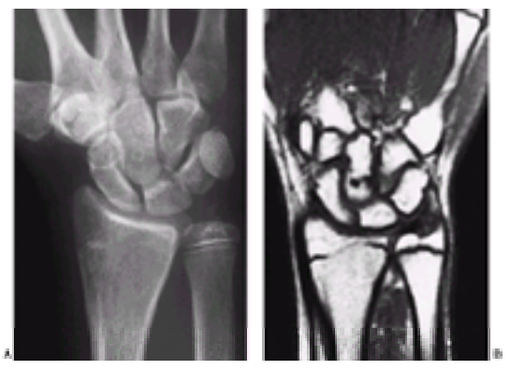

FIGURE 9-26. A: Anteroposterior radiograph of growth arrest with open ulnar physis. **B:** Magnetic resonance imaging scan of large area of growth arrest that was not deemed resectable by mapping.

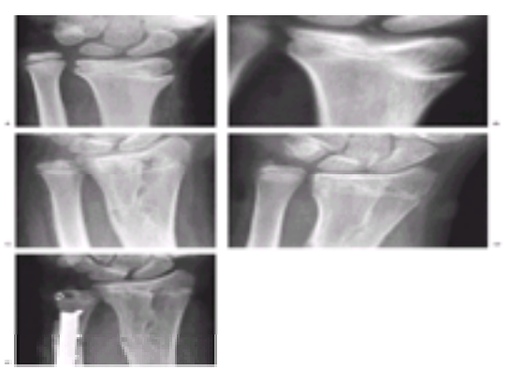

FIGURE 9-27. Osseous bridge resection. **A:** This 10-year-old had sustained a distal radial physeal injury 3 years previously and now complained of prominence of the distal ulna with decreased supination and pronation. **B:** Polytomes revealed a well-defined central osseous bridge involving about 25% of the total diameter of the physis. **C:** The bridge was resected, and autogenous fat was inserted into the defect. Growth resumed with resumption of the normal ulnar variance. Epiphysiodesis of the distal ulna was postponed for 6 months. **D:** Unfortunately, the radius slowed its growth, and a symptomatic positive ulnar variance developed. **E:** This was treated with an epiphysiodesis (*open arrow*) and surgical shortening of the ulna. The clinical appearance and range of motion of the forearm returned to essentially normal.

Ulnocarpal Impaction Syndrome

The growth discrepancy between the radius and ulna can lead to relative radial shortening and ulnar overgrowth (Fig. 9-28). The distal ulna can impinge on the lunate and triquetrum and cause pain with ulnar deviation, extension, and compression activities (41). Loading the ulnocarpal joint in ulnar deviation and compression will recreate the pain. Radiographs show the radial arrest, ulnar overgrowth, and distal ulnocarpal impingement. The ulnocarpal impaction may be caused by a hypertrophic ulnar styloid fracture union (Fig. 9-29) or an ulnar styloid nonunion (44,68) (Fig. 9-30). An MRI scan may reveal chondromalacia of the lunate or

triquetrum, a tear of the TFCC, and the extent of the distal radial physeal arrest.

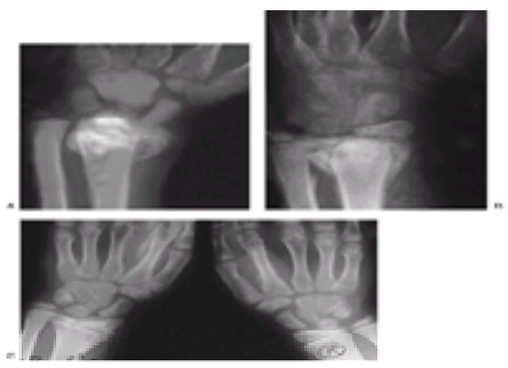

FIGURE 9-28. A: A markedly displaced Salter-Harris type IV fracture of the distal radius in an 11-year-old boy who fell from a horse. **B:** Film taken 3 weeks after closed reduction demonstrates displacement of the comminuted fragments. **C:** Eighteen months postinjury, there was 15 mm of radial shortening, and the patient had a pronounced radial deviation deformity of the wrist.

FIGURE 9-29. Anteroposterior radiograph revealing hypertrophic ulnar styloid healing as the source of the ulnar carpal impaction pain in this patient.

FIGURE 9-30. A: Anteroposterior radiograph of distal radial growth arrest, ulnar overgrowth, and an ulnar styloid nonunion. Wrist arthroscopy revealed an intact triangular fibrocartilage complex. **B:** Anteroposterior and lateral radiographs after ulnar shortening osteotomy.

Treatment should correct all components of the problem. The ulnar overgrowth is corrected by either an ulnar shortening osteotomy or radial lengthening. Most often a marked degree of positive ulnar variance requires ulnar shortening to neutral or negative variance. If the ulnar physis is still open, a simultaneous arrest should be performed to prevent recurrent deformity. If the degree of radial deformity is marked, this should be corrected by a realignment or lengthening osteotomy. Criteria for radial correction is debatable, but I have used radial inclination of less than 11 degrees on the AP radiograph (Fig. 9-31) (72). In the rare case of complete arrest in a very young patient, radial lengthening is preferable to ulnar shortening.

FIGURE 9-31. A: More severe ulnar overgrowth with dislocation of the distal radioulnar joint and flattening of the radial articular surface. **B:** Intraoperative fluoroscopic view of ulnar shortening and radial osteotomy to corrective deformities.

Triangular Fibrocartilage Complex Tears

Triangular fibrocartilage complex tears should be repaired. The presence of an ulnar styloid nonunion is often indicative of an associated peripheral tear of the TFCC (72,93). The symptomatic ulnar styloid nonunion is excised (44,68,76) and any TFCC repaired. If physical examination or preoperative MRI scan indicates a TFCC tear in the absence of an ulnar styloid nonunion, an initial arthroscopic examination can define the lesion and appropriate treatment. Peripheral tears (Palmer type B) are the most common TFCC tears in children and adolescents and can be repaired arthroscopically by an outside-in suture technique. Central tears (Palmer type A) are rare in children and can be debrided arthroscopically. Tears off the sigmoid notch (Palmer type D) can be repaired open or arthroscopically. Distal volar tears (Palmer type C) are repaired open, at times with ligament reconstruction.

Neuropathy

Median neuropathy can occur from direct trauma from the initial displacement of the fracture, traction ischemia from a persistently displaced fracture, or the development of a compartment syndrome in the carpal canal or volar forearm (Fig. 9-32) (95). All patients with displaced distal radial fractures should undergo a

careful motor-sensory examination upon presentation to an acute care facility. The flexor pollicis longus, index flexor digitorum profundus, and abductor pollicis brevis muscles should be tested. Light touch and two-point discrimination sensibility of the thumb and index finger should be tested in any child over 5 years of age with a displaced Salter-Harris type I or II fracture. The presence of median neuropathy and marked volar soft tissue swelling are indications for percutaneous pin stabilization of the fracture to lessen the risk of compartment syndrome in a cast.

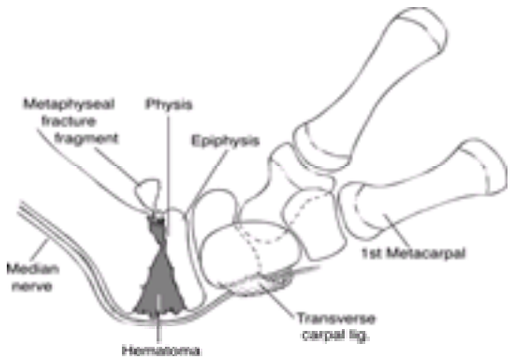

FIGURE 9-32. Volar forearm anatomy outlining the potential compression of the median nerve between the metaphysis of the radius and dorsally displaced physeal fracture. The taut volar transverse carpal ligament and fracture hematoma are also contributing factors. (Redrawn from Waters PM, Kolettis GJ, Schwend R. Acute median neuropathy following physeal fractures of the distal radius. *J Pediatr Orthop* 1994;14:173–177; with permission.)

Median neuropathy caused by direct trauma or traction ischemia generally resolves after fracture reduction. The degree of neural injury will determine the length of time to recovery. Recovery can be monitored with an advancing Tinel's sign along the median nerve. Motor-sensory testing can define progressive return of neural function.

Carpal Tunnel Syndrome

Median neuropathy caused by a carpal tunnel syndrome will not recover until the carpal tunnel is decompressed. After anatomic fracture reduction and pin stabilization, volar forearm and carpal tunnel pressures are measured. Gelberman (51) recommended waiting 20 minutes or more to allow for pressure-volume equilibration before measuring pressures. If the pressures are elevated beyond 40 mm Hg or the difference between the diastolic pressure and the compartment pressure is less than 30 mm Hg (58), an immediate release of the affected compartments should be performed. The carpal tunnel is released through a palmar incision in line with the fourth ray, with care to avoid injuring the palmar vascular arch and the ulnar nerves exiting Guyon's canal. The transverse carpal ligament is released with a Z-plasty to prevent late bow-stringing of the nerve against the palmar skin. The volar forearm fascia is released in the standard fashion.

RADIAL PHYSEAL STRESS FRACTURES

Repetitive axial loading of the wrist in dorsiflexion can lead to physeal stress injuries (Fig. 9-12), almost always involving the radius. Competitive gymnastics is by far the most common cause (6,7,21,33,45,69,87). Other activities reported to cause radial physeal stress fractures include break dancing (15). Factors that predispose to this injury include excessive training, poor techniques, and attempts to advance too quickly in competitive level. Proper coaching is important in preventing these injuries.

A child with a radial physeal stress fracture has recurring, activity-related wrist pain, usually aching and diffuse, in the region of the distal radial metaphysis and physis. Extremes of dorsiflexion and palmar flexion reproduce the pain. There is local tenderness over the dorsal, distal radial physis. Resistive contracture strength testing of the wrist dorsiflexors often reproduces the pain. There may be fusiform swelling about the wrist if there is reactive bone formation. The differential diagnosis includes physeal stress injury, ganglion, ligamentous or TFCC injury, tendonitis or muscle–tendon tear, fracture such as a scaphoid fracture, and avascular necrosis of the scaphoid (Preiser's disease) or lunate (Kienbock's disease). Radiographs may be diagnostic. Physeal widening and reactive bone formation are indicative of chronic physeal stress fracture. Premature physeal closure indicates long-standing stress (27,98). In this situation, continued ulnar growth leads to an ulnar positive variance and pain from ulnocarpal impaction or a TFCC tear (1,33). Normal radiographs may not show an early physeal stress fracture. If the diagnosis is suggested clinically, a bone scan or MRI scan is indicated. Bone scans are sensitive but nonspecific. MRI scans usually are diagnostic.

Treatment first and foremost involves rest. This may be difficult depending on the skill level of the athlete and the desires of the child, coach, and parents. Short arm cast immobilization for several weeks may be the only way to restrict stress to the radial physis in some patients. Splint protection is appropriate in cooperative patients. Protection should continue until there is resolution of pain with examination and activity. The athlete can maintain cardiovascular fitness, strength, and flexibility while protecting the injured wrist. Once the acute physeal injury has healed, return to weight-bearing activities should be gradual. This requires the cooperation of the coach and parents. Adjustment of techniques and training methods often is necessary to prevent recurrence. The major concern is development of a radial growth arrest in a skeletally immature patient. This is an avoidable complication with well-trained coaches and athletes.

If a radial growth arrest has already occurred upon presentation, treatment depends on the degree of deformity and the patient's symptoms. Physeal bar resection usually is not possible because the arrest is usually too diffuse in stress injuries. If there is no significant ulnar overgrowth, a distal ulnar epiphysiodesis will prevent the development of an ulnocarpal impaction syndrome. For ulnar overgrowth and ulnocarpal pain, an ulnar shortening osteotomy is indicated. Techniques include transverse, oblique, and Z-shortening osteotomies. Transverse osteotomy has a higher risk of nonunion than either oblique or Z-shortening and should be avoided. The status of the TFCC also should be evaluated by MRI scan or wrist arthroscopy. If there is an associated TFCC tear, it should be debrided or repaired as appropriate.

ULNAR PHYSEAL FRACTURES

Isolated ulnar physeal fractures are rare injuries. Most ulnar physeal fractures occur in association with radial metaphyseal or physeal fractures. Physeal separations are classified by the standard Salter-Harris criteria. These injuries include types I, II, III, and rarely IV fractures. The rare pediatric Galeazzi injury usually involves an ulnar physeal fracture rather than a soft tissue disruption of the distal radioulnar joint. Another ulnar physeal fracture is an avulsion fracture off the distal aspect of the ulnar styloid (91). Although an ulnar styloid injury is an epiphyseal avulsion, it usually is associated with soft tissue injuries of the TFCC and ulnocarpal joint and does not cause growth-related complications.

Physeal growth arrest is frequent with distal ulnar physeal fractures. The incidence has been cited from 21% (73) to 55% (52). It is unclear why the distal ulna has a higher incidence of growth arrest after fracture than does the radius.

Treatment

Treatment options are similar to those for radial physeal fractures: immobilization alone, closed reduction and cast immobilization, closed reduction and percutaneous pinning, and open reduction. Often these fractures are minimally displaced or nondisplaced. Immobilization until fracture healing at 3 to 6 weeks is standard treatment. Closed reduction is indicated for displaced fractures with more than 50% translation or 20 degrees angulation. Most ulnar physeal fractures reduce to a near anatomic alignment with reduction of the radial fracture. Failure to obtain a reduction of the ulnar fracture may indicate that there is soft tissue interposed in the fracture site. This is an indication for open reduction. Exposure should be from the side of the torn periosteum. The interposed soft tissue (periosteum, extensor tendons, and flexor tendons (48,60,74)) must be extracted from the fracture site. If reduction is not stable, a small-diameter smooth pin can be used to maintain alignment until healing at 3 to 4 weeks. Further injury to the physis should be avoided during operative exposure and reduction because of the high risk of growth arrest (Fig. 9-33, Fig. 9-34 and Fig. 9-35).

FIGURE 9-33. A and B: A 10-year-old boy sustained a closed Salter-Harris type I separation of the distal ulnar physis (*arrows*), combined with a fracture of the distal radial metaphysis. **C:** An excellent closed reduction was achieved atraumatically. **D:** Long-term growth arrest of the distal ulna occurred.

FIGURE 9-34. A: The appearance of the distal ulna in the patient seen in Fig. 9-21 3 years after injury, demonstrating premature fusion of the distal ulnar physis with 3.2 cm of shortening. The distal radius is secondarily deformed, with tilting and translocation toward the ulna. **B:** In the patient in Fig. 9-21 with distal ulnar physeal arrest, a lengthening of the distal ulna was performed using a small unipolar distracting device. The ulna was slightly overlengthened to compensate for some subsequent growth of the distal radius. **C:** Six months after the lengthening osteotomy, there is some deformity of the distal ulna, but good restoration of length has been achieved. The distal radial epiphyseal tilt has corrected somewhat, and the patient has asymptomatic supination and pronation to 75 degrees.

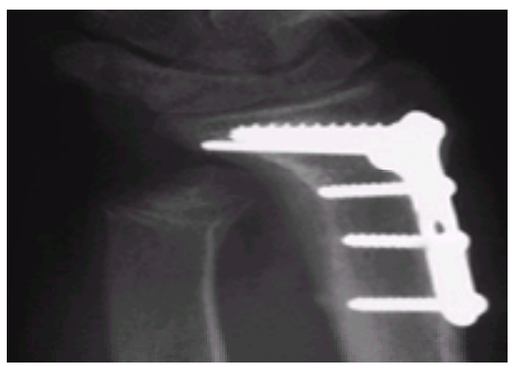

FIGURE 9-35. Similar case to Fig. 9-34, but with more progressive distal radial deformity treated with corrective osteotomy and epiphysiodesis of the distal radius.

ULNAR STYLOID FRACTURES

Ulnar styloid avulsion fractures are common in association with radial fractures (91) and represent a soft tissue avulsion of the attachment of the TFCC or ulnocarpal ligaments. Treatment consists of immobilization and monitoring of long-term outcome, and most heal without sequelae (62). However, an acute displaced fracture of the base of the styloid represents a disruption of the TFCC. Most of these injuries occur in adolescents with high-velocity trauma at or near skeletal maturity. Treatment should be by tension band reinsertion of the styloid to the metaphysis and repair of the TFCC (Fig. 9-36). The tension band wire is removed at 3 to 6 weeks.

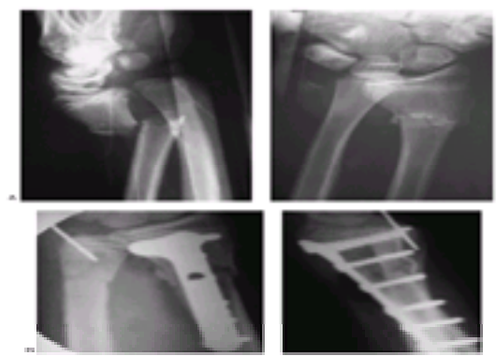

FIGURE 9-36. A: An adolescent with an open, comminuted fracture of the distal radius metaphysis and a base of ulnar styloid fracture with disruption of the triangular fibrocartilage complex (TFCC). **B:** After thorough irrigation and debridement of the radius, internal fixation of the radius was performed with care taken to not violate the physis with hardware. The ulna styloid base fracture and TFCC was repaired with an open tension band technique with a suture and smooth wire.

Some ulnar styloid fractures result in nonunion (Fig. 9-30) or hypertrophic union (Fig. 9-29) (44,68,76,93). Nonunion may be associated with TFCC tears or ulnocarpal impaction. The hypertrophic healing represents an ulnar positive variance and ulnocarpal impaction. Both cause ulnar-sided wrist pain. Compression of the lunate or triquetrum on the distal ulna reproduces the pain. Clicking with ulnocarpal compression or forearm rotation represents either a TFCC tear or chondomalacia of the lunate or triquetrum. Surgical excision of the nonunion or hypertrophic union with repair of the TFCC to the base of the styloid is the treatment of choice. Postoperative immobilization for 4 weeks in a long arm cast followed by 2 weeks in a short arm cast protects the TFCC repair.

Complications

Growth Arrest

The most common complication of distal ulnar physeal fractures is growth arrest. Golz (52) described 18 such fractures, with growth arrest in 10%. If the patient is

young enough, continued growth of the radius will lead to deformity and dysfunction. The distal ulnar aspect of the radial physis and epiphysis appears to be tethered by the foreshortened ulna (Fig. 9-34 and Fig. 9-35). The radial articular surface develops increased inclination toward the foreshortened ulna. This is similar to the deformity Peinado (78) created experimentally with arrest of the distal ulna in rabbits' forelimbs. The distal ulna loses its normal articulation in the sigmoid notch of the distal radius. The metaphyseal-diaphyseal region of the radius often becomes notched from its articulation with the distal ulna during forearm rotation. Frequently, these patients have pain and limitation of motion with pronation and supination (41).

Ideally, this problem is identified before the development of marked ulnar foreshortening and subsequent radial deformity. Because it is well known that distal ulnar physeal fractures have a high incidence of growth arrest, these patients should have serial radiographs to identify growth arrest early. Unfortunately, in the distal ulnar physis, physeal bar resection generally is unsuccessful. Surgical arrest of the radial physis can prevent radial deformity. Usually this occurs late enough in growth that the forearm length discrepancy is not a problem.

Most often these patients present late with established deformity. Treatment then involves rebalancing the length of the radius and ulna. The options include hemiphyseal arrest of the radius, corrective closing wedge osteotomy of the radius, ulnar lengthening (41,52,73), or a combination of these procedures (Fig. 9-34 and Fig. 9-35). The painful impingement of the radius and ulna with forearm rotation can be corrected with reconstitution of the DRUJ. If the radial physis has significant growth remaining, a radial physeal arrest should be performed at the same time as the surgical rebalancing of the radius and ulna. Treatment is individualized depending on the age of the patient, degree of deformity, and level of pain and dysfunction.

METAPHYSEAL FRACTURES

The metaphysis of the distal radius is the most common site of forearm fracture in children and adolescents (19,32,154). They occur most commonly in boys in the nondominant arm (168). These fractures have a peak incidence during the adolescent growth spurt, which in girls is age 11 to 12 years and in boys is 12 to 13 years (2). During this time of extensive bone remodeling, there is relative osteoporosis of the distal radial metaphysis, which makes this area more susceptible to fracture with a fall.

Diagnosis

The mechanism of injury is generally a fall on an outstretched hand. The usual dorsiflexion position of the wrist leads to tension failure on the volar side. Fracture type and degree of displacement depend on the height and velocity of the fall (154). These fractures can be nondisplaced torus or buckle injuries (common in younger children with a minimal fall) or dorsally displaced fractures with apex volar angulation (more common in older children with higher velocity injuries) (Fig. 9-37). Displacement may be severe enough to cause foreshortening and bayonet apposition (Fig. 9-38). Rarely, a mechanism such as a fall from a height can cause a distal radial fracture associated with a more proximal fracture of the forearm or elbow (97,143,155) (Fig. 9-39). A fall with a palmar flexed wrist can produce a volarly displaced fracture with apex dorsal angulation (Fig. 9-38, Table 9-2).

TABLE 9-2. CLASSIFICATION: DISTAL METAPHYSEAL FRACTURES

Children with distal radial fractures present with pain, swelling, and deformity of the distal forearm (Fig. 9-40 and Fig. 9-41). The clinical signs depend on the degree of fracture displacement. With a nondisplaced torus fracture in a young child, medical attention may not be sought until several days after injury, because the intact periosteum is protective in this situation, lessening pain and the child's restriction of activities. Most distal radius fractures, however, will present acutely after the fall with an obvious deformity. Physical examination is limited by the patient's pain and anxiety. It is imperative to obtain an accurate examination of the motor and sensory components of the radial, median, and ulnar nerves before treatment. Median nerve motor function is evaluated by testing the abductor pollicis brevis (intrinsic) and flexor pollicis longus (extrinsic) muscles. Ulnar nerve motor evaluation includes testing the first dorsal interosseous (intrinsic), abductor digit quinti (intrinsic), and flexor digitorum profundus to the small finger (extrinsic) muscles. Radial nerve evaluation involves testing the common digital extensors for metacarpophalangeal joint extension. Sensibility to light touch and two-point discrimination should be tested. Normal two-point discrimination is less than 5 mm but is not present until age 5 to 7 years. Pin-prick sensibility testing will only hurt and scare the already anxious child and should be avoided. A recent prospective study indicated an 8% incidence of nerve injury in children with distal radial fractures (168).

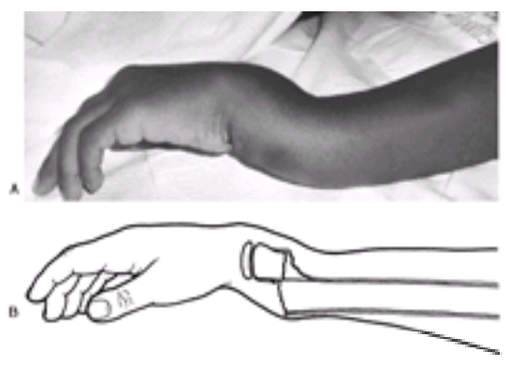

FIGURE 9-40. Dorsal bayonet deformity. **A:** Typical distal metaphyseal fracture with dorsal bayonet showing a dorsal angulation of the distal forearm. **B:** Usually the periosteum is intact on the dorsal side and disrupted on the volar side.

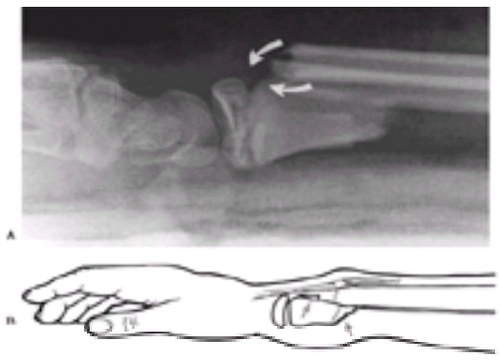

FIGURE 9-41. Reverse bayonet. **A:** Typical volar bayonet fracture. Often the distal end of the proximal fragment is buttonholed through the extensor tendons (*arrows*). (Reprinted from Wilkins KE, ed. *Operative management of upper extremity fractures in children.* Rosemont, IL: American Academy of Orthopaedic Surgeons, 1994:27; with permission.) **B:** Intact volar periosteum and disrupted dorsal periosteum (*arrows*). The extensor tendons are displaced to either side of the proximal fragment.

The ipsilateral extremity should be carefully examined for fractures of the carpus, forearm, or elbow (107,128,129,133,147,155,160–162) because 3% to 13% of distal radial fractures have associated ipsilateral extremity fractures (Fig. 9-42) (120,155), increasing the risk of neurovascular compromise and compartment syndrome (Papavasilious, Staninski, ring).

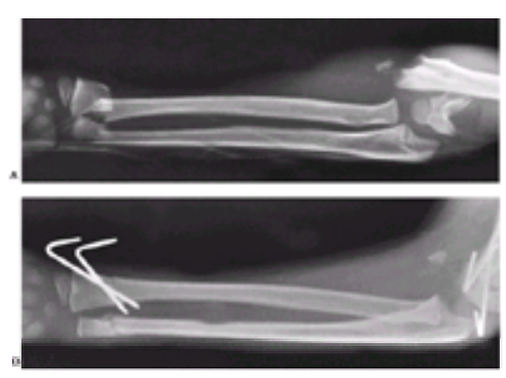

FIGURE 9-42. Ipsilateral fractures. **A:** Markedly displaced ipsilateral distal radial and supracondylar fractures. **B:** Both fractures were reduced and stabilized with pins placed percutaneously. (Wilkins KE, ed. *Operative management of upper extremity fractures in children.* Rosemont, IL: American Academy of Orthopaedic Surgeons, 1994:29; with permission.)

Radiographs are diagnostic of the fracture type and degree of displacement. Standard AP and lateral radiographs usually are sufficient. Complete wrist, forearm, and elbow views are necessary for high-velocity injuries or when there is clinical tenderness. More extensive radiographic studies (CT scan, tomograms) usually are not necessary unless there is intraarticular extension of the metaphyseal fracture in a skeletally mature adolescent.

Classification

These fractures are classified by fracture pattern, type of associated ulnar fracture, and direction of displacement. Fracture displacement is broadly classified as dorsal or volar. Most distal radial metaphyseal fractures are displaced dorsally with apex volar angulation (32) Volar displacement with apex dorsal angulation can occur with palmar flexion injuries.

Metaphyseal fracture patterns are either torus, incomplete or greenstick, or complete fractures. Torus fractures are axial compression injuries. The site of cortical failure is the transition from metaphysis to diaphysis (138). These injuries are stable because of the intact periosteum. On rare occasion, they may extend into the physis, putting them at risk for growth impairment (80,81). Incomplete or greenstick fractures occur with a combination of compressive and rotatory forces, generally a dorsiflexion force and supination deforming force. This leads to a volar tension side failure and a dorsal compression injury. The degree of force determines the amount of plastic deformation, dorsal comminution, and fracture angulation and rotation. If the force is sufficient, a complete fracture occurs with disruption of both the volar and dorsal cortices. Length may be maintained with apposition of the proximal and distal fragments. Frequently, the distal fragment lies proximal and dorsal to the proximal fragment in bayonet apposition (Table 9-2).

The ulnar fracture often associated with radial metaphyseal fracture can be metaphyseal or physeal, or an ulnar styloid avulsion. Similar to radial metaphyseal fractures, the ulnar fracture can be complete or incomplete.

Distal radial fractures also can occur in conjunction with more proximal forearm fractures (101), Monteggia fracture–dislocations (102), supracondylar distal humeral fractures (Reis, ring, Staninski), or carpal fractures (102,128,129,133,161,162). The combination of a displaced supracondylar distal humeral fracture and a displaced distal radial metaphyseal fracture has been called the pediatric floating elbow. This injury combination is unstable and has an increased risk for malunion and neurovascular compromise.

Pediatric distal radial metaphyseal fractures are not classified by degree of instability. Unstable fractures have been predominately identified retrospectively by the failure to maintain a successful closed reduction (Fig. 9-43). This occurs in approximately 30% of complete distal radial metaphyseal fractures (139,146,167). This high percentage of loss of alignment has been tolerated because of the remodeling potential of the distal radius. Anatomic remodeling is possible because the extension deformity is in the plane of motion of the wrist joint, the metaphyseal fracture is juxtaphyseal, and most of these fractures occur while there is still significant growth remaining. However, concern has increased about the high failure rate of closed reduction to maintain anatomic alignment of these fractures. Factors that have been identified as increasing the risk of loss of reduction with closed manipulation and casting include poor casting, bayonet apposition, translation greater than 50% the diameter of the radius, apex volar angulation greater than 30 degrees, isolated radial fractures, and radial and ulnar metaphyseal fractures at the same level (139,146,167). These factors define in general terms unstable fractures.

FIGURE 9-43. Results of angulation. **A:** Significant apex volar angulation of the distal fragment. **B:** The appearance was not as apparent cosmetically as in another patient with less angulation that was directed apex dorsally. (Reprinted from Wilkins KE, ed. *Operative management of upper extremity fractures in children.* Rosemont, IL: American Academy of Orthopaedic Surgeons, 1994:27; with permission.)

Treatment

Treatment options are similar to those for radial physeal fractures: immobilization alone, closed reduction and cast immobilization, closed reduction and percutaneous pinning, and open reduction. The fracture type, degree of fracture instability, associated soft tissue or skeletal trauma, and the age of the patient all influence choice of treatment.

Torus Fractures

Torus fractures are compression injuries with minimal cortical disruption. If only one cortex is violated, the injury is stable. Treatment should consist of protected immobilization to prevent further injury and relieve pain. Once the patient is comfortable, range-of-motion exercises and nontraumatic activities can begin. Fracture healing usually occurs in 2 to 4 weeks (20,40,68,74). Simple torus fractures usually heal without long-term sequelae.

Bicortical disruption on both the AP and lateral views indicates a more severe injury than a stable torus fracture. Splint or limited immobilization in this situation puts the child at risk for displacement. More prolonged immobilization, long arm cast protection in a young patient, and closer follow-up are generally recommended to lessen the risk of malunion. These fractures generally heal in 3 to 6 weeks.

Incomplete/Greenstick Fractures

Immobilization Alone

Treatment of incomplete distal radial and ulnar fractures depends on the age of the patient, the degree and direction of fracture displacement and angulation, the surgeon's biases regarding remodeling, and the surgeon's and community's biases regarding deformity. In younger patients, the remodeling potential of an acute distal radial malunion is extremely high. Acceptable sagittal plane angulation of an acute distal radial metaphyseal fracture has been reported to be from 10 to 35 degrees in patients under 5 years of age (74,103,108,141,145,153,168). Similarly, in patients under 10 years of age, the degree of acceptable angulation has ranged from 10 to 25 degrees (74,103,108,141,153,168). In patients over 10 years of age, acceptable malunion has ranged from 5 to 20 degrees depending on the skeletal maturity of the patient (74,103,108,112,141,153,167,168) (Table 9-3).

	Saggital Plane		Frontal Plane
Age (yr)	Boys	Girls	Boys & Girls
4–9	20	15	15
9–11	15	10	5
11–13	10	10	0
>13	5	0	0

Acceptable residual angulation is that which will result in total radiographic and functional correction.

TABLE 9-3. ACCEPTABLE ANGULAR CORRECTIONS IN DEGREES

The high potential for remodeling of a distal radial metaphyseal malunion has led some researchers to recommend immobilization alone. As mentioned, the range of accepted malalignment has been broad as well as age and researcher dependent (Fig. 9-44 and Fig. 9-45).

FIGURE 9-44. Extensive remodeling. **A:** Injury film of a 7-year-old with a tension failure greenstick fracture. **B and C:** Lateral and anteroposterior views of the same patient taken 1 month later showing development of 45 degrees angulation in the sagittal plane and 40 degrees in the coronal plane. **D and E:** True appearance taken 4 years later shows only residual angulation of 10 degrees in the sagittal plane and full correction of radial angulation in the coronal plane. The patient had a range of forearm motion equal to that of the opposite extremity and was asymptomatic.

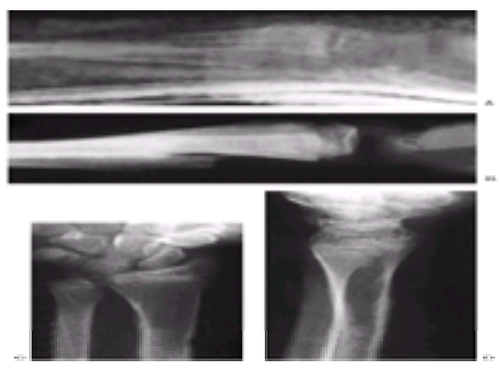

FIGURE 9-45. Bayonet remodeling. **A:** After numerous attempts at closed reduction, the best alignment that could be obtained was dorsal bayonet apposition in this 8-year-old. **B:** Three months postfracture, there is good healing and early remodeling. **C and D:** Five years after the injury (age 13), remodeling was complete and the patient had normal appearance and forearm motion.

Acceptable frontal plane deformity has been more uniform. The fracture tends to displace radially with an apex ulnar angulation. This does have the potential to remodel (144), but less so than sagittal plane deformity. Most researchers agree that only 10 degrees or less of acute malalignment in the frontal plane should be accepted. More malalignment than this may not remodel and may result in loss of forearm rotation because of the loss of interosseous space between the radius and ulna (169) (Table 9-3).

Closed Reduction

Most researchers agree that displaced and malaligned incomplete fractures should be reduced closed. The areas of controversy are the degree of acceptable deformity, whether the intact cortex should be fractured, and the position of immobilization.

Controversies about acceptable angulation of the fracture after closed reduction involve the same differences discussed in the immobilization section. As mentioned, more malalignment can be accepted in younger patients, in those with sagittal plane deformity, and in those without marked cosmetic deformity. Malaligned apex volar incomplete fractures are less obvious than the less common apex dorsal fractures.

As Evans (115) and Rang (86)emphasized, incomplete forearm fractures have a rotatory component to their malalignment. The more common apex volar fractures represent a supination deformity, whereas the less common apex dorsal fractures are malrotated in pronation. Correction of the malrotation is necessary to achieve anatomic alignment. Controversy exists regarding completion of greenstick fractures (18,86,111,118,151). Most researchers advocate completion of the fracture to reduce the risk of subsequent loss of reduction from the intact periosteum and concave deformity acting as a tension band (157,168) to redisplace the fracture. Completing the fracture increases the risk of instability and malunion.

The position and type of immobilization also have been controversial. Recommendations for the position of postreduction immobilization include supination, neutral, and pronation. The rationale for immobilization in pronation is that reduction of the more common apex volar fractures requires correction of the supination deformity (115). Following this rationale, apex dorsal fractures should be reduced and immobilized in supination. Pollen (145) believed that the brachioradialis was a deforming force in pronation and was relaxed in supination (Fig. 9-46) and advocated immobilization in supination for all displaced distal radial fractures. Kasser (58) recommended immobilization in slight supination to allow better molding of the volar distal radius. Some researchers advocate immobilization in a neutral position, believing this is best at maintaining the interosseous space and has the least risk of disabling loss of forearm rotation in the long term (113,141,158). Davis and Green (111) and Ogden (74) advocate that each fracture seek its own preferred position of stability. Gupta and Danielsson (130) randomized immobilization of distal radial metaphyseal greenstick fractures in neutral, supination, or pronation to try to determine the best position of immobilization. Their study showed a statistical improvement in final healing with immobilization in supination.

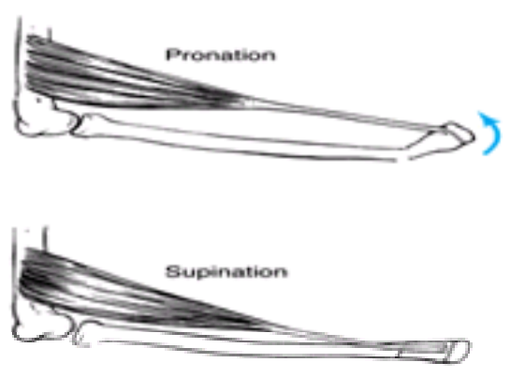

FIGURE 9-46. The brachioradialis is relaxed in supination but may become a deforming force in pronation. (Reprinted from Pollen AG. *Fractures and dislocations in*

children. Baltimore: Williams & Wilkins, 1973; with permission.)

Another area of controversy is whether long arm or short arm cast immobilization is better. Most publications on pediatric distal radial fracture treatment advocate long arm cast treatment for the first 3 to 4 weeks of healing (20,40,58,74,103,158). The rationale is that elbow flexion reduces the muscle forces acting to displace the fracture. In addition, a long-arm cast may further restrict the child's activity and therefore decrease the risk of displacement. However, Chess (104,105) published reported redisplacement and reduction rates with well-molded short arm casts similar to those with long arm casts. They used a cast index (sagittal diameter divided by coronal diameter at the fracture site) of 0.7 or less to indicate a well-molded cast. Wilkins achieved similar results with short-arm cast treatment (168). However, in most centers, the standard is still long arm cast immobilization (20,40,58,103,158).

COMPLETE FRACTURES

Complete fractures of the distal radius, with or without an associated displaced ulnar fracture, are unstable fractures. Generally these fractures are displaced dorsally, tearing the volar periosteum and soft tissues. The distal fragment of epiphysis and metaphysis often is in bayonet apposition with the proximal fragment (Fig. 9-38). Concomitant radial and ulnar fractures at the same level may be more unstable than isolated fractures (167) (Fig. 9-47). However, Gibbons reported loss of reduction in 91% of isolated radial fractures after closed reduction. Although a rare fracture with bayonet apposition in a very young patient may remodel (168), the standard treatment for completely displaced fractures is reduction and stabilization. The current controversy is whether cast immobilization alone is adequate stabilization or whether percutaneous pin fixation is more appropriate for displaced, complete, distal radial metaphyseal fractures.

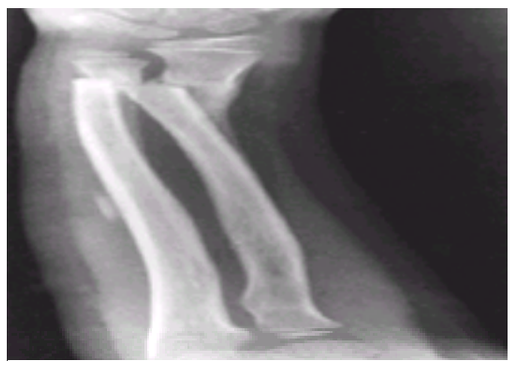

FIGURE 9-47. Radial deviation constricts the interosseous space, which may decrease forearm rotation. (Reprinted from Wilkins KE, ed. *Operative management of upper extremity fractures in children.* Rosemont, IL: American Academy of Orthopaedic Surgeons, 1994:28; with permission.)

Reduction Techniques

Techniques of reduction have included initial distraction with finger traps (111,157) followed by manipulation and direct manipulation of the fracture by accentuating the deformity (Fig. 9-48 and Fig. 9-49). Both Rang (86) and Fernandez (118) expressed concern about the success of finger trap distraction because the intact dorsal periosteum will not stretch adequately to allow reduction. They advocated sequential reduction maneuvers: initial manipulation of the distal fragment dorsally to accentuate the deformity (Fig. 9-48), thumb pressure on the relaxed dorsal edge of the distal fragment to correct the overriding, and reduction of the fracture by forceable application of distal and volar pressure (Fig. 9-49). Anatomic reduction may require repetitive “toggling” of the distal fragment volarly.

FIGURE 9-48. A and B: Use of the thumb to push the distal fragment hyperdorsiflexed 90 degrees (*solid arrow*) until length is reestablished. Countertraction is applied in the opposite direction (*open arrows*).

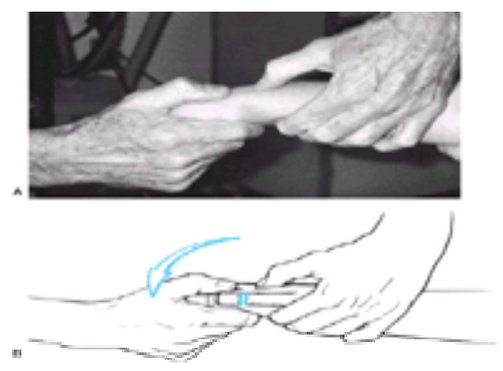

FIGURE 9-49. A and B: Once length has been reestablished, the distal fragment is flexed into the correct position. Alignment is checked by determining the position of the fragments with the thumb and forefingers of each hand.

There is considerable controversy about what constitutes an acceptable reduction (76,110,111,121,123,131,137,148,149,163). This is clearly age dependent, because the younger the patient, the greater the potential for remodeling (Fig. 9-50). Volar-dorsal malalignment has the greatest potential for remodeling because this is in the plane of predominant motion of the joint. Marked radioulnar malalignment is less likely to remodel. Malrotation will not remodel (Fig. 9-51). The ranges for acceptable reduction according to age are given in the immobilization section on incomplete fractures and apply to complete fractures as well.

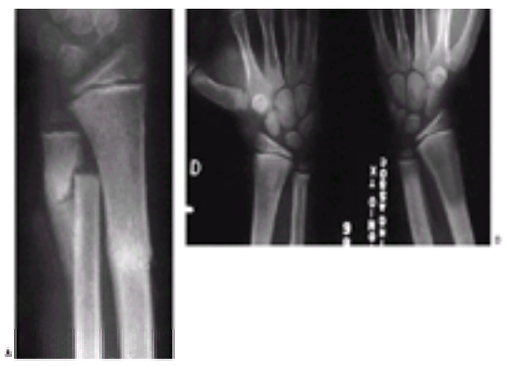

FIGURE 9-50. A: Appearance 6 weeks after closed reduction of a distal forearm fracture in an 8½-year-old boy. The radius was reduced, and the ulnar fracture remained overriding. **B:** Eighteen months after injury the ulnar fracture had remodeled completely with symmetric distal radioulnar joints.

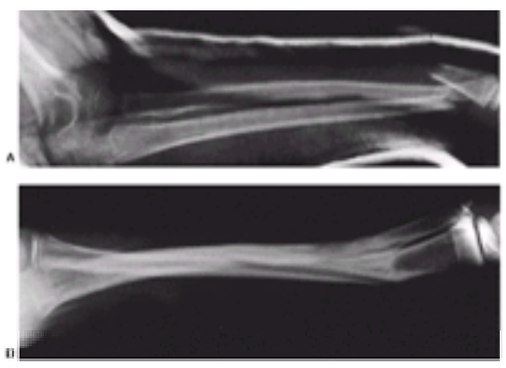

FIGURE 9-51. A: This 7-year-old with bayonet apposition was immobilized in a long arm cast in full pronation. **B:** One year later, there was still considerable angulation with significant loss of forearm rotation and an unacceptable cosmetic appearance.

Cast Immobilization

As discussed earlier there is some disagreement regarding short arm or long arm cast immobilization (104,105,168). However, regardless of the length of the cast, it is imperative to have a well-molded cast over the fracture site (Fig. 9-52). After reduction of a dorsally displaced fracture, three-point fixation is used with dorsal pressure proximal and distal to the fracture site and volar pressure over the reduced fracture. Excessive swelling should be monitored. If there is any concern regarding impending compartment syndrome, the cast and webril should be immediately bivalved and the patient's clinical status monitored closely.

