As with type I injuries, type II lesions usually have a satisfactory result after closed reduction (61,77,82,89,127). The ulnar fracture is reduced by longitudinal traction in line with the long axis of the forearm while the elbow is held at 60 degrees of flexion. The radial head may reduce spontaneously or may require gentle, anteriorly directed pressure applied to its posterior aspect. The elbow is extended once the radial head is reduced and is immobilized in that position to stabilize the radial head and allow molding posteriorly to maintain the ulnar reduction (28,56,82,123) (Fig. 12-24).

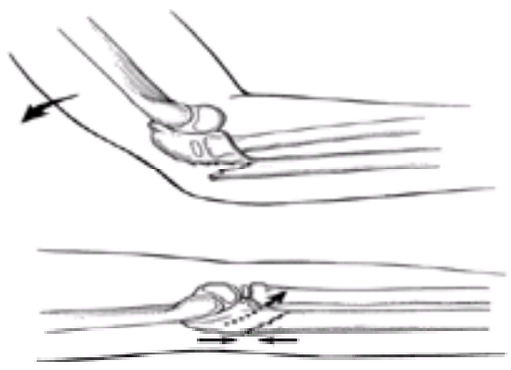

FIGURE 12-24. Reduction of type II lesion. The elbow is held at 60 degrees of flexion; traction is applied in line with the forearm and the elbow is extended. It may be necessary to apply pressure over the radial head to complete the reduction.

Operative

Because of the rarity of the lesion, there are no established indications for operative treatment. Treatment goals are stable concentric reduction of the radial head and alignment of the ulnar fracture. The radial head should be reduced by open technique if there is interposed tissue or if it is accompanied by a fractured capitellum or radial head. The ulnar fracture is exposed along its subcutaneous border if necessary and fixed internally. Fixation can be accomplished by plating or intramedullary fixation. Because of children's ability to heal rapidly, intramedullary fixation is adequate and sometimes can be done percutaneously after a closed reduction of the ulna (80,85).

AUTHORS' PREFERRED METHOD OF TREATMENT

The goals of treatment in the type II Monteggia lesion are to obtain a stable concentric reduction of the radial head, with adequate alignment of the ulna.

First, ulnar length is reestablished by applying longitudinal traction and straightening the angular deformity. The radial head may reduce spontaneously or with gentle, anteriorly directed force directly over the radial head. Once reduced, the position of the head can be stabilized by holding the elbow in extension. The alignment of the ulnar fracture can be maintained by applying a cast with the elbow in extension or by using percutaneous intramedullary fixation. If intramedullary pinning is used, the elbow may be flexed to 80 degrees and a cast applied. Radiographs should be taken after cast application and approximately every 7 to 10 days to confirm continued reduction of the radial head.

The Boyd approach can be used to obtain reduction of the radial head if it cannot be obtained through closed manipulation. Management of the annular ligament is the same as described previously in type I Monteggia lesions.

The cast, either in full extension or flexed to 80 degrees at the elbow, is maintained for 3 to 4 weeks, then changed to a removable splint. This allows early intermittent range of motion in a protected manner for 3 to 4 more weeks. At 6 to 8 weeks after injury, the patient may be released to full activities. This protocol may avoid the necessity for formal physical therapy (82).

Type III Lesions

Clinical Findings

Lateral swelling and varus deformity of the elbow and significant limitation of motion, especially supination, are the hallmarks of lateral Monteggia fracture–dislocations, or type III Monteggia lesions.

Incidence

Type III lesions are common in children, occurring second in frequency to anterior Monteggia fracture–dislocations (8,72,77,82,127). Injuries to the radial nerve, particularly the posterior interosseous branch, occur frequently with this lesion (11,105). Open reduction of the radial head often is necessary because of interposition of soft tissue between it and the ulna or capitellum (11,46,114,128,129).

Radiographic Evaluation

The radial head may be displaced laterally or anterolaterally (80,82). The ulnar fracture often is in the metaphyseal region (8,11,46,82,128,129), but it can occur more distally (77,127,128). Radial angulation at the fracture site is common to all lesions, regardless of the level. Radiographs of the entire forearm should be obtained because of the association of distal radial and ulnar fractures with this elbow injury complex (115).

Mechanism of Injury

Wright (129) studied fractures of the proximal ulna with lateral and anterolateral dislocations of the radial head and concluded that the mechanism of injury was varus stress at the level of the elbow, in combination with an outstretched hand planted firmly against a fixed surface (Fig. 12-25). This usually produces a greenstick ulnar fracture with tension failure radially and compression medially. The radial head dislocates laterally, rupturing the annular ligament. Hume (46) suggested that the injury may be the result of hyperextension of the elbow combined with pronation of the forearm. Other authors confirmed the mechanism of varus force at the elbow as the cause of these injuries (8,28,72,82,115). The direction of the radial head dislocation is probably determined by the rotation and angulation force applied simultaneously with the varus moment at the elbow (72).

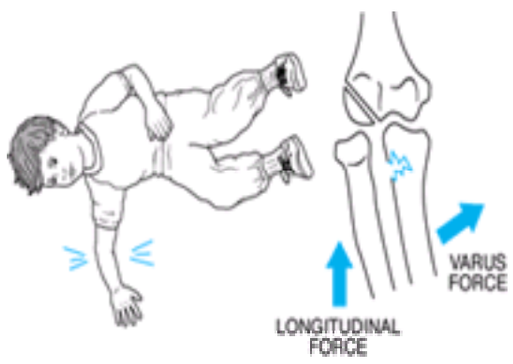

FIGURE 12-25. Mechanism of injury for type III lesions. A forced varus stress causes a greenstick fracture of the proximal ulna and a true lateral or anterolateral radial head dislocation.

Treatment

Nonoperative

Nonoperative treatment is effective in nearly all patients (8,11,28,46,61,72,77,82,115,127,129), although the rate of operative treatment has been reported to be as high as 12% (77).

Focus on Ulnar Reduction. Reduction is carried out by reversing the mechanism of injury (28,72,82,116). The elbow is held in extension with longitudinal traction. Valgus stress is placed on the ulna at the site of the fracture, producing clinical realignment. The radial head may spontaneously reduce or need assistance with gentle pressure applied laterally (Fig. 12-26). Reduction is sometimes heralded by a palpable click (116).

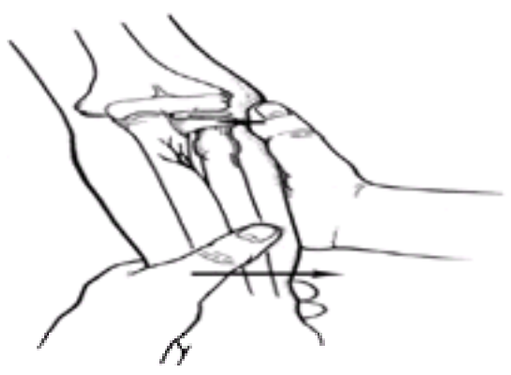

FIGURE 12-26. Reduction of type III lesion. Valgus stress is placed on the ulna at the fracture site *(arrow),* producing clinical realignment. The radial head may

spontaneously reduce or need an assistive push.

Confirm Radial Head Reduction. Radiographs are obtained in the standard views (69). The position of the radial head is important. Any malalignment in either view implies the possibility of interposed tissue or persistent malalignment of the ulna. The angular alignment of the ulna must be as straight as possible to allow and maintain reduction of the radial head (36).

Maintenance of Reduction. Degree of Flexion. Reduction is maintained by a long arm cast with the elbow in flexion. The degree of flexion varies depending on the direction of the radial head dislocation. When the radius is in a straight lateral or anterolateral position, flexion to 110 to 120 degrees improves stability (28,72,89,127). If there is a posterolateral component to the dislocation, a position of only 70 to 80 degrees of flexion has been recommended (116).

Forearm Rotation. Forearm rotation usually is in supination, which tightens the interosseous membrane and further stabilizes the reduction (8,28,72,127). Over the years, one researcher has changed the suggested position of immobilization from pronation (115) to semisupination (116). Ramsey and Pedersen (89) recommended neutral as the best position of rotation to avoid loss of motion; their patients demonstrated no loss of reduction using that position.

Operative

Surgical intervention has two goals: reduction and stabilization of the radial head and the ulnar fracture.

Radial Head Reduction. The radial head is reduced through a Boyd approach (16,128). This allows removal of the interposed tissues (76,121,128) and repair or reconstruction of the annular ligament if necessary (12,20,36,38,102,114) (Fig. 12-27). The surgical technique is essentially the same as previously described for the type I Monteggia fracture–dislocation.

FIGURE 12-27. Irreducible type III lesion. **A:** Injury films showing typical greenstick olecranon fracture and lateral dislocation of a type III Monteggia lesion. **B:** After manipulation and correction of the ulnar deformity, the radial head still was not reduced. **C:** Open reduction was performed to extract the interposed torn orbicular ligament. (From Wilkins KE, ed. *Operative management of upper extremity fractures in children.* American Academy of Orthopaedic Surgeons Monograph Series. Rosemont, IL: American Academy of Orthopaedic Surgeons, 1994:50; with permission.)

Ulnar Stabilization. Stabilization of the ulna is necessary to prevent recurrent lateral dislocation of the radial head. Varus alignment or radial bow, particularly with oblique fractures, may lead to subluxation of the radius (36,77) (Fig. 12-28). Fixation with plates (36) and Kirschner wires (6) has been performed with satisfactory results. Up to 25 degrees of varus angulation is consistent with normal alignment and function (77), and any residual deformity decreases with time (89).

FIGURE 12-28. Radial bow of the ulna. **A:** Anteroposterior views of both elbows showing residual radial bow of the proximal ulna after an incompletely reduced Monteggia type III lesion. **B:** This bow has produced a symptomatic lateral subluxation of the radial head. (From Wilkins KE, ed. *Operative management of upper extremity fractures in children.* American Academy of Orthopaedic Surgeons Monograph Series. Rosemont, IL: American Academy of Orthopaedic Surgeons, 1994:51; with permission.)

AUTHORS' PREFERRED METHOD OF TREATMENT

We concur with Cunningham (25), who believed that reduction of the dislocated radial head is an important part of the management of the Monteggia fracture–dislocation. Our method of treatment is aimed primarily at obtaining and maintaining reduction of the radial head, either by open or closed technique. The type of treatment of the ulnar fracture we choose is determined by its effect on the primary goal, radial head reduction.

Nonoperative

The results of nonoperative reduction of a type III lesion are shown in Fig. 12-29.

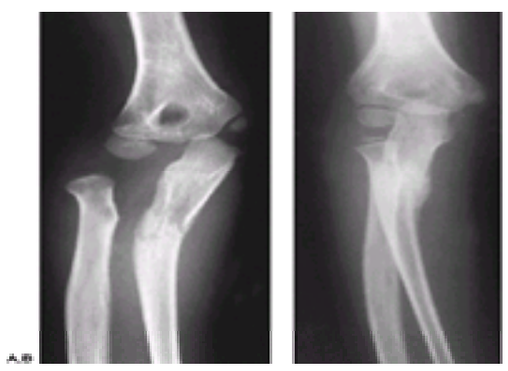

FIGURE 12-29. Type III lesion, nonoperative treatment. **A:** Injury film showing lateral dislocation of the radial head. **B:** Radiograph taken after closed reduction showing reduction of the radial head and healing of the ulna by nonoperative methods.

Reduction Technique. We hold the elbow in extension to control the proximal fragment by locking the olecranon into the humerus. We then can apply longitudinal traction in line with the forearm with valgus stress applied at the ulnar fracture site (Fig. 12-26). This usually allows the radial head to become reapposed to the capitellum, but pressure laterally over the prominence of the radial head may be necessary.

Radiographic Evaluation. Radiographs are taken in the AP and lateral planes to confirm the reduction of the radial head and assess the ulnar alignment. Up to 10 degrees of ulnar angulation is acceptable in younger children, provided the radial head reduction is concentric and stable.

Immobilization. A long arm cast is applied in two portions. First, a Muenster type of short arm cast is applied with the forearm in neutral rotation. This allows careful molding of the cast to maintain the alignment of the ulnar fracture. The elbow is then flexed to approximately 110 degrees in lateral or anterolateral dislocations, and the cast is completed to the axilla. In younger children, where the cast may be hard to mold, a loop sling is incorporated into the cast to prevent it from migrating distally. Although we have no experience with the method, treatment of a posterolateral dislocation with an extended elbow cast with valgus molding seems logical.

After Care. Radiographs should be taken in the completed cast to confirm continued reduction of the radial head and satisfactory ulnar alignment. The cast is left in place for 3 to 4 weeks, depending on the age of the child. It is replaced by a removable splint for an additional 3 to 4 weeks while early ranging of the elbow has begun. Restoration of rotation is particularly important at this time. Before application of the splint 3 to 4 weeks postinjury and at discontinuation at 6 to 8 weeks postfracture, radiographs are taken to assess the reduction. At 6 to 8 weeks after injury, sufficient healing has occurred to allow gradual return to full activities.

Operative

Similar to our goals for closed reduction, our operative indications are failure to obtain and maintain reduction of the radial head and alignment of the ulnar fracture.

Reducing the Radial Head. Failed closed reduction of the radial head implies interposition of soft tissue, which we remove through a Boyd approach (Fig. 12-20). If possible, the annular ligament is repaired, but we find that formal reconstruction usually is unnecessary if the radiocapitellar relation is restored and stable. If stability is in question, we reconstruct the annular ligament as described for the type I Monteggia lesion.

Ulnar Realignment. Before a formal annular ligament reconstruction, ulnar alignment must be evaluated critically. If inadequate, the ulnar alignment may prevent relocation of the radial head. The ulnar fracture can usually be reduced closed, but open realignment may be necessary due to interposed tissue. Once reduced, the ulna can be maintained by the insertion of intramedullary pins, either in a retrograde fashion or percutaneously. The ends of the pins can be buried subcutaneously and removed later with minimal surgery.

After Care. Postoperative care is the same as for a fracture treated nonoperatively, with emphasis on early motion.

Type IV Lesions

Clinical Findings

The appearance of the patient and limb with a type IV lesion is similar to that of the type I lesion. More swelling and pain would be expected because of the magnitude of force required to create this complex injury. Particular attention should be given to the neurovascular status of the limb, anticipating the possible increased risk for a compartment syndrome. Although this injury is uncommon in general and rare in children, the radiocapitellar joint should be examined in all midshaft forearm fractures to avoid missing this injury complex (Fig. 12-30). Failure to recognize the radial head dislocation is the major complication of this fracture (10).

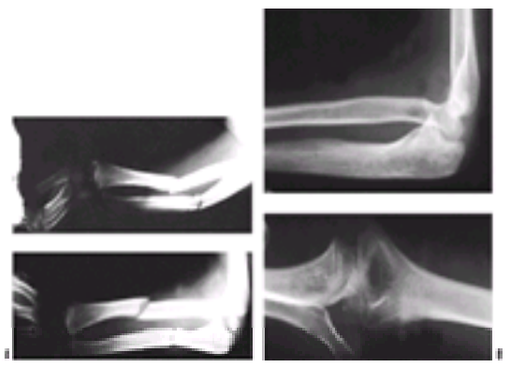

FIGURE 12-30. Type IV Monteggia lesion. **A** Anterior dislocation of the head of the radius with fracture of the upper third of the radial shaft with the ulna angulated anteriorly. The dislocation of the radial head was not recognized. **B** Five years later, the radial head was still dislocated, misshapen, and prominent. A full range of motion was present, with the exception of a loss of 10 degrees of full supination. The patient had no pain, but generalized weakness was noted in this extremity, especially in throwing motions. (Courtesy of Fred C. Tucker, MD.)

Radiographic Evaluation

The pattern of radial head dislocation is similar to that in a type I Monteggia lesion—that is, it is directed anteriorly (Fig. 12-31). The radial and ulnar fractures usually are seen at any level in the middle third (30), with the radial fracture usually distal to the ulnar injury. They may be complete or greenstick.

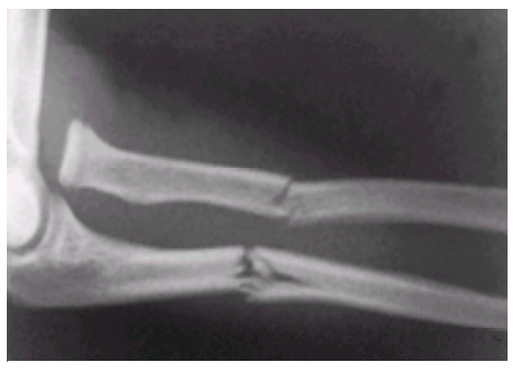

FIGURE 12-31. Type IV lesion. There is an anterior dislocation of the radial head. The radius and ulna fractures are usually in the middle third of the shaft, with the radial fracture distal to the ulnar fracture.

Mechanism of Injury

Bado proposed that the type IV lesion is caused by hyperpronation (6). Two case reports discuss the mechanism of injury. One implies that the injury is due to the hyperpronation mechanism of Evans (39), and the other demonstrates a type IV lesion caused by a direct blow (96). Olney and Menelaus (77) report a single type IV lesion in their series but do not discuss the mechanism. Our preferred mechanism for this type of lesion was described in the section on type I lesions.

Treatment

This complex lesion has been treated by both closed (77) and open (8) techniques. Two clinicians (39,96) treated the radial and ulnar fractures with percutaneous intramedullary fixation using flexible pins. This allowed closed reduction of the radial head. One of the authors of this chapter has reported on four type IV Monteggia lesions in children, treated by both operative and nonoperative techniques. He recommends plating of the radius in older children.

AUTHORS' PREFERRED METHOD OF TREATMENT

The goals of treatment for a type IV Monteggia lesion are similar to those of the other Bado types. The presence of the free-floating proximal radial fragment hampers the ability to reduce the radial head. Stabilization of the radial fracture converts the type IV lesion to a type I lesion, greatly facilitating treatment. The goals for treatment of a type IV lesion are, therefore, stabilization of the radial fracture, restoration of the ulnar alignment, and concentric reduction of the radial head.

Nonoperative. Closed reduction should be attempted initially, especially if the radial and ulnar fractures have greenstick patterns. Use of the image intensifier facilitates treatment by allowing immediate confirmation of reduction of the elements of the injury complex, especially the radial head. Closed treatment of unstable lesions may be attempted, but it is our experience that multiple remanipulations are required to obtain a satisfactory outcome (Fig. 12-32).

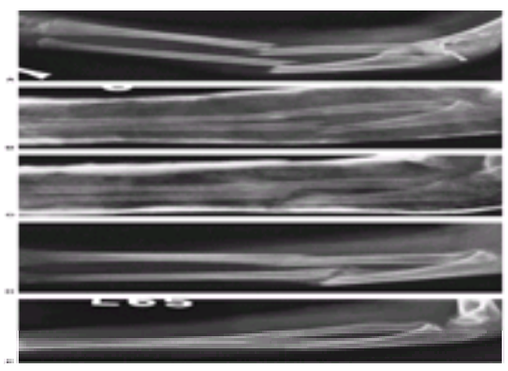

FIGURE 12-32. Type IV closed reduction. **A:** Injury film in a 7-year-old with fractures of the shafts of the radius and ulna and associated dislocation of the radial head. **B:** Initial closed reduction with some residual posterior angulation. **C:** At 3 weeks postinjury, the forearm was remanipulated to correct the posterior angulation. **D:** Appearance 8 weeks postreduction, still with slight posterior angulation. **E:** Six months later, there has been considerable remodeling. (From Wilkins KE, ed. *Operative management of upper extremity fractures in children.* American Academy of Orthopaedic Surgeons Monograph Series. Rosemont, IL: American Academy of Orthopaedic Surgeons, 1994:51-52; with permission.)

Operative. If the fractures are unstable, we reduce the fractures closed and fix them percutaneously with intramedullary pins. In children 12 years of age or older, plating the radius through Henry's extensile approach (43) provides more rigid stabilization (Fig. 12-33). Once stability is achieved, a closed reduction of the radial head is attempted. This is usually successful, but any intraarticular obstruction can be removed using the Boyd approach, which is more direct than extending Henry's approach.

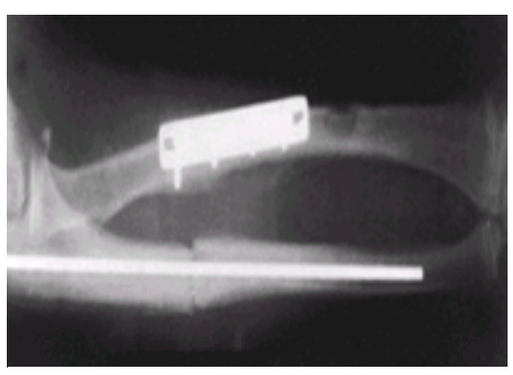

FIGURE 12-33. Operative treatment, type IV lesion. The initial goal is to stabilize the radius. In older children, a plate may be indicated. Intramedullary pinning usually is adequate. (See Fig. 12-31 for injury film.)

After Care. The elbow is immobilized for 4 weeks in 110 to 120 degrees of flexion with the forearm in neutral rotation. The cast is reduced to a short arm cast for an additional 4 weeks while beginning early range of motion at the elbow and forearm. Forearm rotation, within the limits of cast restrictions, is specifically encouraged to avoid permanent loss of rotation. At 8 weeks postinjury, there is gradual return to full activities.

Bado's Equivalent Lesions

Clinical Findings

Clinical findings are similar to those for the corresponding Bado lesion, with the common triad of pain, swelling, and deformity.

Radiographic Evaluation

As with the Bado types, careful radiographic study should be made with at least two orthogonal views. Special views such as obliques should be obtained to delineate the associated injuries (e.g., radial head or neck fractures, lateral humeral condyle fractures) clearly to allow adequate pretreatment planning.

Mechanism of Injury

The mechanism of injury by which the fracture occurs helps define its equivalent type and is discussed in the sections on the relevant Bado type.

Treatment

As with the other Bado types, treatment addresses two general components of the lesion: ulnar fracture and associated injury.

Ulnar Fracture

This fracture is treated as for the other Bado types. The method is dictated by the fracture pattern and location and its stability after reduction.

Associated Injury

These associated fractures and dislocations are evaluated and treated using principles based on the particular injury. They are discussed thoroughly in other sections of this chapter.

Complications (All Lesions)

Old Undetected Fracture–Dislocations

An undetected dislocation of the radial head is uncommon (28,36,100,113). Isolated radial head dislocations with no apparent lesion of the ulna caused by remote trauma have been mistaken for radial head dislocations of congenital etiology (29,66). Subsequent authors have refuted the existence of a unilateral congenital dislocation of the radial head (64). Observations of the shape of the ulna in patients with an isolated dislocation of the radial head have indicated the existence of persistent plastic deformation of the ulna associated with this radial lesion (63) (Fig. 12-34 and Fig. 12-35). The diagnosis of a dislocated radial head has been aided by the acceptance of the veracity of the radiocapitellar line (69,100,109) (Fig. 12-9).

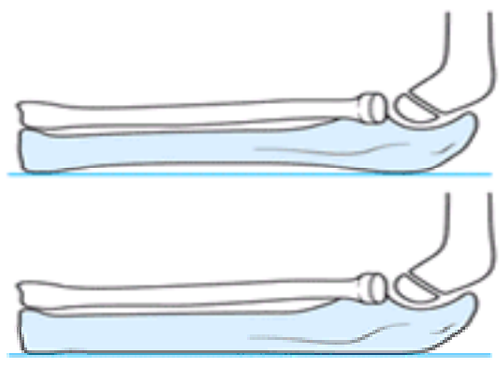

FIGURE 12-34. The ulnar bow line. This line, drawn between the distal ulna and the olecranon, defines the ulna bow. The “ulnar bow sign” is defined as deviation of the ulnar border from the reference line of more than 1 mm. (From Lincoln TL, Mubarak SJ. “Isolated” traumatic radial head dislocation. *J Pediatr Orthop* 1994;14:455; with permission.)

Note anterior bow of the ulna *(black arrows)* and loss of the radiocapitellar relation *(open arrow).* **B:** Film at time of diagnosis. Note persistent ulnar bow and overgrowth of radius. (Courtesy of David Mann, MD, VW Hospital and Clinics, Madison, Wisconsin.)

Natural History

The ability to diagnose the dislocated radial head at the time of injury has helped prevent the difficult problem of persistent radial head dislocation. When a previously undetected dislocation is encountered, the natural history of the untreated lesion should be considered in determining the method of treatment. The belief that many children with persistent dislocation of the radial head do well has been supported by several investigators (73,87,98,107). Fahey (34) believed that although in the short term persistent dislocations do well, they present problems later. At that time, the problem can be treated by resection of the radial head.

Other reports, however, suggested that the natural history of persistent dislocation is not benign and is associated with restricted motion, deformity, functional impairment (weakness, instability), pain, degenerative arthritis, and late neuropathy (5,13,14,22,38,40,46,47,50,52,63). Kalamchi (50) reported pain, instability, and restricted motion, especially loss of pronation and supination. He also noted that children have a valgus deformity and a prominence on the anterior aspect of the elbow. Tardy nerve palsies have been reported as developing subsequent to an unrecognized Monteggia lesion of long-standing duration (1,5,45,62).

Indications for Treatment

As experience has developed with reconstructive relocation of the radial head in Monteggia lesions, the indications have become clear. Blount (15), in his classic monograph, and Fowles et al. (36), in their analysis, suggested that reconstruction provides the best results in patients who have had a dislocation for 3 or 6 months or less, respectively. Fowles et al., however, reported successful relocations up to 3 years after injury, and Freedman et al. (38) up to 6 years after injury. Throughout the literature, the appropriate age seems to be younger than 10 years (108). Hirayama et al. (44) suggested that the procedure not be performed if there is significant deformity of the radial head, flattening of the capitellum, or valgus deformity of the neck of the radius.

In a more recent report, however, Seel and Peterson (99) suggested that the age of the patient and the duration of the dislocation are unimportant. Their criteria for surgical repair were (a) normal concave radial head articular surface and (b) normal shape and contour of the ulna and radius (deformity of either was corrected by osteotomy). They treated seven patients (all girls) ranging in age from 5 to 13 years for chronic dislocations that had been present from 3 months to 7 years. All seven were fully active with no elbow pain or instability at an average of 4 years after surgery.

Although they recommended surgical treatment of chronic Monteggia lesions in children because of the long-term sequelae, Rodgers et al. (97) cautioned that the results of reconstructive procedures are unpredictable and associated with a number of serious complications. Fourteen complications occurred in their seven patients (11 months to 12 years of age) treated from 5 weeks to 39 months after injury, including malunion of the ulnar shaft, residual radiocapitellar subluxation, radiocapitellar dislocation, transient ulnar nerve palsy, partial laceration of the radial nerve, loss of fixation, nonunion of the ulnar osteotomy, compartment syndrome, conversion reaction, and possible fibrous synostosis.

Historical Development of Surgical Repair

The technique for delayed reduction of the radial head in a Monteggia fracture is attributed to Bell-Tawse (12). He used the surgical approach described by Boyd (16). Other surgical approaches have been developed subsequent to Boyd, but are not as adaptable to annular ligament reconstruction (41,110).

Annular Ligament Reconstruction

Once the capsule has been debrided from the joint, consideration is given as to whether the annular ligament needs to be reconstructed. Kalamchi (50) restored stability after open reduction and osteotomy by reefing the remnants of the annular ligament.

Various authors have considered it necessary to reconstruct the annular ligament, probably because of insufficiency of the natural structure. Although Bell-Tawse (12) used a strip of triceps tendon, other authors have tried other material. Corbett (24) reported stabilizing an open reduction of the radial head using the lacertus fibrosus through an anterior approach. Speed and Boyd (102) used a strip of the forearm fascia to establish stability of the radial neck. Watson-Jones (124) used a strip of palmaris longus tendon. May and Mauck (65) used chromic ligature. Bell-Tawse (12) used the central portion of the triceps tendon passed through a drill hole and around the radial neck to stabilize the reduction. This was aided by immobilizing the elbow in a long arm cast in extension. Bucknill (20) and Lloyd-Roberts (64) used the Bell-Tawse procedure but modified it by changing the site of procurement of the ligament to the lateral portion of the triceps tendon. They found that immobilizing the elbow in flexion and using a transcapitellar pin to establish stability worked well, avoiding the inconvenience of a long arm cast in extension. Hurst and Dubrow (47) used the central portion of the triceps tendon. Distally, their dissection of periosteum was carried along the ulna to the level of the radial neck, providing more stable fixation than the technique of stopping at the olecranon described by Bell-Tawse. Further, a periosteal tunnel was used rather than a drill hole to establish fixation for the tendinous strip of the ulna. Thompson and Lipscomb (117) have used a fascia lata graft passed through a drill hole in the ulna to stabilize an unstable radial head.

Osteotomy

In a Monteggia lesion with a mildly displaced ulnar fracture but persistent dislocation of the radial head, an osteotomy of the ulna usually is not indicated (64). However, various types of osteotomies have been used to facilitate reduction of the radial head, as well as to prevent recurrent subluxation after annular ligament reconstruction (Fig. 12-36). Kalamchi (50) reported using a drill osteotomy and allowing it to float, thus facilitating reduction of the radial head. He stated that this afforded the advantages of minimal periosteal stripping, allowing the osteotomy to heal rapidly. Hirayama et al. (44) and Mehta (67,68) used ulnar osteotomies to facilitate and stabilize the reduction of the radial head. Hirayama did a 1-cm distraction osteotomy approximately 5 cm distal to the tip of the olecranon. Internal fixation in the form of plate and screws was used, but there were significant complications with loosening and plate breakage. Mehta used an osteotomy of the proximal ulna in which a bone graft was used to stabilize the osteotomy. In neither series was an annular ligament repair performed. Oner and Diepstraten (78) suggested avoiding radial osteotomies because of the restriction of motion thought to occur owing to adhesions, as well as ulnar osteotomies because of the high rate of complications. Although they did not perform routine ulnar osteotomy, they pointed out that in type III lesions in which osteotomies were not performed, there was recurrent subluxation because of the persistent ulnar angulation (Fig. 12-28). Freedman et al. (38) reduced a delayed type I Monteggia lesion using open reduction of the head without annular ligament reconstruction, ulnar osteotomy combined with radial shortening, and deepening of the radial notch of the ulna.

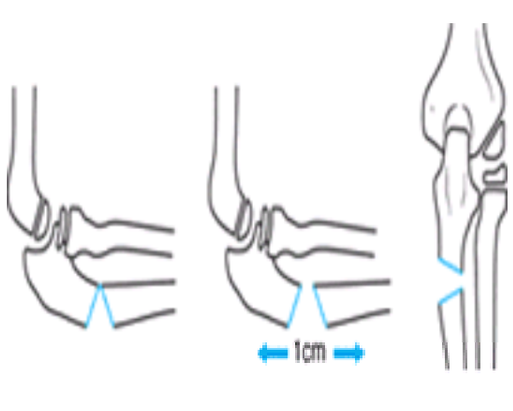

FIGURE 12-36. Ulnar osteotomies. **Left** Floating open osteotomy without fixation or bone graft. **Center** Hirayama distraction osteotomy, grafted and fixed with a plate and screws. Mehta's osteotomy is similar but is held with a bone graft only. **Right** Valgus osteotomy for a type III lesion: floating osteotomy with bone graft. This osteotomy may be easily stabilized with an intramedullary pin.

Inoue and Shionoya (48) compared the results of simple corrective ulnar osteotomy in six patients with those of posterior angular (overcorrected) osteotomy in six others and found that better clinical outcomes were obtained with the angular osteotomy. Tajima and Yoshizu (112), in a series of 23 neglected Monteggia fractures, found that the best results were obtained by opening wedge osteotomy of the proximal ulna without ligament reconstruction.

AUTHORS' PREFERRED METHOD OF TREATMENT

Indications. If a patient younger than 12 years of age presents with delayed diagnosis of a Monteggia lesion, the radial head should be replaced in its appropriate relation with the capitellum. The child does well in the short term, but problems develop later. As the child matures to adulthood, there is a significant chance of progressive instability, pain, weakness of the forearm, and restriction of motion. There is also a risk of tardy radial nerve or ulnar nerve palsies. There should be no radiocapitellar incongruity due to radial head deformity after reduction.

Surgical Approach. The skin incision begins approximately halfway between the central portion of the triceps and the lateral border, beginning proximal enough to obtain 6 to 7 cm of tendinous strip. The incision continues distally along the lateral border of the ulna just past the level of the radial neck. Dissection is carried deep, lifting the anconeus off the ulna sharply in an extraperiosteal manner. The capsule is entered and any interposed capsule, old ligament, or osteochondral fragment is removed from the joint. The radial notch of the ulna is also cleaned to allow the radial head to fall into place once reduced. Capsular adhesions are removed from the radial head to allow it to fall away from the anterior capsule.

Radial Head Reduction. Radial head reduction is then attempted. If it is accomplished, it is scrutinized for congruity between the radial head and the capitellum. If this is satisfactory, a ligamentous reconstruction can be performed. If the radius cannot be reduced, the ulna is osteotomized. The osteotomy is formed at the site of maximum deformity through a small incision, leaving the periosteum as undisturbed as possible. If reduction of the radial head still cannot be achieved, radial shortening can be considered, but we have no experience with this procedure.

After ligament reconstruction, the ulnar osteotomy can be stabilized or left to float. Stabilization can be performed by several techniques, including plating, bone graft, or intramedullary fixation. Percutaneous intramedullary fixation with flexible Kirschner wires allows self-adjustment but adds stability to the entire reconstruction; it is our preferred treatment.

Annular Ligament Reconstruction. At the time of exposure, the triceps aponeurosis and tendon are examined for their thickest portion. A 1- ´ 6-cm strip is developed and carried distally, carefully elevating the periosteum from the proximal ulna down to the level of the radial neck. In the Bell-Hawse technique, a drill hole slightly larger than the strip of tendon is made in the ulna. The strip of tendon is then passed around the radial neck and through the drill hole in the ulna. The ligament is then brought back and sutured to itself (Fig. 12-37).

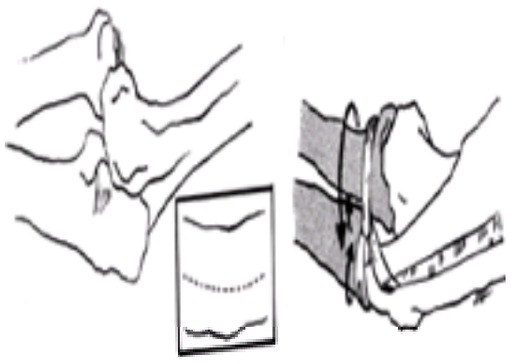

FIGURE 12-37. The central slip of the triceps is used to reconstruct an annular ligament. (Redrawn from Bell-Tawse AJS. The treatment of malunited anterior Monteggia fractures in children. *J Bone Joint Surg Br* 1965;47:718; with permission.)

More recently, Seel and Peterson (99) described the use of two holes drilled in the proximal ulna. The holes are placed at the original attachments of the annular ligament and thereby allow repair of the annular ligament (frequently avulsed from one attachment and trapped within the joint) or reconstruction of the annular ligament with whatever tissue or material is desired (they suggested triceps tendon). It secures the radial head in its normal position from any dislocated positions and allows osteotomy for correction of any accompanying deformity of the ulna or radius. Seel and Peterson noted that the Bell-Tawse procedure tends to pull the radius posterolaterally (Fig.12-38, left) and possibly constricts the neck of the radius, thereby potentially limiting the growth of the radial neck (“notching”) and reducing forearm rotation. They suggested that although this repair might be satisfactory for anteromedial dislocations, it may not be optimal for anterior, anterolateral, lateral, and posterolateral dislocations. Initially, Seel and Peterson placed a single drill hole obliquely across the ulna to exit medially at the site of the medial attachment of the annular ligament on the coronoid process of the ulna (Fig. 12-38, center). The tendon was routed through the tunnel, brought around the neck, and sutured to the lateral side of the ulna. With this construct, the direction of stability was posteromedial. The use of two drill holes to secure the annular ligament or other reconstructive tendon at both normal attachments of the annular ligament on the ulna achieved a more normal posteromedial holding force on the neck of the radius (Fig. 12-38, right).

FIGURE 12-38. Drawings of transverse cuts of the proximal right radius and ulna (viewed distally) at the level of the radial head. **Left:** Route of the triceps tendon in Bell-Tawse reconstruction. The direction of stability is posterior *(large arrow).* **Center:** Drill hole placed obliquely to exit the ulna at the site of the medial annular ligament attachment. The direction of stability is posteromedial *(large arrow).* **Right:** Two drill holes exit the ulna at sites of medial and lateral annular ligament attachments. The direction of stability is anatomic *(arrow).* (From Seel MJ, Peterson HA. Management of chronic posttraumatic radial head dislocation in children. *J Pediatr Orthop* 1999;19:306-312; with permission.)

An alternative to the drill hole is to use a small bone staple or bone-anchoring device (Fig. 12-39).

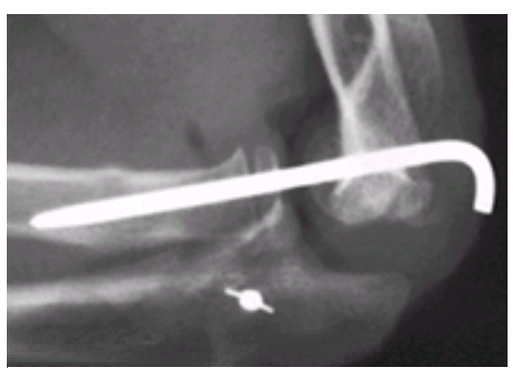

FIGURE 12-39. Fixation of radial head. After the ligament is reconstructed, the radial head is stabilized using a transcapitellar pin. Note the use of a bone anchor as an alternative to the drill hole.

Stabilizing the Radial Head. Once concentric reduction is achieved, the radiocapitellar relation is secured by passing a transcapitellar Steinmann pin through the posterior aspect of the capitellum into the radial head and neck with the elbow at 90 degrees and the forearm in supination (Fig. 12-39). A pin of sufficient size is mandatory to avoid pin failure (55); a small pin will fatigue (Fig. 12-40). Alternative techniques to secure the reduction of the radius include transversely pinning the radius to the ulna (61) and immobilizing the elbow in extension (12).

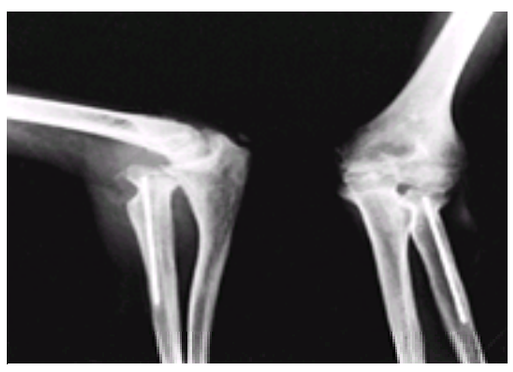

FIGURE 12-40. Radiograph showing a broken transcapitellar wire with subsequent dislocation of the radial head. A pin of sufficient size is mandatory to avoid pin failure

After Care. After wound closure, a long arm cast is applied with the forearm in 60 to 90 degrees of supination. The position of the elbow is predetermined by the transcapitellar Steinmann pin. This position relaxes the biceps and maintains the ulna in neutral position. The cast is maintained for 6 weeks, after which the cast and pin are removed and active motion is begun, especially pronation and supination. Elbow flexion and extension return rapidly but rotary motion of the forearm may take 6 to 9 months to improve, with pronation possibly being limited permanently (96).

Nerve Injuries

Radial Nerve

The literature reflects a 10% to 20% incidence of radial nerve injury, making it the most common complication associated with Monteggia fractures (49). It is most commonly associated with type I and III injuries, with the latter being more frequent (11,73,100). The posterior interosseous nerve is most commonly injured because of its proximity to the radial head and its intimate relation to the arcade of Frohse (Fig. 12-7). The arcade may be thinner and therefore more pliable in children (103). This may account in part for the rapid resolution of the nerve injury in children.

Such a lesion in a child is treated expectantly. Nerve function usually returns by approximately 9 weeks after reduction, if not sooner (104,106). It has been recommended that the nerve be explored if there is no clinical or electromyographic return of neurologic function by 12 weeks (104,106). These recommendations are drawn from series of adult patients and may be premature and unnecessary in children. A review of a series of children's Monteggia lesions (77) recommends waiting 6 months before intervention in a posterior interosseous nerve injury. Most series report 100% resolution both in fractures treated promptly and in those treated remotely from the date of injury (1,5,62).

Spinner (103) reported three posterior interosseous nerve injuries in children. All function returned spontaneously, but he recommended that if no clinical or electromyographic return occurs in approximately 6 weeks, exploration and neurolysis of the nerve should be performed. There are two reports (71,101) of irreducible Monteggia fractures caused by interposition of the radial nerve posterior to the radial head. After the nerve was replaced to its normal anatomic position and the head reduced, function returned in approximately 4 months. Morris (71), in cadaveric studies, demonstrated that significant anterior dislocation of the radial head and varus angulation of the elbow allowed the radial nerve to slide posterior to the radial head and, with subsequent reduction of the radial head, become entrapped.

Ulnar Nerve

Bryan (19) reported one adult with an ulnar nerve lesion associated with a type II Monteggia lesion, with spontaneous resolution. Stein and colleagues (106) reported three combined radial nerve and ulnar nerve injuries, two of which required exploration for functional return of the nerve.

Median Nerve

The association of median nerve injuries with Monteggia fractures is low. Injury to the anterior interosseous nerve has been reported in two series (124,127). In one case, exploration was necessary to release the entrapped nerve from the ulna (124). Both cases had complete resolution of the neurologic deficit. Stein et al. (106), in their report specifically examining nerve injuries in Monteggia lesions, reported no median nerve deficits. Watson and Singer (125) reported entrapment of the main trunk of the median nerve in a greenstick ulnar fracture in a 6-year-old girl. Completion of the fracture was necessary for release of the nerve. At 6 months after surgery, there was full motor recovery but sensation was slightly reduced in the tips of the index finger and thumb.

Tardy Nerve Palsy

The literature highlights seven cases of tardy radial nerve injury associated with radial head dislocation (1,5,45,62,130). The type of treatment has varied. Usually, excision of the radial head is included with exploration and neurolysis of the nerve, with uniformly good results (1,5). Other surgeons have explored the nerve alone, with good but variable results (45,62). Yamamoto and associates (130) combined radial head resection and nerve exploration with tendon transfers, producing good results in two patients.

One patient, who had a combination of radial head dislocation and a malunited distal humerus fracture, presented with combined tardy radial and ulnar nerve palsies (1). The ulnar nerve lesion was treated with anterior transposition, which provided resolution of the paresis. The radial nerve was treated by resection of the radial head and exploration of the nerve.

Associated Fractures and Unusual Lesions

Monteggia lesions have been associated with fractures of the wrist and the distal forearm (8). Distal radial and ulnar joint dislocation or sprain and fracture of the distal radius through the physis or distal metaphysis are most frequently reported (8,14,51,96) (Fig. 12-41). Galeazzi fractures may also occur concurrently with Monteggia lesions (8,75). Radial head and neck fractures are commonly associated with type II fractures (8,32), but may occur with others (35,37,51). With a type II lesion, the radial head may fracture, usually on its anterior rim (32). Strong et al. (111) reported two cases of a type I equivalent lesion consisting of a fractured radial neck and midshaft ulnar fracture. This equivalent was unique in having significant medial displacement of the distal radial fragment. They had significant difficulty in obtaining and maintaining reduction of the radius through closed technique in this fracture pattern.

FIGURE 12-41. Associated injuries. An 8-year-old child with a high-velocity injury to the entire forearm. **A:** Radiograph of a type III Monteggia fracture and associated lateral condyle *(black arrow)* and distal radial physeal *(white arrow)* fractures. **B:** Postoperative management with percutaneous pin fixation.

Fractures of the lateral condyle have been associated with Monteggia fractures (82). Ravessoud (90) reported an ipsilateral ulnar shaft lesion and a lateral condyle fracture without loss of the radiocapitellar relation, suggesting a Monteggia type II equivalent.

Periarticular Ossification

Two patterns of ossification have been noted radiographically. Various investigators have commented on the formation of ossification around the radial head and neck (12,46,62,64,107,109). It appears as a thin ridge of bone in a caplike distribution and may be accompanied by other areas resembling sesamoid bones (Fig. 12-42); they resorb with treatment and time. Ossification may also occur in the area of the annular ligament (31). Although noting their appearance, none of the authors detailed elbow function after the formation of these lesions (12,46,64,107,109).

FIGURE 12-42. Periarticular ossification. Persistent dislocations of the radial head are frequently accompanied by a thin cap of bone and other areas resembling sesamoid bones

The other form of ossification is true myositis ossificans. This occurred in approximately 3% of elbow injuries and 7% of Monteggia lesions in a series of adults and children (120). Myositis ossificans has a good prognosis in patients younger than 15 years of age, appearing at 3 to 4 weeks postinjury and resolving in 6 to 8 months (Fig. 12-43). Its occurrence is related to the severity of the initial injury, association with a fractured radial head, the number of remanipulations during treatment, and passive motion of the elbow during the postoperative period (74,120).

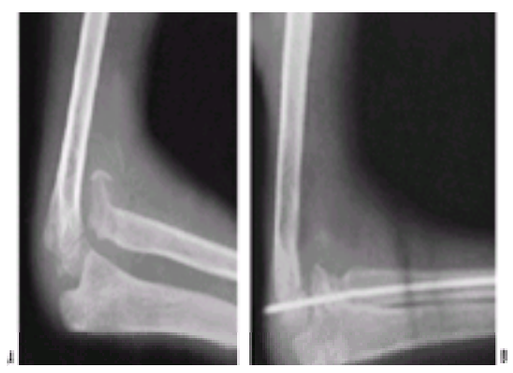

FIGURE 12-43. Periarticular ossification. **A:** Lateral radiograph of an old anterior dislocated radial head. **B:** Two months after treatment, with resolution of ossification.

SUMMARY

Adherence to several fundamental principles helps ensure good outcomes after Monteggia fractures in children:

- If, in a radiograph of the forearm, one bone overlaps or angulates, subluxation of either radioulnar joint should be considered.
- Evaluation of the radial head location requires an AP view of the proximal forearm and a true lateral view of the elbow.
- The radiocapitellar line must be intact in both views.
- Achievement of concentric, congruent radial head reduction is of primary importance, whether by open or closed means.
- In type IV injuries, the radial fracture must be stabilized before radial head reduction.
- Stability of the ulnar reduction is required to help maintain reduction of the radial head. Stability may be inherent to the fracture pattern or achieved by internal fixation.
- If additional stability of the radial head reduction is necessary, it can be achieved by reconstruction of the annular ligament.
- Immobilization should be in the position that best achieves stability of the radial head and maintains the position of the ulna.
- Early mobilization, especially rotation, is important to avoid stiffness.
- Frequent radiographic evaluation is necessary to monitor the position of the radial head and ulnar fracture.

13
THE ELBOW REGION: GENERAL CONCEPTS IN THE PEDIATRIC PATIENT

JAMES H. BEATY
JAMES R. KASSER

We thank Kaye Wilkins for his contribution to this chapter and previous editions. Much of this chapter is his effort.

At the turn of the century, Sir Robert Jones (30) echoed the opinion of that era about elbow injuries: “The difficulties experienced by surgeons in making an accurate diagnosis; the facility with which serious blunders can be made in prognosis and treatment; and the fear shared by so many of the subsequent limitation of function, serve to render injuries in the neighborhood of the elbow less attractive than they might otherwise have proved.” These concerns are applicable even today. The presentation of a child with a swollen, injured elbow still brings some anxiety to the treating orthopaedic surgeon. Fractures in other regions of the body can often be managed with minimal treatment to obtain uniformly good results. In the region of the elbow, however, there are often more indications for aggressive treatment, including operative management. Due to the high incidence of injuries and complications in children's elbow injuries, the orthopaedic surgeon must devote much time to learning the basic principles.

INCIDENCE

Vulnerability of Upper Extremities

Children tend to protect themselves with their outstretched arms when they fall, thus accounting for the vulnerability of the upper extremities to fractures. In the three major series reviewing large numbers of fractures sustained by children (3,24,35), the upper extremity consistently accounted for 65% to 75% of all the fractures sustained. The most common area of the upper extremity injured is the distal forearm (3,36). In these and other series, again the incidence of fractures about the elbow was consistent, ranging from 7% to 9% (3,24,35,36,43).

Specific Percentages

Considerable data are available relating the specific percentages of the various fractures in the elbow region to the total number of elbow injuries. The distal humerus accounts for 86.4% of the fractures about the elbow region. In a combined series of 5,228 fractures (3,4,7,8,15,16,21,27,34,36,37 and 38,45,49) of the distal humerus, 79.8% involved the supracondylar area, 16.9% involved the lateral condyle, and 12.5% represented avulsion of the medial epicondyle. Both T-condylar fractures and fractures of the medial condyle had an incidence of less than 1%. In this large series, there was no mention of any fracture of the lateral epicondyle.

Higher in 5- to 10-Year-Old Boys

Elbow injuries are much more common in the skeletally immature than in older people (11,53). The peak for fractures in the distal humerus is in the first decade of life, with most of the injuries occurring between ages 5 and 10 years (27). Elbow injuries are more common in boys. In the Northern Hemisphere, the seasonal peak is during the summer, the low point during the winter (27,34). Thus, the most likely candidate for an elbow injury is a boy 5 to 10 years of age playing during summer vacation.

The peak incidence of physeal (epiphyseal plate) injuries in most parts of the body is toward the termination of skeletal maturity. The Petersons (42) found that the incidence of physeal injuries in all parts of the body peaked between ages 10 and 13 years. However, the peak age for injuries to the distal humeral physes was 4 to 5 years in girls and 5 to 8 years in boys. In most physeal injuries, the increased incidence with advanced age is said to be due to weakening of the perichondrial ring as it matures (see Chapter 5). Thus, some different biomechanical forces and conditions must exist about the elbow to make the physis more vulnerable to injuries at an earlier age. (For more data on the relationship of fractures about the elbow to all types of fractures, see Chapter 1).

ANATOMY

The elbow is a complex joint composed of three individual joints contained within a common articular cavity. This chapter emphasizes anatomic concepts unique to the growing elbow.

The Ossification Process

Central-Distal Process

The process of differentiation and maturation begins at the center of the long bones and progresses distally. The ossification process begins in the diaphysis of the humerus, radius, and ulna at the same time. By term, ossification of the humerus has extended distally to the condyles. In the ulna, it extends to greater than half the distance between the coronoid process and the tip of the olecranon. The radius is ossified proximally to the level of the neck. The bicipital tuberosity remains largely unossified (Table 13-1) (23). Brodeur et al. compiled a complete atlas of ossification of the structures about the elbow (9), and their work is an excellent reference source for finer details of the ossification process about the elbow.

	Girls (yr)	Boys (yr)
Capitellum	1.0	1.0
Radial head	5.0	6.0
Medial epicondyle	5.0	7.5
Olecranon	8.7	10.5
Trochlea	9.0	10.7
Lateral epicondyle	10.0	12.0

Data from Cheng JC, Wing-Man K, Shen WY, et al. A new look at the sequential development of elbow-ossification centers in children. *J Pediatr Orthop* 1998;18:161–167.

TABLE 13-1. SEQUENCE AND TIMING OF OSSIFICATION IN THE ELBOW

Distal Humerus

Sex Variation

Ossification of the distal humerus proceeds at a predictable rate. In general, the rate of ossification in girls exceeds that of boys (20,22,25). In some areas, such as the olecranon and lateral epicondyle, the difference between boys and girls in ossification age may be as great as 2 years (22).

Initial Symmetry

During the first 6 months, the border of ossification of the distal humerus is symmetric (Fig. 13-1).

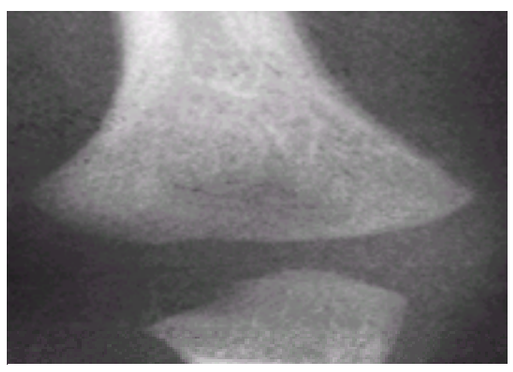

FIGURE 13-1. During the first 6 months, the advancing ossifying border of the distal humerus is symmetric.

Lateral Condyle

The ossification center of the lateral condyle, on average, appears just before 1 year of age but may be delayed as late as 18 to 24 months (11).

When the ossific nucleus of the lateral condyle first appears, the distal humeral metaphyseal border becomes asymmetric. The lateral border slants and becomes straight to conform with the ossification center of the lateral condyle (Fig. 13-2). By the end of the second year, this border becomes well defined, possibly even slightly concave. This ossification center is usually spherical when it first appears. It becomes more hemispherical as the distal humerus matures (10). This ossific nucleus is now extending into the lateral ridge of the trochlea (Fig. 13-3). On the lateral view, the physis of the capitellum is wider posteriorly. This is a normal variation and should not be confused with a fracture (10).

FIGURE 13-2. Ossification at 12 months. As the ossification center of the lateral condyle develops (*arrow*), the lateral border of the metaphysis becomes straighter.

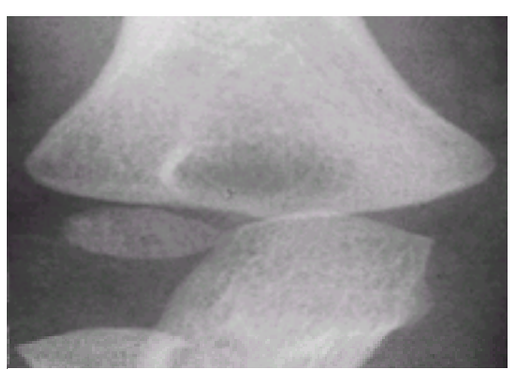

FIGURE 13-3. At 24 months, the oval-shaped secondary ossification center of the lateral condyle extends into the lateral crista of the trochlea. The lateral border of the neck (metaphysis) of the radius is normally angulated both anteriorly and laterally.