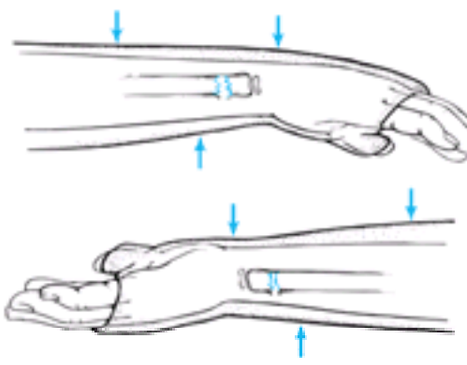

FIGURE 9-52. Three-point molding. **Top:** Three-point molding for dorsally angulated (apex volar) fractures, with the proximal and distal points on the dorsal aspect of the cast and the middle point on the volar aspect just proximal to the fracture site. **Bottom:** For volar angulated fractures, where the periosteum is intact volarly and disrupted on the dorsal surface, three-point molding is performed with the proximal and distal points on the volar surface of the cast and the middle point just proximal to the fracture site on the dorsal aspect of the cast.

The primary problem with closed reduction and cast immobilization is loss of reduction (Fig. 9-53). Mani et al. (139) and Proctor et al. (146) described remanipulation rates of 21.3% and 23.5%, respectively. Mani et al. (139) concluded that initial displacement of the radial shaft of over 50% was the single most reliable predictor of failure of reduction. Proctor et al. (146) found that complete initial displacement resulted in a 52% incidence of redisplacement of distal radial fractures in children. Gibbons et al. (126) noted that completely displaced distal radius fractures with intact ulnas had a remanipulation rate of 91% after closed reduction and cast immobilization alone versus a 0% rate of remanipulation when the same fractures were treated with closed reduction, Kirschner wire fixation, and cast immobilization. All three researchers strongly advocated percutaneous pinning of distal radial fractures at risk of redisplacement (Fig. 9-54). Widmann and Waters (167) prospectively studied all distal radial fractures in children requiring reduction over the course of 1 year (POSNA). Of the 86 distal radial metaphyseal fractures, 31% lost reduction and required further intervention with repeat reduction, casting, or pinning. In patients over 10 years of age with angulation of more than 30 degrees, the remanipulation rate was 75%. These findings led to a more recent prospective, randomized study by Waters et al. (166) of distal radial metaphyseal fractures treated by either closed reduction and cast immobilization or closed reduction and percutaneous pinning. Selection criteria were a closed metaphyseal fracture angulated more than 30 degrees in a skeletally immature patient over 10 years of age. To maximize the outcome of the cast immobilization group, these patients were treated by a member of the Pediatric Orthopedic Society of North America with expertise in trauma care. General anesthesia, fluoroscopic control, and a long arm cast were used. Despite these optimal conditions, 7 of 18 patients in the cast immobilization group lost reduction and required remanipulation.

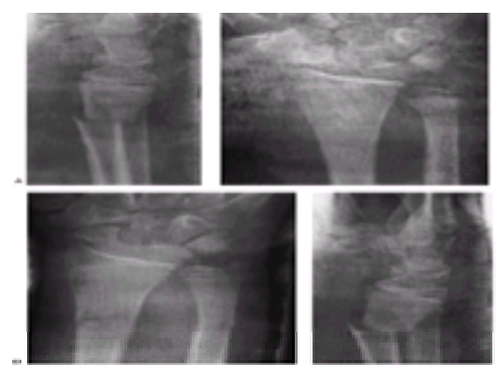

FIGURE 9-53. Serial radiographs at 3 days **(A)** and 10 days **(B)** revealing slow loss of reduction that is commonplace after distal radial metaphyseal fracture closed reduction.

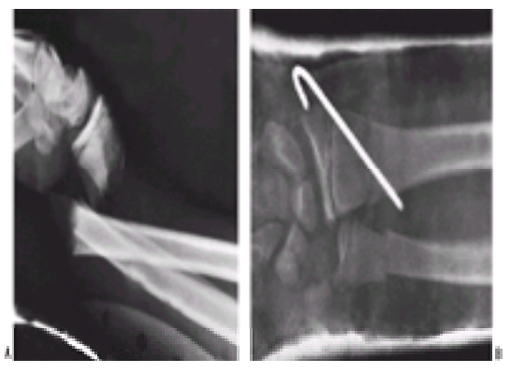

FIGURE 9-54. Severe swelling. **A:** An 11-year-old with marked displacement and severe swelling from a high-energy injury. **B:** Once reduced, the fragment was secured with an oblique percutaneous pin across the fracture site. (Reprinted from Wilkins KE, ed. *Operative management of upper extremity fractures in children.* Rosemont, IL: American Academy of Orthopaedic Surgeons, 1994:29, with permission.)

The results of all of these studies indicate that distal radial metaphyseal fractures with initial displacement of more than 30 degrees are inherently unstable. Loss of reduction is common, with the risk in the 30% to 40% range. Incomplete reduction (139,146) and poor casting techniques (104,105,168) increase the risk of loss of reduction. In addition, the risk of loss of reduction increases with the age of the patient and the degree of initial displacement.

Loss of reduction requires repeat manipulation or it will result in a malunion. Although the rate of malunion is frequent after these fractures (40,46,54,58,67,89,104,105,109,111,165), because of the potential for remodeling in skeletally immature patients, it has not been considered a serious problem (17,37,38,103,121–124). Distal radial fractures are juxtaphyseal, the malunion often is in the plane of motion of the wrist joint (dorsal displacement with apex volar angulation), and the distal radius accounts for 60% to 80% of the growth of the radius. All these factors favor remodeling of a malunion. However, deCourtivron et al. (112) reported that of 602 distal radial fractures, 14% had an initial malunion of more than 5 degrees. Of these, 78% corrected the frontal plane deformity and only 53% remodeled completely in the sagittal plane. In addition, 37% had loss of forearm rotation.

Closed Reduction and Percutaneous Pinning

In the past 10 years, closed reduction and percutaneous pinning have become more common as the primary treatment of distal radial metaphyseal fractures in children and adolescents (125,139,146,166,167). The indications cited include fracture instability and high risk of loss of reduction (125,139,146), excessive local swelling that increases the risk of neurovascular compromise (95,166,168), ipsilateral fractures of the distal radius and elbow region (floating elbow) that increase the risk of compartment syndrome (Fig. 9-43) (155,169), and any remanipulation (Fig. 9-55) (167,168).

FIGURE 9-55. Remanipulation. **A and B:** Two weeks after what appeared to be initially an undisplaced greenstick fracture, a 14-year-old boy was found to have developed late angulation of 30 degrees in both the coronal and sagittal planes. **C:** Because this was beyond the limits of remodeling, a remanipulation was performed. To prevent reangulation, the fracture was secured with a pin placed percutaneously obliquely through the dorsal cortex.

Pinning usually is done from distal to proximal under fluoroscopic guidance. When possible, the physis is avoided. Adequate exposure should be obtained to avoid radial sensory nerve or extensor tendon injury. Smooth Kirschner or **C**-wires are used. In younger patients, a single pin with supplemental cast immobilization may be adequate fixation. Crossed pins are more stable (Fig. 9-56). The first pin, or single pin, enters from the radial side distal to the fracture and passes obliquely to the ulnar aspect of the radius proximal to the fracture. The second pin enters the radius distal to the fracture between the fourth and fifth compartments and passes obliquely across the fracture into the proximal radial side of the radius. The pins are left out through the skin to allow easy removal in the ambulatory setting. A supplemental, loose-fitting cast is applied. The advantage of pin fixation is that a tight, well-molded cast is not necessary to maintain reduction. This lessens the risk of neurovascular compromise with associated excessive swelling or ipsilateral fractures. Obviously, pin fixation avoids the risk of loss of reduction in an unstable fracture. Pinning does have the risk of infection and concerns regarding growth injury.

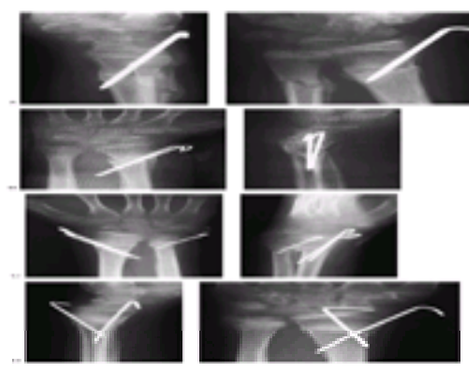

FIGURE 9-56. Different pinning techniques for unstable distal radius and ulnar metaphyseal fractures. **A:** A single oblique pin in the radius. **B:** Two parallel pins in the radius. **C:** Two parallel pins in the radius and a single pin in the ulna. **D:** Crossed pins in the radius.

External Fixation

Unlike distal radial fractures in adults, external fixation rarely is indicated in skeletally immature patients. Although it can be used successfully (152,165), the success rates of both closed reduction and percutaneous pinning techniques make it unnecessary for uncomplicated distal radial fractures in children. The best indication is severe associated soft tissue injuries. A severe crush injury, open fracture, or replantation after amputation that requires extensive soft tissue care and surgery are all indications for the use of external fixation. Supplemental external fixation also may be necessary for severely comminuted fractures to maintain length and provide additional stability to pin fixation (Fig. 9-22). Standard application of the specific fixator chosen is performed with care to avoid injury to the adjacent sensory nerves

and extensor tendons.

Open Reduction

Open reduction is indicated for open or irreducible fractures (Fig. 9-36, Fig. 9-57, and Fig. 9-58). Open fractures constitute approximately 1% of all distal radial metaphyseal fractures. All open fractures, regardless of grade of soft tissue injury, should be irrigated and debrided in the operating room. The open wound should be enlarged adequately to debride the contaminated and nonviable tissues and protect the adjacent neurovascular structures. After thorough irrigation and debridement, the fracture should be anatomically reduced and stabilized, usually with two smooth pins. If the soft tissue injury is severe, supplemental external fixation allows for observation and treatment of the wound without jeopardizing the fracture reduction. The original open wound should not be closed primarily. Appropriate prophylactic antibiotics should be used depending on the severity of the open fracture.

FIGURE 9-57. Open fractures. Radiograph **(A)** and clinical photo **(B)** of an open fracture of the distal radius. This patient needs formal irrigation and debridement in the operating room.

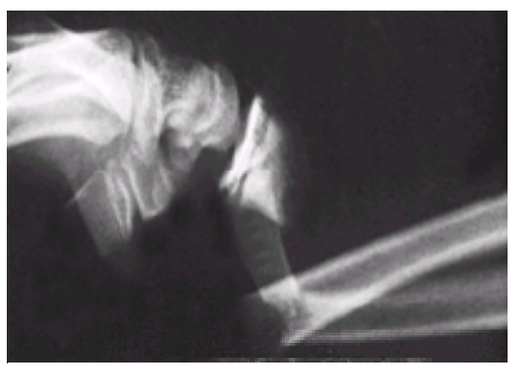

FIGURE 9-58. A 10-year-old girl with a markedly displaced closed fracture of the distal radius with an angulated ulnar fracture. Note the wide separation between the radial fragments. Dimpling of the skin was noted when longitudinal traction was applied and reduction was impossible. At open reduction, the proximal fragment was buttonholed through the forearm fascia and located between the median nerve and finger flexor tendons. The pronator quadratus muscle was also interposed between the two fragments.

Irreducible fractures are rare (Fig. 9-58) and generally are secondary to interposed soft tissues. With dorsally displaced fractures, the interposed structure usually is the volar periosteum or pronator quadratus (132) and rarely the flexor tendons or neurovascular structures. In volarly displaced fractures, the periosteum or extensor tendons may be interposed. The fracture should be approached in a standard fashion opposite the side of displacement (i.e., volar approach for an irreducible dorsal fracture). The adjacent neurovascular and tendinous structures are protected and the offending soft tissue is extracted from the fracture site. Pin stabilization is recommended to prevent problems with postoperative swelling or loss of reduction in cast.

Closed reduction rarely fails if there is no interposed soft tissue. However, occasionally multiple attempts at reduction of a bayonet apposition fracture can lead to significant swelling that makes closed reduction impossible. If the patient is too old to remodel bayonet apposition, open reduction is appropriate. Pin fixation without violating the physis is recommended.

AUTHOR'S PREFERRED METHOD OF TREATMENT

Nondisplaced Fractures

Nondisplaced metaphyseal compression fractures, including torus and unicortical compression greenstick fractures, are inherently stable. These include torus and unicortical compression greenstick fractures. Immobilization is used until resolution of pain and radiographic evidence of healing, generally about 3 weeks. Depending on the activity level of the patient, a volar wrist splint or a short arm cast can be used. Immobilization provides comfort from pain during healing and protects against displacement with secondary injury. It is important that an unstable bicortical fracture not be unrecognized on radiograph. Bicortical fractures need more protection, longer restriction of activity, and closer follow-up to avoid displacement and malunion. A well-molded long arm cast is applied and radiographs obtained every 7 to 10 days until evidence of early radiographic healing. A short-arm cast is then worn until clinical and radiographic healing is complete. Any loss of reduction is treated with repeat reduction. Return to contact sports is restricted until the patient regains full motion and strength.

Minimally Displaced Fractures

Displaced greenstick fractures that are reduced are at risk for redisplacement. If left unreduced or poorly immobilized, a mild deformity can become severe during the course of healing. Therefore, closed anatomic reduction is performed in all bicortical fractures with more than 10 degrees of malalignment. Generally these fractures have apex volar angulation and dorsal displacement. Conscious sedation is used with portable fluoroscopy in the emergency care setting. The distal fragment and hand are distracted and then reduced volarly. With isolated distal radial fractures, it is imperative to reduce the DRUJ with appropriate forearm rotation. For apex volar fractures, this usually is with pronation. If the fracture is apex dorsal with volar displacement, the reduction forces are the opposite. A long arm cast with three-point molding is used for 3 to 4 weeks. Radiographs are obtained every 7 to 10 days until there is sufficient callus formation. A short arm cast or volar wrist splint is used until full healing, generally at 4 to 6 weeks after fracture reduction. The patient is then restricted from contact sports until full motion and strength are regained, which may take up to 3 weeks after cast removal. Formal therapy rarely is required. The patient and parents should be warned at the start of treatment of the risk of redisplacement of the fracture.

Bayonet Apposition

Marked displacement of distal radial metaphyseal fractures usually results in foreshortening and dorsal overlap of the distal fragment on the proximal fragment. This often is associated with a same-level ulnar metaphyseal fracture, similarly in bayonet apposition. Rarely, the distal fragment is in volar bayonet apposition. Both of these situations require more skill of reduction and complete analgesia at the fracture site. At our institution, we reduce this fracture in the operating room with general anesthesia or in the emergency room with conscious sedation and supplemental local hematoma block. In either situation, portable fluoroscopy is used. The fracture usually is reduced in the emergency room in young patients with minimal swelling and no neurovascular compromise, and in whom cast treatment will be sufficient. Reduction with general anesthesia is preferred for older patients and for those with marked displacement, swelling, or associated neurovascular compromise in whom

percutaneous pin treatment is chosen.

AUTHOR'S PREFERRED METHOD OF TREATMENT

The reduction maneuver is the same regardless of anesthesia type or stabilization method. As opposed to a Colles' fracture in an adult, traction alone will not reduce the fracture because the dorsal periosteum acts as a tension band that does not respond to increasing linear traction with weights. Finger traps with minimal weight (less than 10 pounds) can be used to balance the hand and help with rotational alignment (the “steel resident”) (Fig. 9-59). However, applying progressive weight will only distract the carpus and will not alter the fracture alignment.

FIGURE 9-59. Once reduced, the fracture is maintained with finger trap traction and countertraction on the arm. The quality of reduction is assessed quickly with the image intensifier.

After applying preliminary traction with either light-weight finger traps or hand traction, a hyperdorsiflexion maneuver is performed (Fig. 9-48). The initial deformity is accentuated and the distal fragment is brought into marked dorsiflexion. The dorsum of the hand should be brought more than 90 degrees, and at times parallel to the dorsum of the forearm to lessen the tension on the dorsal forearm. Thumb pressure is used on the distal fragment while still in this deformed position (Fig. 9-48) to restore length by bringing the distal fragment beyond the proximal fragment. Reduction is then obtained by flexing the distal fragment while maintaining length (Fig. 9-49). Often this initial reduction maneuver restores length and alignment, but translational reduction is incomplete. The fracture should be completely reduced by toggling the distal fragment all the way volarly by repetitive slight dorsiflexion positioning of the distal fragment followed by volar pressure with the thumbs. It is important to anatomically reduce the fracture. Loss of reduction with cast immobilization is more likely if the fracture remains translated or malaligned.

If the patient presents late with marked swelling and the reduction is difficult, it is useful to try to lever the proximal fragment distally with a percutaneous smooth wire (Fig. 9-60). This may prevent an unnecessary open reduction. Percutaneous pin fixation is used after reduction.

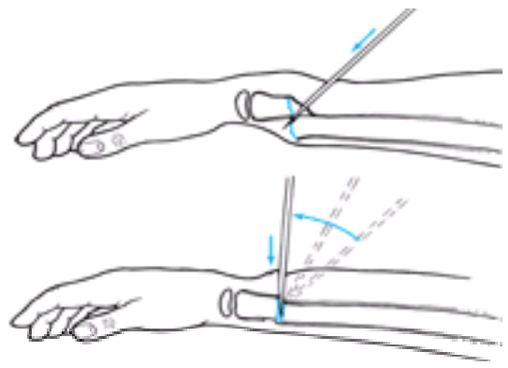

FIGURE 9-60. Pin leverage. **A:** If a bayonet is irreducible, after sterile preparation, a chisel-point Steinmann pin can be inserted between the fracture fragments from a dorsal approach. Care must be taken not to penetrate too deeply past the dorsal cortex of the proximal fragment. **B:** Once the chisel is across the fracture site, it is levered into position and supplementary pressure is placed on the dorsum of the distal fragment (*arrow*) to slide it down the skid into place. This procedure is usually performed with an image intensifier.

Cast Treatment

If the patient is under 10 years of age, has no prereduction signs or symptoms of neurovascular impairment, or has minimal swelling, then cast immobilization is used (Fig. 9-61 and Fig. 9-62). I use a long arm cast. The cast is applied with the aid either of an assistant or finger traps and balancing counter weights on the upper arm (Fig. 9-59). The advantage of the finger trap steel resident is that there is no risk of muscle fatigue, mental distraction, or failure to maintain elbow flexion at 90 degrees that can occur with a human assistant. The cast is applied with the elbow flexed 90 degrees, the wrist in slight palmar flexion, and the forearm in the desired rotation for stability and alignment. This varies with each fracture and each surgeon. My preference is slight supination (20–30 degrees) unless the fracture dictates differently. This allows excellent molding against the volar aspect of the distal radius at the fracture site.

FIGURE 9-61. A: Lateral radiograph of displaced metaphyseal radius and ulna fractures. **B:** Anteroposterior and lateral healed radiographs with anatomic alignment after closed reduction.

FIGURE 9-62. Anteroposterior and lateral radiographs of anatomic alignment with closed reduction of a distal radius metaphyseal fracture.

One of the most important elements in a successful long arm cast for a forearm fracture is the application of the webril. The webril should be applied in a continuous roll with overlap of one third to one half its width. Extra padding is applied over the olecranon, along the volar and dorsal forearm where the cast may have to be split, and at the ends of the cast to prevent irritation from fraying. Plaster of paris is used for the cast to obtain the best mold possible. Initially a single layer is applied, followed by splints five layers thick along the volar and dorsal forearm and the extension region of the elbow. This lessens the bulk of the cast and still allows deep molds. The cast is completed with plaster of paris rolls over the splints. A three-point mold is applied at the fracture site (Fig. 9-61) as the cast hardens. In addition, molds are applied to maintain a straight ulnar border, the interosseous space, and straight posterior humeral line. This creates the classic “box” long arm cast rather than the all too frequent “banana” cast that allows for displacement. Final radiographs are obtained, and if the reduction is anatomic, the cast is overwrapped with fiberglass to lessen the weight, increase patient satisfaction, and prevent cast breakdown that could lead to loss of reduction.

Patients are either discharged or admitted to the hospital depending on the degree of concern regarding risk of excessive swelling, neurovascular compromise, and patient and parental reliability. If there is any doubt, the patient is admitted for observation. The cast is split anytime there are signs of neurovascular compromise. The patient is instructed to maintain elevation for at least 48 to 72 hours after discharge and return immediately if excessive swelling or neurovascular compromise occurs. The patient and family are warned of the risk of loss of reduction and the need for close follow-up. We inform our patients and parents that the risk of return to the day surgery unit for repeat reduction is approximately 30% during the first 3 weeks.

Follow-up examinations and radiographs are obtained every 7 to 10 days for 3 weeks. If there is loss of reduction, I individualize treatment depending on the patient's age, degree of deformity, time since fracture, and remodeling potential (Fig. 9-53). If restoration of alignment with growth occurs, I reassure the family that the child should achieve anatomic alignment over time with growth. If the child is older, there is risk of further displacement, or the deformity is marked, repeat reduction in the day surgery unit with fluoroscopy is performed. Most often, a percutaneous pin is used for the second reduction (Fig. 9-55).

Cast immobilization usually is for 4 to 6 weeks. The long arm cast is changed to a short arm cast at 3 to 4 weeks. With clinical and radiographic healing (Fig. 9-61 and Fig. 9-62), a protective volar splint is used and activities are restricted until the patient regains full motion and strength, usually in 1 to 3 weeks after cast removal. As with other distal radial fractures, formal physical therapy is rarely required.

Percutaneous Pin Fixation

Percutaneous pinning of distal radial metaphyseal fractures is most often used in patients with excessive swelling or signs of neurologic injury. In these situations, the patient is at risk for development of a forearm or carpal tunnel compartment syndrome with a well-molded, tight-fitting cast. Similarly, concurrent displaced supracondylar and distal radial fractures are treated with percutaneous fixation of both fractures to lessen the risk of neurovascular compromise. Older patients near the end of growth with bayonet apposition fractures also are treated with percutaneous pin fixation because they have less ability to remodel and their fractures are very unstable with a high risk of displacement. Finally, open fractures usually are treated with pin fixation.

The pinning technique for the radius is either a single radial-sided pin or crossed radial- and ulnar-sided pins. Fixation of the ulna rarely is necessary (Fig. 9-56). Stability with a single pin is checked with fluoroscopy, and if further fixation is needed, a second pin is added. The physis is avoided if possible. A small incision is made for the insertion of each pin to protect the radial sensory nerve and adjacent extensor tendons. Smooth pins are used and are removed in the office as soon as there is sufficient healing to make the fracture stable in a cast or splint, usually at 4 weeks. Rehabilitation is similar to that for cast-treated fractures.

Open Reduction

The two most common indications for open reduction are an open fracture (Haasbeck) and an irreducible fracture. All open fractures are irrigated and debrided in the operating room. The initial open wound is extended adequately to inspect and cleanse the open fracture site. After thorough irrigation and debridement, the fracture is reduced and stabilized. A cast is rarely applied in this situation because of concern about fracture stability, soft tissue care, and excessive swelling. Crossed pin fixation often is used with Gustib grade 1 or 2 open fractures. More severe soft tissue injuries usually require external fixation with a unilateral frame, with care taken to avoid soft tissue impingement during pin placement. If flap coverage is necessary for the soft tissue wounds, the fixator pins should be placed in consultation with the microvascular surgeon planning the soft tissue coverage.

Irreducible fractures are usually secondary to soft tissue entrapment. With dorsal displacement, this is most often either the volar periosteum or pronator quadratus, and open reduction through a volar approach is necessary to extract the interposed soft tissues and reduce the fracture (Fig. 9-63). Percutaneous pin fixation usually is used to stabilize the fracture in patients with open physes. If plate fixation is used, it should avoid violation of the physis (Fig. 9-36). Displaced intraarticular injuries in skeletally immature patients are adultlike and require standard treatment such as open reduction and internal fixation (Fig. 9-21) or combination treatment with internal and external fixation (Fig. 9-22).

Complications

Distal radial metaphyseal fractures have complications similar to physeal fractures but with different frequencies. Loss of reduction and malunion are the most

common problems, and growth-related complications are infrequent. Neurovascular compromise does occur and should be considered in the acute management of this fracture.

Malunion

Loss of reduction is a common complication of distal radial metaphyseal fractures treated with cast immobilization. Because this complication occurs in at least 30% of bayonet apposition fractures (126,139,146,166,167), many surgeons treat this fracture primarily with pin fixation to avoid the problems that can occur with malunion (Fig. 9-51). Otherwise it is clear that patients treated with cast immobilization need to be monitored closely (172).

Fortunately, many angular malunions of the distal radius will remodel (13,74,76,103,111,121,122 and 123,137,144,149), probably because of asymmetric physeal growth (136,137). The younger the patient, the less the deformity, and the closer the fracture is to the physis, the greater the potential for remodeling. It is unclear whether there is any capacity for rotational malunion remodeling (124,150). Angular and rotational malunion that does not remodel can lead to loss of motion. The degree and plane of loss of motion, as well as the individual affected, determine if this is functionally significant (172). Cadaveric studies indicate that residual malangulation of more than 20 degrees of the radius or ulna will lead to loss of forearm rotation (140,158,159). Less than 10 degrees of malangulation did not alter forearm rotation significantly in either study. Distal third malunion affected rotation less than middle or proximal third malunion. Radioulnar malunion affected forearm rotation more than volar-dorsal malunion. Malangulation may lead to a loss of rotation at a 1 : 2 degree ratio, whereas malrotation may lead to rotational loss at only a 1 : 1 degree loss (86). The functional loss associated with rotational motion loss is difficult to predict. This has led some clinicians to recommend no treatment (110,111), arguing that most of these fractures will remodel, and those that do not remodel will not cause a functional problem (134). However, a significant functional problem is present if shoulder motion cannot compensate for loss of supination.

I prefer to reduce these fractures as anatomically as possible and lessen the risk of malunion. No element of malrotation is accepted in the reduction. As indicated in the treatment sections, fractures at high risk of loss of reduction and malunion are treated with anatomic reduction and pin fixation. Fractures treated in a cast are followed closely and re-reduced for any loss of alignment of more than 10 degrees. Although loss of rotation can occur with anatomic reduction (32,142,168), it is less likely than with malunions.

Nonunion

Nonunion of a closed radial or ulnar fracture is rare. In children, nonunion has been universally related to a pathologic condition of the bone or vascularity (168). Congenital pseudarthrosis or neurofibromatosis (135) (Fig. 9-64) should be suspected in a patient with a nonunion after a benign fracture. This occurs most often in an isolated ulnar fracture. The distal bone is often narrowed, sclerotic, and plastically deformed. These fractures rarely heal with immobilization. Vascularized fibular bone grafting usually is necessary for healing of a nonunion associated with neurofibromatosis or congenital pseudarthrosis. If the patient is very young, this may include a vascularized epiphyseal transfer to restore distal growth.

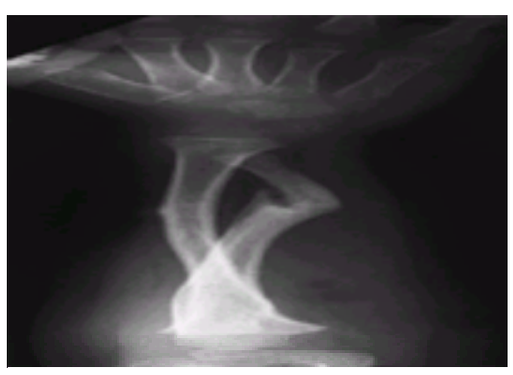

FIGURE 9-64. This 3-year-old presented to the emergency room with pain after an acute fall on his arm. The ulna is clearly pathologic with thinning and deformity prior to this injury. This represents neurofibromatosis.

Vascular impairment also can lead to nonunion. Distal radial nonunion has been reported in a child with an ipsilateral supracondylar fracture with brachial artery occlusion. Revascularization of the limb led to eventual union of the fracture. Nonunion also can occur with osteomyelitis and bone loss (44). Debridement of the necrotic bone and either traditional bone grafting, osteoclasis lengthening, vascularized bone grafting, or creation of a single-bone forearm are surgical options. The best choice depends on the individual patient.

Cross-Union

Cross-union is a rare complication of pediatric distal radial and ulnar fractures. It has been described after high-energy trauma and internal fixation (164). A single pin crossing both bones increases the risk of cross-union (164). Synostosis take-down can be performed, but the results usually are less than full restoration of motion. It is important to determine if there is an element of rotational malunion with the cross-union because this will affect the surgical outcome.

Soft tissue contraction across both bones also has been described (116). Contracture release resulted in restoration of forearm motion.

Refracture

Fortunately, refractures after metaphyseal radial fractures are rare and much less common than after diaphyseal level radial and ulnar fractures. Most commonly, refracture occurs with premature discontinuation of immobilization or early return to potentially traumatic activities. It is advisable to protectively immobilize the wrist until full radiographic and clinical healing (usually 6 weeks) and to restrict activities until full motion and strength are regained (usually an additional 1–3 weeks). Individuals involved in high-risk activities, such as downhill ski racing, snowboarding, or skateboarding, should be protected with a splint during those activities for much longer.

Growth Disturbance

Growth arrest of the distal radius after metaphyseal fracture is rare. Abram and Connolly each reported one patient with physeal arrest after nondisplaced torus fractures. Two additional patients were reported in a series of 150 distal radial metaphyseal fractures (119). Wilkins and O'Brien (168) proposed that these arrests may be in fractures that extend from the metaphysis to the physis. This coincides with a Peterson type I fracture (81,82) (Fig. 9-65) and in essence is a physeal fracture. These fractures should be monitored for growth arrest.

FIGURE 9-65. Peterson type I physeal injury. **A:** A comminuted distal metaphyseal fracture that extends to the physis (*open arrow*). **B:** Six weeks after the fracture, the callus also extends up to the physis (*open arrow*).

Both undergrowth and overgrowth of the distal radius after fracture has been described by DePablos (114). The average difference in growth was 3 mm, a range of —5 to +10 mm of growth disturbance compared with the contralateral radius. Maximal overgrowth occurred in the 9- to 12-year-old age group. As long as the patient is asymptomatic, under- or overgrowth is not a problem. If ulnocarpal impaction or DRUJ disruption occurs, then surgical rebalancing of the radius and ulna may be necessary.

Neurovascular Injuries

Both the median and ulnar (106,163) nerves are less commonly injured in metaphyseal fractures than in physeal fractures. The mechanisms of neural injury in a metaphyseal fracture include direct contusion from the displaced fragment, traction ischemia from tenting of the nerve over the proximal fragment (144), entrapment of the nerve in the fracture site (40,170), rare laceration of the nerve (Fig. 9-66), and the development of an acute compartment syndrome. If signs or symptoms of neuropathy are present, a prompt closed reduction should be performed. Extreme positions of immobilization should be avoided because this can lead to persistent traction or compression ischemia and increase the risk of compartment syndrome. If there is marked swelling, it is better to percutaneously pin the fracture than to apply a constrictive cast. If there is concern about compartment syndrome, the forearm and carpal canal pressures should be measured immediately. If pressures are markedly elevated, appropriate fasciotomies and compartment releases should be performed immediately. Finally, if the nerve was intact before reduction and is out after reduction, neural entrapment should be considered, and surgical exploration and decompression may be required. Fortunately, most median and ulnar nerve injuries recover after anatomic reduction of the fracture.

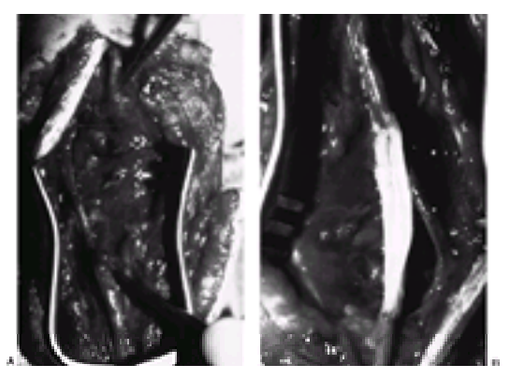

FIGURE 9-66. A grade III open fracture of the radius resulted in complete disruption of the ulnar nerve. Intraoperative photographs of the nerve deficit between the operative jeweler's forceps **(A)** and sural nerve grafting **(B)** after the wound was clean enough to allow for nerve reconstruction.

Infection

Infection after distal radial fractures is rare and is associated with open fractures or surgical intervention. Fee et al. (117) described the development of gas gangrene in four children after minor puncture wounds or lacerations associated with distal radial fractures. Treatment involved only local cleansing of the wound in all four and wound closure in one. All four developed life-threatening clostridial infections. Three of the four required upper limb amputations, and the fourth underwent multiple soft tissue and bony procedures for coverage and treatment of osteomyelitis.

Infections related to surgical intervention also are rare. Superficial pin site infections can occur and should be treated with pin removal and antibiotics. Deep-space infections from percutaneous pinning of the radius has not been described, but it is only reasonable to think that it will occur at some point. All deep-space infections should be treated with appropriate surgical debridement, antibiotics, and wound management.

PEDIATRIC GALEAZZI FRACTURES

Fractures of the distal radius associated with DRUJ disruption have been called Galeazzi fracture–dislocations. Although Sir Ashley Cooper is credited with the first description of this injury in 1824, Riccardo Galeazzi (177,188) (Fig. 9-67) gave this fracture–dislocation its name with his 1934 report of 18 such injuries. In children, this injury may involve either disruption of the DRUJ ligaments or, more commonly, a distal ulnar physeal fracture. The former is called a true Galeazzi lesion and the latter is a Galeazzi equivalent lesion (Fig. 9-68) (60,181,182,187,188).

permission.)

Anatomy

The radius normally rotates around the relatively stationary ulna. The two bones of the forearm articulate at the proximal and distal radioulnar joints. In addition, proximally the radius and ulna articulate with the distal humerus and distally with the carpus. These articulations are responsible for forearm pronation and supination, as well as elbow and wrist flexion and extension. At the DRUJ, the concave sigmoid notch of the radius incompletely matches the convex, asymmetric, semicylindrical shape of the distal ulnar head (Fig. 9-69) (3). This allows some translation at the DRUJ with rotatory movements. The ligamentous structures are critical in stabilizing the radius as it rotates about the ulna.

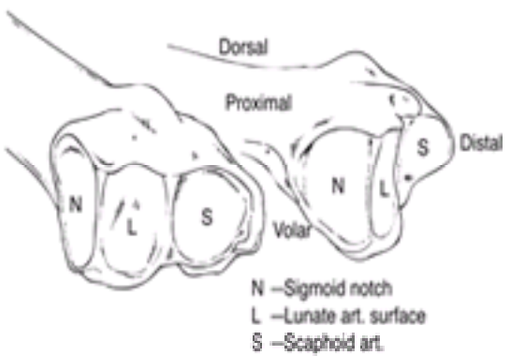

FIGURE 9-69. (Redrawn from Bowers WH. *Green's Operative Hand Surgery*. New York: Churchill–Livingstone, 1993:988.)

The DRUJ includes multiple soft tissue attachments, the most important of which is the TFCC. The TFCC includes the volar and dorsal ligamentous attachments of the distal ulna to the radial sigmoid notch, as well as the distal extension to the ulnar styloid, carpus, and base of the fifth metacarpal. The volar ulnocarpal ligaments (V ligament) from the ulna to the lunate and triquetrum are important ulnocarpal stabilizers (3,190,196). The central portion of the TFCC is the articular disk (Fig. 9-70). The interaction between the bony articulation and the soft tissue attachments accounts for stability of the DRUJ during pronation and supination. At the extremes of rotation, the joint is most stable. The compression loads between the radius and ulna are aided by the tensile loads of the TFCC to maintain stability throughout rotation (Fig. 9-71).

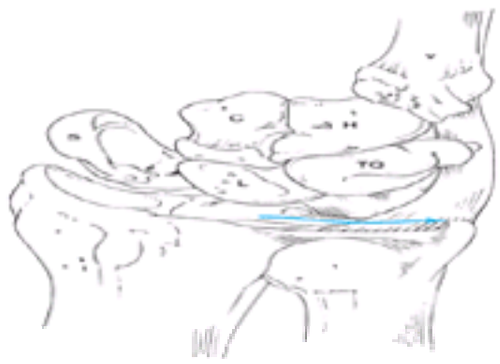

FIGURE 9-70. Diagrammatic drawing of the meniscal reflection and the prestyloid recess. The meniscal reflection runs from the dorsoulnar radius to the ulnovolar carpus. The arrow denotes access under the reflection to the tip of the styloid—the so-called prestyloid recess. (Redrawn from Bowers WH. *Green's Operative Hand Surgery*. New York: Churchill–Livingstone, 1993.)

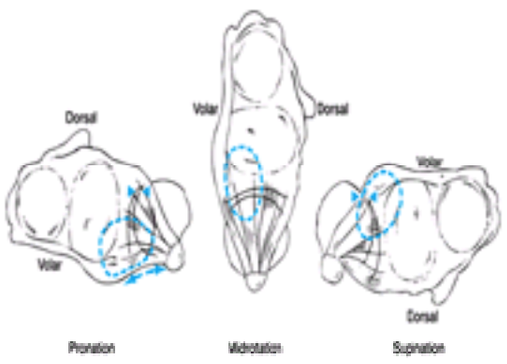

FIGURE 9-71. Distal radioulnar joint stability in pronation (left) is dependent on (1) tension developed in the volar margin of the triangular fibrocartilage (*TFC, small arrows*) and (2) compression between the contact areas of the radius and ulna (volar surface of ulnar articular head and dorsal margin of the sigmoid notch, *large arrows*). Disruption of the volar TFC would therefore allow dorsal displacement of the ulna in pronation. The reverse is true in supination, where disruption of the dorsal margin of the TFC would allow volar displacement of the ulna relative to the radius as this rotational extreme is reached. The dark area of the TFC emphasizes the portion of the TFC that is not supported by the ulnar dome. The dotted circle is the arc of load transmission (lunate to TFC) in that position. (Redrawn from Bowers WH. *Green's Operative Hand Surgery*. New York: Churchill–Livingstone, 1993.)

Throughout the mid-forearm, the interosseous ligament (Fig. 9-72) connects the radius to the ulna. It passes obliquely from the proximal radius to the distal ulna. However, the interosseous ligament is not present in the distal radius. Moore et al. found that injuries to the TFCC and interosseous ligament were responsible for progressive shortening of the radius with fracture in a cadaveric study. The soft tissue component to the injury is a major factor in the deformity and instability in a Galeazzi fracture–dislocation.

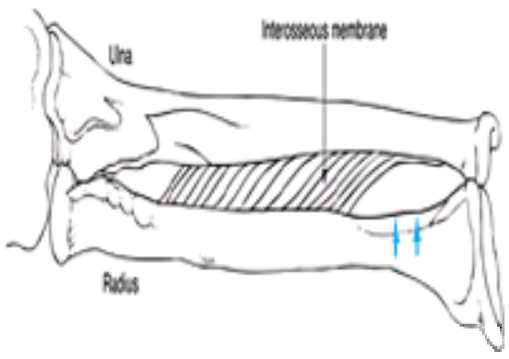

FIGURE 9-72. The attachment and the fibers of the interosseous membrane are such that there is no attachment to the distal radius. (Redrawn from Kraus B, Horne G. Galeazzi fractures. *J Trauma* 1985;25:1094; with permission.)

Diagnosis

Galeazzi fracture–dislocations are relatively rare injuries in children. Walsh and McLaren (194) cited an incidence of 3% of pediatric distal radial fractures in their study. Most series of Galeazzi fracture contain a relatively small number of pediatric patients (81,182,183,194).

The mechanism of injury is axial loading in combination with extremes of forearm rotation (175,187,189,191). In adults, the mechanism of injury usually is an axially loading fall with hyperpronation. This results in a distal radius fracture with a dorsal ulnar dislocation. However, in children, both supination (apex volar) and pronation (apex dorsal) deforming forces have been described (181,182,194). The mechanism of injury is most obvious when the radial fracture is an incomplete fracture. With an apex volar (supination) radial fracture, the distal ulna is displaced volarly, whereas with an apex dorsal (pronation) radial fracture, the distal ulna is displaced dorsally (Fig. 9-68 and Fig. 9-69). This is evident both on clinical and radiographic examinations. In addition, the radius is foreshortened in a complete fracture, causing more radial deviation of the hand and wrist (Fig. 9-70). A child with a Galeazzi injury has pain and limitation of forearm rotation and wrist flexion and extension. Neurovascular impairment is rare.

The radial fracture is evident on radiographs, and concurrent injuries to the ulna or DRUJ should be identified. A true lateral view is necessary to identify the direction of displacement, which is imperative to determine the method of reduction. Rarely are special radiographs, such as a CT scan, necessary.

Classification

Galeazzi fracture–dislocations are most commonly described by direction of displacement of either the distal ulnar dislocation or the radial fracture. Letts (181,182) preferred to describe the direction of the ulna: volar or dorsal. Walsh and McLaren (194) classified pediatric Galeazzi injuries by the direction of displacement of the distal radial fracture. Dorsal displacement (apex volar) fractures were more common than volar displacement (apex dorsal) fractures in their series (Fig. 9-73). Wilkins and O'Brien (168) modified the Walsh and McLaren method by classifying radial fractures as incomplete and complete fractures and ulnar injuries as true dislocations and physeal fractures (Table 9-4). DRUJ dislocations are called true Galeazzi lesions and distal ulnar physeal fractures are called Galeazzi equivalent lesions (60,178,181,182).

FIGURE 9-73. Walsh's classification. **A:** The most common pattern, in which there is dorsal displacement with supination of the distal radius (*open arrow*). The distal ulna (*black arrow*) lies volar to the dorsally displaced distal radius. **B:** The least common pronation pattern. There is volar or anterior displacement of the distal radius (*open arrow*), and the distal ulna lies dorsal (*black arrow*). (Reprinted from Walsh HPJ, McLaren CANP. Galeazzi fractures in children. *J Bone Joint Surg [Br]* 1987;69:730–733; with permission.)

Type I: Dorsal (apex volar) displacement of distal radius
- Radius fracture pattern
  - Greenstick
  - Complete
- Distal ulna physis
  - Intact
  - Disrupted (equivalent)

Type II: Volar (apex dorsal) displacement of distal radius
- Radius fracture pattern
  - Greenstick
  - Complete
- Distal ulna physis
  - Intact
  - Disrupted

TABLE 9-4. CLASSIFICATION: GALEAZZI FRACTURES IN CHILDREN

Treatment

Pediatric Galeazzi fractures have a higher success rate with nonoperative treatment than similar injuries in adults (183,187). In adults, it is imperative to anatomically reduce and internally fix the distal radial fracture (180,183,184,185,187). Generally the DRUJ is reduced with reduction and fixation of the radius. In pediatric patients, the distal radial fracture often is a greenstick type that is stable after reduction and cast immobilization is sufficient (183,194). However, adolescents with complete fractures should be treated with internal fixation similar to adults.

Closed Reduction

The method of reduction for greenstick radial fractures depends on the type of displacement. With apex volar dorsally displaced fractures of the radius, the rotatory deformity is supination. Pronating the radius and applying dorsal-to-volar reduction force should align the fracture and reduce the DRUJ (Fig. 9-74). Similarly, if the incomplete radial fracture is an apex dorsal volar displaced fracture, the rotatory deformity is pronation (Fig. 9-75). Supinating the forearm and applying volar-to-dorsal force should reduce the incomplete fracture of the radius and the DRUJ dislocation (168,181,182,193). In both these situations, portable fluoroscopy

can be used to evaluate the fracture–dislocation reduction and to test the stability of the distal ulna. If anatomically reduced and stable, a long arm cast is applied with appropriate rotation and three-point molds. The cast is left in place for 6 weeks to allow the soft tissue injuries to heal.

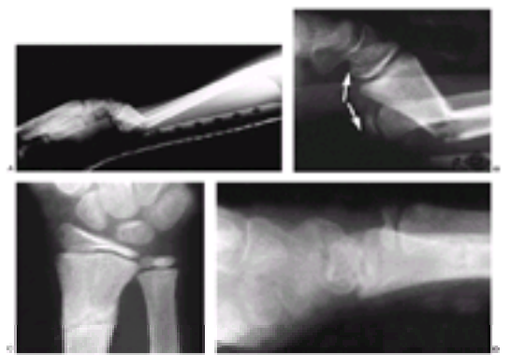

FIGURE 9-74. Supination-type Galeazzi fracture. **A:** View of the entire forearm of an 11-year-old boy with a Galeazzi fracture–dislocation. **B:** Close-up of the distal forearm shows that there has been disruption of the distal radioulnar joint (*arrows*). The distal radial fragment is dorsally displaced (apex volar), making this a supination type of mechanism. Note that the distal ulna is volar to the distal radius. **C and D:** The fracture was reduced by pronating the distal fragment. Because the distal radius was partially intact by its greenstick nature, the length was easily maintained, reestablishing the congruity of the distal radioulnar joint. The patient was immobilized in supination for 6 weeks, after which full forearm rotation and function returned.

FIGURE 9-75. Pronation Galeazzi. This 8-year-old sustained a pronation Galeazzi fracture. **A:** The anteroposterior view shows some shortening of the distal radius (*arrow*) in relation to the distal ulna, which has a small greenstick component. **B:** The pronation component (*arrow*) is better appreciated on this lateral view. The distal ulna lies dorsal to the distal radius (*open arrow*).

In a Galeazzi equivalent injury with a radial fracture and an ulnar physeal fracture, both bones should be reduced. Usually this can be accomplished with the same methods of reduction if the radial fracture is incomplete. The distal ulnar physis can remodel a nonanatomic reduction if there is sufficient growth remaining and the ulnar physis continues to grow normally. Unfortunately, the risk of ulnar growth arrest after a Galeazzi equivalent has been reported to be as high as 55% (52).

Complete fractures of the distal radius have a higher rate of loss of reduction after closed treatment (168). If not monitored closely and re-reduced if necessary, loss of reduction can lead to malunion with loss of motion and function. These injuries may be best treated with open reduction as in adults.

Open Reduction

The indication for open reduction of the radial fracture is failure to obtain or maintain fracture reduction. This most often occurs with unstable complete fractures (Fig. 9-76). Open reduction and internal fixation of the radius are performed via an anterior approach (Fig. 9-77). Standard compression plating is preferred to intramedullary or cross-pinning techniques. Stable, anatomic reduction of the radius almost always leads to stable reduction of the DRUJ dislocation. A long arm cast is used for 6 weeks to allow fracture and soft tissue healing.

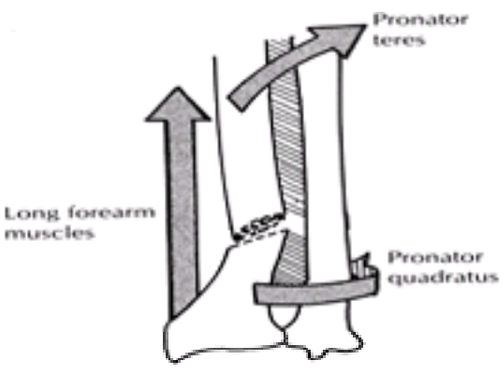

FIGURE 9-76. Fractures of the distal radius are angulated toward the ulna due to the pull of the long forearm muscles and the pronator quadratus. (Redrawn from Cruess RL. The management of forearm injuries. *Orthop Clin North Am* 1973;4:969–982; with permission.)

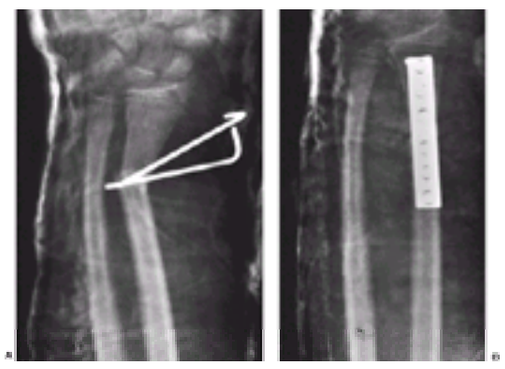

FIGURE 9-77. A: The patient with the pronation injury shown in Fig. 9-69 had a closed reduction and attempted fixation with pins placed percutaneously across the fracture site. However, this was inadequate in maintaining the alignment and length of the fracture of the distal radius. **B:** The length of the radius and the distal radioulnar relationship were best reestablished after internal fixation of the distal radius with a plate placed on the volar surface. The true amount of shortening present on the original injury film (see Fig. 9-69A) is not really appreciated until the fracture of the distal radius is fully reduced. (Reprinted from Wilkins KE, ed. *Operative management of upper extremity fractures in children.* Rosemont, IL: American Academy of Orthopaedic Surgeons, 1994:34; with permission.)

Occasionally, the DRUJ dislocation cannot be reduced (Fig. 9-78) because of interposed soft tissues, most commonly the periosteum, extensor tendons (extensor carpi ulnaris, extensor digit quinti), TFCC, or other ligamentous structures (173,174,179,182). The easiest approach for open reduction of the DRUJ is an extended ulnar approach. Care should be taken to avoid injury to the ulnar sensory nerve. This approach allows for exposure both volarly and dorsally to extract the interposed soft tissues and repair the torn structures. Smooth pin fixation of the DRUJ can be used to maintain reduction and allow application of a loose-fitting cast. The pin is removed in the office at four weeks with continuation of the cast for 6 weeks.

FIGURE 9-78. An adolescent girl presented 4 weeks postinjury with a painful, stiff wrist. **A:** By examination, she was noted to have a volar distal radioulnar dislocation that was irreducible even under general anesthesia. **B:** At the time of surgery the distal ulna was noted to have buttonholed out of the capsule, and there was entrapped triangular fibrocartilage and periosteum in the joint.

Similarly, the ulnar physeal fracture can be irreducible in a Galeazzi equivalent injury. This also has been reported to be secondary to interposed periosteum (60,187), extensor tendons (48,57,103), or joint capsule (176). Open reduction must be executed with care to avoid further violating the physis.

AUTHOR'S PREFERRED METHOD OF TREATMENT

Incomplete Fractures

Incomplete fractures of the distal radius with either a true dislocation of the DRUJ or an ulnar physeal fracture are treated with closed reduction and long arm cast immobilization. This can be performed in the emergency setting with conscious sedation or in the operating room with general anesthesia. Portable fluoroscopy is used. If the fracture is apex volar with dorsal displacement of the radius and volar dislocation of the DRUJ, then pronation and volar-to-dorsal force on the radial fracture is used for reduction. If the fracture is apex dorsal with volar displacement of the radius and dorsal dislocation of the DRUJ, then supination and dorsal-to-volar force is applied to the distal radius for reduction. The reduction and stability of the fracture and DRUJ dislocation are checked on dynamic fluoroscopy before long arm cast immobilization. If both are anatomically reduced and stable, the cast is used for 6 weeks to allow soft tissue and fracture healing. In a Galeazzi equivalent injury, there is potential for remodeling of the physeal fracture if sufficient growth remains. As long as the DRUJ is reduced, malalignment of less than 10 degrees can remodel in a young child. The risk of physeal growth arrest is high with this physeal injury, and operative exposure may increase the of growth impairment. If the fracture is severely malaligned, the DRUJ cannot be reduced, or the patient is older and remodeling is unlikely, open reduction and smooth pin fixation are indicated (168).

Complete Fractures

Open reduction and internal fixation with an anterior plate and screws are used for complete Galeazzi fractures of the radius. The DRUJ usually reduces anatomically and is stable with reduction and fixation of the radius. The patient is immobilized in a long arm cast for 4 weeks and a short arm cast for 2 more weeks. Return to unrestricted activities and sports depends on restoration of full motion and strength.

Irreducible Dislocations

Irreducible dislocations are treated with open reduction. Extensile exposure is necessary to define the pathologic anatomy and carefully reduce the DRUJ. The interposed soft tissues are extracted and repaired. Depending on the stability of the reduction and repair, a supplemental smooth pin may be used across the DRUJ for 4 weeks to maintain the joint reduction. This is particularly true if the patient presents late.

Complications

Malunion and DRUJ Subluxation

Malunion of the radius can lead to subluxation of the DRUJ, limited forearm rotation, and pain, usually secondary to persistent shortening and malrotation of the radial fracture. Most often this occurs when complete fractures are treated with closed reduction and there is failure to either obtain or maintain reduction of the radial fracture. The ulna remains subluxed and heals with an incongruent joint. Treatment for this requires proper recognition and corrective osteotomy. If physical examination is not definitive for diagnosis, then a CT scan in pronation, neutral rotation, or supination may be helpful. An MRI scan or wrist arthroscopy will aid in the diagnosis and management of associated ligamentous, chondral, or TFCC injuries that will benefit from debridement or repair. It is important to understand that if the DRUJ subluxation is caused by a radial malunion, a soft tissue reconstruction of the DRUJ alone will fail (3).

Ulnar Physeal Arrest

Golz and Ogden (52) cited a 55% incidence of ulnar physeal arrest with Galeazzi equivalent fractures. If the patient is young enough, this ulnar growth arrest in the presence of ongoing radial growth will lead to deformity. Initially there will be ulnar shortening. Over time, the foreshortened ulna can act as a tether, causing asymmetric growth of the radius. There will be increased radial articular inclination on the AP radiograph and subluxation of the DRUJ. Operative choices include ulnar lengthening, radial closing wedge osteotomy, radial epiphysiodesis, and a combination of the above procedures that is appropriate for the individual patient's age, deformity, and disability.

Nerve Injury

Injuries to the ulnar nerve (183) and anterior interosseous nerve (192,195) have been described with Galeazzi fracture–dislocations. These injuries have had spontaneous recovery. Moore et al. (186) described an 8% incidence of injury to the radial nerve with operative exposure of the radius for internal fixation in their series. Careful surgical exposure, dissection, and retraction can decrease this risk.

ACKNOWLEDGMENT

I thank the previous authors of this section, Drs. Kaye E. Wilkins and Eugene O'Brien, for their outstanding contributions and previous work. It is a pleasure to continue their fine chapter in this edition.

Peter M. Waters: Department of Orthopedic Surgery, Children's Hospital, Harvard School of Medicine, Boston, Massachusetts.

INJURIES TO THE SHAFTS OF THE RADIUS AND ULNA

CHARLES T. PRICE
GREGORY A. MENCIO

FRACTURES OF THE SHAFTS OF THE RADIUS AND ULNA

Fractures of the radius and ulna shafts account for only 3% to 6% of all children's fractures (64,65) (Fig. 0-1). In boys, there is a bimodal peak, the first at approximately age 9 years and the second at approximately 13 or 14 years of age. Girls show a single peak at approximately age 5 or 6 years (65). Approximately 75% of fractures of the shafts of the radius and ulna are in the distal third, 15% in the middle third, and 5% in the proximal third. Monteggia fracture–dislocations and complex injuries account for the remaining 5% (25,38,123).

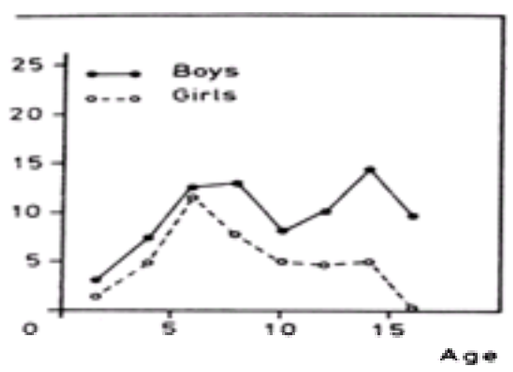

FIGURE 10-1. The annual incidence per 10,000 children of fractures of the shaft of the radius and ulna for the various age groups. Note the bimodal peaks for boys and single peak for girls. (From Landin LA. Fracture patterns in children: analysis of 8,682 fractures with special reference to incidence, etiology and secular changes in a Swedish urban population, 1950–1979. *Acta Orthop Scand Suppl* 1983;202:65; with permission.)

Traditional teaching (30,42) developed a concept of postreduction positioning based on which third of the radial and ulnar shafts was fractured:

1. If the fracture of the shafts was *proximal* to the insertion of the pronator teres, the forearm should be held in *supination.*
2. If the fracture was in the *middle third, mid-position* was advised.
3. If the fracture was in the *distal third, pronation* was the position of choice.

This concept was challenged by Evans, who recognized two groups of fractures: those in which the shaft of the radius remained in continuity and those in which it was completely displaced. He advocated pronation or supination of greenstick, Monteggia, and Galeazzi fractures based on the mechanism of injury (29,30). For complete fractures, Evans recommended determining the position of the bicipital tuberosity of the radius on an anteroposterior (AP) radiograph, then placing the distal fragment in the same amount of rotation to effect reduction (Fig. 10-2). He found that all such fractures usually needed to be immobilized in some degree of supination (Fig. 10-3).

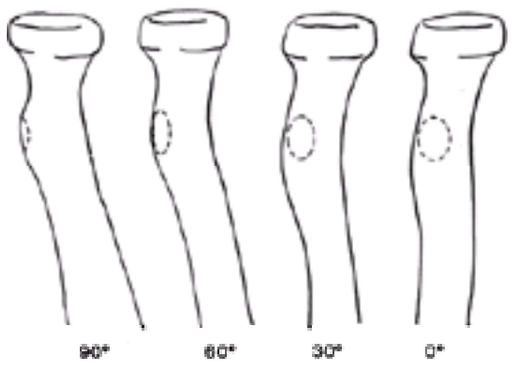

FIGURE 10-2. The normal bicipital tuberosity from full supination (90 degrees) to mid-position (0 degrees). In children, these characteristics are less clearly defined. (Redrawn from Evans EM. Fractures of the radius and ulna. *J Bone Joint Surg Br* 1951;33:548; with permission.)

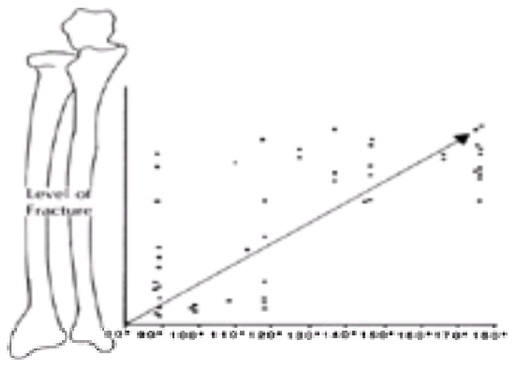

FIGURE 10-3. The rotational position of the upper radial fragment in 50 cases, plotted against the level of fracture. Each case is represented by a black dot. (Redrawn from Evans E. M. Fractures of the radius and ulna. *J Bone Joint Surg Br* 1951;33:548; with permission.)

Diagnosis

Mechanism of Injuries

Because cortical bone is strong, it often requires greater trauma to produce failure of the diaphysis than the metaphysis. As is typical of most fractures in the upper extremity, fractures of the radial and ulnar shafts usually are caused by indirect forces, such as landing on the outstretched upper extremity (Fig. 10-4). When the child falls, the main deforming force is transmitted to the radius. The radius usually fails first, followed by the ulna (128). Shaft fractures are more common in younger children because the cortical bone is more porous and the transition from diaphysis to metaphysis is less distinct than in older children (128).

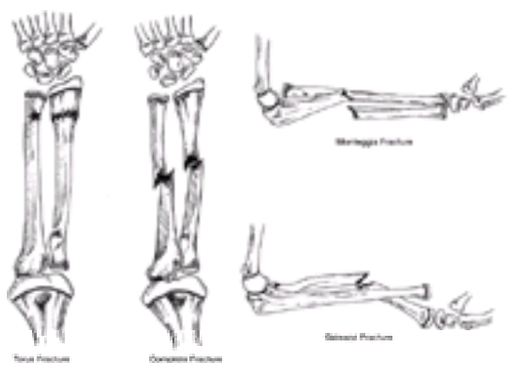

FIGURE 10-4. A fall on the outstretched hand can produce any of these shaft fractures: torus fracture **(A);** complete fracture **(B);** Monteggia fracture–dislocation **(C);** Galeazzi fracture–dislocation **(D).**

Signs and Symptoms

Pain, swelling, crepitus, and deformity make the diagnosis obvious. However, plastic deformation injuries present primarily with deformity, mild tenderness, and limited forearm rotation. Pain and swelling may be minimal and crepitus is absent in plastic deformation injuries and minor greenstick fractures.

Radiographic Findings

Rotational Alignment

Anteroposterior and lateral radiographs that include both the proximal and distal radioulnar joints are essential for an accurate analysis of rotation of the fracture fragments. The radius is a curved bone and malrotation can be recognized by a break in the smooth curve of the radius and a sudden change in the width of the cortex (17,68,76,82). Radiographs should also reveal whether fractures are complete or incomplete. Incomplete, or greenstick, fractures with angulation usually have a rotational deformity (Fig. 10-5). If the fracture is complete, the distal fragment may be in any position, but the position of the proximal fragment is determined by muscle pull.

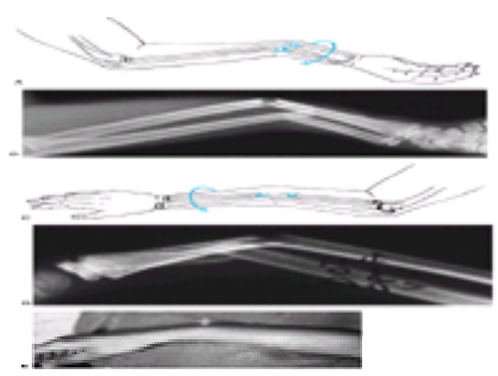

FIGURE 10-5. Angulation plus rotation. **A and B:** Forced supination of the forearm produces a fracture pattern with apex volar angulation in addition to dorsal displacement with supination of the distal fragment. **C and D:** Forced pronation of the forearm can result in a fracture pattern with apex dorsal angulation, in addition to pronation and volar displacement of the distal fragment. **E:** Clinically, the apex dorsal angulation *(arrow)* in pronation injuries is much more prominent.

For complete fractures, it is necessary to determine the position of the proximal fragment so that the distal fragment can be positioned to align with the same amount of rotation as the proximal fragment. This can be determined by the position of the bicipital tuberosity in the fractured radius. The bicipital tuberosity is medial when the forearm is supinated, posterior when in mid-position, and lateral when pronated (Fig. 10-2). If in doubt, radiographs of the opposite normal forearm should be obtained in supination, mid-position, and pronation to compare the position of the bicipital tuberosity.

Milch proposed the following anatomic criteria to determine proper torsional alignment of the forearm bones, regardless of the degree of rotation (76):

1. The coronoid process of the ulna points anteriorly and the styloid process of the ulna points posteriorly in the lateral projection. The radial styloid is not seen in the normal lateral projection with the forearm supinated.
2. In the normal AP view with the forearm supinated, the coronoid and styloid processes of the ulna are hidden but the radial styloid and bicipital tuberosity are seen. For example, in a completely supinated normal forearm, an AP view shows both the bicipital tuberosity and the radial styloid, but neither the coronoid process nor the ulnar styloid is seen. The lateral view shows both the coronoid process and the ulnar styloid, but neither prominence of the radius is seen. Thus, if the styloid process of the ulna is seen on the AP view and is absent on the lateral view, a torsional deformity of the ulna is present. If the bicipital tuberosity of

the radius projects medially in the AP view and the radial styloid is not seen, torsional deformity of the radius is present.

3. In the mid-position no bony prominences are seen in the AP projection, but all four prominences are seen on the lateral view. Angulation usually is associated with rotation (Fig. 10-5).

Classification

The Orthopaedic Trauma Association (OTA) has classified fractures of the radius and ulna with the numeric designation of “2.” Diaphyseal fractures are classified with a second number “2.” Thus, all shaft fractures of the radius and ulna are designated “22.” Simple fractures are given the letter “A,” wedge fractures are “B,” and complex fractures are “C” (Fig. 10-6). Wedge and complex fractures are uncommon in children, so most pediatric shaft fractures are designated 22-A. When only the ulna is fractured, this is identified with an additional numeral “1” (22-A1). An isolated simple radial fracture is identified with an additional “2” (22-A2). The most common fracture is a simple fracture of both bones. Simple both-bone shaft fractures are identified by adding the numeral “3” (22-A3) (Fig. 10-7). Subgroups are identified by placing a decimal and using additional numerals. For example, a simple fracture of the ulnar shaft with radial head dislocation, Monteggia fracture–dislocation, is identified as 22-B1.3 (Fig. 10-8). More complex fractures have additional alphanumeric classifications to allow for standardization of research and communication (92).

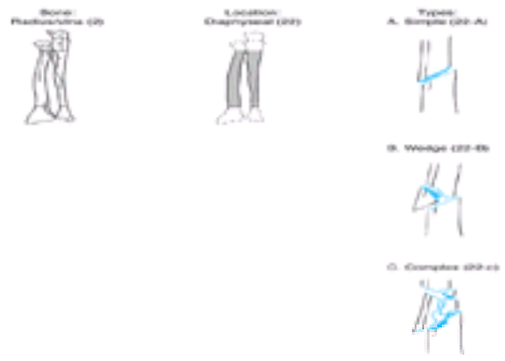

FIGURE 10-6. Orthopedic Trauma Association Classification. Fractures of the radius and ulna are designated by the numeral “2.” Diaphyseal fractures are identified by a second numeral “2.” Simple fractures are given the letter “A,” wedge fractures are “B,” and complex fractures are “C.” (Redrawn from Orthopaedic Trauma Association Committee for Coding and Classification. Fracture and dislocation compendium. *J Orthop Trauma* 1996;10[Suppl 1]:1; with permission.)

FIGURE 10-7. Orthopedic Trauma Association Classification. When only the ulna is fractured, this is identified by the additional numeral “1.” Isolated radius fracture is identified with an additional “2.” Both bone fractures are identified by adding the numeral “3.” (Redrawn from Orthopaedic Trauma Association Committee for Coding and Classification. Fracture and dislocation compendium. *J Orthop Trauma* 1996;10[Suppl 1]:1; with permission.)

FIGURE 10-8. Orthopedic Trauma Association Classification. Subgroups of forearm fractures are identified by the use of a decimal and additional numerals. Monteggia fracture dislocation is classified 22-B1.3. (Redrawn from Orthopaedic Trauma Association Committee for Coding and Classification. Fracture and dislocation compendium. *J Orthop Trauma* 1996;10[Suppl 1]:1; with permission.)

The OTA Classification System has some deficiencies when applied to pediatric and adolescent forearm fractures. Greenstick fractures and plastic deformation are not classified separately. Comminution is rare in children and often has little clinical significance. Treatment decisions in the pediatric age group rarely depend on specific classification. Closed reductions are common in the pediatric age group and clinical decisions are based on degree of completion and level of the fracture, combined with severity and direction of deformity.

The traditional classification of shaft fractures of the radius and ulna is outlined in the following sections.

Joints Intact

Shaft fractures in which the proximal and distal radioulnar joints remain intact can be subcategorized by their degree of completion, direction of deformity, or level of fracture (Table 10-1):

Radioulnar Joint Intact
- *Degree of completeness*
  - Plastic deformation
  - Greenstick fracture
  - Complete disruption
- *Direction of deformity (greenstick)*
  - Apex volar (supination injury)
  - Apex dorsal (pronation injury)
- *Level of fracture*
  - Proximal third
  - Middle third
  - Distal third

Radioulnar joints disrupted
- Proximal—Monteggia fracture–dislocation complex
- Distal—Galeazzi fracture

TABLE 10-1. CLASSIFICATION: SHAFT FRACTURES

Degree of completion: The degree of completion usually is defined as plastic deformation, greenstick, or complete. Proper identification is important because each of these types is managed differently.

Direction of deformity: The direction of the deformity can be identified as either apex volar (supination injury) or apex dorsal (pronation injury). This distinction is particularly important for management of greenstick fractures.

Level of fracture: The level of fracture is identified as occurring in the proximal, middle, or distal third.

Joints Disrupted

These types of forearm shaft fractures include Monteggia fracture–dislocation, when the ulnar shaft fracture is associated with radial head dislocation proximally, and Galeazzi fracture–dislocation, when the radial shaft fracture is associated with dislocation of the distal radioulnar joint. Monteggia and Galeazzi fractures are discussed elsewhere in this textbook, but the clinician must always be cognizant of the possibility of occult or missed joint disruption whenever a forearm fracture is identified.

Unusual Fracture Patterns

Plastic deformation injuries also may be difficult to detect and require special management techniques.

The so-called floating elbow (Fig. 10-9) is a special variant that combines a fracture of the humerus with a forearm fracture. Ipsilateral forearm fractures are seen in 3% to 13% of supracondylar fractures (99,119,149). The supracondylar fracture usually is displaced and requires closed reduction with pinning before the forearm fracture can be treated. Nondisplaced supracondylar fractures may not require pinning (149). After stabilization of the supracondylar fracture, the forearm fracture can be treated with closed reduction and plaster immobilization if the forearm fracture is stable or minimally displaced (99,119,149). However, when the forearm fracture is unstable or open, or if there is extensive soft tissue injury, plate or intramedullary fixation may be a more appropriate method to maintain reduction (Fig. 10-10).

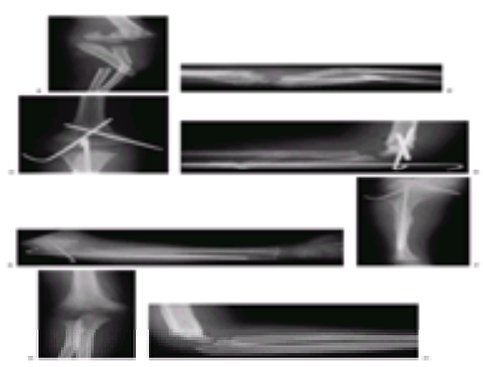

FIGURE 10-9. "Floating elbow" injury. **A and B:** A 5-year-old with ipsilateral grade II open fracture of the radius and ulna and a type III, closed supracondylar humerus fracture. **C and D:** Irrigation and debridement of the forearm wound followed by intramedullary stabilization of the ulna. The supracondylar fracture was treated by open reduction and pinning. **E and F:** All fractures healed at 4 weeks after surgery before pin removal in the office. **G and H:** Forearm and elbow at 1 year after surgery are virtually anatomic.

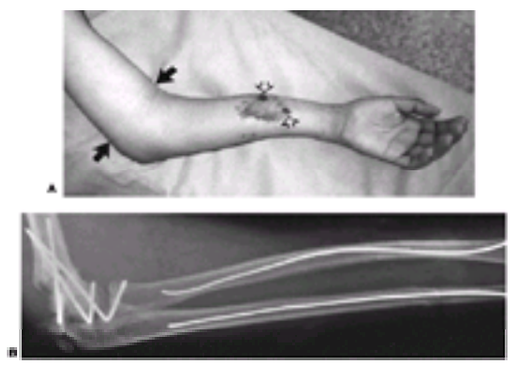

FIGURE 10-10. Ipsilateral supracondylar fractures. **A:** A 10-year-old with grade I open fractures of the radius and ulna *(open arrows).* An ipsilateral supracondylar fracture is manifest by considerable swelling at the elbow *(large black arrows).* **B:** The supracondylar fracture was first manipulated and reduced and then secured with pins placed percutaneously. The forearm fracture was then cleaned and debrided, and secured with intramedullary pins inserted distally.

Segmental, comminuted, or open forearm fractures usually indicate high-energy trauma. More aggressive management usually is warranted for these types of injuries.

Anatomy

The radius bows laterally immediately distal to the bicipital tuberosity. The bicipital tuberosity is distal to the neck on the medial aspect of the shaft and slightly anterior. The radius has one distinct border for the attachment of the interosseous membrane. The proximal radius is cylindrical, changing to a triangular shape at the junction of the proximal and middle thirds and flattening at its lower end. The radius, like the ulna, is a thick-walled bone throughout the greater part of the shaft.

The radius is bound to the ulna by the interosseous membrane and annular ligament at the proximal radioulnar joint. The triangular articular disk binds the radius to the ulna at the distal radioulnar joint. These structures allow pronation and supination movements of the forearm. The interosseous distance is greater distally than proximally because of the curve of the radius. In pronation, the radius rotates diagonally across the ulna and the palm faces posteriorly. The crossover point of the two bones is in the proximal forearm. Walker demonstrated that longitudinal forces of less than 9.8 kg are transmitted by the interosseous membrane to the ulnohumeral

joint and loads of greater magnitude are transmitted to the radiohumeral joint (142).

Treatment Principles

The objective of successful treatment of greenstick or complete fractures is full recovery of forearm rotation without cosmetic deformity. Delayed unions and nonunions are rare in children. Thus, closed reduction and cast immobilization is often successful and should be attempted in most fractures.

Cadaver studies (76,122) have demonstrated that 10 degrees of residual fixed angular deformity in the middle or distal third of the radius or ulna does not cause functional loss of forearm rotation. Rotatory deformities produced losses of pronation and supination equal to the degree of rotational deformity (122). Sarmiento et al. compared experimental results from cadaver studies with clinical radiographic findings in 105 patients with residual deformities and concluded that limitation of rotation is within clinically acceptable ranges with residual angulation of 10 degrees or less (113).

Spontaneous correction of residual angulation can occur in children. The amount of correction depends on age, the distance from the physis, the severity of deformity, and the direction of angulation. Greater degrees of correction can be expected in younger children and in more distal fractures (11,24,38,54,89,139,153). Onne and Sandblom observed that during the first decade of life, the shafts of the forearms have an excellent capacity of correcting angulation up to 20 degrees spontaneously (89). Others have confirmed this remodeling potential (38,50,79,95,96,123,139). The capacity for remodeling diminishes after the age of 10 years. Angulation of more than 10 degrees after the age of 10 years is unlikely to remodel (35,50,54,89,95,96,139).

Malrotation is difficult to measure and may or may not remodel (21,35,42,95,96). Fuller and McCullough observed that malrotation of the fracture limited movement to the same degree as the rotational deformity (35). Grant and Weiss observed that malrotation does not correct with growth, but noted that 30 degrees of malrotation may be accepted without functional deficit (42).

Determining acceptable limits for angulation at the time of reduction is complicated by the fact that malunion does not always correlate with loss of forearm rotation. Daruwalla observed that it is difficult to predict the extent of limitation of forearm movement with varying degrees of angulation (24). Hogstrom et al. observed that the correlation between final angulation and range of pronation and supination is weak (50). This observation has been confirmed by others (42,51,84,95,96,153).

From a functional standpoint, Carey et al. (15) noted that patients older than 10 years of age might have residual changes on radiographs without a commensurate loss in range of motion. They reported on nine patients, 11 to 15 years of age, with an average angulation of 13 degrees (range, 5–30 degrees). Five of the nine patients lost forearm rotation ranging from 20 to 35 degrees, but none had functional deficits. They concluded that none of these patients would have been better off with open reduction. Thomas et al. (123) reviewed 65 malunions in children up to age 15 years and concluded that up to 15 degrees of angular deformity is acceptable because the final loss of function is negligible. When treating forearm fractures, the clinician should consider the statement by Hey Groves that “art should secure supination and nature be trusted to secure pronation” (48). A supination loss cannot be compensated well by adduction at the shoulder, but a pronation loss can be masked by abduction at the shoulder.

Nilsson and Obrant examined 18 adults who had sustained displaced forearm fractures as children (84). All had been reduced and maintained in good position without displacement or angulation. The average loss of pronation–supination motion was 19 degrees, even in the absence of malunion. Thus, factors other than residual angulation may also be responsible for loss of forearm rotation (84,122).

Another difficulty in predicting functional outcome is that some younger patients lose forearm rotation regardless of remodeling (95,96). Younger et al. noted that the mean age of patients with restricted movement was 7.2 years (153). Holdsworth and Sloan noted that functional improvement is complete by 3 years after injury, but radiographic appearances may continue to improve beyond that time (51). As a rule, older patients are at greater risk for loss of pronation–supination motion, but this is not always the case (24,35,105).

Length discrepancy between the radius and ulna is uncommon after shaft fracture of one or both bones (21,27,95,96,139). Limb overgrowth or shortening does not occur if the physis is undamaged (15,27). This suggests that remodeling can occur with regard to length as well as angulation.

Overriding of fracture fragments is another consideration. Blount and Johnson stated that overriding with bayonet apposition is acceptable if the angular alignment is satisfactory (11) (Fig. 10-11). This observation has been confirmed by others (41,95,96,98).

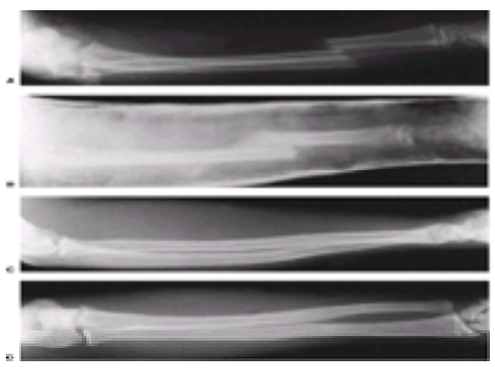

FIGURE 10-11. Bayonet apposition. **A:** An 11-year-old sustained a fracture of the radial and ulnar shafts with bayonet apposition but excellent alignment. **B:** Four weeks after the fracture, there is early callus with maintenance of the bayonet apposition but satisfactory linear alignment. **C and D:** Five years postinjury (age 16 years), there is excellent linear alignment and full supination and pronation.

The direction of angulation may influence loss of forearm rotation. Daruwalla (24) observed that angulation of both bones, with the apex of the angle toward the interosseous space, resulted in loss of motion. Roberts (104) confirmed this finding, but Price et al. (95,96) stated that interosseous encroachment is an unpredictable indicator of loss of motion.

Location of the fracture is another factor that influences outcome. Numerous researchers have noted that proximal shaft fractures have a worse prognosis than distal shaft fractures (10,21,24,38,95,96,123,130,153).

Recommendations for acceptable reduction vary. Moesner and Ostergaard (79) stated that children younger than 9 years of age with angulation of less than 20 degrees will regain full range of motion and 90% remodeling. This conclusion has been supported by Carey et al. (15) and others (54,89,39). However, Blount (10) cautioned, “fractures of the middle third of the forearm should not be allowed to remain angulated to any appreciable degree except in very young children.” Daruwalla (24) concluded that after age 6 years, remodeling is unlikely to correct a deformity of more than 10 degrees. Daruwalla believed that angulation of 15 degrees is acceptable in children younger than 5 years. Hogstrom et al. (50) noted that young children have a good chance of achieving correction of angular deformity, but concluded that all deformities exceeding 10 degrees should be corrected because it is impossible to predict remodeling. Price et al. (95,96) concluded that 10 degrees of angulation, complete displacement, and loss of radial bow can be accepted rather than resorting to open reduction (Table 10-2).

Age	Angulation	Malrotation	Displacement	Loss of Radical Bow
Age <5 yr	15 degrees	45 degrees	Complete	Yes
Age >5 yr	10 degrees	30 degrees	Complete	Partial

TABLE 10-2. LIMITS OF ALIGNMENT

Treatment Options

Closed Management

Greenstick Fractures

Skillful closed management usually is successful for this injury. Greenstick fractures may appear to be angulated and may also have a rotational element. Holdsworth and Sloan compared this fracture with a cardboard tube that, when twisted, tends to bend; unbending it is possible only if it is untwisted (51). When the apex is toward the dorsum of the hand (apex dorsal-pronation injury), the forearm should be supinated to achieve reduction (Fig. 10-12). When the apex is toward the palm of the hand (apex volar-supination injury), a pronation force must be applied to secure reduction (Fig. 10-13).

FIGURE 10-12. A: Greenstick fracture of both shafts of the forearm at the distal third with pronation of the distal forearm and apex dorsal angulation at the fracture site. **B and C:** The fracture was manipulated into supination and placed in a long arm cast, correcting the angular and rotational malalignment.

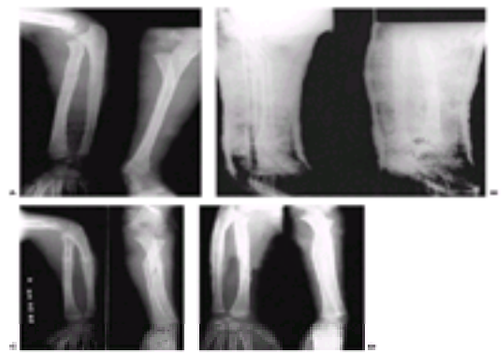

FIGURE 10-13. A: Greenstick fracture of the proximal third of the radius and ulna, with apex volar angulation of the radius. **B:** Postreduction view in long arm cast shows 40-degree angulation of the radius. This original reduction was in neutral but should have been in full pronation. As a result, there is some residual angulation at the fracture site. **C:** At 1 month, there was 15-degree residual angulation of the proximal radius, which was thought would remodel to some degree. **D:** At 8 months postinjury, angulation of the radius persisted, with supination of 45 degrees and pronation to 70 degrees. Despite the residual angulation, the patient does not complain of any functional impairment.

Should greenstick fractures be made complete? There appears to be no unanimity of opinion. Advocates for breaking the intact cortex believe that angulation will recur if it is not done (11,43,53,98,146). Others believe it is unnecessary to break the intact cortex (1,25,30,33,123). Instead, the intact cortex is used as an aid to reduction. Advocates for leaving the hinged cortex intact emphasize the need for full pronation for apex volar (supination) greenstick fractures and full supination for apex dorsal (pronation) greenstick fractures (1,25,33) (Fig. 10-12 and Fig. 10-13).

Another reason to break the intact cortex was proposed by Gruber (43), who noted that greenstick forearm fractures have the highest risk of refracture of all pediatric fractures. He postulated that the intact cortex heals by primary bone healing with little callus. Simultaneously, a resorption zone develops on the side of the broken cortex. Thus, the weakness of the bone persists beyond the initial healing phase. He recommended initial fracturing of the intact cortex to reduce the risk of fracture recurrence.

AUTHORS' PREFERRED METHOD OF TREATMENT

Even with minimally angulated greenstick fractures, the elbow should be evaluated carefully to ensure that a Monteggia type IV lesion with an ipsilateral radial head dislocation is not present.

Minimal angulation can be accompanied by significant rotational deformity. Any angulation should be reduced if a family member or other observer has made specific comments that the forearm appears deformed. The deformity present immediately after injury often is the final position into which the fracture tends to drift when the swelling has subsided.

Pain relief for fracture reduction may be achieved by a variety of methods (5,20,31,46,55,57,72,88,133,145,147). The American Academy of Pediatrics has published guidelines for the monitoring and management of children during and after sedation (2) (see also Chapter 3). For greenstick fractures, I prefer a minidose Bier block as described by Juliano (57), or intravenous sedation as described by Varela et al. (133). Intravenous sedation provides adequate analgesia for one reduction attempt, which usually is sufficient. A Bier block provides more prolonged analgesia.

Supinating and extending the wrist while gently correcting the angulation (Fig. 10-12) reduces apex dorsal angulated greenstick fractures (pronation injuries). Volar

angulated greenstick fractures (supination injuries) are reduced by pronating and flexing the wrist while gently correcting the angulation. I do not intentionally fracture the opposite cortex, but a crack often is heard as the reduction is completed. Full pronation or full supination maintains the reduction if the opposite cortex remains intact. A sugar-tong splint is then applied, with the elbow flexed to a right angle.

Approximately 1 week later, the splint is removed and a well-molded long arm cast is applied. Radiographs should be made at that time to determine whether reduction has been maintained. Cast immobilization is continued for 6 weeks. I recommend a Velcro splint for an additional 6 weeks because of the high incidence of refracture with this injury.

Complete Fractures

If the fracture is complete, an entirely different situation exists. The distal fragment may be in any position, but muscle pull determines the position of the proximal fragment (Fig. 10-14). Thus, it becomes necessary to determine the position of the proximal fragment so that the distal fragment can be aligned with it.

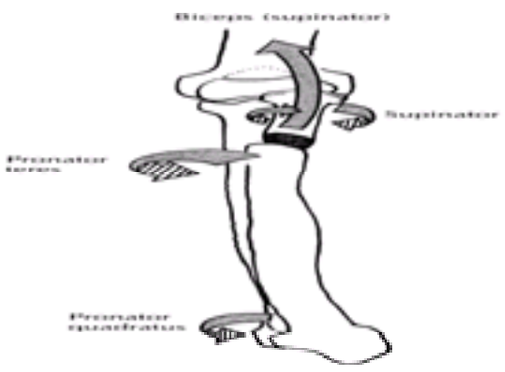

FIGURE 10-14. Muscle forces that deform fractures of the radius above the level of the insertion of the pronator teres. The proximal fragment supinates because of the unopposed pull of the supinator and biceps muscles. (Redrawn from Cruess RL. The management of forearm injuries. *Orthop Clin North Am* 1973;4:969; with permission.)

If both fractures are complete and overriding, Davis and Green (25) advocated fingertrap traction of 10 to 15 pounds to bring out to length and to let the fracture seek its own correct rotational alignment. Traction through fingertraps with countertraction on the arm tends to stretch an intact periosteum to allow bone ends to oppose (Fig. 10-15).

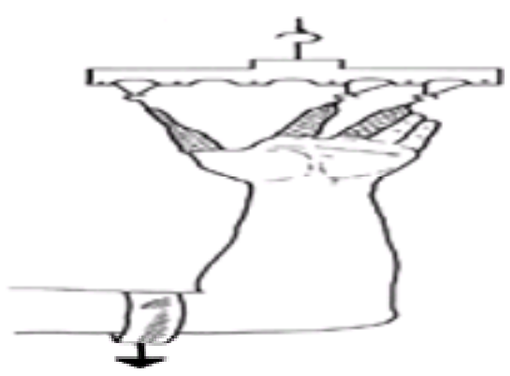

FIGURE 10-15. Application of traction-countertraction using fingertraps. (Redrawn from Weber BG, Brunner C, Freuler F. *Treatment of fractures in children and adolescents.* New York: Springer-Verlag, 1980; with permission.)

Alternatively, it is possible to increase the deformity and toggle one bone at a time by thumb pressure, and then immobilize in a long arm cast in correct rotation with the elbow flexed to 90 degrees (Fig. 10-16). The cast should be molded into an oval (Fig. 10-17). If the reduction is unsatisfactory, remanipulation is necessary.

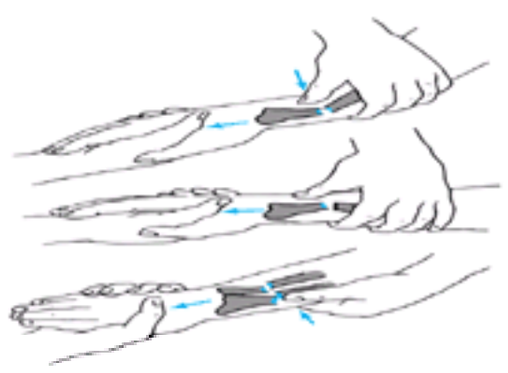

FIGURE 10-16. Top: Traction and countertraction of the thumb is used to increase the deformity. **Center:** With traction still maintained, the thumb slips farther distally to correct the angulation. It is best to avoid disrupting the periosteum, but on occasion this is necessary. **Bottom:** Ulnar or radial deviation can also be corrected by traction and thumb pressure. (Redrawn from Weber BG, Brunner C, Freuler F. *Treatment of fractures in children and adolescents.* New York: Springer-Verlag, 1980; with permission.)