Medial Epicondyle

At about 5 to 6 years of age, a small concavity develops on the medial aspect of the metaphyseal ossification border. In this area, a medial epicondyle begins to ossify (Fig. 13-4).

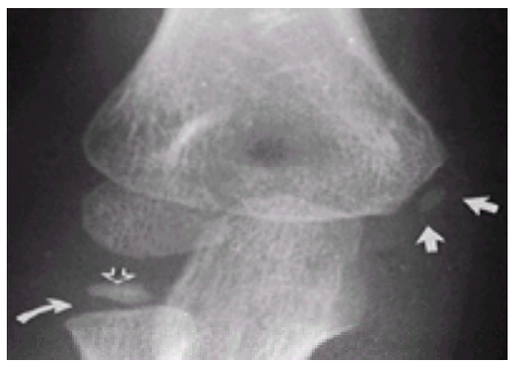

FIGURE 13-4. At about 5 or 6 years of age, a secondary center develops in the medial epicondylar apophysis (*white arrows*). At this same time, the ossification center of the radial head also develops (*open arrow*). Note that the physis of the proximal radius is widened laterally (*curved arrow*).

Trochlea

At about 9 to 10 years of age, the trochlea begins to ossify. Initially, it may be irregular with multiple centers (Fig. 13-5).

FIGURE 13-5. At about 9 years of age, the ossification of the medial crista of the trochlea may begin as two well-defined centers (*arrows*). These multiple centers can give the trochlea a fragmented appearance.

Lateral Epicondyle

The lateral epicondyle is last to ossify and is not always visible (Fig. 13-6). At about 10 years of age, it may begin as a small, separate oblong center, rapidly fusing with the lateral condyle (10).

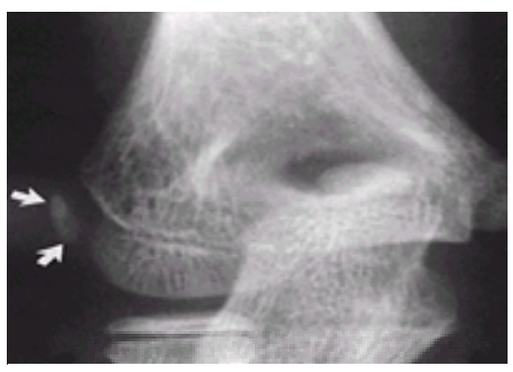

FIGURE 13-6. The apophysis of the lateral epicondyle ossifies as either an oblong or a triangular center (*arrows*). The wide separation of this center from the metaphyseal and epiphyseal borders of the lateral condyle is normal.

The Fusion Process

Just before completion of growth, the capitellum, lateral epicondyle, and trochlea fuse to form one epiphyseal center. Metaphyseal bone separates the extraarticular medial epicondyle from this common humeral epiphyseal center (Fig. 13-7). The common epiphyseal center ultimately fuses with the distal humeral metaphysis. The medial epicondyle may not fuse with the metaphysis until the late teens.

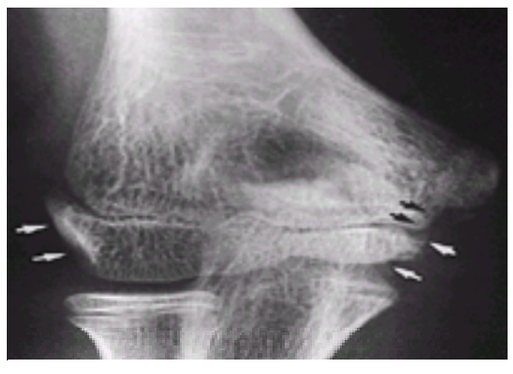

FIGURE 13-7. The secondary ossification centers of the lateral condyle, trochlea, and lateral epicondylar apophysis fuse to form one center (*white arrows*). This common center is separated from the medial epicondylar apophysis by advancing metaphyseal bone (*black arrows*).

Proximal Radius

The head of the radius begins to ossify at about the same time as the medial epicondyle (Fig. 13-4). The ossification center is present in at least 50% of girls by 3.8 years of age but may not be present in the same proportion of boys until around 4.5 years (20). Initially, the ossification center is elliptical and the physis is widened laterally because of the obliquity of the proximal metaphysis. The ossification center flattens as it matures. At about age 12, it develops a concavity opposite the capitellum (10).

Ossification of the radial head may be bipartite or may produce an irregularity of the second center. These secondary or irregular ossification centers should not be interpreted as fracture fragments.

Olecranon

There is a gradual proximal progression of the proximal ulnar metaphysis. At birth, the ossification margin lies halfway between the coronoid process and the tip of the olecranon. By about 6 or 7 years of age, it appears to envelop about 66% to 75% of the capitellar surface. The final portion of the olecranon ossifies from a secondary ossification center that appears around 6.8 years of age in girls and 8.8 years in boys (Fig. 13-8A). Porteous (43) described two separate centers, one articular and the other a traction type (Fig. 13-8B). This secondary ossification center of the olecranon may persist late into adult life (41).

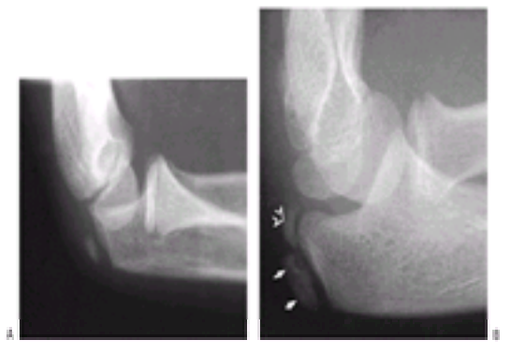

FIGURE 13-8. Ossification of the olecranon. **A:** Secondary ossification begins as an oblique oblong center at about 6 to 8 years of age. **B:** It may progress as two separate ossification centers: articular (*open arrow*) and traction (*closed arrows*).

Fusion of the Ossification Centers

The epiphyseal ossification centers of the distal humerus fuse as one unit and then fuse later to the metaphysis. The medial epicondyle is the last to fuse to the metaphysis. The ranges of onset of ossification of the various centers and their fusion to other centers or the metaphysis are summarized in Fig. 13-9. Each center contributes to the overall architecture of the distal humerus (Fig. 13-9C).

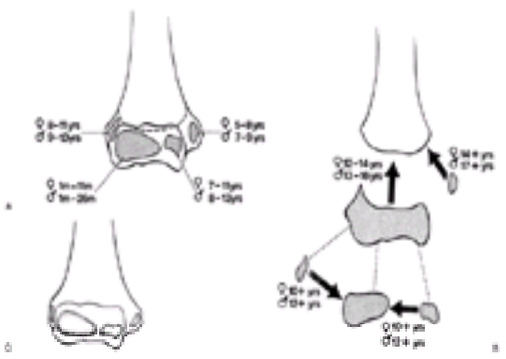

FIGURE 13-9. Ossification and fusion of the secondary centers of the distal humerus. **A:** The average ages for the onset of ossification of the various ossification centers are shown for both boys and girls. **B:** The ages at which these centers fuse with each other are shown for both boys and girls. (Redrawn from Haraldsson S. On osteochondrosis deformans juvenilis apituli humeri including investigation of the intra-osseous vasculature in the distal humerus. *Acta Orthop Scand Suppl* 1959;38; with permission.) **C:** The contribution of each secondary center to the overall architecture of the distal humerus is represented by the stippled areas.

Fusion of the proximal radial and olecranon epiphyseal centers with their respective metaphyses occurs at around the same time that the common distal humeral epiphysis fuses with its metaphysis (i.e., between 14 and 16 years of age) (5,9,47).

Noting that the pattern and sequence of ossification of the six secondary ossification centers around the elbow were mainly derived from studies conducted more than 30 years ago, Cheng et al. evaluated elbow radiographs of 1,577 Chinese children (14). They found that the sequence of ossification was the same in boys and girls—capitellum, radial head, medial epicondyle, olecranon, trochlea, and lateral epicondyle—but ossification was delayed by about 2 years in boys in all ossification centers except the capitellum (Table 13-1).

Blood Supply

Extraosseous

There is a rich arterial network around the elbow (Fig. 13-10) (55). The major arterial trunk, the brachial artery, lies anteriorly in the antecubital fossa. Most of the intraosseous blood supply of the distal humerus comes from the anastomotic vessels that course posteriorly.

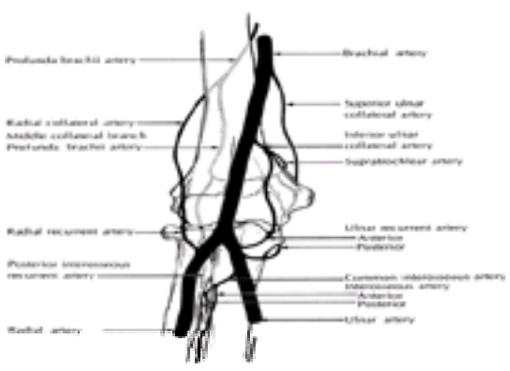

FIGURE 13-10. The major arteries about the anterior elbow.

Three structural components govern the location of the entrance of the vessels into the developing epiphysis. First, there is no communication between the intraosseous metaphyseal vasculature and the ossification centers. Second, vessels do not penetrate the articular surfaces. The lateral condyle is nonarticular only at the origin of the muscles and collateral ligaments. Third, the vessels do not penetrate the articular capsule except at the interface with the surface of the bone. Thus, only a small portion of the lateral condyle posteriorly is both nonarticular and extracapsular (Fig. 13-11) (26).

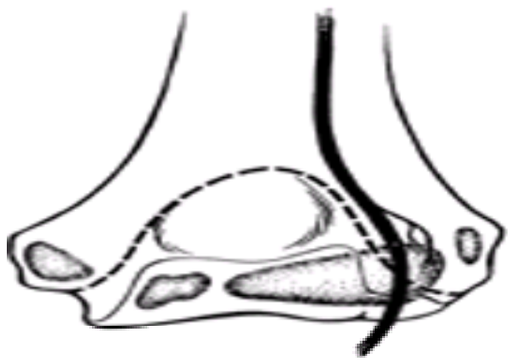

FIGURE 13-11. The vessels supplying the lateral condylar epiphysis enter the posterior aspect of the condyle, which is extraarticular.(Redrawn from Haraldsson S. On osteochondrosis deformans juvenilis capituli humeri including investigation of the intra-osseous vasculature in the distal humerus. *Acta Orthop Scand Suppl* 1959;38; with permission.)

Intraosseous

Posterior End Vessels

The most extensive study of the intraosseous blood supply of the developing distal humerus was conducted by Haraldsson (Fig. 13-12) (25,26). He demonstrated that two types of vessels exist in the developing lateral condyle. These vessels enter the posterior portion of the condyle just lateral to the origin of the capsule and proximal to the articular cartilage near the origin of the anconeus muscle. They penetrate the nonossified cartilage and traverse it to the developing ossific nucleus. In the young child, this is a relatively long course (Fig. 13-12A). These vessels communicate with one another within the ossific nucleus but do not communicate with vessels in either the metaphysis or nonossified chondroepiphysis. Thus, for practical purposes, they are end vessels.

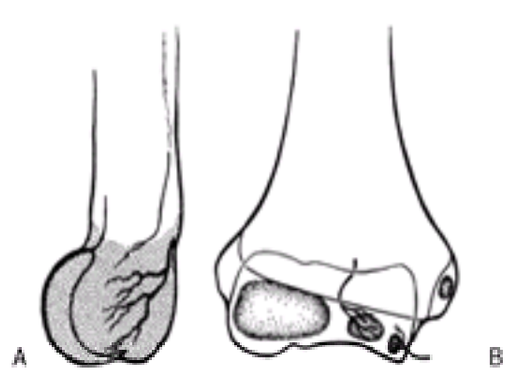

FIGURE 13-12. Intraosseous blood supply of the distal humerus. **A:** The vessels supplying the lateral condylar epiphysis enter on the posterior aspect and course for a considerable distance before reaching the ossific nucleus. **B:** Two definite vessels supply the ossification center of the medial crista of the trochlea. The lateral one enters by crossing the physis. The medial one enters by way of the nonarticular edge of the medial crista. (Redrawn from Haraldsson S. On osteochondrosis deformans juvenilis capituli humeri including investigation of the intra-osseous vasculature in the distal humerus. *Acta Orthop Scand Suppl* 1959;38; with permission.)

Lateral Crista Is Part of Lateral Condyle

The ossification center of the lateral condyle extends into the lateral portion of the trochlea. Thus, the lateral crista or ridge of the trochlea derives its blood supply from these condylar vessels. The medial ridge or crista remains unossified for a longer period of time.

Trochlear Vessels Traverse Physis

The trochlea is covered entirely by articular cartilage and lies totally within the confines of the articular capsule. The vessels that supply the nucleus of the ossific centers of the trochlea must therefore traverse the periphery of the physis to enter the epiphysis.

Two Separate Trochlear Vessels

Haraldsson's (26) studies have shown two sources of blood supply to the ossific nucleus of the medial portion of the trochlea (Fig. 13-12B). The lateral vessel, on the posterior surface of the distal humeral metaphysis, penetrates the periphery of the physis and terminates in the trochlear nucleus. Because this vessel supplying the trochlea is an end vessel, it is especially vulnerable to injury by a fracture that courses through either the physis or the very distal portion of the humeral metaphysis. Injury to this vessel can markedly decrease the nourishment to the developing lateral ossific nucleus of the trochlea. The medial vessel penetrates the nonarticulating portion of the medial crista of the trochlea. This multiple vascular source may account for the development of multiple ossification centers in the maturing trochlea, giving it a fragmented appearance (Fig. 13-5).

Final Anastomosis

When growth is complete, metaphyseal and epiphyseal vessels anastomose freely. The blood supply from the central nutrient vessel of the shaft reaches the epicondylar regions in the skeletally mature distal humerus (33).

Capsule

Intraarticular Structures

The articular surface lies within the confines of the capsule, but nonarticulating areas involving the coronoid and radial fossae anteriorly and the olecranon fossa posteriorly are also within the confines of the articular cavity (54). The capsule attaches just distal to the coronoid and olecranon processes. Thus, these processes

are intraarticular (29). The entire radial head is intraarticular, with a recess or diverticulum of the articular cavity of the elbow extending distally under the margin of the orbicular ligament. The medial and lateral epicondyles are extraarticular.

Anterior Portion Strongest

The anterior capsule is thickened anteriorly. These longitudinally directed fibers are very strong and become taut with the elbow in extension. In hyperextension, the tight anterior bands of the capsule force the ulna firmly into contact with the humerus. Thus, the fulcrum of rotation becomes transmitted proximally into the tip of the olecranon in the supracondylar area. This is an important factor in the etiology of supracondylar fractures.

Fat Pads

At the proximal portion of the capsule, between it and the synovial layer, are two large fat pads (Fig. 13-13). The posterior fat pad lies totally within the depths of the olecranon fossa when the elbow is flexed. The anterior fat pad extends anteriorly out of the margins of the coronoid fossa. The significance of these fat pads in the interpretation of radiographs of the elbow is discussed later.

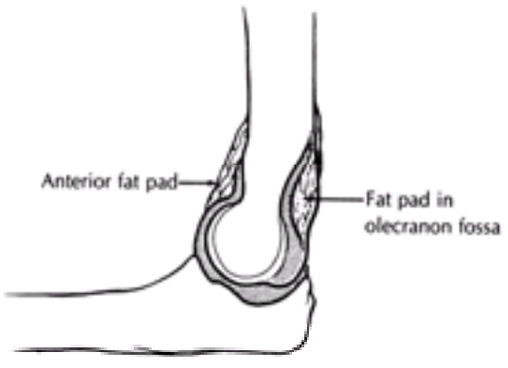

FIGURE 13-13. The elbow fat pads. Some of the coronoid fat pad lies anterior to the shallow coronoid fossa. The olecranon fat pad lies totally within the deeper olecranon fossa.

Ligaments

The pertinent ligamentous anatomy involving the orbicular and collateral ligaments is discussed in the sections on the specific injuries involving the radial neck, medial epicondyle, and elbow dislocations.

RADIOGRAPHIC FINDINGS

Because of the ever-changing ossification pattern, identification and delineation of fractures about the elbow in the immature skeleton may be subject to misinterpretation. The variables of ossification of the epiphyses should be well known to the orthopaedic surgeon who treats these injuries.

Standard View

The standard radiographs of the elbow include an anteroposterior view with the elbow extended and a lateral view with the elbow flexed to 90 degrees and the forearm neutral.

Jones View

In the injured elbow, it is often difficult to extend the elbow. In these cases, an axial view of the elbow, the Jones view, may be helpful (Fig. 13-14). The distal humerus is often difficult to interpret because of the superimposed proximal radius and ulna. Often there is a high index of suspicion for a fracture, but none is visualized on the routine anteroposterior and lateral radiographs. In this case, internal and external oblique views may be helpful. This is especially true in visualizing fractures of the radial head and coronoid process.

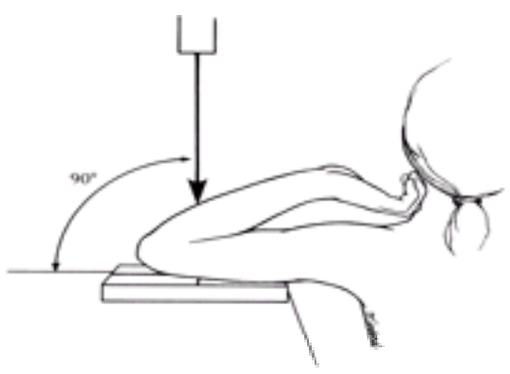

FIGURE 13-14. Jones axial radiographic view of the elbow.

Anteroposterior Landmarks

Baumann's Angle

In the standard anteroposterior view, the major landmark is the angulation of the physeal line between the lateral condyle and the distal humeral metaphysis. The ossification center of the lateral condyle extends into the radial or lateral crista of the trochlea (Fig. 13-9C). This physeal line forms an angle with the long axis of the humerus. The angle formed by this physeal line and the long axis of the humerus is termed Baumann's angle (Fig. 13-15A) (1). Baumann's angle is not equal to the carrying angle of the elbow in the older child (10). This is a consistent angle when both sides are compared and the x-ray beam is directed perpendicular to the long axis of the humerus.

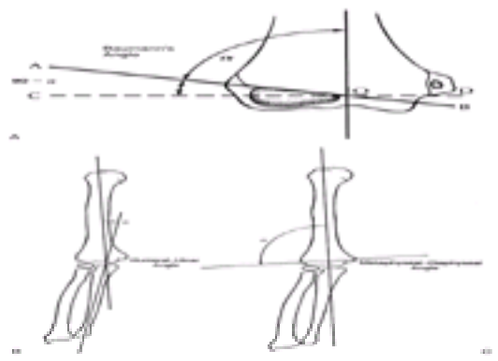

FIGURE 13-15. Anteroposterior radiograph angles of the elbow. **A:** Baumann's angle (a). **B:** The humeral-ulnar angle. **C:** The metaphyseal-diaphyseal angle. (Reproduced from O'Brien WR, Eilert RE, Chang FM, et al. The metaphyseal-diaphyseal angle as a guide to treating supracondylar fractures of the humerus in children. Unpublished data; with permission.)

Effects of Angulation

Caudad-cephalad angulation of the x-ray tube or right or left angulation of the tube by as much as 30 degrees changes Baumann's angle by less than 5 degrees. If, however, the tube becomes angulated in a cephalad-caudad direction by greater than 20 degrees, the angle is changed significantly and the measurement is inaccurate.

Effects of Rotation

Camp et al. (12) found in their cadaver studies that rotation of the distal fragment or the entire reduced humerus also can alter the projection of Baumann's angle. They found that to be accurate, the humerus must be parallel to the x-ray plate, with the beam directed perpendicular to the film as well.

Thus, in the routine anteroposterior radiographs of the distal humerus including the Jones view, Baumann's angle is a good measurement of any deviation of the angulation of the distal humerus (16).

Other Angles

Two other angles are commonly used in anteroposterior radiographs to determine the proper alignment of the distal humerus or carrying angle. The humeral-ulnar angle is determined by lines longitudinally bisecting the shaft of the humerus with the shaft of the ulna (Fig. 13-15B) (2,28,41). The metaphyseal-diaphyseal angle is determined by a line that longitudinally bisects the shaft of the humerus with a line that connects the widest points of the metaphysis of the distal humerus (see Fig. 13-15C) (40). The humeral-ulnar angle is the most accurate in determining the true carrying angle of the elbow. Baumann's angle also has a good correlation with the clinical carrying angle. However, it may be difficult to measure in the adolescent when the ossification center of the lateral condyle is beginning to fuse with other centers. The metaphyseal-diaphyseal angle is the least accurate of the three (50).

Lateral Landmarks

Teardrop

The lateral projection of the distal humerus presents a teardrop-like shadow above the capitellum (47). The anterior dense line making up the teardrop represents the posterior margin of the coronoid fossa. The posterior dense line represents the anterior margin of the olecranon fossa. The inferior portion of the teardrop is the ossification center of the capitellum. On a true lateral projection, this teardrop should be well defined (Fig. 13-16A).

Shaft-Condylar Angle

On the lateral radiograph, there is an angulation of 40 degrees between the long axis of the humerus and the long axis of the lateral condyle (Fig. 13-16B). This also can be measured by the flexion angle of the distal humerus, which is calculated by measuring the angle of the lateral condylar physeal line with the long axis of the shaft of the humerus (18).

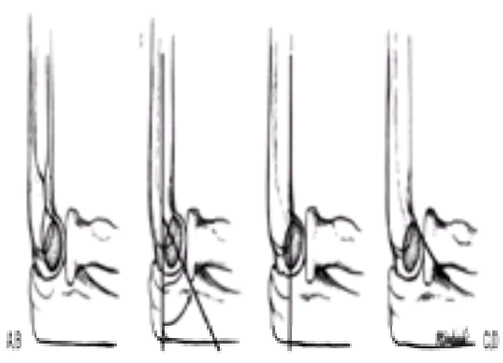

FIGURE 13-16. Lateral radiographic lines of the distal humerus. **A:** The teardrop of the distal humerus. **B:** The angulation of the lateral condyle with the shaft of the humerus. **C:** The anterior humeral line. **D:** The coronoid line.

Anterior Humeral Line

If a line is drawn along the anterior border of the distal humeral shaft, it should pass through the middle third of the ossification center of the capitellum. This is referred to as the anterior humeral line (Fig. 13-16C). Passage of the anterior humeral line through the anterior portion of the lateral condylar ossification center or anterior to it indicates the presence of posterior angulation of the distal humerus. In a large study of minimally displaced supracondylar fractures, Rogers et al. (44) found that this anterior humeral line was the most reliable factor in detecting the presence or absence of occult fractures.

Coronoid Line

A line directed proximally along the anterior border of the coronoid process should barely touch the anterior portion of the lateral condyle (Fig. 13-16D). Posterior displacement of the lateral condyle projects the ossification center posterior to this coronoid line (47).

Pseudofracture

Some vagaries of the ossification process about the elbow may be interpreted as a fracture (47). For example, the ossification of the trochlea may be irregular, producing a fragmented appearance (Fig. 13-5). This fragmentation can be misinterpreted, especially if the distal humerus is slightly oblique or tilted. These

secondary ossification centers may be mistaken for fracture fragments lying between the semilunar notch and lateral condyle (Fig. 13-17).

FIGURE 13-17. Pseudofracture of the elbow. The trochlea with its multiple ossification centers may be misinterpreted as fracture fragments lying between the joint surfaces (*arrow*).

On the lateral projection, the physeal line between the lateral condyle and the distal humeral metaphysis is wider posteriorly. This may give a misinterpretation that the lateral condyle is fractured and tilted (10).

In the anteroposterior projection before the radial head ossifies, there is normally some lateral angulation to the radial border of the neck of the radius that may give the appearance of subluxation (Fig. 13-3). The true position of the radial head can be confirmed by noting the relationship of the proximal radius to the ossification center of the lateral condyle on the lateral projection (46).

Fat Pad Signs of the Elbow

Three Fat Accumulations

There are three areas in which fat pads overlie major structures of the elbow. Displacement of any of the fat pads can indicate the presence of an occult fracture. The first two are the fat pads that overlie the capsule in the coronoid fossa anteriorly and the olecranon fossa posteriorly. Displacement of either or both of these fat pads is usually referred to as the classic elbow fat pad sign. A third accumulation of fat overlies the supinator muscle as it wraps around the proximal radius.

Olecranon (Posterior) Fat Pad

Because the olecranon fossa is deep, the fat pad here is totally contained within the fossa. It is not visualized on a normal lateral x-ray of the elbow flexed to 90 degrees (Fig. 13-18A). Distention of the capsule with an effusion, as occurs with an occult intraarticular fracture, a spontaneously reduced dislocation, or even an infection, can cause the dorsal or olecranon fat pad to be visualized (56).

FIGURE 13-18. Radiographic variations of the elbow fat pads. **A:** Normal relationships of the two fat pads. **B:** Displacement of both fat pads (*arrows*) with an intraarticular effusion. **C:** In some cases, the effusion may displace only the anterior fat pad (*arrows*). **D:** In extension, the posterior fat pad is normally displaced by the olecranon. **E:** An extraarticular fracture may lift the distal periosteum and displace the proximal portion of the posterior fat pad. (Redrawn from Murphy WA, Siegel MJ. Elbow fat pads with new signs and extended differential diagnosis. *Radiology* 1977;124:656–659; with permission.) **F:** An x-ray showing displacement of both fat pads (*arrows*) from an intraarticular effusion.

Coronoid (Anterior) Fat Pad

Likewise, the ventral or coronoid fat pad may be displaced anteriorly (Fig. 13-18B) (6). Because the coronoid fossa is shallow, the fat pad in this area projects anterior to the bony margins and can be seen normally as a triangular radiolucency anterior to the distal humerus. Although displacement of the classic elbow fat pads is a reliable indication of an intraarticular effusion, there may be instances in which only one of the fat pads is displaced. Brodeur and colleagues (10) and Kohn (32) have shown that the coronoid fat pad is more sensitive to small effusions. It can be displaced without a coexistent displacement of the olecranon fat pad (Fig. 13-18C).

Supinator Fat Pad

A layer of fat on the anterior aspect of the supinator muscle wraps around the proximal radius. This layer of fat or fat pad may normally bow anteriorly to some degree. Brodeur et al. (10) stated displacement may indicate the presence of an occult fracture of the radial neck. Displacement of the fat line or pad is often difficult to interpret; in a review of fractures involving the proximal radius, Schunk et al. (47) found it to be positive only 50% of the time.

Fat Pad Variations

For the fat pads to be displaced, the capsule must be intact. This can explain why there may be no displacement of the fat pads with an elbow dislocation that has spontaneously reduced because of rupture of the capsule. Murphy and Siegel (39) have shown other variations of displacement of the classic fat pads. If the elbow is extended, the fat pad is normally displaced from the olecranon fossa by the olecranon (Fig. 13-18D). Distal humeral fractures may cause subperiosteal bleeding and may lift the proximal portion of the olecranon fat pad without the presence of an effusion (Fig. 13-18E). These false-negative and false-positive findings must be kept in mind when interpreting the presence or absence of a fat pad with an elbow injury.

Posterior Fat Pad Is Most Reliable

Corbett's (16) review of elbow injuries indicated that if a displacement of the posterior fat pad existed, a fracture was almost always present. Displacement of the anterior fat pad alone, however, could occur without a fracture. Corbett also determined that the degree of displacement bore no relation to the size of the fracture. Skaggs and Mirzayan (48) reported that 34 of 45 children (76%) with a history of elbow trauma and an elevated posterior fat pad had radiographic evidence of elbow fractures at an average of 3 weeks after injury, although anteroposterior, lateral, and oblique radiographs at the time of injury showed no other evidence of fracture. They recommended that a child with a history of elbow trauma and an elevated fat pad be treated as if a nondisplaced elbow fracture were present. Donnelly et al.

(19), however, found evidence of fracture in only 9 of 54 children (17%) who had a history of trauma and elbow joint effusion but no identifiable fracture on initial radiographs. They concluded that joint effusion without a visible fracture on initial radiographs does not correlate with the presence of occult fracture in most patients (83%). Persistent effusion did correlate with occult fracture: 78% of those with occult fractures had persistent effusions, compared with 16% of those without fractures.

Comparison Radiographs

Often it is tempting to order comparison radiographs in a child with an injured elbow because of the difficulty evaluating the irregularity of the ossification process. However, the indications for ordering comparison radiographs are rare. Kissoon et al. (13,31) found that the use of routine comparison radiographs in children with injured elbows did not significantly increase the accuracy of diagnosis, regardless of the interpreter's training.

SUPRACONDYLAR FRACTURES OF THE DISTAL HUMERUS

JAMES R. KASSER
JAMES H. BEATY

We thank Kaye Wilkins for his contribution to this chapter and previous editions. Much of this chapter is his effort.

Between the mid-20th century, when early reports of pinning of fractures of the distal humerus first appeared, and now, treatment of supracondylar fractures has evolved tremendously. Blount's caution against operative management (26) has given way to modern concepts of treatment involving skeletal stabilization and soft tissue management, which have greatly improved outcome (29,48,69,147,181).

Both cost and clinical result have been significantly affected over the past 25 years (176). Problems of vascular compromise, Volkmann ischemic contracture, and neurovascular entrapment in the fracture callus have been greatly decreased, but not eliminated.

INCIDENCE AND GENERAL CONSIDERATIONS

The peak age at which supracondylar fractures occur is between 5 and 7 years. The rate of occurrence increases steadily in the first 5 years of life, and traditionally boys have had a higher incidence of this fracture than girls. Combining 61 reports of supracondylar fractures totaling 7,212 displaced fractures of the distal humerus yields a consistent pattern, as shown in Table 14-1. Boys have outnumbered girls by about 3 to 2. The average age at fracture is 6.7 years. The left or nondominant side predominates in almost all studies. Two thirds of children hospitalized with elbow injuries have supracondylar fractures. Nerve injury occurs in at least 7%. The radial nerve has been the most frequently involved nerve in older studies; however, the median nerve is much more commonly injured, particularly the anterior interosseous nerve (AIN), in more recent studies (49,174). The ulnar nerve is most commonly injured iatrogenically during pinning or in a flexion-type of supracondylar fracture. It is possible that there has been a change in the pattern of displacement of these fractures, accounting for the change in frequency of median nerve injuries, but it is more likely that the subtle loss of thumb and finger flexion that indicates an AIN injury is more frequently recognized.

Incidence	Percentage of Total Number of Fractures (%)	Nerve Involved	Percentage of Total Nerve Injuries (%)*
Side involved		Radial	41.2
Right	39.2	Median	36.0
Left	60.8	Ulnar	22.8
Sex incidence			
Male	62.8		
Female	37.2		
Ipsilateral fractures	1.0		
Open fractures	1.0		
Volkmann contracture	0.5		
Flexion type	2.0		
Fractures with nerve injuries	7.7		

Data were compiled from 7212 fractures occurring in 61 major series.
Data from References, 3, 5, 11, 13, 17, 18, 22, 23, 27, 29, 34, 41, 45, 47, 51, 53, 59, 60–63, 66, 68, 82, 84, 85, 91, 93, 94, 97, 103, 107, 109, 116, 117, 118, 124, 130, 132, 134, 136, 137, 144, 145, 148, 152, 155, 156, 167, 168, 173, 180, 183, 184, 186, 187, 188, 195, 197.
* Average age was 6.7 years.

TABLE 14-1. EFFICIENCE OF SUPRACONDYLAR FRACTURES

Increased ligamentous laxity (Fig. 14-1) has been correlated with the occurrence of supracondylar fractures (25,139) and with ulnar nerve subluxation (198). Supracondylar fractures are more likely in children with ulnar nerve subluxation, which makes the nerve vulnerable in medial pinning techniques.

FIGURE 14-1. Hyperflexibility. At the peak age for supracondylar fractures there is a naturally occurring hyperextension of the elbow, which predisposes the distal humerus to this type of fracture. (Reprinted from Wilkins KE. The operative management of supracondylar fractures. *Orthop Clin North Am* 1990;21:269-289; with permission.)

Almost all supracondylar fractures are caused by accidental trauma. A fall from a height accounts for 70% of all supracondylar fractures (64). In children under 3 years of age, the fracture usually occurs in a fall from a bed, from furniture, or down stairs. In children over 3 years of age, the fracture generally results from a fall from

monkey bars, swings, or other playground equipment. In one study of 99 patients with supracondylar fractures seen over a 15-month period, only 1 was secondary to abuse (175). When a child under 15 months of age has a supracondylar fracture of the distal humerus, abuse should be considered; with a reasonable history, however, such a cause is unlikely.

The most commonly associated fractures are distal radial fractures, but fractures of the scaphoid and proximal humerus do occur. Pulse is absent at presentation in 12% to 15% of patients, but vascular insufficiency requiring operative intervention is relatively rare (32,36,44,162) (2%–4%). Volkmann ischemic contracture is rare, occurring in about 0.5% of patients. Most distal humeral supracondylar fractures are displaced in extension, but flexion-type injuries do occur.

EXTENSION-TYPE SUPRACONDYLAR FRACTURES

Mechanism of Injury

Supracondylar fractures generally occur as a result of a fall onto the outstretched hand with the elbow in full extension (40) (Fig. 14-2). The flexed elbow may be stabilized by the biceps, brachialis, and triceps muscles, but once extended beyond neutral, the elbow flexor muscles are at a poor mechanical advantage and there is little resistance to injury. The olecranon in its fossa in the distal humerus acts as a fulcrum, whereas the capsule transmits an extension force to the distal humerus just proximal to the physis as the elbow hyperextends. The capsular insertion, distal to the olecranon fossa and proximal to the physis, is critical in producing a consistent failure pattern of a transcondylar fracture in children. In full extension the elbow becomes tightly interlocked, concentrating bending forces in the distal humerus (133).

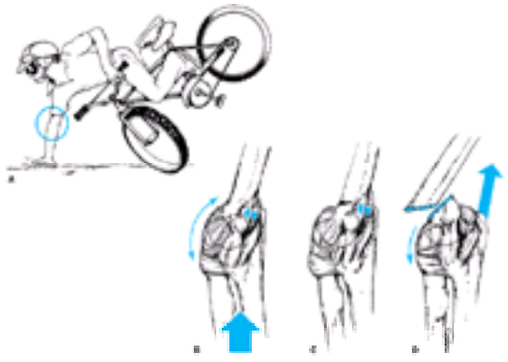

FIGURE 14-2. Hyperextension Forces. **A:** Most young children attempt to break their falls with the upper extremity extended. Because of the laxity of the ligaments, the elbow becomes locked into hyperextension. **B:** This converts the linear applied force (*large arrow*) to an anterior tension force. Posteriorly, the olecranon is forced into the depths of the olecranon fossa (*small arrow*). **C:** As the bending force continues, the distal humerus fails anteriorly in the supracondylar area. **D:** When the fracture is complete, the distal fragment becomes posteriorly displaced. The strong action of the triceps (*large arrow*) produces proximal displacement of the distal fragment.

Posterior displacement of the distal fragment occurs, with the proximal or metaphyseal fragment impaling the anterior soft tissue structures. The fracture in the sagittal plane was classically described by Kocher (106) as extending obliquely from anterior and distal to posterior and proximal. However, clinical studies by Holmberg (91) and Nand (137) have demonstrated that the fracture pattern is transverse on lateral radiographs in more than 80% of patients (Fig. 14-3). The fracture line in the anteroposterior (AP) view extends transversely across both the medial and lateral columns of the distal humerus at the level of the middle of the olecranon fossa.

FIGURE 14-3. Orientation of fracture lines. **A:** The typical transverse fracture line originates just above the epicondyles and courses through the supracondylar area (*arrows*). **B:** In the lateral projection, the fracture line is usually also transverse.

Role of the Periosteum

As the supracondylar fracture displaces posteriorly, the anterior periosteum fails and tears away from the displaced distal fragment. The anterior loss of periosteal integrity leads to frequent failure of anterior callus formation in early fracture healing, which is of little significance clinically (Fig. 14-4). Further fracture displacement is accompanied by corresponding increased periosteal disruption with decreased fracture stability.

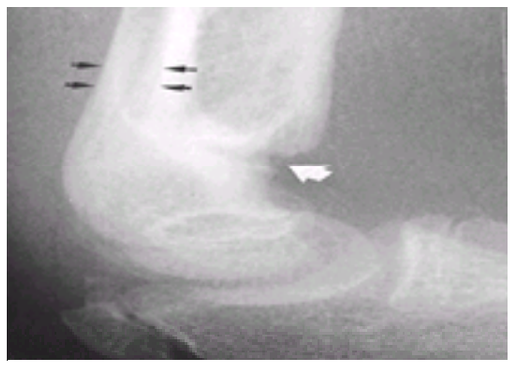

FIGURE 14-4. Periosteal changes. Radiographs taken 2 months after fracture. Lateral view demonstrates a persistent gap (*white arrow*) in the anterior cortical margin where interposed periosteum prevented anatomic reduction. Note the absence of periosteal new bone anteriorly on the proximal fragment, although there is abundant periosteal new bone (*black arrows*) on the posterior surface.

Intact medial or lateral periosteum, the periosteal hinge, has been said to provide stability after fracture reduction (81,103,161). Pronation of the forearm (13,104) after reduction of a posteromedially displaced supracondylar fracture is said to stabilize reduction by closing the fracture gap laterally, tensioning the medial periosteal hinge, and tightening the lateral ligaments of the elbow (Fig. 14-5). Conversely, a laterally displaced supracondylar fracture is more stable in supination. Experimental

data by Abraham (2) questioned this generally accepted concept, suggesting that little stability results from an intact periosteal hinge. If the periosteum is intact medially and laterally in a supracondylar fracture with pure posterior displacement, it may yield a very stable reduction.

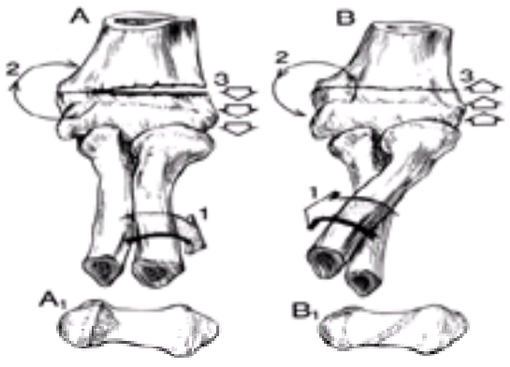

FIGURE 14-5. Intraarticular stabilizing forces. **A:** Supination of the forearm (*1*) creates a downward lateral tilt of the distal fragment (*3*). This produces compressive forces between the articulating surface of the ulna and the medial border of the trochlea (*A1, stippled area*), which in turn generates clockwise forces (*2*) about the medial side of the fracture. **B:** Pronation of the forearm (*1*) creates an upward tilt of the distal fragment (*3*) because of the compressive forces between the articulating surface of the ulna and the lateral border of the trochlea (*B1, stippled area*), which in turn generates counterclockwise forces (*2*) about the medial side of the fracture. (Reprinted from Abraham E, Powers T, Witt P, et al. Experimental hyperextension supracondylar fractures in monkeys. *Clin Orthop* 1982;171:309-318; with permission.)

Posteromedial versus Posterolateral Displacement of Extension-Type Supracondylar-Type Fractures

Generally, medial displacement of the distal fragment is more common than lateral displacement, occurring in approximately 75% of patients in most series (191). However, in one series with a high preponderance of median nerve and brachial artery injuries, 47% of patients had posterolateral displacement of the distal humeral fragment (36). The biceps tendon insertion and axis of muscle pull lies medial to the shaft of the humerus, and Holmberg (91) suggested that this anatomic location of muscle pull created a force that tended to displace the distal humeral fragment medially.

The position of the hand and forearm at the time of injury plays a role in the direction of displacement of the distal humeral fragment. In a patient who falls onto an outstretched supinated arm, the forces applied tend to disrupt the posteromedial periosteum first and displace the fragment posterolaterally. Conversely, if a patient falls with the arm pronated, the distal fragment tends to become displaced posteromedially. Whether the displacement is medial or lateral is important because it determines which soft tissue structures are at risk from the penetrating injury of the proximal metaphyseal fragment. Medial displacement of the distal fragment places the radial nerve at risk, and lateral displacement of the distal fragment places the median nerve and brachial artery at risk (Fig. 14-6). The brachial artery and median nerve may become entrapped in the fracture site with lateral displacement, but they are highly unlikely to become entrapped with the distal fragment displaced medially. The brachial artery is placed further at risk by the ulnar-sided tether of the supratrochlear artery (Fig. 14-7).

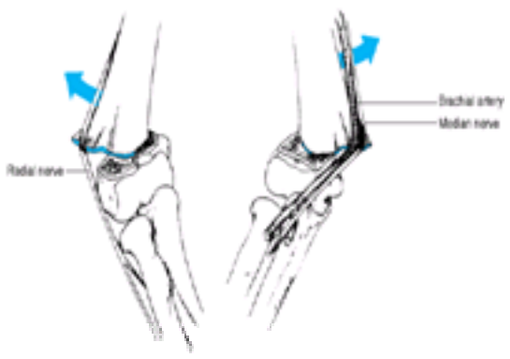

FIGURE 14-6. Neurovascular relations. **Left:** If the distal spike penetrates the brachialis muscle laterally (posteromedial fractures), the radial nerve may be tethered. **Right:** If the spike penetrates medially (posterolateral fractures), both the median nerve and brachial artery can be tethered.

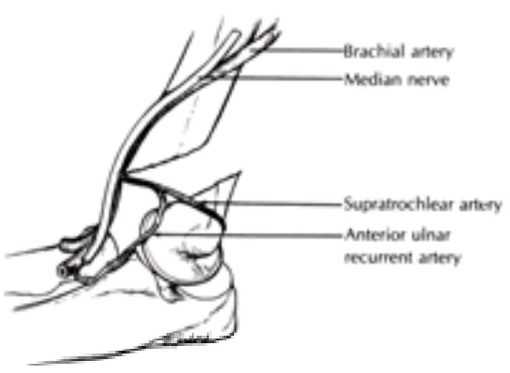

FIGURE 14-7. Arterial pathology. The supratrochlear branch that arises from the anterior ulnar recurrent artery may bind the main trunk of the brachial artery against the sharp end of the proximal fragment. (Redrawn from Rowell PJW. Arterial occlusion in juvenile humeral supracondylar fracture. *Injury* 1974;6:254-256; with permission.)

The Gartland classification of supracondylar fractures is currently the most commonly used system based on its prevalence in the literature and use in pediatric fracture texts. It is easy to use and facilitates treatment decisions and communication. The Gartland (74) classification (Table 14-2) is based on the radiographic appearance of fracture displacement. A type I or nondisplaced fracture (Fig. 14-8) has an anterior humeral line that intersects the capitellum, an intact olecranon fossa, no medial or lateral displacement, no medial column collapse, and a normal

Type I	Undisplaced
Type II	Displaced (with intact posterior cortex)
Type III	Displaced (no cortical contact)
	Posteromedial
	Posterolateral

TABLE 14-2. CLASSIFICATION OF SUPRACONDYLAR FRACTURES

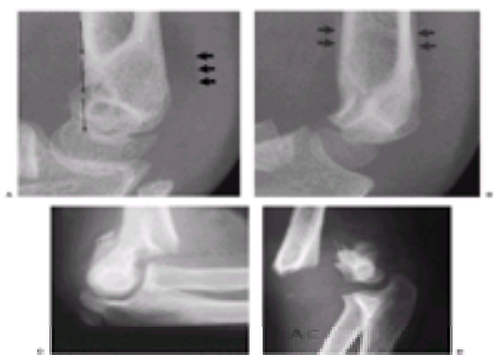

FIGURE 14-8. Types of supracondylar fractures. **A:** Type I fracture, where the anterior humeral line (*long arrows*) crosses through the ossification center of the capitellum. There is also posterior displacement of the olecranon fat pad (*large arrows*). **B:** Three weeks postinjury, there is evidence of new periosteal bone formation from both the anterior and posterior cortices (*arrows*). Because a definite fracture line was not seen in the original radiographs, this new bone formation confirms the original suspicion of a fracture. **C:** Type II. Lateral view of a displaced supracondylar fracture with the posterior cortex intact. There is both rotation and angulation of the distal fragment. **D:** Type III. Totally displaced fracture. There is no contact between the fragments.

Baumann angle. A type II fracture is extended but not translated with an intact posterior cortex. The anterior humeral line does not intersect the capitellum. Some rotational displacement and tilt into varus, as determined by the Baumann angle, may be present. A type III fracture has a circumferential break in the cortex with displacement of the fracture fragments. In the common extension type supracondylar fracture, the distal fragment is displaced posteriorly with the metaphyseal fragment impaled into the brachialis muscle and anterior soft tissues. The radiographic appearance of the distal fragment may be highly variable depending on (a) the degree of ossification of the distal humeral epiphysis, (b) size of the ossified metaphyseal fragment, and (c) position of flexion and rotation of the distal humeral fragment.

Signs and Symptoms

An elbow or forearm fracture should be suspected in a child with elbow pain or failure to use the upper extremity after a fall. Initial radiographs should include the entire extremity, because multiple fractures may be present even with what seems like minor trauma. In children with elbow pain and failure to use the upper extremity, the differential diagnosis should include occult fracture, nursemaid's elbow, and infection. With a clear history of a “pulling type” of injury, manipulation for a nursemaid's elbow may be performed before a radiograph is obtained. In general, if the history is not clear or there is any question of a fall onto an outstretched hand as the mechanism of injury, a radiograph should always be obtained before elbow manipulation. With a type I supracondylar fracture, there may be distal humeral tenderness, lack of the anconeus soft spot (elbow effusion), restriction of motion, and evidence of bruising. In type III fractures, gross displacement (Fig. 14-9) of the elbow is evident. An anterior pucker sign (191) may be present if the proximal fragment has penetrated the brachialis and the anterior fascia of the elbow (Fig. 14-10). When the proximal fragment is disengaged from its pucker in the skin, there is sometimes bleeding with signs of a grade I open fracture. Careful motor, sensory, and vascular examinations should be performed in all patients. This may be quite difficult in a young child but should be attempted. Sensation should be tested in discrete sensory areas of the radial nerve (dorsal first web space), medial nerve (palmar index finger), and ulnar nerve (palmar little finger). Motor examination should include finger, wrist, and thumb extension (radial nerve), index distal interphalangeal and thumb interphalangeal flexion (AIN), and thenar (median) and interossei (ulnar nerve) muscle function. The vascular examination should include determining the presence of pulse, as well as warmth, capillary refill, and color of the hand. Tenseness of the volar compartment should be evaluated, and the amount of swelling about the elbow should be noted. Passive finger extension and flexion should be tested and findings accurately recorded. In the initial examination of a child with a severe supracondylar fracture with high parental and patient anxiety, it is easy to overlook vital information. However, because further decision making is dependent on an accurate initial examination, care should always be taken to obtain all of the above information as accurately as possible. When the elbow injury is obvious, its examination should be delayed until the proximal humerus and distal radius have been fully examined for associated or occult fractures.

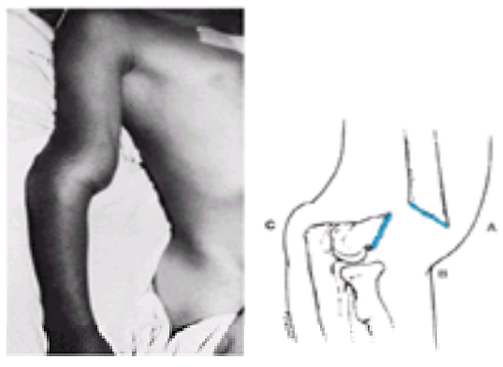

FIGURE 14-9. Clinical appearance. The S-shaped configuration is created by the prominence of the spike of the proximal fragment *(A)*, flexion of the distal fragment *(B)*, and the posterior prominence of the olecranon *(C)*.

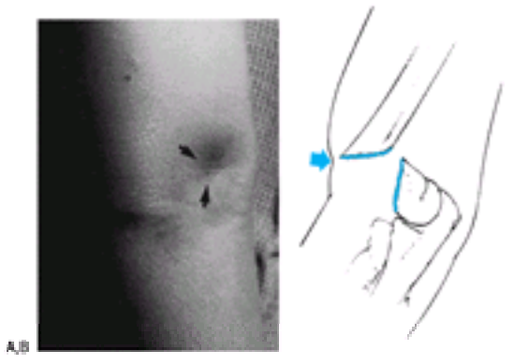

FIGURE 14-10. The pucker sign. This patient had penetration of the spike of the proximal fragment into the subcutaneous tissue. In the anteroposterior view **(A)**, there is a large puckering or defect in the skin where the distal fragment has pulled the skin inward. Laterally **(B)**, there is puckering of the skin (*arrow*) in the area where the spike has penetrated into the subcutaneous tissue.

Radiologic Evaluation

All patients with a history of a fall onto an outstretched hand and pain and inability to use the extremity should undergo a thorough radiologic evaluation. This may include obtaining AP views of the entire upper extremity (Fig. 14-11). Comparison views rarely are required by an experienced physician, but occasionally may be needed in the evaluation of an ossifying epiphysis. The AP radiograph should always be taken as an AP of the distal humerus rather than an AP of the elbow in which the elbow is held in flexion. This allows more accurate evaluation of the distal humerus and decreases the error in determining angular malalignment in the distal humerus. It also allows better evaluation of the olecranon fossa as an indication of injury in the distal humerus. The lateral film should be taken as a true lateral with the humerus held in the anatomic position and not externally rotated (Fig. 14-12). Oblique views of the distal humerus (Fig. 14-13) occasionally may be helpful when a supracondylar fracture or occult lateral condylar fracture is suspected but not seen on standard AP and lateral views, but should not be routinely ordered in the evaluation of an elbow injury.

FIGURE 14-11. Occult ipsilateral fractures. **A:** Type II supracondylar fracture (*open arrow*) with an occult distal radial fracture (*solid arrows*). **B:** Type II supracondylar fracture (*open arrows*) with an occult proximal humeral fracture (*solid arrows*).

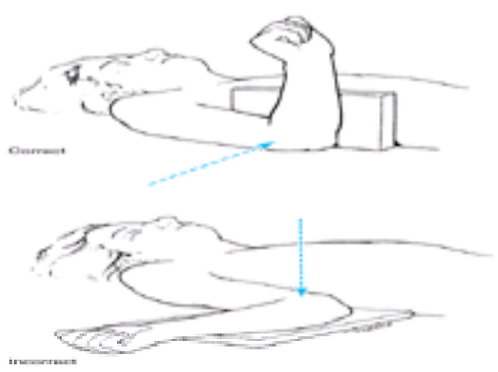

FIGURE 14-12. Radiographic positioning. The correct method of taking a lateral view is with the upper extremity directed anteriorly rather than externally rotated.

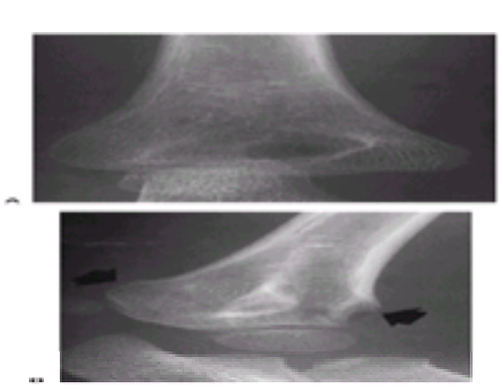

FIGURE 14-13. Oblique views. Often, the fracture line is not visualized on any of the lateral or anteroposterior views **(A)**. An oblique view **(B)** of the distal humerus may demonstrate the extent of the fracture line (*arrows*)

If the AP and lateral views show a displaced type II or III supracondylar fracture but do not show full detail of the distal humeral fragment, we usually obtain further radiologic evaluation in the operating room with the patient anesthetized. Repeat trips for radiologic evaluation in the emergency setting generally result in increased pain without significant improvement in radiograph quality. Detailed radiographs need to be obtained at some point, however, to define the fracture anatomy with particular emphasis on (a) impaction of the medial column, (b) supracondylar comminution, and (c) vertical split of the epiphyseal fragment. T-condylar fractures (Fig. 14-14) can initially appear to be supracondylar fractures, but these generally occur in children 8 to 10 years of age, in whom supracondylar fractures are less likely, although T-condylar fractures have been reported in young children.

FIGURE 14-14. Occult T-condylar. **A:** Original radiographs appear to show a type III posteromedial supracondylar fracture. **B:** After manipulation, the vertical intercondylar fracture line (*arrows*) was visualized.

In a young child, an epiphyseal separation (55,56,200) can mimic an elbow dislocation. In an epiphyseal separation, the fracture propagates through the physis without a metaphyseal fragment. This fracture occurs in very young children with primarily chondral epiphyses. On physical examination, the patient appears to have a supracondylar fracture with gross swelling about the elbow and marked discomfort. The key to making the diagnosis and differentiating this injury from an elbow dislocation is seeing that the capitellum moves with the radial head. Sometimes a supracondylar fracture with a small metaphyseal fragment can mimic a lateral condylar fracture (Fig. 14-15). In such cases, more data are required to initiate treatment. An arthrogram may be helpful to determine the extent of the elbow injury. In

selected patients, magnetic resonance imaging or ultrasonography (200) also may aid in evaluation of injury to the unossified epiphysis.