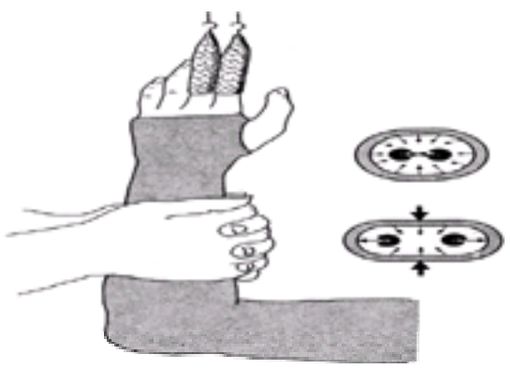

FIGURE 10-17. While the cast hardens, it is pressed together by both hands to form an oval. This increases the width of the interosseous space. Traction should be released gradually while this is done. (Redrawn from Weber BG, Brunner C, Freuler F. *Treatment of fractures in children and adolescents.* New York: Springer-Verlag,

1980; with permission.)

The proper position for immobilization depends on the fracture. Evans recommended that all complete both-bone fractures should be immobilized in some degree of supination (29). Carey et al. (15) advocated immobilization of all fractures in neutral position without extremes of pronation or supination. Proximal fractures are more likely to require supination for maintenance of reduction (11,29,30).

One of the major difficulties in treating fractures of the shafts of the radius and ulna is the development of late angulation because of slippage of the forearm proximally in the long arm cast when the elbow is flexed to 90 degrees (Fig. 10-18). In an effort to prevent this, Rang (98) originally placed a ring proximally on the cast to counteract this migration (Fig. 10-18). Another option is to immobilize the forearm with the elbow in extension.

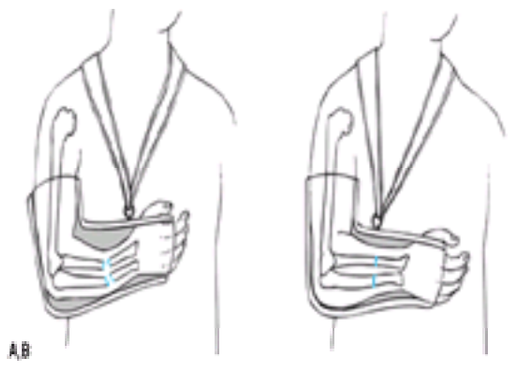

FIGURE 10-18. Movement within the cast. **A:** As the swelling subsides, the forearm migrates proximally in the cast, causing it to angulate. **B:** This migration can be prevented to some extent by attaching the suspension eyelet proximally. (Redrawn from Rang M. *Children's fractures,* 2nd ed. Philadelphia: JB Lippincott, 1983:207; with permission.)

The elbow usually is immobilized in flexion, but this is not always necessary or desirable. The use of a long arm cast in extension was originally described in the 1940s by Thorndike and Dimmler (126). It was also advocated by Watson-Jones (144) in the 1950s. In a series of 130 pediatric forearm fractures, Gainor and Hardy (37) found it necessary to treat eight patients in elbow extension because reduction was unstable in flexion. Walker and Rang (142) reported satisfactory results in 15 patients who required management with the elbow in extension. They noted that most forearm fractures, which are stable in flexion, should still be treated in a conventional cast, but unstable fractures can safely be treated with the elbow in extension (Fig. 10-19 and Fig. 10-20).

FIGURE 10-19. Long arm extension cast. **A:** Postreduction film in an 8-year-old boy showing satisfactory alignment with elbow in 90 degrees of flexion and the forearm in mid-position. **B:** Radiographs taken 4 weeks postfracture show 30 degrees of angulation at the fracture site. **C:** The forearm was remanipulated and placed in a long arm cast in extension. **D:** Six weeks after remanipulation, there is satisfactory alignment of both fracture fragments. Subsequently, the patient regained full supination and pronation of the forearm. (From Wilkins KE, ed. *Operative management of upper extremity fractures in children.* Rosemont, IL: American Academy of Orthopaedic Surgeons, 1994:36; with permission.)

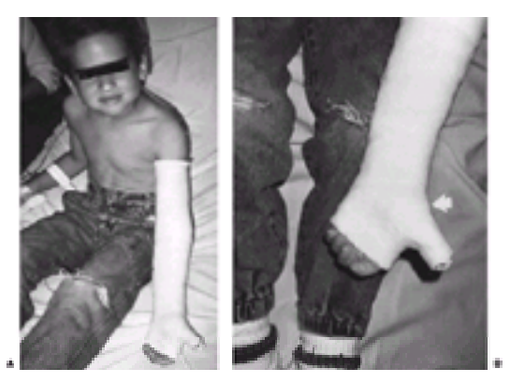

FIGURE 10-20. A: An extension cast on a 7-year-old with fractures of the shafts of the radius and ulna. **B:** The thumb must be incorporated in the cast, with extra padding placed over the base of the thenar eminence *(arrow)* to prevent the development of pressure areas from the distal migration of the cast.

Radiographs should be made at intervals for up to 3 weeks after reduction. Minor loss of alignment at this time is observed. Major loss of alignment requires remanipulation under anesthesia. Voto et al. (140) noted that 7% of their pediatric forearm fractures required remanipulation. Jones and Weiner (56) advocate closed management with pins and plaster technique as a salvage technique when casting alone is insufficient.

AUTHORS' PREFERRED METHOD

When fractures of both bones are complete, the muscle pull on the fragments becomes important. It is necessary to determine the rotation of the proximal fragment and then place the distal fragments in the same amount of rotation.

For these fractures, I prefer prolonged and complete pain relief, because more than one attempt may be required. Regional anesthetic techniques such as Bier or axillary blocks or general anesthesia are often better for this injury than hematoma block or intravenous sedation.

Initially, I attempt a manual closed reduction. An assistant applies countertraction at the elbow. I use one hand to apply traction while the other manipulates the fracture site. If necessary, I increase the deformity by thumb pressure and hitch one bone at a time. The forearm is then placed in the selected position of rotation.

This position is almost always neutral to supination and rarely requires any degree of pronation. The elbow usually is flexed to 90 degrees and a well-molded sugar-tong splint is applied.

If the initial or subsequent attempts at manual reduction fail, then traction is applied by fingertraps (Fig. 10-15). The arm is allowed to seek its own position of rotation, as described by Carey et al. (16). Plain radiographs or image intensification is used to check alignment with the arm in traction. A long arm cast is then applied with careful molding to maintain the interosseous space and the alignment (Fig. 10-17). When the cast hardens, the traction is released and further radiographs are obtained. The cast is split on one side in the recovery room. I leave the padding intact unless problems with swelling are likely.

I tend to use the ulna as the primary indicator of angulation and the radius as the indicator of rotation. Initially, I accept overriding but I try not to accept angulation; angulation tends to lead to increasing deformity on follow-up. In a child younger than 9 years of age, I accept 15 degrees of angulation, 45 degrees of malrotation, complete displacement, and straightening of the radius. From ages 9 to 14 years in girls and 9 to 15 years in boys, I accept 10 degrees of angulation, 30 degrees of malrotation, complete displacement, and some loss of radial bow (Table 10-2).

Radiographs are made at 1 week, 2 weeks, and occasionally at 3 weeks after reduction. It is necessary to change the cast as swelling subsides after reduction. Changing the splint or cast at 1 week is painful and often unnecessary. I prefer to wait until 10 to 14 days after injury for the first cast change. At that time, the fracture is “sticky” and gentle molding can be performed to correct any mild loss of alignment. Severe loss of alignment requires remanipulation under anesthesia with or without surgical stabilization. Remanipulation is an effective means to manage reangulation up to 21 days after initial management.

OPERATIVE TREATMENT: OPEN REDUCTION AND INTERNAL FIXATION

Indications

Operative indications are controversial for radial and ulnar shaft fractures in children. Holdsworth and Sloan (51), in a report of 51 children with malunions of proximal shaft fractures, noted only three unsatisfactory results and concluded, “there is little place for internal fixation of proximal forearm fractures in children under the age of 12 years.” There is no argument that open fractures require surgical debridement and good evidence that internal fixation of the fracture facilitates management of the soft tissue component of the injury (44,86,152). For similar reasons, a compartment syndrome or soft tissue interposition can be a primary indication for surgical intervention (36,39,40,45,62,100,108,150). Open reduction and internal fixation may also be indicated as the primary treatment after refracture of the radius or ulna (4,51). In this group of fractures, callus and soft tissue scarring often impede satisfactory reduction, and osteopenia caused by immobilization of the original fracture contributes to prolonged healing. Fractures that occur shortly before the cessation of growth often require internal fixation to achieve an acceptable result (146).

Considerable controversy exists regarding the indications for surgery when alignment is difficult to maintain after closed reduction. Many researchers have noted that open reduction with internal fixation is rarely necessary for forearm fractures in children. Mild to moderate deformity is well tolerated even in older children (15,24,35,51,95,96,123). However, Fuller and McCullough (35) recommended surgical intervention for children 8 years of age or older if the fracture defies all attempts at closed reduction. Kay et al. (59) recommended open reduction and internal fixation for patients older than 10 years of age if the fracture proves unstable by closed methods. Many other investigators (1,10,33,51,83,86,118,130,141) have also recommended surgical intervention in older children when adequate reduction cannot be obtained by closed means.

Modern surgical and anesthetic techniques, prophylactic antibiotics, and intraoperative fluoroscopy have improved the results of operative management. Thus, there has been a trend toward more aggressive operative treatment of these fractures (23,34,52,69,91,102,132,152,154). Frequent indications for operative treatment of forearm shaft fractures in children are listed in Table 10-3.

Unstable fracture after attempted closed reduction
Unacceptable closed reduction (Table 10-2)
Open fracture
Multiple trauma—floating elbow
Refracture with displacement
Compartment syndrome
Segmental or comminuted fractures (these usually are unstable but can sometimes be managed closed)
Age
Female ≥14 yr
Male ≥15 yr

TABLE 10-3. INDICATIONS FOR OPERATIVE TREATMENT OF FOREARM SHAFT FRACTURES IN CHILDREN

Specific Operative Techniques

Several methods of surgical stabilization have been used in children (3,52,66,83,91,93,107,130,132,141,152), including compression plates and screws, intramedullary rods, and external fixation with pins and plaster or with external fixation devices. Oblique cross-pin fixation usually is inadequate for diaphyseal forearm fractures because the bone diameter is small (148).

Compression Plates. Several clinicians (1,18,59,83,124,130,152) have reported the occasional use of plate and screw osteosynthesis for pediatric forearm fractures. Nielsen and Simonsen (83) reported results of plate fixation in 29 children with forearm fractures. They emphasized that internal fixation was used for only 8% of the displaced forearm fractures when closed reduction was unsuccessful. One of their 29 patients contracted a deep infection, 1 had a refracture after plate removal, 2 reported slight sensory disturbance, and 8 had scars exceeding 5 mm in width. All fractures healed, and none lost more than 20 degrees of forearm rotation. Vainionpaa et al. (130) also reported open reduction with plate fixation when closed management was unsuccessful. Nine percent of forearm fractures at their institution required surgical intervention. Thirteen of 14 patients regained satisfactory forearm rotation. There was one refracture and one unsightly scar. They concluded that the results of open reduction and internal fixation were satisfactory, considering the severity of the fractures.

Compression plate fixation should be considered in patients who have sustained refractures of original diaphyseal fractures (Fig. 10-21) because in many cases poor results have followed closed management. These patients often have a intramedullary canal full of old callus or bone septa from the previous fractures that makes passage of intramedullary devices difficult. Price et al. (96) and Creasman et al. (21) recommended that refractures in these patients should be stabilized internally with compression plates.

FIGURE 10-21. Refractures. **A:** This 6-year-old boy sustained displaced greenstick fractures of the mid-shaft radius and ulna. He underwent satisfactory closed reduction and long arm cast application for 8 weeks with good healing. **B:** Two months later, he fell and sustained refractures through the old fracture sites with minimal displacement. **C:** After reimmobilizing for 6 weeks, satisfactory healing was achieved. **D:** Seven years later, he sustained a third fracture in essentially the same area. Closed reduction and long arm casting failed to obtain a satisfactory alignment. **E:** Because of the previous two fractures, compression plate fixation was used instead of intramedullary pin fixation. Subsequent healing was uneventful, with complete resumption of normal forearm motion.

Although there has been a reluctance to use plates in open fractures, in the series reported by Moed et al. (78), Haasbeek and Cole (43), and Wyrsch et al. (152), the use of compression plates in open fractures did not increase the problems of wound or fracture healing, and in fractures with more extensive soft tissue injury, it was thought that plate fixation facilitated wound care and fracture healing. The principles and techniques of open reduction and plate fixation are the same in children as in adults, except that smaller plates may be used in children. (81,105). A volar approach is preferred for fractures of the distal and middle thirds of the radius. For fractures in the proximal third of the radius, a dorsal approach is usually better. When both bones require stabilization, two incisions should be used to reduce the risk of synostosis. The ulna is easily accessed through a direct approach. (137,138). Accurate contouring of the radial plate is necessary to avoid loss of radial bow.

The main advantage of compression plate fixation is that it produces an accurate reduction with sufficient stability to begin early motion. However, supplemental immobilization is recommended in children because they are active (83,130,152).

Disadvantages include the soft tissue exposure, which can alter healing at the fracture site, scarring and problems with cosmesis, and the possibility of infection. (132)

Subsequent plate removal requires a second operation, which is not always a benign procedure. Refractures and neurapraxia have been reported in children after forearm plate removal (83,130). The complications after routine metal removal have caused some surgeons to question the value of this practice (6,58,74,114). We do not recommend routine plate removal unless the plate is causing discomfort or the child anticipates participating in activities that place him or her at unusual risk for refracture.

Intramedullary Fixation. Intramedullary nails have been used to stabilize adult forearm fractures since 1913, when Schone (115) first described the use of silver rods in the radius and ulna. Various types of nail or wire implants have been used since then (13,28,61,66,70,109,111,121). However, supplemental immobilization is often required, and nonunion rates in *adults* have ranged from 6% to 20% (61,70,90,111,117,121). In children, nonunions are rare, and minimal intramedullary fixation can maintain acceptable alignment until fracture healing occurs. Thus, intramedullary nailing of forearm fractures is more practical in children than in adults. The advent of image intensification has made it easier to stabilize a closed reduction with intramedullary devices inserted through percutaneous routes. The relative simplicity and low morbidity of intramedullary fixation have popularized this technique for pediatric forearm fractures in which the reduction may be difficult to maintain by cast immobilization alone (3,34,66,69,86,91,93,94,102,107,135,152,154).

Amit et al. (3) reported excellent results with no complications in a series of 20 adolescent forearm fractures managed by closed reduction and intramedullary fixation. Intramedullary fixation using elastic nails proved to be stable enough that postoperative immobilization was eliminated in the series reported by Verstreken et al. (135) and Lascombes et al. (66). Verstreken et al. reported excellent results with no complications in all 57 children in their series. Lascombes et al. reported 85 patients ranging in age from 4 to 16 years, 92% of whom regained full range of motion: only 1 patient lost more than 30 degrees of forearm rotation. There was one case of sensory neuropathy, nine instances of skin irritation over the end of the nail, three refractures, and four secondary angulations of less than 10 degrees, which were believed to be due to inadequate anchorage of the nail. There were no infections, nonunions, or cross-unions. Because Lascombes et al. did not accept theories of remodeling in malunited diaphyseal fractures, they advocated elastic stable intramedullary nailing of displaced forearm shaft fractures in all children older than 10 years of age and after failed conservative management in younger children.

More recently, other investigators have reported equally impressive results with flexible intramedullary nailing of forearm fractures in children. Richter et al. (102) reported excellent (24 fractures) or good (5 fractures) functional results in 29 of 30 children with “unstable” proximal- or middle-third forearm fractures treated by elastic stable intramedullary nailing. Luhman et al. (69) reported excellent or good results with intramedullary fixation of all 25 patients in their series with unstable diaphyseal forearm fractures. There were no infections, delayed unions or malunions, or synostoses. Based on this experience, they concluded that intramedullary nailing is a safe, effective, and user-friendly technique for management of unstable forearm fractures in children. Flynn and Waters (34) described excellent results in 16 children with both-bone forearm fractures using a modification of the technique in which fixation of only one bone is done and the other is treated closed.

Cullen et al. (23) reported 18 complications in 10 of 20 patients who had undergone intramedullary fixation of their forearm fractures. Problems included hardware migration, infection, loss of reduction, reoperation, nerve injury, loss of motion, synostosis, muscle entrapment, and delayed union. In spite of these complications, 19 of the 20 patients had excellent (n = 17) or good (n = 2) outcomes. Similarly, Shoemaker et al. (116) reported 9 complications in 8 of 32 patients with unstable forearm fractures treated with intramedullary fixation. In spite of these complications, 31 of the 32 patients had excellent results, and 1 had a good result. Complications in both series were more frequent when only one bone was stabilized or when immobilization was discontinued prematurely.

Van de Reis et al. (132) compared results of intramedullary nailing to plate fixation for treatment of forearm fractures in children. Results were excellent in 78% of the patients in either treatment group. Functional outcome, rate of union, and number of complications were statistically similar for the two groups. The advantages of intramedullary nailing included shorter operative time, better cosmesis, less soft tissue dissection, and easier hardware removal.

Techniques of Intramedullary Fixation. Contoured Kirschner wires or elastic nails can be introduced proximally or distally in the ulna but are always introduced distally in the radius (Fig. 10-22). Amit et al. (3) recommended pinning the ulna first through a 1-cm incision over the olecranon apophysis. Lascombes et al. (66) entered the ulna just distal and lateral to the olecranon apophysis. The radius is approached radially just proximal to the distal physis with protection of the superficial radial nerve. A 45-degree oblique hole is drilled in the lateral cortex of the metaphysis to allow nail insertion. Blunt-ended 1.5- to 2.5-mm diameter stainless steel or titanium nails are used. The nails are curved slightly to allow three-point fixation. The tip is bent 30 to 40 degrees to allow manipulation in the medullary canal. The bent tip should not exceed 5 mm in length. The nail is manipulated across the fracture site and advanced to the cancellous bone of the metaphysis. Rotation of the curved nail allows correction of angulation and restoration of radial bow. The nail is then bent at the insertion site and cut short enough to avoid skin irritation. Alternatively, the nail can be left percutaneously. The latter technique allows the implant to be removed in the office, although it may be associated with a slightly higher incidence of soft tissue problems. Approximately 15% to 20% of the fractures require a limited, direct exposure of the fracture site to achieve reduction (148,154).

FIGURE 10-22. Intramedullary fixation. **A:** In the Marote technique, a wire is inserted through a small opening in the distal radial metaphysis and through another small opening in the olecranon. (From Parsch K. The Marote wiring in proximal and midshaft fractures of the child. *Operat Orthop Traumatol* 1990;2:249; with permission.) **B:** This 10-year-old sustained a grade I open fracture midshaft to the ulna with a closed fracture of the radius. **C:** After debridement, fixation was achieved using wires inserted distally in the radius and proximally in the ulna.

The advantages of intramedullary nailing include minimal dissection at the fracture site, small incisions, low refracture rate, and easier removal than plates and screws. Elastic nail fixation has also been successfully used for open fractures in children (66).

Disadvantages include the possibility of infection when closed fractures are managed surgically, the need for a subsequent procedure to remove the implants, skin irritation from the nail tip, and the risk of injury to the superficial radial nerve. Rigid immobilization of the fracture is difficult with elastic intramedullary fixation. Postoperative immobilization is recommended (3) but is not always necessary (66,135). Stabilization with compression plates is recommended when early mobilization is desirable. Compression plate fixation may be preferred for correction of malunions or when stabilization is required after re-fracture.

Pins and Plaster, or External Fixation. Voto et al. (141) reported the use of pins and plaster in 20 pediatric forearm fractures when a satisfactory reduction could not be managed by closed means alone. One Steinmann pin was placed through the first or second metacarpal neck and another transversely through the proximal ulna. Traction was then applied for reduction and was released after the pins were incorporated in a plaster cast. All patients obtained subjective satisfactory results without complications. A subsequent series by Jones and Weiner (56) confirmed the usefulness of this technique when closed management fails.

External fixators are rarely used for pediatric forearm fractures (95,115). The indications for use in children are rare and are similar to the indications for use in adults. These include extensive comminution, segmental bone loss, or grossly inadequate soft tissue coverage (97).

AUTHORS' PREFERRED METHOD

Some investigators (59,66,83,130,135) reporting internal fixation of pediatric forearm fractures have indicated that 8% to 31% of midshaft fractures require surgery. (86) Voto et al. (140) reported surgical stabilization of only 1.5% of all pediatric forearm fractures.

Greenstick fractures rarely require internal fixation. Displaced forearm fractures almost always require operative intervention. The incidence of operative treatment should be less than 10% with proper closed management.

Intramedullary Fixation. When stabilization is required, I prefer intramedullary nailing with Kirschner wires or titanium rods. The tip must be blunt to prevent it from impaling the inner cortex. Because of their flexibility, the newer intramedullary nails or pins usually allow reconstruction of the normal bow of the radius. If a Steinmann or large straight pin is used, it may alter the normal bow of the radius, which may in turn affect forearm rotation (Fig. 10-23). A limited surgical exposure of the fracture site occasionally is needed to facilitate reduction. Reduction with small wires may not be anatomic but usually is adequate for healing and restoration of function. Fixation of only one bone (when both are fractured) is a less invasive modification of the technique that facilitates treatment by allowing the other fracture to be rotated into reduction. Although Flynn and Waters (34) have reported good results with this technique, others have cited a slightly higher risk of loss of reduction with single-bone fixation (23).

FIGURE 10-23. The natural bow of the radius may be lost, thus inhibiting forearm rotation, if a solid, straight intramedullary pin is used for internal fixation. (From Wilkins KE, ed. *Operative management of upper extremity fractures in children.* Rosemont, IL: American Academy of Orthopaedic Surgeons, 1994:41; with permission.)

The fracture is manipulated under the image intensifier and an attempt is made to obtain as nearly anatomic a reduction as possible. There should be at least 50% apposition of the bone ends at the fracture site. With less reduction, it is difficult to pass the wire across the fracture site. Passage is done with the patient supine and the forearm on a radiolucent arm board (Fig. 10-24 and Fig. 10-25).

FIGURE 10-24. Correct positioning of the forearm on a radiolucent arm board. The image intensifier must be perpendicular to the long axis of the forearm and away from the operating surgeon.

FIGURE 10-25. The image monitor *(arrows)* must be in the direct line of vision of the operating surgeon so that he or she can visualize pin migration at all times without turning his or her head.

If the fracture is open, I first do a standard debridement to decrease contamination. The preferred technique of treating open fractures is outlined in Chapter 4. The fracture is then reduced by direct or indirect means.

I follow the technique outlined by Klaus Parsch (93), who has used this procedure extensively in Europe. I try to reduce the radius first. The incision for introducing the pin into the distal radial metaphysis is made just proximal to the radial styloid. A small incision is made to allow visualization of the two branches of the superficial radial nerve (Fig. 10-26). Once the metaphysis of the distal radius is exposed, a drill hole (usually 2.5 mm in diameter) is made through the metaphysis, directing it somewhat craniad (Fig. 10-27). To allow the insertion of the pin and passage proximally up the shaft of the radius, the pin needs two bends in the distal portion. In the terminal 5 mm, a 30-degree bend is made in the rod, which eases its transfer across the fracture site. The second bend, a gradual curve approximately 1 to 1.5 cm proximal, allows the rod to bounce off the opposite internal cortex (Fig. 10-28). The rod is repeatedly rotated in each direction to facilitate its passage up the medullary canal; it can also be tapped with a small mallet.

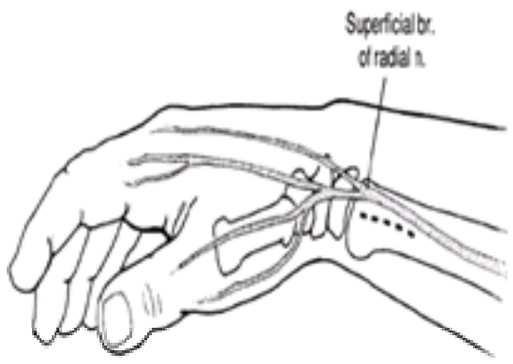

FIGURE 10-26. Entrance of the radial pin. The incision is made over the radial aspect of the distal metaphysis, just below the two branches of the superficial radial nerve.

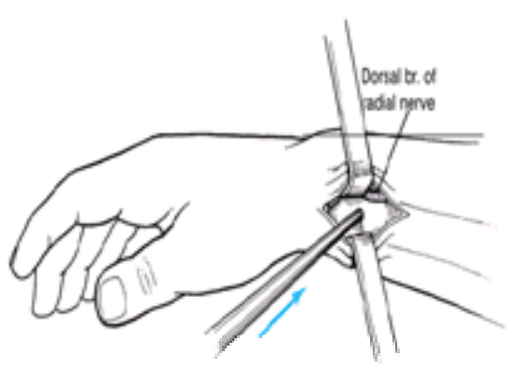

FIGURE 10-27. The entrance hole is drilled craniad under direct vision through the exposed distal radial metaphysis.

FIGURE 10-28. A 0.062² Kirschner wire is inserted through the drill hole into the metaphysis. The long curve *(large arrow)* of the distal pin facilitates passing it up the medullary canal. The 30-degree terminal bend *(small arrow)* is used to facilitate reduction.

When it reaches the fracture site, the second gentle curve in the rod usually has disappeared. The portion that remains is a small 30-degree bend in the tip of the rod, which facilitates its crossing the fracture site. Often, if the fracture is offset a bit, this bend can be set to engage the opposite cortex. The rod tip is then rotated to obtain reduction and passage up into the medullary canal of the proximal fragment (Fig. 10-29).

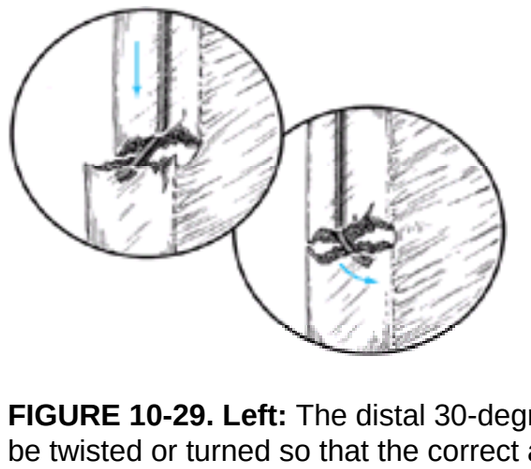

FIGURE 10-29. Left: The distal 30-degree angulation is used to facilitate entering the proximal fragment. **Right:** Once the proximal fragment is entered, the rod can be twisted or turned so that the correct alignment is achieved. The pin is then passed up the proximal fragment.

Once the reduction is achieved and the rod enters the proximal fragment, it is then passed up to the level of the radial tuberosity. The distal end of the rod is cut off and bent slightly to allow it to lie just outside the metaphyseal cortex (Fig. 10-30).

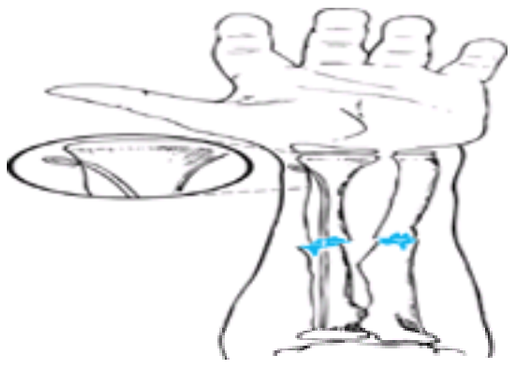

FIGURE 10-30. Once the pin enters the proximal fragment, it is passed to the level of the proximal radius. It is bent to 180 degrees and secured just outside the cortex, next to the metaphyseal cortex *(inset).*

The ulnar rod is inserted through the posterior aspect of the olecranon using a small stab incision (Fig. 10-31). The rod can be left percutaneously and removed in the office at 3 to 4 weeks after insertion at which time the ulnar fracture is sufficiently healed to avoid displacement with continued cast immobilization, particularly if the radius has also been stabilized. Verstreken et al. (135) recommended inserting the ulnar pin from the distal metaphysis, citing advantages of ease of passage and avoidance of soft tissue problems associated with subcutaneous or percutaneous pin location about the olecranon (Fig. 10-32, Fig. 10-33, Fig. 10-34 and Fig. 10-35). However, antegrade insertion of the intramedullary rod through the olecranon takes advantage of the straight anatomy of the ulna, which, in my opinion, facilitates passage of the implant. The arm must be abducted and either internally or externally rotated with the elbow flexed to start the nail and follow its path past the fracture site with the image intensifier.

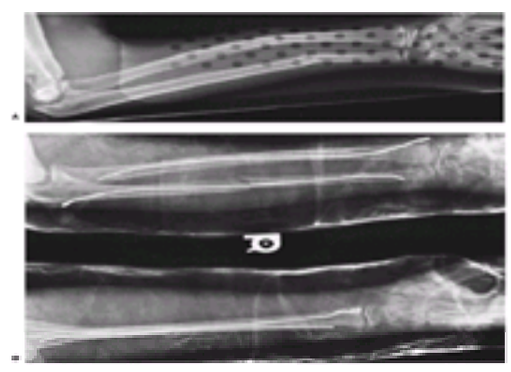

FIGURE 10-31. A: Injury films of a 13-year-old with midshaft fractures of the radius and ulna. **B:** After closed reduction, fixation was achieved with 0. 062² Kirschner wires. The original Marote technique of inserting the ulnar rod into the olecranon was used in this case.

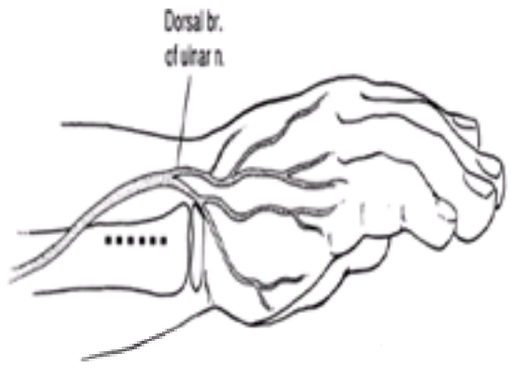

FIGURE 10-32. Location of the skin incision for insertion of the pin in the distal ulna.

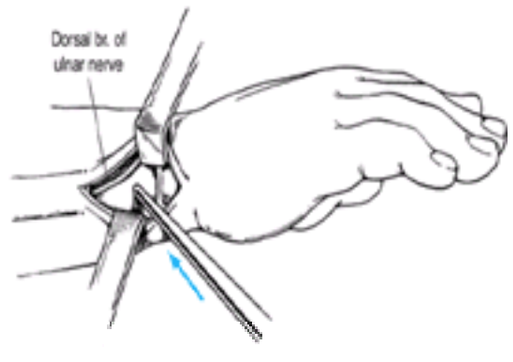

FIGURE 10-33. The ulnar metaphysis is also drilled cephalad with a 2.5-mm drill bit, retracting the skin and nerves.

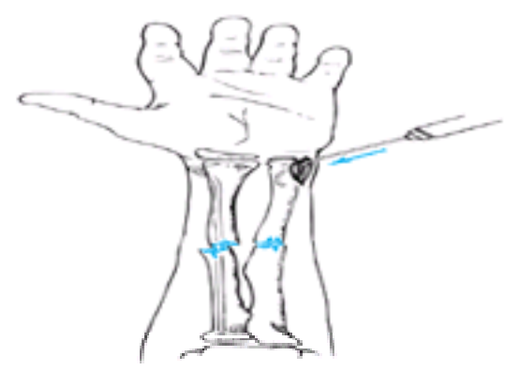

FIGURE 10-34. In the same manner, the rod is passed proximally up the ulnar shaft to cross the fracture site into the olecranon.

FIGURE 10-35. Intramedullary fixation using the distal ulna as the entrance site. Note that the bent ends of the rod are juxtaposed against their respective metaphyses *(arrows).*

The incisions are then closed. Delayed primary closure at the fracture site is done for open fractures. When closing the distal insertion incisions, care is taken to ensure that the protruding portions of the wire are not impinging on the superficial radial or ulnar nerves.

Postoperative Management. The usual postoperative wound care that is necessary for open fractures is followed. I immobilize the forearm with a sugar-tong splint for 3 to 4 weeks, after which I remove the ulnar rod in the office and then use a short arm cast for an additional 3 weeks. At 6 weeks, if there is adequate callus, elbow and forearm motion are initiated. Patients are instructed to avoid strenuous activities for approximately 3 months after injury.

I usually leave the radial pin in place for a total of 6 to 9 months. The criteria for removal are a solid callus across the fracture site and obliteration of the fracture lines. Pin removal does require a second surgical procedure under regional or general anesthesia.

Plate Fixation. My primary indication for plate fixation is a refracture in which the medullary canal has a high risk of being obstructed by fracture callus (Fig. 10-21). This is not to say that I use plates in all refractures. Each fracture is evaluated to determine if an intramedullary device can be passed with ease. In addition, some severely comminuted fractures or those with segmental blood loss may require plate fixation because they may be unstable with intramedullary fixation. This is especially true when rotational alignment is an issue. But with the level of stable fixation achieved with the current intramedullary devices in most fractures, rarely do I find an indication for plate fixation in a skeletally immature patient.

ASSOCIATED INJURIES AND COMPLICATION

Refracture

Refracture of the forearm occurs in approximately 5% of patients, despite the appearance of solid union at the original fracture site (43,53,96,136). Refracture is more likely to occur after greenstick than complete fractures. Gruber (43) postulated that the intact cortex of a greenstick fracture heals by primary bone healing and maintains length as a resorption zone develops on the side of the broken cortex. Refractures also are common after plate removal (6,49,60,106,120). Complications after routine plate removal have caused some surgeons to question the value of this practice (6,58,74,114).

Refractures with displacement can be difficult to reduce. Poor results are common after closed management (4,51). Open reduction and internal fixation are justified unless excellent alignment can be maintained by closed means (Fig. 10-21).

Malunion

Despite every precaution, some fractures heal with deformity. If the angulation develops up to 3 to 4 weeks after fracture, often the forearm can be remanipulated into a satisfactory position and placed in a cast for another 4 to 6 weeks (140,141) (Fig. 10-36). After 8 weeks, unless the deformity is severe, it is best to wait 4 to 6 months before considering corrective osteotomy.

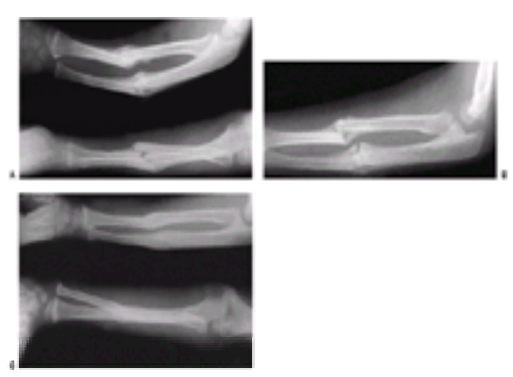

FIGURE 10-36. Remanipulation. **A:** Radiographic appearance of a 6-year-old 6 weeks after fracture with approximately 20 degrees of angulation at the fracture sites. This was unacceptable functionally and cosmetically. **B:** The fracture was remanipulated under general anesthesia into a satisfactory position, correcting the angulation. **C:** Three months after remanipulation, there was full forearm rotation.

Remodeling is unpredictable and may be surprising. Also, muscular atrophy and joint stiffness after immobilization initially exaggerate the appearance of deformity. Function may return to normal despite malunion (Fig. 10-37, Fig. 10-38 and Fig. 10-39). Numerous clinicians (24,50,51,84,95) have noted that there is poor correlation between residual deformity and limitation of forearm rotation.

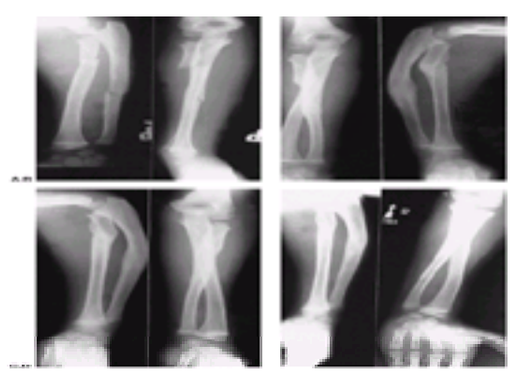

FIGURE 10-37. Proximal remodeling potential. **A:** Fracture of the proximal third of the radius with bayonet apposition of the radius and the undisplaced lower third of the ulna. **B:** Position and remodeling at 6 weeks. **C:** Status at 4 months. **D:** At 2.5 years, note almost complete remodeling.

FIGURE 10-38. Midshaft remodeling. **A:** A 7-year-old patient with almost 20 degrees of angulation of both the radial and ulnar shafts. There was limitation of forearm motion. **B:** Two years later, there was complete remodeling of the radius and only slight angulation of the ulna. The patient regained essentially 75% normal forearm rotation. The parents and patient were satisfied with the cosmetic and functional outcome.

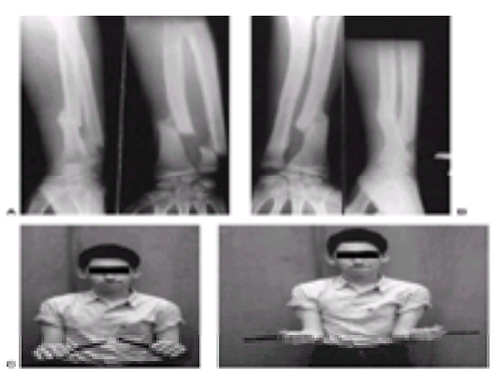

FIGURE 10-39. A: A 13-year-old sustained a fracture of the distal radius and ulna that healed with 1 cm of shortening and distal bayonet apposition. **B:** Ten weeks after injury, there is early remodeling. **C:** Six months after injury, the patient had essentially equal forearm rotation and did not appreciate any clinical shortening.

Linscheid and Trousdale (67) reported 19 patients who had corrective osteotomy of the forearm to improve rotation after malunion. Patients treated within 12 months of the initial injury regained an average of 81 degrees of rotation; those treated later gained an average of 42.5 degrees. Drill osteoclasis to correct deformity in children was reported by Blount (9). Blackburn et al. (8) used this method in 15 children with disability and cosmetic deformity from malunited midshaft forearm fractures. After osteotomy, 10 patients were immobilized solely in plaster casts. Results were satisfactory in 10 of 12 patients with adequate follow-up.

AUTHORS' PREFERRED METHOD OF TREATMENT

When the malunion is recognized at time of cast removal, I prefer to allow 6 to 8 weeks for mobilization of the soft tissues before correction of deformity. An accurate preoperative analysis of the deformity is required. Plain radiographs may suffice, but three-dimensional computed tomographic scanning may aid in planning the proper location, direction, and magnitude of rotational and angular correction. I prefer adequate exposure to perform the osteotomies and fixation with a compression plate. Occasionally, single-plane deformity can be corrected by osteotomy through a limited exposure and stabilized with intramedullary fixation and cast immobilization (Fig. 10-40).

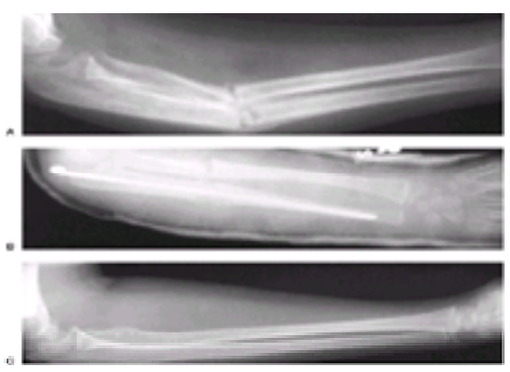

FIGURE 10-40. Corrective osteotomy. **A:** This girl, 5 years and 1 month of age, acquired severe angulation 5 weeks after closed reduction. **B:** Because of the abundant callus, osteotomies of the radius and the ulna were performed with intramedullary stabilization of the ulna. **C:** Five years after injury, alignment, range of motion, and function are normal.

Synostosis

Synostosis is a rare complication of forearm fractures in children. It is more likely to follow high-energy trauma, surgical intervention, repeated manipulations, or fractures associated with head injury (137,138). Vince and Miller (138) reported 10 children with cross-union after forearm fracture. None was in the distal third, four were in the middle third, and six were in the proximal third. Surgical excision was performed in six patients. The synostosis recurred in three patients. The remaining three patients regained 25, 40, and 70 degrees, respectively, of forearm rotation. The authors observed that results after excision of cross-union were not as good in children as in adults (Fig. 10-41).

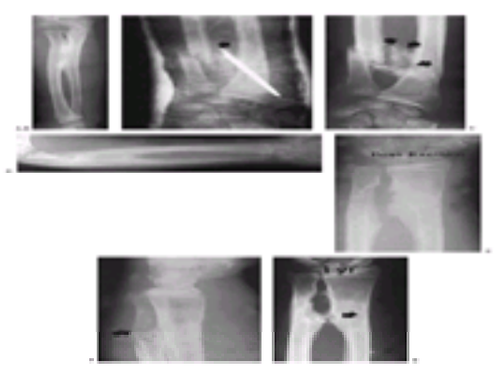

FIGURE 10-41. A: Type II cross-union (middle third). (Courtesy of K. G. Vince, MD.) **B:** Type I cross-union after open reduction and fixation with wires. Note protrusion of wires. **C:** Cross-union fully established at 3 months. No pronation or supination possible. (B and C from Vince KG, Miller JE. Cross-union complicating fracture of the forearm. Part II: children. *J Bone Joint Surg Am* 1987;69:655; with permission.) **D:** Type III cross-union (proximal third). (Courtesy of K. G. Vince, MD) **E:** Cross-union (type I). Initial treatment consisted of open reduction and fixation with Steinmann pin performed within 24 hours. Displacement recurred and unsuccessful closed reduction was performed at 7 days. Thirteen days after injury, open reduction and fixation of the radius and ulna with plate was done through two incisions. The radiograph was taken 11 months after injury, immediately after removal of plate and excision of cross-union. **F:** Refracture of ulna that occurred during excision of cross-union. **G:** Recurrence of cross-union 1 year after excision.

Compartment Syndrome

There are several reports of compartment syndrome after forearm fractures in children (47,71,108). Most have resulted from severely displaced distal radial and ulnar fractures.

Casts should be split at the time of reduction if swelling is present or anticipated. As a rule, the child is much more comfortable after reduction and cast stabilization of the fracture, and the development of a compartment syndrome should be considered when severe pain or loss of active or passive finger motion persists after the reduction. Compartment pressure measurements should be obtained if signs and symptoms of compartment syndrome develop. The indications and techniques for forearm fasciotomy are the same in children as in adults.

Nerve Injury

Injuries to the median, ulnar, and posterior interosseous nerves have been reported. These usually are transitory. Entrapment of the median nerve in a greenstick fracture has been reported (40,87,150). Geissler et al. (39) described anterior interosseous nerve palsy complicating a closed fracture of both bones of the forearm in an 8-year-old child. Surgical exploration revealed a bone spike from the fracture of the proximal radius perforating the median nerve. Isolated injuries to the ulnar nerve (75,151) and to the anterior interosseous branch of the median nerve (143) also have been reported. Gainor and Olson reported entrapment of both the median and anterior interosseous nerves (36). Rijnberg and MacNicol reported entrapment of a superficial radial nerve (103). Moore et al. (80) reported an 8.5% incidence of iatrogenic injury in fractures that were stabilized surgically.