FIGURE 14-15. This 1.2-year-old girl sustained a fracture that on the anteroposterior view **(A)** appears like an elbow dislocation and on the lateral view **(B)** has the appearance of a lateral condyle fracture. **(C)** Arthrography showed the outline of the entire cartilaginous epiphysis. This is an epiphyseal separation with a metaphyseal fragment (Salter II).

Treatment

General Principles

Initial management of all patients suspected of having an elbow injury is splinting in a comfortable position, generally 20 to 30 degrees of elbow flexion, pending careful physical examination and radiologic evaluation. The initial responder to a child with an elbow injury and polytrauma should make an assessment of neurovascular status and other injuries, including but not limited to head injury and general cardiorespiratory status. Excessive flexion or forced extension should be avoided, because both may lead to vascular compromise.

Type I (Nondisplaced)

The distal humeral injury may not be the primary problem: neurologic compromise has been reported with nondisplaced supracondylar fractures (160). Radiographs of the entire extremity should be reviewed to be sure that there is no injury in other parts of the humerus or in the forearm bones. On radiography, a type I supracondylar fracture has a visible fracture line traversing the medial and lateral columns at the level of the olecranon fossa without displacement. The anterior humeral line transects the capitellum. In general, in a type I fracture, the periosteum is intact with significant inherent stability of the fracture.

Simple immobilization with a posterior splint applied in 90 degrees with side supports or simple collar and cuff is all that is necessary (40,193). This allows swelling to occur and does not put the brachial artery at risk of compression. Mapes and Hennrikus (121), using Doppler examination of the brachial artery after supracondylar fractures, found that flow was decreased in the brachial artery in positions of pronation and increased flexion. A simple splint with the forearm in neutral position and the elbow flexed no more than 90 degrees should be used initially. Before the splint is applied, it should be confirmed that the pulse is intact and that there is good capillary refill. A circumferential cast may be applied if additional fractures require treatment, but careful observation is necessary to avoid any risk of compartment syndrome.

Radiographs are obtained 3 to 7 days after fracture to document lack of displacement, and a long arm cast can be applied with a ring over the distal portion of the cast and a sling around the neck to support the weight of the cast (Fig. 14-16). Without support, the weight of the cast applies an extension torque about the distal humerus, leading to fracture displacement. If there is any evidence of extension of the distal fragment, as judged by lack of intersection of the anterior humeral line with the capitellum, the fracture should be reduced with hyperflexion of the elbow to 120 degrees with pinning. The most common cause of cubitus varus deformity is inadequate treatment of types I and II fractures, rather than the deformity complicating type III fractures.An acceptable position is determined by the anterior humeral line transecting the capitellum, a Baumann angle of 70 to 78 degrees or equal to the other side, and an intact olecranon fossa. Medial column collapse can lead to varus deformity in an otherwise minimally displaced and normally healing distal humeral fracture. The duration of immobilization for supracondylar fractures is about 3 weeks, whether type I, II or III. In general, no physical therapy is required after this injury. Patients are seen at 2 to 4 weeks after immobilization is removed to be sure that range of motion and strength are returning normally.

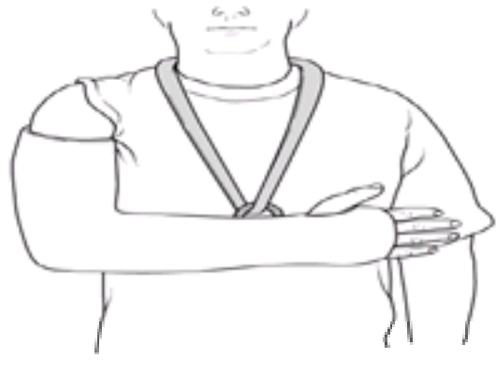

FIGURE 14-16. Because the weight of the cast can produce an extension movement about the distal humerus, a sling to support the weight of the cast is necessary.

Type II Fracture (Displaced with an Intact Posterior Cortex)

This fracture category encompasses a broad array of distal humeral hyperextension injuries, depending on the degree of rotation. Even greater than the variation in fracture stability is the spectrum of soft tissue injuries with type II supracondylar fractures. Careful assessment of the soft tissue injury is critical in treatment decision making. Radiologic definition of this injury demonstrates an incomplete osseous separation with some posterior cortical contacts. Therefore, good stability should be obtained with closed reduction. Medial column collapse (Fig. 14-17) or buckling must be identified because a varus deformity may result from a simple closed reduction without stabilization when these are present. For closed reduction, traction is applied first, followed by correction of rotational deformity. The extension deformity is corrected with pressure by the surgeon's thumb over the olecranon and posterior humeral condyles. The alignment of the distal humeral fragment is verified in AP and lateral views. With the elbow held in hyperflexion, Jones' views, rotating the arm slightly to expose the medial and lateral column of the distal humerus, are valuable to document reduction.

FIGURE 14-17. Greenstick medial collapse. **A:** An anteroposterior view of a type II fracture showing greater collapse of the weaker medial column (*arrows*). **B:** Lateral view showing the posterior cortex is still partially intact. (Reprinted from Wilkins KE. The management of severely displaced supracondylar fractures of the humerus. *Techniques Orthop* 1989;4:12-24; with permission.)

Millis (132), as well as others (13,26,86,94,147,161), have shown the necessity of elbow hyperflexion to more than 120 degrees to maintain reduction of an extension-type supracondylar fracture without pinning (Fig. 14-18). Therefore, the decision must be made to either place Kirschner wires in the distal humerus to stabilize the fracture, allowing immobilization in a comfortable position of less than 90 degrees of elbow flexion, or to place the child in a cast with the elbow in 120 degrees of flexion. The presence of significant swelling, obliteration of pulse with flexion, neurovascular injuries, and other injuries in the same extremity are indications for pin stabilization of a type II fracture. If pinning is chosen, two lateral pins (42,181) through the distal humeral fragment, engaging the opposite cortex of the proximal fragment, are generally sufficient to maintain fracture alignment (Fig. 14-19). Some degree of inherent stability is provided by the posterior cortex and the intact periosteum. Cross pinning of this fracture rarely is needed. The techniques for crossed and lateral pinning are described later on in this chapter. If pin stabilization is used, the pins are left protruding through the skin and are removed at 3 to 4 weeks after fixation, generally without the need for sedation or anesthesia.

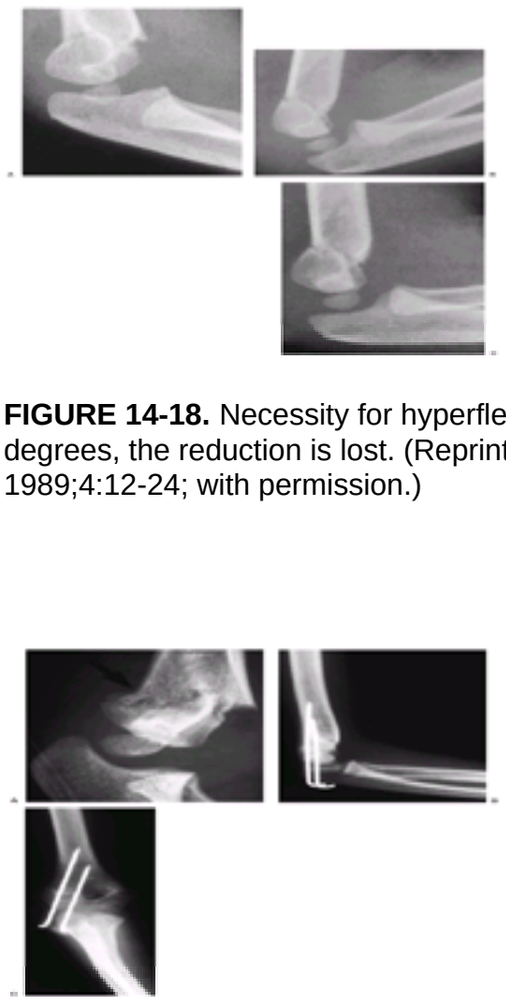

FIGURE 14-18. Necessity for hyperflexion. **A:** Injury film. **B:** Hyperflexion of the elbow adequately reduced the fracture. **C:** When the elbow is extended to only 90 degrees, the reduction is lost. (Reprinted from Wilkins KE. The management of severely displaced supracondylar fractures of the humerus. *Techniques Orthop* 1989;4:12-24; with permission.)

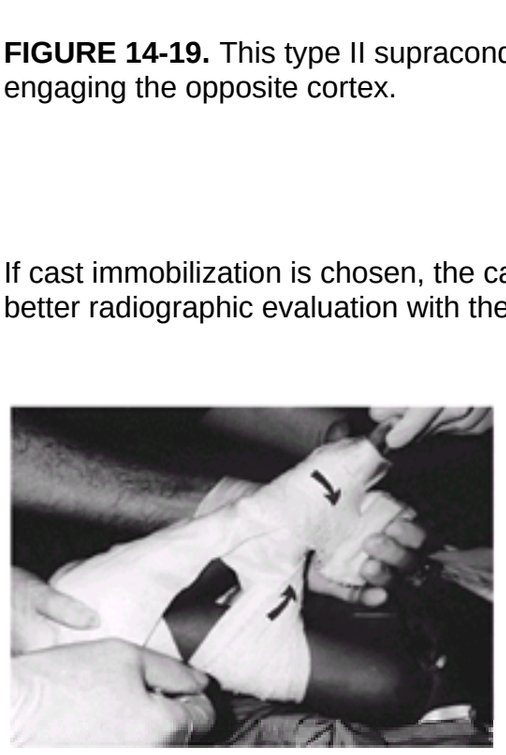

FIGURE 14-19. This type II supracondylar fracture **(A)** is stable after closed reduction and is ideal for pinning with two lateral pins **(B and C)** placed parallel and engaging the opposite cortex.

If cast immobilization is chosen, the cast should be a figure-of-eight (Fig. 14-20) cast sparing the antecubital fossa. We generally make this with fiberglass to allow better radiographic evaluation with the cast in place. Hadlow (83) reported that closed reduction and casting were satisfactory without pinning in 37 of his 48 patients.

FIGURE 14-20. Figure-of-eight wrap. In the figure-of-eight cast, both the padding and the plaster are wrapped in a figure-of-eight manner (*arrows*). (Reprinted from Wilkins KE. The management of severely displaced supracondylar fractures of the humerus. *Techniques Orthop* 1989;4:5-24; with permission.)

An alternative method of closed management is the use of a collar and cuff (40) (Fig. 14-21). The advantages of this treatment are a lack of circumferential rigid casting and the avoidance of the weight of the cast, which may produce an extension moment. In this technique, the elbow is held in hyperflexion by the collar and cuff, but not in a rigid manner, which decreases the risk of vascular compromise. After 3 weeks of immobilization, the patient is allowed to begin active motion out of the collar and cuff.

FIGURE 14-21. A collar and cuff is a safe treatment that can be used to maintain reduction in hyperflexion.

Type III Extension Supracondylar Fracture

In this fracture the periosteum is torn, there is no cortical contact between the fragments, and soft tissue injury may accompany the fracture. Careful preoperative evaluation is mandatory. If circulatory compromise is indicated by absent pulse and a pale hand, or if compartment syndrome is suspected, immediate reduction and skeletal stabilization are mandatory. Alternative methods of management, including traction and closed reduction with collar and cuff or casting can be used in the absence of acute vascular insufficiency. There are two viable alternatives for achieving fracture alignment: acute manipulative reduction and traction.

Technique of Reduction

Whether a fracture is held in place with pins or a cast, realignment of the humerus is necessary and the technique of manipulative reduction is the same (Fig. 14-22). The patient is anesthe- tized and the affected arm is extended over the screen of the **C**-arm fluoroscopic unit. Longitudinal traction is applied first to dislodge the proximal fragment, which may be entrapped in the brachialis muscle, the antecubital fascia, or the superficial fat and skin. If traction does not restore length and alignment, a “milking maneuver” has been described by Archibeck (11) and Peters (145) to disengage the proximal fragment from the soft tissue. This is done by manipulating the soft tissue over the fracture to pull the soft tissue away from the proximal fragment rather than simply applying traction on the bones, which may not allow reduction of a buttonholed proximal fragment. Once length is restored, medial or lateral translation is corrected. The image intensifier is helpful for this because the medial and lateral columns should be realigned on the AP image. Rotation is corrected simultaneously, but in general, malrotation resolves as traction is applied and the medial and lateral alignment corrected, because of the effect of the surrounding soft tissue. A flexion reduction maneuver is then performed with pressure of the thumb over the olecranon and to a variable degree over the distal condyles of the humerus. Generally the fracture reduction can be felt, and the elbow is then held in hyperflexion and pronation to achieve a stable reduction.

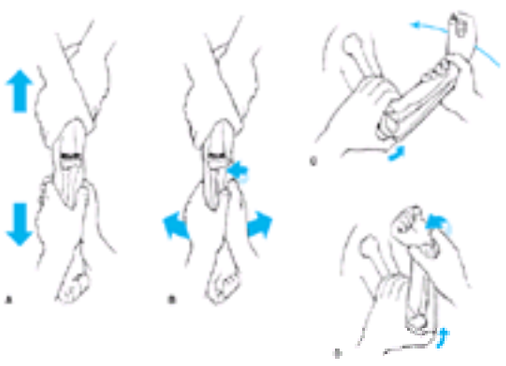

FIGURE 14-22. Manipulative closed reduction. **A:** Traction is applied with the elbow in extension and the forearm in supination. The assistant stabilizes the proximal fragment. After traction has been applied and the length regained, the fracture is hyperextended to obtain apposition of the fragments. **B:** With traction being maintained, the varus or valgus angulation along with the rotation of the distal fragment is corrected. **C:** Once the length and alignment have been corrected, the elbow is flexed. Pressure is applied over the posterior aspect of the olecranon to facilitate reduction of the distal fragment. **D:** The distal fragment is finally secured to the proximal fragment by pronating the forearm.

Anteroposterior and lateral views are obtained using the image intensifier. With the elbow flexed, a pure AP view is nearly impossible to interpret, so the actual AP view is taken by rotating the arm slightly medially and laterally to view the columns of the distal humerus and the reduction of the fracture (Fig. 14-23). The arm is then externally rotated to obtain a lateral view of the distal humerus. The surgeon rotates the entire arm by placing one hand on the proximal humerus and the other holding the wrist pronated with the elbow hyperflexed. This is generally a stable position that will allow rotation of a reduced supracondylar fracture. The lateral image is then evaluated for restoration of the cortical contour of the distal humerus, reduction of the fracture gap, and presence of the anterior humeral line intersecting the capitellum.

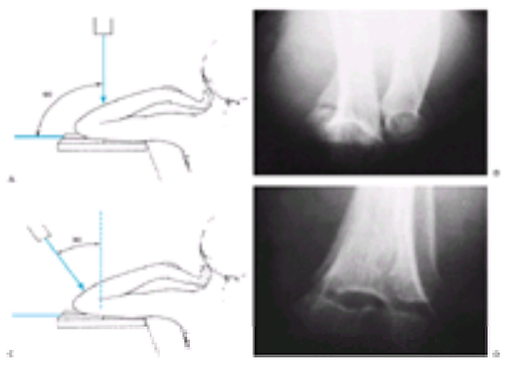

FIGURE 14-23. Jones view. **A:** The proper elbow position and tube direction for the Jones view. **B:** radiograph of an elbow taken with the tube 90 degrees to the film. **C:** Cephalad angulation of the tube distorts the image of the distal humerus. **D:** Radiograph of the same elbow with the tube angulated cephalad.

Rotating the arm with the fracture reduced and held in a stable position is possible in nearly all posteromedially displaced supracondylar fractures (Fig. 14-24). In posterolaterally displaced supracondylar fractures, however, the reduction is frequently unstable in hyperflexion and may be less stable in pronation. If the fracture reduction is unstable, the **C**-arm should be rotated to obtain AP and lateral views rather than attempting to rotate the arm and losing a tenuous reduction. An anatomic or nearly anatomic reduction is a prerequisite for skeletal stabilization. If this cannot be achieved by closed reduction, traction or open reduction can be used.

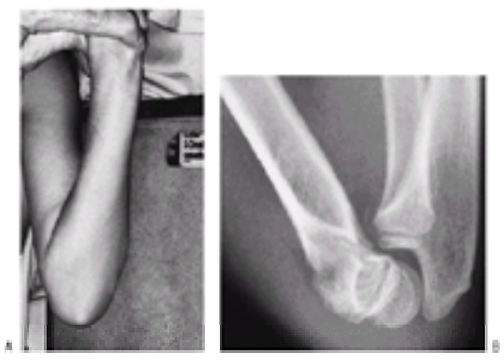

FIGURE 14-24. Stability in external rotation. **A:** The stability of type II fractures is tested by taking a lateral radiograph with the extremity fully externally rotated. **B:** If there is sufficient intrinsic stability, the fracture will remain reduced on the radiograph.

Cast Immobilization Technique

Because type III fractures are intrinsically unstable, the elbow must be held in extreme flexion to prevent the distal fragment from rotating; these fractures tend to rotate with flexion of less than 120 degrees (132). Usually, however, severe swelling prevents the elbow from being kept in hyperflexion. When the swelling subsides, the distal fragment tends to rotate horizontally, making it susceptible to varus angulation, particularly if the fracture line is angulated (Fig. 14-25). In most series (48,110,147,186) the results of type III fractures treated with closed reduction and cast immobilization are not as good as those treated with pinning. However, Hadlow et al. (83) suggested that selective use of casting is beneficial, reporting that in their series, 61% of type III and 77% of type II fractures were successfully treated without pinning.

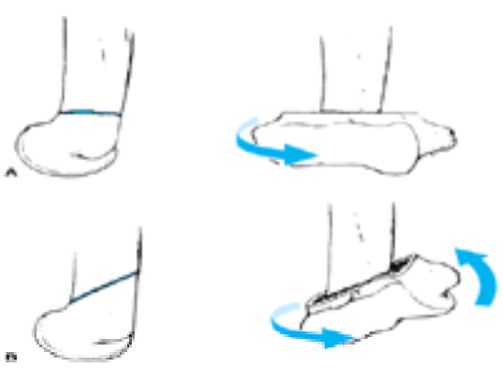

FIGURE 14-25. Effects of obliquity of the fracture line. If the fracture line is transverse **(A)**, pure rotation does not produce angulation. If the fracture line is oblique **(B)**, rotation of the distal fragment produces a secondary distal angulation.

A figure-of-eight cast is used to maintain flexion of at least 120 degrees. If the arm can be flexed to 120 degrees with an intact pulse, casting can be used as primary treatment. Alburger et al. (4) reported that using skin traction initially until swelling decreases allowed successful use of casting without pinning. Although a number of historic series used casting as primary treatment, most recent reports favor pinning of this fracture. When a cast is used as primary treatment, it should be worn for 3 to 4 weeks. After cast removal, motion is encouraged and the patient is placed in a sling until comfortable, which may vary from hours to days. Physical therapy usually is not required, because simple active motion is encouraged and usually is sufficient.

Technique of Pin Fixation

Pin fixation of supracondylar fracture of the humerus has been performed for over 50 years (131). Jones (99) and Swenson (178) were early advocates of this technique. Before the development of the fluoroscopic unit, blind pinning (91) was performed; Jones noted that this could be done without complications by even the “average surgeon.” Modern imaging techniques and improved power equipment have made percutaneous pinning the standard treatment for this difficult fracture. Flynn (66,67), and later Wilkins (190,191), among others (29,127,128,147,148) popularized modern pinning techniques and documented their value. Present controversy includes (a) crossed pins (Fig. 14-26) or two lateral pins; (b) burying pins or leaving them out through the skin; (c) timing of pinning, that is, emergent, urgent, or elective; and (d) the role of open reduction. Absorbable polyglycolide pins have not been found suitable for fixation of supracondylar fractures (28).

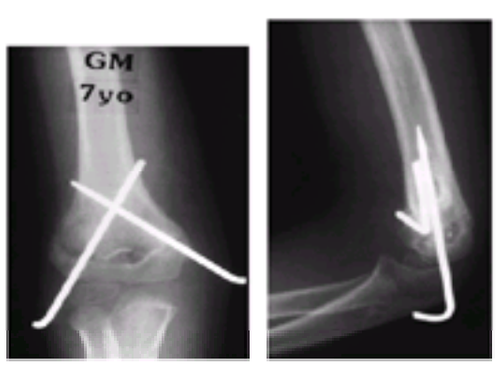

FIGURE 14-26. Crossed pinning is a more stable configuration than two lateral pins. The lateral pin is placed at the border of the ossified lateral condyle. The medial pin enters the medial epicondyle and is generally more transverse than the lateral pin.

Zionts (199) evaluated the torsional strength of pin configurations in an adult humeral cadaver model. The maximal strength was gained by using two crossed pins with one placed through the medial condyle and one through the lateral condyle, extending up the corresponding columns and engaging the opposite cortex. The torque required to produce 10 degrees of rotation averaged 37% less with two lateral pins parallel and 80% less with two lateral pins crossed than with medial and lateral crossed pins. Thus, lateral pinning required significantly less force to produce 10 degrees of displacement than did crossed pinning (Fig. 14-27). The question, however, is whether the resistance to torque provided by lateral pinning is sufficient to allow fracture healing without displacement, if supplemented by cast immobilization in the clinical setting. In addition, the experimental models have no intact periosteum, which will provide further fracture stability, nor do they have pediatric cancellous bone, which may be quite different in terms of pin fixation mechanics.

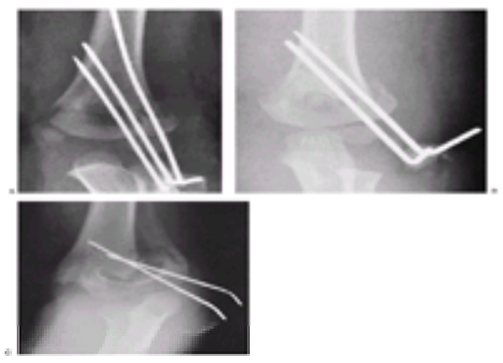

FIGURE 14-27. Lateral pin constructs. **A:** Three lateral pins. **B:** Two parallel pins. **C:** Late displacement in a patient with two small lateral pins that crossed at the fracture site. (Reprinted from Wilkins KE. The management of severely displaced supracondylar fractures of the humerus. *Techniques Orthop* 1989;4:212-224; with permission.)

Onwuanyi (141), in a clinical series, also concluded that there was greater stability or ability to maintain reduction with the crossed pinning technique. Cheng (42) reported 180 type III supracondylar fractures treated with lateral pinning as primary treatment in nearly all. He reported very low incidences of cubitus varus deformity and loss of reduction and concluded that in actual practice there was no difference between two lateral pins and crossed pins. He recommended lateral pins as the treatment of choice because there is less risk of ulnar nerve injury with this technique.

The primary risk with crossed pinning is injury to the ulnar nerve by a medial pin. The frequency of ulnar nerve injury in reported series ranges form 0 to 5% (33,93,153,157). Because the ulnar nerve may sublux anteriorly when the elbow is hyperflexed in as many as 30% of patients (198), it is at significant risk in the crossed pinning technique. Locating the ulnar nerve with a nerve stimulator has been suggested (129). Making a small 1.5-cm incision over the medial epicondyle for placement of the medial pin also has been proposed as a way to locate and protect the ulnar nerve. This technique works well and may avert the problem of iatrogenic ulnar nerve injury when crossed pinning is required for very unstable fractures. Also, placing the lateral side pin first with the elbow hyperflexed and then placing the medial pin with the elbow in only 90 degrees of flexion lessens this risk.

Technique of Pinning: Crossed Pins

Steel pins 0.062 or 0.075 mm (5/64th inches) in diameter are used. (Fig. 14-28). After reduction of the fracture and with the **C**-arm screen used as an operating table, the arm is held with the elbow hyperflexed and the forearm pronated to maintain the reduction. Anatomic reduction is confirmed with the image intensifier before pinning. The lateral pin is inserted first. The insertion site is made so that the pin will traverse the lateral portion of the ossified capitellum, cross the physis, proceed up the lateral column, and engage the opposite medial cortex proximally. Using a Kirschner wire or radiodense object, the position for insertion of the pin is documented. A small incision is made in the skin. The pin is placed using a power drill and sharp Kirschner wire or Steinmann pin. Provisional stability is achieved with the first pin. Then the elbow is gently extended to about 45 degrees of flexion to allow a perfect AP radiograph of the distal humerus to ensure anatomic alignment. The elbow is then flexed to 120 degrees and externally rotated and a lateral image is obtained with fluoroscopy. A second pin is then placed medially. A small 1.5-cm incision is made over the medial epicondyle and dissection is performed down to the level of the medial epicondyle. If the ulnar nerve has subluxed over the medial epicondyle, sometimes blunt dissection stimulates the nerve and the fingers will move slightly. If the ulnar nerve is found, it should be retracted posteriorly and a pin placed through the medial epicondyle under direct vision. The position of the Kirschner wire from the medial side is confirmed with fluoroscopy. The pin should enter the medial epicondyle and not the ulnar groove. The medial pin is generally more horizontal than the lateral pin and should traverse the medial column and engage the opposite lateral cortex.

FIGURE 14-28. Lateral pin placement. **A:** The lateral pin is placed first using the C-arm screen as an operating room table. The elbow is held in hyperflexion for the placement of the lateral pin. **B:** The lateral view is obtained by externally rotating the arm, holding the elbow in hyperflexion for stability.

Variations in the crossed pinning technique include: (a) no medial incision (Fig. 14-29); (b) maintenance of reduction by strapping the arm in a position of hyperflexion before pinning (Wilkins; Fig. 14-30) (191); (c) using a bar as a fulcrum to facilitate reduction, as described by Flynn (66); and (d) pinning the medial side first with the elbow in hyperflexion. If no medial incision is used, the ulnar nerve is palpated and pushed posteriorly as the pin is inserted. Pinning medially with the elbow in hyperflexion, as described by Wilkins, has the benefit of holding the fracture in better position while pinning, but does place the ulnar nerve at higher risk.

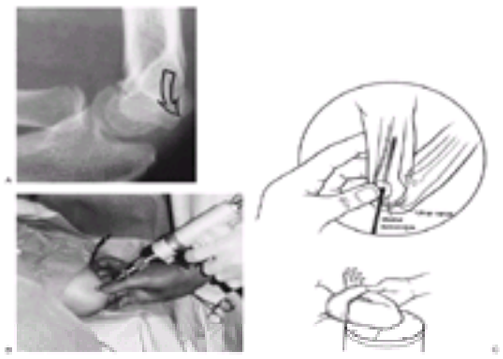

FIGURE 14-29. Medial pin placement. **A:** The medial epicondyle is posteromedial (*arrow*). **B:** The medial pin is placed directly through the medial epicondyle, using the opposite thumb to pull posterior the soft tissues, thus protecting the ulnar nerve. **C:** The relationship of vital structures during medial pin placement. The pin is directed from posteromedial to anterolateral directly through the center of the medial epicondyle under control of the image intensifier, with the upper extremity fully externally rotated.

FIGURE 14-30. Temporary stabilization. Once reduced, the elbow is taped into hyperflexion **(A)**. This allows the elbow to be manipulated into full external **(B)** and internal **(C)** rotation, providing direct lateral visualization of the respective medial and lateral condyles. (Reprinted from Wilkins KE. The operative management of supracondylar fractures. *Orthop Clin North Am* 1990;21:269-289; with permission.)

Two Lateral Pins

Two lateral pins (12,42,141) (0.062 or 0.75 mm) provide less stability than crossed pins, but there is no risk to the ulnar nerve, which is a significant benefit of this technique. The operating room set up for two lateral pins is exactly the same as that for crossed pins. After achieving closed reduction and confirming the position on AP and lateral views, the first pin site should be chosen with the second pin in mind. The goal is to have two pins that are parallel on the AP and lateral views. If the pins are placed so that they cross well proximal to the fracture, this may be satisfactory, but is not as secure as parallel pins. Two pins crossing at the fracture is unsatisfactory because torque will not be satisfactorily resisted and a rotational deformity may result.

In choosing a site for the first pin, we generally place it up through the center of the ossified capitellum. It engages the edge of the olecranon fossa, giving it greater stability, and then further penetrates the opposite cortex. A second pin is placed through the distal humeral epiphysis lateral to the capitellum but clearly within the epiphysis. It proceeds parallel to the first pin up the lateral column and engages the opposite cortex. If the first pin is placed centrally in the lateral column, the second pin will nearly always cross the first just above the fracture, and this will be a less satisfactory lateral pinning. Maximal pin separation and parallel alignment increase the stability with this technique.

The “shake test” can be used to test the stability of two lateral pins. If the arm can be grasped by the proximal humerus and shaken mildly without displacement of the fracture, the fixation is satisfactory. If displacement occurs, it is generally rotational with loss of reduction of the medial column. We simply reduce the fracture to an anatomic position and place a medial pin as described in the technique for crossed pinning. A third lateral pin will increase stability slightly, but is rarely necessary.

After pinning by any technique, the patient is placed in a splint or bivalved long arm cast with the forearm in neutral and the elbow flexed slightly less than 90 degrees. Although this position of flexion is chosen as a general rule, it is imperative that the elbow be placed in a position that is most favorable for neurovascular structures. If the pulse becomes weak or obliterated at 80 degrees of flexion, the arm should be put in a position where the pulse is strongest. The study by Mapes and Hennrikus (121), using Doppler evaluation of the brachial artery, showed that with progressive flexion and pronation, the pulse pressure and therefore flow was incrementally diminished. Fracture stability is gained by skeletal stabilization, and the splint or cast is simply placed to protect the patient. If a circular cast is used, it should be bivalved and spread to prevent constriction. In no case should a child be in a circular cast with the elbow hyperflexed following this procedure.

Iyengar et al. compared early and delayed pinning to determine whether fractures treated more than 8 hours after trauma had higher incidences of open reductions and complications (96). They concluded that there was no difference. However, this was a retrospective review and it is possible that severe fractures were treated emergently, which would bias the conclusion. In general, these fractures are treated emergently. With smooth pins left out through the skin, there is rarely a need for anesthesia for pin removal. A very low infection rate accompanies pinning (less than 1%) because they are in place only 3 to 4 weeks.

Intramedullary Pin Fixation

Prevot et al. (149) reported their experience with intramedullary fixation of supracondylar fractures in children. After closed reduction, the pins were inserted proximally at the junction of the middle and proximal third and passed distally in the shaft, diverging in each of the supracondylar columns. Their laboratory experiments comparing this type of fixation with medial-lateral and lateral pins demonstrated that proximally placed pins diverging in the distal fragment were more stable than other methods of percutaneous pin fixation.

AUTHORS' PREFERRED METHOD OF TREATMENT

When possible, we prefer closed reduction and pinning of type 2 and type 3 supracondylar fractures. Two lateral pins are chosen for a “stable” fracture, and crossed pins are used for very unstable fractures. We always make a small incision over the medial epicondyle to protect the ulnar nerve when using crossed pins.

Open Reduction

Closed reduction may not be possible because of interposed soft tissue, especially in posterolaterally displaced supracondylar fractures. Open reduction should be considered to obtain alignment if there is vascular compromise or neural entrapment, as judged by soft tissue interposition. An open reduction is also indicated if there is an open fracture that requires irrigation and debridement or simply if a satisfactory closed reduction cannot be performed.

During the early part of this century there was a reluctance to recommend open reduction of supracondylar fractures. With improvement in operative techniques and more experience with surgical intervention, open reduction of acute supracondylar fractures has now become widely accepted.

Fleuriau-Chateau et al. (65) reported excellent results with open reductions of irreducible fractures. The range of motion was satisfactory in 94% of patients, and none had myositis or cubitus varus deformity. Fifteen of the 25 children with irreducible fractures had entrapment of neurovascular structures preventing reduction. The high incidence of entrapment of neurovascular structures in individuals skilled in closed reduction supports the use of open reduction in irreducible fractures. The approach for open reduction has been somewhat controversial. Anterior, medial, lateral, and posterior approaches have all been recommended. Those who advocate medial and lateral approaches (189) operate through the side in which the periosteal hinge is torn; that is, a lateral approach is used for posteromedial displacement or a medial approach is used for posterolateral displacement. The posterior approach (166) to the elbow through the triceps muscle and tendon has been used with excellent results. Our preference is the direct anterior approach (52,77) through a transverse anterior incision in the antecubital fossa, extending proximally, medially as needed. The brachialis muscle is generally transected by the proximal humeral fragment. The structures remaining intact anteriorly are the biceps tendon and neurovascular bundle (Fig. 14-31). The anteromedial approach gives easy access to an entrapped neurovascular bundle and allows anatomic reduction of the humeral fracture under direct vision by simply placing a retractor on the remaining portion of the brachialis muscle.

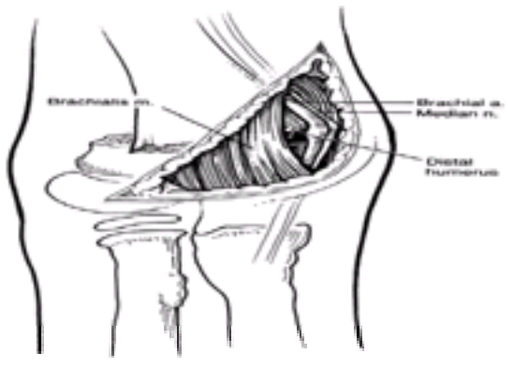

FIGURE 14-31. Tenting of neurovascular bundle. With posterolateral fractures, the neurovascular structures often are tented over the medial spike of the proximal fragment. This fragment can be “buttonholed” through the brachialis muscle.

Pins are then placed either medially and laterally or two lateral pins are used, as described above, to provide stable fixation. After open reduction, pins may be left in place slightly longer than after closed reduction, but there are no firm data on this. Good callus should be observed at the fracture before pin removal, generally 3 to 4 weeks after injury. Prolonged pin fixation is not necessary.

Incidence of Complications Lessened

One of the reasons for an increase in open reductions has been the recognition that complications are relatively few. The fears of infection, myositis ossificans, and neurovascular injury (74,163,170,187) have been dispelled by surgical experience (10,14,39,48,65,71,76). In a combined series of 470 fractures treated by open reduction, the incidence of infection was 2.5%, all of which resolved (5,21,37,52,75,79,82,85,103,108,138,147,151,165,186,189). The incidence of neurovascular complications from the procedure itself was essentially zero. Four patients with myositis ossificans (1.4%) were reported, all in a single series (79).

The most frequent complication of surgical management appears to be a loss of range of motion. One of the reasons given in the past for loss of motion was the use of a posterior approach. It has been stated that approaching the fracture through the relatively uninvolved posterior tissues, induces added scar leading to stiffness. In earlier reported series using a posterior approach, loss of range of motion was significant. However, in the past decade, use of a posterior approach with no significant increase in postoperative elbow stiffness has been reported. Residual cubitus varus occurred in as many as 33% of patients in some of the earlier series (7,51,79,189), most due to inadequate surgical reduction. When good reduction was accomplished, the incidence of cubitus varus was low. Surgical intervention does not guarantee an anatomic reduction; it is the quality of the reduction achieved at the time of surgery that is important.

Lal and Bahn (112) reported that delayed open reduction, 11 to 17 days after injury, did not increase the frequency of myositis ossificans. If a supracondylar fracture is unreduced or poorly reduced, delayed open reduction and pin fixation appear to be justified.

Open supracondylar fractures generally have an anterior puncture wound where the metaphyseal spike penetrates the skin. Even if the open wound is only a small puncture in the center of an anterior pucker, open irrigation and debridement are indicated. The anterior approach, using a transverse incision with medial or lateral extension as needed, is recommended. The neurovascular bundle is directly under the skin and tented over the metaphyseal fragment, so care should be taken in approaching this fracture surgically. Whereas the skin incision can be extended medially proximally and laterally distally, often only the transverse portion of the incision is required, which gives a better cosmetic result. The brachialis muscle usually is transected, because it is a muscle belly to its insertion on the coronoid attachment and is highly vulnerable to trauma from the proximal metaphyseal fragment. The fracture surfaces are examined and washed, and a curet is used to remove any dirt or entrapped soft tissue. Once the debridement and washing are complete, the fracture is stabilized with Kirschner wires. All patients with open fractures are also treated with antibiotics: cephalothin for Gustilo types 1, 2, and 3A injuries, with the addition of an aminoglycoside for types 3B and C fractures.

Traction Management of Type III Supracondylar Fractures

Traction can be used in two ways in the management of type III supracondylar fractures: to allow swelling to decrease and to facilitate closed reduction, as described by Alburger et al. (4) and others (171,197). In this technique, patients are placed in sidearm or overhead skin traction for 3 to 5 days until elbow hyperflexion can be tolerated for closed reduction. Alburger et al. reported 92% good or excellent results in 39 patients treated in this manner.

Definitive treatment of the fracture with 14 days of traction or until healing has occurred historically has led to a very low incidence of cubitus varus deformity, as documented by Smith (171,172). D'Ambrosia (51) in a series of supracondylar fractures treated with overhead skeletal traction, found no cubitus varus deformities; with sidearm or skin traction for definitive treatment, the rate of varus deformity was 33%. Piggot (146) documented the efficacy of straight lateral skin traction with a report of only 4% cubitus varus deformities and no vascular complications. A comparison by Prietto (150) of pinning and Dunlop's traction demonstrated the relative benefits of pinning in decreased costs and shorter hospital stays in addition to a lower cubitus varus rate. He reported a 5% rate of cubitus varus deformity in the pinning group and 33% in the Dunlop's traction group. Skeletal traction overhead with use of an olecranon wing nut (Fig. 14-32) has been advocated by Palmer (144), Worlock (197), and Badhe (16). Overhead traction was superior to sidearm traction and had a low incidence of cubitus varus (2%–9%) in these series. The olecranon wing nut is a simple device that can be placed in the proximal ulna without risk of injury to the ulnar nerve, as might occur in placing a transverse traction pin. The wing nut offers the advantage of applying a torque about the distal humeral fragment by changing the position of the traction rope into the holes in the wing nuts.

FIGURE 14-32. The olecranon wing nut is a simple skeletal traction device. Varying the insertion point of the rope alters torque about the distal fragment.

The indications for traction as the definitive management of a supracondylar fracture are (a) an unstable fracture reduction or pattern that cannot be pinned, and (b) supracondylar comminution or medial column comminution that is not suitable for pinning and would certainly collapse with simple casting after reduction. The duration of traction usually is about 14 days before cast immobilization in this rapidly healing fracture. Prolonged traction may be necessary if poor reduction is obtained in traction, because significant callus must be present for fracture stability before casting.

Technique of Traction Wing Nut Insertion

With the arm prepped in a sterile manner, a hole is drilled in the cortex opposite the coronoid process of the ulna. A 3.2-mm drill bit is used and a hole is made through both cortices just distal to the coronoid process. A wing nut is then placed through the small incision. The wing nut engages the opposite cortex but does not penetrate it. A sterile dressing is placed around the interface between the wing nut and skin. A traction rope and weights are applied (Fig. 14-33). A sling is used to support the hand and forearm. Initially, traction of about 5 pounds is applied, depending on the size of the patient. The shoulder should be lifted just off the bed (144).

AP and lateral radiographs should be taken in traction to judge the adequacy of reduction. After there is good callus formation (generally after 10 to 15 days), the patient is removed from traction and placed in a long arm cast, which is worn for about 2 weeks.

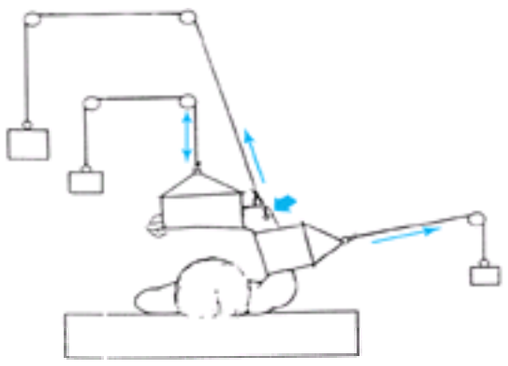

FIGURE 14-33. Overhead olecranon pin traction. The arm is suspended by a pin through the olecranon (*short arrow*). The forces maintaining the reduction (*long arrows*) are exerted upward through the pin and sideways through a counter-sling against the arm. The forearm is supported with a small sling (*double arrow*).

AUTHORS' PREFERRED METHOD OF TREATMENT

For supracondylar comminution (Fig. 14-34) where stable pinning is impossible to achieve, we have uniformly chosen traction. Although these fractures are relatively rare, they do occur, and orthopaedic surgeons should be familiar with the use of traction as a technique of management of this fracture. We use a traction wing nut rather than a transverse traction pin, but this is a matter of choice. Anatomic reduction of the fracture is not critical with traction, but maintenance of alignment is. Callus formation is rapid in the area of the fracture, and the distal fragment should be confirmed to be neither hyperextended nor rotated into varus or valgus malalignment, based on radiographic evaluation while in traction. After good callus formation (generally after about 14 days), the patient can be removed from traction and placed in a long arm cast.

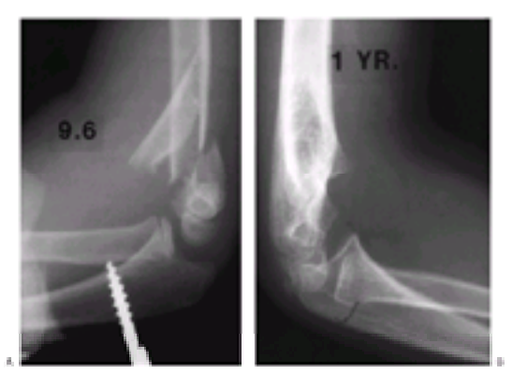

FIGURE 14-34. A: Because of supracondylar comminution, stable pinning could not be achieved and traction was chosen. **B:** Remodeling occurred over 1 year, and the patient regained full motion with normal alignment.

Vascular Injury

Type III supracondylar fractures have significant incidences of brachial artery injury, vascular insufficiency, and compartment syndrome, each of which should be evaluated separately in a patient with a severe elbow injury.

Brachial Artery Injuries and Vascular Insufficiency

About 10% to 20% of patients with type III supracondylar fractures present with an absent pulse (44,58,164). In the emergency management of a patient with a type III supracondylar fracture, the arm should be splinted with the elbow in about 30 degrees of flexion. This will facilitate transport of the patient to the appropriate facility for care and radiographic evaluation. The presence of a pulse and perfusion of the hand should be documented. Perfusion is estimated by color, warmth, and capillary refill. The question sometimes raised in the emergency room evaluation of a patient with supracondylar fracture and poor blood flow to the hand is whether an arteriogram should be performed as part of the preoperative evaluation. The answer is an emphatic “no” (164). The initial approach to management of a patient with vascular compromise secondary to a supracondylar fracture should be immediate closed reduction and stabilization with Kirschner wires. If an anatomic reduction cannot be obtained closed, open reduction through an anterior approach (14,65) with medial extension allows evaluation of the brachial artery and removal of the neurovascular bundle entrapped within the fracture site.

After closed reduction and stabilization, the pulse and perfusion of the hand should be evaluated. Most extension type supracondylar fractures are reduced and pinned with the elbow in hyperflexion. With more than 120 degrees of elbow flexion, the radial pulse generally is lost, even in patients with an initially intact pulse. After pinning when the arm is extended, the pulse frequently does not return immediately. This is presumably secondary to arterial spasm, aggravated by swelling about the artery and decreased peripheral perfusion in the anesthetized, somewhat cool intraoperative patient.

Because of this phenomenon, 10 to 15 minutes should be allowed for recovery of perfusion in the operating room before any decision is made about the need for exploration of the brachial artery and restoration of flow to the distal portion of the extremity. Because most patients without a palpable pulse maintain adequate distal perfusion, the absence of a palpable pulse alone is not an indication for exploration of a brachial artery. Gillingham and Rang (78) recommended observation of patients with absent pulse, because most pulses returned within 10 days. The decision to explore a brachial artery needs to be based on objective criteria, if possible.

Traditionally, the decision has been based only on whether the hand was warm and pink. The following case indicates the difficulty with this. A 2-year-old girl was injured in a fall from a couch (Fig. 14-35). A type III supracondylar fracture and a pale, cool hand were documented on presentation to a local emergency department. Two hours later, the patient was brought to the operating room, where a cool, pale hand with poor capillary refill and an absent pulse was noted. Immediate closed reduction and pinning was performed with nearly anatomic reduction. The hand felt warmer and capillary refill was present. The pulse was not palpable, but because of the improved state of the hand, no exploration of the brachial artery was performed. During the next 4 hours the patient was observed closely with increasing fussiness, a nonpalpable pulse, and slow capillary refill. At this point an arteriogram was performed, showing brachial artery obstruction. Compartment pressures were measured, and increased pressure was noted in the volar compartment. A decision was made to return to the operating room for exploration and repair of the brachial artery and forearm fasciotomy. Whereas the outcome in this case was satisfactory with no long-term sequelae, other than scarring, the question is whether the low perfusion with subsequent ischemia and compartment syndrome could have been identified at the time of the closed reduction and immediate repair done.

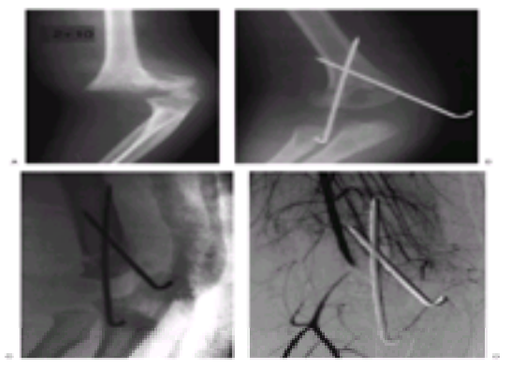

FIGURE 14-35. A: This 2-year-old patient sustained a type III supracondylar fracture with vascular compromise. **B:** Pinning was performed in a nearly anatomic position. **C and D:** Six hours postoperatively, increasing pain, a pale hand, and evolving compartment syndrome prompted arteriography, showing brachial artery occlusion.

What would happen if no repair had been performed in the above case? Had a repair been performed immediately, could the development of a compartment syndrome have been averted? What is the relationship between compartment syndrome and perfusion? Is there a way to determine when flow is insufficient in a more objective way?

Several investigators have attempted to provide criteria for repair in addition to warmth and color in the patient with absence of a palpable pulse. The use of simple Doppler ultrasonography in the operating room has been studied by two groups (162,164). In the absence of a palpable pulse, a Doppler device can be used to measure lower flow states with small pulse amplitude. Shaw (164) found no false-positive explorations when patients with pulses that could not be palpated but were identified on Doppler evaluation were observed and exploration was performed in those in whom no pulse was found with either palpation or Doppler. The brachial artery was either transected or entrapped in all patients with surgical exploration, and none with “spasm” had surgery. Schoenecker et al. (162), using the same criteria, identified six patients for exploration. Three had a damaged or transected brachial artery with no flow, and three had an artery kinked or trapped in the fracture. At follow-up, all patients with vascular repair had a radial pulse. One patient with more than 24 hours of vascular insufficiency had an unsatisfactory outcome. Copley et al. (44) reported that of 17 patients with type III supracondylar fractures and no palpable pulse at presentation, 14 recovered pulse after reduction. The three explorations identified significant vascular injury, and the brachial artery was repaired. In addition to Doppler evaluation, pulse oximetry (104,154) has been recommended. Our experience with the use of a Nelkor system for this technique is that when used in the operating room, it often underestimates perfusion. We believe this is secondary to its use in an anesthetized person with low blood pressure and peripheral vasoconstriction. As a patient is waking up and pulse pressure and peripheral circulation are increased, pulse oximetry becomes a valid way to determine perfusion. We have found it useful for evaluating patients after vascular repair or pinning but not for intraoperative decision making. Copley and Dormans, (44) reported that some patients who initially had good perfusion and an intact pulse lost both in the postoperative period. Two of 14 patients showed signs of increased vascular insufficiency over a 48-hour period and required subsequent reconstruction. Data such as this supports in-hospital observation of patients with supracondylar fractures, especially those with evidence of vascular compromise.

Obliteration of the radial pulse after closed reduction and pinning is a strong indication for brachial artery exploration. After 10 to 15 minutes is allowed for resolution of arterial spasm as a cause for loss of pulse, the brachial artery should be explored. Either direct arterial entrapment at the fracture or arterial compression by a fascial band pulling across the artery may cause loss of pulse after fracture reduction. As described above, the other indication for brachial artery exploration is persistent vascular insufficiency after reduction and pinning.

Exploration of the Brachial Artery

The orthopaedic surgeon and vascular surgeon need to work together in the management of this problem. Often release of a fascial band or adventitial tether resolves the problem of obstructed flow. This is a simple procedure performed at the time of exploration of the antecubital fossa and identification of the brachial artery. In some patients, however, a formal vascular repair and vein graft are required. The brachial artery should be approached through a transverse incision across the antecubital fossa, with a medial extension turning proximally at about the level of the medial epicondyle (Fig. 14-36). Care must be taken because the neurovascular bundle may be difficult to identify when it is surrounded by hematoma, but it may lie in a very superficial position. At the level of the fracture, the artery may seem to disappear into the fracture site, covered with shredded brachialis muscle. This occurs when the artery is tethered by a fascial band or aterial adventitia attached to the proximal metaphyseal spike pulling the artery in the fracture site. Dissection should occur proximally to distally, along the brachial artery, identifying both the artery and the median nerve. Arterial injury generally is at the level of the supratrochlear artery (Fig. 14-7), which provides a tether, making the artery vulnerable at this location. Arterial transection or direct arterial injury can be identified at this level. Entrapment of the neurovascular bundle in the fracture is best identified by proximal to distal dissection.

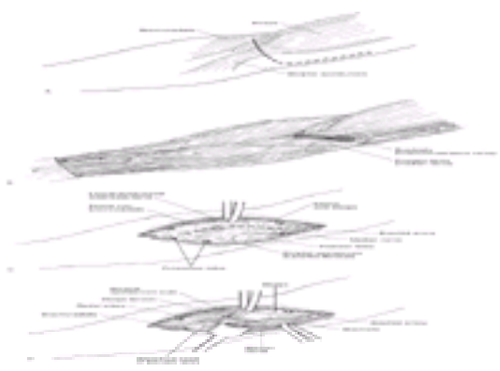

FIGURE 14-36. Brachial artery exploration through anteromedial approach.

The decision to repair a damaged artery or use a vein graft is generally made by the vascular surgeon. If spasm is the cause of arterial insufficiency, several techniques have been recommended. If arterial spasm is the cause of inadequate flow, and collateral flow is not sufficient to maintain the hand, attempts to relieve the spasm may be tried. Both stellate ganglion block and application of Paverin or local anesthetic to the artery have been found to be beneficial in this situation. If spasm is not relieved by these techniques and collateral flow is insufficient, the injured portion of the vessel is excised and a vein graft is inserted. When flow is restored, the wound is closed and the patient is placed in a splint with the elbow flexed less than 90 degrees and the forearm supinated. Postoperative monitoring should include temperature, pulse oximetry, and frequent examinations for signs of compartment syndrome or ischemia. Injection of urokinase has been suggested to increase flow (35); we have had no experience with this technique.

Sabharwal et al. (159) documented that 3.2% of patients with type III supracondylar fractures have an absent pulse at presentation, for which they recommended noninvasive monitoring. Magnetic resonance angiography and color flow duplex Doppler were helpful in deciding whether or not to explore the brachial artery. Although repair is technically feasible, Sabharwal et al. cautioned that high rates of reocclusion and residual stenosis argued against early revascularization if not absolutely necessary. Early reocclusion, however, was not reported by Schoenecker et al. (162) or Shaw et al. (164).

The necessity of early treatment of vascular compromise was emphasized by Ottolenghi (143), who found no Volkmann ischemic contractures (135) in patients in whom vascular compromise was treated within 12 hours. The frequency of this complication increased steadily with repair between 12 and 24 hours; after 24 hours of delay in treatment, outcomes were uniformly poor. This series presents convincing evidence that prompt exploration of arterial insufficiency markedly decreases the incidence of Volkmann ischemic contracture. However, it should be understood that brachial artery obstruction and compartment syndrome, although related, are not

equivalent, and both are fortunately rare problems. Ischemia will lead to a compartment syndrome, but the presence of a radial pulse does not preclude it.

Compartment Syndrome

In acute compartment syndrome (90,135), increased pressure in a closed fascial space causes muscle ischemia. With untreated ischemia, muscle edema increases, further increasing pressure, decreasing flow, and leading to muscle necrosis, fibrosis, and death of involved muscles. Forearm compartment syndrome occurs after 1% or fewer supracondylar fractures. A compartment syndrome of the forearm may occur with or without brachial artery injury and in the presence or absence of a radial pulse. The diagnosis of a compartment syndrome is based on resistance to passive movement of the fingers and dramatically increasing pain after fracture. The classic five “P's” for the diagnosis of compartment syndrome—pain, pallor, pulselessness, paresthesias, and paralysis—are poor indicators of a compartment syndrome.

Mubarak and Caroll (135) recommended forearm fasciotomy if clinical signs of compartment syndrome are present or if intracompartmental pressure is greater than 30 mm Hg. Heppenstal et al. (88) suggested that a difference of 30 mm Hg between diastolic blood pressure and compartment pressure should be the threshold for release. If pain is increasing and finger extension is decreasing, fasciotomy is clearly indicated. Measuring compartment pressures in a terrified, crying child is difficult, and if clinical signs of compartment syndrome are present, a trip to the operating room for evaluation and possible fasciotomy is often a better course of action than pressure measurement and observation.

Clinical conditions that contribute to the development of compartment syndrome are direct muscle trauma at the time of injury, swelling with intracompartmental fractures (associated forearm fracture), decreased arterial inflow, and restricted venous outflow. The mechanism of injury of the supracondylar fracture is critical. An associated forearm fracture or forearm crush injury significantly increases the likelihood of compartment syndrome. An arterial injury in association with multiple injuries or crush injury further diminishes blood flow to the forearm musculature and increases the probability of a compartment syndrome.