In almost every reported instance of nerve entrapment after closed treatment, the initial reduction was difficult or incomplete. Surgical exploration was delayed from 5 days to 5 months after injury. Recovery was complete or almost complete in all but one patient after surgical repair.

A thorough prereduction neurologic examination is recommended, although this may be difficult with an anxious, uncooperative patient. Nerve entrapment should be suspected when the prereduction examination was negative, the reduction was incomplete, and the postreduction examination indicated a neurologic deficit. When neurologic deficit is noted after reduction, the appropriate length of observation before surgical exploration is unclear. I recommend 8 weeks when the reduction is anatomic and early exploration if entrapment is suspected.

Other Complications

Muscle entrapment can prevent reduction of complete fractures and also has been reported with greenstick fractures (45,62). More serious complications, including hematogenous osteomyelitis (14,134) after closed treatment and gas gangrene (32) after open fractures, also have been reported. Nonunion is rare and usually heals with appropriate management.

PLASTIC DEFORMATION OF THE RADIUS AND ULNA

Plastic deformation, or bending of bone, was described by Barton in 1821. This reference is quoted by Sir Astley Cooper (19):

> Dr. Barton recognizes two varieties of it which, however, are scarcely more than different degrees of the same injury; first, a simple bending of the bone, and the second, what he regards as truly a partial or incomplete fracture.

In 1975, Borden (12) reported traumatic bowing of the bones of the forearm in children. Since then, other reports emphasized the difficulty in diagnosis and treatment of these fractures (22,26,63,73,77,85,110,112,125).

Surgical Anatomy

A child's bone is more flexible than an adult's because the haversian canals are larger and thus render the bone more porous. This allows a greater degree of flexibility—and hence more plastic deformation—to occur before fracture.

Mechanism of Injury

Chamay (16) showed that low-level stresses applied to bone cause bending proportional to the stress applied, but the bone retains its normal configuration when stress is removed. This results in elastic deformation (Fig. 10-42).

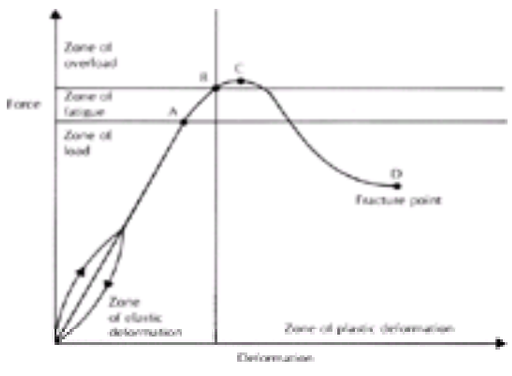

FIGURE 10-42. Graphic relation of bony deformation (bowing) and force (longitudinal compression) showing that the limit of an elastic response is not a fracture but plastic deformation. If the force continues, a fracture results. (Redrawn from Borden S IV. Roentgen recognition of acute plastic bowing of the forearm in children. *AJR Am J Roentgenol* 1975;125:524; with permission.)

Stress that exceeds the elastic limit but is less than the fracture limit causes fixed bending that does not change when the stress is removed. This fixed bending is not associated with gross fracture and is called *plastic deformation.* Plastic bowing has been reported in young adults (101,131), but is more common in children because of the larger plateau of plastic response in children than in adults.

Longitudinal compression forces applied to a naturally curved bone have been shown to cause plastic deformation (16,129), and lateral bending or tangential forces caused by compression around a cylindrical object have been shown to produce traumatic bowing (7,101,131). Tensile stress is produced at the convex surface and

compression stress occurs at the concave surface. Bending occurs though oblique slip lines or microfractures along the concave border of the bone. These slip lines extend from the periosteum to the medullary canal at an angle of approximately 30 degrees to the long axis to the bone (16).

Classification

Plastic deformation can occur in the radius, the ulna, or both. Other patterns show either the radius or ulna deformed in combination with a fracture of the diaphysis of the other bone.

Demos (26) reviewed 74 cases of plastic deformation and found that 58 (78%) occurred in the forearm: 26 (35%) in the ulna, 15 (20%) in the radius, 11 (15%) in both bones, and 6 (8%) unspecified.

Signs and Symptoms

Plastic deformation appears clinically with deformity, tenderness, pain, and, if both bones are involved, a decrease in pronation and supination (Fig. 10-43).

FIGURE 10-43. A: A 7-year-old boy with plastic deformation of the radius and ulna consisting only of a gradual curvature of the forearm. **B:** The curvature is more apparent when compared with the normal right forearm. **C:** Because of the plastic deformation, there is limitation of supination and pronation.

Radiographic Findings

Characteristically, there is a broad fixed curvature of the entire bone (Fig. 10-44). In doubtful cases, a radiograph of the unaffected forearm in the same position reveals subtle deformation. A bone scan can differentiate a fresh injury from an old injury when physical signs are inconsistent (77). The elbow and wrist must be included in the radiograph to rule out disruption at these levels.

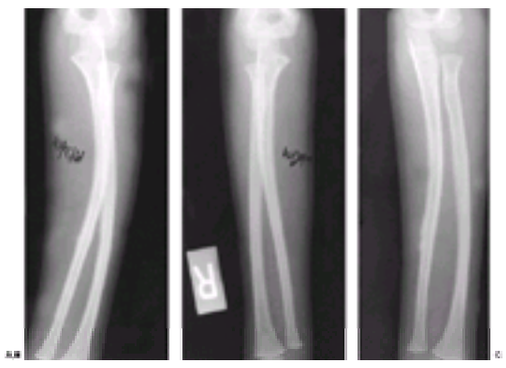

FIGURE 10-44. A: A 4-year-old sustained acute injury to the left forearm. Both the radius and ulna demonstrate plastic deformation. The patient had supination only to neutral. **B:** Unaffected right forearm for comparison. **C:** After reduction, most of the angulation has been corrected, but there is still a slight residual. Full forearm rotation has been reestablished.

The most common pattern is plastic deformation of the ulna with a greenstick fracture of the radius (Fig. 10-45). The plastic deformation of the ulna must be corrected before the radius can be fully reduced.

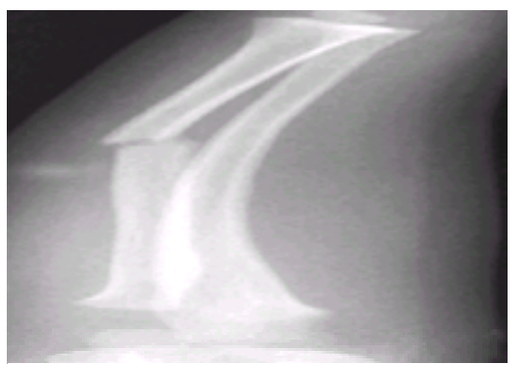

FIGURE 10-45. Plastic deformation of ulna. In this 3-year-old, there is an obvious greenstick fracture of the radius. However, to achieve a full reduction, the plastic deformation of the ulna must first be corrected.

In 4 to 6 weeks, gradual bony remodeling manifests itself by cortical thickening in the concavity of the deformity. However, there may be no periosteal callus even after several months (125).

Treatment

Early Recognition Critical

Early recognition of plastic deformation is important. The deformity may hinder reduction of a true fracture in the adjacent bone of the forearm. If not recognized, the residual deformity may cause limitation of pronation and supination. Rydholm and Nilsson (110), along with Demos (26), believed that some remodeling can occur in patients younger than 10 years of age even without correction of the bowing. Plastic deformation in a child younger than 4 years of age probably does not need correction because the bone will remodel sufficiently to give full function (112). Parents should be cautioned that this remodeling will take 6 months to 1 year. Older

children may have residual loss of pronation and supination if the bowing is not reduced.

Considerable but Gradual Force Needed

If the curvature is significant, correction should be attempted in the acute phase (63,73) under general anesthesia. Correction may be difficult, and considerable force is required. Borden (12), in his experiments with dogs, showed that a force of 100% to 150% of body weight was required to produce plastic deformation and concluded that a similar force was needed to effect reduction. This amount of force cannot be obtained by longitudinal traction, but must be effected by placing the apex of the curve over a fulcrum and applying the force at right angles to the deformity. Sanders and Heckman (112) have effectively used this method to correct the deformity by the use of a wooden cylinder wrapped in a towel (Fig. 10-46). They caution that a great deal of pressure must be applied gradually over several minutes to straighten the curvature slowly and that care should be taken not to apply this pressure over the physes.

FIGURE 10-46. The deformity is gradually corrected by twisting the deformity with the apex in a roll, wrapped in a towel *(white arrow).* The correcting force is applied proximally and distally *(black arrows)* on the concave side of the deformity.

If both bones are deformed, the one with the greatest deformity is reduced first (Fig. 10-44). If one bone is deformed and the other fractured, the plastically deformed bone must be reduced before the fracture (Fig. 10-45).

Immobilization in a long arm cast is necessary for 6 weeks to achieve adequate healing and to avoid recurrence of the deformity.

Blount (9) proposed drilling the apex of the deformed bone through a small incision to fracture the bone and effect the reduction. This seems no longer necessary in view of the effective means of reduction described by Sanders and Heckman (112).

AUTHORS' PREFERRED METHOD OF TREATMENT

The gradual and sustained reduction method described by Sanders and Heckman (112) usually is effective (Fig. 10-46). The bone most deformed must be reduced first to achieve a reduction of the other, whether deformed or fractured. If the forearm cannot be fully supinated and pronated after manipulation, reduction has not been successful. It is advisable to caution the parents that it may be necessary to fracture one or both bones to effect a reduction.

A long arm cast is applied with the elbow flexed 90 degrees and the forearm in full supination. This cast is worn for 6 to 8 weeks, depending on the child's age.

Prognosis

Full reduction may not be achieved, but the clinician should strive for 85% correction (Fig. 10-44C). There should be no recurrence of the deformity, but a check radiograph should be made at weekly intervals for the first 2 or 3 weeks. Healing should be expected in 6 to 8 weeks.

Complications

With bowing of the proximal ulna, it may be difficult to apply adequate pressure to effect a reduction and the deformity may persist, but it usually is not sufficient to produce significant loss of pronation and supination. The major complication is failure to recognize or correct the deformity fully, with residual angulation and loss of motion. A more significant problem may be caused by failure to recognize subluxation of the radial head, which typically requires anatomic reduction of the ulnar deformity (Fig. 10-47).

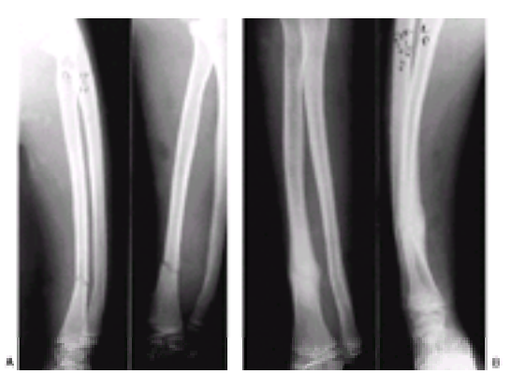

FIGURE 10-47. Persistent deformation. **A:** Fracture of the distal third of both the radius and ulna. The ulna has plastic deformation. **B:** The fracture healed uneventfully; however, the plastic deformation of the ulna had not been corrected, which led to some residual bowing with loss of forearm rotation. The persistent deformation of the ulna influenced the development of an angular deformity of the radius as it healed.

FRACTURES OF THE PROXIMAL RADIUS AND ULNA

HENRY G. CHAMBERS

Fractures of the proximal radius in skeletally immature patients usually involve the metaphysis or physis. True isolated radial head fractures are rare. In the proximal ulna, the olecranon, which biomechanically is a metaphysis, often fails with a greenstick pattern. Fractures in this area also may involve the physis. Fractures of the olecranon associated with proximal radioulnar joint disruption are considered part of the Monteggia fracture–dislocation complex and are discussed in Chapter 12.

FRACTURES OF THE PROXIMAL RADIUS

Incidence (Overall Percentage)

Fractures of the radial neck account for slightly more than 1% of all children's fractures (47). In skeletally immature children, the radial head or epiphysis is rarely fractured, probably because of the large amount of cartilage in the radial head. If the fracture involves the epiphysis, it usually is part of a Salter-Harris type IV fracture pattern. In 90% of proximal radial fractures, the fracture line involves either the physis or the neck (39). In six large series of elbow fractures, the incidence of fracture of the radial neck was remarkably consistent, varying only from 5% to 8.5% (10,27,39,41,51,68). Fractures of the radial neck and head in skeletally immature patients account for only 14% to 20% of the total injuries of the proximal radius occurring in all age groups (31,41).

In most series, the age of occurrence varies from 4 to 14 years of age, with the median age ranging from 9 to 10 years (16,39,48,67,84,98,106,110). There is very little difference in the occurrence rates between boys and girls (16,39,67). On the average, however, this injury seems to occur in girls approximately 2 years earlier than in boys (98).

Anatomy

Ossification Process

In the embryonic development of the proximal radius, the neck and head become well defined by 9 weeks of gestation. At 4 years of age, the radial head and neck have assumed the same overall shape as in an adult (68). Ossification of the epiphysis begins at approximately 5 years of age as a small, flat nucleus (Fig. 11-1). Some variation in ossification pattern can occur. This ossific nucleus can originate as a small sphere or it can be bipartite, which may be misinterpreted as a fracture (13,59,94).

FIGURE 11-1. Ossification pattern. **A:** At 5 years, ossification begins as a small oval nucleus. **B:** As the head matures, the center widens but remains flat.

Angulation Normal

In the preossification stage, on the anteroposterior (AP) projection radiograph, the edge of the metaphysis of the proximal radius slopes distally on its lateral border, and may give the false impression that the radial neck is angulated.

Some angulation of the radial head is normal compared with the radial shaft. In the AP view, the lateral angulation varies from 0 to 15 degrees, with the average being 12.5 degrees (110). In the lateral view, the angulation can vary from 10 degrees anterior to 5 degrees posterior, with the average being 3.5 degrees anterior (110).

Soft Tissue Attachments

No ligaments attach directly to the radial neck or head. The radial collateral ligaments attach to the orbicular ligament, which originates from the radial side of the ulna. The articular capsule takes its origin from the proximal third of the neck. From there, the capsule protrudes distally from under the orbicular ligament to form a pouch (recessus sacciformis). Thus, only a small portion of the neck lies within the articular capsule (113). Because much of the neck is extracapsular, fractures involving only the neck may not produce an intraarticular effusion. Therefore, the fat pad sign may be negative with some of these injuries (13,94,40).

The “Cam” Effect

The proximal radioulnar joint has an exacting congruence. The axis of rotation lies directly in the center of the radial neck. Any deviation of the center of the radial head from its alignment with the center of the radius of the neck changes the arc of rotation of the head. If the head is displaced on the neck, instead of rotating smoothly in a pure circle, the radial head rotates with a “cam” effect. This disrupts the congruity of the proximal radioulnar joint, with subsequent loss of supination and pronation (115) (Fig. 11-2).

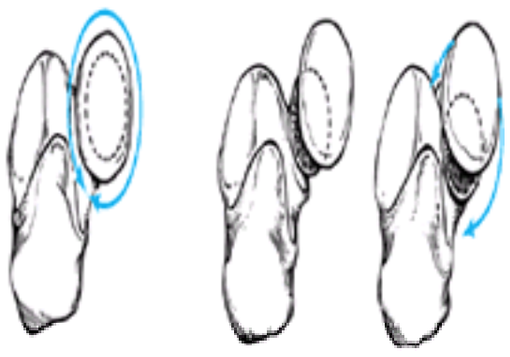

FIGURE 11-2. A: Normal rotation of the forearm causes the radial head to circumscribe an exact circle within the proximal radioulnar joint. **B:** Any translocation of the radial head limits rotation because of the “cam” effect described by Wedge and Robertson (115)

Diagnosis

Clinical Findings

The symptoms of proximal radial fractures vary with the magnitude of the injury. Because of minimal initial symptoms, the patient or patient's parents may not seek medical treatment until a few days after the initial injury. Much of the swelling and pain is caused by the distention of the elbow joint with blood, and a few hours may be required to develop enough pressure in the joint to cause significant symptoms.

Often the pain is localized over the radial head or neck. The pain usually is increased more with passive forearm supination and pronation than with elbow flexion and extension. In a young child, the primary complaint may be wrist pain (2), and pressure over the proximal radius may accentuate this referred wrist pain. The wrist pain may be secondary to radial shortening and subsequent distal radioulnar joint dysfunction.

Radiographic Evaluation

Supination–Pronation Views

On radiography, the fracture is usually easily seen on both AP and lateral views. Occasionally, the forearm may need to be both supinated and pronated to reveal the fracture line fully.

Perpendicular Views

If the elbow cannot be extended because of pain, two views and oblique views may be necessary to see the elbow in full AP profile. One view is taken with the beam perpendicular to the distal humerus, and the other with the beam perpendicular to the proximal radius. This allows the physeal line of the radius to be seen in full profile.

In a minimally displaced or undisplaced fracture, the fracture line may be difficult to visualize because it is superimposed on the proximal ulna. In these cases, oblique views of the proximal radius may be helpful in bringing the fracture line into view (13,113). One oblique view that is especially helpful is the radiocapitellar view suggested by Greenspan et al. and Hall-Craggs et al. (36,37 and 38). This projects the radial head anterior to the coronoid process (Fig. 11-3). It is especially helpful if full supination and pronation views are difficult to obtain because of acute injury.

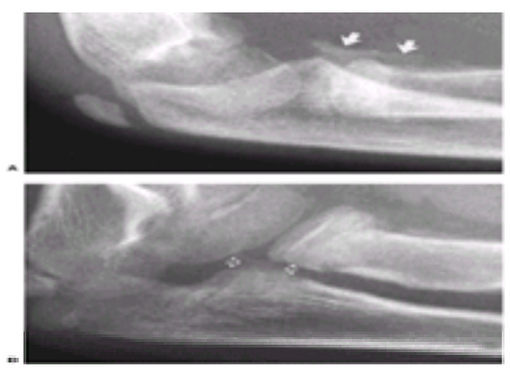

FIGURE 11-3. The radiocapitellar view. **A:** Radiographs of a 13-year-old girl who had sustained a radial neck fracture associated with an elbow dislocation. There is ectopic bone formation *(arrows).* In this view, it is difficult to tell the exact location of the ectopic bone. **B:** The radiocapitellar view separates the radial head from the coronoid process. This demonstrates that the ectopic bone is from the coronoid process *(arrows)* and not the radial neck.

If the epiphysis is ossified, the displacement of the head is usually obvious, but displacement may be difficult to determine before ossification (85). The key to diagnosis is a thorough clinical examination, including careful palpation of the radial neck. On radiography, the smoothness of the metaphyseal margin may be lost. Ultrasonography can be used to evaluate for hemarthrosis and displacement of the fracture. It also allows a dynamic range-of-motion evaluation (49).

The supinator fat pad is a small layer of fat that overlies the supinator muscle in the proximal forearm. In soft tissue views of the proximal forearm or elbow, this layer of fat is often well defined. Displacement of the supinator fat pad may indicate that the injury is localized to the proximal radius (88). The supinator fat pad and distal humeral fat pads are not always displaced with occult fractures of the radial neck or physis (40,92,94).

Arthrography or magnetic resonance imaging (MRI) can be used to determine any displacement of the unossified radial head.

Classification

Jeffrey's classification (41) is the most widely used. It is based on the two major mechanisms of injury (valgus stress and those associated with a dislocation of the elbow).

AUTHORS' CLASSIFICATION

We have classified these fractures, on the basis of the mechanism of injury and displacement of the radial head, into three major groups (Table 11-1):

Group I: Primary displacement of the radial head
A. Valgus fractures
   1. Type A—Salter-Harris type I and II injuries of the proximal radial physis
   2. Type B—Salter-Harris type IV injuries of the proximal radial physis
   3. Type C—Fractures involving only the proximal radial metaphysis
B. Fractures associated with elbow dislocation
   1. Type D—Reduction injuries
   2. Type E—Dislocation injuries
Group II: Primary displacement of the radial neck
A. Angular injuries (Monteggia type III variant)
B. Torsional injuries
Group III: Stress injuries
A. Osteochondritis dissecans of the radial head
B. Physeal injuries with neck angulation

TABLE 11-1. CLASSIFICATION OF FRACTURES INVOLVING THE PROXIMAL RADIUS

Group I: Those in which the radial head is primarily displaced (most proximal radial injuries are in this group)

Group II: Those in which there is primary displacement of the radial neck

Group III: Stress injuries

Head-Displaced Fractures

For the head-displaced fractures (group I), we combined the classifications of Jeffrey (41) and Newman (67) to produce a new classification based primarily on the mechanism of injury. The two main subclasses of fractures in group I are valgus injuries and those associated with elbow dislocations. Valgus injuries are subdivided into three types (A, B, and C) based on the location of the fracture line (Fig. 11-4). Fractures associated with an elbow dislocation are subdivided into two types. The first, type D, is based on the original concept proposed by Jeffrey (41) that the fracture occurs during the period of spontaneous reduction (Fig. 11-5A). In this case, the radial head lies proximal to the posterior aspect of the joint. The second, type E, is based on Newman's concept (67) that the fracture and displacement occur during the process of dislocation of the elbow. In this type, the radial head lies distal to the anterior portion of the joint (Fig. 11-5B). There appears to be no need to separately classify fractures involving only the radial head. Most radial head fractures in children described in the literature have been Salter-Harris type IV injuries containing portions of both the epiphysis and metaphysis.

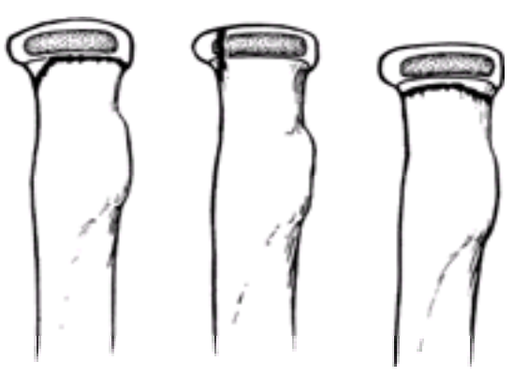

FIGURE 11-4. Types of valgus injuries. **Left:** Type A: Salter-Harris type I or II physeal injury. **Center:** Type B: Salter-Harris type IV injury. **Right:** Type C: Total metaphyseal fracture pattern.

Neck-Displaced Fractures

For the neck-displaced fractures (group II), there are two subgroups, angular and torsional.

Stress Injuries

The final group (group III), stress injuries, includes osteochondritis of the radial head and physeal injuries of the neck that produce angular deformities.

Mechanisms of Injury

Table 11-2 lists the proposed mechanisms for fractures of the radial head and neck in children.

I. Primary displacement of the head (incongruous)
   A. Valgus injuries
   B. Associated with dislocation of the elbow
      1. During reduction
      2. During dislocation
II. Primary displacement of the neck
   A. Angular forces
   B. Rotational forces
III. Chronic stress forces

TABLE 11-2. FRACTURES OF THE RADIAL HEAD AND NECK: PROPOSED MECHANISMS IN CHILDREN

Primary Displacement of the Radial Head (Group I)

In general, when these fractures occur, the major force is applied to the radial head and is secondarily transmitted to the radial neck, which fractures because it is weaker metaphyseal bone. As a result, the radial head usually is displaced by angulation, rotation, translocation, or complete separation of the radial head from the neck. This displacement of the radial head produces an incongruity of the proximal radioulnar joint, which is the major cause of dysfunction. In this type of injury, treatment emphasizes reduction of the head to its normal congruous position with the shaft and proximal radioulnar joint.

Valgus Injuries

Angular Force on the Neck. Most of these injuries appear to be caused by a fall on the outstretched arm with the elbow in extension (32,39,41,67,68,113) and an

associated valgus thrust to the forearm (Fig. 11-6). This valgus strain puts a compression force across the radiocapitellar joint. Because much of the head is cartilage, the valgus force is transmitted to the weaker physis or metaphysis of the neck (113). These fractures characteristically appear as an angular deformity of the head with the neck (Fig. 11-6A). The direction of angulation depends on whether the forearm is in a supinated, neutral, or pronated position at the time of the fall. Vostal (113) has shown that in neutral, the pressure is concentrated on the lateral portion of the head and neck. In supination, the pressure is concentrated anteriorly, and in pronation it is concentrated posteriorly.

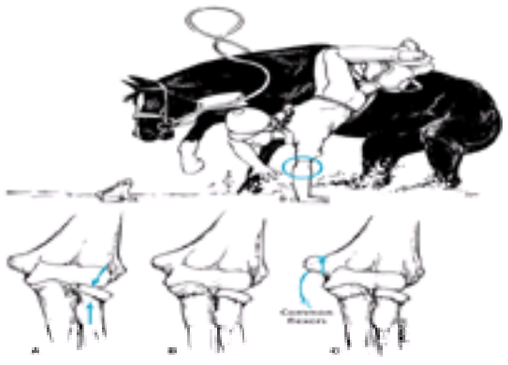

FIGURE 11-6. The most common mechanism of radial neck fractures involves a fall on the outstretched arm. This produces an angular deformity of the neck **(A).** Further valgus forces can produce a greenstick fracture of the olecranon **(B)** or an avulsion of the medial epicondylar apophysis **(C).** (Redrawn with permission from Jeffery CC. Fracture of the head of the radius in children. *J Bone Joint Surg Br* 1950;314-324.)

Associated Injuries. This valgus stress pattern causes associated injuries about the elbow (41,42,68,98,32) (Fig. 11-6B,Fig. 11-6C) such as greenstick fracture of the olecranon (Fig. 11-7), which Bado (4) considered an equivalent of a type I Monteggia lesion. An avulsion fracture of the medial epicondylar apophysis may also occur (15). In Fowles and Kassab's series of patients with radial neck fractures (27), more than 61% had one of these associated injuries.

FIGURE 11-7. Associated fractures of valgus stress. Anteroposterior view of a fracture of the radial neck associated with a greenstick fracture of the olecranon *(arrows)*.

Children with an increased carrying angle may be predisposed to injury of the proximal radius. Henrikson (39) found that the degree of cubitus valgus in patients who sustained this injury was greater than in patients with other types of elbow fractures.

Fracture Patterns. With these valgus injuries, the fracture pattern can be one of three types (Fig. 11-4). In the first two types, the fracture line involves the physis. Type A represents either a Salter-Harris type I or II physeal injury. In a Salter-Harris type II injury, the metaphyseal fragment is triangular and lies on the compression side. In type B fractures, the fracture line courses vertically through the metaphysis, physis, and epiphysis to produce a Salter-Harris type IV physeal fracture pattern (Fig. 11-8). This is the only fracture type that involves the articular surface of the radial head. In type C fractures, the fracture line lies completely within the metaphysis (Fig. 11-9), and the fracture can be transverse or oblique. Type B fractures are rare. The incidences of types A and C fractures are approximately equal (98).

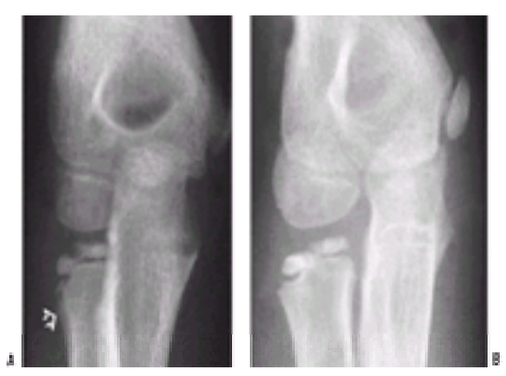

FIGURE 11-8. Valgus (type B) injury. **A:** Three weeks after the initial injury, there was evidence of distal migration of this Salter-Harris type IV fracture fragment. Periosteal new bone formation has already developed along the distal metaphyseal fragment *(arrow).* **B:** Six months after the initial injury, there is evidence of an osseous bridge formation between the metaphysis and the epiphysis. Subsequently, the patient had secondary degenerative arthritis with loss of elbow motion and forearm rotation.

FIGURE 11-9. Valgus type C injury. The fracture line is totally metaphyseal and oblique *(arrows)*

Displacement Patterns. Regardless of the type of fracture pattern, displacement can vary from minimal angulation to complete separation of the radial head from the neck (Fig. 11-10). With minimal angulation alone, the congruity of the proximal radioulnar joint usually is retained. If the radial head is displaced in relation to the radial neck, the congruity of the proximal radioulnar joint is lost because of the cam effect. With complete displacement, there is very little contact between the fracture surfaces. Completely displaced fractures often are associated with more severe injuries.

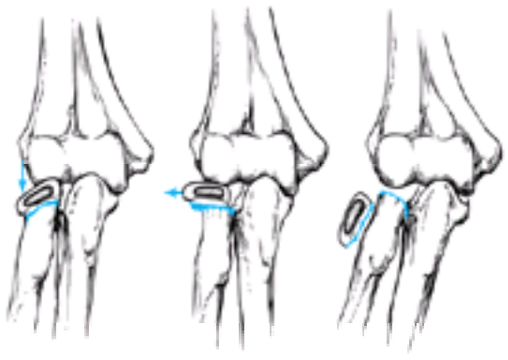

FIGURE 11-10. Displacement patterns. The radial head can be angulated **(A),** translated **(B),** or completely displaced **(C)**.

Neck Migration. Distally, there is also displacement of the neck and shaft fragment. Patterson (72) believed that once the stabilizing effect of the radial head is lost, the distal fragment can migrate proximally. This proximal migration of the distal fragment tends to be ulnarward because of the forces exerted in this direction by the supinator and biceps muscles (Fig. 11-11). Patterson attempted to counteract these forces in his manipulative technique (see section on Patterson's Manipulative Technique). When there is a strong valgus component, the proximal portion of the distal fragment of the radius can get locked medial to the coronoid process, making a closed reduction almost impossible (26,55).

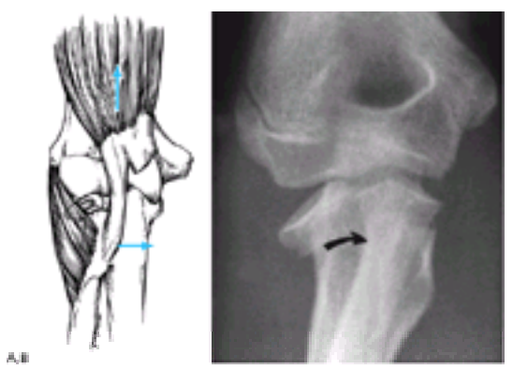

FIGURE 11-11. Forces producing displacement. **A:** Once the stabilizing effect of the radial head is lost, the distal fragment (radial neck and proximal shaft) is displaced ulnarward and proximally by the unopposed biceps and supinator muscles *(arrows).* (Redrawn with permission from Patterson RF. Treatment of displaced transverse fractures of the neck of the radius in children. *J Bone Joint Surg* 1934;16:695.) **B:** Radiograph demonstrating proximal and medial (ulnar) displacement of distal neck fragment *(arrow).* (From Wilkins KE, ed. *Operative management of upper extremity fractures in children.* Rosemont, IL: American Academy of Orthopaedic Surgeons, 1994:55).

Associated with Elbow Dislocation

In two rare types of fractures of the radial neck, the head fragment is totally displaced from the neck (5,15,28,41,67,114). These types are associated with an elbow dislocation. The proposed mechanism is a fall on the hand with the elbow flexed, which causes a momentary partial dislocation of the elbow and forces the radial head posterior to the capitellum.

During Reduction (Type D). In the original description of this injury, Jeffrey (41) suggested that displacement and fracture occurred during spontaneous reduction of the transiently dislocated elbow. During this reduction process, the capitellum applies a proximal force to the distal lip of the radial head, causing it to separate as the forearm and distal radius are reduced distally (Fig. 11-5A). The radial neck and olecranon return to their anatomic locations while the radial head remains in the posterior aspect of the joint (114).

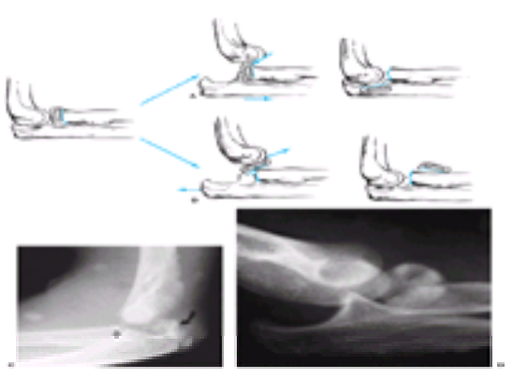

FIGURE 11-5. Dislocation fracture patterns. **A:** Type D: The radial neck is fractured during the process of reduction by the capitellum pressing against the distal lip of the radial head (41). **B:** Type E: The radial neck is fractured during the process of dislocation by the capitellum pressing against the proximal lip of the radial head (67). **C:** Radiographs of a radial head that fractured during the reduction of the dislocation (type D). The radial head *(solid arrow)* lies posterior to the distal humerus, and the distal portion of the neck *(open arrow)* is anterior. (Courtesy of Richard E. King, MD.) **D:** Radiograph of the dislocated elbow in which the fracture of the radial neck occurred during the process of dislocation (type E).

During Dislocation (Type E). Newman (67) described a type of radial head fracture in which the fracture occurs during the process of dislocation. In this case, the capitellum applies a distally directed force to the proximal lip of the radial head as the elbow is dislocated (Fig. 11-5B). The elbow may remain dislocated with the radial head lying anterior and often parallel to the long axis of the neck fragment. If the dislocation is reduced, either by manipulation or spontaneously, the radial head lies free in the anterior portion of the elbow joint (67,110,114).

Primary Displacement of the Radial Neck (Group II)

Rarely, angular or torsional forces cause a primary disruption or deformity of the neck, while the head remains congruous within the proximal radioulnar joint.

Treatment of these injuries is manipulation of the distal neck fragment to align it with the head.

Angular Forces

Angular forces always produce type III Monteggia equivalents. A Monteggia type III fracture pattern is created when a varus force is applied across the extended elbow, resulting in a greenstick fracture of the olecranon or proximal ulna and a lateral dislocation of the radial head (120). Occasionally, however, the failure occurs at the radial neck (Monteggia III equivalent), and it displaces laterally, leaving the radial head and proximal neck fragment reduced under the orbicular ligament (69) (Fig. 11-12). The problem in the management of this injury is alignment of the distal neck fragment with the proximal radial and neck fragments.

FIGURE 11-2. Angular forces. This 8-year-old sustained a type III Monteggia equivalent in which the radial neck fractured *(arrow),* leaving the radial head reduced proximally. (Courtesy of Ruben D. Pechero, MD.)

Rotational Forces

Rotational forces appear to occur in young children before ossification of the proximal radial epiphysis. Both reports of this injury are in the European literature (32,39), and in both, the initial rotational force was in supination. Reduction was achieved by pronation of the forearm. Diagnosis of these injuries is difficult and may require arthrography or an examination under general anesthesia. This injury should be differentiated from the more common subluxation of the radial head (pulled elbow syndrome), in which the forearm usually is held in pronation with resistance to supination. In addition, on radiography there usually are no signs of hemarthrosis, as may be seen in the torsional fractures.

Stress Injuries (Group III)

A final mechanism is chronic, repetitive stress, both longitudinal and rotational, on either the head or the proximal radial physis. These injuries usually are the result of high-performance athletic activity in which the upper extremity is required to perform repetitive motions. These repetitive stresses disrupt growth of either the neck or the head, with eventual deformity. These are actually forms of stress fractures.

In the United States, the popularity of organized sports has produced a number of unique injuries in pediatric athletes related to repetitive stress applied to growth centers. This is especially true in the immature elbow. Most injuries are related to throwing sports, primarily Little League baseball. Most of this “Little League pathology” involves tension injuries on the medial epicondyle. In some athletes, however, the lateral side may be involved as well because of the repetitive compressive forces applied to the capitellum and radial head and neck. In the radial head, lytic lesions similar to osteochondritis dissecans may occur (22,108,118) (Fig. 11-13 and Fig. 11-14). If the stress forces are transmitted to the radial neck, the anterior portion of the physis may be injured, producing an angular deformity of the radial neck (23) (Fig. 11-15).

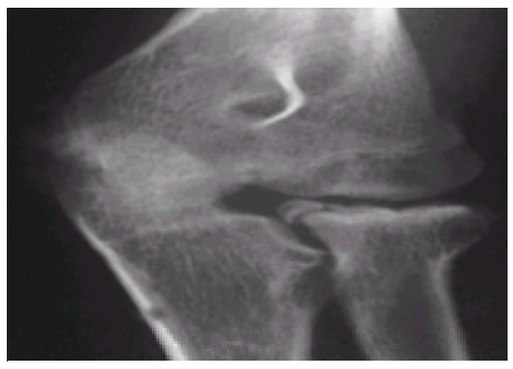

FIGURE 11-13. Osteochondritis dissecans. Radiograph of this 11-year-old Little League pitcher's elbow shows fragmentation of the subchondral surfaces of the radial head. These changes and the accelerated bone age are evidence of overuse.

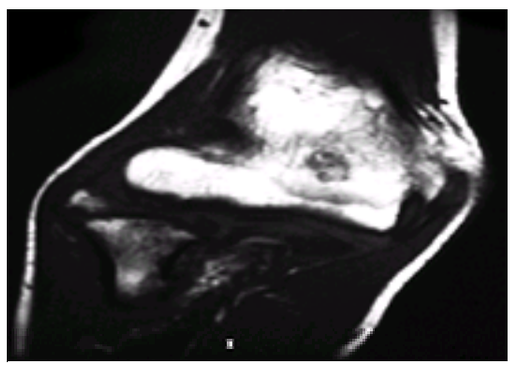

FIGURE 11-14. Baseball player with osteochondritis dissecans lesion and fragmentation after direct blow to elbow.

Treatment

The methods of treatment for radial head injuries include:

1. Simple immobilization with no manipulation
2. Manipulative closed reduction
3. Percutaneous pin reduction
4. Intramedullary pin reduction
5. Open reduction with or without internal fixation

6. Excision of either the entire head or the small head fragment

Determination of the proper method of treatment depends on many factors, including the degree and type of displacement, the association of other injuries, the age of the patient, and the time elapsed since the injury.

Prognostic Factors

Severity of Injury

Some factors may be more important than the type of treatment in determining the final result. It is still controversial whether age has a favorable or unfavorable effect on the outcome (98). A poor result can be expected if the fracture is associated with other injuries, such as an elbow dislocation, a fracture of the olecranon, or avulsion of the medial–epicondylar apophysis (27,92). The magnitude of injurious force to the elbow appears to be a major factor in determining the quality of the result (51,98).

Quality of Reduction

Another factor that appears to influence the result is the quality of the reduction. Residual tilt of the head is tolerated better than displacement of the head. Tibone and Stoltz (106) reported that the number of good results decreased if the initial angulation exceeded 30 degrees or the amount of displacement exceeded 3 mm. Newman (67,98) found that more than 4 mm of displacement increased the frequency of poor results and the risk of synostosis with the proximal ulna.

Acceptable Angulation

The amount of acceptable angulation varies. Some clinicians accept up to 30 degrees of residual angulation (51,59,67,110,80), whereas others believe that up to 45 degrees of residual angulation can yield a satisfactory result (9,16,68,112). At the other end of the spectrum, Pollen (78) believed that in older children, only 15 degrees of angulation should be accepted without attempting manipulation. The spontaneous correction that can be expected to occur with growth in younger children is approximately 10 degrees.

Outcomes

In theory, the cam effect should limit supination and pronation if there is significant displacement of the proximal fragment. However, adequate remodeling with a functional range of motion can occur with as much as 40% displacement (Fig. 11-16).

FIGURE 11-16. Translocation remodeling. **A:** Injury film of a 9-year-old who had 60 degrees of supination and pronation by clinical examination with local anesthesia into the elbow joint. Because range of motion was functional, the position was accepted. **B:** Two months postfracture, there was almost complete remodeling of the translocation. The patient's forearm rotation was 75 degrees in both directions. (Courtesy of Earl A. Stanley, Jr, MD.)

In general, fractures in which an adequate closed reduction can be obtained have better results than those requiring open reduction. This may be because injuries that can be managed by closed methods are the result of less severe trauma than those requiring open reduction. The poor results in those managed with open methods may be due just as much to the associated soft tissue injuries as to the surgical insult.

The overall incidence of poor results in large series varies from 15% to 33% (27,39,42,98,110). If only severely displaced fractures were considered, the incidence of poor results could be as high as 50% (98). Thus, at least one in five or six children can be expected to have a poor result despite adequate treatment. Predicting which children will have poor results before treatment is initiated can be valuable. Forewarning the parents of a possible poor result is much wiser than telling them after the treatment has been completed. A child of approximately 7 years of age with minimal angulation or displacement and no associated injuries can be expected to have a good result. In a 12-year-old with a fracture associated with a dislocation and with complete displacement of the radial head, motion of the elbow may be significantly limited.

After 6 months, very little improvement in motion can be expected. Steinberg et al. (98) found that function in their patients at 6 months was almost equal to that when the patients were examined years later.

Nonoperative Methods

Simple Immobilization (Up to 30 Degrees of Angulation)

Fractures in younger children in which the angulation of the head is less than 20 to 30 degrees usually can be managed with some type of simple immobilization. A collar and cuff, a posterior splint, or a light long arm cast usually is sufficient to provide comfort and protection from further injury. Aspiration of the intraarticular hematoma may provide added comfort.

Manipulative Closed Reduction (30 to 60 Degrees)

In uncomplicated fractures with angulation of up to 60 degrees, a satisfactory result usually can be achieved with manipulative closed reduction (9,41,115). The chance of achieving a satisfactory reduction when the initial angulation exceeds 60 degrees is much less. Although angulation of up to 45 degrees can produce acceptable results, fractures with more than 30 degrees of angulation should probably be manipulated.

Patterson's Manipulative Technique

Many authors (20,59) have adopted a technique of manipulative reduction with the elbow in extension, as advocated by Patterson (72). Adequate relaxation is required and can be achieved only by a general or some type of regional anesthetic technique. The orbicular ligament should be intact to stabilize the proximal radial head fragment (59). In Patterson's technique, an assistant grasps the arm proximal to the elbow joint with one hand (Fig. 11-17, left) and places the other hand medially over the distal humerus to provide a medial fulcrum for the varus stress applied across the elbow. The surgeon applies distal traction with the forearm supinated to relax the supinators and biceps. A varus force is applied across the elbow to overcome the ulnar deviation of the distal fragment so that it can be aligned with the proximal fragment. This varus force also helps open up the lateral side of the joint, which facilitates manipulation of the head fragment.

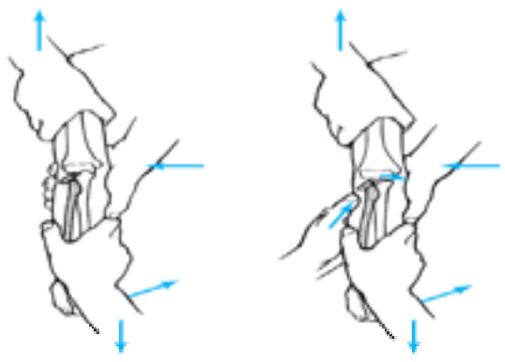

FIGURE 11-17. Patterson's manipulative technique. **Left:** The assistant grabs the arm proximally with one hand placed medially against the distal humerus. Distal traction with the forearm supinated is applied by the surgeon. A varus force is also applied to the forearm. **Right:** Digital pressure is then applied directly over the tilted radial head to complete reduction. (Redrawn with permission from Patterson RF. Treatment of displaced transverse fractures of the neck of the radius in children. *J Bone Joint Surg* 1934;16;696-698.)