Even if distal pulse is found by palpation or Doppler examination, an evolving compartment syndrome may be present. Increased swelling over the compartment, increased pain, and decreased finger mobility are cardinal signs of an evolving compartment syndrome. Evaluation of possible compartment syndrome cannot be based on the presence or absence of a radial pulse alone. If a compartment syndrome does appear to be evolving, initial management includes removal of all circumferential dressings. The volar compartment should be palpated and the elbow should be extended. We believe that the fracture should be immediately stabilized with Kirschner wires to allow proper management of the soft tissues.

Another factor that contributes to the development of compartment syndrome is warm ischemic time after injury. When blood flow is compromised and the hand is pale with no arterial flow, muscle ischemia is possible, depending on the time of oxygen deprivation. After fracture reduction and restoration of flow, the warm ischemic time should be noted. If this time is more than 6 hours, compartment syndrome secondary to ischemic muscle injury is likely. Prophylactic volar compartment fasciotomy can be performed at the time of arterial reconstruction. The exact indication for prophylactic fasciotomy in the absence of an operative revascularization is uncertain. Even when the diagnosis is delayed or the compartment syndrome is chronic, fasciotomy has been shown to be of some value.

Technique for Volar Fasciotomy

The volar compartment of the forearm can be approached through the classic Henry approach or the ulnar approach (Fig. 14-37). If the compartment syndrome is associated with a brachial artery and median nerve injuries, We generally use the Henry approach as an extension of the vascular repair. The advantage of the ulnar approach, as described by Willis and Rorabeck (194) is that it produces a more cosmetically pleasing scar. A volar fasciotomy involves opening the volar compartment from the carpal tunnel distally to the lacertus fibrosa and antecubital fascia proximally. The fascia over the deep flexors is opened, as is the superficial fascia, to decompress the deep volar compartment of the forearm. Failure to release the deep volar fascia may cause contracture of the deep finger flexors. Generally only the volar compartment is released, with an associated decrease in pressure in the dorsal or extensor compartment. If the volar Henry approach is used, the interval between the brachioradialis and flexor carpi radialis and radial artery are retracted ulnarward. The deep volar compartment is exposed. The flexor digitorum profundus and flexor pollicis longus are exposed along with the pronator teres proximally and the pronator quadratus distally.

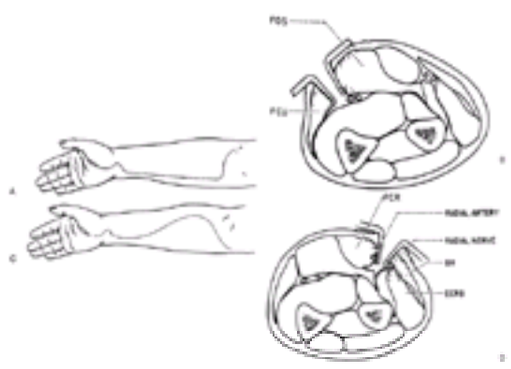

FIGURE 14-37. Surgical approach for forearm fasciotomy. **A:** Ulnar approach, skin incision. **B:** Ulnar approach, intermuscular interval (*FDS,* flexor digitorum sublimis; *FCU,* flexor carpi ulnaris). **C:** Henry approach, skin incision. **D:** Henry approach, FCR, flexor carpi radialis interval (*BR,* brachioradialis; *ECRB,* extensor carpi radialis brevis). (Reprinted from Willis RB, Rorabeck CH. Treatment of compartment syndrome in children. *Orthop Clin North Am* 1990;21:407-408; with permission.)

If the ulnar approach is used, as described by Willis and Rorabeck (194), the release is performed from the carpal canal to the antecubital fossa, as with the Henry approach. The skin incision begins above the elbow crease, medial to the biceps tendon (Fig. 14-37); it crosses the elbow crease and extends distally along the ulnar border to the volar wrist, where it courses radially across the carpal canal. The fascia over the flexor carpi ulnaris is incised, and the interval between the flexor carpi ulnaris and the flexor digitorum sublimis is identified. The ulnar nerve and artery are retracted, exposing the deep flexor compartment of the forearm. The deep flexor fascia is incised. The ulnar nerve and artery, as well as the carpal tunnel, are decompressed distally.

After fasciotomy the wound generally is left open. An effective way to manage the wound is with a criss-crossed rubber band technique, securing the rubber bands in place with skin staples. An alternative is to simply place a sterile dressing over the open wound, but this makes wound closure difficult and probably increases the need for skin grafting. Definitive closure or skin grafting generally is performed within 5 to 7 days. Skeletal stabilization of the supracondylar and forearm fractures is necessary for proper management of compartment syndrome.

Neurologic Deficit

In most modern series, the incidence of neurologic deficit with supracondylar fractures is 10% to 20% (127,160), with an incidence as high as 49% in one series (36). Reports differ as to whether the radial or median nerve is the most frequently injured. In modern series, the AIN appears to be the most commonly injured (49,58,126), with loss of motor power to the flexor pollicis longus and the deep flexor to the index finger as first described by Spinner in 1969 (174). The direction of the displacement of the fracture determines the nerve most likely to be injured. If the distal fragment is displaced posteromedially, the radial nerve is more likely to be injured. Conversely, if the displacement of the distal fragment is posterolateral, the neurovascular bundle is stretched over the proximal fragment, injuring the median nerve or AIN or both. In a flexion type of supracondylar fracture, which is rare, the ulnar nerve is the most likely nerve to be injured.

In general, if the nerve deficit is present when the patient arrives in the emergency department and if the fracture is reducible, open reduction of the fracture and exploration of the injured nerve are not indicated. In most series, nerve recovery, whether radial, median, or ulnar, generally occurs at an average of 2 to 2 1/2 months. Culp et al. (50) reported identification of eight injured nerves in 5 patients in which spontaneous recovery did not occur by 5 months following injury. Neurolysis was successful in restoring nerve function in all but one. Nerve grafting may be indicated for nerves not in continuity at the time of exploration. Neurolysis for perineural fibrosis is generally successful in restoring nerve function. There is no indication for early electromyographic analysis or treatment other than observation for nerve deficit until 5 to 6 months after fracture.

In their series of radial nerve injuries with humeral fractures, Amillo et al. (8) reported that of 12 injuries that did not spontaneously recover within 6 months of injury, only 1 was associated with a supracondylar fracture. Perineural fibrosis was present in 4 patients, 3 nerves were entrapped in callus, and 5 were either partially or totally transected.

In the supracondylar area, perineural fibrosis appears to be the most common cause of prolonged nerve deficit. Although nerve injury is related to fracture displacement, a neural deficit can exist with even minimally displaced fractures. Sairyo et al. (160) reported one patient in whom radial nerve palsy occurred with a slightly angulated fracture that appeared to be a purely extension type fracture on initial radiographs. Even in patients with mild injuries, a complete neurologic examination should be performed before treatment. An irreducible fracture with nerve deficit is an indication for open reduction of the fracture to be sure that there is no nerve entrapment. Chronic nerve entrapment in healed callus can give the appearance of a hole in the bone, Metev's sign. Nerve transection is rare, and almost always involves the radial nerve (19,30,50,123,126).

Iatrogenic injury to the ulnar nerve has been reported to occur in 1% to 5% of patients with supracondylar fractures (33,93,153,157). In a large series of type III supracondylar fractures, the rate of iatrogenic injury to the radial nerve was less than 1%. The course of the ulnar nerve through the cubital tunnel, between the medial epicondyle and the olecranon, makes it vulnerable when a medial pin is placed. The ulnar nerve generally is injured by direct trauma from the medial pin, with or without actual penetration of the nerve. If the pin is placed in the ulnar groove rather than in the medial epicondyle, injury is likely. The ulnar nerve may sublux over the medial epicondyle in as many as 30% of patients; this usually is bilateral and associated with ligamentous laxity. Ulnar nerve subluxation occurs most commonly with hyperflexion of the elbow and injury to the nerve is most likely when a medial pin is placed with the elbow in hyperflexion.

If an ulnar neuropathy is documented postoperatively when one was not present preoperatively and a medial pin has been placed, what is appropriate treatment? Brown and Zinar (33) reported four ulnar nerve injuries associated with pinning of supracondylar fractures, all of which resolved spontaneously 2 to 4 months after pinning. Lyons et al. (118) documented ulnar nerve injuries associated with pinning in 19 of 375 patients who had cross-pinning of supracondylar fractures. In only 4 was the medial pin removed. Two had explorations, which found no nerve transection. These researchers recommended leaving the medial pin in place until the fracture heals. Rasool (153) reported six patients with ulnar nerve injuries in whom early exploration was performed. In two the nerve was penetrated, and in three it was constricted by a retinaculum over the carpal tunnel, aggravated by the pin. In one patient, the nerve was subluxed and was fixed anterior to the cubital tunnel by the pin. Full recovery occurred in three patients, partial recovery in two, and no recovery in two. Royce et al. (157) reported spontaneous recovery of ulnar nerve function in three patients. One nerve that was explored had direct penetration of the nerve, and the pin was replaced in proper position. Two patients had late-onset ulnar nerve palsies, discovered during healing, and the medial pin was removed.

If a postoperative neural injury is documented, we prefer to explore the ulnar nerve and replace the pin in proper position. If an ulnar nerve lesion is documented late in the course of fracture healing, we remove the pin but do not explore the nerve.

Prevention of ulnar nerve injury is obviously more desirable than treatment of ulnar neuropathy. Because of the frequency of ulnar nerve injury with crossed pinning, most surgeons prefer to use two lateral pins if possible and no medial pin. Nevertheless, it should be recognized that two lateral pins are about 30% less resistant to torque than crossed pins. However, successful maintenance of alignment of type III supracondylar fractures with two lateral pins has been reported (42). If cross-pinning is to be used, nerve penetration and indirect trauma to the nerve can be prevented by making a 1.5-cm incision over the medial epicondyle and being certain that the ulnar nerve is protected when the medial pin is placed. Another alternative for protection of the ulnar nerve was described by Michael and Stanislas, who attached a nerve stimulator to a needle, which was used for localization of the ulnar nerve (129). Once the ulnar nerve was identified, a standard pinning technique was used, placing the medial pin 0.5 to 0.75 mm anterior to the nerve. We have no experience with this technique. The contralateral elbow should always be examined for ulnar nerve subluxation in flexion because it usually is bilateral and associated with ligamentous laxity. Some surgeons palpate the ulnar nerve and push it posteriorly (Fig. 14-29).

Radial nerve injuries are rare complications of pinning of supracondylar fractures. The most common cause is probably a direct piercing injury to the radial nerve, as the medial pin exits the anterolateral cortex of the humerus. This injury can be best prevented by ensuring that pin penetration in the opposite cortex is limited to 1 to 2 mm. The medial pin should be backed out slightly if it protrudes significantly beyond the cortex. Spontaneous recovery of radial nerve function generally occurs.

Elbow Stiffness

Loss of motion after extension-type supracondylar fractures is rare in children. Two series analyzed this complication in detail (47,87) and found that fractures treated closed had an average loss of motion of 4 degrees and a residual flexion contracture of 4 degrees. In those treated with open reduction, the loss of flexion was 6.5 degrees and the flexion contracture was 5 degrees or 1.2 degrees of hyperextension. Loss of motion has been reported with the posterior triceps splitting incision for open reduction (79,82,122).

Although loss of motion usually is minimal, significant loss of flexion can occur. This is generally caused by either posterior angulation of the distal fragment, posterior translation of the distal fragment with anterior impingement, or medial rotation of the distal fragment with a protruding medial metaphyseal spike proximally (Fig. 14-38). In young children with significant growth potential, there may be significant remodeling of anterior impingement, and any corrective surgery should be delayed at least 1 year. Although anterior impingement can significantly remodel, there is little remodeling to persistent posterior angulation or hyperextension.

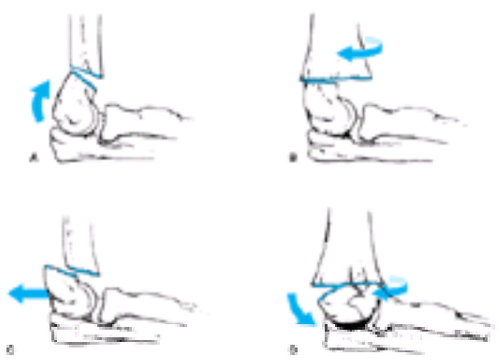

FIGURE 14-38. Distal fragment rotation. **A:** Posterior angulation only of the distal fragment. **B:** Pure horizontal rotation without angulation. **C:** Pure posterior translocation without rotation or angulation. **D:** Horizontal rotation with coronal tilting, producing a cubitus varus deformity. There is a positive crescent sign. (Redrawn from Marion J, LaGrange J, Faysse R, et al. Les fractures de l'extremite inferieure de l'humerus chez l'enfant. *Rev Chir Orthop* 1962;48:337-413; with permission.)

Myositis Ossificans

Myositis ossificans is often mentioned as a possible complication (79,169) of supracondylar fractures, but it is remarkably rare (Fig. 14-39). This complication has been described after open reduction, but vigorous postoperative manipulation or physical therapy is believed to be the most commonly associated factor (6,107,147,167).

FIGURE 14-39. Myositis ossificans. Ossification of the brachialis muscle developed in this 8-year-old who had undergone multiple attempts at reduction. (Courtesy of John Schaeffer, M.D.)

In a report of two patients with myositis ossificans after closed reduction of supracondylar fractures, Aitken (3) noted that limitation of motion and calcification disappeared after 2 years. Postoperative myositis ossificans can be observed with the expectation of spontaneous resolution of both restricted motion and the myositis ossificans. There is no indication for early excision.

Nonunion

The distal humeral metaphysis is a well-vascularized area with remarkably rapid healing, and nonunion of a supracondylar fracture is rare, with only a single case described by Wilkins and Beaty (191). We have not seen nonunion of this fracture. With infection, devascularization, and soft tissue loss, the risk of nonunion increases.

Avascular Necrosis

Avascular necrosis of the trochlea after supracondylar fracture has been reported. The blood supply of the ossification center of the trochlea is fragile, with two separate sources. One small artery is lateral and courses directly through the physis of the medial condyle. It provides blood to the medial crista of the trochlea. If the fracture line is very distal, this artery can be injured, producing avascular necrosis of the ossification center and resulting in a classic fishtail deformity (Fig. 14-40). Symptoms of avascular necrosis of the trochlea do not occur for months or years. Healing is normal and motion is regained, but mild pain and occasional locking develop with characteristic radiologic findings. Routine follow-up radiographs of supracondylar fractures are not necessary because this complication is highly unusual and the fishtail deformity of the distal humerus does not compromise function.

FIGURE 14-40. Avascular necrosis of the trochlea. **A:** Anteroposterior injury film of an 8-year-old with a distal type III supracondylar fracture. **B:** The distal extension of the fracture (*arrow*) is best appreciated on the lateral reduction film. Postfracture, the patient was asymptomatic until 2 years later, when elbow stiffness developed. **C:** Repeat radiographs at that time showed atrophy of the trochlea (*arrows*). **D:** Three-dimensional computed tomographic reconstruction demonstrates atrophy of the trochlea.

Angular Deformity

Angular deformities of the distal humerus after supracondylar fractures are much less common since the development of modern techniques of skeletal stabilization. In the past, the incidence of cubitus varus deformity after supracondylar fractures ranged from 9% to 58% (60,92,122). Pirone et al. (147) reported cubitus varus deformities in 14% of patients treated with cast immobilization compared with 3% in patients with percutaneous pin fixation. A decrease in frequency of cubitus varus deformity after the use of percutaneous pin fixation has been reflected in other recent series (28,29,66,67,101,128,147,148). The usual etiology of cubitus varus deformity is malunion of the distal humeral fragment rather than growth arrest. Distal humeral varus is generally believed to be a result of residual coronal angulation aggravated by malrotation and hyperextension.

Malunion of the distal humerus usually creates a static deformity (Fig. 14-41), which becomes evident as the patient gains full motion. A flexion deformity obscures the true varus deformity, which is generally associated with hyperextension. Although some investigators have proposed that unequal growth in the distal humerus causes varus deformity (17,31,91,92,144,167), this is unlikely to cause a significant varus deformity in the first few months after fracture. The growth of the distal humerus is 20% of that of the overall length of the humerus. In a 5-year-old, therefore, the amount of distal humeral growth in 1 year is approximately 2 mm, making it unlikely that growth asymmetry is a significant cause of varus deformity that occurs within the first 6 to 12 months after fracture. However, avascular necrosis of the trochlea or medial portion of the distal humeral fragment can result in progressive varus deformity. In a series of 36 varus deformities reported by Voss et al. (185), four patients had medial growth disturbance and distal humeral avascular necrosis as a cause of progressive varus deformity.

FIGURE 14-41. Cosmetic effects. A combination of varus coronal rotation and medial horizontal rotation of the distal fragment causes the lateral condyle to be unduly prominent (*arrow*). This accentuates the unpleasant appearance of the cubitus varus deformity. (Reprinted from Wilkins KE. Residuals of elbow trauma in children. *Orthop Clin North Am* 1990;21:291-314; with permission.)

Horizontal rotation (59,191) in a medial direction or internal rotation of the distal fragment is believed to predispose to distal fragment varus angulation (Fig. 14-38). Eccentric position of the biceps has been suggested as a cause of varus tilting by the distal fragment. Chess et al. (43) evaluated the clinical appearance of cubitus varus in an anatomic study of 256 combinations of varus angulation, internal rotation, and posterior angulation. They found that the major component of cubitus varus deformity was true varus angulation in the coronal plane. Internal rotation did appear to worsen the deformity. In a clinical study (119,120), the true distal humeral rotation was measured on wedges removed from osteotomies of the distal humerus; the horizontal rotation of the distal humerus did not correlate with the severity of cubitus varus (185). Horizontal rotation may accentuate the clinical varus deformity, but it is not the primary cause. Coronal plane deformity and hyperextension are the factors in cubitus varus deformity and are important in planning surgical correction.

Some researchers have suggested that cubitus varus deformity may produce weakness, but most believe that the effects are primarily cosmetic. An increased risk of fracture (54), especially of the lateral condyle, has been linked with cubitus varus deformity (Fig. 14-42). Varus angulation may complicate throwing. However, the functional effects of cubitus varus deformity are minimal and, other than decreasing fracture risk, the main indication for correction of a varus deformity is to improve the appearance of the elbow rather than to improve function.

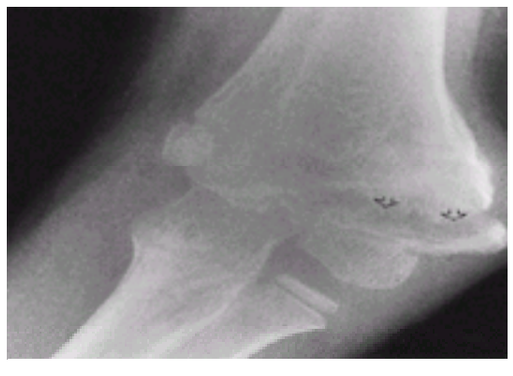

FIGURE 14-42. Predisposition to lateral condyle fracture. This 5-year-old sustained a supracondylar fracture of this extremity 1 year before this acute stage II fracture of the lateral condyle (*arrows*). It was thought that the cubitus varus deformity predisposed the patient to this second fracture. (Courtesy of Kenneth P. Butters, M.D.)

The radiologic appearance of cubitus varus deformity is distinctive. On the AP view, the angle of the physis of the lateral condyle (Baumann angle) is more horizontal than normal. On the lateral view, a crescent sign is produced by the superimposition of the capitellum on the olecranon (Fig. 14-43).

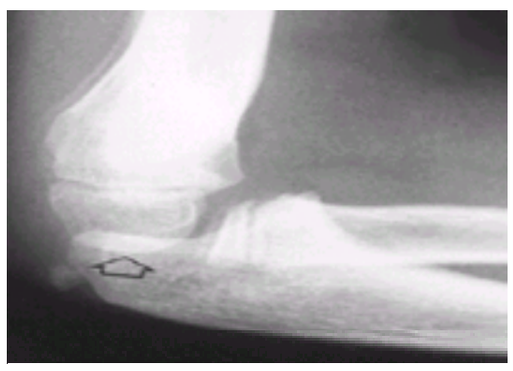

FIGURE 14-43. A patient with cubitus varus shows overlapping of the distal humerus, with the olecranon (*arrow*) producing the typical crescent sign.

Cubitus varus deformity also is associated with a significant increase in late ulnar nerve palsies, as reported in the Japanese literature (1,24,182). With a cubitus varus deformity, the olecranon fossa moves to the ulnar side of the distal humerus (140), and the triceps shifts a bit ulnarward. Investigators theorized that this ulnar shift may compress the ulnar nerve against the medial epicondyle, narrowing the cubital tunnel and resulting in chronic neuropathy. In a recent report (1), a fibrous band running between the heads of the flexor carpi ulnaris was thought to cause ulnar nerve compression.

Treatment of Cubitus Varus Deformity

As for the treatment of any posttraumatic malalignment, options include (a) observation with expected remodeling, (b) hemiepiphysiodesis and growth alteration, and (c) corrective osteotomy. Bracing of this deformity is not effective for improving alignment or preventing increasing varus. Observation generally is not appropriate because although hyperextension may remodel to some degree in a young child (Fig. 14-44), in an older child, little remodeling occurs even in the plane of motion of the joint.

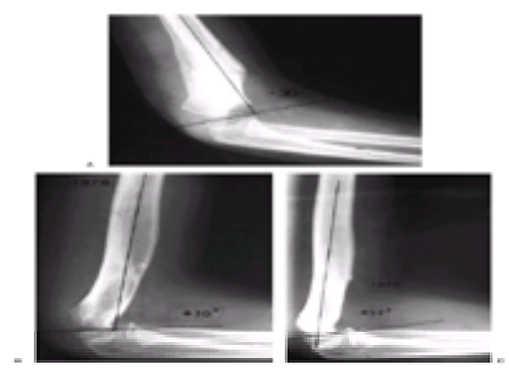

FIGURE 14-44. A hyperextension deformity in the distal humerus may remodel somewhat, whereas varus and valgus deformity do not. Hyperextension deformity in the distal humerus following fracture **(A)**. Four years later **(B)**, a more normal distal humeral anatomy is seen with remodeling of the hyperextension deformity; 2 years later, **(C)**, a normal distal humeral anatomy is reconstituted.

Hemiepiphysiodesis of the distal humerus may occasionally be of value, particularly to prevent cubitus varus deformity from developing in a patient with clear medial growth arrest or trochlear avascular necrosis. If untreated, medial growth disturbance will lead to lateral overgrowth and progressive deformity. Lateral epiphysiodesis will not correct the deformity, but will prevent it from increasing. Voss et al. (185) used hemiepiphysiodesis with osteotomy in two patients with growth arrest and varus deformity. The humerus varies in length by a few centimeters from one individual to another, but in general is about 30 cm long at skeletal maturity. Approximately 65% of the length of the humerus is achieved by age 6 years. A 6-year-old child has approximately 10 cm of growth left in the entire humerus, with only approximately 2 cm provided by the distal physis. Growth arrest, in the absence of avascular necrosis or collapse, will be a very slowly evolving phenomenon, and epiphysiodesis in a child older than 6 years will have little effect on longitudinal growth. In general, prevention of increasing deformity from medial growth arrest is the only role for lateral epiphysiodesis. Because of the slow rate of growth in the distal humerus, we do not believe there is any role for lateral epiphysiodesis in correction of a varus

deformity in a child with otherwise normal physis.

Osteotomy

Osteotomy is the only way to correct a cubitus varus deformity with a high probability of success. A variety of corrective osteotomies have been described, almost all with significant complications (Table 14-3). Stiffness, nerve injury, and recurrent deformities are the most commonly reported complications. An overall complication rate approaching 25% in many series has led to some controversy about the value of a distal humeral corrective osteotomy for cubitus varus deformity.

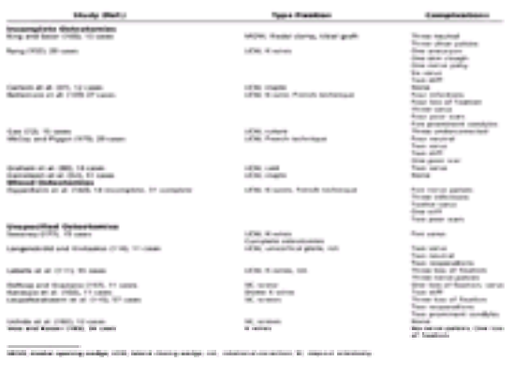

TABLE 14-3. RESULTS OF SEVERAL STUDIES USING VARIOUS OSTEOTOMIES

To choose an appropriate osteotomy, the exact location of the deformity must be determined. Because malunion is the cause of most cubitus varus deformities, the angular deformity usually occurs at the level of the fracture. If the deformity is caused by growth arrest, the actual deformity will be centered at the site of the growth arrest. Rotation and hypertension contribute to the deformity, but varus is the most significant factor (43). Hyperextension can produce a severe deformity in some patients. After determining the location and cause of the deformity, the appropriate osteotomy can be chosen. In general, a lateral closing wedge osteotomy with a medial hinge will correct the varus deformity, with some minor correction of hyperextension (9,20,46,70,72,80,98,100,111,177,185,196).

An oblique configuration (Fig. 14-45) places the center of rotation of the corrective osteotomy as close to the actual level of the deformity as possible. Oppenheim et al. recommended osteotomy at a higher level, emphasizing that the length of the cuts should be equal (Fig. 14-46) (142). The higher the osteotomy, the more translation is produced in correcting the angular deformity. Proper preoperative planning places the apex of the osteotomy close to the level of the deformity and obtains the best anatomic result. On an AP radiograph of the humerus with the forearm in full supination, the size of the wedge and the angular correction needed are determined. An “incomplete” lateral closing wedge osteotomy is performed, leaving a small medial hinge of bone intact. The osteotomy usually is fixed with two Kirschner wires placed laterally. In the absence of an intact medial hinge, two lateral wires probably are not sufficient to secure this osteotomy (185).

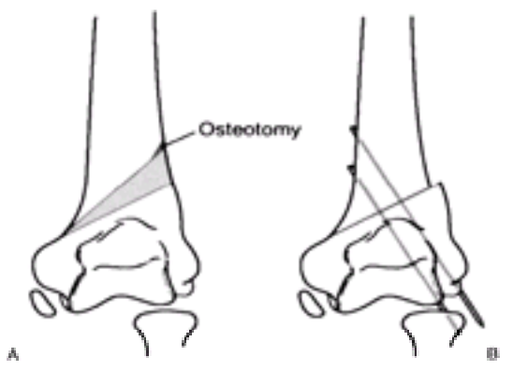

FIGURE 14-45. A: By moving the apex of the closing wedge distally, the center of rotation of the osteotomy is moved closer to the deformity. **B:** Upon closing a distally based wedge osteotomy, there is less translational effect than in a more proximally based osteotomy.

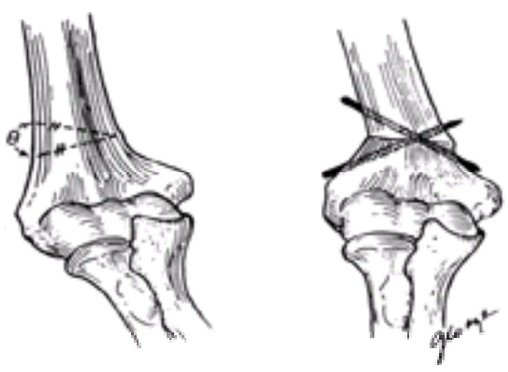

FIGURE 14-46. Technique of the lateral closing wedge osteotomy. The limbs should be of equal length, and the medial cortex should remain intact. (Reprinted from Oppenheim WL, Clader TJ, Smith C, et al. Supracondylar humeral osteotomy for traumatic childhood cubitus varus deformity. *Clin Orthop* 1984;188:36; with permission.)

Wilkins and Beaty (191) recommended crossed wires in this situation. With this incomplete osteotomy, rotation cannot be corrected, but rotational deformity was not found to be a significant problem in studies by Voss (185) and Oppenheim (142).

A dome osteotomy has been described by Japanese surgeons (89) in which a curved osteotomy is made in the supracondylar area. Proponents of this osteotomy suggest that multiplane correction is possible without inducing translation in the distal fragment and that rotation can be corrected. This osteotomy is often performed through a posterior approach.

DeRosa and Graziano (57) described a step cut osteotomy (Fig. 14-47) in which the distal fragment is slotted into the proximal fragment and the osteotomy is secured with a single screw. Multiple osteotomies with varying degrees of complexity have been recommended. In general, increasing complexity means increasing complications. No series of osteotomies has been reported without some significant complications.

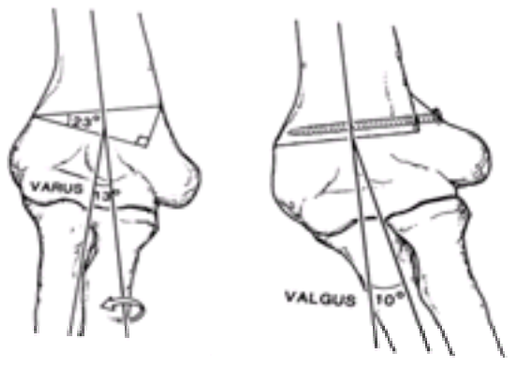

FIGURE 14-47. The step-cut osteotomy. The distal fragment can be rotated in the horizontal plane (*circular arrow*) to correct that part of the deformity. (Reprinted from De Rosa GP, Graziano CP. A new osteotomy for cubitus varus. *Clin Orthop* 1988;236:160-165; with permission.)

Results of Osteotomy

Functional outcomes are generally good, but the preoperative functional deficit is nearly always minor in patients with cubitus varus deformities. Complications of humeral osteotomy include stiffness, nerve injury, and persistent deformity (Table 14-3); however, with a properly performed osteotomy, complications are relatively few. Ippolito et al. (95) reported long-term follow-up of patients with supracondylar osteotomies, 50% of whom had poor results. Increasing deficit has been reported after osteotomy in young children, but this did not occur in the series reported by Voss et al. (185), in which four patients had growth arrest and avascular necrosis; lateral epiphysiodesis was performed to prevent recurrent deformity in two of these patients.

Hyperextension deformity may remodel over time (Fig. 14-44), but correction is slow and inconsistent. In the series from Children's Hospital (185), hyperextension deformities remodeled as much as 30 degrees in young children, but in children facing maturity, there was no significant remodeling in the flexion/extension plane. If hyperextension appears to be a major problem, osteotomy also should be directed at this deformity rather than simple correction of the varus deformity; this requires a multiplane osteotomy.

AUTHORS' PREFERRED METHOD OF TREATMENT

I prefer an incomplete lateral closing wedge osteotomy for correction of most cubitus varus deformities. It is a simple procedure and in our hands has had a very low complication rate. A simple lateral approach is used rather than a posterior approach, and it is a muscle-preserving osteotomy that allows rapid rehabilitation after healing. Stiffness and nerve injury are rare complications of this procedure. Performing the procedure with the patient supine allows easy observation of the correction achieved. Kirschner wire fixation can be used in the juvenile age group and screw fixation in adolescents.

There is no reason to mobilize the ulnar nerve, but care is taken not to penetrate the medial cortex with a saw. The position of the radial nerve limits proximal lateral dissection. Symeonides et al. (179) reported finding a radial nerve entrapped within fracture callus in the lateral aspect of the metaphysis. With severe deformity or neurologic abnormality, anatomy of neurovascular structures is unlikely to be normal.

Wilkins recommended combining dome and lateral closing wedge osteotomies through a posterior approach for multiplanar correction. This procedure is performed with the patient prone. For patients with significant hyperextension deformity, we would choose this procedure for multiplanar correction.

FLEXION-TYPE SUPRACONDYLAR FRACTURE

Flexion-type supracondylar humeral fractures account for about 2% of humeral fractures. A flexion pattern of injury may not be recognized until reduction is attempted because initial radiographs are inadequate. A key to the recognition of a flexion-type supracondylar fracture is that it is unstable in flexion, whereas extension-type fractures generally are stable in hyperflexion. A laterally displaced supracondylar fracture may actually be a flexion-type injury.

Etiology and Pathology

The mechanism of injury is generally believed to be a fall directly onto the elbow rather than a fall onto the outstretched hand with hyperextension of the elbow (Fig. 14-48). The distal fragment is displaced anteriorly and may migrate proximally in a totally displaced fracture. The ulnar nerve is vulnerable in this fracture pattern (3,68,84,158), and it may be entrapped in the fracture or in the healing callus (113).

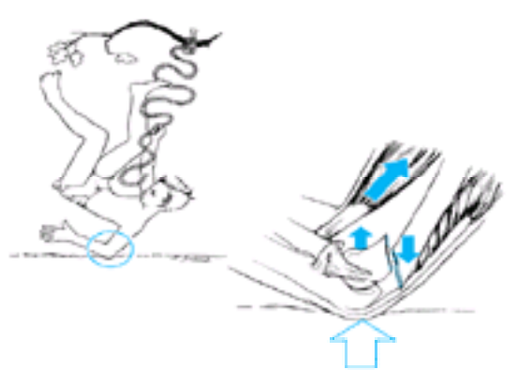

FIGURE 14-48. Flexion mechanism. Flexion-type fractures usually result from a blow to the posterior aspect of the elbow. The obliquity of the fracture line may be opposite that of an extension type. The large black arrows demonstrate the usual direction of displacement of the fragments.

Radiographic Findings

The radiographic appearance of the distal fragment varies from mild angular deformity to complete anterior displacement. Anterior displacement often is accompanied by medial or lateral translation (Fig. 14-49). Associated fractures of the proximal humerus and radius mandate full radiographic evaluation of the upper extremity. Fracture classification is the same as for extension-type supracondylar fractures (Gaetland): type I, nondisplaced fracture; type II, minimally angulated greenstick fracture; and type III, totally unstable displaced distal fracture fragment.

FIGURE 14-49. Flexion valgus deformity. Lateral **(A)** and anteroposterior views **(B)** of a flexion-type supracondylar fracture. The distal fragment (*arrow*) is laterally displaced in the coronal plane as well. Despite aggressive treatment, there was mild residual cubitus valgus plus a flexion contracture when the fracture healed **(C)**. (Reprinted from Wilkins KE. Residuals of elbow trauma in children. *Orthop Clin North Am* 1990;21:291-314; with permission.)

Treatment

In general, type I flexion-type supracondylar fractures are stable nondisplaced fractures that can simply be protected in a long arm cast (62,137,152). If mild angulation, as in a type II fracture, requires some reduction in extension, the arm can be immobilized with the elbow fully extended. Radiologic evaluation with the elbow extended is easily obtained and accurate in determining the adequacy of reduction. Reduction is assessed by evaluating the olecranon fossa, Baumann angle, and the anterior humeral line intersecting the lateral condyle. If reduction cannot be obtained, as is often the case, or if rotation persists, soft tissue interposition, possibly the ulnar nerve, should be suspected.

A problem with type III flexion supracondylar fractures is that reduction is difficult to achieve and when achieved the elbow usually is in extension, making stabilization of the distal fragment with pins quite difficult.

Type I and II fractures (Fig. 14-50 and Fig. 14-51) generally are reduced if any angular displacement is seen on fluoroscopic intraoperative evaluation. Type II fractures can be immobilized in an extension cast with the elbow fully extended (Fig. 14-51). A ring is applied so that the weight of the cast can be supported by a sling around the neck. The cast is removed at 3 weeks. If closed reduction is performed without skeletal stabilization, follow-up radiographs usually are taken at 1 week and then when the cast is removed at 3 weeks.

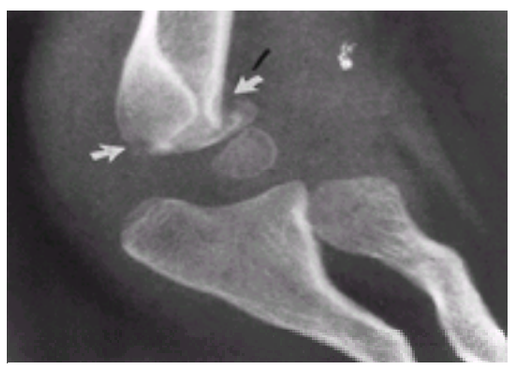

FIGURE 14-50. Type I flexion injury. A type I flexion supracondylar fracture pattern (*arrows*) in a 6-year-old below-the-elbow amputee. There is only about a 10 degree increase in the shaft condylar angle. He was treated with a simple posterior splint.

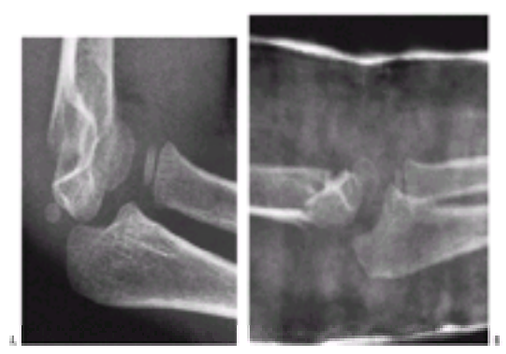

FIGURE 14-51. Closed reduction, extension cast. **A:** A 5-year-old girl sustained a type II flexion pattern. **B:** She was manipulated into extension and found to be stable, and thus was maintained in a long-arm cast in extension.

For unstable type II and III flexion supracondylar fractures, pinning is generally required. The pinning technique described for extension-type supracondylar fractures is not appropriate for this fracture, because its instability in flexion precludes pinning with the elbow hyperflexed. Pinning should be performed after closed reduction with the elbow in mild flexion or full extension.

In a flexion-type supracondylar fracture, if reduction can be obtained in extension, it is rarely if ever stable in flexion. In general, a slightly less than anatomic reduction can be accepted as long as there is no soft tissue interposition of tissue, the Baumann angle is close to the other side, and neither flexion nor extension is seen on the lateral view. Although rotation of the arm is often possible for a lateral view of extension supracondylar fracture, the **C**-arm must be moved to get satisfactory radiographs when pinning a flexion-type supracondylar fracture, because they usually are rotationally unstable even when reduced.

Pinning is generally performed with the elbow in about 30 degrees of flexion, holding the elbow in a reduced position (Fig. 14-52). If closed reduction can be obtained, pinning can be accomplished in this position. Reduction may be facilitated by placing a traction type of olecranon wing nut through the proximal ulna to give a better grip on the distal fragment.

FIGURE 14-52. Closed reduction, pin fixation. **A:** Injury film of a 9-year-old with a type II flexion injury. **B:** A satisfactory reduction was achieved by fully extending the elbow. **C:** The elbow was then gradually flexed to full flexion, maintaining pressure proximally through the forearm (*arrows*) to keep the distal humeral fragment extended. **D:** The distal fragment was then secured with three pins placed laterally.

The lateral pin is generally placed first through the lateral condyle, extending through the proximal fragment and engaging the opposite cortex. The medial pin is then placed through the medial epicondyle. We make a small incision over the medial epicondyle to ensure that the ulnar nerve is not entrapped in the fracture.

After pinning of a flexion-type supracondylar fracture, the arm should be placed in a cast. If the fracture is held in anatomic position with pins, a flexed-arm cast can be used to provide better patient comfort, but a cast with the elbow in maximal extension is acceptable.

Open reduction frequently is required for flexion-type supracondylar fractures. Open reduction is best performed through an anteromedial approach, rather than an anterior approach, as is used for extension-type supracondylar fractures. With flexion-type fractures, brachialis remains intact and must be retracted in order to expose the fracture, necessitating a medial extension to the anterior approach. To be sure that the ulnar nerve is not entrapped in the fracture site, exploration of the ulnar nerve or at least identification is probably advisable with this fracture. Fracture reduction should be obtained under direct vision of the fracture, and pins should be used to stabilize the fracture fragments.

Anteromedial Open Reduction of Flexion-Type Supracondylar Fractures

A transverse incision is made across the antecubital fossa, curving proximally posterior to the neuromuscular bundle. Dissection is carried down to the level of the superficial fascia of the forearm and antecubital fossa. The neurovascular bundle is identified and retracted medially. The brachialis and biceps tendons are retracted laterally to expose the fracture site and facilitate reduction. If there is medial soft tissue impingement or a question of ulnar nerve entrapment within the fracture, the dissection should be carried around posterior to the medial epicondyle, so the ulnar nerve and fracture can be identified.

Wound closure is performed with interrupted stitches, either absorbable or nylon. Postoperative immobilization is maintained for 3 or 4 weeks until good callus formation is present. Pins generally are left out through the skin and removed in the office without need for anesthetic. No immediate rehabilitation is given, but the patient is encouraged to begin gentle activities with the arm and to begin regaining motion without a stressful exercise program.

Traction

Traction can be used for this fracture, but the elbow generally is unstable in increased flexion, which is a position of comfort for the patient in traction. Although overhead traction works best for extension-type supracondylar fractures, we think that side arm traction might be better for this fracture; however, there is no data on this issue that we are aware of. Radiographic evaluation in traction is mandatory to confirm the adequacy of reduction. After 14 days or so in traction, with a stable distal humeral fracture and good callus formation, the arm is immobilized in a cast with the elbow in extension, and radiographs are obtained. We prefer wing nut–type traction for this to apply skeletal traction with the elbow flexed 30 to 40 degrees for comfort. This may require some sling suspension, as well as a skeletal traction pin or wing nut. If an ulnar neuropathy develops in traction, the nerve is probably trapped in the fracture and open reduction and ulnar nerve exploration are indicated.

AUTHORS' PREFERRED METHOD OF TREATMENT

In general, we treat type I flexion supracondylar fractures with a splint or cast with the elbow flexed for comfort. Minimally displaced type II fractures that reduce in extension are treated in an extension cast. Unstable types II and III fractures are pinned. We make a small incision over the medial epicondyle if a medial pin is placed. Open reduction is used if an anatomic closed reduction cannot be obtained.

THE ELBOW: PHYSEAL FRACTURES, APOPHYSEAL INJURIES OF THE DISTAL HUMERUS, AVASCULAR NECROSIS OF THE TROCHLEA, AND T-CONDYLAR FRACTURES

JAMES H. BEATY
JAMES R. KASSER

We thank Kaye Wilkens for his contribution to this chapter and previous editions. Much of this chapter is his effort.

PHYSEAL FRACTURES

All the physes of the distal humerus are vulnerable to injury, each with a distinct fracture pattern. This vulnerability of the various physes to injury is altered by two major factors: age and mechanism of injury. Next to those of the distal radius, injuries to the distal humeral physes are the most common physeal injuries. The peak age incidences of these physeal injuries vary considerably. In general, the physes of the major long bones are most vulnerable to fracture just before puberty, when the perichondral ring is weakest (1,11). Fractures involving the medial epicondylar apophysis are most common in preadolescents, with the peak ages 11 to 15 years. This is probably because many avulsions of this apophysis are associated with posterolateral dislocations, which also are common in this age group. Fractures involving the lateral condylar physis occur early, with the average age around 6 years (2,4,7,9,10,11 and 12). Fractures involving the medial condylar physis are rare and occur most often in children 8 to 12 years of age (3,6,8). Fractures involving the total distal humeral physis may occur in neonates or within the first 2 to 3 years of life (5).

The specific fracture patterns, incidence, and mechanism of injury are discussed in detail in the following sections dealing with these specific fractures.

Fractures Involving the Lateral Condylar Physis

Incidence and Outcome

Fractures involving the lateral condylar region in the immature skeleton either cross the physis or follow it for a short distance into the trochlea. Fractures of the lateral condylar physis constitute 16.9% of fractures of the distal humerus.

Fractures of the lateral condylar physis are only occasionally associated with injuries outside the elbow region. Within the elbow region, the associated injuries that can occur with this fracture include dislocation of the elbow (which may be a result of the injury to the lateral condylar physis rather than a separate injury), fractures of the radial head, and fractures of the olecranon, which are often greenstick in nature. True acute fractures involving only the anatomic capitellum are rare in the immature skeleton.

The diagnosis of lateral condylar physeal injuries may be less obvious both clinically and radiographically than that of supracondylar fractures, especially if the fracture is minimally displaced. The incidence of a functional loss of range of motion in the elbow is much greater with fractures of the lateral condylar physis because the fracture line often extends into the articular surface. A difficult supracondylar fracture with cubitus varus, barring the immediate neurovascular complications, is likely to result in a surgically correctable cosmetic deformity with an essentially normal range of motion in the elbow. A poorly treated lateral condylar physeal injury, however, is likely to result in a significant loss of range of motion that is not as responsive to surgical correction. The complications of supracondylar fractures are usually evident in the immediate postinjury period. The poor outcome of a lateral condylar physeal fracture may not be obvious until months or even years later. Ippolito et al. (54) evaluated 49 individuals with humeral condylar fractures 18 to 45 years after the injury. Twenty fractures with displacement of 2 to 10 mm with no tilting of the osteochondral fragment had been treated without reduction and 16 fractures with marked displacement and tilting of the fragment had been treated surgically; all 36 had good results. All 13 patients treated operatively or nonoperatively for old, displaced fractures had poor results. Nonunion developed in 4 and osteonecrosis in 6. Arthrosis of the elbow was found in fractures complicated by osteonecrosis and nonunion, and in old fractures when the humeral condyle was resected, but it was not observed in uncomplicated fractures.

Pathology

Early Descriptions

Milch (66,67) defined the fracture that exited through the trochleocapitellar groove as a type I (Milch type I). The type II (Milch type II) exits through the trochlea. Cotton (29) around the same time described more of the details of the various subluxations of both the fragment and elbow joint that occurred with this type of fracture. He noted that because the fragment usually was still attached to the proximal radius, both the radius and ulna were subluxed. The most common displacement was "outward and backward"; "inward and forward" displacement was rare. Cotton also noted that the main pathology was associated with the rotation of the condylar fragment. He observed that this fracture often resulted in limited extension, had some local lateral outgrowth at the fracture site, and rarely resulted in axial deviation of the elbow unless there was a resultant nonunion. Little has been added to his description of the pathology of this lesion by more recent investigators.

Fracture Anatomy and Classification

Classification of lateral condylar physeal fractures can be described by either the anatomic location of the fracture line or the stage of displacement. An understanding of both of these classifications is essential in the management of these fractures.

Anatomic Location. Salter and Harris classified lateral condylar physeal injuries as type IV injuries in their classification of physeal fractures (83). A true Salter-Harris type IV injury through the ossific nucleus of the lateral condyle is rare. Although lateral condylar fractures are similar to Salter-Harris type II and IV fractures, treatment guidelines follow those of a type IV injury: open reduction and internal fixation of displaced intraarticular fractures, with the potential for mild growth disturbance of the distal humeral physis. There is no contact between the ossification center of the epiphysis and the exposed bone in the metaphyseal fragment.

The Milch classification is based on the location of the fracture line through the epiphysis of the distal humerus.

Milch Type I. In this type, the fracture line originates in the metaphysis, crosses the physis more or less obliquely, and finally traverses the ossification center of the lateral condylar epiphysis to exit in the area of the capitulotrochlear groove (Fig. 15-1). There can be contact between the bony ossification center of the epiphysis and the bony metaphysis, leading to growth arrest due to an osseous bridge, especially in very young children. Fortunately, less than 20% of the growth of the humerus occurs through the distal humeral physis.

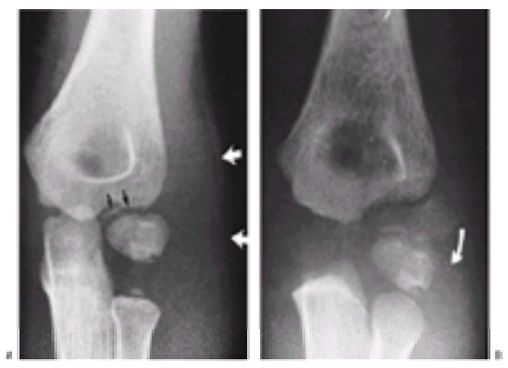

FIGURE 15-1. A: Injury film of a 7-year-old with an undisplaced fracture of the lateral condyle (*small arrows*). Attention was drawn to the location of the fracture because of extensive soft tissue swelling on the lateral aspect (*white arrows*). **B:** Because of the extensive soft tissue injury, there was little intrinsic stability, allowing the fracture to become displaced at 7 days (*arrows*).

Milch Type II. This more common fracture line originates in the posterolateral metaphysis, where there is a fragment of variable size (Fig. 15-2). The fracture then usually courses within the physis down to the depths of the trochlea. The fracture line does not traverse the lateral condylar epiphysis or ossification center. The ossification center of the lateral condyle extends to the lateral crista of the trochlea. Thus, the terminal portion of the fracture line courses through the physeal cartilage that lies between the ossification centers of the lateral condyle and the medial condyle. In the age group in which most of these fractures occur, there is little ossification of the medial crista of the trochlea.

FIGURE 15-2. Physeal fractures of the lateral condyle. **A:** Physeal injury (Milch type II) through the nonossified trochlea. **B:** Physeal injury (Milch type I) through the ossific nucleus of the lateral condyle. (Redrawn from Milch HE. Fractures and fracture = ndislocations of the humeral condyles. *J Trauma* 1964;4:59-607; with permission.)

Because the fracture line starts in the metaphysis and then courses along the physeal cartilage, it has some of the characteristics of both type II and IV injuries according to the Salter-Harris classification. This fracture classification is debatable, because the fracture exits the joint in the not-yet-ossified cartilage of the trochlea.

Mirsky, Karas, and Weiner (71) compared intraoperative findings to preoperative radiographic classification in 25 displaced fractures of the lateral condyle and found that in 13 (52%) the Milch classification did not correlate with intraoperative findings. Eight of 17 fractures (47%) classified preoperatively as Milch type I fractures were unstable, and 5 of 8 fractures classified preoperatively as Milch type II fractures were extraarticular, extending across the distal humeral physis medially. Mirsky et al. identified three distinct fracture patterns: 9 fractures exited the distal humeral epiphysis just medial to the capitellum, 11 exited through the trochlear epiphysis, and 5 extended across the physis medially. No fracture appeared to traverse the ossified portion of the capitellum (Milch type I).

Stage of Displacement

Displacement has been described as occurring in three stages (Fig. 15-3) (55,61,99). In the first stage, the fracture is relatively undisplaced and the articular surface is intact (Fig. 15-3A and Fig. 15-3B). Because the trochlea is intact, there is no lateral shift of the olecranon.

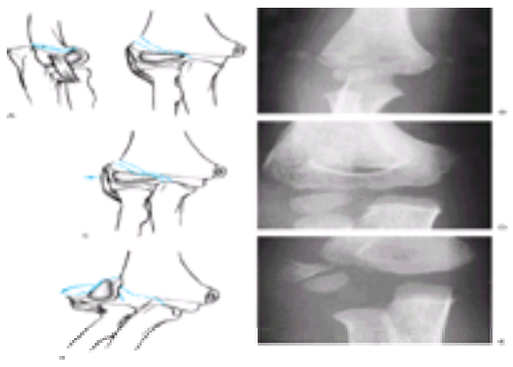

FIGURE 15-3. Stages of displacement.**A and B:** Stage I displacement—articular surface intact. **C and D:** Stage II displacement—articular surface disrupted. **E and F:** Stage III displacement—fragment rotated. (A, C, and E: Reprinted from Jakob R, Fowles JV, Rang M, et al. Observations concerning fractures of the lateral humeral condyle in children. *J Bone Joint Surg [Br]* 1975;57:430-436; with permission.)

In the second stage, the fracture extends completely through the articular surface (Fig. 15-3C and Fig. 15-3D). This allows the proximal fragment to become more displaced and can allow lateral displacement of the olecranon. In the third stage, the condylar fragment is rotated and totally displaced laterally and proximally, which allows translocation of both the olecranon and the radial head (Fig. 15-3E and Fig. 15-3F).

Badelon et al. (14) modified the description of stage I displacement to include fractures with less than 2 mm of displacement seen on the anteroposterior or lateral radiograph only or seen on both views.

Soft Tissue Injuries

The fracture line usually begins in the posterolateral metaphysis, with a soft tissue tear in the area between the origins of the extensor carpi radialis longus and the brachioradialis muscle. The extensor carpi radialis longus and brevis muscles remain attached to the free distal fragment, along with the lateral collateral ligaments of the elbow. If there is much displacement, both the anterior and posterior aspects of the elbow capsule usually are torn.

This soft tissue injury, however, is usually localized to the lateral side and may help identify a minimally displaced fracture. More extensive soft tissue swelling at the fracture site may indicate more severe soft tissue injury, which may be an indication that the fracture is prone to late displacement.

Displacement of the Fracture and Elbow Joint

The degree of displacement varies according to the magnitude of the force applied and whether or not the cartilaginous hinge of the articular surface remains intact. If the articular surface is intact, the resultant displacement of the condylar fragment is simply a lateral tilt hinging on the intact medial articular surface. If the fracture is complete, the fragment can be rotated and displaced varying degrees; in the most severe fractures almost the full 180° so that the lateral condylar articular surface opposes the denuded metaphyseal fracture surface. Wilson (101) showed that in addition to this coronal rotation of the distal fragment, rotation also can occur in the horizontal plane. The lateral margin is carried posteriorly, and the medial portion of the distal fragment rotates anteriorly.

Pattern Determines Stability

Because the usual fracture line disrupts the lateral crista of the trochlea (Milch type II), the elbow joint is unstable, creating the possibility of posterolateral subluxation of the proximal radius and ulna. Thus, the forearm rotates along the coronal plane into valgus, and there also may be lateral translocation of the lateral condyle with the radius and ulna (Fig. 15-4). This concept of lateral translocation is important in the late reconstruction of untreated fractures.