Although forearm supination may relax the supinator muscle, it may not be the best position for manipulation of the head fragment. Jeffrey (41) points out that the tilt of the radial head can be anterior or posterior depending on the position of the forearm at the time of injury. The forearm should be rotated until the maximal tilt of the proximal fragment is felt laterally. The direction of maximal tilt can be confirmed on radiography. If the x-ray beam is perpendicular to the head in maximal tilt, it casts an oblong or rectangular shadow. If not, the shadow is oval or almost circular (41). With the varus force applied across the extended elbow and the maximal tilt directed laterally, digital pressure is applied over the radial head to manipulate it back into position (Fig. 11-17, right).

Kaufman et al. (44) proposed another technique in which the elbow is manipulated in the flexed position. The surgeon's thumb is pressed against the anterior surface of the radial head and the forearm is forced into pronation (Fig. 11-18).

FIGURE 11-18. Flexion = npronation (Israeli) technique of reduction. **A:** The thumb is placed over the radial head fracture site. The forearm is grasped distally. **B:** The forearm is then gradually pronated *(arrow)* until full pronation is achieved. During this procedure, pressure is maintained proximally over the area of the radial head fracture.

After the quality of the reduction is confirmed radiographically, the arm usually is immobilized in pronation. Pronation is recommended because it is the forearm motion most often restricted after fracture (115). Some have recommended that the forearm be placed in supination because they believe it is easier for the patient to regain active pronation than active supination during rehabilitation. Whether pronation or supination is chosen, the elbow is placed in 90 degrees of flexion.

Although most fractures are stable after reduction, redisplacement can occur, especially if the initial tilt was more than 60 degrees (21,42). Fractures with more than 90 degrees of angulation, especially those in which the head fragment is lying free in the joint, are almost impossible to reduce by closed methods.

Since the late 1960s, four patients have been reported in whom the head fragment was lying proximal to the neck and parallel to its long axis (28,117,119). In each, manipulation was attempted and initially a satisfactory position appeared to be achieved. A closer inspection showed, however, that the head had been completely rotated 180 degrees so that the articular surface of the head was facing the fracture surface of the radial neck (Fig. 11-19).

FIGURE 11-19. One hundred eighty-degree rotation. Radiograph of a radial head that was rotated 180 degrees in which the articular surface *(arrows)* is facing the fracture surface of the distal fragment. (From Fraser KE. Displaced fracture of the proximal end of the radius in a child: a case report of the deceptive appearance of a fragment that had rotated 180°. *J Bone Joint Surg Am* 1995;77;782-783; with permission.)

Operative Techniques

Percutaneous Pin Reduction

The use of percutaneous pin reduction with an image intensifier has become a popular method of satisfactorily reducing moderately to severely displaced fractures without the trauma of a formal surgical incision (3,6,20,75,97). The radial head is manipulated into place under image control with a single-pointed awl, a Steinmann pin (86), a periosteal elevator (29), or a double-pointed “bident” (3). The latter in theory controls rotation better. Pesudo et al., in their series of 22 displaced radial neck fractures, found that the results after percutaneous pin reduction were superior to those after open reduction (75).

Biyani et al. (7) drive the pin that is used to reduce the radial head across the fracture site to stabilize it. The pin is left in for 3 weeks and then removed to allow motion.

Intramedullary Pin Reduction

In 1980, Metaizeau et al. (61) proposed reducing severely tilted radial neck fractures with an intramedullary wire passed from the distal metaphysis. A report 13 years later (60) demonstrated the effectiveness of this technique. The wire is inserted into the medullary canal through an entrance hole in the distal metaphysis (Fig. 11-20). Once the wire reaches the fracture site, the angulation at the tip enables it to engage the proximal fracture site at the neck. Once engaged, the wire is then twisted to reduce the head and neck fragment. This technique has produced results superior to open reduction with fewer complications (33,93).

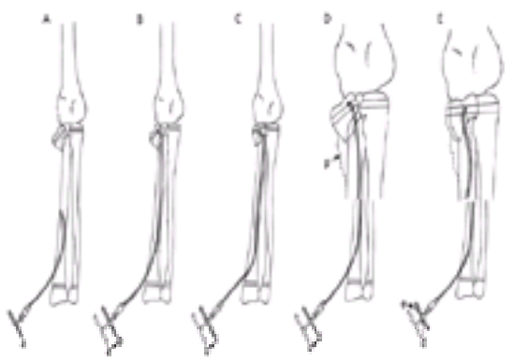

FIGURE 11-20. Intramedullary pin reduction. **A:** The curved flexible pin is inserted distally in the metaphysis and passed up the shaft proximally. **B:** The curved end of the rod is engaged into the proximal fragment. **C:** The rod is used to distract and disimpact the head fragment. **D and E:** Once the head fragment is disimpacted, it is then rotated into position with the intramedullary rod. (From Metaizeau JP, Lascombes P, Lemelle JL, et al. Reduction and fixation of displaced radial neck fractures by closed intramedullary pinning. *J Pediatr Orthop* 1993;13;55-356; with permission.)

Open Reduction

The primary consideration in treatment choice is whether open reduction produces better results than manipulative closed reduction. With valgus injuries, a residual tilt of 45 degrees probably produces as good a result as trying to achieve a perfect reduction surgically. A satisfactory closed reduction produces better results than an anatomically perfect open surgical reduction (Table 11-3).

50 to 60 degrees of pronation and supination on clinical examination	

TABLE 11-3. ACCEPTABLE REDUCTION

Early reviews reported poor results with significant loss of range of motion in cases managed operatively (16,67,106,115). In a more recent review, Steinberg et al. (98) combined their results of open reduction of severely displaced fractures with those of five other series (41,42,75,106) and reported 49% good results compared with 25% in those treated nonoperatively. Percutaneous pin reduction was not used in any of these series. The results of moderately displaced fractures treated operatively were equal to the results of those treated nonoperatively.

If the head of the radius is completely displaced, results are usually better with surgical intervention. Several authors have shown that the completely separated head remains viable if surgically replaced as late as 48 hours after injury (31,45).

Some fractures may be irreducible by closed means because interposition of the capsule or annular ligament between the head and neck impedes reduction (113).

Strong et al. (100) described an unusual fracture pattern in which the radial head remained reduced by the orbicular ligament. They found that these fractures were irreducible by closed methods and required open reduction.

Surgery should be done as soon as possible after the injury. The later the surgical intervention, the poorer the results. McBride and Monnet (58) reported three patients in whom an osteotomy of the neck was done for residual angulation 3 to 5 weeks after injury. All had further loss of range of motion because of the development of a proximal cross-union. Blount (9) set a limit of 5 days, after which surgical intervention is more likely to produce a poorer result than if the fracture is left untreated.

Fixation Methods. A small wire through the capitellum across the radial head and into the neck has been recommended for fixation of radial head fractures (59,85,86), but this technique has a high incidence of complications (27,67,92,115). Even in a long arm cast the elbow joint has slight motion, which can cause the pin to fatigue, with subsequent breakage (Fig. 11-21). The retrieval of the remaining portion of the pin from the proximal radius is almost impossible without imposing considerable trauma. Even if the pin does not break, the slight motion of the pin has been reported to cause erosion of the joint surface and even fragmentation of the radial head (67,115).

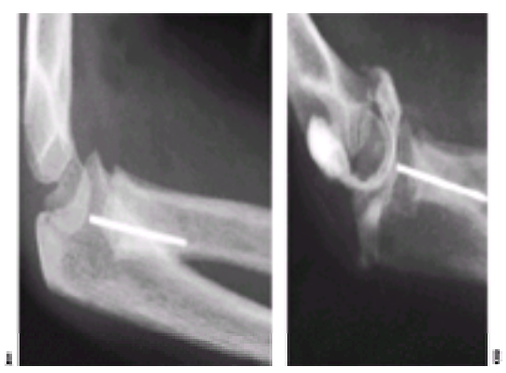

FIGURE 11-21. Transcapitellar pin in a 4-year-old with a completely displaced fracture of the radial neck. Open reduction was performed and fixation achieved with a small transcapitellar pin. **A:** Three weeks after injury, when the pin was removed, it had fractured distally and a portion remained in the proximal radius. **B:** An arthrogram revealed that the pin was fractured at the joint surface of the radial head. The pin was left in place, with subsequent resumption of normal elbow motion.

Other suggested methods of fixing the displaced radial neck after open reduction include direct pin insertion through the head through an olecranon osteotomy (52) and intramedullary bone pegs with a forked plate (50).

The most common technique in current use involves placement of a pin obliquely across the fracture site into the head (20,27,42). The pin can be placed either proximal to distal (Fig. 11-22) or, preferably, distal to proximal. The pin is left protruding from the skin for easy removal.

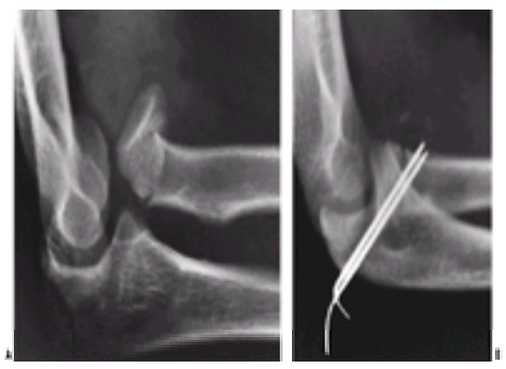

FIGURE 11-22. Oblique pin. **A:** Displaced fracture of the radial neck in a 10-year-old. **B:** A closed reduction was performed, and to stabilize the head fragment two pins were placed percutaneously and obliquely across the fracture site from proximal to distal. If this is performed open, the preferred alignment is to go obliquely across the fracture site from distal to proximal. (From Wilkins KE, ed. *Operative management of upper extremity fractures in children.* Rosemont, IL: American Academy of Orthopaedic Surgeons, 1994;57; with permission.)

Many surgeons believe that internal fixation is unnecessary after open reduction (9,67,115). Wedge and Robertson (115) found that patients without internal fixation had more good results than those in whom internal fixation was used. Use of internal fixation does not guarantee that the fragment will not slip. Newman (67) reported two patients in whom the head slipped postoperatively despite Kirschner wire fixation.

One complication of open reduction is injury to the posterior interosseous nerve. To avoid this complication, Jones and Esah (42) recommended that the nerve first be identified and isolated as it courses through the supinator muscle. Kaplan (43) and Strachan and Ellis (99) demonstrated that with the forearm in pronation, the posterior interosseous nerve is displaced ulnarward, out of the way of the surgical dissection. They also recommended that the patient be placed prone during exploration of the proximal radius to facilitate keeping the forearm pronated.

The orbicular ligament should be preserved if possible. If it is necessary to cut it to achieve an adequate reduction, careful repair is important (27).

Type B Injuries. Type B (Salter-Harris type IV) injuries can be successfully treated by removing the small marginal fragment. If the remaining large portion of the head is also displaced, it is simply reduced without internal fixation (115).

Radial Head Fractures. Pelto et al. (74) reported good to excellent results with the use of absorbable polyglycolide pins in patients older than 13 years of age. There was a significant “transient local abacterial tissue reaction” that did not lead to any long-term reactions. The effect on the physis was not mentioned.

In the rare Salter-Harris types III and IV fracture patterns in which there is a large head fragment, fixation can be achieved with a small minifragment plate placed in a transepiphyseal manner (Fig. 11-23).

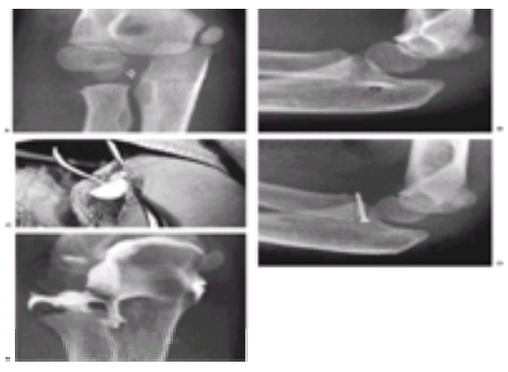

FIGURE 11-23. Mini-screw fixation. **A and B:** Anteroposterior and lateral views of the elbow of a 6-year-old boy in whom the head fragment is lying posterior to the capitellum *(arrows).* **C:** An open reduction was performed, and it was discovered that this was a Salter-Harris type III fracture through the epiphysis and proximal physis. The fragment involved 60% of the head diameter. It still had soft tissue attachments. **D:** The fracture was reduced and fixation was achieved with a screw placed through the epiphysis. **E:** Six months after surgery, when the screw was removed, an arthrogram showed maintenance of the architectural structure of the medial head. The patient had 60 degrees of supination and pronation. (From Wilkins KE, ed. *Operative management of upper extremity fractures in children.* Rosemont, IL: American Academy of Orthopaedic Surgeons, 1994:58; with permission.)

Radial Head Excision

Resection of the radial head fragment was popular in the 1920s and 1930s, but reported results have been uniformly poor (21,39,42). Cubitus valgus and radial deviation at the wrist are common sequelae.

AUTHORS' PREFERRED METHOD OF TREATMENT

We tend to be as conservative as possible in treating these fractures (Table 11-4). Although they may appear reasonably minor, both radiographically and clinically, we initially emphasize to the parents that some loss of motion may occur even though an anatomic reduction is achieved. The problem is usually a loss of range of motion in supination and pronation. Little pain or loss of upper extremity function occurs despite the residual loss of range of motion.

Fracture Status	Treatment
Minimally displaced (<30 degrees angulation, no translation)	Long arm cast or posterior splint (7–10 days) Early motion
Angulation >30 degrees	Closed reduction under general anesthesia using flexion–pronation [Israeli] technique Long arm cast (10–14 days)
Angulation >45 degrees	Elastic bandage wrap reduction Flexion–pronation [Israeli] reduction technique Percutaneous pin reduction Long arm cast (10–14 days)
Angulation fixed at >40 degrees, translation >3 mm displacement, with <60 degrees supination–pronation, radial head completely displaced	Intramedullary wire reduction Open reduction (± internal fixation)

TABLE 11-4. TREATMENT OF RADIAL HEAD FRACTURES

Aspiration Facilitates Evaluation

If there is a great amount of pain or resistance to pronation and supination, we aspirate the elbow and frequently inject 2 to 3 mL of 1% lidocaine after a sterile preparation (19).

Nonoperative Methods

Moderate Tilt (30 to 60 Degrees). If the radial head is tilted more than 30 degrees, we usually attempt a manipulative closed reduction. This should be done with the use of a general anesthetic to achieve full relaxation. We prefer the Israeli technique (Fig. 11-18) for simple, moderately displaced radial head fractures (Fig. 11-24). The important aspect is to ensure that the manipulation is done with the elbow flexed at 90 degrees. Usually there is resistance to pronation (Fig. 11-25). Once the pressure is applied to the radial head with the thumb, the opposite hand forces the forearm into full pronation (Fig. 11-25). After reduction, the forearm is tested for range of motion to ensure there are at least 60 degrees of supination and pronation. Follow-up radiographs usually reveal a near-anatomic reduction (Fig. 11-24B). If, however, there is an adequate range of supination and pronation, we accept the reduction regardless of the radiographic appearance. We have also used this as an initial attempt even in completely displaced radial neck fractures, with surprising results (Fig. 11-26).

FIGURE 11-24. Flexion-pronation (Israeli) reduction technique. **A:** Radiograph of the best reduction obtained by the Patterson method. **B:** Position of the radial head after use of the flexion = npronation method. (Courtesy of Gerald R. Williams, MD.)

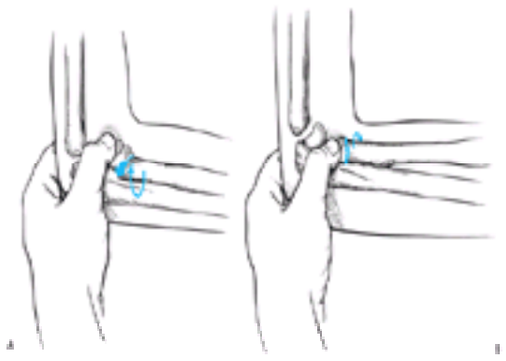

FIGURE 11-25. Flexion = npronation (Israeli) reduction technique. **A:** With the elbow in 90 degrees of flexion, the thumb stabilizes the radial head, which is displaced. Usually the distal radius is fixed in a position of supination. The forearm is then pronated to swing the shaft up into alignment with the neck *(arrow).* **B:** The final alignment is achieved by continuing to force the forearm into full pronation *(arrow).* (See also Fig. 11-18.)

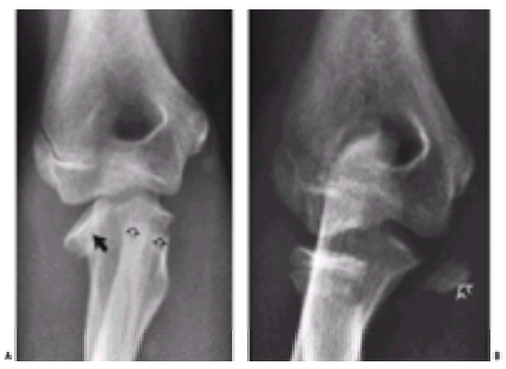

FIGURE 11-26. Widely displaced fracture. **A:** A 9-year-old girl sustained this widely displaced fracture in which the neck fragment *(open arrows)* was medial and the head fragment *(closed arrow)* remained within the orbicular ligament. **B:** A satisfactory reduction was achieved using the flexion = npronation method. The small fragment medially *(arrow)* is from the metaphysis. The patient resumed full rotation of the forearm after reduction. (From Wilkins KE, ed. *Operative management of upper extremity fractures in children.*Rosemont, IL: American Academy of Orthopaedic Surgeons, 1994:55; with permission.)

Elastic Bandage Wrap. If we cannot get an adequate reduction using the Patterson or Israeli technique, we try some other techniques before surgical intervention. In a few patients we have found that, after wrapping the extremity tightly from distal to proximal with an elastic Esmarch, a satisfactory reduction was serendipitously achieved (Fig. 11-27).

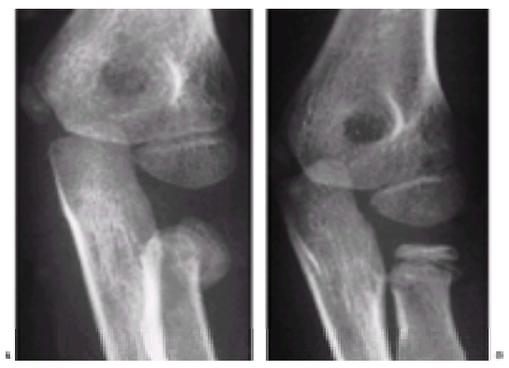

FIGURE 11-27. Elastic bandage wrap reduction. **A:** The final position achieved after manipulation by the Patterson method. **B:** Position of the radial head after an elastic bandage had been applied to exsanguinate the extremity.

Operative Techniques

Percutaneous Pin Reduction. For most moderately or severely displaced fractures, we prefer to attempt a semiclosed reduction using the percutaneous pin reduction technique (Fig. 11-28). A good image intensifier is essential. We have found that a single-point awl or the blunt end of a Steinmann pin is adequate. If the head is small or soft, a small Craig biopsy needle or the blunt end of the Steinmann pin can be used to prevent penetration of the radial head with a sharp Steinmann pin.

FIGURE 11-28. Percutaneous pin reduction. **A:** Under an image intensifier, the sharp-pointed object (awl) is inserted next to the olecranon and directed up proximally toward the radial head fragment. This is to avoid injury to the posterior interosseous nerve. **B:** Totally displaced valgus injury. **C:** Position of the Steinmann pin during reduction. **D:** Appearance 2 months after surgery. The patient has 60 degrees of supination and pronation with full elbow extension and flexion.

To avoid injury to the posterior interosseous nerve, we try to insert the pin as closely as possible to the lateral aspect of the olecranon (Fig. 11-28A). Again, we accept 45 to 60 degrees of angulation as long as the displacement is corrected and the patient has at least 50 to 60 degrees of supination and pronation after reduction.

Intramedullary Pin Reduction. Before open reduction of fractures that are severely angulated but still have some apposition, we attempt to achieve reduction using an intramedullary pin passed from distal to proximal, as described by Metaizeau et al. (60) (Fig. 11-20). Although this method has achieved success where other manipulative techniques failed, in most patients simple percutaneous pin manipulation produces reductions equal to this technique. We try every manipulative technique before we resort to open reduction.

Open Reduction. If an adequate closed reduction cannot be obtained and loss of motion is still significant, we prefer an open reduction with as little dissection as possible. We approach the fracture with the patient prone and the forearm pronated. After making the skin incision, we dissect between the anconeus and extensor carpi ulnaris muscles to reach the orbicular ligament. The head is repositioned as gently as possible. Usually, we have found the head fragment to be stable after reduction. If it is not, fixation is achieved with a small pin placed obliquely through a separate stab incision from distal to proximal across the fracture site. Two oblique, crossed pins also can be inserted at the articular margin in very unstable fractures.

Delayed Reduction. If the fracture is more than 4 days old and there is no significant supination or pronation forearm motion, we often reduce the head surgically if it cannot be done closed. However, we warn the parents that myositis ossificans and proximal radioulnar synostosis can occur.

Reduction After Immobilization. After the reduction, we prefer to immobilize the upper extremity with the elbow in 90 degrees of flexion and the forearm in slight pronation. Active motion is started as soon as possible. If a closed reduction was done, we start gradual active motion at 10 to 14 days, depending on the initial displacement and the degree of stability achieved at the time of reduction. We prefer to use a long arm cast that can be bivalved and used as a splint during rehabilitation.

ASSOCIATED INJURIES AND COMPLICATIONS

Complications of fractures of the radial neck and head, especially those associated with other fractures or a dislocation of the elbow, range from the most common problem of loss of range of motion to rare nerve injuries (Table 11-5). The most complete reviews of these complications can be found in reports by Steinberg et al. (98) and D'Souza et al. (16).

Failure to obtain acceptable reduction
Loss of motion (expected)
Radial head overgrowth
Notching of the radial neck
Premature physeal closure
Angular deformities
Nonunion
Avascular necrosis
Radioulnar synostosis
Problems with initial diagnosis

TABLE 11-5. COMPLICATIONS OF RADIAL HEAD AND NECK FRACTURES

Loss of Motion

Loss of motion is secondary to a combination of loss of joint congruity and fibrous adhesions. Loss of pronation appears to be more common than loss of supination. Flexion and extension are rarely significantly limited. Enlargement of the radial head, a common sequela, can contribute to the subsequent loss of elbow motion (31).

Radial Head Overgrowth

Next to loss of range of motion of the elbow and forearm, radial head overgrowth is probably the most common sequela (20%–40%) (16,110). The increased vascularity from the injury probably stimulates epiphyseal growth. Radial head overgrowth usually does not compromise functional results (20,42), but it may produce some crepitus or clicking with forearm rotation (16).

Notching of the Radial Neck

O'Brien (68) suggested that notching of the radial head in several patients was caused by scar tissue forming around the neck from the orbicular ligament. It did not seem to result in any functional deficit.

Premature Physeal Closure

Although premature physeal closure has been reported in many series (27,31,67,68,98,115), this complication did not appear to affect the overall results significantly, except in one patient reported by Fowles and Kassab (27), in whom it produced a severe cubitus valgus. Newman (67) found that shortening of the radius was never any greater than 5 mm compared with the opposite uninjured side.

Nonunion of the Radial Neck

Nonunion of the radial neck is rare; union eventually occurs (92) if enough time elapses (Fig. 11-29).

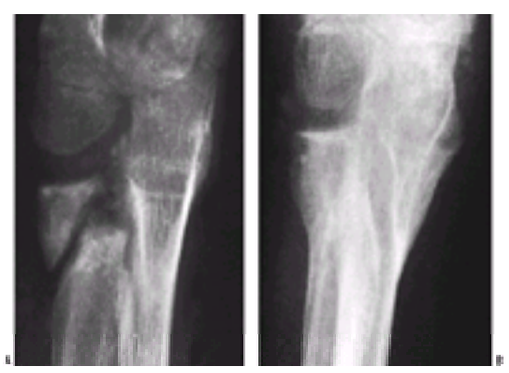

FIGURE 11-29. Nonunion. **A:** Eight months after radial neck fracture in an 8.5-year-old girl. Patient had mild aching pain, but no loss of motion. There was some suggestion of proximal subluxation of the distal radioulnar joint. **B:** Patient was immobilized in a long arm cast with external electromagnetic stimulation. Three months later, there was evidence of union of the fracture. (Courtesy of Charles T. Price, MD.)

Avascular Necrosis of the Radial Head

The incidence of avascular necrosis is probably higher than recognized. D'Souza et al. (16) reported the frequency to be 10% to 20% in their patients, 70% of whom had open reductions. In patients with open reduction, the overall incidence of avascular necrosis was 25%. Jones and Esah (42) and Newman (67) found that patients with avascular necrosis had poor functional results. It has been our experience, however, that revascularization can occur without any significant functional loss. Only in those in whom a residual functional deficit occurs is avascular necrosis considered a problem (Fig. 11-30).

FIGURE 11-30. Avascular necrosis with nonunion in a radial head 1 year after open reduction. Both nonunion and avascular necrosis of the radial neck and head are demonstrated. Severe degenerative arthritis developed subsequently. (Courtesy of Richard E. King, MD.)

Changes in Carrying Angle (Cubitus Valgus)

In patients who have fractures of the radial neck, the carrying angle often is 10 degrees greater (increased cubitus valgus) than on the uninjured side (16,42). The increase in carrying angle appears to produce no functional deficit and usually is insignificant cosmetically.

Vascular Injuries

No major vascular injuries have been reported as occurring with isolated fractures of the proximal radius.

Nerve Injuries

Partial ulnar nerve injury (39) and posterior interosseous nerve injury have been reported as a direct result of the fracture, but most injuries to the posterior interosseous nerves have occurred during surgical exploration (16) or with percutaneous pin reduction (5). These posterior interosseous nerve injuries usually are transient.

Compartment Syndrome

Peters and Scott (76) reported three patients with volar forearm compartment syndrome after minimally displaced or angulated fractures of the radial head. All

required volar fasciotomy.

Radioulnar Synostosis

Proximal synostosis is the most serious complication that can occur after radial head fracture (Fig. 11-31). It occurs most often after open reduction of severely displaced fractures (31,39,67,97), but it can occur after closed reduction. Delayed treatment seems to increase the likelihood of this complication. All of the three patients reported by Gaston et al. (31) were treated more than 5 days after injury.

FIGURE 11-31. Radioulnar synostosis. **A:** Surgical intervention with wire fixation was necessary to perform a satisfactory reduction in this patient who had a totally displaced radial neck fracture. **B:** Six weeks after surgery, there was evidence of a proximal radioulnar synostosis. **C:** Radiograph taken 6 months after reduction shows a solid synostosis with anterior displacement of the proximal radius. (Courtesy of R.E. King, M.D.)

Myositis Ossificans

Myositis ossificans is relatively common, but usually does not impair function. Vahvanen (110) noted that some myositis ossificans occurred in almost 32% of his patients. In most, it was limited mainly to the supinator muscle. If ossification was more extensive and was associated with a synostosis, the results were poor.

Some variants in the ossification process can resemble a fracture. Most of these involve the radial head, although a step-off can also develop in the normal growth process of the metaphysis. There may be a persistence of the secondary ossification centers of the epiphysis. If unusual ossification centers are seen after an acute elbow injury, comparison views should be obtained.

The diagnosis of a partially or completely displaced fracture of the radial neck may be difficult in the preosseous age group. The only clue may be a little irregularity in the smoothness of the proximal metaphyseal margin (Fig. 11-32). Rokito et al. (89) reported complete displacement of the radial head in a 5-year-old boy, in whom the only clue on radiography was a very small speck of ossification in the elbow joint (Fig. 11-33A). The full extent of the injury was not appreciated until the radial head was outlined with MRI (Fig. 11-33B).

FIGURE 11-32. Preosseous fracture. The only clue to the presence of a fracture of the radial neck with displacement of the radial head was loss of smoothness of the metaphyseal margin *(arrow)*.

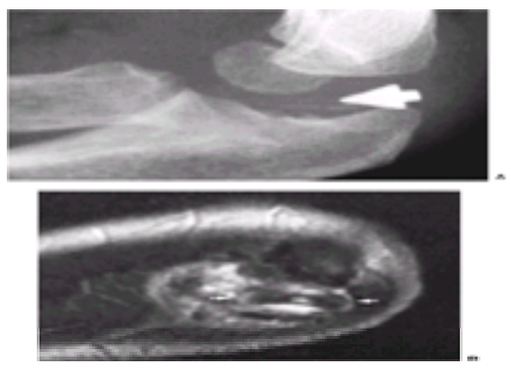

FIGURE 11-33. Unappreciated diagnosis. **A:** Radiographs of a 5-year-old taken 4 weeks after injury. Despite immobilization in the cast, the patient continued to have swelling and very limited motion. There is a small flake of ossification between the capitellum and the olecranon *(arrow).* The proximal aspect of the radial neck is also somewhat irregular. There is continued effusion, as manifested by displaced fat pads. **B:** Because of the persistent effusion and suspected intraarticular fragments, magnetic resonance imaging was performed and demonstrated that the unossified radial head was lying distal and somewhat posterior to the capitellum *(arrows).* An open reduction was performed and the patient regained a satisfactory range of forearm motion and was pain free at 1-year follow-up. (From Rokito SE, Anticevic D, Strongwater AM, et al. Chronic fracture-separation of a radial head in a child. *J Orthop Trauma* 1995;9:260; with permission.)

Osteomyelitis

A rare case of hematogenous osteomyelitis after a closed fracture of the radial neck was reported by Veranis et al. (111). The initial diagnosis was not appreciated despite the fact that the child had fever and continuous pain after the fracture.

Malunion

Failure to reduce a displaced and angulated proximal radius in a young child often results in an angulated radial neck with subsequent incongruity of both the proximal radioulnar joint and the radiocapitellar joint (Fig. 11-34). Partial physeal arrest also can create this angulation (Fig. 11-15).

FIGURE 11-34. Angulation. **A:** Injury film showing 30 degrees of angulation and 30% lateral translocation of a radial neck fracture in a 10-year-old. **B:** Radiographic appearance of the proximal radius taken about five months later, showing lateral angulation of the neck. **C:** Lateral view showing the anterior relationship of the radial neck with proximal migration. At this point the patient had full supination and pronation but a clicking sensation with forearm rotation in the area of the radial head. **D:** 3-D reconstruction showing the incongruity of the proximal radiocapitellar joint. (Courtesy of Vince Mosca, MD.)

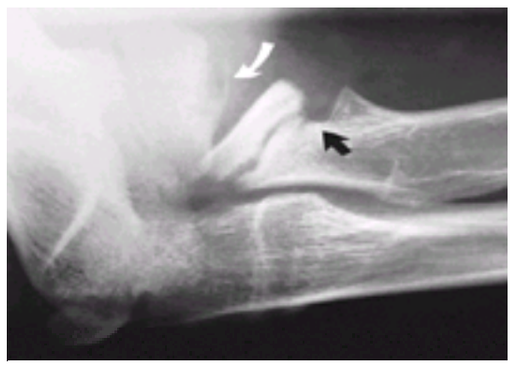

FIGURE 11-15. Angular stress deformity: anterior angulation of the radial head and neck in a 12-year-old baseball pitcher. There is evidence of some disruption of the normal growth of the anterior portion of the physis *(black arrow).* The capitellum also demonstrates radiographic signs of osteochondritis dissecans *(white arrow).* (Courtesy of Kenneth P. Butters, MD.)

In our experience, this malunion, because of the incongruity of the radiocapitellar joint, often results in erosion of the articular surface of the capitellum, with subsequent degenerative joint disease. In the English literature, there is little information about using osteotomies of the radial neck to correct this deformity.

Summary

In summary, results after open reduction of radial head fractures are less favorable than those after closed reduction. However, fractures requiring open reduction usually are the result of a more severe injury. Closed reductions with angulations of up to 45 degrees produce clinical results as good as those in which a more anatomic reduction is achieved by operative methods. The surgeon should warn the parents of the likelihood of residual loss of motion after open reduction. Whenever possible, internal fixation should be avoided.

FRACTURES OF THE PROXIMAL ULNA (OLECRANON)

Fractures Involving the Proximal Apophysis

Incidence

“Separation of the olecranon epiphysis is the rarest form of epiphyseal detachment” (77). This quote from Poland's 1898 textbook on epiphyseal fractures is appropriate even today. Only 16 acute fractures in which apophyseal involvement is mentioned can be found in the recent English literature (34,77,91,96). In addition to these acute injuries in children, seven have been described in young adults in whom there has been persistence of the physeal line (46,73,95,107). In the French literature, Bracq (12) described 10 patients in whom the fracture was just distal and parallel to the apophyseal line and then crossed it at the articular surface.

Anatomy

The Ossification Process

At birth, the metaphysis of the proximal ulna extends only to the mid-portion of the semilunar notch. At this age, the leading edge of the metaphysis usually is perpendicular to the long axis of the olecranon (Fig. 11-35A,Fig. 11-35B). As ossification progresses, the leading edge of the metaphysis becomes more oblique. The anterior margin migrates proximally and extends to almost three fourths of the semilunar notch by 6 years of age. At this point, some of the physis and cartilage still extends distally to include the coronoid process (Fig. 11-35C). A secondary center of ossification never develops in the coronoid process. Just before the development of the secondary center of ossification of the epiphysis of the olecranon, the leading edge of the metaphysis develops a well-defined sclerotic margin (91). Ossification of the olecranon develops in the area of the triceps insertion at approximately 9 years of age (91) (Fig. 11-35D). Once this secondary ossification begins, the tongue of the physeal and epiphyseal cartilage that extends up to include the coronoid process disappears (77). All that remains of this tongue is a fine line of articular cartilage.

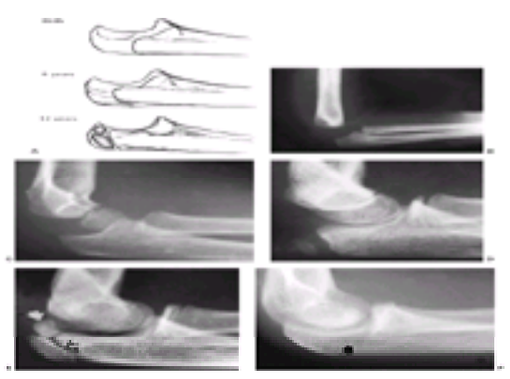

FIGURE 11-35. Olecranon ossification. **A:** Limits of the border of ossification at birth, 8 years, and 12 years. **B:** Lateral view of olecranon at 6 months of age. The proximal margin is perpendicular to the long axis of the ulna. **C:** Lateral view of the olecranon at 6 years of age. The proximal margin is oblique. **D:** Secondary ossification center developing in the olecranon in a 10-year-old. A sclerotic border has developed on the proximal metaphyseal margin. **E:** Bipartite secondary ossification center. The larger center is the traction center *(open arrow).* The smaller, more proximal center is the articular center *(white arrow).* **F:** Before complete fusion, a partial line remains *(arrow),* bordered by a sclerotic margin.

Bipartite Centers

The secondary ossification center of the olecranon may be bipartite (79) (Fig. 11-35E). The major center lies within the tip of the olecranon and is enveloped by the triceps insertion. This was referred to by Porteous (79) as a *traction center.* The second and smaller center, an articular center, lies under the proximal fourth of the articular surface of the semilunar notch.

Closure Process

Fusion of the epiphysis with the metaphysis, which progresses from anterior to posterior, occurs at approximately 14 years of age. Often a posterior aspect of the physeal line can be mistaken for a fracture. This line is always surrounded by a well-defined sclerotic margin (91) (Fig. 11-35F). Rarely, the physeal line persists into adulthood (46,73,107), usually in athletes who have used the extremity in high-performance throwing activities (17,83,95,109,116). The chronic tension forces applied across the apophysis are believed to prevent its normal closure.

Patella Cubiti

Occasionally, a separate ossification center called a *patella cubiti* develops in the triceps tendon at its insertion on the tip of the olecranon (105). This ossicle is completely separate and can articulate with the trochlea. It usually is unilateral, unlike the persistent secondary ossification centers, which are more likely to be bilateral and familial. Zeitlin (121) believed that the patella cubiti was a traumatic ossicle rather than a developmental abnormality.

Signs and Symptoms

Clinical: Swelling Plus Defect

The primary clinical findings are tenderness over the olecranon and localized soft tissue swelling. If the fragment is completely displaced, there is a lack of active extension of the elbow. A palpable defect may be present between the apophysis and the proximal metaphysis. Poland (77) described the crepitus between the fragments as being muffled because cartilage covers the fractured surfaces.

Radiography: Proximal Metaphyseal Displacement

The radiographic diagnosis may be difficult before ossification of the olecranon apophysis. The only clue may be a displacement of the small ossified metaphyseal fragment (Fig. 11-36). The diagnosis may have to be based only on the clinical signs of tenderness over the epiphyseal fragment. If there is any doubt about the degree of displacement, injection of radiopaque material into the joint may delineate the true nature of the fracture.

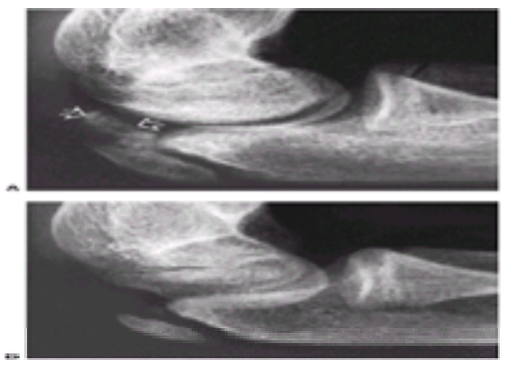

FIGURE 11-36. Apophysitis. **A:** Chronic stimulation with irregular ossification of the articular apophyseal center *(arrows)* in a basketball player who practiced dribbling 3 hours per day. **B:** Normal side for comparison.

Mechanism of Injury

The fact that much of the triceps expansion inserts on the metaphysis distal to the physis probably accounts for the rarity of this injury. Only a few reports mention the mechanism of these physeal injuries. In most of the fractures reported by Poland (77), three of which were confirmed by amputation specimens, the force of the injury was applied directly to the elbow. The force may be applied indirectly, producing an avulsion type of injury.

In our experience, this fracture usually is due to avulsion forces across the apophysis occurring with the elbow flexed, similar to the more common flexion metaphyseal injuries.

Children with osteogenesis imperfecta (usually the tarda form) seem especially predisposed to this injury (18,63).

Stress fractures of this apophysis are not uncommon in athletes (especially baseball players) who place considerable recurrent tension forces across the apophysis (71). Stress injuries also have been reported in elite gymnasts (54) and tennis players (83). If the recurring activity persists, a symptomatic malunion can develop (73,83,107,109,116).

Classification

Injuries to the apophysis of the olecranon can be one of three types (Table 11-6).

Type I: Apophysitis
Type II: Incomplete stress fracture
Type III: Complete fractures
  A. Pure apophyseal avulsions
  B. Apophyseal-metaphyseal combinations

TABLE 11-6. CLASSIFICATION OF APOPHYSEAL INJURIES OF THE OLECRANON

The first type is a simple apophysitis in which there is irregu- larity in the ossification process of the secondary ossification center (17,54) (Fig. 11-37A). In addition,

there may be some widening of the apophyseal line.

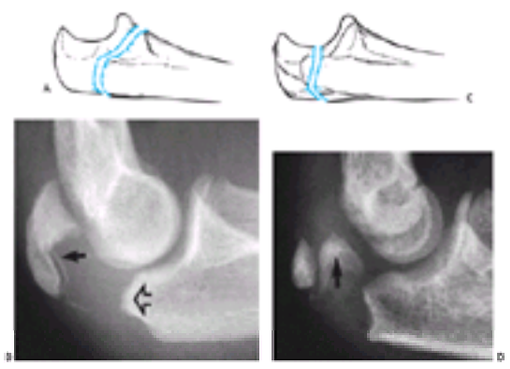

FIGURE 11-37. Apophyseal avulsions. Pure apophyseal avulsions. **A:** The fracture follows the contour of the apophyseal line. **B:** The distal fracture line is in the shape of the apophyseal line *(open arrow)* with a small metaphyseal flake attached to the apophysis *(solid arrow).* Apophyseal-metaphyseal combination. **C:** The fracture line follows the line of tension stress. **D:** A large portion of the metaphysis *(arrow)* is often with the proximal metaphyseal fragment.

The second type is more of an incomplete stress fracture that involves primarily the apophyseal line, with widening and irregularity (Fig. 11-37B). There may be some small adjacent cyst formation, but usually the architecture of the secondary ossification center is normal. These injuries are seen primarily in sports requiring repetitive extension of the elbow, such as baseball pitching (71), tennis (83), or gymnastics (54).

The third type involves a complete avulsion. There appear to be two separate patterns in which the apophysis is completely avulsed. Pure apophyseal avulsions occur in younger children as a pure fracture through the apophyseal plate (Fig. 11-37A,Fig. 11-37B). In some of his amputation specimens, Poland (77) found that the proximal apophyseal fragment included the distal tongue, which extends up to the coronoid process. Apophyseal–metaphyseal combination fractures usually occur in older children. Large metaphyseal fragments may be attached to the apophysis (Fig. 11-37C,Fig. 11-37D). Grantham and Kiernan (34) likened it to a Salter-Harris type II physeal injury, in some instances involving a small metaphyseal fragment. Proximal displacement of the fragment by the triceps may be the only radiographic clue to this type of injury.

Treatment

Because of the few fractures described, there is no standard method of treatment. In fractures with significant displacement, treatment most often must be open reduction with internal fixation using a combination of axial pins and tension-band techniques (34,77,96) (Fig. 11-38).

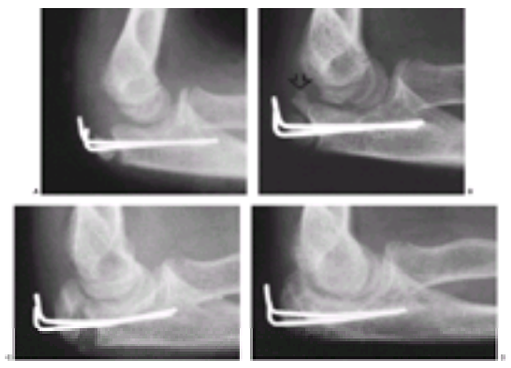

FIGURE 11-38. Operative treatment of an apophyseal fracture. **A:** Postoperative radiograph of the patient seen in Fig. 11-40D who was stabilized with small Steinmann pins alone. **B:** Five months later, there is continued growth of the traction center and the articular center has become ossified *(arrow).* **C:** One year after injury, the apophysis was partially avulsed a second time. The two secondary ossification centers are now fused. **D:** Three months after the second fracture, the fracture gap has filled in, producing a normal olecranon.

There has been some concern about applying compressive forces across the apophysis because this may lead to growth arrest. In our experience, fusion of the apophysis to the metaphysis is accelerated, but in all apophyseal injuries we have treated there was already a well-developed ossification of the apophysis itself. In addition, the apophysis of the olecranon appears to be like that of the greater trochanter (i.e., most of the growth proximally is appositional rather than lengthwise across the apophyseal plate itself). As a result, we have not found any functional shortening of the olecranon because of the early fusion of the apophysis to the metaphysis (Fig. 11-38D).

Young children who sustain injuries before the development of the secondary ossification center may have some deformity on radiographs, especially if the center primarily is affected (Fig. 11-39). Although there may be shortening of the olecranon, it does not appear to produce functional problems. There are no reports of the effects of this injury in very young children or infants, in whom there is very little proximal migration of the metaphyseal margin.

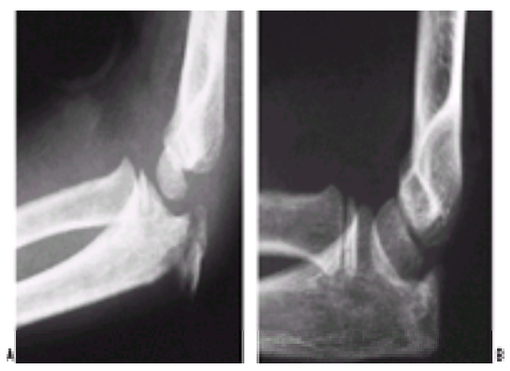

FIGURE 11-39. Preosseous apophyseal arrest. **A:** Comminuted fracture of the proximal olecranon from a direct blow to the elbow in an 8-year-old boy. This fracture was treated nonoperatively. **B:** Radiograph 18 months later shows cessation of the proximal migration of the metaphyseal margin and a lack of development of a secondary ossification center. Despite this arrest of the apophysis, the patient had a full range of elbow motion.

Most stress injuries respond to simple rest from the offending activity. However, a chronic stress fractures can proceed to a symptomatic nonunion that requires operative intervention. Simple application of a compressive internal fixation device alone across the nonunion often is sufficient (54). Supplemental bone grafting may be necessary to achieve union (46,73).

AUTHORS' PREFERRED METHOD OF TREATMENT

Undisplaced Injuries

For apophysitis and undisplaced stress fractures, we have the patient cease the offending activity. However, during this period of rest, the patient, usually a high-performance athlete, should maintain upper extremity strength with a selective muscle exercise program. In addition, he or she must maintain cardiovascular condition with a program of appropriate aerobic exercises.

When a persistent nonunion of the apophyseal line in an older child (usually an adolescent) does not demonstrate healing in a reasonable period of time with simple rest, we place a cannulated compression screw across the apophysis to stimulate healing.

Displaced Fractures

For displaced fractures, if there is minimal displacement and a satisfactory closed reduction can be achieved with the elbow extended, we usually use immobilization in a long arm cast with the elbow extended. However, we rarely find this to be possible. Occasionally, percutaneous pinning can be done, if there is anatomic reduction on the AP and lateral radiographs.

Completely displaced fractures are treated operatively using a tension-band technique. In young children, we use small Steinmann or Kirschner pins. The tension band is a strong absorbable suture of one of the polyglycolic acid substances. Alternatively, standard 16- to 18-gauge wire can be used in older adolescents. Patients with large ossification centers are treated the same as those with metaphyseal fractures.

ASSOCIATED INJURIES AND COMPLICATIONS

Spur Formation

Smith (96) noted that overgrowth of the epiphysis proximally sometimes occurred with spur formation. In some patients these proximal spurs became symptomatic and had to be removed.

Nonunion

The cause and treatment of nonunion were discussed in the previous section.

Apophyseal Arrest

Apophyseal arrest has not been reported. If it does occur, it appears to have no significant effect on elbow function (Fig. 11-39).

Metaphyseal Fractures of the Olecranon

Incidence

Isolated metaphyseal fractures of the olecranon are relatively rare (Table 11-7). They often are associated with other fractures about the elbow. In the combined series of 4,684 elbow fractures reviewed, there were 230 olecranon fractures reported, for an incidence of 4.9%. This agrees with the incidence of 4% to 6% in the major series reported (24,57,70). Only 10% to 20% of the total fractures reported in these series were considered displaced significantly enough to require surgical intervention.

Age distribution: first decade, 25%; second decade, 25%; third decade 50%
Peak age: 5–10 yr
Extremity predominance: left (55%)
Sex predominance: male (65%)
Associated elbow injuries: 20%
Requiring surgical intervention: 19%

TABLE 11-7. INCIDENCE OF METAPHYSEAL FRACTURES OF THE OLECRANON

The rarity of this injury and the relative unimportance given to it are reflected by the paucity of reports in the literature. Reports dealing only with fractures of the olecranon in children did not appear in the English literature until 1975. Since then there have been six reports, totaling 302 patients (30,34,57,66). When fractures of the olecranon for all age groups are considered, 25% occur in the first decade and another 25% in the second decade (48). During the first decade, the peak age for this type of fracture is between age 5 and 10 years (35,66). Twenty percent had an associated fracture or dislocation of the elbow region, most involving the proximal radius. Only 10% to 20% were classified as being displaced enough to require surgical intervention.

Anatomic Considerations

Because the olecranon is a metaphyseal area, the cortex is relatively thin, allowing for the development of greenstick-type fracture deformities. The periosteum is immature and thick, which may prevent the degree of separation seen in adults. Likewise, the larger amount of epiphyseal cartilage in children may serve as a cushion to lessen the effects of a direct blow to the olecranon.

In the production of supracondylar fractures, ligamentous laxity in this age group tends to force the elbow into hyperextension when the child falls on the outstretched upper extremity. This puts a compressive force across the olecranon and locks it into the fossa in the distal humerus, where it is protected. An older person, whose elbow does not go into hyperextension, is more likely to fall with the elbow semiflexed. This unique biomechanical characteristic of the maturing olecranon predisposes it to different fracture patterns than those in adults.

Signs and Symptoms

Flexion injuries cause soft tissue swelling over the olecranon. The abrasion or contusion associated with a direct blow to the posterior aspect of the elbow may provide a clue as to the nature of the injury. If there is wide separation, a defect may be palpable between the fragments. In addition, there may be weakness or even lack of active extension of the elbow. This latter finding may be difficult to evaluate in an anxious young child with a swollen elbow.

On radiography, the fracture lines associated with flexion injuries usually are perpendicular to the long axis of the olecranon. This differentiates them from the residual

physeal line, which is oblique and directed proximal and anterior (91). In extension injuries, the longitudinally directed greenstick fracture lines may be difficult to appreciate. The radiograph should be carefully studied to look for associated injuries of the proximal radius or distal humerus.

Classification

Papavasiliou et al. (70) defined two major groups of olecranon fractures in which the fracture line is either intraarticular or extraarticular. Subclassifications in each group are determined by the degree of displacement.

We prefer to classify these fractures based on the mechanism of injury (Table 11-8): those associated with flexion injuries, those associated with extension injuries, and shear injuries. Extension injuries are further divided into varus and valgus patterns.

Group A: Flexion injuries
Group B: Extension injuries
1. Valgus pattern
2. Varus pattern
Group C: Shear injuries

TABLE 11-8. CLASSIFICATION OF METAPHYSEAL FRACTURES OF THE OLECRANON

Mechanism of Injury

Three main mechanisms produce metaphyseal olecranon fractures, depending on whether the elbow is flexed or extended at the time of injury. First, in injuries occurring with the elbow flexed, posterior tension forces play an important role. Second, in injuries in which the fracture occurs with the elbow extended, a varus or valgus bending stress is placed across the olecranon, which is responsible for the typical fracture pattern. Third, a less common mechanism involves a direct blow to the elbow that produces an anterior bending or shear force across the olecranon. In this type, the tension forces are concentrated on the anterior portion of the olecranon.

Flexion Injuries

A fall with the elbow semiflexed places considerable tension forces across the posterior aspect of the olecranon process. Proximally, the triceps applies a force to the tip of the olecranon process. Distally, there is some proximal pull by the insertion of the brachialis muscle. Thus, the posterior cortex is placed in tension. This tension force alone, if applied rapidly enough and with sufficient force, may be enough to cause the olecranon to fail at its mid-portion (Fig. 11-40). A direct blow applied to the posterior aspect of the stressed olecranon makes it more vulnerable to failure. With this type of mechanism, the fracture line usually is transverse and perpendicular to the long axis of the olecranon (Fig. 11-41). Because the fracture extends into the articular surface of the semilunar notch, it is classified as intraarticular.

FIGURE 11-40. Mechanism of flexion injuries. **Center:** In the flexed elbow, a tension force develops on the posterior aspect of the olecranon *(small double arrow)* because of the pull of the brachialis and triceps muscles *(large arrows).* **Right:** Failure occurs on the tension side, which is posterior as a result of the muscle pull or a direct blow to the prestressed posterior olecranon.

FIGURE 11-41. Radiograph of flexion injury showing greater displacement on the posterior surface.

The degree of separation of the fracture fragments depends on the magnitude of the forces applied versus the integrity of the soft tissues. The low incidence of displaced olecranon fractures indicates that the soft tissues are quite resistant to these avulsion forces. In flexion injuries, there are relatively few associated soft tissue injuries or fractures (66).

Extension Injuries

Because the ligaments are more flexible in children, the elbow tends to become hyperextended when a child breaks a fall with the outstretched upper extremity. In this situation, the olecranon may become locked into its fossa of the distal humerus. If the elbow is forced into extreme hyperextension, usually the supracondylar area fails. If, however, the major direction of the force across the elbow is abduction or adduction, a bending movement is created across the olecranon. Most of this movement is concentrated in the distal portion of the olecranon. Because the olecranon is composed of metaphyseal bone, fractures here are usually greenstick type with multiple longitudinal fracture lines (Fig. 11-42). Most of these fracture lines are linear and remain extraarticular. In addition, because the fulcrum of the bending force is more distal, many of the fracture lines may extend distal to the coronoid process into the proximal ulnar shaft regions. The major deformity of the olecranon

with this type of fracture pattern usually is an angulated greenstick type of fracture.

FIGURE 11-42. A: Anteroposterior view of a linear greenstick fracture line *(arrow)* in the medial aspect of the olecranon. **B:** Lateral view showing the posterior location of the fracture line *(arrow)*

Many of these fractures are associated with other injuries in the elbow region, which are determined by whether the bending force is directed toward varus or valgus. If a child falls with the forearm in supination, the carrying angle tends to place a valgus stress across the elbow. The result may be a greenstick fracture of the ulna with an associated fracture of the radial neck or avulsion of the medial epicondylar apophysis (Fig. 11-43). If the fracture involves the radial neck, Bado (4) classified it as an equivalent of the type I Monteggia lesion.

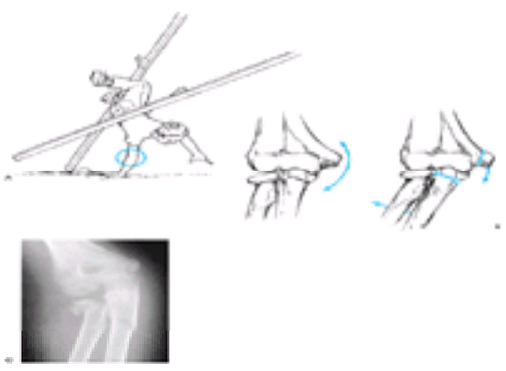

FIGURE 11-43. Valgus pattern of an extension fracture. **A:** A fall with the elbow extended places a valgus stress on the forearm. **B:** With increased valgus, there can be a greenstick fracture of the olecranon with or without a fracture of the radial neck or avulsion of the medial epicondylar apophysis. **C:** Radiograph of a valgus extension fracture of the olecranon with an associated fracture of the radial neck.

If the body falls against the inner aspect of the elbow or if the forearm is pronated, a varus force may be placed across the elbow (Fig. 11-44). The major injury associated with this varus force is a partial or total lateral dislocation of the radial head. Bado (4) classified this as a type III Monteggia lesion. In this type of fracture, the posterior interosseous nerve may be injured.

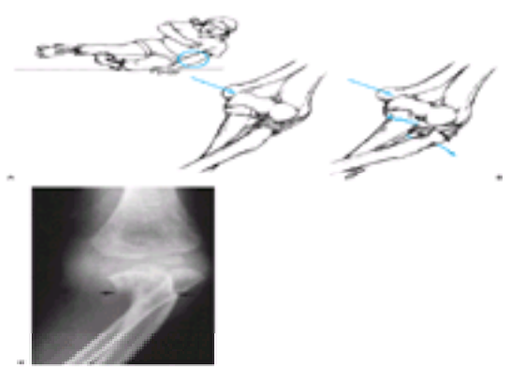

FIGURE 11-44. Varus pattern of an extension fracture. **A:** A fall against the extended elbow places a varus stress on the forearm. **B:** The result is a greenstick fracture of the olecranon with a lateral dislocation of the radial head (type III Monteggia lesion). **C:** Radiograph of a varus extension injury showing subluxation of the radial head and greenstick fracture of the ulna *(arrows).*

Shear Injuries

Anterior tension failure is a rare injury that can occur when a direct blow to the proximal ulna causes it to fail with an anterior tension force; the integrity of the proximal radioulnar joint is maintained.

The most common type of shear injury occurs when a shear force is applied directly to the posterior aspect of the olecranon and the distal fragment is displaced anteriorly (Fig. 11-45 and Fig. 11-46). The intact proximal radioulnar joint is displaced with the distal fragment. In this type of injury, the elbow may be either flexed or extended when the direct shear force is applied to the posterior aspect of the olecranon.

FIGURE 11-45. Flexion shear injuries. **A:** Fracture with the elbow flexed. The direct blow to the distal portion of the posterior olecranon causes the fracture to fail in tension of the anterior surface. The intact proximal radioulnar joint is displaced anteriorly. **B:** Radiograph of a flexion shear injury showing the distal fragments that are

displaced anteriorly as a unit.

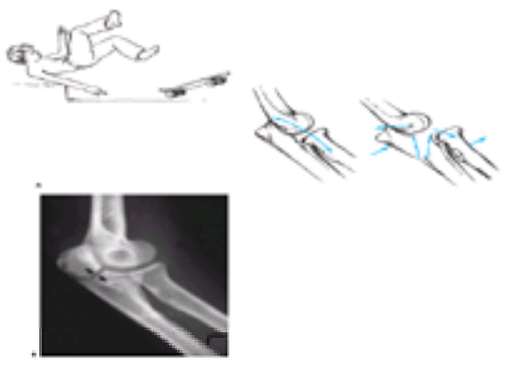

FIGURE 11-46. Extension shear injuries. **A:** Fracture with the elbow extended. If the elbow is extended when the direct blow is applied to the posterior aspect of the elbow, the olecranon fails in tension but with an oblique or transverse fracture line *(arrows).* **B:** With the elbow extended, the initial failure is in the anterior articular surface *(arrows).*

These fractures can be considered as failing in tension, with the force concentrated along the anterior cortex. This is opposite to the tension failure occurring on the posterior aspect of the cortex in the more common flexion injuries. In these shear types, the fracture line may be transverse or oblique. The differentiating feature from the more common flexion injury is that the proximal olecranon fragment is often not displaced proximally. Instead, it is the distal fragment that becomes displaced anteriorly by the brachialis and biceps muscles. The thick posterior periosteum usually remains intact.

Newman (67) described one patient in whom a shear force was directed medially; the radial neck was fractured and the radial head remained with the proximal fragment.

Associated Injuries

Associated injuries occur in 48% to 77% of patients with olecranon fractures (14,35,70,104), especially varus and valgus greenstick extension fractures, in which the radial head and neck are most commonly injured (Fig. 11-43). Other associated injuries include fractures of the ipsilateral radial shaft (101), Monteggia type I lesions with fractures of both the ulnar shaft and olecranon (69), and fractures of the lateral condyle (12) (Fig. 11-47).

FIGURE 11-47. A: Undisplaced fracture of the lateral condyle *(arrow)* associated with a varus greenstick fracture of the olecranon. **B:** Lateral view showing greenstick fractures in the olecranon *(solid arrows)* and a nondisplaced fracture of the lateral condyle *(open arrows).*

Treatment

The mechanism of injury can serve as a useful guide in choosing the proper treatment method.

Flexion Injuries

Flexion injuries are the most common olecranon fractures. Most are minimally displaced and require only simple immobilization with the elbow in no more than 75 to 80 degrees of flexion (Fig. 11-48). Even if the fracture is severely displaced, immobilization in full or partial extension usually allows the olecranon to heal satisfactorily (24,96,122).

FIGURE 11-48. Simple immobilization of a flexion injury. **A:** Injury film, lateral view, showing minimal displacement. **B:** Three weeks later, some displacement has developed. Periosteal new bone is seen along the posterior border of the olecranon *(arrow).* Healing was complete with a normal range of motion. (Courtesy of Jesse C. DeLee, MD.)

If the fracture is significantly displaced or comminuted, open reduction with some method of internal fixation usually is required. Recommended fixation devices vary from catgut or absorbable suture (56) to an axial screw (52), to tension-band wiring with axial pins (25,34,56,87,90,96,122) or a plate (103). This usually allows sufficient fixation to begin early motion. No significant growth disturbances from internal fixation have been reported.

Murphy et al. (64) compared the failure of various fixation devices to rapid loading: (a) figure-of-eight wire alone, (b) cancellous screw alone, (c) AO tension band, and (d) a cancellous screw with a figure-of-eight wire combination. The cancellous screw alone or figure-of-eight wire alone was by far the weakest. The greatest resistance to failure was provided by the combination of a screw plus figure-of-eight wire, followed closely by the AO tension-band fixation. In their clinical evaluation

of patients, comparing the AO tension band and combination screw and figure-of-eight wire, they found that more clinical problems were associated with the AO technique (65). The main problem with the AO technique is the subcutaneous prominence of the axial wires (53). To prevent proximal migration of these wires, Montgomery (62) devised a method of making eyelets in the proximal end of the wires through which he passes the figure-of-eight fixation wire.

Extension Injuries

Treatment of extension injuries requires both adequate realignment of the angulation of the olecranon and treatment of the secondary injuries. Often in varus injuries, correction of the alignment of the olecranon also reduces the radial head. The olecranon angulation must be corrected with the elbow in extension. This locks the proximal olecranon into the olecranon fossa of the humerus so that the distal angulation can be corrected at the fracture site with a valgus force applied to the forearm. Occasionally, in extension fractures, complete separation of the fragments requires open reduction and internal fixation (Fig. 11-49).

FIGURE 11-49. Open reduction of a valgus extension injury. **A:** Anteroposterior view of the injury film shows complete displacement of the radial head. **B:** Lateral view also shows the degree of displacement of the olecranon fracture. This patient required surgical intervention with internal fixation to achieve a satisfactory reduction.

Zimmerman (122) reported that the original angulation tends to redevelop in some fractures. If it is a varus fracture, the proximal ulna or olecranon may drift back into varus, which can cause a painful subluxation of the radial head. A delayed osteotomy of the proximal ulna or olecranon may be necessary if the angulation becomes significant.

Shear Injuries

In anterior shear fractures, the key to management is recognition that the distal fragment is displaced anteriorly and the posterior periosteum remains intact. The intact posterior periosteum can serve as an internal tension band to facilitate reduction.

Some of these fractures are best reduced in flexion so that the posterior periosteum serves as a compressive force to maintain the reduction. Smith (96) reported treatment of this fracture using an overhead sling placed to apply a posteriorly directed force against the proximal portion of the distal fragment. The weight of the arm and forearm helps supplement the tension-band effect of the posterior periosteum.

If the periosteum is torn or early motion is desirable, Zimmerman (122) advocated internal fixation of the two fragments with an oblique screw perpendicular to the fracture line (Fig. 11-50).

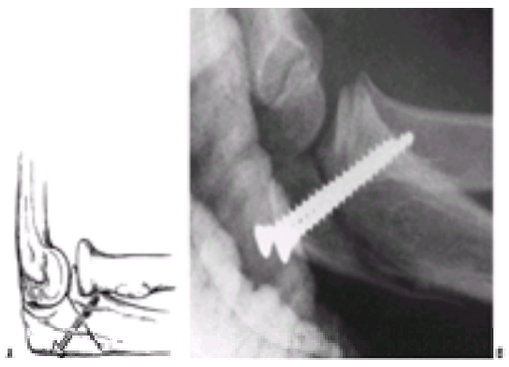

FIGURE 11-50. Operative treatment of extension shear fractures. **A:** If the periosteum is insufficient to hold the fragments apposed, an interfragmental screw may be used, as advocated by Zimmerman (122). **B:** An extension shear type of fracture secured with two oblique interfragmentary screws.

AUTHORS' PREFERRED METHOD OF TREATMENT

We use a classification based on the mechanism of injury in deciding on the method of treatment (Table 11-8).

Type I: Avulsion of the tip of the coronoid process only
Type II: A single or comminuted fragment involving ≤50% of the coronoid process
Type III: A single or comminuted fragment involving >50% of the coronoid process

TABLE 11-9. CLASSIFICATION OF FRACTURES OF THE CORONOID PROCESS

Flexion Injuries

Nonoperative. We immobilize most nondisplaced flexion injuries with the elbow in 5 to 10 degrees of flexion for approximately 3 weeks. It is important to obtain radiographs of these fractures at approximately 5 to 7 days in the cast to ensure that there has not been any significant displacement of the fragment.

Operative: Tension Band. To determine which injuries need internal fixation, we usually palpate the fracture for a defect or flex the elbow to determine the integrity of the posterior periosteum. If the fragments separate with either of these procedures, they are considered unstable and are fixed internally so that active motion can be started as soon as possible.

We prefer a modification of the tension-band technique. Originally, we used the standard AO technique with axial Kirschner wires or Steinmann pins and figure-of-eight stainless steel as the tension band (Fig. 11-51A). Because removal of the wire often required reopening the entire incision, we now use an absorbable suture for the figure-of-eight tension band. Number 1 polydioxanone (PDS) suture, which is slowly absorbed over a few months, is ideal (Fig. 11-51B). When rigid internal fixation is applied, rapid healing at the fracture site produces internal stability before the integrity of the PDS is lost. We prefer Kirschner wires in patients who are very young and have very little ossification of the olecranon apophysis (Fig. 11-38). If the axial wires become a problem, they can be removed with only a small incision. Most recently, we have used a combination of an oblique cortical screw with PDS as the tension band (Fig. 11-51C,Fig. 11-51D) and have been pleased with the results. In the past we had to remove almost all the axial wires; very few of the screws have become symptomatic enough to require removal. Occasionally, the tension-band wire technique with 16- or 18-gauge wire must be used if compression is necessary.

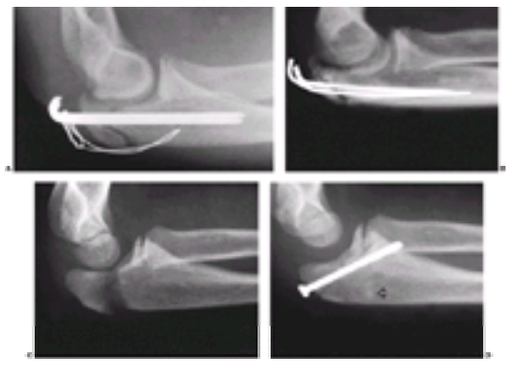

FIGURE 11-51. Internal tension-band techniques. **A:** Standard AO technique with stainless steel wire (see Fig. 11-40D for original injury film). The wire can be prominent in the subcutaneous tissues. **B:** Axial wires plus polydioxanone (PDS) 6 weeks after surgery. **C:** A displaced flexion-type injury in an 11-year-old boy. There is complete separation of the fracture fragments. **D:** This fracture was secured with a cancellous lag screw plus PDS suture. The screw engages the anterior cortex of the coronoid process. The PDS is passed through the olecranon through a separate drill hole *(open arrow),* crossed in a figure-of-eight manner over the fracture site, and then tied over the neck of the screw.

Extension Injures

In extension injuries, adequate relaxation should be achieved to allow a forceful manipulation of the olecranon while it is locked in its fossa in extension. Because this is a greenstick fracture, we try to achieve a slight overcorrection to prevent the development of reangulation. These fractures should be followed closely and possibly remanipulated in 1 to 2 weeks if the original angulation recurs. The associated injuries are treated as if they were isolated fractures.

Most shear fractures can be treated nonoperatively. We usually immobilize them in enough hyperflexion to hold the fragments together, providing the posterior periosteum is intact (Fig. 11-52).

FIGURE 11-52. Shear injuries. **A:** Flexion pattern: radiograph of the patient seen in Fig. 11-45A after the elbow was flexed. The intact posterior periosteum acted as a tension band and held the fracture reduced. **B:** Radiograph taken 4 weeks after surgery shows new bone formation under the intact periosteum *(arrows)* on the dorsal surface of the olecranon. **C:** Extension pattern: radiograph of patient with an extension shear injury showing an increase in the fracture gap *(arrows)* (see also Fig. 11-45B). **D:** Because the dorsal periosteum and cortex were intact, the fracture gap *(arrows)* closed with flexion of the elbow.

If the periosteum is torn, an oblique screw is an excellent way to secure this type of fracture pattern (Fig. 11-50). It also can be used if there has been considerable swelling, which prevents the elbow from being hyperflexed enough to use the posterior periosteum as a tension band.

Postoperative Care

The elbow is placed at a 70- to 80-degree angle and a long arm cast is placed. The cast can be bivalved and the anterior portion removed if there is excessive swelling. This cast or posterior splint is used for 3 weeks, at which time active range of motion is begun.

ASSOCIATED INJURIES AND COMPLICATIONS

Relatively few complications arise from the olecranon fracture itself.

Irreducibility

An and Loder (1) reported inability to reduce the fracture in one of their patients because the proximal fragment had been entrapped in the joint.

Nonunion

Nonunion is unusual. A true nonunion from a fracture should not be confused with a rare form of congenital pseudarthrosis of the ulna (Fig. 11-53). In the latter condition, there is usually no known antecedent trauma.

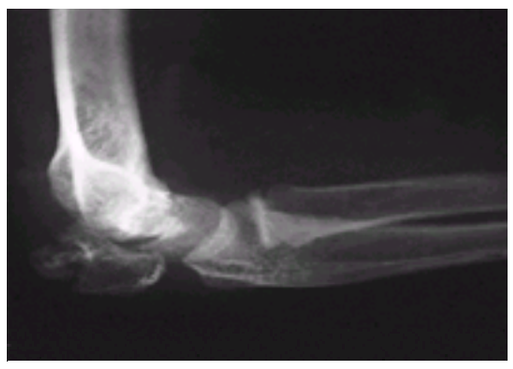

FIGURE 11-53. Congenital pseudarthrosis of the olecranon in a 9-year-old girl who had limited elbow extension and no antecedent trauma. The edges of the bone were separated by thick fibrous tissue. (Courtesy of Michael J. Rogal, MD.)

Delayed Union

Delayed radiographic union is usually asymptomatic (56). In Mathews' series (56), one fracture that was internally secured with catgut ultimately progressed to a nonunion. Despite this, the patient had only a 10-degree extension lag and grade 4 triceps strength. The presence of an accessory ossicle such as a patella cubiti should not be confused with nonunion.

Compartment Syndrome

Mathews (56) reported one patient with Volkmann ischemic contracture after an undisplaced linear fracture in the olecranon.

Nerve Injuries

Transient neurapraxia of the ulnar nerve has been reported. Zimmerman (122) reported ulnar nerve irritation from the development of a pseudarthrosis of the olecranon where inadequate fixation was used.

Elongation

One complication recently observed has been elongation of the tip of the olecranon. This was seen in a young boy who had a partial avulsion of the tip of the apophysis (Fig. 11-54). Because of the delayed union, the apophysis became elongated to the point that it limited extension. This proximal overgrowth of the tip of the apophysis has also been reported in other simple olecranon fractures after routine open reduction and internal fixation (70).

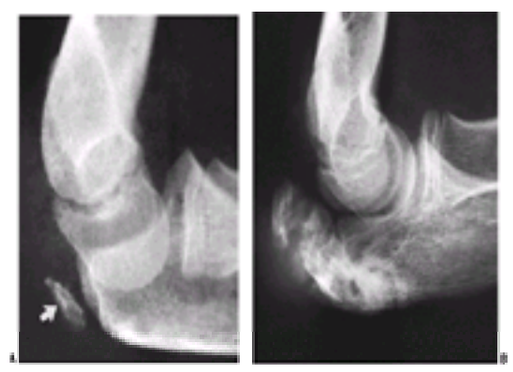

FIGURE 11-54. A: Injury film showing partial avulsion of the tip of the olecranon apophysis *(arrow).* **B:** Radiograph taken 4 years later showed a marked elongation and irregular ossification of the apophysis. (Courtesy of Joel Goldman, MD.)

Loss of Reduction

Apparently stable fractures treated with external immobilization must be watched closely for a delayed loss of reduction that can result in a significant loss of elbow function (Fig. 11-55).

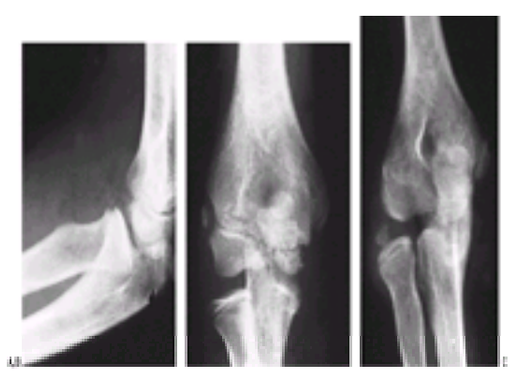

FIGURE 11-55. Loss of reduction. **A:** Lateral radiograph of what appeared to be a simple undisplaced fracture *(arrow)* of the olecranon in a 13-year-old girl. **B:** On the anteroposterior radiograph, the fracture also appears undisplaced. The mild lateral subluxation of the radial head was not appreciated initially. **C:** Radiographs taken 5 months later showed further lateral subluxation with resultant incongruity of the elbow joint. (Courtesy of Richard W. Williamson, MD.)

Fractures of the Coronoid Process

Anatomy

Up to age 6 years, the coronoid process is mostly epiphyseal and physeal cartilage at the distal end of a tongue extending from the apophysis of the olecranon. The coronoid process does not develop a secondary center of ossification, but instead is ossified by the advancing edge of the metaphysis (Fig. 11-35).

Incidence

The incidence in some major series of elbow fractures varies from less than 1% to 2% (57).

Because most fractures of the coronoid process occur with dislocations of the elbow, it seems logical that they would happen in older children. However, in a review of 23 coronoid fractures in children, Bracq (11) found that the injuries occurred in two peak age groups: one was between 8 and 9 years of age and the other between 12 and 14 years.

Although most coronoid fractures are associated with elbow dislocations, fractures of the olecranon, medial epicondyle, and lateral condyle also have been reported (11). The fracture of the coronoid may be part of a greenstick olecranon fracture (i.e., the extension-type metaphyseal fracture; Fig. 11-56). Isolated coronoid fractures are thought to be due to pure avulsion by the brachialis or secondary to an elbow dislocation that reduced spontaneously, which usually is indicated by hemarthrosis and a small avulsion of the tip of the olecranon process (Fig. 11-57).

FIGURE 11-56. Fracture of the coronoid *(arrows)* as part of an extension valgus olecranon fracture pattern. There was an associated fracture of the radial neck. Both the neck fracture and the distal portion of the coronoid process demonstrate periosteal new bone formation *open arrows).*

Diagnosis

The radiographic diagnosis of this fracture often is difficult because on the lateral view the radial head is superimposed over the coronoid process. Evaluation of a minimally displaced fracture may require oblique views (13) (Fig. 11-58). The radiocapitellar view (Fig. 11-3) provides good visualization of the profile of the coronoid process.

In young children, in whom the coronoid process contains considerable cartilage, an unusual flap injury has been described (8). In this rare injury, the elbow is dislocated and the articular surface is flipped back into the joint. The only clue to this fracture may be the presence of a small flake of bone in the anterior part of the joint on the lateral radiograph.

Classification

Regan and Morrey (82) classified coronoid fractures into three types based on the amount of the coronoid process involved (Table 11-9). This classification was found to be useful in predicting the outcome and in determining the treatment. Type I fractures involve only the tip of the process (Fig. 11-57); type II fractures involve more than just the tip but less than 50% of the process (Fig. 11-58), and type III fractures involve more than 50% of the process.

FIGURE 11-57. Lateral radiograph of an 11-year-old boy who injured his left elbow. The presence of displaced anterior and posterior fat pads, plus a small fracture of the coronoid *(arrow),* indicates a probable partially dislocated elbow as the primary injury.

FIGURE 11-58. A: Based on this original lateral radiograph, a 12-year-old boy with a swollen elbow was thought to have a fracture of the radial neck *(arrow). B:* With an oblique view, it is now obvious that the fragment is from the coronoid process. **C:** Five months later, the protuberant healed coronoid process *(arrow)* is seen on this radiocapitellar view.

Treatment

Treatment is based on the degree of displacement or the presence of elbow instability. The associated injuries are also a factor in treatment.

Regan and Morrey (81,82) determined that types I and II could be treated with early motion if there were no contradicting associated injuries.

In initially immobilizing these fractures, if they are associated with an elbow dislocation, the elbow should be placed in approximately 100 degrees of flexion, with the forearm in full supination (11). Occasionally, in isolated avulsion fractures in which the fragment is attached distally, reduction is better accomplished with the elbow

held in some extension. In these rare cases, it is believed that the brachialis muscle may be an aid in reducing the fragment in extension (102).

Regan and Morrey (81) found that the elbow was often unstable in type III fractures. As a result, they thought that the fragment must be reduced and secured with internal fixation. In their review, satisfactory results could be expected with type I and II injuries, but in only 20% of type III injuries.

AUTHORS' PREFERRED METHOD OF TREATMENT

We usually treat coronoid fractures with early motion, much as we do elbow dislocations. The presence of a coronoid fracture alerts us to be especially thorough in looking for other injuries. In children, it is rarely necessary to replace the fragments surgically. If there is a large fragment and marked displacement, open reduction and internal fixation can be done through a Henry anterior approach to the elbow. The fragment can be fixed with a mini-fragment screw or sewn in place through two drill holes to the posterior aspect of the ulna.

ASSOCIATED INJURIES AND COMPLICATIONS

Complications are rare. In fractures with a large fragment (type III), the elbow may be unstable and prone to recurrent dislocations. Nonunion with the production of a free fragment in the joint occurs rarely in children (96).

MONTEGGIA FRACTURE–DISLOCATION IN CHILDREN

EARL A. STANLEY
JOSE F. DE LA GARZA

Monteggia fracture–dislocations are a complex of injuries that represent a link between injuries of the forearm and the elbow. The original description of an anterior dislocation of the proximal radius and fracture of the proximal ulna has been expanded to include dislocations of the radial head in multiple directions and combinations of injuries to the ulna and distal humerus. The mechanisms of injury and protocols for treatment are similar in the different types of Monteggia fracture–dislocations. Fortunately, if the injury is recognized, the fracture course follows closely that of the forearm fractures rather than the more complex injuries of the child's elbow. Treatment results are better in children than in adults.

HISTORICAL BACKGROUND

Original Description

Giovanni Batista Monteggia, a surgical pathologist and public health official in Milan, first described the Monteggia fracture in 1814. He observed the original two injuries in cadavers and provided the description, “A traumatic lesion distinguished by a fracture of the proximal third of the ulna and an anterior dislocation of the proximal epiphysis of the radius.” Monteggia also described the injury in a young girl who was treated late with external compression, which failed to reduce the radial head, leading to a loss of elbow function. The complexity of this fracture–dislocation was not fully appreciated until the classic monograph coining the term *Monteggia lesion* was written in English by Jose Luis Bado (7).

Defining The Monteggia Lesion

Jose Luis Bado, while Chief Director of the Institutado Orthopedia y Tramatogico in Montevideo, Uruguay, studied proximal radial dislocations in association with fractures of the ulna, writing extensively on this subject in the late 1950s. In this monograph, Bado defined the Monteggia lesion as an association of a radial head fracture or dislocation with a fracture of the middle or proximal ulna.

Classification

Numerous classification schemes have been developed and are useful in various situations, but Bado's classification has stood the test of time. It is used widely when a series of injuries are analyzed and new variations of Monteggia fractures are discovered. Bado's classification divides Monteggia fractures into four types of true Monteggia lesions and equivalent lesions (Fig. 12-1).

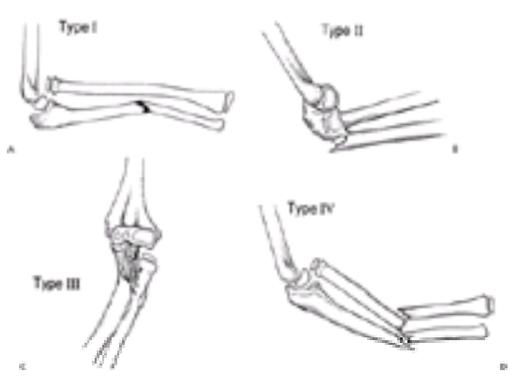

FIGURE 12-1. Bado's classification. **A:** Type I (anterior dislocation): the radial head is dislocated anteriorly; and the ulna has a short oblique or greenstick fracture in the diaphyseal or proximal metaphyseal area. **B:** Type II (posterior dislocation): the radial head is posteriorly and posterolaterally dislocated; the ulna is usually fractured in the metaphysis in children. **C:** Type III (lateral dislocation): there is lateral dislocation of the radial head with a greenstick metaphyseal fracture of the ulna. **D:** Type IV (anterior dislocation with radius shaft fracture): the pattern of injury is the same as with a type I injury, with the inclusion of a radius shaft fracture below the level of the ulnar fracture.

True Lesions

Type I

A type I lesion (Fig. 12-2) is described as an anterior dislocation of the radial head with a fracture of the ulnar diaphysis. The ulnar fracture can be at any level, but usually is described as midshaft. Most Monteggia injuries in children are of this type (approximately 70% in most series).

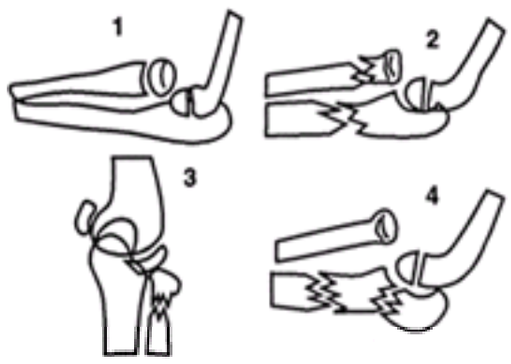

FIGURE 12-2. Type I Monteggia equivalents. **1** Isolated anterior radial head dislocation. **2** Ulnar and proximal radius fractures, including fractures of the radial neck. **3** Isolated radial neck fractures. **4** Elbow (ulnohumeral) dislocation with or without fracture of the proximal radius.

Type II

Posterior dislocation of the radial head with associated ulnar diaphyseal or metaphyseal fracture with posterior angulation is defined as a type II lesion. This lesion is uncommon in children, with most early series recognizing this as a fracture of adults only. Peiró et al. (82) reported one type II lesion in their series of 25 acute Monteggia lesions in children. In 1965, Pavel et al. (81), in their review of a series of posterior Monteggia fracture dislocations, reported only one type II lesion in a child. In both series, the children were older, approximately 13 years of age. Although reported as high as 6% by some authors, the overall prevalence of type II fractures in children is 3% when all studies are considered. In their series of 36 consecutive Monteggia fracture–dislocations in children, Ring and Waters found only 1 (3%) type II injury (94).

Type III

A type III lesion consists of a lateral or anterolateral dislocation of the radial head associated with a fracture of the ulnar metaphysis. The ulnar metaphyseal fracture usually is a greenstick type in children. This is the second most common type of Monteggia fracture–dislocation in children (23%). This fracture pattern often is associated with radial nerve injuries and a coexisting intraarticular obstruction to radial head reduction, which requires surgical reduction of the radial head.

Extension of the ulnar fracture into the olecranon leads some investigators to classify this type of fracture–dislocation as a different lesion (11,18,46,116). If there is no concurrent radioulnar disassociation with the proximal ulnar fracture and radiocapitellar dislocation, the injury should be considered a fracture–dislocation of the elbow, and not strictly a Monteggia fracture. This lesion is included by others in series of Monteggia fractures, classifying them by the direction of the radial head dislocation, usually lateral and anterolateral (36,77,79,127).

Type IV

Type IV Monteggia lesions, characterized by anterior dislocation of the radial head with fractures of the ulna and radius at the same level, or with the radial fracture distal to the ulnar fracture, are relatively rare in children, ith an average incidence of 1% (Fig. 12-1D). Wiley and Galey (127), Olney and Menelaus (77), and Dormans and Rang (28) each reported an average frequency of approximately 1% for type IV lesions. Ring and Waters, however, reported 4 type IV fractures (11%) in 36 consecutive Monteggia fracture–dislocations in children; they recorded any otherwise unclassified fracture of both bones of the forearm with proximal radioulnar dislocation as a type IV lesion (94).

Monteggia Equivalent Injuries

Bado classified certain injuries as equivalents to the classic or true Monteggia lesions because of their associated mechanism of injuries, radiographic pattern, or methods of treatment.

Type I Equivalents

Type I equivalents include an isolated anterior dislocation of the radial head; however, minimal plastic deterioration at the ulna accompanies the radial head dislocation, so “isolated” dislocation probably is a misnomer. Also included in this subclassification is the pulled elbow syndrome. If one considers the typical mechanism of longitudinal traction with pronation, possibly combined with hyperextension of the elbow joint, the relationship between the pulled elbow syndrome and the type I Monteggia fracture is evident. Other type I equivalent lesions include a fracture of the ulnar diaphysis with fracture of the radial neck. Fracture of the radius and ulnar shafts may be considered a type I equivalent if the radial fracture is above the junction of the middle and proximal thirds. Two additional type I equivalents are fracture of the ulnar diaphysis with either anterior dislocation of the radial head and an olecranon fracture, or posterior dislocation of the ulnohumeral joint with or without fracture of the proximal radius.

Type II Equivalents

In his original classification, Bado stated that there were no equivalents to type II Monteggia lesions other than epiphyseal fracture of the radial head or fracture of the radial neck. Considering the mechanism of this injury, as defined by Penrose (84), a posterior elbow dislocation could be included as a type II equivalent in children.

Types III and IV Equivalents

Bado stated that there were no equivalents for types III and IV lesions. More recent reviews have reported fracture patterns that, when the mechanism of injury is considered, might be classified as type III or IV equivalents. Ravessoud reported an oblique fracture of the ulna with varus alignment and a displaced lateral condyle fracture in a 13 year-old patient (90). This fracture pattern, which suggests hyperextension of the elbow combined with varus force, is produced by the same mechanism of injury as a type III lesion, as described by Wright (129).

De la Garza described fractures of the distal humerus, ulnar diaphysis, and radial neck, which he classified as equivalent to a type III Monteggia fracture–dislocation because of the mechanism of injury. Bhandari and Jindal reported a type IV variant that included a fracture of the mid-third radial shaft, an anterolaterally angulated fracture of the proximal ulna, and a posterior lateral dislocation of the radial head. A similar lesion was reported by Givon et al. (40).

Hybrid Lesion

A hybrid lesion similar to a type III Monteggia lesion has been described in which anterior dislocation of the radial head was associated with a fracture of the metaphyseal region of the ulna that extended into the olecranon. Other studies noted the radial head to be dislocated in multiple directions. The treatment and outcome of each fracture are determined by the direction of the radial head dislocation combined with the pattern of the ulnar fracture.

Other Classifications

Dormans and Rang (28) extended Bado's classification by adding a type V, the intermittent and habitual dislocation of the radiocapitellar joint and proximal radioulnar joint. Others (76,127) have considered the Bado type IV lesion to be a variant of Bado's type I and have excluded it from their classifications.

Letts et al. (61) devised a classification of Monteggia fractures in children based on both the direction of the radial head dislocation and the type of ulnar fracture (Fig. 12-3). The Bado type I class was subdivided into three subtypes. Letts type A is anterior bowing of the ulna due to plastic deformation with anterior dislocation of the radial head. Type B includes a greenstick fracture of the ulna, and type C has a complete ulnar fracture. Letts types D and E correspond, respectively, to Bado types II

and III.