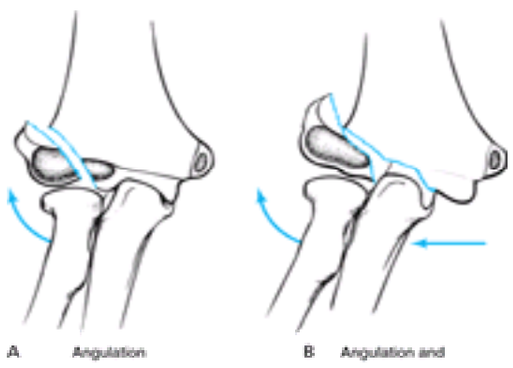

FIGURE 15-4. Angular deformities.**A:** Milch type I fractures tend only to angulate. **B:** Milch type II fractures are unstable with lateral translocation in addition to angulation. (Redrawn from Milch HE. Fractures and fracture-ndislocations of the humeral condyles. *J Trauma* 1964;4:592-607; with permission.)

In Milch type I physeal fractures, where the fracture line traverses the lateral condylar epiphysis, the elbow remains reasonably stable because the trochlea remains intact. Total coronal rotation of the condylar fragment can occur with this injury. The axial deformity that results is pure valgus without translocation (Fig. 15-4).

This posterolateral elbow instability with the lateral condylar physeal injury has led to the mistaken concept that this injury is associated with a primary dislocation of the elbow (26). Such rarely is the case. The posterolateral instability of the elbow usually is a result of the injury, not a cause of it (80).

Mechanism of Injury

As Heyl (49) has stated, the local biomechanics of the distal humerus must be different in children because of the rarity of this injury in adults. Two mechanisms have been suggested: “push off” or “pull off.”

The pull off or avulsion theory has more advocates (13,15,55,79,95). In early studies (13,95) this injury was consistently produced in young cadavers by adducting the forearm with the elbow extended and the forearm supinated. The results of these studies were confirmed by the work of Jakob and Fowles (55).

Some of Stimson's (95) work strengthens the push off theory. In his cadaver studies, he produced the injury by applying a sharp blow to the palm when the elbow was flexed (15,29,34,42). Others who support the push off theory have speculated that because the forearm goes into valgus when extended, the radial head can thus push off the lateral condyle. Some researchers have even proposed that it can be a result of a direct blow to the olecranon (24,34).

It is likely that both mechanisms can produce this injury. The more common type of fracture, which extends to the apex of the trochlea, is probably a result of avulsion forces on the condyle, with the sharp articular surface of the olecranon serving to direct the force along the physeal line into the trochlea (Fig. 15-5). When a child falls forward on the palm with the elbow flexed, the radial head is forced against the capitellum and may cause the less common Milch type I physeal fracture that courses through the capitulotrochlear notch.

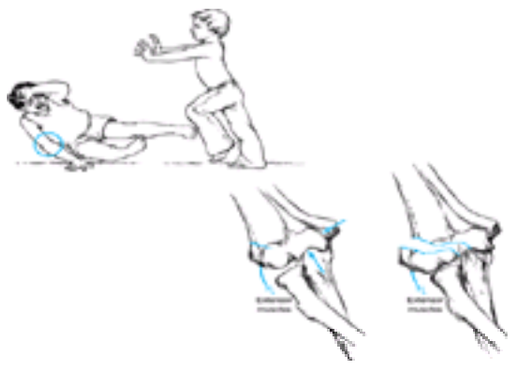

FIGURE 15-5. The most common mechanism of injury is believed to occur when the elbow is forced into varus (*bottom left*), which, along with the extensor muscles and lateral collateral ligaments, applies an avulsion force to the lateral condyle. When the fracture line extends to the trochlear notch (*bottom right*), the elbow becomes unstable.

Signs and Symptoms

Compared with the marked distortion of the elbow that occurs with displaced supracondylar fractures, little distortion of the elbow, other than that produced by the fracture hematoma, may be present with lateral condylar fractures. The key to the clinical evaluation of this fracture is the location of soft tissue swelling concentrated over the lateral aspect of the distal humerus. Stage I displacement may produce only local tenderness at the condylar fracture site, which may be increased by forcibly flexing the wrist (52). Stage II or III displacement may result in some local crepitus with motion of the lateral condylar fragment. The benign appearance of the elbow with some stage I and II displacements may account for the delay of parents seeking treatment for a child with a minimally displaced fracture.

Radiographic Findings

The radiographic appearance varies according to the anatomic location of the fracture line and the stage of displacement. In the anteroposterior view, the metaphyseal flake may be small and seemingly minimally displaced. The degree of displacement can often be better appreciated on the true lateral view. In determining whether the articular hinge is intact (i.e., stage I vs. stage II), the relationship of the proximal ulna to the distal humerus is evaluated for the presence of lateral translocation. Oblique views are especially helpful in patients in whom a stage I displacement is suspected.

In a prospective study of 112 children with nondisplaced and minimally displaced fractures of the lateral condyle, Finnbogason et al. (36) identified three groups of fractures: stable fractures, fractures with an undefinable risk, and fractures with a high risk of later displacement. Stable fractures had no gap or a small gap and did not extend all the way to the epiphyseal cartilage; most of these 65 fractures were in younger children and none had later displacement. Fractures with undefinable risk of displacement were of the same type as stable fractures but the fracture could be clearly observed extending all the way to the epiphyseal cartilage; displacement occurred in 6 (17%) of these 35 fractures. High-risk fractures had a gap that was as wide or almost as wide laterally as medially; displacement occurred in 5 of 12 (42%) of these fractures.

Kamegaya et al. (59) reported that magnetic resonance imaging (MRI) evaluation of 12 minimally displaced (<2 mm on radiography) lateral condylar fractures identified 5 fractures that crossed the physis into the joint space and were unstable fractures. One of 5 fractures with 1-mm displacement was unstable, and 4 of 7 with 2-mm displacement were unstable. They suggested that MRI evaluation might prevent late displacement or delayed union by identifying those minimally displaced fractures that required percutaneous pin fixation rather than cast immobilization.

A major diagnostic difficulty lies in differentiating this fracture from a fracture of the entire distal humeral physis. In a young child in whom the condyle is unossified, an arthrogram or MRI may be helpful (Fig. 15-6 and Fig. 15-7). Potter (76) recommended MRI with thin (1.5–2 mm) sections and appropriate pulse sequencing to provide differential contrast between subchondral bone, cartilage, and joint fluid.

FIGURE 15-6. Unossified lateral condyle. **A:** Anteroposterior view. A small ossific nucleus can barely be seen (*arrow*) in the swollen lateral soft tissues. **B:** An arthrogram shows the defect left by the displaced lateral condyle (*open arrow*). The displaced condyle is outlined in the soft tissues (*solid arrow*).

FIGURE 15-7. Arthrogram of stage I fracture of the lateral condyle (*large arrows*). Articular surface is intact with no displacement (*small arrows*).

In fractures of the entire distal humeral physis, the proximal radius and ulna usually are displaced posteromedially (Fig. 15-8A). The relationship of the lateral condylar ossification center to the proximal radius remains intact. In true fractures involving only the lateral condylar physis, the relationship of the condylar ossification center to the proximal radius is lost (Fig. 15-8B). In addition, any displacement of the proximal radius and ulna is more likely to be lateral because of the loss of stability provided by the lateral crista of the distal humerus.

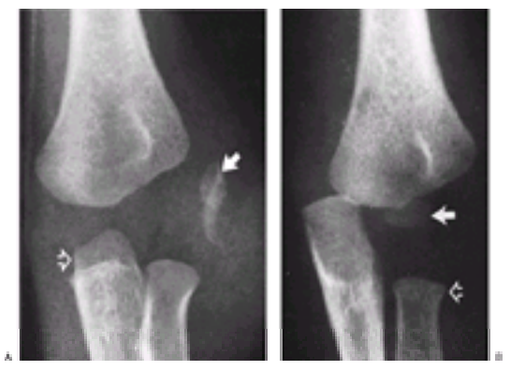

FIGURE 15-8. A: Total distal humeral physeal fracture in a 2-year-old. The lateral condyle (*closed arrow*) has remained in line with the proximal radius. The proximal radius, ulna, and lateral condyle have all shifted medially (*open arrow*). **B:** Displaced fracture of the lateral condyle in a 2-year-old. The relationship of the lateral condyle (*closed arrow*) to the proximal radius is lost. Both the proximal radius and ulna (*open arrow*) have shifted slightly laterally.

Methods of Treatment

Fractures involving the lateral condylar physis can be treated with simple immobilization alone, closed reduction and percutaneous pinning, or open surgical reduction.

Fractures Requiring Immobilization Only

Minimally displaced fractures are stable and have considerable intrinsic soft tissue attachments that prevent displacement of the distal fragment. About 40% of lateral condylar physeal fractures are sufficiently undisplaced that they can be treated by simple immobilization without surgical intervention (55,63,84). If the fracture line is barely perceptible on the original radiograph (stage I displacement), the degree of displacement usually is minimal and the chance for subsequent displacement is low (Fig. 15-9).

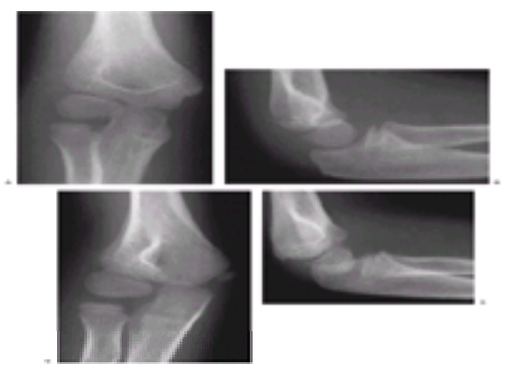

FIGURE 15-9. Stage I fracture of the lateral condyle. **A:** Anteroposterior radiograph shows 1-mm fracture line. **B:** Lateral view shows 2 mm of displacement with posterolateral Thurston-Holland fragment. **C and D:** Anteroposterior and lateral radiographs 4 weeks later show healed fracture with callus formation.

Badelon et al. (14) determined in their long-term study of fractures treated nonoperatively that only fractures with type I displacement (i.e., the fracture line is seen on only one radiographic view) can be safely treated nonoperatively. In their experience, any fracture with displacement, even of less than 2 mm, can displace later in the cast or splint. Beaty and Wood (18), in a review of 57 fractures of the lateral condyle, found that 2 of 24 fractures with stage I displacement displaced late. Bast, Hoffer, and Aval (16) reported a union rate of 98% after nonoperative treatment of 95 nondisplaced or minimally displaced fractures of the lateral humeral condyle. Their criteria for nonoperative treatment were acute fracture (less than 24 hours at initial evaluation) and displacement of less than 2 mm in three radiographic planes (anteroposterior, lateral, and internal oblique). Two fractures that displaced 6 and 9 days after closed reduction required open reduction and internal fixation before they united without complications.

Late Displacement

Careful clinical examination is important in predicting which fractures will displace later. The potential to displace often depends more on the degree of associated soft tissue injury and whether the articular cartilage of the trochlea is intact, rather than on the amount of initial displacement. Considerable soft tissue swelling on the lateral aspect of the distal humerus, which can be appreciated both clinically and on radiographs, should alert the physician to the fact that the fracture may be unstable and has the potential to displace. If crepitus between the fragments is detected with motion of the forearm or elbow, significant loss of soft tissue attachments and a potentially unstable fracture should be suspected (17).

Critical Value

Undisplaced fractures usually can be treated with simple immobilization with good results. Speed and Macey (93) reported uniformly excellent results both anatomically and functionally in patients with undisplaced fractures, none of whom had any abnormalities of growth or premature physeal fusion. Simple immobilization of nondisplaced or minimally displaced (<2 mm) fractures in a sling, collar and cuff, or posterior splint appears adequate (93,99,103). Close follow-up and repeat radiographs to detect any late displacement are mandatory if this method is used.

Closed Reduction and Percutaneous Pinning

Several techniques have been described for initial reduction, with the recommended elbow position ranging from hyperflexion to full extension; however, it appears from clinical experience (425) and experimental studies that reduction is best achieved with the forearm supinated and the elbow extended. Placing a varus stress on the extended elbow allows further room for manipulation of the fragment. Unfortunately, it is difficult to maintain reduction of a displaced lateral condylar fracture with closed techniques, and closed reduction is not recommended for treatment of type III displaced lateral condylar fractures. It has become popular to reduce minimally displaced fractures initially by closed manipulation, and then stabilize them by percutaneously placing pins across the fracture. In some fractures of the lateral condylar physis, simple immobilization is all that is necessary. In those with moderate displacement, confirmation of fracture stability by stress testing and arthrography may precede percutaneous pin fixation. Mintzer et al. (69) reported good results after percutaneous pin fixation of 12 lateral condylar fractures with displacement of more than 2 mm. They believed this method is appropriate for selected fractures with more than 2 mm of displacement and an arthrographically demonstrated congruent joint surface. If a satisfactory reduction cannot be obtained, then reduction should be achieved and maintained by open reduction and internal fixation.

Fractures Requiring Open Reduction

Because of the high incidence of poor functional and cosmetic results with closed reduction methods, open reduction has become the most widely advocated method for unstable fractures with stage II displacement and fractures with stage III displacement (15,19,20,21,22,25,26,30,33,34,47,53,55,56,63,64,77,79,86,87,89,90,96,99,100,102,103). About 60% of all fractures involving the lateral condylar physis require reduction and internal fixation (55,63,84).

There is almost uniform agreement about the need for open reduction of displaced fractures of the lateral condylar physis. Most investigators recommend fixation with smooth Kirschner wires in children or screws in adolescents nearing skeletal maturity.

Pin and Screw Fixation

Smooth pins are the most frequently used method of fixation of the fragment (18,23,34,40,42,53,55,63,79,84,90,93,99,102 and 103). Blount et al. (19) believed that at least two pins were necessary to prevent rotation. The passage of a smooth wire through the physis does not result in any growth disturbance (84,93). This is of note because only 20% of the growth of the humerus occurs through the distal humeral physis. It also appears that the wires can be placed either parallel or crossed in the distal fragments.

The ideal place for the pins is in the metaphyseal fragment. They should cross at the lateral aspect of the metaphysis and diverge as much as possible to enhance the stability of fixation. If there is only a small metaphyseal fragment, the pins can be placed across the physis without concern.

When adequate reduction and internal fixation are performed early (i.e., within the first few days of the injury), the results are uniformly good. The key, however, is to be sure that the reduction is adequate. Hardacre et al. (47) found that poor results with open reduction occurred when the reduction was incomplete. Surgery alone does not ensure a good result unless the reduction is nearly anatomic and the fixation is secure.

Early surgical intervention is essential, because organization of the clot with early fibrin development makes it difficult to achieve a reduction without extensive soft tissue dissection in fractures treated late. The pins can be buried or left protruding through the skin with no increase in the incidence of infection. Leaving pins buried requires a second operative procedure, even though it usually can be accomplished with a local anesthetic. The fracture is usually sufficiently stable to allow pin removal by 3 to 4 weeks and to allow the patient to begin protected active range of motion of the elbow at 2 to 3 weeks.

Screw fixation has been used less frequently in children, although it was recommended by Jeffrey in 1958. Connor and Smith (56) used fully threaded Glasgow screws in 35 patients and found limitations of 5 to 25 degrees of extension in 9; in 5 patients the screw backed out and was found loose. Sharma et al. (85) reported painless, full range of elbow motion in 36 of 37 children who had displaced (> 2 mm in any direction) lateral condylar fractures fixed with partially threaded 4-mm AO cancellous screws. One patient had delayed union, with loss of 10 degrees of elbow motion.

AUTHORS' PREFERRED METHOD OF TREATMENT

Immobilization

If the fracture is minimally displaced on the radiograph (i.e., the metaphyseal fragment is <2 mm from the proximal fragment on anteroposterior and lateral views) and the clinical signs also indicate there is reasonable soft tissue integrity, we simply immobilize the elbow in a posterior splint with the forearm in neutral rotation and the elbow flexed 90 degrees (Fig. 15-9). Radiographs are taken within the first 3 to 5 days after the fracture with the splint removed and the elbow comfortably extended. If there is no displacement, the radiographs are repeated in another 3 to 5 days. If the radiographs again show no displacement, then a long arm cast is applied and is worn for about 3 weeks, or until fracture union is apparent.

In some fractures with more than the allowable 2 mm of displacement (type II injury), the fracture pattern is such that the articular cartilage appears intact. If there is any question about the stability at the time of the fracture, the extremity should be examined with the patient under general anesthesia. Gentle varus stress views with the forearm supinated and the elbow extended should be taken to determine if the fracture displaces significantly. Arthrography may be performed to determine the stability of the nonossified articular cartilage of the trochlea.

Percutaneous Pins

For fractures with stage II displacement (2–4 mm), varus stress views should be obtained and arthrography performed with the patient under anesthesia. If the fracture is stable, percutaneous pinning is indicated (Fig. 15-10).

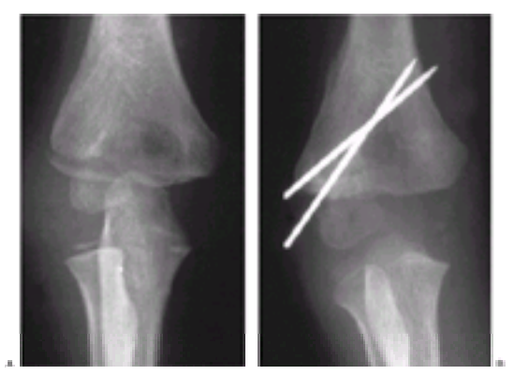

FIGURE 15-10. Stage II fracture of the lateral condyle. **A:** Anteroposterior radiograph shows 4 mm of displacement of the metaphyseal segment; however, the fracture was stable by stress examination and arthrography. **B:** Four weeks after percutaneous pinning, the fracture is healed.

Open Reduction

If the fracture is grossly unstable, open reduction and internal fixation should be performed. We prefer open reduction and internal fixation of all fractures with stage III displacement. It is important to perform the open reduction as soon as possible after the injury. The standard lateral Kocher approach provides sufficient exposure of the fragment. Often a tear in the aponeurosis of the brachioradialis muscle laterally leads directly to the fracture site. Extreme care must be taken to avoid dissecting near the posterior portion of the fragment, because this is the entrance of the only blood vessel supplying the lateral condylar epiphysis.

A posterolateral approach was recommended by Mohan, Hunter, and Colton (71) because of the excellent exposure it provides with minimal dissection. Another suggested advantage is the improved cosmetic results by more posterior placement of the surgical scar. Mohan et al. reported no complications in 20 patients in whom this approach was used.

The quality of the reduction is determined by evaluating the fracture line along the anterior aspect of the articular surface. This can usually be determined either by direct vision or by digital palpation. We prefer to use smooth Kirschner wires that cross just medial to the condylar fragment to maintain the reduction. The wires penetrate the skin through a separate stab incision posterior to the main incision. A long arm cast is applied with the elbow flexed 90 degrees and the forearm in neutral or slight pronation. The cast and pins are removed in 3 weeks if there is adequate healing on radiographs. Early active motion is started at that time. If necessary, pin removal can be delayed 1 to 2 weeks to allow further healing in older children.

Technique of Open Reduction and Internal Fixation of Fractures of the Lateral Humeral Condyle

The elbow is exposed through a 5- to 6-cm lateral approach, placing two thirds of the incision above the joint and one third distal (Fig. 15-11). In the interval between the brachioradialis and the triceps, the dissection is carried down to the lateral humeral condyle. The anterior surfaces of the joint are exposed by separating the fibers of the common extensor muscle mass. Soft tissue detachment is limited to only that necessary to expose the fragment, the fracture, and the joint; the posterior soft tissues are left intact. The anterior joint surface is exposed by retracting the antecubital structures. The trochlea and the more medial point of entry of the condylar

fracture are inspected. The displacement and the size of the fragment are always greater than is apparent on the radiographs because much of the fragment is cartilaginous. The fragment usually is rotated as well as displaced. The joint is irrigated to remove blood clots and debris, the articular surface and the metaphyseal fragment are reduced accurately, and the reduction is confirmed by observing the articular surface, particularly at the trochlear ridge. The position is held with a small tenaculum, bone holder, or towel clip. When a large metaphyseal fragment is present, two smooth Kirschner wires are inserted across it into the medial portion of the metaphysis. When the epiphyseal portion is small, as is more common, two smooth Kirschner wires are inserted through the condyle, across the physis, and into the humeral metaphysis, penetrating the medial cortex of the humerus. The wires are directed 45 to 60 degrees; the reduction and the position of the internal fixation are checked by anteroposterior and lateral radiographs before closing the wound. The ends of the wires are cut off beneath the skin but are left long enough to allow easy removal. The arm is placed in a posterior plaster splint with the elbow flexed 70 to 90 degrees.

FIGURE 15-11. Lateral approach for open reduction and internal fixation of a lateral humeral condylar fracture of the left elbow. The approach is made through the brachioradialis-ntriceps interval, an anterior retractor is used to expose the joint surfaces, and the fracture is reduced and pinned percutaneously posterior to the incision.

The splint is worn for 2 to 3 weeks after surgery. The pins can be removed at 3 weeks if union is progressing. Gentle active motion of the elbow is then usually resumed and continued until full range of motion returns.

Delayed Union and Nonunion

If sophisticated surgical treatment is unavailable, these fractures may go untreated or unrecognized for a prolonged period. Even in modern medical settings, elbow injuries may be treated as “sprains,” and the diagnosis of a displaced lateral condylar fracture is not made. Thus, patients often present months or even years later with a nonunited or malunited fracture fragment.

Delayed Union

Delayed union, in contrast to nonunion or malunion, occurs in a fracture in which the fracture fragments are in satisfactory position but union of the lateral condylar fragment to the metaphysis is delayed. Various reasons have been suggested for delayed union of lateral condylar fractures. Flynn and Richards (37) speculated that it was caused by poor circulation to the metaphyseal fragment. Hardacre and colleagues (47) believed that bathing of the fracture site by articular fluid inhibited fibrin formation and subsequent callus formation. Probably a combination of these two factors, in addition to the constant tension forces exerted by the muscle arising from the condylar fragment, is responsible for delayed union.

This complication is most common in patients treated nonoperatively. The aggressiveness of treatment is determined by the symptoms and clinical examination. The fragment usually is stable during clinical examination, the elbow is nontender, and the range of elbow motion increases progressively. On radiography, the position of the fragment remains unchanged. With time, these fractures usually heal (Fig. 15-12). Lateral spur formation or cubitus varus is relatively common with these fractures. The need for further treatment depends on the presence of significant symptoms or further displacement that may disrupt the joint surface and cause functional impairment. If neither of these conditions is present, the radiographic persistence of the fracture line requires only follow-up observation. If there is any question as to the integrity of the joint surface, an arthrogram may help determine any loss of continuity and the need for surgical treatment as a nonunion rather than a simple delayed union.

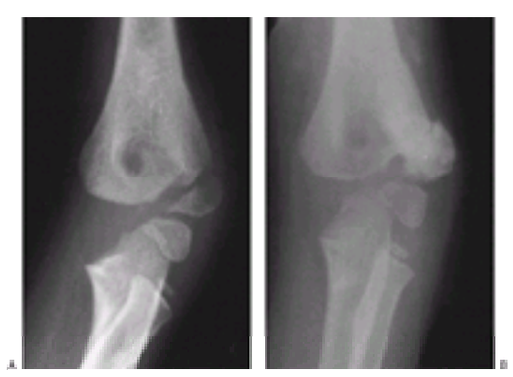

FIGURE 15-12. Delayed union and cubitus varus. **A:** Stage III lateral condylar fracture in a 7-year-old boy was treated in a cast. **B:** Seven months later, delayed union with malunion of the fracture and cubitus varus deformity were present.

Flynn (37,38 and 39) recommended long-term immobilization for minimally displaced fractures with delayed union. He found that 70% of minimally displaced fractures had united by 12 weeks. Jeffrey (56) recommended screw fixation with bone grafting. Hardacre et al. (47), however, found that minimally displaced fractures with delayed union ultimately united if there was no significant displacement of the condylar fragment.

Controversy exists as to whether elbow function can be improved by a late open reduction and internal fixation of the fracture fragment. Delayed open reduction has been complicated by osteonecrosis and further loss of elbow motion. Speed and Macey (93) were among the first investigators to question whether patients treated with late surgery did better than those not treated. In patients with malunion who were treated late, they found a high incidence of poor results due to “epiphyseal changes” that probably represented osteonecrosis. There have been many subsequent reports of osteonecrosis occurring after late open reduction. The high incidence of osteonecrosis of the fragment is believed to be due to the extensive soft tissue dissection necessary to replace the fragment. Böhler (21), on the other hand, had good results in his patients with delayed treatment. He avoided extensive soft tissue dissection by approaching the fragment transarticularly after performing an osteotomy of the olecranon.

The key to preventing osteonecrosis is to recognize the course of the blood supply to the lateral condyle. Only a small portion of the condyle is extraarticular. In his studies, Haraldsson (46) found that the vessels that supply the lateral condylar epiphysis penetrate the condyle in a small posterior nonarticular area (Fig. 15-13).

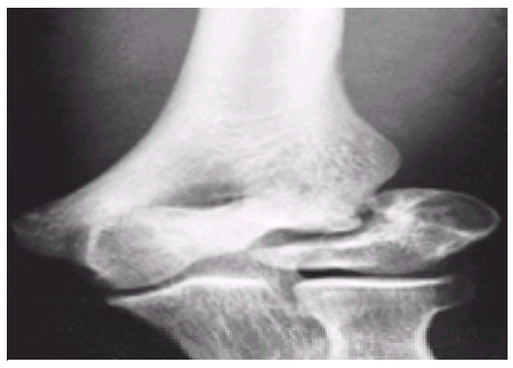

FIGURE 15-13. Asymptomatic nonunion of a lateral condyle in a 19-year-old military recruit. Because the patient had a completely normal and asymptomatic range of motion in his nondominant extremity, operative stabilization was not thought to be necessary.

Jakob and Fowles (55) reported that patients treated later than 3 weeks after the fracture did no better than those who received no treatment at all. They found that early callus and fibrous tissue made it extremely difficult to obtain a satisfactory open reduction without performing considerable soft tissue dissection. All their patients treated after 3 weeks lost range of motion, the average being at least 34 degrees, and osteonecrosis, premature physeal closure, and valgus deformity were common. In patients who received no treatment, valgus deformity due to nonunion and malunion was frequent, but no osteonecrosis of the lateral condylar epiphysis occurred. They recommended that no open reduction be performed for fractures older than 3 weeks, but that early ulnar nerve transposition be performed to eliminate the possibility of late ulnar nerve symptoms that occur with cubitus valgus deformity after nonunion. Dhillon et al. (32) and Zionts and Stolz (104) also reported that osteonecrosis was frequent after late open reduction and recommended no treatment for these fractures.

Nonunion

In 1932, Cooper (28) drew attention to the development of nonunion after lateral humeral condylar fractures when he described his findings in two cadaver specimens. He pointed out that there was absolutely no bony continuity between the distal humerus and the condylar fragment. True nonunion with significant deformity is rare because it is usually the result of nontreatment of a displaced fracture of the lateral condylar physis (19,64,84).

True nonunion occurs in patients with progressive displacement of the fragment. The mobile fragment can be palpated, or the patient has weakness or pain in the elbow. According to the criteria of Flynn et al. (39), if the fracture has not united by 12 weeks, it is classified as a nonunion.

Nonunion can occur with or without angular deformity. Many patients with nonunions and minimal displacement of the fragment have no angulation and remain relatively asymptomatic for normal activities (Fig. 15-13). Others have weakness or symptoms when the arm is used for high-performance activities. Because they are not significantly displaced, these fractures can often be stabilized with minimal extraarticular dissection using a combination of screw fixation and a laterally placed bone graft.

Nonunion with subsequent displacement of the fragment is more common after unstable fractures with stage II and III displacement. If the fragment becomes free, it tends to migrate proximally with a subsequent valgus deformity of the elbow. Nonunion can lead to a cubitus valgus deformity, which in turn is associated with the development of a tardy ulnar nerve palsy.

Nonunion seems to occur when the distal fragment is displaced enough to allow the cartilaginous articular surface of the condylar fragment to oppose the bony surface of the humeral metaphysis. In such a situation, union is impossible.

Patients with established nonunion lose some range of motion but still function well. Smith (91) reported an 85-year follow-up of a patient with a nonunion, cubitus valgus, and mild ulnar neuropathy. Despite these complications, the patient was a musician, playing the French horn for over 35 years. Kalenak (58) reported a similar 50-year follow-up of nonunion of the lateral condyle in a 74-year-old laborer who had minimal symptoms. Other than the secondary effects of a tardy ulnar nerve palsy, the functional difficulties caused by an established nonunion are not severe (55,72,79). This has led many investigators to recommend no treatment at all or no treatment until the patient has achieved full skeletal growth for an established nonunion elbow deformity (18,20,47,55). Flynn and Richards (37), however, reported successful treatment of nonunion 9 months to 3 years after fracture and strongly advised early surgery for established nonunion when the condylar fragment is in “good position” in a child with open physes.

The most common sequela of nonunion with displacement is the development of a progressive cubitus valgus deformity. The fragment migrates both proximally and laterally, giving not only an angular deformity but also lateral translocation of the proximal radius and ulna (Fig. 15-14). Milch (67) noted that lateral translocation is not as likely to develop in the more lateral type of these fractures (Milch type I) because the lateral crista of the trochlea is intact (Fig. 15-15).

FIGURE 15-14. A:A 10-year-old boy with cubitus valgus resulting from a fracture of the lateral condylar physis with nonunion. **B:** Nonunion with cubitus valgus. Radiograph showing both angulation and translocation secondary to nonunion of the condylar fragment.

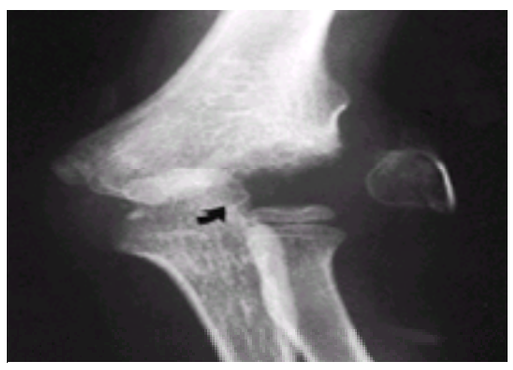

FIGURE 15-15. Nonunion without translocation. Milch type I fracture pattern. Despite nonunion, elbow stability was maintained because the lateral crista of the trochlea had remained intact (*arrow*). Valgus angulation also developed.

Surgical treatment of the nonunion deformity of the lateral condylar fragment is difficult and requires correction of two problems. First, articular cartilage may be opposing the distal humeral metaphysis, and union seldom can be obtained without mobilization of the fragments and application of an internal compressive device. The second problem is correction of the angular deformity. In a Milch type I fracture pattern, correction of the angulation may require only a simple closing wedge osteotomy (Fig. 15-16). Correction of the angular deformity in a Milch type II fracture pattern may involve not only correction of the angulation, but also translocation of the distal fragment back to its original linear alignment. Achieving solid fixation with this type of osteotomy is difficult without using appropriate internal fixation. Often the deformity is corrected, but because of the extensive soft tissue dissection required, the patient loses range of elbow motion postoperatively. Jakob and Fowles (55) pointed out that even with correction of the deformity, tardy ulnar nerve paralysis can still develop because it is trapped in the cubital tunnel. They recommended simply transposing the ulnar nerve and not treating the deformity.

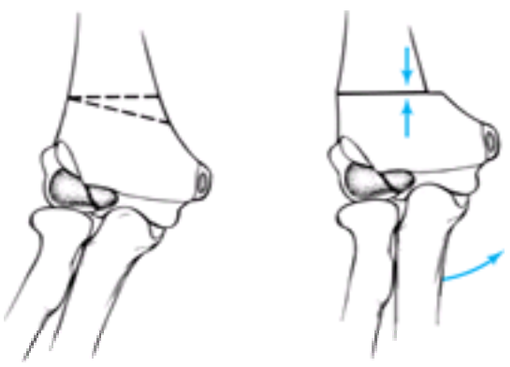

FIGURE 15-16. In the Milch type I fracture pattern, there is only an angular deformity that can be easily corrected with a closing wedge osteotomy. (Redrawn from Milch HE. Fractures and fracture-ndislocations of the humeral condyles. *J Trauma* 1964;4:592-607; with permission.)

Shimada et al. (88) reported excellent or good results in 15 of 16 patients at an average follow-up of 11 years after osteosynthesis for nonunion of fractures of the lateral humeral condyle. The one patient with a poor result had evidence of osteonecrosis of the fragment. The average interval between injury and osteosynthesis was 5 years (range 5 months to 10 years). Presenting symptoms were elbow pain (n = 7), apprehension (n = 9), cubitus valgus deformity (n = 6), limitation of motion (n = 3), and dysfunction of the ulnar nerve (n = 4). Osseous union was obtained after the initial operation in 13 of the 16 patients. Of the 3 patients with persistent nonunions, 2 had union after a second osteosynthesis with bone-grafting and the other, who was asymptomatic, refused additional treatment. To prevent progression of cubitus valgus deformity and subsequent ulnar nerve dysfunction, Shimada et al. (88) recommended osteosynthesis for nonunion of lateral humeral condylar fractures in children because union is easily achieved, the range of motion is maintained, the function of the ulnar nerve usually returns, and remodeling of the articular surfaces can be expected. They noted that bone grafting is essential to bridge the defect, to obtain congruity of the joint, and to promote union; damage to the blood supply should be avoided to prevent osteonecrosis.

AUTHORS' PREFERRED METHOD OF TREATMENT

We distinguish between fractures seen late (>7–14 days after injury) and established nonunions (usually from 3 months to several years after injury). If we believe that we can obtain fracture union without loss of elbow motion and avoid osteonecrosis of the lateral condyle, then we recommend surgery for selected patients.

Treatment of an established nonunion of a lateral humeral condylar fracture poses a difficult dilemma. If no treatment is rendered, a progressive cubitus valgus deformity occurs with growth. Patients usually are asymptomatic except for those with high-demand athletic or labor activities. A mild flexion contracture of the elbow is present, but the cubitus valgus deformity is more cosmetic than functional. The danger in this approach is failure to recognize and treat early a tardy ulnar nerve palsy. If surgery is performed for an established nonunion, the potential risks of osteonecrosis and loss of elbow motion must be carefully considered.

We believe the criteria outlined by Flynn et al. (37,39) are helpful in determining if surgical treatment is appropriate for an established nonunion:

1. A large metaphyseal fragment
2. Displacement of less than 1 cm from the joint surface
3. An open, viable lateral condylar physis

It also is helpful to distinguish between three distinct clinical situations. First, for an established nonunion with a large metaphyseal fragment, minimal migration, and an open lateral condylar physis, we recommend modified open reduction, screw fixation, and a lateral extraarticular iliac crest bone graft. This technique is markedly different from the surgical treatment of an acute lateral condylar fracture. The metaphyseal fragment of the lateral condyle and the distal humeral metaphysis are exposed, but no attempt is made to realign the articular surface. Intraarticular dissection should be avoided to help prevent any further loss of elbow motion. The metaphyseal fragments are debrided by gentle removal of any interposed fibrous tissue. The lateral condylar fragment usually can be moved distally a small distance. The metaphyseal fragments are firmly opposed, and a cancellous or cortical screw is used to fix the fragments with interfragmentary compression. Iliac crest bone graft may be placed between the metaphyseal fragments and laterally. The elbow is immobilized in 80 to 90 degrees of flexion for 3 to 4 weeks (Fig. 15-17).

FIGURE 15-17. A: Established nonunion with a large metaphyseal fragment. **B and C:** After fixation with a cancellous screw and bone grafting of the metaphyseal fragment.

Second, in patients with a nonunion who have cosmetic concerns but no functional complaints, treatment is similar to that for cubitus varus deformity after a supracondylar humeral fracture. If the patient and family desire, a supracondylar osteotomy may be performed (62). Rigid internal fixation should be used to allow early motion. Rarely in an adolescent or young adult with high functional demands and symptoms of instability, late osteosynthesis of the lateral condyle may be performed.

Third, patients with asymptomatic nonunion, cubitus valgus deformity, and symptomatic tardy ulnar nerve palsy should be treated with transposition of the ulnar nerve.

Complications

If an adequate reduction is obtained promptly and maintained with solid fixation, results are uniformly good. In supracondylar fractures, an incomplete reduction may result in a cosmetic deformity, but functional results usually are good. In displaced fractures of the lateral condylar physis, a marginal reduction can result in both cosmetic deformities and functional loss of motion.

The complications that affect the outcome can be classified as either biologic or technical. Biologic problems occur as a result of the healing process, even if a perfect reduction is obtained. These problems include spur formation with pseudo–cubitus varus or a true cubitus varus. The technical problems arise usually from errors in management and result in nonunion or malunion with or without valgus angulation, and osteonecrosis. Other technical problems can arise from the injury itself, including neurologic injuries and myositis ossificans.

Lateral Spur Formation

Lateral condylar spur formation is one of the most common deformities after a fracture involving the lateral condylar physis. Cotton (29) believed that it is caused by coronal rotation of the distal fragment, which tends to displace laterally the flap of periosteum associated with the distal fragment. This periosteum then produces new bone formation in the form of a spur. He believed that this spur formation produces no functional deformity. Maylahn and Fahey (63) found that this occurred in at least 28% of their patients. Wadsworth (99) agreed with Cotton that it was of no functional importance, and he also believed that the cosmetic effect is insignificant.

The spur occurs after both nonoperative and operative treatment. After nonoperative treatment, it results from the minimal displacement of the metaphyseal fragment and usually has a smooth outline. In patients with no real change in carrying angle, the lateral prominence of the spur may produce an appearance of mild cubitus varus (pseudovarus). In patients in whom a true cubitus varus develops, the presence of the lateral spur accentuates the varus alignment (Fig. 15-18A and Fig. 15-18B). The spur that occurs after operative treatment has a more irregular outline and usually is the result of hypertrophic bone formation from extensive dissection at the time of open reduction and internal fixation (Fig. 15-18C and Fig. 15-18D). When performing an open reduction, care should be taken to limit the aggressiveness of the dissection and to carefully replace the lateral periosteal flap of the metaphyseal fragment.

FIGURE 15-18. Spur formation. **A:** Follow-up radiograph of a boy whose lateral condyle was treated nonoperatively. The periosteal flap produced a spur on the lateral aspect of the metaphysis (*arrow*). This fracture healed with a mild varus angulation as well. **B:** Clinically, the spur accentuated the lateral prominence (*arrow*) of the elbow, which in turn accentuated the mild valgus angulation. (Reprinted from Wilkins KE. Residuals of elbow fractures. *Orthop Clin North Am* 1990;21:289-312; with permission.) **C:** Considerable soft tissue dissection was performed in the process of open reduction of this lateral condylar fracture. **D:** At 2 months postsurgery, there is a large irregular spur formation secondary to periosteal new bone formation from the extensive dissection.

Before treatment, the parents should be warned that either lateral overgrowth with mild cubitus varus or lateral spur may develop, regardless of the method of treatment. They should be told that this mild deformity is usually not of cosmetic or functional significance. If these problems are explained to the parents beforehand, they are less likely to be anxious and critical of the result should it be less than perfect.

Cubitus Varus

Reviews of lateral condylar fractures demonstrate that a surprising number heal with some residual cubitus varus angulation (34,41,48,50,60,64,73,81,82,92,97). In some series, the incidence of cubitus varus is as high as 40% (41,92), and the deformity seems to be as frequent after operative treatment as after nonoperative treatment (50,81,92). The exact cause is not completely understood. In some instances, it is probably a combination of both an inadequate reduction and stimulation of growth of the lateral condylar physis from the fracture insult (Fig. 15-19) (82,92).

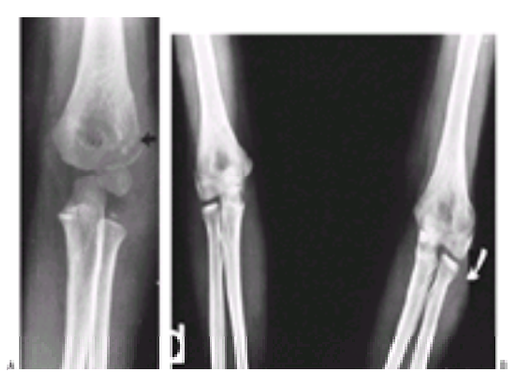

FIGURE 15-19. True varus. **A:** The injury film with a minimally displaced fracture (*arrow*). This 5-year-old child was treated with simple immobilization until the fracture was healed. **B:** Five years later, the patient had a persistent cubitus varus (*arrow*) that remains clinically apparent. The carrying angle of the uninjured right elbow measures 5 degrees of valgus; the injured elbow has 10 degrees of varus. (Reprinted from Wilkins KE. Residuals of elbow trauma in children. *Orthop Clin North Am* 1990;21:289-312; with permission.)

Rarely is the cubitus varus deformity severe enough to cause concern or require further treatment. This is probably because it is a pure coronal varus angulation and does not have the horizontal anterior rotation of the lateral condyle along with the sagittal extension that makes the cubitus varus that occurs after supracondylar fractures such an unacceptable deformity. Some investigators have noted that children with cubitus varus deformities have pain, decreased range of motion, epicondylitis, and problems with sports such as sidearm pitching, swimming, judo, and pushups. Davids and colleagues (31) reported lateral condylar fractures in six children with preexisting cubitus varus deformities from previous elbow fractures, usually supracondylar humeral fractures. They concluded that posttraumatic cubitus varus deformity may predispose a child to subsequent lateral condylar fracture and should be viewed as more than just a cosmetic deformity. They recommended a two-stage correction of the deformity: anatomic reduction and internal fixation of the lateral condyle, followed by valgus supracondylar osteotomy of the distal humerus.

Cubitus Valgus

Cubitus valgus is much less common after united lateral condylar fractures than cubitus varus. It rarely has been reported to result from premature epiphysiodesis of the lateral condylar physis (50,98). As with cubitus varus, it is usually minimal and rarely of clinical or functional significance. The more difficult type of cubitus valgus associated with nonunions was discussed in the preceding section on nonunions.

Technical Problems

Nonunion/Delayed Union

The most common technical problem is nonunion, usually due to inadequate treatment. Management of this problem was discussed in the previous section dealing with treatment of nonunions. Delayed union was also discussed in that section.

Fishtail Deformity

Two types of fishtail deformity of the distal humerus may occur. The first, a sharp-angled wedge, commonly occurs after fractures of the lateral condyle (Fig. 15-20). This type is believed to be caused by persistence of a gap between the lateral condylar physis ossification center and the medial ossification of the trochlea (98,102). Because of this gap, the lateral crista of the trochlea may be underdeveloped, and this may represent a small “bony bar” in the distal humeral physis (48). Rutherford (81) found that this type of deformity occurred only in fractures that were inadequately reduced. Despite some reports of loss of elbow motion with this type of fishtail deformity (99), most investigators (14,18,32,41) have not found this type of radiographic deformity to produce any functional deficiency.

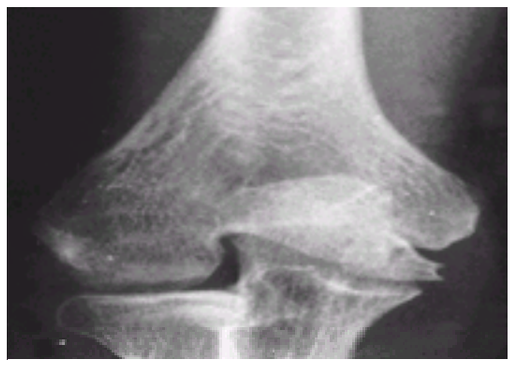

FIGURE 15-20. An angular fishtail deformity has persisted in this 14-year-old boy who sustained a lateral condylar fracture that was treated operatively 6 years previously.

The second type of fishtail deformity is a gentler smooth curve. It is usually believed to be associated with osteonecrosis of the lateral part of the medial crista of the trochlea (74). The mechanisms of the development of this type of deformity are discussed in the section on osteonecrosis of the trochlea.

Neurologic Complications

The neurologic complications can be divided into two categories: acute nerve problems at the time of the injury and delayed neuropathy involving the ulnar nerve (the so-called tardy ulnar nerve palsy).

Acute Nerve Injuries

Reports of acute nerve injuries associated with this injury are rare. Smith and Joyce (89) reported two patients with posterior interosseous nerve injury after open reductions of the lateral condylar fragment, both of whom recovered spontaneously. McDonnell and Wilson (64) reported a transient radial nerve paralysis after an acute injury.

Friedman and Smith (43) reported a delayed radial nerve laceration from the tip of the screw that was used to stabilize a lateral condylar fracture 26 years earlier. This occurred when the patient sustained a hyperextension injury to the elbow.

Tardy Ulnar Nerve Palsy

Tardy ulnar nerve palsy as a late complication of fractures of the lateral condylar physis is well known. One of the earliest and most complete studies of this problem in the United States was conducted by Miller (68) in 1924. Forty-seven percent of his patients with tardy ulnar nerve palsy had fractures of the lateral condylar physis as a child. The onset of the symptoms varied from 30 to 40 years. Subsequently, reports by numerous other investigators confirmed the frequency of this complication after the development of cubitus valgus from malunion or nonunion of fractures of the lateral condylar physis (27,35,45,57,65). The symptoms are usually gradual in onset. Motor loss occurs first, with sensory changes developing somewhat later (27,45). In Gay and Love's series (45) of 100 patients, the average interval of onset was 22 years.

Various methods of treatment have been advocated, ranging from anterior transposition of the ulnar nerve (originally the most commonly used procedure) to simple relief of the cubital tunnel. In 1972, Wadsworth (99) listed nine operative procedures described between 1898 and 1957 for treatment of tardy ulnar palsy. We prefer simple subcutaneous anterior transposition of the nerve.

Physeal Arrest

Physeal arrest may be manifest by no more than premature fusion of the various secondary ossification centers to each other, with little or no deformity. Such a situation occurs much later than the original fracture. This phenomenon probably occurs because the fracture stimulates the ossification centers to grow more rapidly and thus they reach maturity sooner, or, rarely, it is caused by inadvertent dissection in the lateral condylar physis. Because only 20% of humeral growth occurs in the distal physis, physeal arrest rarely causes any significant angular or length deformities.

Malunion

Rarely, the fragment unites in an undesirable position. Cubitus valgus has been reported to occur as a result of malunion of the fracture fragments (94,99). Malunion of a Milch type I fracture pattern can result in the development of a bifid lateral condyle (Fig. 15-21). No reliable operative treatment has been described to reestablish the congruity of the articular surfaces in condylar malunions, and they probably are best left untreated. We have seen several patients with malunions in which the lateral condyle rotates in the coronal plane, with subsequent cubitus varus deformity.

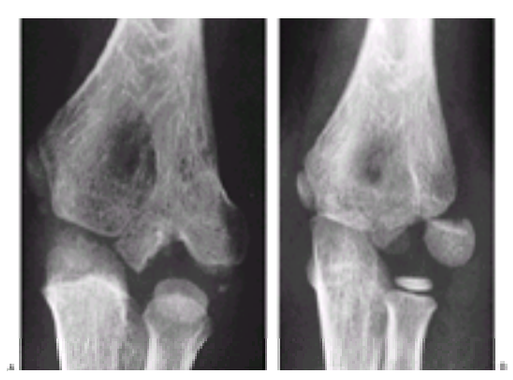

FIGURE 15-21. A: Injury film of a 7-year-old who sustained a Milch type I lateral condylar fracture. This patient was treated with cast immobilization alone. **B:** Film taken 2 years later showed complete fusion of the condylar epiphysis to the metaphysis, with the development of a “bifid” condyle.

Osteonecrosis

Osteonecrosis of the condylar fragment may be iatrogenic in origin and is most commonly associated with the extensive dissection necessary to effect a late reduction (H. Brindley, personal communication) (47,55,64). Wilson (102), however, described partial osteonecrosis in an essentially nondisplaced fracture of the lateral condylar physis that had a radiographic appearance and clinical course similar to those of osteochondritis dissecans. Osteonecrosis is rare in fractures of the lateral condylar physis that receive little or no initial treatment and result in nonunion (55,101).

Overly vigorous dissection of fresh fractures can result in osteonecrosis of either the lateral condylar ossification center (41,75) or, rarely, the metaphyseal portion of the fragment, leading to nonunion (Fig. 15-22). If the fracture unites, osteonecrosis of the lateral condyle reossifies over many years, much like Legg-Calvé-Perthes disease in the hip. Any residual deformity usually is related to loss of motion.

FIGURE 15-22. Avascular necrosis developed in this child because of extensive dissection and difficulty in obtaining a primary open reduction. **A:** Injury film. **B:** Two years later, there was extensive loss of bone in the metaphysis and a nonunion of the condyle.

Myositis Ossificans

The only report of myositis ossificans after lateral condylar fracture is that of Sandegard (84). In his patient, the fracture was associated with a dislocation. The myositis resolved with no functional residua. We have seen one patient with myositis ossificans after a delayed open reduction 1 week after injury. This patient had some residual loss of elbow extension.

Ipsilateral Injuries

Fractures of the lateral condyle have been associated with elbow dislocations (14), fracture of the ulnar shaft (78), and fracture of the medial epicondyle (44). Often an elbow dislocation is misdiagnosed in a patient with a lateral condylar fracture. Loss of the lateral crista can make the elbow unstable and allow the proximal radius or ulna to translocate laterally. This is a part of a normal pathologic condition associated with completely displaced lateral condylar fractures. In a true elbow dislocation, the proximal radius and ulna are displaced, not only medially or laterally but also proximally (Fig. 15-23).

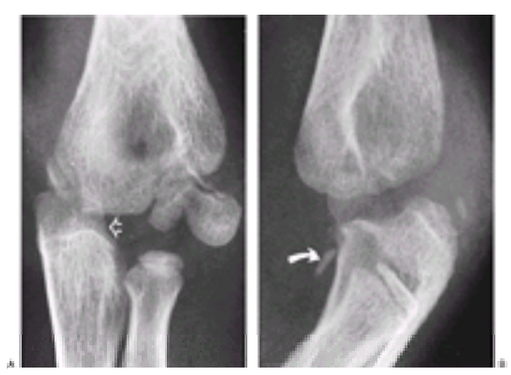

FIGURE 15-23. Ipsilateral injury. **A:** Anteroposterior lateral radiographs of an 8-year-old boy with a true posteromedial elbow dislocation (*open arrow*) and a Milch type I lateral condylar fracture. **B:** A small fracture of the coronoid process of the ulna (*closed arrow*) confirms the primary nature of the elbow dislocation.

Fractures of the Capitellum

Fractures of the capitellum involve only the true articular surface of the lateral condyle. This includes, in some instances, the articular surface of the lateral crista of the trochlea. Usually this fragment comes from the anterior portion of the distal articular surface. There is some variation in the terminology used for this intraarticular fracture. It was originally described as Mouchet's fracture (118). Most articles in the English literature prefer the term *capitellum,* but occasionally the Latin term *capitulum humeri* is used. In the European literature, these fractures may be described as involving the eminentia capitata.

Incidence

In adults these fractures are not uncommon, but they are rare in children. Marion and Faysse (117), in their review of 2,000 elbow fractures in children, found only one fracture of the capitellum. Since then, this fracture has been frequently reported in older adolescents (110,113,117,121). Marion and Faysse (117) pointed out that verified fractures of the capitellum have not been described in children under 12 years of age.

However, there have been two reports (105,108) of so-called anterior sleeve fractures of the lateral condyles, both in 8-year-olds (Fig. 15-24). These involved a good portion of the anterior articular surface. However, technically they could not be classified as pure capitellar fractures because they contained nonarticular epicondylar and metaphyseal portions in the fragment. This fracture often is difficult to diagnose because there is little ossified tissue. It is composed mainly of pure articular surface from the capitellum and essentially nonossified cartilage from the secondary ossification center of the lateral condyle.

FIGURE 15-24. Fracture of the capitellum. **A:** Osteochondral fracture of the capitellum in an 8-year-old girl. Note small fleck of bone (*arrow*), which indicates possible osteochondral fragment. **B:** Single-spot lateral radiograph after double-contrast arthrography outlines the large osteoarticular fragment in the anterior recess of the elbow. **C:** Intraoperative photograph shows the size of the fracture fragment and its origin from the lateral humeral epiphysis. **D:** Intraoperative photograph after reduction of the fragment into the bed of the capitellum. **E:** Healed fracture with articular congruity, restoration of cartilage space, and no avascular necrosis. (Reprinted from Drvaric DM, Rooks MD. Case report. Anterior sleeve fracture of the capitellum. *J Orthop Trauma* 1990;4:188; with permission.)

Classification

Two fracture patterns have been described. The first is the more common Hahn-Steinthal type (112,120), which usually contains a rather large portion of cancellous bone of the lateral condyle. Often the lateral crista of the trochlea is also included (Fig. 15-25). The second, or Kocher-Lorenz, type (114,116) is more of a pure articular fracture with little if any subchondral bone attached, and may represent a piece of articular cartilage from an underlying osteochondritis dissecans. This type of fracture is rare in children (105).

FIGURE 15-25. Fracture of the capitellum in a 13-year-old girl. **A:** Injury film, lateral view, shows the large capitellar fragment lying anterior and proximal to the distal humerus. Both the radiocapitellar (*solid arrow*) and trochlear grooves (*open arrow*) are seen in the fragment. **B:** In the anteroposterior view, only a faint outline of the fragment is seen (*arrows*).

Mechanism of Injury

The most commonly accepted mechanism is that the anterior articular surface of the lateral condyle is sheared off by the radial head (106,110). The presence of cubitus recurvatum or cubitus valgus seems to predispose the elbow to this fracture pattern.

Diagnosis

Often, swelling is minimal. Flexion is restricted by the presence of the fragment. If the fragment is large, it may be readily apparent on the lateral radiographs (Fig. 15-26). On the anteroposterior radiographs, however, the fragment may be obliterated by the overlying distal metaphysis (Fig. 15-25). If the fragment is small, oblique views may be necessary to show the fragment (106). In younger children, arthrography or MRI may be necessary to diagnose this rare fracture. Letts et al. (115) recommended computed tomography (CT) to help delineate the fracture type.