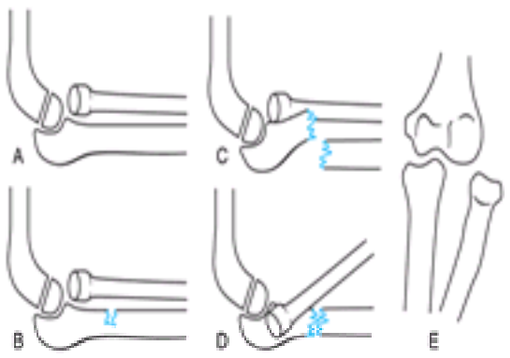

FIGURE 12-3. Pediatric Monteggia lesion classification by Letts. **A:** Anterior dislocation of the radial head with plastic deformation of the ulna. **B:** Anterior dislocation of the radial head with greenstick fracture of the ulna. **C:** Complete fracture of the ulna with anterior dislocation of the radial head. **D:** Posterior dislocation of the radial head with fracture of the ulnar metaphysis. **E:** Lateral dislocation of the radial head and metaphyseal greenstick fracture of the ulna.

AUTHORS' PREFERRED CLASSIFICATION

We prefer to use Bado's classification in evaluating and treating the Monteggia lesion (Table 12-1). Although recognizing the contributions of other researchers, we believe that treatment principles are better determined by the direction of the radial head dislocation than the pattern of the ulnar fracture. Further, it is important not to exclude a type IV lesion from any classification scheme because the recognition and proper management of the radial fracture is important to the success of its treatment.

Type	Dislocation	Fracture
True lesions		
I	Anterior	Metaphysis–diaphysis
II	Posterior	Metaphysis–diaphysis
III	Lateral	Metaphysis
IV	Anterior	Radial diaphysis, ulnar diaphysis
Hybrid Lesion	Anterior, posterior, or lateral	Metaphysis or olecranon

Type	Description
Equivalent lesions	
I	Isolated dislocation of radial head Radial neck fracture (isolated) Radial neck fracture in combination with a fracture of the ulnar diaphysis Radial and ulnar fractures with the radial fracture above the junction of the middle and proximal thirds Fracture of ulnar diaphysis with anterior dislocation of radial head and an olecranon fracture
II	Posterior dislocation of the elbow
III	Ulnar fracture with displaced fracture of the lateral condyle
IV	Bone described

TABLE 12-1. AUTHORS' CLASSIFICATION OF MONTEGGIA FRACTURE - DISLOCATIONS

We also recognize a hybrid lesion consisting of a radial head dislocation and metaphyseal ulnar fracture extending into the olecranon. In this fracture–dislocation pattern, there may or may not be disassociation of the proximal radioulnar complex. The technique of treatment of the hybrid lesion is the same as for the comparable true Monteggia lesion. This necessitates including these hybrid lesions when considering the recognition and management of Monteggia fracture–dislocations in general.

ANATOMY AND BIOMECHANICS

Certain anatomic relations between the proximal radius and ulna and their surrounding structures must be taken into account in the management of the Monteggia fracture. They are divided into four anatomic categories: ligaments, bones, muscles, and nerves.

Ligaments

Annular Ligament

Stability of the proximal radioulnar joint is provided by the surrounding ligaments, primarily the annular ligament. Failure of this structure usually leads to failure of the others. It maintains the position of the radial head within the radial notch of the ulna through the entire range of rotation, becoming tighter in supination because of the shape of the radial head. The substance of the annular ligament is reinforced by the radial collateral ligament at the elbow joint (Fig. 12-4).

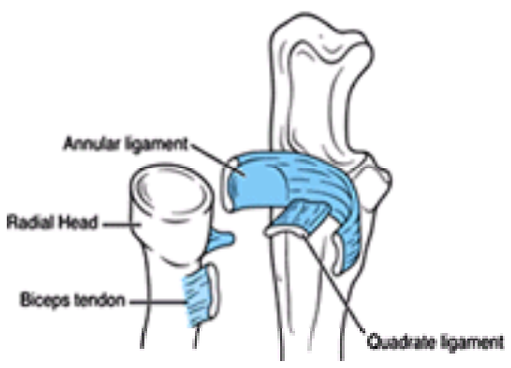

FIGURE 12-4. Ligamentous anatomy of the proximal radioulnar joint.

Quadrate Ligament

The quadrate ligament (52), or ligament of Denucé (27), is located between the radius and ulna distal to the annular ligament (Fig. 12-4). It consists of a dense anterior border and a thinner posterior border with an even thinner central portion. The two borders limit rotation and stabilize the radial head at limits of supination and pronation. The anterior border becomes tight in supination, adding stability to the proximal radioulnar joint. Excessive pronation causes the posterior border to fail, producing instability of the radial head.

Oblique Ligament

The oblique ligament, or ligament of Weitbrecht (126), extends from the ulna proximally to the radius distally (Fig. 12-5). It begins below the radial notch of the ulna and ends just below the biceps tuberosity on the radius. The bow of the radius tightens the oblique ligament when the radius is in supination and provides additional stability to the proximal radioulnar joint.

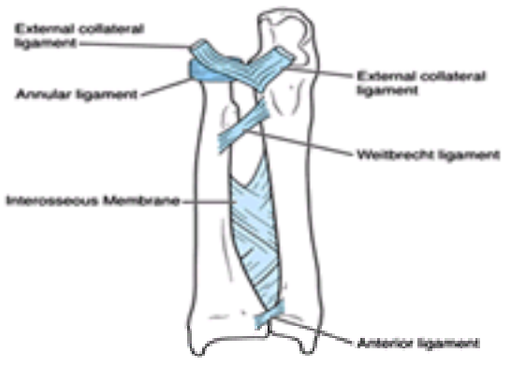

FIGURE 12-5. Ligaments of the forearm. In supination, the annular ligament, quadrate ligament, Weitbrecht ligament, and interosseous membrane are taut, stabilizing the radial head.

Interosseous Membrane

The interosseous membrane is distal and separate from the oblique ligament, with its fibers running in the opposite direction (Fig. 12-5). It acts in concert with the oblique ligament to approximate the radioulnar joint. The fibers of both the oblique and interosseous membranes tighten with supination of the radius.

Osseous Relations

There is little inherent osseous stability to the proximal radioulnar joint. The shape of the radial head contributes to tightness of the ligament as the radius rotates.

Shape of the Radial Head

The head of the radius is elliptic in its cross section (Fig. 12-6). In supination, the long axis of the ellipse is perpendicular to the ulna, causing the annular ligament and the anterior border of the quadrate ligament to stabilize the proximal radioulnar joint further by tightening.

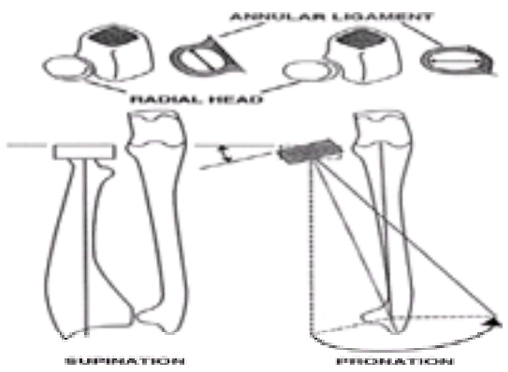

FIGURE 12-6. The radial head is an elliptic structure secured by the annular ligament, which allows movement and gives stability. Because of the shape of the radial head, the stability provided by the annular ligament is maximized in supination.

The contact area between the radius and the radial notch is greater in supination because of the broadened surface area of the circumference of the radial head in that position. The portion of the radial head circumference adjacent to the radial notch, when supinated, is less curved and is longer, proximal to distal, than other portions of the circumference. This provides a minimal increase in stability as the ligaments tighten.

Bow of the Radius

In the anatomic position, the apex of the radial bow is lateral (Fig. 12-5). This curvature allows increased range of pronation as the radius rotates along the axis between the proximal and distal radioulnar joints. When the radius is in supination, the bow tightens the oblique and interosseous ligaments and increases proximal radioulnar stability.

Muscles

Whereas the ligaments help stabilize the humeral–radioulnar complex, the muscles play an active role in the mechanism of injury that produces the Monteggia fracture–dislocation.

Biceps Brachii

The biceps, inserting into the biceps tuberosity on the proximal radius, is a major deforming force. It is active in the pathomechanics of the Monteggia fracture–dislocation, violently pulling the proximal radius away from the capitellum as the elbow goes into extension. During treatment, the effect of the biceps must be regulated by elbow flexion, preventing recurrence of the radial head dislocation.

Anconeus and Forearm Flexors

The anconeus and forearm flexors act together to create a radially angulated bow in the ulna in a Monteggia fracture–dislocation. The function of the anconeus in the uninjured person is enigmatic. Electromyographic studies show that it helps stabilize the elbow as it goes into extension, creating a valgus moment at the joint, and during forearm pronation counteracts the varus moment produced by the pronator teres against an intact ulna (9,121).

The forearm flexors create a bowstring effect, producing a tendency for the fractured ulna to shorten and angulate radially after reduction (121).

Nerves

Posterior Interosseous Nerve

There is a close relation between the posterior interosseous nerve and the proximal radius, with the nerve coursing anterior and anterolateral to the radial head and neck on its path through the supinator muscle. With anterolateral dislocations of the radial head, this relation becomes particularly intimate, causing a paresis of the

nerve. In adults, there is a more discrete organization of the proximal border of the superficial head of the supinator, forming the arcade of Frohse (103) (Fig. 12-7). This band is not as well defined in children, which may partially account for the lower incidence of permanent injury to the posterior interosseous nerve in children, as well as the high incidence of resolution once reduction of the radius is obtained (104).

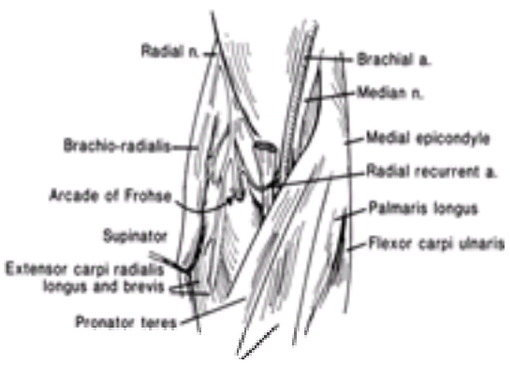

FIGURE 12-7. Dissection of the forearm at the level of the elbow. (Redrawn from Spinner M. *Injuries to major branches of peripheral nerves of forearm,* 2nd ed. Philadelphia: WB Saunders, 1978; with permission.)

Ulnar Nerve

The ulnar nerve, relatively tethered by the cubital tunnel, can be at risk in Monteggia fractures involving the proximal end of the ulna, particularly type II injuries (106).

CHARACTERISTICS AND MANAGEMENT OF MONTEGGIA INJURIES

Type I Lesions

Clinical Findings

Bado, in his original description, provided an accurate clinical picture of the Monteggia fracture–dislocation. In general, there is fusiform swelling about the elbow. The child has significant pain and cannot move the elbow in either flexion and extension or pronation and supination. There is usually an angular change to the forearm itself, with the apex shifted anteriorly. There may be tenting of the skin or an area of ecchymosis on the volar aspect of the forearm. Later, as the swelling subsides, there still may be an anterior fullness in the cubital fossa. If this lesion is seen late, as in a Monteggia fracture with only plastic deformation of the ulna but complete dislocation of the radial head, there is a persistent anterior prominence at the elbow and loss of full flexion at the elbow. On further observation, it may be noted that the patient cannot extend the digits at the metacarpophalangeal joint or at the interphalangeal joint in the thumb because of a paresis of the posterior interosseous nerve.

Radiographic Evaluation

The standard evaluation of a type I Monteggia fracture includes anteroposterior (AP) and lateral radiographs of the forearm. Any disruption of the ulna, especially an apparently innocuous bowing, should alert the physician to look for a disruption of the joints at either end of the forearm, in this case proximally (26,53,63).

Radiocapitellar Relation

The radiocapitellar relation is particularly important and is best defined by a true lateral view of the elbow. This relation in a type I Monteggia fracture may appear normal on an AP radiograph despite obvious disruption on the lateral view (Fig. 12-8). If there is doubt regarding the radiocapitellar relation, a true lateral view of the opposite elbow should be obtained for comparison. Smith (100) and, later, Storen (109) noted that a line drawn through the center of the radial neck and head should extend directly through the center of the capitellum. This alignment should remain intact regardless of the degree of flexion or extension of the elbow (Fig. 12-9). In some instances, there is disruption of the radiocapitellar line in a normal elbow. Miles and Finlay (69) pointed out that the radiocapitellar line passes through the center of the capitellum only on a true lateral projection. They reported five patients in whom the elbow was clinically normal but the radiocapitellar line appeared disrupted. In analyzing the radiographs, they found that the radiographic projection of the elbow usually was an oblique view or that the forearm was pronated in the radiograph. If this disruption appears on radiographs in a child with an acute injury, however, it is the treating surgeon's responsibility to ensure that it is an insignificant finding.

FIGURE 12-8. Anteroposterior view **(A)** demonstrates an apparently located radial head, but the lateral view **(B)** shows an anterior dislocation of the radial head. Note the disruption of the radiocapitellar line.

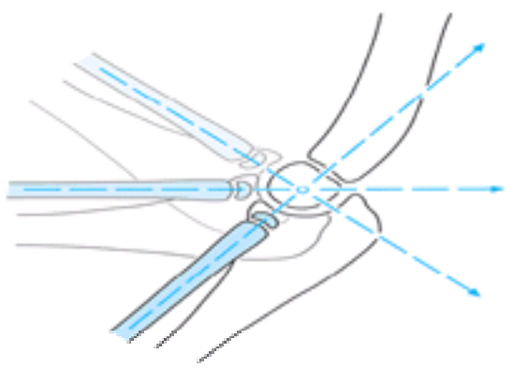

FIGURE 12-9. Composite drawing with the elbow in various degrees of flexion. A line drawn down the long axis of the radius bisects the capitulum of the humerus regardless of the degree of flexion or extension of the elbow. (Redrawn from Smith FM. Children's elbow with injuries: fractures and dislocations. *Clin Orthop* 1967;50:25-26; with permission.)

Traumatic Versus Congenital Dislocation

When the radiocapitellar relation is disrupted, radiographic evaluation of the shape of the radial head and neck helps determine the cause of the disruption, especially if there is no history of trauma or the significance of the trauma is questioned. Bucknill (20) reviewed the difference between congenital and old traumatic dislocations of the radial head. He believed that McFarland's (66) classic description of a atypical deformed radial head with a dysplastic capitellum and concavity of the posterior border of the proximal ulna and the association of paraarticular ossifications probably represented old traumatic dislocations. Lloyd-Roberts and Bucknill (64) believed that the congenital nature of some unilateral anterior dislocations remained unproved and that their existence as old traumatic dislocations should be suspected. Lloyd-Roberts acknowledged Caravias (22) as recognizing that the existence of a congenital anterior dislocation as a separate entity was doubtful and that true congenital dislocation of the head was indeed rare. When true congenital dislocation occurs, it is usually bilateral and posterior and is often associated with various syndromes such as Ehlers-Danlos, nail-patella, and Silver's syndrome (2,64) (Fig. 12-10). Therefore, all isolated anterior and anterolateral dislocations of the radial head, regardless of symptoms, should be considered as having a traumatic origin. Their management should be the same as for known, previously undetected, posttraumatic dislocations of the radial head.

FIGURE 12-10. Congenital versus traumatic dislocation. **A:** Anteroposterior (AP) view of the elbow of a 7-year-old who presented with limited forearm rotation. **B:** Lateral radiograph of the same child. Note dysplastic radial head and an attempt at synostosis with the ulna. There is also anterior bowing of the ulna. Note also the hypoplastic capitellum. Is this congenital or old trauma? **C:** AP radiograph of congenital synostosis. **D:** Lateral radiograph of congenital synostosis and posterior dislocation. Note posterior bow of the ulna and hypoplasia of the capitellum. This is congenital. (Interestingly, these are opposite elbows of the same child.)

Mechanism of Injury

The mechanisms of injury of type I lesions have been studied thoroughly (8,19,33,73,75,89,91,102,121). Three separate mechanisms have been developed to describe the production of this injury. Each mechanism probably can occur under specific conditions (19,91).

Direct Blow Theory

The first theory proposed in the English literature was the direct blow mechanism by Speed and Boyd (102) (Fig. 12-11). This was later confirmed by Smith (100), but actually this theory was proposed by Monteggia himself (70). He noted that the fracture occurs when a direct blow on the posterior aspect of the forearm first produces a fracture through the ulna. Then, either by continued deformation or direct pressure, the radial head is forced anteriorly with respect to the capitellum, causing the radial head to dislocate. Monteggia explained that these injuries sometimes resulted from a blow by a staff or cudgel on the forearm raised to protect the head (83). Another eponym for the Monteggia fracture–dislocation, the *parry fracture,* has been mentioned in the literature. During the American Civil War, there was a high incidence of Monteggia fractures owing to direct blows on the forearm received while attempting to parry the butt of a rifle during hand-to-hand combat. The major argument presented against this theory as being the sole mechanism is that in the usual clinical situation there rarely is evidence of a direct blow to the posterior aspect of the forearm, such as a contusion or laceration (33,121).

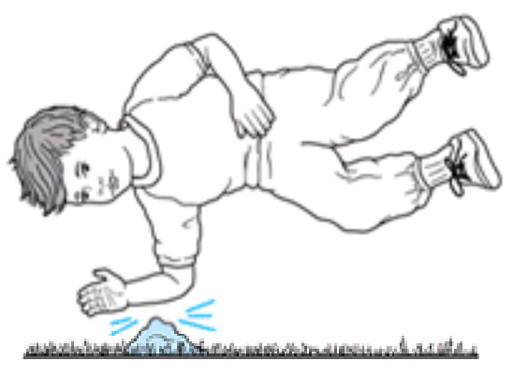

FIGURE 12-11. The fracture-dislocation is sustained by direct contact on the posterior aspect of the forearm, either by falling onto an object or by the object striking the forearm. The continued motion of the object forward dislocates the radial head after fracturing the ulna.

Hyperpronation Theory

In 1949, Evans (33) published his observations regarding the anterior Monteggia fracture. Previous investigators had based their direct blow theory purely on clinical observation, but Evans used cadaveric experiments to support his hypothesis. He demonstrated that hyperpronation of the forearm produced a fracture of the ulna with a subsequent dislocation of the radial head. It was postulated that during a fall, the outstretched hand, initially in pronation, is forced into further pronation as the body twists above the planted hand and forearm (Fig. 12-12). This hyperpronation causes the radius to be crossed over the mid-ulna, resulting in anterior dislocation of the radial head or fracture of the proximal third of the radius and fracture of the ulna. In the patients reported in Evans' article, the ulnar fractures demonstrated a pattern consistent with anterior tension and shear or longitudinal compression. His cadaveric studies, however, showed the ulna fracture pattern to be consistent with a spiral or torsional force. This theory also was supported by Bado (7).

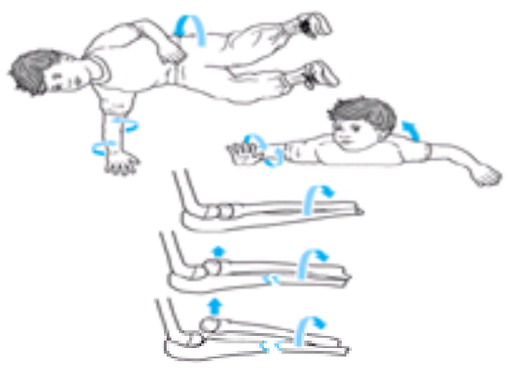

FIGURE 12-12. Hyperpronation theory (Evans). Rotation of the patient's body externally forces the forearm into pronation. The ulnar shaft fractures with further rotation, forcibly dislocating the radial head

Two arguments have been used to dispute Evans' mechanism (121). First, the ulnar fracture rarely presents clinically in a spiral pattern; it is usually oblique, indicating an initial force in tension with propagation in shear rather than rotation. Second, Evans' experiments, which were done on totally dissected forearms, did not take into consideration the dynamic muscle forces at play during a fall on an outstretched hand *in vivo.*

Hyperextension Theory

In 1971, Tompkins (121) analyzed both theories and presented good clinical evidence that the type I Monteggia fracture was caused by a combination of dynamic and static forces. His study postulated three steps in the fracture mechanism (Fig. 12-13): hyperextension, radial head dislocation, and ulnar fracture.

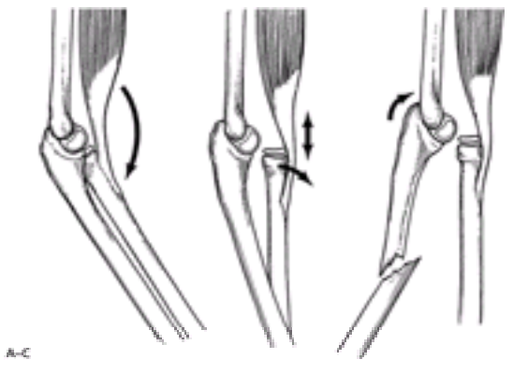

FIGURE 12-13. Hyperextension theory. **A:** Hyperextension: forward momentum caused by a fall on an outstretched hand forces the elbow into extension. **B:** Radial head dislocation: the biceps contracts, forcibly dislocating the radial head. **C:** Ulnar fracture: forward momentum causes the ulna to fracture because of tension on the anterior surface.

Hyperextension. The patient falls on an outstretched arm with forward momentum, forcing the elbow joint into hyperextension (Fig. 12-13*A*).

Radial Head Dislocation. The radius is first dislocated anteriorly by the violent reflexive contracture of the biceps, forcing the radius away from the capitellum (Fig. 12-13).

Ulnar Fracture. Once the radius is dislocated, the weight of the body is transferred to the ulna. Because the radius is usually the main weight-transmitting bone in the forearm, the ulna cannot handle the longitudinal force and subsequently fails in tension (Fig. 12-13C). This tension force produces an oblique fracture line, often with a butterfly fragment, or a greenstick fracture in the ulnar diaphysis or diaphyseal–metaphyseal junction. In addition to the momentum of the injury, the anterior angulation of the ulna results from the pull of the intact interosseous membrane on the distal fragment, causing it to follow the radius. The brachialis muscle causes the proximal ulnar fragment to flex at the elbow.

Summary of Mechanisms of Injury

The Monteggia lesion can probably occur by any of the three proposed mechanisms in a given situation. We believe that the most common mechanism is a fall on an outstretched hand that forces the elbow into complete extension, locking the olecranon into the humerus. The forearm is in a rotational position of neutral to mid-pronation. As the ulna locks into the humerus, the bending force stresses the radioulnar joint. Because of the relatively pronated position of the joint, the ligamentous restraints are lax, providing only tenuous stability for the radial head. The anterior bending force, combined with a reflexive contraction of the biceps, violently dislocates the radial head anteriorly.

The radioulnar joint and its ligamentous complex are at risk because of the ligamentous laxity and decreased contact area between the proximal radius and ulna created by the rotational attitude of the forearm. At mid-rotation, the short axis of the elliptical radial head is perpendicular to the ulna, causing the annular ligament and the dense anterior portion of the quadrate ligament to be relaxed. The contact area of the proximal radioulnar joint, owing to the shape of the radial head, is also decreased, further reducing the stability of the joint. The ulna, now the main weight-bearing member of the forearm, is loaded by a continued bending moment, causing tension on the anterior cortex and producing failure. The force at the site of failure is propagated in shear at approximately 45 degrees to the long axis of the ulna. This mechanism may produce plastic deformation with an anterior bow, a greenstick fracture, or an oblique fracture pattern, all of which are seen clinically. As the anterior bending movement continues, the vector of the biceps changes, acting as a tether and resisting any further advance of the proximal radius. The distal fragment of the ulna continues to advance, acting as a fulcrum against the radial shaft. The anteriorly directed force of the distal ulnar fragment, combined with the retrograde resistance of the biceps, may create a fracture of the radius, or a type IV Monteggia lesion.

Treatment

Although most treatment recommendations are based on the Bado classification, Ring and Waters based their treatment choices on the type of ulnar fracture rather than on the Bado type. *Plastic deformation* of the ulna is treated with reduction (with general anesthesia) of the ulnar bow to obtain stable reduction of the radioulnar joint. *Incomplete (greenstick or buckle) fractures* are treated with closed reduction and casting. They suggested that almost all Monteggia fractures in children (types I and III) are most stable when immobilized in 100 to 110 degrees of flexion and full supination. For a *nearly complete* greenstick fracture or one associated with a radial fracture (type IV), intramedullary Kirschner wire is considered for more stability. For *complete transverse* or *short oblique fractures,* which often are in bayonet apposition with malalignment or shortening, Kirschner wires are used to manipulate the proximal fragment into a reduced position and to hold the reduction. Long oblique or comminuted fractures, which may develop shortening and malalignment even with intramedullary fixation, are stabilized with a short plate and screw. Using this treatment protocol, Ring and Waters reported excellent results in all 28 patients treated within 24 hours of injury (Table 12-2). Two poor results occurred in patients who referred late with persistent radial head dislocations.

Type of Ulnar Injury	Treatment
Plastic deformation	Closed reduction of the ulnar bow and cast immobilization
Incomplete (greenstick or buckle) fracture	Closed reduction and cast immobilization
Complete transverse or short oblique fracture	Closed reduction and intramedullary Kirschner wire fixation
Long oblique or comminuted fracture	Open reduction and internal fixation with plate and screws

TABLE 12-2. TREATMENT OF MONTEGGIA FRACTURE - DISLOCATIONS IN CHILDREN ACCORDING TO ULNAR INJURY

Nonoperative Treatment

In all series (4,17,19,28,36,61,77,82,91,92,100,127), anterior Monteggia lesions in children have uniformly good results when treated by manipulative closed reduction.

AUTHORS' PREFERRED METHOD OF TREATMENT—NONOPERATIVE

Nonoperative treatment should generally involve three steps: correcting the ulnar deformity, providing a stable reduction of the radial head, and relieving the deforming muscle forces to prevent recurrent radial head dislocation and ulnar angulation.

Reduction of the Ulnar Fracture. The first step is to reestablish the length of the ulna by longitudinal traction and manual correction of any angular deformities present. The forearm is held in relaxed supination as longitudinal traction is applied, with manual pressure directed over the apex until the angular deformity is corrected clinically and radiographically (Fig. 12-14). With greenstick fractures, the plastic deformity must be corrected or the fracture completed to prevent recurrence of the angular deformity and, possibly, dislocation of the radial head (Fig. 12-15). Up to 10 degrees of angulation is acceptable in a complete fracture, providing a concentric radial head reduction is maintained (88). Angulation up to 25 degrees was noted in one series (77) to be compatible with full elbow and forearm motion. This degree of deformity usually remodels with time (89) (Fig. 12-16).

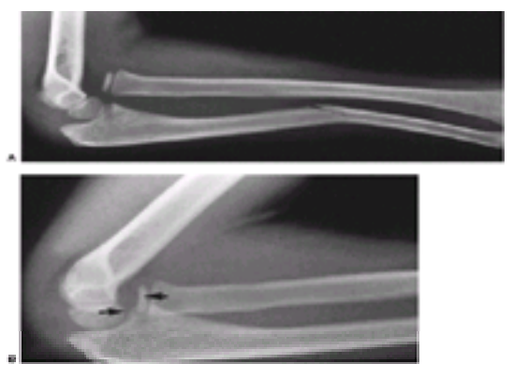

FIGURE 12-14. Closed reduction, type I lesion. **A:** Injury film of a typical type I lesion in a 7-year-old. **B:** The deformity of the ulna is corrected first, and then the elbow is hyperflexed. However, the radial head is still anteriorly subluxed *(arrows),* and the ulna still has some anterior plastic deformation

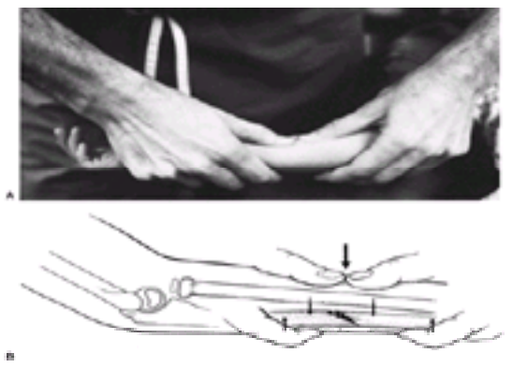

FIGURE 12-15. A and B: Correction of plastic deformation. Plastic deformation of the ulna must be corrected to prevent recurrence of the angular deformity. This allows reduction of the radial head and prevents its late subluxation. (From Wilkins KE, ed. *Operative management of upper extremity fractures in children*. Reduction of the Radial Head. Once ulnar length and alignment have been reestablished, the radial head can be relocated. This often is accomplished simply by flexing the elbow to 90 degrees or more, thus producing spontaneous reduction (Fig. 12-17). Occasionally, posteriorly directed pressure over the anterior aspect of the radial head is necessary to facilitate reduction of the radial head. Flexion of the elbow to 110 to 120 degrees stabilizes the reduction of the radial head. Once the radial head position is thought to be established, it should be scrutinized radiographically in numerous views to ensure a concentric reduction. With a type I fracture, the optimal radiographic view is a true lateral of the elbow with the forearm held in supination. The longitudinal axis of the radius should pass directly through the center of the capitellum (Fig. 12-18).

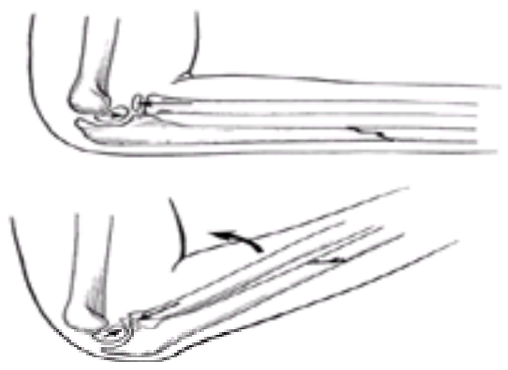

FIGURE 12-17. Reduction of the radial head. Flexing the elbow spontaneously reduces the radial head. Occasionally, manual pressure is required in combination with flexion.

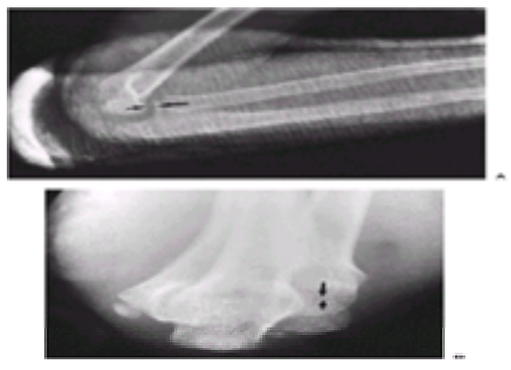

FIGURE 12-18. Once the reduction is complete, radiographs should be analyzed for reestablishment of the radiocapitellar line *(arrows)* and ulnar alignment on both the lateral **(A)** and Jones **(B)** views.

Alleviation of Deforming Forces. Once the concentric reduction of the radial head is confirmed, the elbow should be placed at approximately 110 to 120 degrees of flexion to alleviate the force of the biceps, which could redislocate the radial head (see Fig. 12-17). The forearm is placed in a position of mid-supination to neutral rotation to alleviate the forces of the supinator muscle and the anconeus, as well as the forearm flexors, which tend to produce radial angulation of the ulna.

Immobilization. Once the fracture is reduced and the neutralization position is established, a molded long arm splint or cast is applied (Fig. 12-19) to hold the elbow joint in the appropriate amount of flexion, usually 110 to 120 degrees. Once the cast is completed, careful radiographic assessment should establish the concentric reduction of the radial head with respect to the capitellum, as well as satisfactory alignment of the ulna.

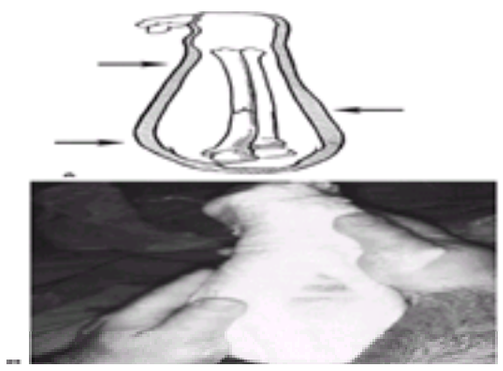

FIGURE 12-19. Postreduction immobilization. **A:** After reduction, the forearm is immobilized with three-point molding *(arrows)* to maintain ulnar alignment. **B:** The forearm component is incorporated into a long arm cast with the elbow flexed to 110 to 120 degrees of flexion.

After Care. The patient is followed at 7- to 10-day intervals to confirm continued satisfactory reduction by radiography. At 4 to 6 weeks after the initial reduction, if there is radiographic evidence of consolidation of the ulnar fracture and stability of the radial head, the long arm cast can be removed, with progressive guarded return to full activity.

Operative Treatment

Indications. Although uncommon, there are two indications for operative treatment of type I fracture–dislocations: failure of ulnar reduction and failure of radial head reduction.

Failure of Ulnar Reduction. If the ulnar fracture cannot be reduced or held in satisfactory alignment by closed treatment, operative intervention is indicated. The quality of the ulnar reduction affects the ability to reduce the radial head, which is of primary importance. Watson and Singer (125) reported median nerve entrapment that prevented ulnar reduction in a greenstick fracture in a 6-year-old with a type I Monteggia lesion. If the ulnar fracture can be reduced but not maintained because of the obliquity of the fracture, internal fixation combined with open or closed reduction may be necessary (36,77). Intramedullary fixation, rather than fixation with a plate, is standard in most series of Monteggia fracture–dislocations in children (8,28,36,58,61,77,82,119,127). This method of fixation may be accomplished percutaneously, using image intensification and flexible nails or Kirschner wires; this avoids the potential complications of open reduction and plate fixation (60,80,85,118,122).

Failure of Radial Head Reduction. The second indication is failure to reduce the radial head satisfactorily by closed means. This is more common in type III Monteggia lesions, but it can also occur in type I lesions. It results from the interposition of material in the joint. The pathologic description of the impeding structures usually includes interposition of torn fragments of the ruptured orbicular ligament and capsule or interposition of an intact orbicular ligament that has been pulled over the radial head (121,128). Interposed cartilaginous or osteochondral fractures may also be found in the radiocapitellar joint or radial notch in the ulna, preventing complete reduction of the radial head (76,121). Morris (71) described a patient in whom reduction of the radial head was obstructed by radial nerve entrapment between the radial head and ulna.

Surgical Approach. The most direct approach to the radiocapitellar joint is from the posterolateral aspect of the elbow. The interval between the anconeus and the extensor carpi ulnaris, using the distal portion of a Kocher “J” incision, provides sufficient visualization of the radial head and the interposed structures (41,110). This approach protects the posterior interosseous nerve, providing the forearm is positioned in pronation. A more extensile approach was described by Boyd (16). This exposure is begun by making an incision following the lateral border of the triceps posteriorly to the lateral condyle and extending it along the radial side of the ulna (Fig. 12-20). The incision is carried under the anconeus and extensor carpi ulnaris in a extraperiosteal manner, elevating the fibers of the supinator from the ulna. This carries the approach down to the interosseous membrane, allowing exposure of the radiocapitellar joint, excellent visualization of the orbicular ligament, access to the proximal fourth of the entire radius, and approach to the ulnar fracture, all through the same incision (16,17,102).

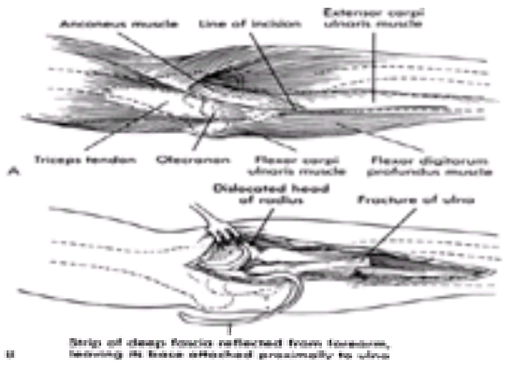

FIGURE 12-20. Surgical Approach. **A:** The incision is carried under the anconeus and extensor carpi ulnaris to expose the radial head and orbicular ligament. **B:** The incision can be extended distally to allow exposure of the ulnar fracture and proximally to facilitate harvesting of the tendinous strip for orbicular ligament reconstruction, if necessary. AUTHORS' PREFERRED METHOD OF TREATMENT—OPERATIVE

The importance of radial head reduction should be emphasized because failure of reduction affects the long-term outcome. Ulnar reduction directly affects the surgeon's ability to reduce the radial head. In children, the preferred treatment is by closed manipulative reduction. If, however, reduction of the radial head or ulnar fracture cannot be obtained or if the instability of the ulnar fracture threatens the radial reduction, operative treatment should be performed.

Surgical Approach. We prefer to use the Boyd approach because of its extensile nature (Fig. 12-20).

Treatment of the Annular Ligament. Once the reduction is obtained through this approach, we repair the annular ligament, providing it can be done simply. If the ligament has been pulled over the radial head, it should be incised, replaced in its normal location, and repaired. Immediate reconstruction of the annular ligament is usually unnecessary because the radial head usually maintains its stability once the ulnar fracture is reduced to a satisfactory position.

If the reduction is unstable, we repair or reconstruct the annular ligament, combining it with the use of a transcapitellar Steinmann pin if necessary. The details of annular ligament reconstruction are discussed later in the section on old, undetected Monteggia lesions.

Treatment of the Ulnar Fracture. The ulnar fracture usually is treated closed, provided a satisfactory alignment can be obtained. If the fracture pattern seems to be unstable on the initial films or at the initial reduction, or if the child is younger than 12 years of age, internal fixation using an intramedullary pinning technique is done (60,80,85,122). This often can be accomplished by using either a single pin of sufficient size or multiple small pins, nesting them within the medullary canal to provide stability (Fig. 12-21). This technique is minimally invasive and provides adequate stability in most fractures. It also allows easy retrieval of the instrumentation and has an overall low complication rate (118). In our experience, more aggressive fixation has been unnecessary in children, but compression plating could be used if more rigid fixation were indicated or in an adolescent with a comminuted fracture.

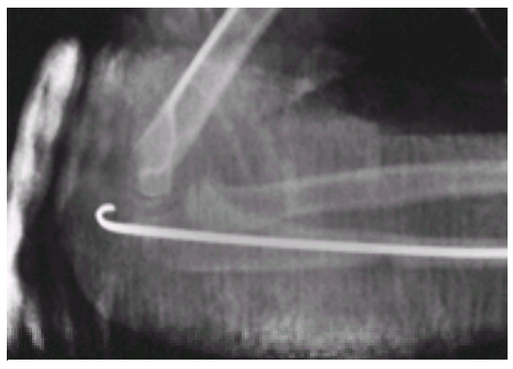

FIGURE 12-21. Stabilization of the ulna. Unstable fractures or those in children 12 years of age or older can be immobilized using a percutaneous pinning technique. (From Wilkins KE, ed. *Operative management of upper extremity fractures in children.* American Academy of Orthopaedic Surgeons Monograph Series. Rosemont, IL: American Academy of Orthopaedic Surgeons, 1994:49; with permission.)

After Care (Same as Closed Reduction). Once reduction is obtained, a long arm cast is applied with the elbow flexed 90 to 100 degrees and the forearm in neutral position.

Type II Lesions

Incidence

Posterior Monteggia fracture–dislocations are uncommon, accounting for 6% in most series of Monteggia lesions in children (59). When it occurs during childhood, it usually is in older patients (approximately 13 years) (81) who have sustained significant trauma (32,91,92). Type II Monteggia lesions are more common than reported. They often go unrecognized, being classified as type III lesions with a posterolateral radial head dislocation.

Clinical Findings

As with type I Monteggia lesions, the elbow region is swollen but exhibits posterior angulation of the proximal forearm and a marked prominence in the area posterolateral to the normal location of the radial head. Examination of the upper extremities should continue in areas remote from the elbow because of the high incidence of associated fractures (57,81).

Radiographic Evaluation

Standard radiographic views of the forearm demonstrate the pertinent features for classifying this fracture. The typical finding is a proximal metaphyseal fracture of the ulna with possible extension into the olecranon (32,77,116) (Fig. 12-22). Midshaft fractures also occur, presenting with an oblique fracture pattern (6,32,77). The radial head is dislocated posteriorly or posterolaterally (8) and should be carefully examined for other associated injuries. Accompanying fractures of the anterior margin of the radial head have been noted in adults (32,81) but not in children.

FIGURE 12-22. Type II fracture-dislocation. The typical radiographic findings include **(A)** a posterior dislocation of the radial head *(arrows)* and **(B)** a proximal metaphyseal fracture, which may extend into the olecranon *(arrows).* In addition to being posterior, the head may be lateral as well *(arrows)* **(C).** (Courtesy of Dr. Gail S. Chorney, MD, Hospital for Joint Diseases, New York, New York.)

Mechanism of Injury

The cause of the type II Monteggia lesion is subject to debate. Bado thought the lesion was caused by direct force and sudden rotation and supination (8). Penrose analyzed a series of seven fractures, all in adults (84), and noted that a proximal ulnar fracture was the typical pattern. He postulated that the injury occurred by longitudinal loading rather than direct trauma (102). Olney and Menelaus (77) reported four type II lesions in their series of children's Monteggia fractures. Three of these patients demonstrated a proximal ulnar fracture and one an oblique midshaft fracture pattern, suggesting possibly two different mechanisms of injury.

The mechanism proposed and experimentally demonstrated by Penrose (84) shows the type II lesion occurring when the forearm is suddenly loaded in a longitudinal direction with the elbow bent to 60 degrees of flexion. He showed that the type II lesion occurred consistently if the anterior cortex of the ulna was weakened; otherwise, a posterior elbow dislocation was produced (Fig. 12-23). The difference in bony integrity of the ulna suggested a reason for the high incidence of type II Monteggia fractures in older adults and its rarity in children. Penrose further noted that the rotational position of the forearm did not seem to affect the type of fracture produced.

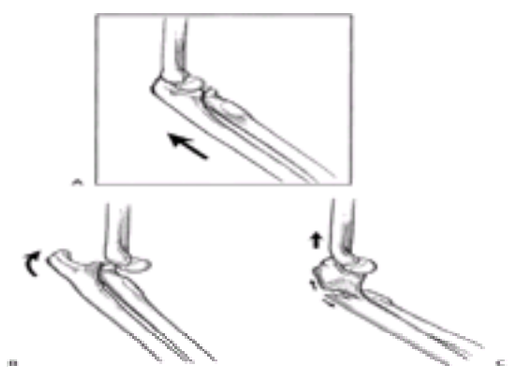

FIGURE 12-23. Mechanism of injury for type II fracture-dislocation. **A:** The elbow is flexed approximately 60 degrees; a force is applied longitudinally, parallel to the long axis of the forearm. **B:** A posterior elbow dislocation may occur. **C:** If the integrity of the anterior cortex of the ulna is compromised, a type II fracture-dislocation occurs.

Haddad et al. (42) described type II Monteggia injuries caused by low-velocity injuries in six adults, five of whom were on long-term corticosteroid therapy. They suggested that this supports the theory that the type II (posterior) Monteggia injury is a variant of posterior elbow dislocation, in that it occurs when the ulna is weaker than the ligaments surrounding the elbow joint, resulting in an ulnar fracture before the ligament disruption associated with dislocation occurs.

Treatment

Nonoperative