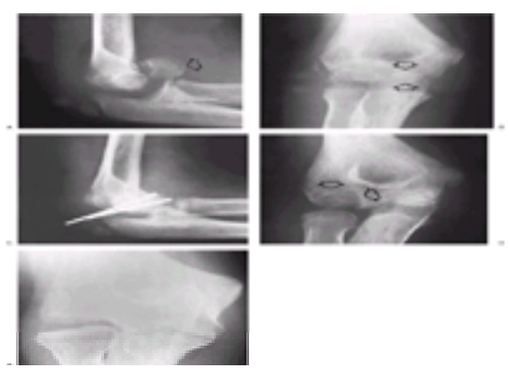

FIGURE 15-26. Fracture of the capitellum. **A:** Injury film. Lateral view of a 10-year-old with an isolated fracture of the capitellum. The capitellar fragment can be seen lying anteriorly (*arrow*). **B:** On the anteroposterior view, the distal outline of the lateral condyle appears intact. The capitellar fragment is seen lying anterior to the trochlea (*arrows*). **C:** Fixation of the fragment was achieved by retrograde placement of pins. **D:** Seven months after injury, the fragment has undergone resorption, leaving a defect in the lateral condyle (*arrows*). **E:** Three years after injury, at the end of skeletal growth, the defect has enlarged. The radial head has migrated proximally into the defect. Elbow motion is greatly restricted. (Courtesy of Jack Earle, M.D.)

Associated Injuries

Because the mechanism is postulated to be a pushing off of the capitellum by the radial head, it stands to reason that there may be an associated radial head or neck fracture (113). In Palmer's (119) large series, including both children and adults, 31% had associated injuries of the proximal radius.

Treatment

Excision of the fragment and open reduction and reattachment are the two most common forms of treatment. Closed reduction is not likely to be successful.

Excision of the Fragment

Through an open arthrotomy, the fragment can be either excised or reattached. Most investigators (106,110,117) favor excision because of its simplicity. In addition, motion and rehabilitation can be initiated early. In those series in which excision and replacement were compared (110,116), excision appeared to provide better results. In addition, the earlier the fragment was excised, the better were the results. Even when large fragments were excised, joint instability did not appear to be a problem (111). In patients in whom treatment is delayed, although the results are not as good as when treatment is provided immediately after injury, improvement in function can be expected, even with late excision (110).

Reattachment of the Fragment

If the fragments are reattached, stability of the fracture is provided by wires or screws inserted through the posterior surface of the lateral condyle. The investigators who have advocated this procedure (489,491,494) have almost equally good results with reattachment. The major problems with reattachment are associated with osteonecrosis of the reattached fragment. Letts et al. (115) reported satisfactory results with fixation of five capitellar fractures with Kirschner wires (three fractures), Herbert screws (one fracture), and cannulated screw (one fracture). An advantage of screw fixation is that it does not require later removal.

AUTHORS' PREFERRED METHOD OF TREATMENT

If the fragment is large, the fracture is acute, and an anatomic reduction can be achieved with a minimum of open manipulation or dissection, then we prefer to reattach it with two small compression or Herbert screws inserted from posterior to anterior through a lateral approach. Enough bone must be present in the capitellar fragment to engage the screw threads and if possible countersink the heads of the cancellous or Herbert screws (Fig. 15-27). However, if it is an old fracture, if there is any comminution of the fragment, or if there is little bone in which to engage the screw threads, we believe the appropriate treatment is simply to excise the fragment and start early motion.

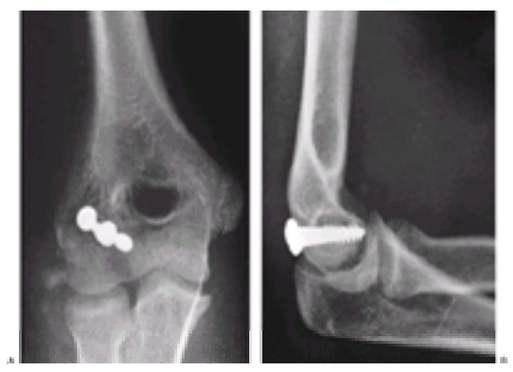

FIGURE 15-27. Postoperative anteroposterior **(A)** and lateral **(B)** radiographs of the patient seen in Fig. 15-26. There was enough bone in the fragment for it to be secured by the screw threads.

Complications

The major complication is osteonecrosis of the fragment (Fig. 15-26). This, of course, occurs only in fractures in which the capitellar fragment is retained. Posttraumatic degenerative arthritis can occur whether the fragments are excised or retained. Many patients who are treated either operatively or nonoperatively can expect to lose some range of motion, but this is not always of functional or cosmetic significance. It is important to emphasize to the parents before the onset of treatment that complications can occur regardless of the method of treatment.

Fractures Involving the Medial Condylar Physis

Fractures involving the medial condylar physis have two components. The intraarticular component involves, in some manner, the trochlear articular surface. The extraarticular portion includes the medial metaphysis and medial epicondyle. Because the fracture line extends into the articular surface of the trochlea, these are often called trochlear fractures. For purposes of description in this chapter, fractures of the trochlea are those that include only the articular surface.

Incidence

Fractures involving the medial condylar physis are rare in skeletally immature children. In the combined series of 5,226 fractures involving the distal humerus mentioned previously, only 37 fractures involved the medial condylar physis. These were all grouped into three series (163).

Many of the large series of elbow fracture in the literature (128,130,133,140,143) and early fracture texts (510,541) do not mention these fractures as a separate entity. Blount (124) described only one such fracture in his classic text. In Faysse and Marion's (135) review of more than 2,000 fractures of the distal humerus in children, only 10 fractures involved the medial condylar physis. It can be safely said that the occurrence rate is less than 1% of all elbow fractures in children.

Although it has been reported in a child as young as 2 years of age (122), this fracture pattern is generally considered to occur during later childhood.

Most series (135,145) show medial condylar fractures occurring somewhat later than lateral condylar fractures. A review of 38 patients in nine series (122,127,129,132,134,135 and 136,147,150) in which the specific ages were given showed that 37 patients were in the age range of 8 to 14 years. Thus, this fracture seems to occur after the ossification centers of the medial condylar epiphysis begin to appear. However, this fracture can occur as early as 6 months of age, before any ossification of the distal humerus has appeared (123,131), making the diagnosis extremely difficult.

Surgical Anatomy and Pathology

Fractures of the medial condylar physis involve both intra- and extraarticular components. They behave as Salter-Harris type IV physeal injuries, but not enough fractures have been described to show whether the fracture line courses through the secondary ossification center of the medial condylar epiphysis or whether it enters the common physeal line separating the lateral condylar ossification center from the medial condylar ossification center. This common physeal line terminates in the notch of the trochlea. The lateral crista of the trochlea is ossified from the lateral condylar epiphysis. Only the medial crista is ossified by the secondary ossification centers of the medial condylar epiphysis. We believe that this fracture is a mirror image of the lateral condylar physeal injury and thus has characteristics of Salter-Harris type IV physeal injuries (Fig. 15-28). The deformity that develops if the fracture is untreated is nonunion, similar to that after lateral condylar physeal fracture, rather than physeal fusion, as occurs after a typical Salter-Harris type IV injury. The resultant deformity is cubitus varus instead of the cubitus valgus deformity that occurs with nonunion of the lateral condyle.

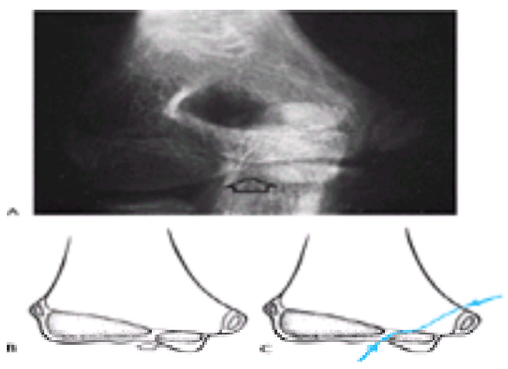

FIGURE 15-28. A: Anteroposterior radiograph of a 9-year-old boy demonstrating the location of the ossification centers. A common physeal line (*arrow*) separates the medial and lateral condylar physes. **B:** Relationship of the ossification centers to the articular surface. The common physis terminates in the trochlear notch (*arrow*). **C:** Location of the usual fracture line involving the medial condylar physis (*arrow*).

Characteristically, the metaphyseal fragment includes the intact medial epicondyle along with the common flexor origin of the muscles of the forearm. These flexor muscles cause the loosened fragment to rotate so that the fracture surface is facing anteriorly and medially and the articular surface is facing posteriorly and laterally (Fig. 15-29) (122,127). Rotation of the fragment is especially accentuated when the elbow is extended. Chacha (127) also noted that often the lateral aspect of the common flexor origin and the anterior capsule of the joint were torn and the fracture surface could usually be reached through this anterior opening into the joint.

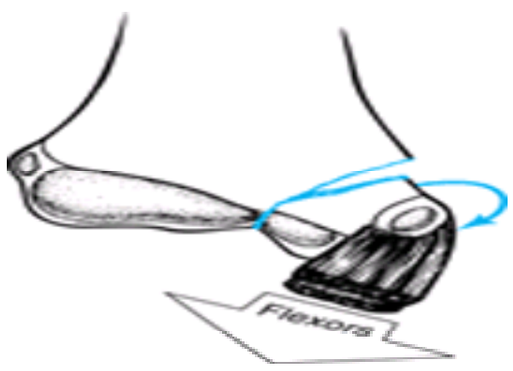

FIGURE 15-29. Displacement of the medial condyle. The pull of the forearm flexor muscles rotates the fragment so that the fracture surface is facing anteromedially and the articular surface is posterolateral. (Redrawn from Chacha PB. Fractures of the medial condyle of the humerus with rotational displacement. *J Bone Joint Surg [Am]* 1970;52:1453-1458; with permission.)

The blood supply to the medial epicondyle and medial metaphysis courses extraarticularly along with the medial flexor muscle groups. The blood supply to the lateral ossification center of the medial crista of the trochlea, however, must traverse the surface of the medial condylar physis. Disruption of these small intraarticular vessels by the fracture line can result in disruption and subsequent loss of circulation to the lateral portion of the medial crista, leading to the development of a fishtail deformity.

Because the fracture line enters the groove of the trochlea, the elbow joint becomes unstable, allowing a varus deformity to develop.

Mechanism of Injury

Two separate mechanisms can produce physeal fractures of the medial condyle. Ashhurst's (122) patients described falling directly on the point of the flexed elbow. This mechanism also was implicated in other reports (123,127,138,147). In this mechanism, it is speculated that the sharp edge of the semilunar notch of the olecranon splits the trochlea directly (Fig. 15-30A). In three more recent series (123,132,136), many patients sustained this injury when they fell on their outstretched arms. The theory is that this is an avulsion injury caused by a valgus strain at the elbow (Fig. 15-30B). Fowles and Kassab (136) reported a patient with a concomitant valgus greenstick fracture of the olecranon associated with a fracture of the medial condylar physis. They believed this provided further evidence that this was a valgus avulsion type of injury.

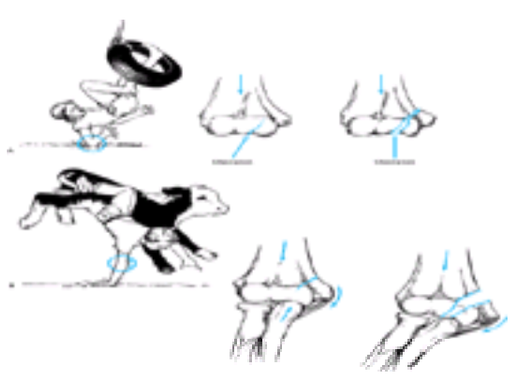

FIGURE 15-30. Medial condyle fracture mechanisms of injury. **A:** A direct force applied to the posterior aspect of the elbow causes the sharp articular margin of the olecranon to wedge the medial condyle from the distal humerus. **B:** Falling on the outstretched arm with the elbow extended and the wrist dorsiflexed causes the medial condyle to be avulsed by both ligamentous and muscular forces.

Once the fragment becomes disassociated from the distal humerus, the forearm flexor muscles produce a sagittal anterior rotation of the fragment.

Classification

Classification, as with fractures of the lateral condylar physis, is based on the location of the fracture line and the degree of displacement of the fracture.

Location of the Fracture Line

Milch (144) classified fractures of the medial condylar physis in adults into two types. In type I fractures, the fracture line traverses the apex of the trochlea. In type II fractures, it traverses the capitulotrochlear groove. He believed that the origin of the fracture line depended on whether the radial head, as in type II, or the semilunar notch of the olecranon, as in type I, served as the impinging force for the abduction injury. Both fracture patterns occur in children (Fig. 15-31), but type I fractures seem to be more common because the common physeal line, which serves as a point of weakness, ends in the apex of the trochlea.

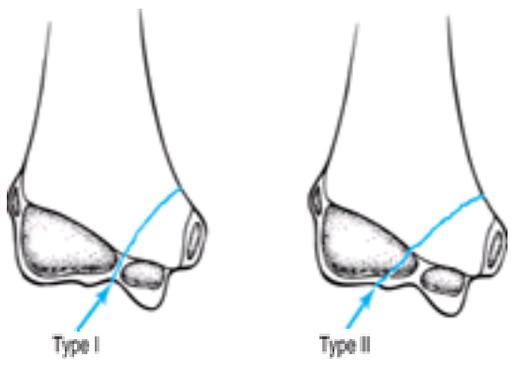

FIGURE 15-31. Medial condyle fracture patterns. Left: In the Milch type I injury, the fracture line terminates in the trochlear notch (*arrow*). **Right:** In the Milch type II injury, the fracture line terminates more laterally in the capitulotrochlear groove (*arrow*). (Redrawn from Milch H. Fractures and fracture-dislocations of the humeral condyles. *J Trauma* 1964;4:592-607; with permission.)

Displacement of the Fracture

Kilfoyle (142) described three fracture displacement patterns that can be helpful in determining appropriate treatment (Fig. 15-32). In type I, the fracture line in the medial condylar metaphysis extends down to the physis. He noted that some of these may represent incomplete supracondylar fractures. Unless there is a greenstick crushing of the medial supracondylar column, these fractures are usually of no clinical significance. In type II, the fracture line extends into the medial condylar physis. The intraarticular portion, as it is in preosseous cartilage, is often not recognized. In this second type, the medial condylar fragment usually remains undisplaced. In type III, the condylar fragment is both rotated and displaced.

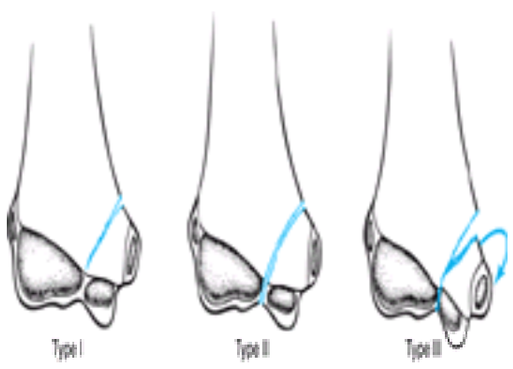

FIGURE 15-32. Kifoyle classification of displacement patterns. (Redrawn from Kifoyle RM. Fractures of the medial condyle and epicondyle of the elbow in children. *Clin Orthop* 1965;41:43-50; with permission.)

Bensahel (123) and Papavasiliou (145) and their co-workers found that type III displacement fractures, which accounted for only 25%, were more likely to occur in older adolescents, and type I fractures were more common in younger children. These studies also confirmed the correlation between the type of displacement and the method of treatment.

Medial condylar physeal fractures have been reported in association with greenstick fractures of the olecranon (130) and with true posterolateral elbow dislocations (Fig. 15-33) (123,149). Some investigators (123,131) found that child abuse was more common in their younger patients with these fractures than with other elbow fractures.

Diagnosis

Clinically and on radiographs, a fracture of the medial condylar physis is most often confused with a fracture of the medial epicondyle. In both types of intra- and extraarticular fractures, swelling is concentrated medially, and there may be valgus instability of the elbow joint. In a true intraarticular fracture, however, there is varus instability as well. Such is usually not the case with an isolated extraarticular fracture of the medial epicondyle. Ulnar nerve paresthesia may be present with both types of fractures.

In older children with a large metaphyseal fragment, involvement of the entire condyle usually is obvious on radiographs; in younger children, in whom only the epicondyle is ossified, fracture of the medial condylar physis may be erroneously diagnosed as an isolated fracture of the medial epicondyle (Fig. 15-34) (129,134,136).

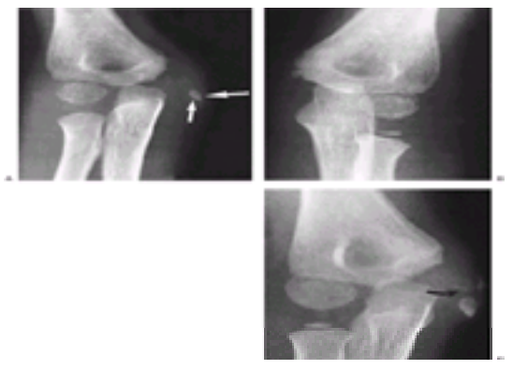

FIGURE 15-34. Missed medial condyle fracture. **A:** Initial film of a 6-year-old who was originally diagnosed as having a displaced fracture of the medial epicondyle (*arrow*). **B:** Normal side for comparison. **C:** Three months later, the patient continued to have a painful elbow, and there was ossification of the metaphysis (*arrow*) adjacent to the epicondyle.

In differentiating these two fractures, it is helpful to remember that medial epicondylar fractures often are associated with elbow dislocations, usually posterolateral, and that elbow dislocations are rare before ossification of the medial condylar epiphysis begins. With medial condylar physeal fractures, the elbow tends to subluxate posteromedially (129) because of the loss of trochlear stability.

Any metaphyseal ossification with the epicondylar fragment suggests the presence of an intraarticular fracture of the medial condyle and is an indication for further evaluation. Often the medial condyle and the medial epicondyle are markedly displaced as a unit (139). A positive fat pad sign indicates that the injury has entered the elbow joint and a fracture of the medial condyle is likely (138). Isolated fractures of the medial epiconydle are extraarticular and usually do not have positive fat pad signs.

If the true location of the fracture line is questionable in a younger child, arthrography or MRI of the elbow should be performed.

Treatment

For displaced fractures, open reduction with internal fixation seems to be the most popular treatment method (123,126,132,136,141,142,145,146,147 and 148). The fracture fragment can be approached by a posteromedial incision that allows good exposure of both the fracture site and the ulnar nerve. Rigid fixation is imperative and is easily achieved with smooth Kirschner wires (Fig. 15-33) or with screws in older adolescents. Two wires are necessary because of the sagittal rotation forces exerted on the fracture fragment by the common flexor muscles. El Ghawabi (132) reported frequent delayed union and nonunion in fractures that were not rigidly stabilized.

In Kilfoyle's displacement type I and II fracture patterns, usually enough residual internal stability is present to allow the fracture to be simply immobilized in a cast or posterior splint (123,132,135,142,145). As with fractures of the lateral condylar physis, union may be slow. In fractures treated promptly, results have been satisfactory (127,134,136). Because there is usually more displacement in older children, the results in this age group are not as satisfactory as those in younger ones, who tend to have relatively nondisplaced fractures (123).

The real problem lies in fractures that are discovered or seen many weeks after the original injury. Fowles and Kassab (136) reported poor results when the fracture was treated surgically 3 to 4 weeks after the original injury. As with lateral condylar fractures, this was believed to be due to the extensive dissection necessary to achieve an adequate reduction. For this reason, they concluded that fractures in which the time span was greater than 3 weeks after injury should be left alone.

AUTHORS' PREFERRED METHOD OF TREATMENT

We usually treat type I nondisplaced fractures with simple observation and a posterior splint. Follow-up radiographs at weekly intervals are taken to ensure there is no late displacement. When there is good callus at the metaphyseal portion of the fracture line, the splint is removed and early active motion initiated. We continue to follow the patient until there is a full range of motion and obliteration of the fracture line.

Type II and III displaced fractures must be reduced and stabilized. Usually this is difficult to do by closed methods because the swelling associated with this injury makes it difficult to identify the landmarks accurately for pin placement. Unless these can be defined without question, we usually proceed with an open reduction through a medial approach. The posterior surface of the condylar fragment and the medial aspect of the medial crista of the trochlea should be avoided in the dissection because these are the sources of blood supply to the ossific nuclei of the trochlea. Fixation with two parallel pins should be in the metaphyseal segment if possible (Fig. 15-35). Cancellous screw fixation can be used in adolescents near skeletal maturity.

FIGURE 15-35. Stage II fracture of the medial condyle in a 10-year-old girl. Anteroposterior **(A)** and lateral **(B)** radiographic views.

Osteonecrosis of the trochlea can occur after both operative and nonoperative treatment (see the following section on Complications). Thus, the parents should be warned of this possible complication before treatment.

Complications

The major complication is failure to make the proper diagnosis. This is especially true in younger children, in whom a medial condylar fracture can be confused with a displaced fracture of the medial epicondyle (Fig. 15-34). When the diagnosis is questionable, especially in a child with no ossification of the trochlea, examination with anesthesia, arthrography, or MRI may be helpful.

Untreated displaced fractures usually result in nonunion with cubitus varus deformity (Fig. 15-36) (136,150). We have seen one nonunion after a fracture of the medial condyle. When the condylar fragment finally ossified, the lateral edge of the fragment appeared to extend to the capitulotrochlear groove.

FIGURE 15-36. Nonunion in addition to cubitus varus deformity. **A:** Original film of a 5-year-old girl who sustained an injury 1 year previously. The metaphyseal fragment (*arrow*) is attached to the medial epicondyle. **B:** Film taken 2 years later. Some ossification has developed in the medial condylar epiphysis (*arrow*). (Courtesy of Roy N. Davis, M.D.)

Delayed union has been reported in patients treated with insecure fixation or simply placed in a cast (132,142). Some disturbance of the vascular supply to the medial condylar fragment appears to occur during open reduction and internal fixation. Several investigators have reported subsequent avascular changes in the medial crista of the trochlea (132,136,142,145). Hanspal (137) reviewed Cothay's original patient (129) 18 years after delayed open reduction and found that despite some minimal loss of motion, the patient was asymptomatic. Radiography, however, demonstrated changes compatible with osteonecrosis of the medial condyle.

Both cubitus varus and valgus deformities have been reported in patients whose fractures united uneventfully. The valgus deformity appears to be due to secondary stimulation or overgrowth of the medial condylar fragment. Some simple stimulation of the prominence of the medial epicondyle also may produce the false appearance of a cubitus valgus deformity. Cubitus varus appears to result from decreased growth of the trochlea, possibly caused by a vascular insult. Principles for treating nonunion of lateral condylar fractures generally are applicable to nonunions of the medial condyle.

El Ghawabi (132) described one partial ulnar neuropathy occurring after this type of injury. The neuropathy almost completely recovered after anterior transposition of the ulnar nerve.

Fractures of the Trochlea

Osteochondral fractures involving only the articular portion of the trochlea are extremely rare in skeletally immature children: only one such fracture has been reported in the English-language literature. Grant and Miller (152) reported on a 13-year-old boy who had a posterolateral dislocation of the elbow with marked valgus instability and fractures of the medial epicondyle and radial neck. When the elbow was explored to secure the epicondyle, a large osteochondral fragment from the medial crista of the trochlea was found lying between the two articular surfaces. The fragment was replaced and fixed with Smillie nails, and a satisfactory result was obtained. However, the presence of the fragment was not detected preoperatively.

In an older child who sustains an elbow dislocation and in whom there is some widening of the joint after reduction, an intraarticular fracture of the trochlea or capitellum should be suspected. Arthrography or MRI, or occasionally CT-arthrography, should be used for confirmation.

Fractures Involving the Entire Distal Humeral Physis

Incidence

After the first period of interest in this injury during the early 1900s, there was almost a complete absence of any discussion of this injury in the English literature until the early 1950s. In fact, two researchers, Siris (186) and Wilson (193), doubted whether this existed as a separate fracture type.

Smith's (187) description in his 1954 textbook, *Surgery of the Elbow,* sparked a renewed interest in this fracture. He focused attention on the maintenance of the relationship between the radius and capitellum as a distinguishing feature in this type of injury.

From 1960 to 1978, many individual patients were reported (159,166,172,175,179,184,185,189). Once the presence of this injury became recognized, larger series appeared. Seven separate series reported a total of 45 fractures (154,162,163,170,176,177,182), and Abe et al. (153) reported on a series of 21 fractures.

Originally thought to be a rare injury, it appears that fractures involving the entire distal humeral physis occur frequently in children. The major problem is the initial recognition of this injury.

Surgical Anatomy

The distal humeral epiphysis extends across to include the secondary ossification of the medial epicondyle until about 6 to 7 years of age in girls and 8 to 9 years in boys. Thus, fractures involving this total physeal line include the medial epicondyle up to this age. In older children, only the lateral and medial condylar physeal lines are included.

Most fractures involving the total distal humeral physis occur before the age of 6 or 7. The younger the child, the greater the volume of the distal humerus that is occupied by the distal epiphysis. As the humerus matures, the physeal line progresses more distally, with a central **V** forming between the medial and lateral condylar physes (Fig. 15-37). Ashhurst (155) believed that this **V**-shaped configuration of the physeal line helps protect the more mature distal humerus from physeal fractures.

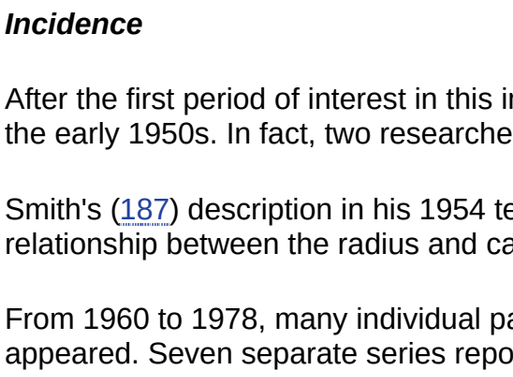

FIGURE 15-37. A: At 5 months of age, the metaphysis has advanced only to the supracondylar ridges. **B:** By 4 years of age, the edge of the metaphysis has advanced well into the area of the epicondyles.

Because fractures coursing along the distal humeral physis traverse the anatomic centers of the condyles, they are the pediatric counterpart of the adult bicondylar fracture. Because the fracture is distal, the fracture surfaces are broader than those proximally through the supracondylar fractures (Fig. 15-38). This broader surface

area of the fracture line may help prevent tilting of the distal fragment. Because the articular surface is not involved by the fracture lines, development of joint incongruity with resultant loss of elbow motion is unlikely if malunion occurs.

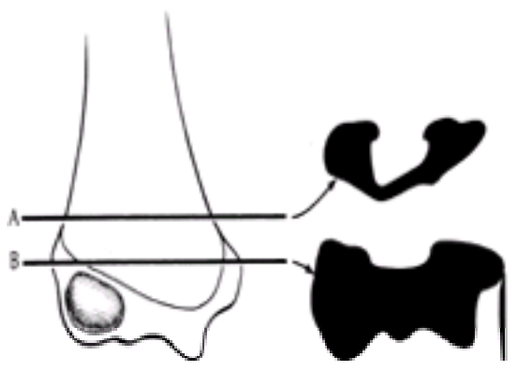

FIGURE 15-38. The cross-sectional surface of the supracondylar area **(A)** is much thinner than the cross-sectional area through the distal physis **(B)**.

Finally, part of the blood supply to the medial crista of the trochlea courses directly through the physis. The blood supply to this area is vulnerable to injury, which may cause avascular changes in this part of the trochlea.

Because the physeal line is more proximal in young infants, it is nearer the center of the olecranon fossa (Fig. 15-37). A hyperextension injury in this age group is more likely to result in a physeal separation than a bony supracondylar fracture (160,161).

Mechanism of Injury

The exact mechanism of this injury is unknown and probably varies with the age group involved. A few consistent factors are evident.

First, many fractures of the entire distal humeral physis have occurred as birth injuries associated with difficult deliveries (154,156,157,165,167,175,185,190). Siffert (185) noted that the clinical appearance of these injured elbows at the time of delivery was not especially impressive. There was only moderate swelling and some crepitus.

Second, DeLee et al. (163) noted a high incidence of confirmed or suspected child abuse in their very young patients. Other reports (154,162,178,180,192) have confirmed the frequency of child abuse in infants and young children with these fractures.

Bright (158) has shown that a physis is more likely to fail with rotary shear forces than with pure bending or tension forces. Young infants have some residual flexion contractures of the elbow from intrauterine positioning; this prevents the hyperextension injury that results in supracondylar fractures of the elbow in older children. Rotary forces on the elbow, which can be caused by child abuse or birth trauma in young infants, are probably more responsible for this injury than hyperextension or varus or valgus forces, which produce other fracture patterns in older children.

Abe et al. (153) reported on 21 children, ranging in age from 1 to 11 years (average 5 years), with fracture–separations of the distal humeral epiphysis, all of which were sustained in falls.

Classification

DeLee et al. (163) classified fractures of the entire distal humeral physis into three groups based on the degree of ossification of the lateral condylar epiphysis (Fig. 15-39). Group A fractures occur in infants up to 12 months of age, before the secondary ossification center of the lateral condylar epiphysis appears (Fig. 15-39A and Fig. 15-39B). They usually are Salter-Harris type I physeal injuries. This injury often is not diagnosed because of the lack of an ossification center in the lateral condylar epiphysis. Group B fractures occur most often in children 12 months to 3 years of age in whom there is definite ossification of the lateral condylar epiphysis (Fig. 15-39C). Although there may be a small flake of metaphyseal bone, this is also essentially a type I Salter-Harris physeal injury. Group C fractures occur in older children, from 3 to 7 years of age, and result in a large metaphyseal fragment that is most commonly lateral but can be medial or posterior (see Fig. 15-39D and Fig. 15-39E).

FIGURE 15-39. A: Group A—anteroposterior view of a small infant who had a swollen left elbow after a difficult delivery. The displacement medially of the proximal radius and ulna (*arrow*) helps to make the diagnosis of a displaced total distal humeral physis. **B:** Normal elbow for comparison. **C:** Group B—anteroposterior view showing the posteromedial displacement of the distal fragment (*arrow*). The relationship between the ossification center of the lateral condyle and the proximal radius has been maintained. **D:** Group C—anteroposterior view with marked medial displacement of the distal fragment. **E:** Group C—lateral view of the same patient showing posterior displacement of the distal fragment. There is also a large metaphyseal fragment associated with the distal fragment (*arrow*).

These fractures are almost always extension-type injuries with the distal epiphyseal fragment posterior to the metaphysis. A rare flexion type of injury can occur in which the epiphyseal fragment is displaced anteriorly (157). Stricker and colleagues (188) reported a coronal plane transcondylar (Salter-Harris type IV) fracture in a 3-year-old child that was initially misdiagnosed as a fracture of the lateral humeral condyle. Three years after open reduction and pin fixation, no growth disturbance was evident.

Clinical Signs and Symptoms

In an infant less than 18 months of age, whose elbow is swollen secondary to trauma or suspected trauma, a fracture involving the entire distal humeral physis should be considered. In a young infant or newborn, swelling may be minimal with little crepitus. Poland (183) described the crepitus as “muffled” crepitus because the fracture ends are covered with softer cartilage than the firm osseous tissue in other fractures about the elbow. The relationship between the epicondyles and the olecranon is maintained. Because of the large, wide fracture surfaces, there is less tendency for tilting with rotation of the distal fragment, and the angular deformity is less severe than that with supracondylar fractures. Often in older children, the elbow is so swollen that a clinical assessment of the bony landmarks is impossible, and radiographic evaluation must provide confirmation of the diagnosis (Fig. 15-39A and Fig. 15-39B).

Radiographic Findings

Radiographic diagnosis can be difficult, especially if the ossification center of the lateral condyle is not visible in an infant. The only relationship that can be determined is that of the primary ossification centers of the distal humerus to the proximal radius and ulna. The proximal radius and ulna maintain an anatomic relationship to each other but are displaced posteriorly and medially in relation to the distal humerus. This posteromedial relationship is diagnostic. Although theoretically the distal fragment can be displaced in any direction, with rare exceptions (157) most fractures reported have been displaced posteromedially. Valdiserri and Kelescian (190) were the first to emphasize the consistency of this posteromedial displacement. Comparison views of the opposite uninjured elbow may be helpful to determine the presence of posteromedial displacement (Fig. 15-39A and Fig. 15-39B).

Once the lateral condylar epiphysis becomes ossified, displacement of the entire distal epiphysis is much more obvious. The anatomic relationship of the lateral condylar epiphysis with the radial head is maintained, even though the distal humeral epiphysis is displaced posterior and medial in relation to the metaphysis of the humerus (Fig. 15-39C and Fig. 15-39D).

Because they have a large metaphyseal fragment, type C fractures may be confused with either a low supracondylar fracture or a fracture of the lateral condylar physis. The key diagnostic point is the smooth outline of the distal metaphysis in fractures involving the total distal physis. With supracondylar fractures, the distal portion of the distal fragment has a more irregular border.

Differentiation from a fracture of the lateral condylar physis and the rare elbow dislocation in an infant can be made on radiography. With a displaced fracture of the lateral condylar physis, the relationship between the lateral condylar epiphysis and the proximal radius is usually disrupted (Fig. 15-8B). If the lateral crista of the trochlea is involved, the proximal radius and ulna may be displaced posterolaterally.

Elbow dislocations are rare in the peak age group for fractures of the entire distal humeral physis. With elbow dislocations, the displacement of the proximal radius and ulna is almost always posterolateral, and the relationship between the proximal radius and lateral condylar epiphysis is disrupted.

If differentiation of this injury from an intraarticular fracture is uncertain, arthrography or MRI may be helpful (Fig. 15-6C) (154,156,159,168,171,177).

In neonates and infants in whom ossification has not begun, ultrasonography can be used to outline the epiphysis of the humerus (164,191). Comparison with the opposite uninjured humeral epiphysis may help determine the presence of a separation.

If the diagnosis is delayed, new periosteal bone forms around the distal humerus, and the whole epiphysis may remain displaced posteriorly and medially (Fig. 15-40).

FIGURE 15-40. The true nature of this injury as involving the entire distal humeral physis was not appreciated until periosteal new bone became visible 3 weeks after injury.

Treatment

Treatment is first directed toward prompt recognition of the injury. Because this injury may be associated with child abuse, the parents may delay seeking treatment.

De Jager and Hoffman (162) reported 12 fracture–separations of the distal humeral epiphysis, three of which were initially misdiagnosed as fractures of the lateral condyle and one as an elbow dislocation. Because of the frequency of cubitus varus after this injury in young children, they recommend closed reduction and percutaneous pinning in children under 2 years of age so that the carrying angle can be evaluated immediately after reduction and corrected if necessary.

Open reduction has been reported by several investigators, usually performed because of misdiagnosis as a displaced fracture of the lateral humeral condyle (154,170,179,184,192). Mizuno (177), however, recommended primary open reduction because of his poor results with closed reduction. He approached the fracture posteriorly by removing the triceps insertion from the olecranon with a small piece of cartilage.

If the fracture is old (>5–6 days) and the epiphysis is no longer mobile, manipulation should not be attempted and the elbow should be splinted for comfort. Many essentially untreated fractures remodel completely without any residual deformity if the distal fragment is only medially translocated and not tilted (Fig. 15-41).

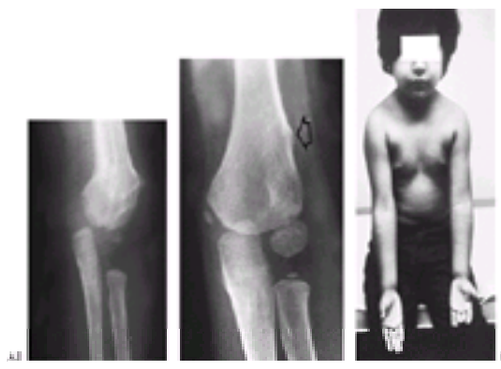

FIGURE 15-41. Remodeling of untreated fractures. **A:** Anteroposterior view of a 2-year-old who had an unrecognized and untreated fracture of the distal humeral physis. The medial translocation is apparent. There was no varus or valgus tilting. **B:** Four years later, there had been almost complete remodeling of the distal humerus. A small supracondylar prominence (*arrow*) remains as a scar from the original injury. **C:** Clinical appearance 4 years after injury shows no difference in the alignment of the elbows.

AUTHORS' PREFERRED METHOD OF TREATMENT

We usually first attempt a manipulative closed reduction of fresh fractures. The elbow is first manipulated into extension to correct the medial displacement, then the fragment is stabilized by flexing the elbow and pronating the forearm. The distal epiphysis is more securely held with the elbow flexed and the forearm pronated (Fig.

15-42). When the forearm is supinated with the elbow flexed, the distal fragment tends to displace medially. This is usually a pure medial horizontal translocation without mediolateral coronal tilting.

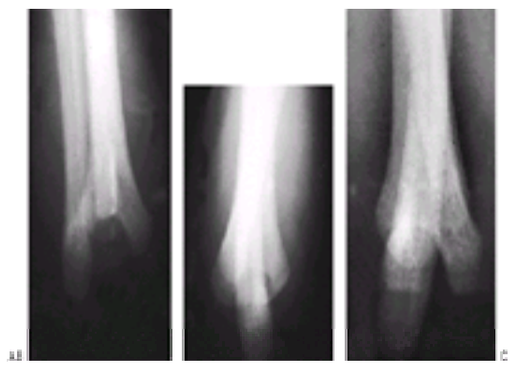

FIGURE 15-42. Supination versus pronation. **A:** In this fracture involving the entire distal humeral physis in a 9-month-old, the elbow was initially flexed with the forearm in supination. The Jones view shows that the proximal radius and ulna remain translocated medially in relation to the distal humerus. **B:** Comparison Jones view of the uninjured elbow shows the true relationship of the proximal radius and ulna to the distal humerus. **C:** When the injured elbow was flexed with the forearm pronated, the normal relationship was reestablished.

In neonates and very small infants in whom general anesthesia or percutaneous pin fixation may be difficult, we usually simply immobilize the extremity in 110 to 120 degrees of hyperflexion with the forearm pronated. The extremity is then externally stabilized with a figure-of-eight splint.

In most older infants and young children, external immobilization usually is not dependable in maintaining the reduction. In these patients, we usually perform the manipulation with the patient under general anesthesia and secure the fragment with two lateral pins (Fig. 15-43). Because of the swelling and immaturity of the distal humerus, the medial epicondyle is difficult to define as a distinct landmark, making it risky to attempt the percutaneous placement of a medial pin. If a medial pin is necessary for stable fracture fixation, a small medial incision can be made to allow direct observation of the medial epicondyle. In small infants and young children with minimal ossification of the epiphyseal fragment, an intraoperative arthrogram is usually obtained to help determine the quality of the reduction.

FIGURE 15-43. A: Injury film of a 20-month-old showing medial displacement of the distal fragment. **B:** The posterior displacement of the condylar fragment (*arrow*) is better defined after an arthrogram. **C:** Manipulation with the forearm in pronation shows the fragment is anatomically reduced. The arthrogram outlines the articular margin of the condyles (*arrow*). **D:** Fixation is achieved by two lateral pins placed percutaneously.

The cast or splint and pins are removed in 3 weeks to allow resumption of active elbow motion. The patient is then followed until full motion is regained and there is radiographic evidence of normal physeal and epiphyseal growth. Usually, 3 weeks of immobilization is sufficient.

If treatment is delayed more than 3 to 5 days and the epiphysis is not freely movable, the elbow is simply immobilized in a splint or cast. Any resulting deformity is probably better treated later with a supracondylar osteotomy rather than risk the complication of physeal injury or devascularization of the epiphysis by performing a delayed open reduction. Only occasionally does an untreated patient have a deformity severe enough to require surgical correction at a later date. Because the articular surface is intact, complete functional recovery can usually be expected.

Complications

Child Abuse

Child abuse should always be considered in children with this injury, especially a type A fracture pattern, unless it occurs at birth. A young infant is unlikely to incur this type of injury spontaneously from the usual falls that occur during the first year of life. Of the 16 fractures reported by DeLee et al. (163), 6 resulted from documented or highly suspected child abuse, all in children under 2 years of age (Fig. 15-44).

FIGURE 15-44. A: A 6-month-old victim of child abuse. The fracture involving the distal humeral physis was old, as indicated by the proliferative new periosteal bone formation (*open arrow*). Acutely there was a separation of the proximal humeral physis (*black arrow*). **B:** Another child, 9 months old, who had an acute fracture through the distal humeral physis, as manifest by posteromedial displacement of the proximal radius and ulna (*closed arrow*). An old healing fracture is also seen in the ipsilateral radius (*open arrow*).

Neurovascular injuries, either transient or permanent, are rare with this fracture, probably because the fracture fragments are covered with physeal cartilage and do not have sharp edges as do other fractures in this area. In addition, the fracture fragments usually are not markedly displaced. Hersch and Sanders (169) reported neurologic injury in one child who was treated for an “elbow dislocation.” About 16 hours after reduction and splinting with the elbow acutely flexed, the child could not move her hand, and no radial, median, or ulnar nerve function was detectable. At last follow-up after open reduction and internal fixation with Kirschner wires, the

neurologic deficit was slowly resolving.

Nonunion

Only one nonunion after this fracture has been reported; it occurred in a patient seen 3 months after the initial injury (177). Because of the extreme vascularity and propensity for osteogenesis in this area, union is rapid even in patients who receive essentially no treatment.

Malunion

Significant cubitus varus deformity is not uncommon after this injury (Fig. 15-45). Marmor and Bechto (174) reported an essentially untreated fracture that resulted in significant cubitus varus. Five of seven fractures in Holda and colleagues' series (170) resulted in angles of cubitus varus of 10 to 15 degrees, even when open reduction was performed. Abe et al. (153) reported cubitus varus deformities in 15 of 21 children, 7 of whom were treated with closed reduction and casting, 2 with closed reduction and percutaneous pinning, 4 with open reduction and internal fixation, and 2 with skin traction. Review of radiographs after reduction revealed that the deformity was caused by incorrect reduction (12 fractures), redisplacement during immobilization (2 fractures), or physeal damage (1 fracture).

FIGURE 15-45. An anteroposterior view of a residual cubitus varus in a 2-year-old 6 months after the original injury. This patient was treated initially with only simple immobilization.

Because the fracture surfaces are wider with this injury than with supracondylar fractures, the distal fragment tends to tilt less, which seems to account for the lower incidence of cubitus varus after this injury than after ntreated supracondylar fractures (Fig. 15-45).

Osteonecrosis

Osteonecrosis of the epiphysis of the lateral condyle or the trochlear epiphysis has rarely been reported after fractures of the entire distal humeral physis. Yoo et al. (194) reported on eight patients with osteonecrosis of the trochlea after fracture–separations of the distal end of the humerus. Six of the eight fractures were misdiagnosed initially as medial condylar fractures, lateral condylar fractures, or traumatic elbow dislocation. All eight patients had rapid dissolution of the trochlea within 3 to 6 weeks after injury, followed by the development of a medial or central condylar fishtail defect. We have noted osteonecrosis of the trochlea after three fractures of the entire humeral physis, two of which were inadequately reduced and one of which was anatomically reduced by closed methods (Fig. 15-46). All three had marked displacement of the distal epiphyseal fragment. In one, the osteonecrosis of the trochlea produced a secondary cubitus varus deformity that continued to progress with growth and a significant loss of elbow motion. The etiology of this complication was discussed in the section on osteonecrosis of the trochlea.

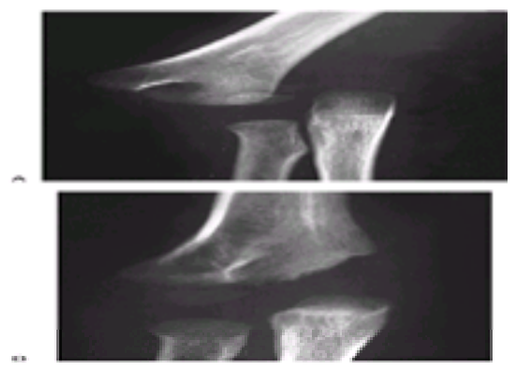

FIGURE 15-46. Avascular necrosis. **A:** Injury film in a 5-year-old with marked displacement of the distal epiphysis. Closed reduction followed by lateral pin fixation was performed. **B:** Nevertheless, radiographs taken 14 months later showed early evidence of avascular necrosis of the medial condyle. APOPHYSEAL INJURIES OF THE DISTAL HUMERUS

Fractures Involving the Medial Epicondylar Apophysis

History Review

Recognition of Entrapment

In the early 1900s, it was recognized that this fracture was often associated with dislocation of the elbow, and the apophyseal fragment could become entrapped within the joint (215,236,247). Much of the discussion of that era centered on the manipulative techniques used to extract the fragment from the joint (215,236).

Operative/Nonoperative Controversy

In 1950, Smith (242) stated that many of the complications previously attributed to this injury were actually misconceptions. Since then, the proponents of uniform nonoperative management (205,224,233,252) have far outnumbered the proponents of uniform operative management (222). In the interval since the third edition of this volume, little has been written about the treatment of this injury; most of the focus has been on the increased recognition of this injury occurring during arm wrestling (227,228,232).

Incidence

In the combined series of 5,226 fractures of the distal humerus (see Chapter 13), the percentage of fractures involving the medial epicondylar apophysis was just behind that of fractures involving the lateral condylar physis. Fractures involving the medial epicondylar apophysis constituted 14.1% of fractures involving the distal humerus and 11.5% of all fractures in the elbow region.

Age

Fractures involving the epicondylar apophysis have a later peak age, much like that of fractures involving the medial condylar physis. The youngest reported patient with this injury was 3.9 years (206). In the large series of fractures of the medial epicondylar apophysis reported, most occurred between ages 9 and 14, with the peak age incidence being 11 to 12 years (199,217,221,222,225,233,242,251,252,279).

Sex

Fractures of the epicondylar apophysis affect boys by a ratio of almost 4 to 1. In the six largest series in the literature on this injury, boys constituted 79% of the patients (217,229,234,237,247,252).

Association with Dislocation of the Elbow

The reported incidence of association with dislocation of the elbow has varied from as low as 30% to as high as 55% in many of the reported series (199,208,213,231,252). Two bilateral injuries associated with bilateral elbow dislocations have been reported (200,246). Both patients sustained their injuries while participating in gymnastics.

In summary, the peak age for fractures of the epicondylar apophysis is 9 to 12 years. The injury occurs in boys four times more often than in girls. About 50% of such injuries are associated with elbow dislocations. In at least 15% to 18%, the fragment is incarcerated in the joint (Table 15-1).

Overall incidence: fractures of the distal humerus, 14.1%
Overall incidence: fractures of the elbow region, 11.5%
Age: peak, 11–12 years
Sex: males, 79% (4:1, male:female)
Association with elbow dislocation: approximately 50% (15%–18% of these involve incarceration of the epicondylar apophysis)

TABLE 15.1. FRACTURES OF THE MEDIAL EPICONDYLAR APOPHYSIS: INCIDENCE

Surgical Anatomy

Ossification

Apophysis. The medial epicondyle is a traction apophysis, so the term *apophysis* rather than *physis* is used throughout the description of this injury. The forces across its physeal plate are tension rather than the compressive forces present across the condylar physeal plates of the distal humerus. Because it is an apophysis, it does not contribute to the overall length of the distal humerus.

In the early ossification process, the medial epicondylar apophysis is part of the total distal humeral epiphysis. With growth and maturity, it becomes separated from the total distal humeral epiphysis by intervening metaphyseal bone. In younger children, when there is a separation of the total distal humeral epiphysis, the medial epicondylar apophysis is included as part of the distal fragment.

Posteromedial Location. The medial epicondylar apophysis actually arises from the posterior surface of the medial distal humeral metaphysis. As was mentioned in Chapter 14, this posterior location is important when percutaneous pin fixation is performed. Likewise, this posterior position affects the image of the apophysis on radiographs (Fig. 15-47).

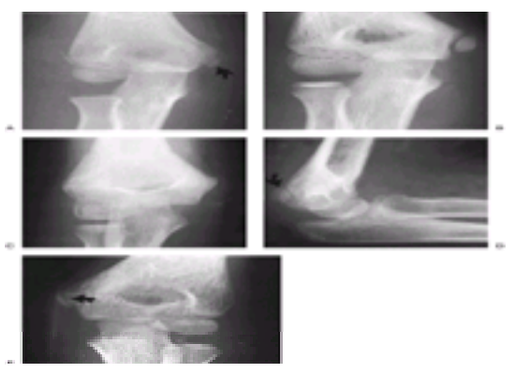

FIGURE 15-47. Ossification of the medial epicondyle. **A:** The concentric oval nucleus of ossification of the medial epicondylar apophysis (*arrow*). **B:** As ossification progresses, parallel smooth sclerotic margins develop in each side of the physis. **C:** Because it is somewhat posterior, on a slightly oblique anteroposterior view the apophysis may be hidden behind the distal metaphysis. **D:** The posterior location of the apophysis (*arrow*) is appreciated on this slightly oblique lateral view. **E:** On the anteroposterior view, the line created by the overlapping of the metaphysis (*arrow*) can be misinterpreted as a fracture line (pseudofracture).

Ossification Sequence. Brodeur and Silberstein (203,240) have described many of the unique aspects of the ossification process of the medial epicondylar apophysis. The following discussion is paraphrased from their work.

Ossification begins from 4 to 6 years of age, with fusion occurring at about 15 years of age. It is the last secondary ossification center to fuse with the distal humeral metaphysis. The ossification center starts as a small eccentric oval nucleus (Fig. 15-47A). As it matures, parallel sclerotic margins develop along both sides of the physis (Fig. 15-47B). There may be some irregularity of the ossification process, which gives the ossific nucleus a fragmented appearance. This fragmentation may be falsely interpreted as a fracture.

Because the apophysis is posteromedial, the ossification center may be difficult to visualize on the anteroposterior radiograph, especially if the elbow is slightly oblique (Fig. 15-47C). The posterior position of the apophysis is best appreciated on the lateral radiograph. If the elbow is slightly oblique, the outline of the epicondyle may be better appreciated (Fig. 15-47D). Because of this posterior location on the anteroposterior radiograph, the distal medial metaphyseal border may overlap the ossific nucleus of the apophysis. This overlapping may appear as a lucent line that can be misinterpreted as a fracture (Fig. 15-47E).

Soft Tissue Attachments

Flexor Mass. The flexor mass, which includes the origin of the flexor carpi radialis, flexor carpi ulnaris, flexor digitorum superficialis, and palmaris longus and part of

the pronator teres, originates from the anterior aspect of the apophysis (Fig. 15-48) (240,250). Part of the flexor carpi ulnaris also originates on the posterior aspect of the epicondyle.

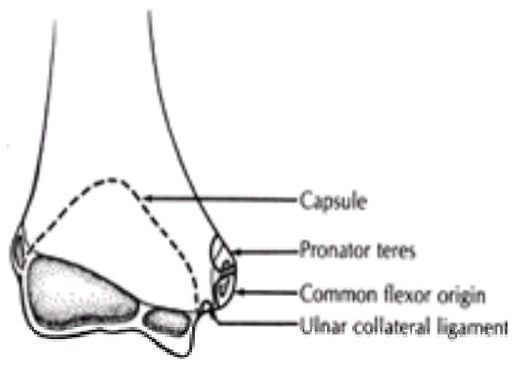

FIGURE 15-48. Soft tissue attachments. Anteroposterior view of the distal humerus demonstrating the relationship of the apophysis to the origins of the medial forearm muscles. The origin of the ulnar collateral ligament lies outside the elbow capsule. The margin of the capsule is outlined by the dotted line.

Capsule. In the younger child, some of the origin of the capsule extends up to the physeal line of the epicondyle. In the older child and adolescent, as the epicondyle migrates more proximally, the capsule is attached only to the medial crista of the trochlea (198,212). Thus, in the younger child, the fracture line involving the medial epicondylar apophysis can enter the joint because part of the capsule is attached to the epicondylar fragment. In the older child, however, if there is a pure avulsion force on the epicondyle, the capsule may remain attached to the outer border of the trochlea. In this age group, the fracture may be totally extraarticular.

Ligamentous Structures

The two major medial collateral ligaments originate from this apophysis. The ulnar collateral ligament is composed of three separate bands (Fig. 15-49) (223,254). Woods and Tullos (254) pointed out that the major stabilizing ligamentous structure in the elbow is the anterior band of the ulnar collateral ligament. The anterior portion of the band is taut in extension, and the posterior fibers are taut in flexion. The fibers of the posterior band of the ulnar collateral ligament are relaxed in extension and are taut in flexion (Fig. 15-49). Thus, this posterior band provides stability only in flexion. Because the radial collateral ligaments do not attach directly to the ulna or radius, but instead attach to the orbicular ligament (239) they provide only minimal stability to the elbow joint.

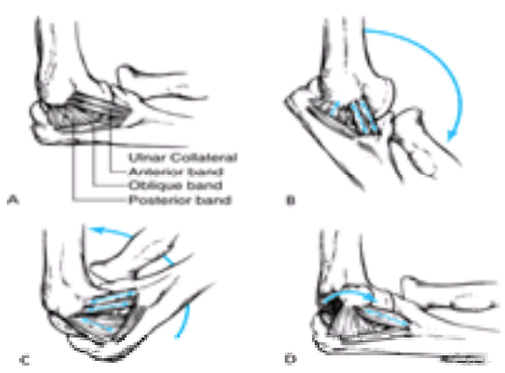

FIGURE 15-49. Ligamentous structures. **A:** The ulnar collateral ligament is divided into anterior, posterior, and oblique bands. **B:** On extension, the anterior fibers of the anterior band are taut. The posterior fibers of the anterior band and the entire posterior band are loose in this position. **C:** In flexion, the posterior fibers of the anterior bands and posterior band become taut. The anterior fibers of the anterior band become loose. **D:** When the epicondyle is rotated anteriorly, the entire anterior band can become loose. (Reprinted from Woods WG, Tullos HS. Elbow instability and medial epicondyle fractures. *Am J Sports Med* 1977;5:23-30; with permission.)

Mechanism of Injury

Acute Injuries

Injuries to the medial epicondylar apophysis most commonly occur as acute injuries in which a distinct event produces a partial or a complete separation of the apophyseal fragment. Three theories have been proposed about the mechanism of acute medial epicondylar apophyseal injuries: a direct blow, avulsion mechanisms, and association with elbow dislocation (Table 15-2).

Acute injuries
Direct blow
Avulsion mechanisms
Avulsion in elbow extension (valgus stress)
Avulsion with elbow flexed (pure muscle forces)
Associated with elbow dislocation
Chronic tension stress injuries

TABLE 15.2. FRACTURES OF MEDIAL CONDYLAR APOPHYSIS: MECHANISM OF INJURY

Direct Blow

Stimson (244) speculated that this type of injury could occur as a result of a direct blow on the posterior aspect of the epicondyle. However, among more recent investigators, only Watson-Jones (248) described this injury as being associated with a direct blow to the posterior medial aspect of the elbow.

In those rare patients in whom the fragment is produced by a direct blow to the medial aspect of the joint, the medial epicondylar fragment is often fragmented (Fig. 15-50). In these injuries, there also may be more superficial ecchymosis in the skin.

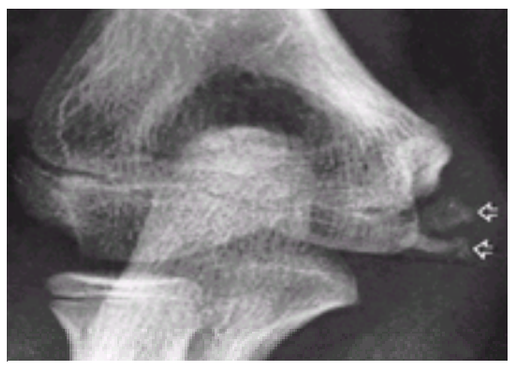

FIGURE 15-50. Direct fragmentation. The fragmented appearance of the medial epicondyle (*arrow*) in a 13-year-old who sustained a direct blow to the medial aspect of the elbow. (Reprinted from Wilkins KE. Fractures of the medial epicondyle in children. *Instr Course Lect* 1991;40:1-8; with permission.)

Avulsion Mechanisms

Many investigators ascribe to the theory that some of these injuries are due to a pure avulsion of the epicondyle by the flexor muscles of the forearm (225,235,238,253). This muscle avulsion force can occur in combination with a valgus stress in which the elbow is locked in extension, or as a pure musculature contraction that may occur with the elbow partially flexed.

Avulsion and Extension (Valgus Stress)

Smith (242) believes that when the child falls on the outstretched upper extremity with the elbow in extension, the wrist and fingers are often hyperextended as well, placing an added tension force on the epicondyle by the forearm flexor muscles (Fig. 15-51). The normal valgus carrying angle tends to accentuate these avulsion forces when the elbow is in extension. Many of the proponents of this theory point to the other associated elbow fractures that have been seen with this injury as evidence to confirm that a valgus force is applied across the elbow at the time of the injury. These associated injuries include fractures of the radial neck with valgus angulation and greenstick valgus fractures of the olecranon (225,243,253).

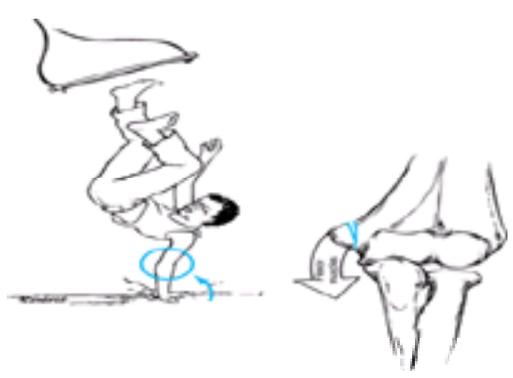

FIGURE 15-51. Hyperextension forces. When a person falls on the outstretched upper extremity, the wrist and fingers are forced into hyperextension (*solid arrow*), which places tension on the forearm flexor muscles. This sudden tension along with the normal valgus carrying angle tends to place a strong avulsion force on the medial epicondyle (*open arrow*).

Isolated Muscle Avulsions

Isolated avulsion also can occur in adolescents with the simple act of throwing a baseball. In this instance, the sudden contracture of the forearm flexor muscles may be sufficient to cause the epicondyle to fail (Fig. 15-52). The literature has reflected a high incidence of medial epicondylar apophyseal avulsions occurring with arm wrestling in patients near skeletal maturity (226,228). The largest series, reported by Nyska et al. (232) from Israel, involved eight boys 13 to 15 years of age, all of whom were treated conservatively with good results.

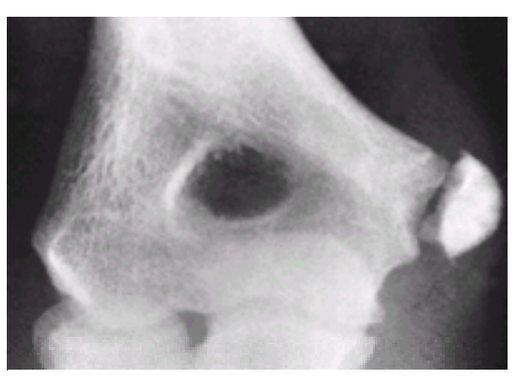

FIGURE 15-52. Muscle avulsion. Isolated avulsion of the medial epicondyle occurred suddenly in this 14-year-old Little League pitcher after throwing a curve ball. (Reprinted from Wilkins KE. Fracture of the medial epicondyle in children. *Instr Course Lect* 1991;40:1-8; with permission.)

Associated with Elbow Dislocations

The final mechanism proposed is that this injury is associated with a dislocation of the elbow in which the ulnar collateral ligament provides the avulsion force. If the elbow is dislocated when the patient is initially seen, there is no doubt that this is a major factor in the production of this fracture. However, the question of this being caused by an occult or partial elbow dislocation that has reduced spontaneously is often raised. Some investigators (199,200,217) have noticed the development of calcification in the lateral collateral ligaments and adjacent lateral periosteum in elbows postfracture. They believed this was evidence that this ligament had been stretched during the process of elbow dislocation. Marion and Faysse (229) found that most elbow dislocations associated with this injury were posterolateral, but some pure lateral, posterior, and posteromedial dislocations were also observed.

The question arises as to whether incarceration of the epicondylar fragment into the joint can occur without a dislocation. Patrick (235) believed that when an extreme valgus stress was applied to the joint, a vacuum was created within the joint that “sucked in” the avulsed epicondylar fragment. This theory has not been universally accepted (238,241).

Acutely, it appears that any of these mechanisms can produce this injury. The direct blow mechanism appears to occur only rarely. Most of these injuries probably are associated with an elbow dislocation that may or may not have reduced spontaneously.

Pathology

Acute Fractures

Usually the epicondyle is displaced distally. Cotton (210) described two patients in whom this fragment was displaced proximally. Avulsion usually involves only the apophysis. However, a small flake of metaphyseal bone is occasionally found attached to the apophyseal fragment. Rarely, the fracture line passes through the apophysis, with only part of the apophysis being avulsed (240). These partial avulsions may appear as only minor injuries. However, the partial fragment can be incarcerated within the joint just as easily as the full apophysis (Fig. 15-53).

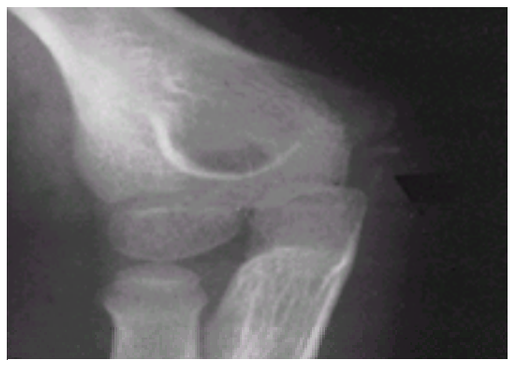

FIGURE 15-53. Partial avulsion. The epicondylar fragment was only partially avulsed. This partial fragment also had an associated portion of the metaphysis (*arrow*), both of which were incarcerated into the elbow joint. (Courtesy of Randal R. Betz, M.D.)

Chronic Incarceration

When the fragment becomes incarcerated into the joint, the raw bone surface may become adherent to the coronoid process of the ulna (237). In late cases, this union of the fragment to the coronoid process may make extraction difficult. A universal finding when the fragment is incarcerated within the joint is a thick fascial band that binds the ulnar nerve to the underlying muscle (197,210,235). The constriction by this band is believed to be responsible for either the immediate or late dysfunction of the ulnar nerve.

Associated Injuries

Other elbow fractures that can be associated with this injury include fracture of the radial neck, olecranon, or coronoid process. If the epicondyle fragment is only rotated on its axis, laxity of the anterior band of the ulnar collateral ligament can occur. This can produce some medial elbow instability during extension (254).

Classification

The various classifications proposed for this injury (199,229,243,249) are pretty much the same. We have combined them to form a comprehensive classification (Table 15-3) that can be useful in determining the proper method of treatment. In the discussion of this classification, the clinical and radiographic findings are delineated for each type of fracture pattern. Initially, we have separated these injuries into two primary categories based on whether the injuries are acute or chronic.

Acute injuries
Undisplaced or minimally displaced
Displaced fractures
Incarcerated fractures (without elbow dislocation)
Incarcerated fractures (with elbow dislocation)
Chronic tension (stress) injuries

TABLE 15.3. FRACTURES OF THE MEDIAL EPICONDYLE APOPHYSIS: CLASSIFICATION

Acute Injuries

Undisplaced or Minimally Displaced Fractures. In undisplaced fractures, the physeal line remains intact. The clinical manifestations usually consist only of swelling and local tenderness over the medial epicondyle. Crepitus and motion of the epicondyle usually are not present. On radiography, the smoothness of the edge of the physeal line remains intact. Although there may be some loss of soft tissue planes medially on the radiograph, displacement of the elbow fat pads may not be present because the pathology is extraarticular (220).

Minimally displaced fractures usually result from a stronger avulsion force, so there is often more soft tissue swelling. Palpation of the fragment may elicit crepitus because the increased displacement allows motion of the fragment. On radiography, there is a loss of parallelism of the smooth sclerotic margins of the physis (Fig. 15-54) (240). The radiolucency in the area of the apophyseal line is usually increased in width.

FIGURE 15-54. Minimally displaced. **A:** Anteroposterior view of a minimally displaced fracture. The smooth sclerotic margins of the physis are disrupted. **B:** Uninjured elbow for comparison.

Significantly Displaced Fractures. In significantly displaced fractures, there is no question as to whether the fragment is displaced: it may be palpable and freely movable. Because it is displaced a considerable distance from the distal humerus, crepitus between the fragments may not be present. There may have been an elbow dislocation that reduced spontaneously or by manipulation. On the other hand, there may have been no documentation of the original dislocation. On radiography, the long axis of the epicondylar epiphysis is rotated medially (Fig. 15-55). The displacement usually exceeds 5 mm, but the fragment remains proximal to the true joint surface. This fragment may contain a metaphyseal fragment.

FIGURE 15-55. Significantly displaced. Anteroposterior view of an elbow in which the epicondyle (*arrow*) is significantly displaced both distally and medially. In addition, the fragment is rotated medially.

Entrapment of the Epicondylar Fragment into the Joint. *Without Elbow Dislocation.* In many instances the elbow appears reduced. The key clinical finding is a block to motion, especially extension. The epicondylar fragment is usually between the joint surfaces of the trochlea and the semilunar notch of the olecranon. On radiography, any time the fragment appears at the level of the joint, it must be considered to be totally or partially within the elbow joint until proven otherwise (Fig. 15-56) (235). If the radiograph is examined carefully, the elbow is usually still found to be incompletely reduced. Because of an impingement of the fragment within the joint, a good anteroposterior view may be difficult to obtain due to the inability to extend the elbow fully. If the fracture is old and the fragment is fused to the coronoid process, widening of the medial joint space may be the only clue that the fragment is lying in the joint (197). The epicondylar ossification center may become fragmented and mistaken for the fragmented appearance of the medial crista of the trochlea (206,237,241). Absence of the apophyseal center on radiographs may be further confirmatory evidence that the fragment is within the joint. Comparison radiographs of the opposite elbow may be necessary to delineate the true pathology.

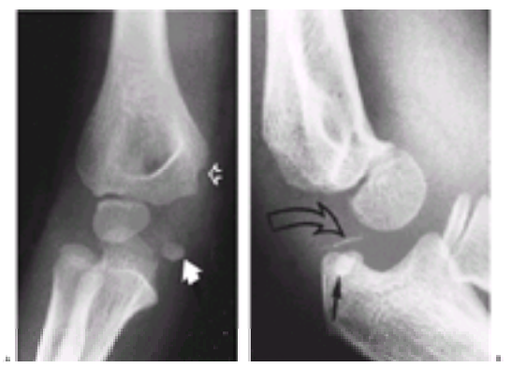

FIGURE 15-56. Incarceration within the joint. **A:** The clues to entrapment are complete absence of the epicondyle from its usual medial location (*open arrow*) and its subsequent location at the level of the joint (*closed arrow*). **B:** On the lateral view the outline of the epicondyle is hidden by the overlying olecranon (*closed arrow*). The fragment also contains a small portion of the metaphysis (*open arrow*).

With Elbow Dislocation. Even if the elbow is dislocated, the fragment can still lie within the joint and prevent reduction. Recognition of this fragment as being within the joint before a manipulation should alert the physician of the possible need for open reduction. There should be adequate relaxation during the manipulative process. An initial manipulation to extract the fragment from the elbow joint may need to be accomplished first before a satisfactory closed reduction of the elbow joint can be obtained (Fig. 15-57).

FIGURE 15-57. Dislocation with incarceration. A: Anteroposterior view showing a posterolateral dislocation of the elbow. The presence of the medial epicondyle within the elbow joint (*arrow*) prevented a closed reduction. **B:** Lateral view of the same elbow demonstrating the fragment (*arrow*) between the humerus and olecranon.

Fractures Through the Epicondylar Apophysis. Fractures through the body of the epicondyle can result from either a direct blow or avulsion of only part of the apophysis. In either case, the fragments may or may not be displaced. The normal lucent line formed by the overlying metaphyseal border should not be confused with this injury. Although described by Silberstein and colleagues (240), this intrafragment fracture is a rare presentation.

Diagnosis

Clinical Findings

Valgus Stress Test. Because many of the clinical diagnostic points have been discussed in the previous section on the classification of this injury, much of the emphasis in this section is on the determination of elbow instability. Because the anterior oblique band of the ulnar collateral ligament may be attached to the medial epicondylar apophysis, the elbow may exhibit some instability postinjury. To evaluate the medial stability of the elbow, a simple valgus stress has been advocated by Woods and Tullos (254) and Schwab et al. (239). This test is performed with the patient supine and the arm abducted 90 degrees. The shoulder and arm are externally rotated 90 degrees. The elbow must be flexed at least 15 degrees to eliminate the stabilizing force of the olecranon. If the elbow is unstable, simple gravity forces will open the medial side. A small additional weight or sedation may be necessary to get an accurate assessment of the medial stability with this test. The

practicality of this valgus stress test is discussed in more detail in the forthcoming section on the AUTHORS' Preferred Method of Treatment.

Evaluate Ulnar Nerve. The function of the ulnar nerve must be carefully assessed. It is especially wise to document the presence or absence of an ulnar nerve injury before instituting therapy.

X-Ray Findings

Beware Absent Apophysis. Widening or irregularity of the apophyseal line may be the only clue in fractures that are only slightly displaced or nondisplaced. If the fragment is significantly displaced, the radiographic diagnosis is usually obvious. However, if the fragment is totally incarcerated in the joint, it may be hidden by the overlying ulnar or distal humerus. The clue here is the total absence of the epicondyle from its normal position just medial to the medial metaphysis.

Potter (76) suggested that properly performed MRI may disclose acute or chronic injury to the medial epicondylar apophysis. Recommended pulse sequences for evaluation of the apophysis include fat-suppressed gradient echo imaging. On MRI, increased signal intensity and abnormal widening of the medial epicondylar physis are seen, typically with surrounding soft tissue edema.

Fat Pad Signs Unreliable. Fractures of the medial epicondyle, even if displaced, may not produce positive fat pad signs (220,240). If the fracture is only minimally displaced and the result of an avulsion injury, there may be no effusion because all the injured tissues remain extraarticular. In those associated with elbow dislocation, there is rupture of the capsule, so its ability to confine the hemarthrosis is lost. In minimally displaced fractures of the medial epicondyle with significant hemarthrosis, one must be especially thorough in the evaluation to ensure that an unrecognized fracture involving the medial condylar physis is not present.

Differential Diagnosis

The major injury to differentiate is one involving the medial condylar physis. This is especially true if the secondary ossification centers are not present (see earlier section on Fractures Involving the Medial Condylar Physis). If there is a significant hemarthrosis or a significant piece of metaphyseal bone accompanying the medial epicondylar fragment, then arthrography may be indicated to determine if there is an intraarticular component to the fracture (Fig. 15-58).

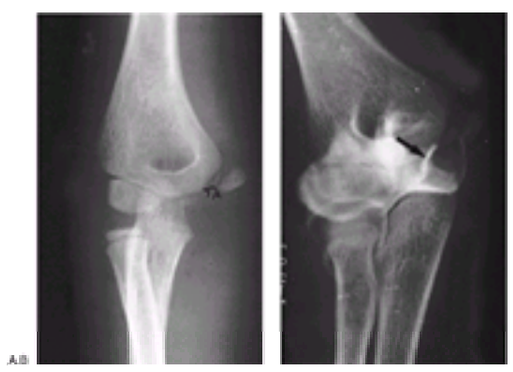

FIGURE 15-58. Intraarticular extension. **A:** Injury film in this 7-year-old girl who was initially suspected of having only a fracture of the medial epicondyle. In addition to moderate displacement, there was a significant metaphyseal fragment (*arrow*). **B:** An arthrogram reveals intraarticular components (*arrow*), which define this instead as a fracture involving the medial condylar physis. (Courtesy of Carl McGarey, M.D.)

Treatment

Areas of General Agreement

There seems to be universal agreement as to the proper method of treating fractures that are undisplaced or only minimally displaced. These first two types are easily treated with simple immobilization for comfort. Many investigators have recommended initiation of motion early to prevent stiffness, the most common complication of this injury (200,242). Likewise, if the fragment is incarcerated in the joint, the accepted treatment is to extract the fragment from the joint by manipulation or surgical intervention.

The controversy seems to be in determining the proper method of treatment for patients with significant displacement (the fragment is displaced >5 mm).

Nonoperative Management

Operative Versus Nonoperative Controversy

Operative Results No Better. In reports in which only one method (i.e., operative or nonoperative) of treatment of all displaced fractures was used, one can find results to support either method. The best argument for surgical management comes from Hines et al. (222) in Oklahoma, where the practice was to surgically repair all fractures displaced more than 2 mm. They found that 96% of their patients had good to excellent results. Bad results were attributed mainly to technical errors. Equal results were obtained by Joseffson and Danielsson (224) from Sweden, where these injuries were all treated nonoperatively. Although more than 60% of their patients demonstrated radiographic nonunion, they had an equal number of good results at a mean follow-up of 11 years. Many more reports in the literature (211,233,252) also demonstrate the overall good results with nonoperative management.

Comparison Studies. The best comparison of the results of operative versus nonoperative treatment comes from reports in which both methods were practiced in the same institution. Bede et al. (199) had superior results in patients treated nonoperatively compared with those treated operatively. This same superiority of nonoperative management has been found in subsequent reports as well (200,217,252).

Results Poorer with Dislocation. The results of fractures associated with a documented elbow dislocation are poorer (199,217) for patients treated operatively and nonoperatively. Fowles and colleagues (217) wrote that surgical intervention only added to the original trauma produced by the dislocation, increasing the residual loss of motion.

Indications for Operative Intervention. The indications for operative intervention in acute injuries are divided into two categories: absolute and relative. The single absolute indication is incarceration of the epicondylar fragment within the joint. The relative indications include ulnar nerve dysfunction and a need for elbow stability.

Incarceration in the Joint—Absolute. If the fragment is found in the joint acutely, it must be removed. However, there are proponents of both nonoperative and operative techniques for extracting the fragment.

Nonoperative Extraction. Various methods of extracting the fragment by nonoperative methods have been proposed. The success rate of extracting the fragment successfully from the joint by manipulation alone is only about 40% (235). All the nonoperative methods require either heavy sedation or light general anesthesia.

Roberts' Manipulative Technique. The manipulative technique most commonly used is the one popularized by Roberts (236) which has gained wide acceptance by many other investigators (202,214,215,221,236,238,249). It involves placing a valgus stress on the elbow while supinating the forearm and simultaneously dorsiflexing the wrist and fingers to place the forearm muscles on stretch; theoretically, this should extract the fragment from the joint. To be effective, this procedure must be performed within the first 24 hours after injury (202,238)

Faradic Stimulation. Patrick (235) recommended stimulating the forearm muscles with faradic electric current to supplement the manual manipulative process.

Joint Distention. Fowles et al. (217) and Masse (230) found that if manipulation fails to dislodge the fragment from the joint, distending it with air or fluid might facilitate the extraction process.

Operative Extraction. Failure to extract the fragment by manipulative techniques is an indication to proceed with open surgical extraction. Once open extraction and reduction have been performed, many methods have been advocated to stabilize the fragment. The simplest appears to be the use of sutures (221). Excision also has been advocated, especially if the fragment is comminuted (197,202,245).

Incarceration Discovered Late.

Original Opinions—No Treatment. If the fragment has been lodged in the joint for more than 4 weeks, the results with late removal have been poor. Patrick (235) found that by 4 weeks, the fragment had become fused to the articular surface of the coronoid process. Forceful removal of the fragment after this period of time produced a raw defect in the articular surface of the coronoid process. This defect subsequently scarified the opposing trochlear articular surface. In addition, the long-term presence of the fragment in the joint subluxates the joint and stretches the capsule and ligaments. If the fragment is removed after these ligaments and capsules have undergone secondary changes, elbow stability may be lost. Blount (201) recommended that these fractures with the fragment incarcerated in the joint be left untreated if more than 6 weeks has passed since the original injury.

More Recent Views—Removal Recommended. The opinion that surgery is detrimental in patients with late incarceration has been challenged by the more recent studies of Fowles et al. from Tunisia (216). In their patients in whom the fragment was surgically extracted an average of 14 weeks after injury, 80% more elbow motion was regained. In addition, the patients' preoperative pain was relieved and the ulnar dysfunction resolved. On a long-term basis, intraarticular retention of the fragment may not be all that disabling. Rosendahl (237) reported an 8-year follow-up of a fragment retained within the joint. The epicondyle had fused to the semilunar surface of the ulna, producing a large bony prominence clinically. There was only minor loss of elbow motion, with little functional disability.

Ulnar Nerve Dysfunction—Relative

Acute Management

Ulnar nerve dysfunction is a relative indication for operative intervention. If there are mild to moderate ulnar nerve symptoms at the time of the injury, usually there is no need to explore the nerve, because most of these mild symptoms resolve spontaneously (200,211). If the dysfunction is complete, then the ulnar nerve is probably wrapped around the fragment and must be explored surgically. One of the original fears was that the raw surface of the fracture fragment would create scar tissue around or adjacent to the nerve and cause continued dysfunction. Thus, originally it was recommended that the ulnar nerve be transposed at the time of open reduction (221,243,248). Subsequent reports have not found this to be necessary (207,246).

Delayed Dysfunction Nonexistent

There is some question as to whether delayed ulnar nerve symptoms can even occur after fractures of the epicondyle that are not associated with dislocation of the elbow. Patrick (235) could not find any instance in which a delayed ulnar neuritis developed in a review of over 100 patients with uncomplicated fractures involving the medial epicondylar apophysis. He found some patients with late ulnar neuritis in fractures that were associated with dislocation of the elbow. Bernstein et al. (200,211) found that their patients with initial ulnar nerve symptoms all did well when treated nonoperatively. Thus, the original fear of delayed ulnar nerve dysfunction has been dispelled.

Joint Stability—Relative

Woods and Tullos (254) believe that athletes can exhibit a significant disability if they have even minor forms of valgus instability after elbow injuries involving the medial epicondylar apophysis. This is especially true in athletes who must have a stable upper extremity, such as baseball pitchers, gymnasts, or wrestlers. In the younger person (<14 years of age), the anterior band of the ulnar collateral ligament often displaces with the apophyseal fragment. In older individuals (15 years or older), large fragments may be avulsed without a ligamentous injury. Rather than depending on arbitrary measurements of fracture displacement, Woods and Tullos (254) recommended the use of the gravity valgus stress test to determine the presence or absence of valgus instability. They believed that demonstration of a significant valgus instability, using this simple gravity test, was an indication for surgical intervention in patients who require a stable elbow for their athletic activities. Pimpalnerkar et al. (146) also suggested that clinical evidence of instability, as shown by gravity valgus stress testing, is an indication for operative fixation.

AUTHORS' PREFERRED METHOD OF TREATMENT

We use the classification scheme (Table 15-3) as a rough guide regarding our treatment options. We also strongly consider the expected activity of the involved extremity in deciding on nonoperative versus operative treatment (Table 15-4).

Nonoperative treatment
Nondisplaced, minimally displaced
Significantly displaced in patients with low-demand upper extremity function
Operative treatment
Absolute: irreducible incarcerated fragment in the elbow joint
Relative: ulnar nerve dysfunction
Relative: patient with high-demand upper extremity function

TABLE 15.4. AUTHOR'S RECOMMENDED TREATMENT

Basically a Nonoperative Fracture

For most uncomplicated fractures, regardless of the number of millimeters of displacement, we prefer nonoperative management (Fig. 15-59). This includes fractures associated with elbow dislocations. The parents are warned that regardless of the type of treatment, some loss of elbow extension may occur. They should be reassured, however, that this loss of motion, if it does occur, is usually not of any functional or cosmetic significance. The elbow is immobilized initially with a removable posterior splint, used mainly for comfort and some support.

FIGURE 15-59. Nonoperative management. **A:** Postreduction film of a 13-year-old girl who sustained a displaced medial epicondyle following an acute elbow dislocation in her nondominant extremity. She was treated nonoperatively. **B:** One year later the fragment has remained distally displaced with an apparent fibrous union. The patient, however, had a full painless range of elbow motion. (Reprinted from Wilkins KE. Fractures of the medial epicondyle in children. *Instr Course Lect* 1991;40:1-8; with permission.)

Early Motion Essential

Because stiffness is the most common complication of this injury, we encourage early active motion. The patient is encouraged to remove the splint and start active motion as soon as 3 to 4 days postinjury. The splint is exchanged for a sling as soon as the patient feels he or she no longer needs it for support. The same goes for the sling: it also is discarded when it is no longer needed. This regimen of early motion also is used in fractures associated with a documented dislocation. Redislocation after elbow dislocation is rare, but elbow stiffness is common, so it is more important to initiate motion as soon as possible after reduction of the elbow. Because of the greater amount of soft tissue injury associated with an elbow dislocation, the patient may not feel comfortable initiating early motion until about 5 to 7 days postreduction.

Avoid Early Aggressive Physical Therapy

Physical therapy should be used only if voluntary active motion is difficult to obtain. The therapist should emphasize modalities designed to decrease swelling and pain and reestablish strength. Range of motion should be achieved only by active means, not by passive stretching.

Operative Indications

Our indications for operative intervention are basically twofold. First and foremost are fractures in which the fragments cannot be extracted by manipulative means from within the elbow joint. Secondly, we stabilize the epicondyles operatively in patients whose expected high-level physical activity requires a stable elbow. We realize, however, that it is difficult to predict the athletic or work potential of a young child.

Acute Incarceration in the Joint

If the elbow is reduced and the ulnar nerve is intact, we use the manipulative technique advocated by Roberts (638) to attempt to extract the fragment before reduction. If this technique fails to remove the fragment, or if there is any ulnar nerve dysfunction, we proceed directly with an open procedure. The fragment is then extracted under direct vision just before reducing the elbow dislocation. If the elbow is reduced and the fragment is incarcerated, we avoid the initial manipulation and proceed directly with an open extraction. We usually stabilize these fractures with a single threaded screw rather than wires or pins (Fig. 15-60). This allows almost immediate motion.

FIGURE 15-60. Pin fixation. Stabilization with pins, although adequate for stability, is unsatisfactory because it prevents early motion, which is essential for full recovery.

Follow-up is essentially the same as with closed treatment. Active motion is initiated 5 to 7 days postoperatively.

Prevention of Valgus Instability

Primarily for High-Demand Athletes

Probably our most common indication for operative intervention is to ensure a stable elbow in patients participating in high-demand activities with their upper extremity (Fig. 15-61). This usually involves the dominant extremity of baseball pitchers, tennis players, or football quarterbacks. In wrestlers and gymnasts, the stability of the nondominant extremity also must be considered. This is best achieved with operative fixation.

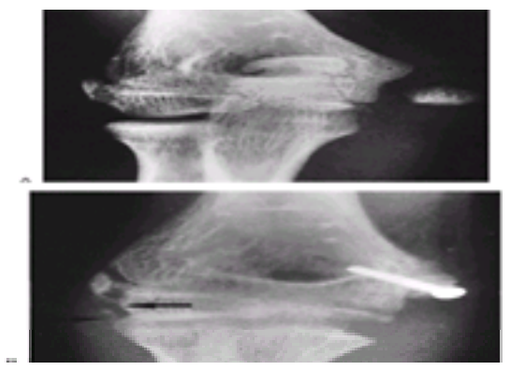

FIGURE 15-61. Operative stabilization. **A:** Injury film in a 12-year-old gymnast. Even though this was a nondominant extremity, it was thought that both elbows needed stability. **B:** Radiographs taken 4 weeks postoperatively showing stabilization of the fragment with a single screw. There was also calcification of the lateral ligaments (*arrow*), confirming that the elbow was probably originally dislocated as well. (Reprinted from Wilkins KE. Fractures of the medial epicondyle in children.

Instr Course Lect 1991;40:1-8; with permission.)

Valgus Stress Test Impractical

We have not found the valgus stress test to be helpful in deciding on the need for operative stabilization of an athlete's medial epicondyle. Almost all of these patients with any significant displacement have a positive valgus stress test. Our decision is based primarily on the patient's need to have a very stable elbow for his or her athletic or work activity.

Stabilize for Early Motion

Fixation must be stable enough to allow early motion. Pins provide stability but do not allow early motion. Fortunately, most patients are mature enough so that the fragment can be secured with a threaded screw. If a fully threaded screw is used, it is overdrilled in the epicondylar fragment to allow compression.

Operative Technique

Our operative technique involves a direct medial approach to the fracture site. We make a longitudinal incision just anterior to the medial epicondyle. The fragment is usually displaced distally and anteriorly. The periosteum is removed from the fracture site and the clot is extracted by irrigation. It is important to identify and protect the ulnar nerve, but a complete dissection of the nerve usually is unnecessary. A small towel clip is used to reduce the fracture while the elbow is flexed and the forearm is pronated. Again, the medial epicondyle is normally situated posteriorly. The fragment is reduced and stabilized temporarily with one or two small Kirschner wires. The final fixation is achieved using a screw, either partially threaded and overdrilled in the epicondylar fragment to compress it against the metaphysis or a cannulated 4.0-mm screw. After removal of the Kirschner wires, the elbow is checked to ensure valgus stability and reestablishment of a full range of motion. After closure of the surgical incision, the extremity is placed in a long arm cast, which is bivalved at 7 to 10 days, and active motion is initiated.

Fragmented Apophysis

If the epicondyle is fragmented and there is a need to achieve elbow stability, an ASIF spike washer can be used to secure the multiple pieces to the metaphysis. This may entail a second procedure to remove the spike washer once the epicondyle is securely united to the metaphysis. If this is impossible, we simply excise the fragments and reattach the ligament to the bone and periosteum at the base of the epicondylar defect.

Complications

Although much has been written about fractures involving the medial epicondylar apophysis, few complications are attributed to the fracture itself. The major complications that result in loss of function are failure to recognize incarceration in the joint and ulnar or medial nerve dysfunction. Most of the other complications are minor and result in only minimal functional or cosmetic sequelae (Table 15-5).

Major
Failure to recognize incarceration in the elbow
Ulnar nerve dysfunction
Minor
Loss of elbow extension
Myositis ossificans
Calcification of the collateral ligaments
Loss of motion
Cosmetic effects
Nonunion in the high-performance athlete

TABLE 15.5. FRACTURES OF THE MEDIAL EPICONDYLAR APOPHYSIS: COMPLICATIONS

Major Complications

Failure to Recognize Incarceration. Failure to recognize incarceration of the epicondylar fragment into the joint can result in significant loss of elbow motion, especially if it remains incarcerated for any length of time (Fig. 15-62). The management for late incarceration was detailed in the previous section on treatment.

FIGURE 15-62. Late incarceration. **A:** Anteroposterior radiograph of a 12-year-old who had unrecognized incarceration of the medial epicondyle. There was also some ulnar nerve dysfunction. **B:** Lateral view shows only a faint overlay (*open arrows*) of the epicondylar fragment. The fragment was extracted late. Normal motion was never regained.

Ulnar Nerve Dysfunction. The other major complication associated with this injury is the development of ulnar nerve dysfunction. The incidence of ulnar nerve dysfunction varies from 10% to 16% (199, 299). If the fragment is entrapped in the joint, the incidence of ulnar nerve dysfunction may be as high as 50% (197).

The incidence of delayed ulnar nerve neuritis is low. More profound ulnar nerve injury has been reported after manipulative procedures (235). Thus, in patients with incarcerated fragments in the joint, manipulation may not be the procedure of choice if a primary ulnar nerve dysfunction is present. Patients in whom the fragment was left incarcerated in the joint for a significant time have experienced poor recovery of the primary ulnar nerve injury (229.

Dysfunction. Although the ulnar nerve is the major nerve injured, the median nerve may be encased between a bony fragment and the distal humerus (181). It is speculated that the nerve can be entrapped between the apophyseal fragment and the distal humerus at the time of the original injury. This type of injury is described in greater detail in the section on complications of elbow dislocations.

Minor Complications. Other complications are minimal in nature. Nonunion of the fragment with the distal metaphysis occurs in up to 50% of fractures with significant displacement (199). This appears to be more of a radiographic problem than a functional problem.

Another common problem is loss of the final degrees of elbow extension. A loss of 5% to 10% can be expected to develop in about 20% of these fractures (243). Little functional deficit is attributed to this loss of elbow dysfunction. Prolonged immobilization seems to be the key factor in loss of elbow extension. Again, it is important to emphasize before treatment is begun that loss of motion is common after this injury, regardless of the method of treatment used.

Myositis ossificans has been described as a rare occurrence following vigorous and repeated manipulation to extract the fragment from the joint (212). As with many other elbow injuries, myositis may be a result of the treatment rather than the injury itself.

Myositis ossificans must be differentiated from ectopic calcification of the collateral ligaments, which involves only the ligamentous structures. This may occur after repeated injuries to the epicondyle and ligamentous structures (Fig. 15-63). Often this calcified ligament is asymptomatic and does not seem to create functional disability.

FIGURE 15-63. Heterotopic calcification. **A:** Injury to an 11-year-old who had moderate displacement of the medial epicondyle (*arrow*). **B:** One year later she had considerable calcification of the ulnar collateral ligament (*arrow*). Other than mild instability with valgus stress, she had full range of motion and was asymptomatic. (Courtesy of Mark R. Christofersen, M.D.)

The cosmetic effects are minimal. In some patients, an accentuation of the medial prominence of the epicondyle creates a false appearance of an increased carrying angle of the elbow (251). Smith (242), in his extensive review, recognized only a slight decrease in the carrying angle in two patients.

Nonunion in the high-performance athlete may be difficult to treat. One of the authors had as a patient a high-performance adolescent baseball pitcher who had to stop pitching after nonoperative management of a medial epicondyle fracture. The patient had developed a fibrous nonunion (Fig. 15-64). Attempts to establish union surgically were unsuccessful. The patient continued playing baseball but had to change to a position in the outfield.

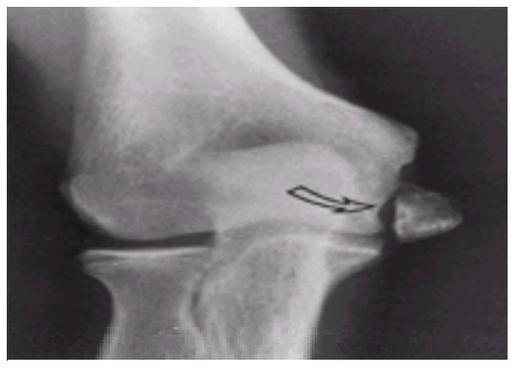

FIGURE 15-64. Nonunion in an athlete. This 15-year-old baseball pitcher had an untreated medial epicondyle fracture 1 year before this radiograph. He developed a fibrous union, but the epicondyle was shifted distally (*arrow*). His elbow was unstable enough to prevent him from pitching.

Fractures Involving the Lateral Epicondylar Apophysis

Incidence

Fracture of the lateral epicondylar apophysis is a rare injury. In the review of 14 reports (see Chapter 13) discussing 5,226 fractures of the distal humerus, only fracture of the lateral epicondylar apophysis was mentioned (663). Five other isolated injuries have been described in textbooks addressing fractures in children (666,668,669).

Anatomic Considerations

Because the presence of this apophysis is often misinterpreted as a small chip fracture, a thorough understanding of the anatomy and ossification process is essential for evaluating injuries in this area.

Late Ossification

The lateral epicondylar apophysis is present for a considerable period but does not become ossified until the second decade. The best discussion of the anatomy of the ossification process is in a report by Silberstein et al. (261), and much of the following discussion is paraphrased from their work. Just before ossification of the apophysis, the ossification margin of the lateral supracondylar ridge of the distal metaphysis curves abruptly medially toward the lateral condylar physis (Fig. 15-65). This causes the osseous borders on the lateral aspect of the distal humerus to take the shape of the number **3**. The central wedge of this defect contains the cartilaginous lateral epicondylar apophysis, which begins to ossify around 10 to 11 years of age. Ossification begins at the level of the lateral condylar physeal line and proceeds proximally and distally to form a triangle, with the apex directed toward the physeal line. The shape of the epicondylar apophyseal ossification center also may be in the form of a long sliver of bone with an irregular pattern of ossification.

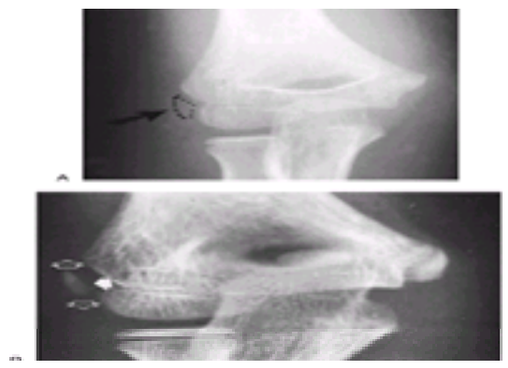

FIGURE 15-65. Lateral epicondylar apophysis. **A:** The cartilaginous apophysis occupies the wedge-shaped defect at the margin of the lateral condyle and metaphysis (*arrow*). The dotted line shows the margin of the cartilaginous apophysis. **B:** Ossification of the apophysis begins at the central portion of the wedge defect (*solid arrow*) and progresses both proximally and distally (*open arrows*) to form a triangular center.

Part of Lateral Condyle

Silberstein et al. (261) noted that the fracture line involving the lateral condylar physis often involves the proximal physeal line of the lateral epicondylar apophysis. Thus, this apophysis is almost always included with the lateral condylar fragment.

Mechanism of Injury

In adults, the most common etiology is that of a direct blow to the lateral side of the elbow. In children, because the forearm extensor muscles originate from this area, it is believed that avulsion forces from these muscles can be responsible for some of these injuries (260). Hasner and Husby (256) believe that the location of the fracture line in relation to the origins of the various extensor muscles determines the degree of displacement that can occur (Fig. 15-66). If the proximal part of the fracture line lies between the origin of the common extensors and the extensor carpi radialis longus, usually there is little displacement. If the fracture lines enter the area of origin of the extensor carpi radialis longus, then considerable displacement can occur.

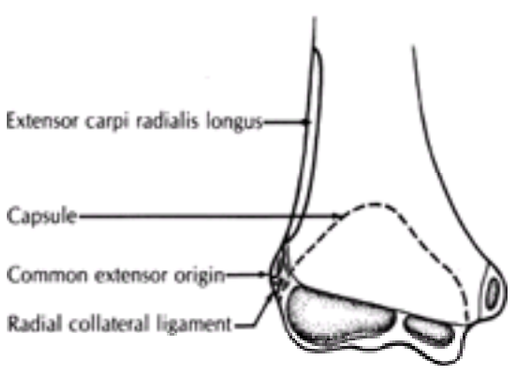

FIGURE 15-66. Soft tissue attachments. The origins of the forearm and wrist extensor muscles, radial collateral ligament, and outline of the capsule are demonstrated in relation to the lateral epicondylar apophysis. (Reprinted from Hasner E, Husby J. Fracture of the epicondyle and condyle of humerus. *Acta Chir Scand* 1951;101:195-202; with permission.)

X-Ray Findings

Because the ossification process starts on the external surface of the apophysis and proceeds centrally, the ossification center often appears separated from the lateral metaphysis and lateral condylar epiphysis. This natural separation can be confused with an avulsion fracture. The key to determining true separation is looking beyond the osseous tissues for the presence of associated soft tissue swelling (Fig. 15-67). If the ossification center lies distal to the osteochondral border of the lateral condylar epiphysis, it should be considered displaced (Fig. 15-68).

FIGURE 15-67. Lateral swelling. **A:** Soft tissue swelling in the area of the lateral epicondylar apophysis (*arrow*) should make one suspect that this is an undisplaced fracture involving the apophysis. The fragmentation of the apophysis is due to irregular ossification. **B:** A small avulsion of the lateral epicondyle (*open arrow*) in an adolescent who is almost skeletally mature. There was considerable soft tissue swelling in this area (*solid arrows*).

FIGURE 15-68. Avulsion injury. **A:** Avulsion of a portion of the lateral epicondyle in an adolescent (*arrow*). The fragment is at the level of the joint. Most of the epicondyle has fused to the condyle. **B:** Appearance 9 months later showing fragmentation and partial union of the fragment. (Courtesy of R. Chandrasekharan, M.D.).

Treatment

Unless the fragment is incarcerated within the joint (257), treatment usually consists of simple immobilization for comfort. Nonunion of the fragment has been reported (255, 258). Even with this radiographic finding, the resultant elbow function has been described as being quite good.

Complications

Only one rare major complication has been described with fractures involving the lateral epicondylar apophysis: entrapment of the fragment, either within the elbow joint (257) or between the capitellum and the radial head (264).

Chronic Tension Stress Injuries (Little League Elbow)

This chronic injury is related to overuse in skeletally immature baseball pitchers. The original radiographic findings were described by Brogdon and Crow in 1960 (204). Later, Adams (195) demonstrated that the radiographic changes were due to excessive throwing and emphasized the need for preventive programs. This injury is thought to be due to excessive tension on the medial epicondyle with secondary tendinitis. There also can be a repeated compression on the lateral condyle, producing an osteochondritis.

Studies have shown that as long as the rules outlined by the Little League are followed (i.e., two innings per game, six innings per week), the incidence of these chronic tension stress injuries is fairly low (218,219,226). Most of the problems arise when overzealous parents and coaches require excessive pitching preseason and at home between practices. Albright (196) found a greater incidence in pitchers who had improper pitching techniques. The spectrum of these chronic injuries is outlined in Table 15-6.

Stress fracture of the epicondylar physis
Calcification of the ulnar collateral ligaments
Hypertrophy of the medial epicondyle
Acceleration of growth maturity with generalized synovitis and stiffness
Osteochondritis of the lateral condyle

TABLE 15.6. SPECTRUM OF CHRONIC TENSION STRESS INJURIES OF MEDIAL EPICONDYLAR APOPHYSIS

In chronic tension stress injuries (Little League elbow syndrome), the history is usually quite characteristic. It is found in young baseball pitchers who are throwing an excessive number of pitches or who are just starting to throw curve pitches (204,234). Clinically, this syndrome is manifested by a decrease in elbow extension. Medial epicondylar pain is accentuated by a valgus stress to the elbow in extension. There is usually significant local tenderness and swelling over the medial epicondyle.

On radiographs, the density of the bone of the distal humerus is increased due to the chronicity of the stress. The physeal line is irregular and widened (Fig. 15-69). If the stress has been going on for a prolonged period, there may be hypertrophy of the distal humerus with acceleration of bone growth. The bone age of the elbow is greater than the patient's chronologic age (Fig. 15-70).

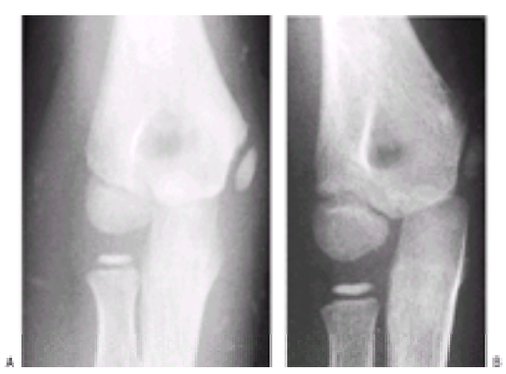

FIGURE 15-69. Acute tension stress. **A:** Anteroposterior view of the pitching arm of a 10-year-old with medial epicondylar pain. The apophyseal line is widened and slightly irregular. **B:** Same view of the opposite elbow for comparison.

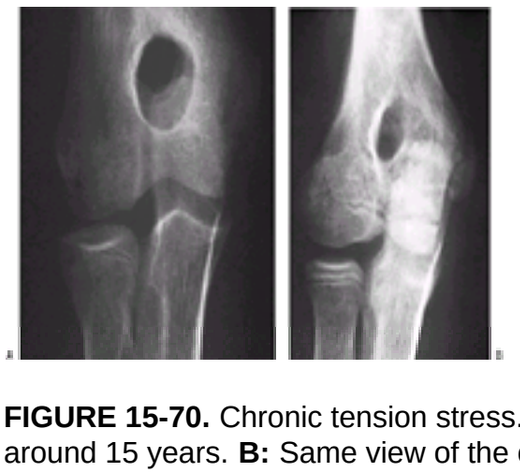

FIGURE 15-70. Chronic tension stress. **A:** Anteroposterior view of a 13-year-old pitcher with chronic pain and significant loss of elbow motion. The bone age is around 15 years. **B:** Same view of the opposite elbow with a bone age of 13 years.

We use a multifaceted approach that involves education of the parents, coaches, and player. Once symptoms develop, all pitching activity must cease until the epicondyle and adjacent flexor muscle origins become nontender. In addition, local and systemic measures to decrease the inflammatory response are used. Once the initial pain and inflammation have decreased, a program of forearm and arm muscle strengthening is initiated. The pitching technique is also examined to see if any corrections need to be made. Once strength has been reestablished in the muscles in the upper extremity and motion has been fully reestablished, the patient is gradually returned to pitching. This is done on a gradual basis, carefully monitoring the number of innings and pitches within a specified period of time.

AVASCULAR NECROSIS OF THE TROCHLEA

Definition

This term is used to define three different pathologies characterized by a disturbance of the growth process of the centers of ossification of the trochlea. These are classified as idiopathic, congenital, and posttraumatic.

Idiopathic

Hagemann's disease (aseptic osteonecrosis of the humeral trochlea, or osteochondritis of the humeral trochlea, or osteochondrosis of the humeral trochlea) is avascular necrosis of the trochlea that appears with no prior history of trauma (268).

Congenital

There are two reports of seemingly congenital forms of trochlear hypoplasia. In a report of Japanese patients (279), the hypoplasia was bilateral, with symptoms present since early childhood. Another report (276) involved an African-American family in which the mother and three offspring had severe bilateral forms of aplasia of the trochlea.

Posttraumatic

This most common form follows some type of elbow trauma. In some cases, the trauma is occult or poorly defined. This form results in a spectrum from simply a small defect of the trochlea (fishtail deformity) to complete destruction of the medial aspect of the distal humerus with a progressive axial deformity, decreased range of motion, and associated disabling instability of the elbow.

Historical Perspective

Idiopathic Cases (Hagemann's Disease)

Osteonecrosis of the trochlea was first described in 1933 by Uhrmacher (284) in a 7-year-old patient. Almost 20 years after this initial description, Hagemann (268) published his classic article on the idiopathic nature of this type of avascular necrosis. Thus, the idiopathic form has become known, at least in the European literature, as Hagemann's disease (263). A close investigation of many of the cases of so-called Hagemann's disease, however, reveals that there was usually some antecedent elbow trauma that may or may not have contributed to the development of the avascular necrosis (263).

Trauma-Related Cases

The first description of avascular necrosis of the trochlea following elbow trauma was in 1948 by McDonnell and Wilson (274). In their series, the problem occurred as a complication of both lateral condylar and supracondylar fractures. Seven years later, Wilson (288) described the typical fishtail deformity occurring after some fractures of the lateral condylar physis. There was little mention as to the consequence or etiology of this complication in these articles. Such was also the case in other articles in which avascular necrosis of the trochlea can be seen in the clinical photographs in many of the cases illustrated (264, 265, 269, 271, 272 and 273, 285, 286, 287 and 288). Usually there was little or no mention of the significance of this finding in the captions.

Vascular Etiology

Not until 1984, when Morrissey and Wilkins (278) reported five cases of avascular necrosis of the trochlea, was its relationship to the unique blood supply of this area suggested. They pointed out that according to the classic articles of Haraldsson (266, 267) on the blood supply of the distal humerus, the medial crista of the trochlea has two separate blood supplies that can be injured with trauma. This relationship of the unique blood supply to the various patterns of avascular necrosis is discussed in detail in the following sections relating to etiology and the patterns of necrosis.

A more recent article by Yoo and co-workers (290) also relates avascular necrosis to a vascular etiology with their observation that it occurred with a higher incidence in their cases of total distal humeral physeal fractures.

Incidence

Seldom Reported

Because it is seldom reported in the literature, the exact incidence is unknown. As mentioned previously, many cases are illustrated in various reports with little or no mention of its occurrence or significance. We recently reported on a series of 30 cases collected over the past 20 years from various sources (283). It is also our experience that it is probably one of the most unrecognized sequela of injuries to the distal humerus.

Trauma to Distal Humerus Most Common Cause

It has been described as a complication of almost any fracture type to the distal humerus, except for isolated epicondylar injuries. Avascular necrosis of the trochlea has been reported as a consequence of the following injuries.

Distal Fractures of the Lateral Condylar Physis

The term *fishtail deformity* was coined in the classic article on lateral condylar fractures by Wilson published in 1955 (288). This term, which usually represents a localized avascular necrosis of the trochlea, has subsequently been used by others in their reports on fractures of the lateral condyle (275, 278, 286, 288,297).

Fractures of the Medial Condylar Physis

This type of fracture is especially vulnerable to developing avascular necrosis of the trochlea because of the close proximity of the fracture line to the blood supply of the trochlea (264,270,273,280,285). It can occur in cases treated either operatively or nonoperatively. Operative management of this fracture can increase the incidence or extent of the avascular necrosis by iatrogenic injury to the most medial blood supply to the trochlea, which is extraarticular.

Supracondylar Fractures

Avascular necrosis of the trochlea also has been described following very distal supracondylar fractures (263, 265, 274, 278). This can occur in both displaced and nondisplaced fractures. The index case for Morrissey and Wilkins' article (278) was actually a very distal nondisplaced supracondylar fracture that developed a typical fishtail deformity.

Separation of the Total Distal Humeral Physis

Again, the very distal location of the fracture line allows it to transect the transphyseal vessels at the lateral portion of the medial crista during the acute fracture (269,278,289,290). Many of these recover, and the avascular necrosis is never evident because this often occurs in the preosseous stage of the development of the trochlea.

T-Condylar Fracture

If comminution occurs, some of the T-condylar fractures can injure the delicate blood vessels that supply the trochlea. Fortunately, most of these occur in the older age group, in which the vulnerability of the distal humerus to avascular necrosis is lessened.

Sprain of the Elbow

This entity also has been described as “following a sprain” of the elbow (265). However, this was probably an unrecognized and undisplaced very distal supracondylar or distal physeal injury.

Iatrogenic

Sometimes an extensive surgical approach and dissection of the soft tissue is necessary to obtain a good open reduction of a fracture about the elbow, especially when seen and treated on a delayed basis. This can injure the vessels that supply the trochlea, with subsequent avascular necrosis (270). When surgically approaching the medial condylar articular surface from a medial approach, the vessels supplying the medial aspect of the medial crista are on the extraarticular surface of the crista of the trochlea and must be carefully avoided.

Etiology

Three theories have been proposed to account for the posttraumatic changes that occur in the distal humerus after fractures in the vicinity of the trochlea: malunion, partial growth arrest, and vascular injury.

Malunion

Wilson (288) thought this was the result of a malunion of a lateral condylar fracture with an intervening gap. This type of deformity is static, often asymptomatic, and nonprogressive.

Partial Growth Arrest

Wadsworth (287) thought this represented a premature fusion of the lateral condylar epiphysis to the metaphysis. Jakob and co-workers (271) thought this was actually due to a primary disturbance of the growth cells adjacent to the fracture line of the lateral condyle. These theories can support the development of hypoplasia of the central or lateral portion of the trochlea. They do not, however, explain the total destruction of the trochlea that can occur. Growth arrest often takes months or years to produce deforming effects, and many of these changes occur rapidly after the initial injury.

Vascular Injury

Two Separate Sources

P>In Haraldsson's classic studies (266,267) of the blood supply of the distal humerus, he demonstrated that the medial crista of the trochlea had two separate sources of blood supply. Neither has anastomoses with each other or with the other metaphyseal vessels. In the young infant, the vessels are small and lie on the surface of the perichondrium (Fig. 15-71A,Fig. 15-71B and Fig. 15-71C). Immediately before and during the deposition of bony salts in the ossification centers of the trochlea, two distinct lateral and medial nonanastomotic sets of nutrient vessels are present.

Lateral Vessels

The lateral vessels supply the apex of the trochlea and the lateral aspect of the medial crista. These vessels cross the growth plate to enter the posterior aspect of the lateral trochlear ossification center. Their terminal branches lie just under the articular surface (Fig. 15-71D). Thus, they are particularly vulnerable to injury when the fracture line occurs through this area, as is typical in fractures of the medial condylar physis or lateral condyle or a T-condylar fracture. By the same token, a fracture in the supracondylar area in which the fracture line is very distal, or a total distal humeral physeal displacement, also can disrupt the lateral trochlear epiphyseal vessels as they course along the surface of the metaphysis or at their entrance into the physeal plate.

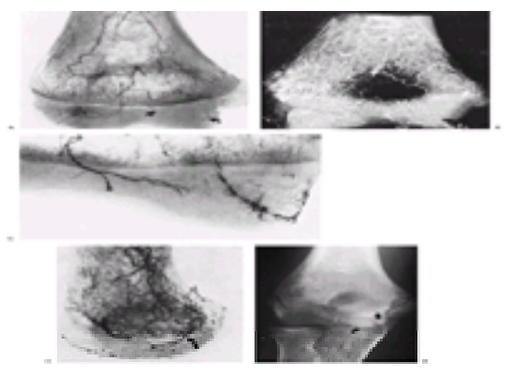

FIGURE 15-71. Blood supply of the trochlea. **A:** Intraosseus vasculature in a 3-year-old boy. Only two small vessels supply the medial crista of the trochlea (*arrow*). The central portion of the crista appears avascular. **B:** Injection studies showing the well-defined medial and lateral vessels (*arrow*) supplying the medial crista of the trochlea. **C:** Close-up view showing the extent of the vascular supply of the trochlea. Note that no anastomoses are seen between these medial and lateral vessels. **D:** Lateral view through the medial crista of the trochlea. Note that the vessels penetrate the physis posteriorly (*arrow*) to enter the epiphyseal cartilage. (A-D: Reprinted from Haraldsson S. On osteochondritis deformans juvenilis capituli humeri. *Acta Orthop Scand Suppl* 1959;38: with permission.) **E:** Radiograph of a 12-year-old boy. The persistence of the two separate ossification centers (*arrow*) of the medial crista is seen. The area supplied by the lateral vessel is larger than that supplied by the medial vessel.

Medial Vessels

Another set of vessels enters medially through the nonarticulating surface of the trochlea (Fig. 15-71B and Fig. 15-71C). This set of vessels supplies the most medial aspect of the medial crista or the medial portion of the trochlear epiphysis. As shown in Haraldsson's (266,267) studies, there appear to be no anastomoses between these two sets of vessels supplying the trochlear epiphysis.

Age Factors

Most of the reported cases of avascular necrosis of the trochlea occur in children who are at least 6 or 7 years of age. However, it has been recently reported in younger patients after fracture-separation of the entire distal physis of the humerus (290).

Ossification centers need blood supply for their appearance and development. Before these centers appear, the vessels are more superficial and less well defined. It is speculated that a lesion in these immature vessels in children leads only to a delay in the appearance of the centers. In older children, where there is already a well-defined ossification center, disruption produces a true bony avascular necrosis of one or both of the ossification centers of the trochlea. This can result in a

partial or total absence of further epiphyseal ossification, leading to hypoplasia of the central or whole medial aspect of the trochlea.

Fracture Location Critical

The common factor of all these fracture pathologies producing avascular necrosis of the trochlea seems to be the presence of a fracture line or other injury in proximity to the lateral aspect of the medial condylar physis or the whole medial crista of the trochlea. These fracture lines injure the vessels as they enter their respective ossification centers of the trochlea.

The direct relationship between trauma and avascular necrosis of the trochlea also has been suggested by its development after surgical intervention of the original fracture, especially after open reduction from a medial approach.

To support the vascular theory, there is also the observation that the necrosis of the trochlea follows the trauma rapidly. When recognized early, the period between the fracture and the development of changes consistent with avascular necrosis is months or weeks (278,290).

Patterns of Necrosis

Avascular necrosis of the trochlea can appear as either a central defect (type A) or total hypoplasia manifest by complete absence of the trochlea (type B), depending on the extent of the vascular injury.

Type A-Fishtail Deformity

In the type A deformity, only the lateral portion of the medial crista or apex of the trochlea becomes involved in the necrotic process. This produces the typical fishtail deformity (Fig. 15-72). This more common pattern of necrosis seems to occur with very distal supracondylar fractures or with fractures involving the lateral condylar physis.

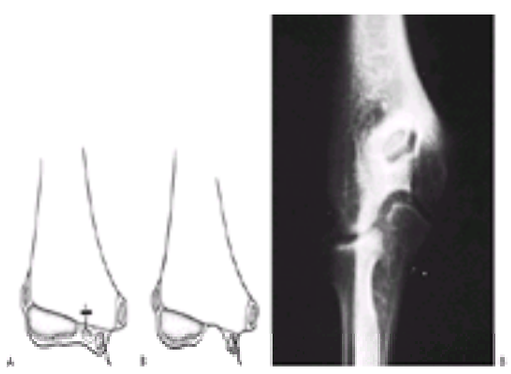

FIGURE 15-72. Fishtail deformity. **A and B:** Type A deformity. Avascular necrosis only of the lateral ossification center creates a defect in the apex of the trochlear groove. **C:** Radiograph of a 14-year-old boy who sustained an undisplaced distal supracondylar fracture 5 years previously. The typical fishtail deformity is seen.

Type B—Malignant Varus Deformity

The type B deformity involves avascular necrosis of the entire trochlea and sometimes part of the metaphysis (Fig. 15-73). This type of necrosis has occurred as a sequela of fractures involving the entire distal humeral physis or fractures of the medial condylar physis (285). This can lead to a cubitus varus deformity in which the angulation progresses as the child matures.

FIGURE 15-73. Avascular necrosis of the entire trochlea. **A:** Type B deformity. Loss of blood supply from both the medial and lateral vessels results in avascular necrosis of the entire medial crista along with a portion of the metachphysis. **B:** Radiograph of a 4-year-old boy who sustained a type II physeal fracture involving the entire distal humeral physis. In this injury film there is a large metaphyseal fragment on the medial side (*arrow*). **C:** Appearance 5 months later. A mild varus deformity present is due to an incomplete reduction. The ossification in the medial metaphyseal fragment has disappeared. **D:** Radiograph taken 4 years after injury. The entire medial crista and adjacent medial metaphysis have remained avascular. The varus deformity has progressed. **E:** Correction was achieved by performing a combination lateral closing wedge and medial translocation osteotomy.

Clinical Signs and Symptoms

There is no particular clinical sign during the evolution of the necrosis. In most cases, the symptoms develop after healing of the fracture. In fact, in the typical scenario, in which avascular necrosis of the trochlea occurs after a supracondylar fracture, the patient initially has full recovery with healing of the fracture. However, as the necrotic process develops, the patient develops the late onset of symptoms of degenerative joint disease such as stiffness, loss of motion, and pain following physical activity.

Sequelae

The clinical signs and symptoms differ considerably between the two patterns of necrosis.

Type A— Symptoms

Patients who have type A or fishtail deformity usually do not develop any angular deformities. Early degenerative joint disease with a loss of range of motion is the most common sequela. The severity of the fishtail deformity is related to the degree of necrosis and seems to dictate the severity of the symptoms. Wilson (288) reported a 47-year follow-up in a patient whose major complaints related primarily to arthritis.

Type B—Progressive Varus

In children who have a pattern of total avascular necrosis of the trochlea, including part of the nonarticular surface, usually a progressive varus deformity develops. Because the total medial trochlear surface is disrupted, significant loss of range of motion also develops. These deformities usually worsen cosmetically and functionally as the child matures (Fig. 15-73C and Fig. 15-73D).

Ulnar Neuropathy

A late-onset ulnar neuropathy can develop in these patients (277,282). The hypoplasia of the medial condyle and its associated epicondyle produces a shallow ulnar groove. This allows the ulnar nerve to slip anteriorly. In addition, the medial head of the triceps muscle also slips anteriorly. There is no consensus on the etiology of the ulnar neuropathy. It is thought to be due to a multiplicity of factors, including malalignment of the joint, abnormal position of the ulnar nerve and triceps tendon, loss of protection by a deep ulnar groove, and the acute angle of entrance of the two heads of the flexor carpi ulnaris. Each of these factors has a variable bearing on the etiology of the neuropathy. In some of those cases reported with late-onset ulnar neuropathy, there were extensive bony changes with the presence of ganglions on the medial aspect of the joint (282). However, late-onset ulnar neuropathy can occur in children after other types of injuries without radiographic findings of trochlear hypoplasia (281).

Treatment

Because the avascular necrosis of the trochlea is a direct consequence of trauma to the vessels occurring at the time of injury, there is no effective prevention or treatment of the primary necrosis. Treatment entails addressing only the sequelae of the avascular necrosis of the trochlea.

Loss of Range of Motion

If the loss of range of motion is due to a significant disruption of the articular surface itself, there does not appear to be any good operative or nonoperative method that significantly improves elbow function. A good program of muscle strengthening may lessen the symptoms to some degree.

In the one case treated surgically by Morrissey (278), he noticed that the olecranon had migrated proximally because of the central necrotic defect of the distal humerus. He felt this created an impingement between the olecranon and the distal humerus during full extension. In that case, a partial resection of the proximal olecranon improved extension of the elbow.

Varus Deformity

If the avascular necrosis of the trochlea has resulted in a varus deformity of the elbow, this deformity can be corrected by a supracondylar osteotomy (Fig. 15-73E). The correction of the carrying angle is mostly cosmetic, with little functional improvement. It does not seem to improve the range of motion. Surgical treatment carries the risk of increased stiffness to the already limited elbow. It can be argued that if this osteotomy is performed relatively early to correct the varus deformity, this could decrease the incidence of late-onset ulnar neuropathy due to the anterior migration of the ulnar nerve and medial head of the triceps.

Ulnar Neuropathy

In the cases of ulnar neuropathy occurring after hypoplasia of the trochlea, relief of ulnar nerve symptoms was achieved by transposing the ulnar nerve anteriorly in addition to releasing it from the adhesions around the hypoplastic medial epicondyle (277,282).

T-CONDYLAR FRACTURES

In T-condylar fractures, the fracture line originates in the central groove of the trochlea and courses proximal to the olecranon and the coronoid fossae, where it divides and separates the medial and lateral bony columns of the distal humerus. If the proximal fracture lines are oblique, the fracture may be termed Y-condylar. This injury is rare in the skeletally immature child.

Incidence

Primarily in Adolescents

The early modern literature reflects only reports by Blount (292) and Zimmerman (319), who each described a case in an 11-year-old patient. The average age of patients reported in the three major recent series (302,303,310) was 12.6 years. Our clinical experience with 11 cases over a 20-year span has confirmed these data, with the average age being 11 years. Thus, Maylahn (306), who reported on six patients near skeletal maturity, was accurate when he said, “the fractures [T-condylar] take on the characteristics of an adult fracture and should be treated as such."

Occurrence in Young

In 1902, Cotton (296) echoed the view of the surgical community at that time when he stated, “the fracture [T-condylar] is not only very uncommon, but very rare [in young children].” The actual incidence in younger children is certainly rare, but it may be underdiagnosed. This is because it is often confused with other fractures, such as those involving the lateral condylar physis or total distal physis. Special imaging studies such as arthrograms were necessary to demonstrate the intracondylar aspect in a recent report involving two patients under 3 years of age (291). The combination of an increased awareness of the possibility of this injury and a more aggressive diagnostic approach may result in more cases being uncovered in this younger age group.

The rare occurrence of the injury is reflected in the importance given in recent textbooks on children's fractures. A few (298,309,312,319) contain only a brief discussion of this fracture pattern; others (294,295,300,311,317) do not mention it at all.

Mechanism of Injury

Wedge Effect of the Olecranon (Semilunar Notch)

The primary mechanism of this injury is the direct wedge effect of the articular surface of the olecranon on the distal end of the humerus. The sharp edge of the semilunar notch or coronoid process acts as a wedge to break the trochlea and split the condyles, which in turn separates the two columns of the distal humerus (297). In our review of 11 skeletally immature patients with this injury, the vertical fracture line always extended down to the apex of the trochlea, tending to confirm this mechanism.

In a biomechanical study performed on adult cadaver specimens, Mehne and Matta (307) examined the force of the olecranon on the trochlea with varying degrees of flexion of the elbow. The situation that most consistently produced T-condylar fractures occurred when the force was applied directly to the olecranon with the elbow in more than 90 degrees of flexion.

The mechanism of these fractures has evolved from both biomechanical and clinical studies. The biomechanical studies involve the wedge mechanism of the olecranon against the distal humerus. The clinical studies are the results of indirect observations as to whether injuring force was applied to the distal humerus in either a flexion or extension position.

Flexion Injuries

The most common mechanism producing this fracture pattern is said to be a direct blow to the posterior aspect of the elbow (313), usually when the child falls directly on the flexed elbow. This flexion mechanism in young children contributes to its rarity because most upper extremity injuries in children have a component of elbow

hyperextension. Injuries to the elbow caused by a flexion mechanism are rare. In these flexion injuries, the wedge effect is produced at the apex of the trochlea by the central portion of the trochlear notch. In these flexion injuries, the condylar fragments usually lie anterior to the shaft (Fig. 15-74A and Fig. 15-74B).

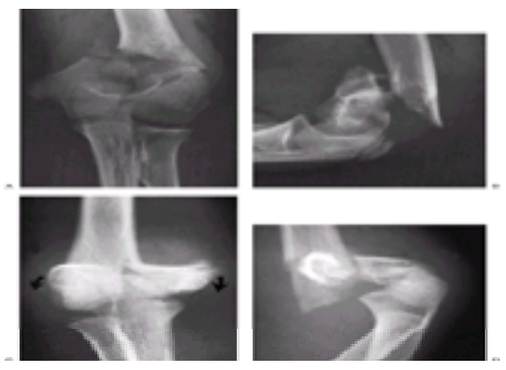

FIGURE 15-74. Mechanism patterns. **A and B:** The more common flexion pattern in which the condylar fragments are situated anterior to the distal shaft. **C and D:** An extensor pattern in which the condylar fragments are situated posterior to the distal shaft. The muscle origins on the respective condyles cause them to diverge in the coronal plane (*arrow*) and flex in the sagittal plane.

Extension Injuries

In a few cases, the T-condylar fracture may be caused by a fall on the outstretched arm with the elbow in only slight flexion. This extension mechanism has been suggested by patients in their description of the dynamics of the fall, and indirectly by the position of the distal fragments in relation to the diaphyses of the humerus—in other words, lying posterior (Fig. 15-74C and Fig. 15-74D). In the extension type of injury, the coronoid portion of the semilunar notch produces the wedge effect.

Role of Muscles

It has been suggested that contraction of the elbow flexor and extensor muscles may play a role in the displacement pattern of this fracture. Because of their origins on the epicondyles, they accentuate both the separation in the coronal plane and the forward displacement in the sagittal plane. This displacement pattern often is evident on the injury films (Fig. 15-74C and Fig. 15-74D).

Pathology

The More Common Adolescent Pattern

The fracture pattern in the adolescent is similar to that of the adult. The condylar fragments are often separated, with the articular surface being completely disrupted. In addition to separation of the condylar fragments by the force of the original injury, the muscles that originate on these condylar fragments rotate them in both the coronal and sagittal planes (Fig. 15-74C and Fig. 15-74D) (297). In the sagittal plane, the position of the condylar fragments in relation to the humeral shaft and metaphysis can either be anterior (flexor mechanism; see Fig. 15-74B) or posterior (extension mechanism; see Fig. 15-74D).

The Rare Patterns in the Young Child

Articular Surface Remains Intact

In the skeletally immature patient, the central portions of the condylar fragments are usually separated, but the articular surface may remain intact because of its large cartilage component (Fig. 15-75) (310). Thus, the disruption and displacement are primarily in the osseous supracondylar area. The elasticity of the cartilage of the distal end of the humerus often protects the articular surface from being completely disrupted.

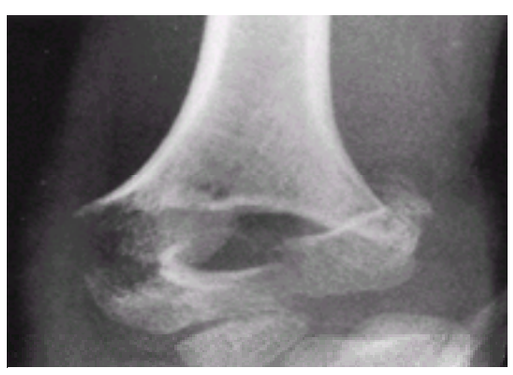

FIGURE 15-75. Intact articular surface. A T-condylar fracture in a 7-year-old boy. The thick articular cartilage remains essentially intact, preventing separation of the condylar fragments. This fracture was secured with simple percutaneous pins.

Variable Resistance to Failure

Cotton (296) reasoned that in the distal humerus, the condyles present variable resistance to failure. The external (lateral) condyle has a weakened resistance. The medial condyle exhibits a stronger resistance to separation. It was his opinion that this variable resistance explained the infrequency of both T-condylar and medial (internal) condyle fractures and the higher incidence of lateral condyle fractures.

Classification

Various classifications (302,308,314) for adult T-condylar fractures have been proposed, but there are problems with applying these classifications to children's injuries. For example, the number of children with this fracture is so small that no clinician can include all types of fracture patterns in his or her own experience. In addition, there is no useful classification for the younger patient, in whom the unossified intact articular cartilage is not visible on radiography. For example, the Jarvis type III (302) fracture-ndislocation or Chutro-Posados fracture has never been observed in our clinical experience, nor has it been reported in other series. The C-3 fracture in the AO classification (308,319), which has articular surface comminution, also has not been reported in the literature in children.

Authors' Suggested Classification

We have tried to simplify the classification so that it will be useful in determining treatment options. We feel there are three major types based on the degree of displacement and comminution of the fracture fragments. Type I fractures are minimally displaced (Fig. 15-76A and Fig. 15-76B). Type II fractures are displaced but do not have comminution of the metaphyseal fragments (Fig. 15-76C). Type III fractures are displaced fractures with comminution of the metaphyseal fragments (Fig.

15-76D and Fig. 15-76E).

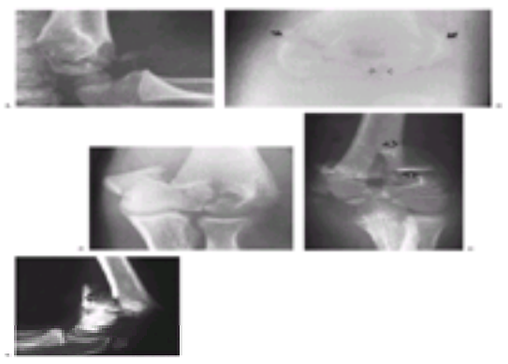

FIGURE 15-76. Types of T-condylar fractures. **A:** Type I—Lateral view of undisplaced T-condylar fracture in a 6-year-old. **B:** The T-condylar fracture line (*open arrows*) was not appreciated until it healed. There are both medial and lateral Thurston-Holland fragments (*solid arrows*). (Courtesy of Ruben D. Pechero, M.D.) **C:** Type II—a displaced T-condylar fracture with very little metaphyseal comminution. **D and E:** Type III—two views of a markedly comminuted T-condylar fracture with multiple displaced fragments (*arrow*) in a 12-year-old.

In a child, the integrity of the articular surface may be difficult to determine without using arthrography or MRI. Because the initial integrity of the articular surface may not be that important to the prognosis, we feel that this factor does not significantly contribute to a general classification scheme. Adolescent T-condylar fractures may be classified as in adults.

Diagnosis

Clinical Signs and Symptoms

Clinically, these fractures are most often confused with extension-type supracondylar fractures. The extended position of the elbow, along with the massive swelling, is almost identical to that of the displaced extension type of supracondylar fracture.

Imaging Studies

Plain X-Rays

Diagnosis Not Always Obvious Plain x-ray films are the cornerstone to the diagnosis. In the older child, the differentiation must be made from that of a comminuted supracondylar fracture. Sometimes the diagnosis is not obvious until the fragments have been partially reduced, which allows the vertical fracture lines splitting the trochlea to become more evident. In the younger child, the diagnosis is much more difficult because the articular surface is not visible. In addition, because of its rarity, the surgeon may not consider the possibility of a T-condylar fracture in this age group.

Differential Diagnosis

The diagnosis must exclude the more common fracture patterns of either the isolated lateral or medial condyles, or the complete separation of the distal humeral physis. In these latter fractures, an important sign is the presence of a medial or lateral Thurston-Holland fragment in the metaphysis (291). The key differential for the T-condylar fracture is the presence of a vertical fracture line extending down to the apex of the trochlea.

Computed Tomography and Magnetic Resonance Imaging

In the acute injury, the use of these imaging modalities does not appear to have much practical value. In younger patients, this often requires a separate anesthesia or heavy sedation outside the operating room.

Dynamic Studies Under Anesthesia

The diagnosis may be suspected after a careful evaluation of the static x-ray films. However, to settle the issue before definitive treatment, the surgeon may need to obtain either varus or valgus stress films under general anesthesia (291). In many cases, the use of contrast medium in the form of an arthrogram is also quite helpful.

Teatment

Basic Principles

Because of the rarity of this injury, no one can recommend a plan of management based on multiple case experience. Most of the experience in the past has been based on isolated cases or small series (291,302,303,305,310). Regardless of the method of treatment, certain basic principles must be considered in treating these fractures. A treatment plan must be individualized for the specific fracture and the surgeon's level of expertise and experience. The following principles must be considered in planning a method of treatment:

1. Elbow articular mobility depends on articular congruity, correct alignment of the axis of motion, and debris- and bone-free fossae.
2. The stability depends on the integrity of the lateral and medial supracondylar columns.
3. The T-condylar fracture is an articular fracture, so the first goal is to restore and stabilize the joint surface.
4. Closed methods alone usually cannot produce an acceptable result because of the muscle forces applied to the fragment.
5. Most patients are adolescents with minimal potential for bone remodeling.
6. Although surgical reduction may produce an acceptable radiograph, it may add to the already extensive damage to soft tissues; this in turn can contribute to postoperative stiffness.

Current Trends Toward Surgical Stabilization

The current literature reflects good results with surgical management. Zimmerman (319) advocated establishing an anatomic reduction with internal fixation so that early motion could facilitate a more rapid rehabilitation. In the two cases in young children described by Beghin and colleagues (291), operative intervention was necessary to achieve a satisfactory reduction. A review of the three most recent series (302,303,310) indicates that surgical management has been established as the present trend by virtue of the fact that 29 of the 31 elbows in these combined series were treated operatively. The investigators in these series maintained that open reduction and internal fixation was the best way to restore the integrity of the articular surface and stabilize the fracture sufficiently to allow early mobilization. All but one of the patients in this combined series who were treated surgically demonstrated good or very good results at follow-up.

Popular Surgical Approaches

The surgical approach most widely accepted is the posterior longitudinal splitting of the triceps without an osteotomy of the olecranon. This approach gives adequate exposure of the fracture and the articular surface and does not seem to produce any loss of strength from splitting the triceps (303). Although one case demonstrated radiographic evidence of avascular necrosis of the trochlea (310), another reported a nonunion (303), and many had some loss of range of motion, none of these

surgically treated cases demonstrated any significant loss of elbow function or discomfort.

Another surgical approach that has become popular is the one advocated by Bryan and Morrey (293). This is a triceps-sparing approach in which the extensor mechanism is reflected laterally, exposing the whole distal humerus.

AUTHORS' PREFERRED METHOD OF TREATMENT

Because of the rarity of this fracture in children, there is no standard recommended treatment. Therefore, we are outlining our recommendations based on a combination of our clinical experience and the experience of others in a few series (302,303,310). Our first consideration in these fractures is to reestablish the integrity of the articular surface to maintain the congruity of the joint. Usually this cannot be achieved adequately by closed methods, so we proceed with an open surgical technique. We have found our simple classification to the three types based on the degree of displacement or comminution to be helpful in guiding the aggressiveness of our treatment.

Type I (Undisplaced or Minimally Displaced)

In type I injuries, there is little displacement of the bony supracondylar columns. In children, the periosteum is often intact and can provide some intrinsic stability. In addition, the thicker articular and epiphyseal cartilage in the skeletally immature child may still be intact, even if the bony epiphysis appears severed by a vertical fracture line. Because of this, we have found two methods to be successful for these types of fractures.

Closed Reduction—Percutaneous Pin Fixation. These fractures require minimal manipulation under general anesthesia and radiographic control to reestablish the supracondylar columns. If there is anterior or posterior rotation in the sagittal plane of the metaphyseal portion of the column, a pin placed into that column can be used as a “joy stick” to manipulate the fragment into a satisfactory position. Once a satisfactory reduction is achieved, the pin can then be advanced across the fracture site for fixation. These fractures usually require multiple pins placed percutaneously, such as those used in comminuted supracondylar fractures (Fig. 15-77). Because of the rapid healing, the pins can be removed at 3 weeks to allow early active motion.

FIGURE 15-77. Closed reduction and pin fixation. **A and B:** Two views of a type II T-condylar fracture in a 15-year-old. **C and D:** Because an anatomic reduction was achieved by manipulative closed reduction, it was secured with simple multiple pin fixation placed percutaneously. The articular surface was minimally displaced. The pins were removed at 3 weeks. At this age, healing was rapid enough to pull the pins at 3 weeks to allow active motion. Ultimately he was deficient only 10 degrees from achieving full extension.

Traction. If the articular cartilage is intact, it may close as a hinge with traction (Fig. 15-78). The rotational displacement of the condyles created by the origins of the forearm muscles can be neutralized with olecranon traction, in which the elbow is suspended at 90 degrees of flexion. There is usually adequate stability from the callus around the fracture site at 2 to 3 weeks to discontinue the traction. The elbow is then immobilized in a hinged cast brace for an additional 2 to 3 weeks. This allows the initiation of protected active motion. However, with the present emphasis on short hospitalization, we find that skeletal traction is less acceptable for both social and financial reasons. Skeletal traction may be the only acceptable method of treatment in patients seen on a delayed basis with extensive skin abrasions, severe soft tissue injury, or gross comminution, in which cast application or other operative interventions might carry a high risk of infection.

FIGURE 15-78. Treatment with traction. Treatment of the 6-year-old child with a T-condylar fracture shown in Fig. 15-76A and Fig. 15-76B. **A:** This patient was treated with traction. Once the fracture was reduced, the T-condylar nature of the fracture line was fully appreciated. The articular cartilage appeared intact and served as a hinge to maintain reduction. **B:** Lateral view in traction. Although the distal fragment remained extended, it was believed to be in an acceptable position. **C and D:** Anterior and lateral views 2 months after injury. The architecture of the condylar articular surface has been well maintained. (Courtesy of Marvin Mumme, M.D.)

Type II (Displaced Without Comminution)

Open Reduction and Internal Fixation. If there is wide separation of the condylar fragments with marked disruption of the articular surface, stability and articular congruity can be established only with an open surgical procedure. We prefer the Bryan-Morrey posterior triceps-sparing approach (293). The patient is placed prone on the operating table with the arm supported on a pillow and the forearm hanging down off the edge of the operating table. This provides the best approach for direct visualization of the posterior surface of the distal humerus. Olecranon osteotomy is reserved for those fractures in adolescents with severe articular comminution.

First, Reconstruct Articular Surface. Our first priority is to reestablish the integrity of the articular fragments—in other words, to convert it to a supracondylar fracture (Fig. 15-79A,Fig. 15-79B and Fig. 15-79C). It is also critical that the olecranon and coronoid fossae be cleared of bony fragments or debris to eliminate the chance of bony impingement with their respective processes. The best way to stabilize the condyles is with a screw passed transversely through the center of the axis of rotation in such a manner as to apply transverse compression. This may require a small temporary secondary transverse pin proximal to the screw to prevent rotation of the fragments as the guide hole is drilled or the compression screw is being applied. This pin can be moved after the fragments are secured.

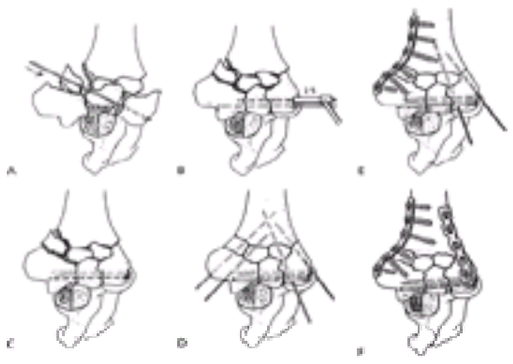

FIGURE 15-79. Sequence of reconstruction of the distal humerus. **A-C:** First, the articular portions are reassembled with provisional Kirschner wire fixation, followed by screw fixation. **D:** Kirschner wires can then also be used to provide temporary fixation of the distal humerus. **E:** A one-third tubular plate is attached to the medial side. **F:** A 3.5 pelvic reconstruction plate was attached to the posterolateral border. (Reprinted from Heim U, Pfeiffer KM. *Internal fixation of small fractures,* 3rd ed. Berlin: Springer-Verlag, 1988; with permission.)

Secondly, Stabilize Supracondylar Columns. Once the condylar and articular integrity has been reestablished, the distal fragments must be secured to the proximal fragment by stabilizing the supracondylar fragment columns. The decision here is how important it is to initiate early motion. If it is a younger child with rapid bony healing, pin fixation is often satisfactory so that they can be removed in 3 weeks to start protected motion, similar to treatment of a supracondylar humeral fracture. If it is an older adolescent nearer to skeletal maturity, we prefer fixation—usually plates or screws—that allows early motion (Fig. 15-79E and Fig. 15-79F and Fig. 15-80). Before application of the plates, the supracondylar columns can be stabilized temporarily with pin fixation (Fig. 15-80D).

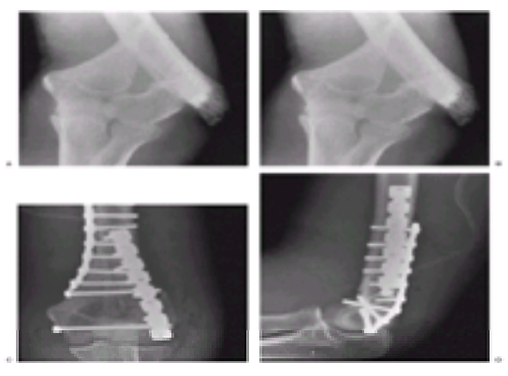

FIGURE 15-80. Plate and screw fixation. **A and B:** Injury films of a type II flexion pattern in a 16-year-old boy. **C and D:** Articular integrity was first restored with a transcondylar compression screw. The condyles were secured to the metaphysis and distal shaft using pelvic reconstruction plates placed at 90 degrees to each other.

Principles of Plate Fixation

The plates must be strong. The thin semitubular plates are inadequate and may break (Fig. 15-81) (318). The reinforced malleable reconstructive type of plates used for fixation of pelvic fractures provide very secure fixation. Recently, a J type of plate has been designed that also can provide rigid fixation when used to stabilize the lateral column (316). It is best to place the plates at 90 degrees to each other, which makes for a more stable construct (301,315).

FIGURE 15-81. Inadequate fixation. **A:** Immediate postreduction film of a 14-year-old secured with short semitubular plates and a small transcondylar screw. **B:** Six weeks later the small compression screw in the condyle had lost fixation and the lateral plate had fractured. The patient was resecured with large pelvic reconstruction plates and a large transcondylar compression screw.

In most cases in the adolescent, this is essentially an adult type of fracture pattern. The reader is therefore referred to *Fractures in Adults* for a more detailed description of the various other techniques used in treating adults with this type of fracture.

Postoperative Care

If plate fixation is used, we place the extremity in a supporting posterior splint for 5 to 7 days to allow the soft tissue swelling to decrease and the incisions to heal. At this time, active flexion and extension are initiated and the arm is protected with a removable cast brace. If there is considerable stiffness after 6 to 8 weeks, then we use the turnbuckle brace as advocated by Green and McCoy (299) to regain extension with increasing active range of motion.

Type III (Displaced with Comminution)

Limited Open Reduction Followed by Traction. Sometimes the supracondylar columns are too fragmented to produce adequate fixation. In such cases, we have found that in children, the best initial method of treatment involves reestablishing the articular surface and joint congruity with a limited open reduction. The separated condyles are secured with a transverse screw providing compression through the axis of rotation. This can usually be done with minimal soft tissue dissection. Once this is stabilized, the supracondylar columns are then reestablished by placing the extremity in olecranon traction and allowing them to reconstitute with callus formation. Traction must be maintained until there appears to be good osseous tissue formed in the supracondylar areas (Fig. 15-82). While in traction, motion can be initiated. This technique also can be used in patients seen late with contaminated soft tissue abrasions or severe soft tissue problems.

FIGURE 15-82. Transcondylar fixation and traction. The anteroposterior and lateral radiographs of a 12-year-old boy who sustained a markedly comminuted T-condylar fracture are seen in Fig. 15-76D and Fig. 15-76E. A major portion of the lateral supracondylar column was a totally avascular free fragment. **A:** Because it was totally avascular, it had to be removed, but the periosteum was preserved. The articular surface was reduced and stabilized with a transcondylar screw. The patient was then placed in overhead olecranon traction. **B:** Radiograph of the elbow 8 months after injury shows that the lateral supracondylar column is completely reconstituted. Even though the articular surface was maintained, there was about 30 degrees of loss of elbow motion ultimately.

Complications

It is important to emphasize to the parents initially that this is a serious fracture. Because of the considerable soft tissue injury and the involvement of the articular surface of the distal humerus, stiffness and loss of motion of the elbow can be expected regardless of the mode of treatment (292,302,306,310). In the adolescent patient, failure to provide solid internal fixation that facilitates early motion (i.e., using only pin fixation) can result in a satisfactory radiographic appearance but considerable dysfunction due to residual loss of elbow motion (Fig. 15-83).

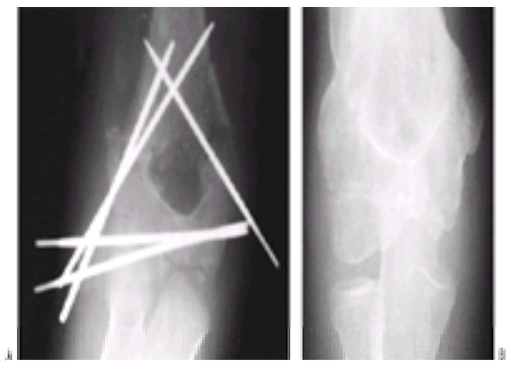

FIGURE 15-83. Stiff residua. **A:** Immediate postoperative film of an 11-year-old boy who sustained a comminuted T-condylar fracture from a direct blow to the flexed elbow. Fixation was achieved by way of a posterior approach, using multiple smooth pins. This prevented the initiation of early motion. **B:** The elbow 5 months postoperatively. Although the bony architecture had been restored, there was considerable restriction of motion from the soft tissue scarring. A better functional result may have resulted had more rigid internal fixation been applied that would not have allowed early motion.

Although neurovascular complications have not been mentioned in the few cases reported in the leterature, it is expected that the incidence is about equal to that of supracondylar fractures. Because these fractures occur late in the growth process, partial or total growth arrest due to internal fixation is not thought to be a major complication. By the same token, because these are older children one cannot expect much in the way of remodeling. Nonunion (303), avascular necrosis of the trochlea (310), and failure of internal fixation (Fig. 15-81) also have been reported as complications.

DISLOCATIONS OF THE ELBOW

GEORGE H. THOMPSON

We thank Kaye Wilkins for his contribution to this chapter and previous editions. Much of this chapter is his effort.

Disruptions of the articular surfaces of the elbow represent a spectrum of injuries ranging from dislocation to subluxation. As such, collectively they are common injuries, although the incidence of each subtype can vary widely. An important anatomic feature of the elbow is its three separate articulations: radiocapitellar, ulnotrochlear, and proximal radioulnar joints. The latter articulation usually functions as a unit but can be disrupted.

CLASSIFICATION

A modification of the classification of elbow dislocations from the previous edition (103) is presented in Table 16-1. Elbow dislocations are described with respect to the position of the proximal radioulnar joint in relation to the distal humerus: posterior, anterior, medial, or lateral. The common posterior dislocation is subdivided into posterolateral and posteromedial dislocations.

Proximal radioulnar joint intact
  Posterior
    Recurrent posterior
    Unreduced posterior
  Anterior
  Medial and lateral
Proximal radioulnar joint displaced
  Divergent
  Translocation
Radial head dislocation
Subluxation of the radial head

Adapted from Wilkins KE, Beaty JH, Chambers HG et al. Fractures and dislocation of the elbow region. In: Rockwood CA, Wilkins KE, Beaty JH eds. *Fractures in Children*, 4th ed. Philadelphia: Lippincott-Raven, 1996.

TABLE 16-1. CLASSIFICATION ELBOW DISLOCATIONS

Occasionally, the proximal radioulnar joint is disrupted. Most commonly, the radius and ulna diverge from each other in a mediolateral direction. Rarely, the radius and ulna translocate, with the radius medial and the ulna lateral.

Isolated dislocations of the radial head are uncommon and must be differentiated from congenital dislocations. Isolated dislocations of the proximal ulna are exceedingly rare and have not been reported in children.

Included in this classification is the very common subluxation of the radial head or “pulled” elbow. This is not a true subluxation but rather a partial entrapment of the annular ligament in the radiocapitellar joint.

POSTERIOR ELBOW DISLOCATIONS

Dislocations of the elbow joint are uncommon in children. Henrikson (36) studied 1,579 injuries about the elbow in skeletally immature patients in Gothenburg, Sweden, in 1966, and found only 45 dislocations, for an overall incidence of 3%. He found that the peak incidence of supracondylar fractures was in the first decade of life, whereas that of elbow dislocation was in the second decade, usually between 13 and 14 years of age, when the physes begin to close. The same second-decade peak incidence was reported by Josefsson and Nilsson (46) in 1986. In their series, most elbow dislocations occurred in conjunction with sports activities.

Within the past four decades, four series (55,71,83,85) have reported elbow dislocations in both adults and children, but some overall statistics regarding the incidence in children can be obtained by combining all four series. In the 317 dislocations reported, including 147 in children, all were posterior (posterior, posterolateral, or posteromedial) except for 10 lateral dislocations, 5 anterior dislocations, and 16 unclassified. Male gender and the left elbow were predominantly involved, and there was a high incidence of associated elbow fractures.

Carlioz and Abols (11) reported 58 elbow dislocations in children and adolescents, of which all were posterior. The mean age at dislocation was 12 years, with a

range from 6 to 15 years. There were 41 boys (71%) and 35 left elbows (60%). Associated elbow fractures occurred in 37 children (64%).

Diagnosis

Mechanism of Injury

In posterior or posterolateral dislocations, first the medial or ulnar collateral ligaments are disrupted, allowing valgus instability. This can result in an avulsion fracture of the medial epicondyle and its associated flexor muscle origin. The proximal radius and ulna become displaced laterally with the intact biceps tendon acting as a center of rotation for the displaced forearm.

The most commonly accepted mechanism of posterior elbow dislocation involves the application of both abduction and extension forces. However, there is controversy as to whether the elbow is initially hyperextended. Osborne and Cotterill (74) believed that initially the elbow was in slight flexion and that the lateral sloping surface of the medial crista of the trochlea served as a cam mechanism to convert the vertical thrust on the forearm into one of lateral rotation and valgus strain. Other investigators believe that there is first hyperextension of the elbow with rupture of the ulnar collateral ligaments (44,87). Once this stabilizing force is disrupted, the elbow is forced into further valgus (Fig. 16-1). Experimentally, in cadavers, posterior dislocations have been most commonly produced by initial hyperextension (87,96). However, Sojbjerg et al. (90), in a study of 10 cadaver elbows, found that a posterior dislocation is the result of a valgus and external rotation force acting on a semiflexed elbow. Dislocation could not be produced with a varus and internal rotation force. O'Driscoll et al. (73) found similar results in their study on 13 fresh autopsy specimens. They also found that the anterior portion of the medial or ulnar collateral ligament remained intact and attributed to this to the frequent valgus stability following closed reduction.

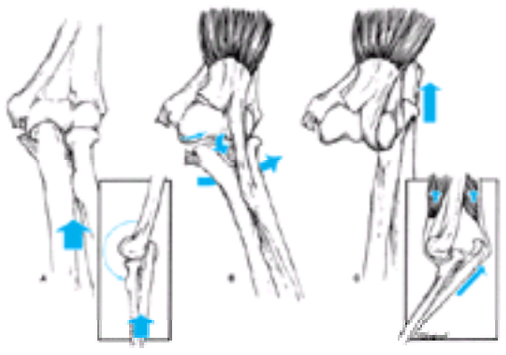

FIGURE 16-1. Mechanism of injury. **A:** Initially the elbow is forced into extension with rupture of the medial collateral ligaments. The normal cubitus valgus accentuates a valgus force at the elbow. **B:** The lateral slope of the medial crista of the trochlea forces the proximal ulna posterolaterally (*small arrow*). The biceps tendon serves as a fulcrum for rotation and valgus hinging of the forearm. **C:** The proximal ulna and radius are then impacted posteriorly and held against the distal articular surface by the contraction of the biceps and triceps

With posterior dislocations there is considerable soft tissue injury: and an associated risk of neurovascular injuries and associated fractures (Fig. 16-2).

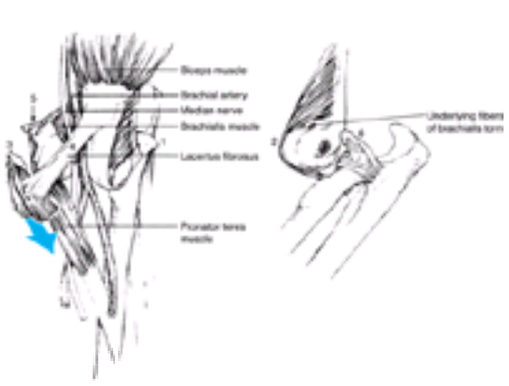

FIGURE 16-2. *Pathology.1:* The radial head and olecranon are dislodged posterolaterally. *2:* The brachialis muscle is stretched across the articular surface of the distal humerus. *3:*) The origins of the medial forearm flexion muscles are either torn or avulsed with the medial epicondyle from the medial condyle. *4:* The median nerve and brachial artery are stretched across the medial condyle and held firmly by the lacertus fibrosus. *5:*) The medial condyle lies in the subcutaneous tissue between the brachialis anteriorly and the pronator teres posteriorly. *6:*) The lateral (radial) collateral ligaments often avulse a piece of cartilage or bone from the lateral condyle

Soft Tissue Injury

The anterior capsule is ruptured with a tension force that allows the joint cavity to be exposed. Posteriorly, the radial head can strip the capsule from the posterolateral aspect of the lateral condyle, along with the adjacent periosteum. Because of the large amount of cartilage on the posterolateral aspect of the lateral condyle, the posterior capsule may not reattach firmly. This lack of a strong reattachment is believed to be a major factor in recurrent elbow dislocations (74).

Medially, the ulnar collateral ligament system is disrupted either by a direct tear of the ligament or avulsion of the medial epicondyle (87,90). Cromack (14) found that with medial epicondylar fractures, the origins of the ulnar collateral ligaments and medial forearm flexor muscles remain as a unit, along with most of the pronator teres, which is stripped from its humeral origin proximal to the epicondyle. These structures are then displaced posterior to the medial aspect of the distal humerus. If the epicondyle remains attached to the humerus, then the ulnar collateral ligaments and muscular origins of the common flexor muscles must be torn. With posterolateral displacement of the forearm, the medial aspect of the distal humerus dissects the intermuscular space between the pronator teres posteriorly and the brachialis anteriorly. The brachialis, because it has little distal tendon, is easily ruptured. The rent in the anterior capsule usually is in this same area.

On the lateral side, the structure most commonly torn is the annular ligament (90). On rare occasions, the entire lateral collateral ligament either avulses a small osteochondral fragment from the lateral epicondyle or tears completely within its substance.

Neurovascular Injuries

When the elbow is dislocated, the medial aspect of the distal humerus lies subcutaneously between the pronator teres posteriorly and the brachialis anteriorly. The median nerve and brachial artery lie directly over the humerus in the subcutaneous tissues. In a cadaver and clinical study by Louis et al. (57), there was a consistent pattern of disruption of the collateral arterial system about the elbow. In almost all extremities studied, there was a complete disruption of the anastomosis between the inferior ulnar collateral artery and the anterior ulnar recurrent artery. If the main brachial arterial trunk is injured, the loss of this collateral system can result in severe compromise of circulation to the forearm and hand.

The ulnar nerve also is at risk because of its anatomic site posterior to the medial epicondyle.

Associated Fractures

Concomitant fractures occur in over one half of posterior elbow dislocations (55,71,83,85). Fractures involving the medial epicondyle, radial head and neck, and coronoid process are most common. Fractures involving the lateral epicondyle, lateral condyle, olecranon, capitellum, and trochlea occur less frequently. In the 58 dislocations reported by Carlioz and Abols (11), there were 24 fractures involving the medial aspect of the elbow, 6 fractures from the lateral region, 2 with fractures from both regions, 2 coronoid process fractures, and 3 radial neck fractures.

Signs and Symptoms

Clinically, the presence of a posterior elbow dislocation usually is obvious. The primary differential diagnosis is an extension-type supracondylar fracture of the distal humerus. With both injuries, the elbow is held semiflexed, and swelling may be considerable. Swelling usually is less with a dislocation than with a supracondylar fracture. However, there is still enough soft tissue disruption, such as tearing of the brachialis muscle and collateral vessels, to produce considerable hemorrhage and swelling. Crepitus usually is absent with a dislocation. With a posterior elbow dislocation, the forearm is shortened. The prominence produced by the distal humeral articular surface is more distal and is palpable as a blunt articular surface. The tip of the olecranon is displaced posteriorly and proximally so that its triangular relationship with the epicondyles is lost. Overlying the olecranon fossa, the skin may have a dimpled appearance. If the dislocation is posterolateral, the radial head also may be prominent and easily palpable in the subcutaneous tissues.

Radiographic and Other Imaging

Routine radiographs usually are diagnostic of a posterior elbow dislocation. In the anteroposterior view, there is a greater superimposition of the distal humerus on the proximal radius and ulna. The radial head may be proximally and laterally displaced, or it may be totally behind the distal humerus, depending on whether it is posterolateral, posterior, or posteromedial (Fig. 16-3). In addition, the normal valgus angulation between the forearm and the arm usually is increased. On the lateral view, the coronoid process lies posterior to the condyles. The radiographs must be examined closely for associated fractures.

FIGURE 16-3. *Radiographic Findings.* **A:** Anteroposterior radiograph. The radial head is superimposed behind the distal humerus. There is increased cubitus valgus. The medial epicondyle has not been avulsed. **B:** Lateral radiograph demonstrating that the proximal radius and ulna are both displaced posteriorly to the distal humerus.

Treatment Options

Nonoperative

Closed Reduction

In the combined series (55,71,83,85) of 317 dislocations, only 2 cases in the series by Linscheid and Wheeler (55) could not be reduced by closed methods. In the Carlioz and Abols series (11), 2 dislocations reduced spontaneously and closed reduction was successful in 50 cases, but failed in 6 cases (10%). Josefsson et al. (45) reported that all 25 dislocations without associated fractures were successfully reduced.

Because of the considerable soft tissue injury, it is essential to reduce the elbow promptly. Royle (85) found that those reduced soon after the injury had better outcomes than those in which reduction was delayed.

All methods of closed reduction are directed toward sufficiently overcoming the muscle forces so that the coronoid process and radial head can slip past the distal end of the humerus. Just before the reducing forces are applied, the forearm should be hypersupinated to dislodge the coronoid process and radial head from their position behind the distal humerus. The reducing forces must be directed in two major directions (Fig. 16-4). The first reducing force must be along the long axis of the humerus to overcome the contractions of the biceps and brachialis anteriorly and the triceps posteriorly. Once these forces are neutralized, the proximal ulna and radius must be passed from posterior to anterior. This requires a second force along the long axis of the forearm. This may require that the elbow be extended or even hyperextended to lever the coronoid process past the distal humerus.

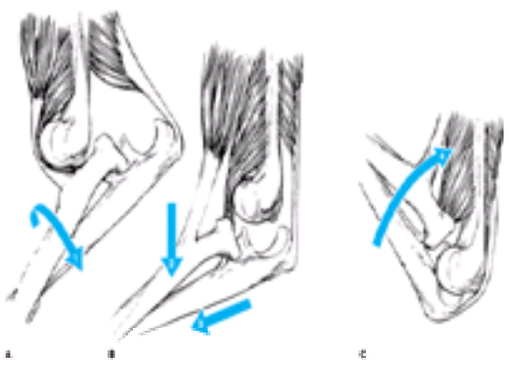

FIGURE 16-4. *Reduction forces of posterior dislocations.* **A:** First the forearm is hypersupinated (*arrow*) to unlock the radial head. **B:** Simultaneous forces must be applied distally along the axis of the humerus (*arrow 2*) and distally along the axis of the forearm (*arrow 3*). **C:** Once the coronoid is manipulated distal to the humerus, the elbow is then flexed (*arrow 4*) to stabilize the reduction.

Some investigators (56,101), however, have strongly advised against initial hyperextension. Loomis (56) demonstrated that when the coronoid process is locked against the posterior aspect of the humerus and the elbow is extended, the force applied is magnified by as much as five times across the anterior muscles because of the increased leverage. This places a considerable strain on the already injured anterior capsule and brachialis muscle (Fig. 16-5). On the other hand, when the distal force is applied to the proximal forearm with the elbow flexed, the force exerted against the muscles across the elbow is equal to the distracting force.

FIGURE 16-5. *Hyperextension forces.* **A:** Normally, the brachialis is stretched across the distal humerus. **B:** Hyperextending the elbow before it is reduced greatly increases the arc of motion and leverage placed across the brachialis. This can result in rupture of large portions of the muscle. (Reprinted from Loomis LK. Reduction and after-treatment of posterior dislocation of the elbow. *Am J Surg* 1944;63:56-60; with permission.)

Osborne and Cotterill (74) suggested that the best way to dislodge the coronoid process and radial head from the distal humerus is initially to hypersupinate the forearm and then to apply traction along the forearm with the elbow flexed. Others (7,8) have warned that with posterolateral dislocations, the lateral displacement of the proximal radius and ulna must first be corrected to prevent the median nerve from being entrapped or injured during reduction. Pronating the forearm during reduction also may be a factor in entrapping the median nerve.

Although numerous reduction techniques have been advocated, they all have the common goal of applying the two major traction forces along the axes of the humerus and forearm. Each of these forces is resisted by its respective counterforce. There appears to be two main groups in the method of applying force to counteract the muscles of the arm: the “pullers” (6,15,75) (Fig. 16-6) and the “pushers” (54,66,68) (Fig. 16-7). There also are combined unassisted pusher-puller techniques (30,53).

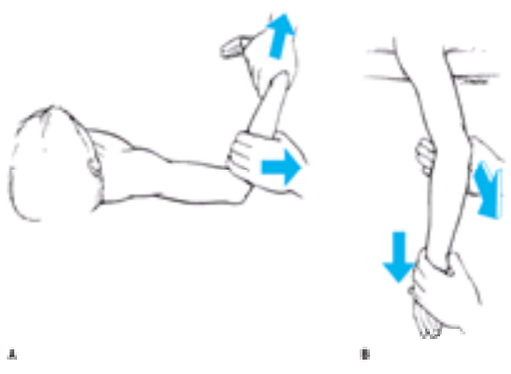

FIGURE 16-6. Reduction by “puller” techniques. **A:** Supine position. With the elbow flexed to almost 90 degrees, a force is applied to the anterior portion of the forearm with one hand while the other hand pulls distally along the forearm. Appropriate counterforces must be applied to counteract these manipulating forces. **B:** Prone position. The same forces are applied to the proximal portion of the anterior forearm and distal forearm. In the prone position the table provides a counterforce against the anterior portion of the distal humerus. (Redrawn from Parvin RW. Closed reduction of common shoulder and elbow dislocations without anesthesia. *Arch Surg* 1957;75:972-975; with permission. Copyright 1957, American Medical Association.)

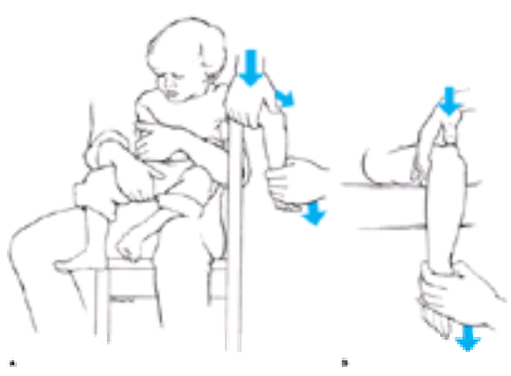

FIGURE 16-7. Reduction by “pusher” techniques. **A:** Lavine's method. The child is held by the parent while the elbow is draped over the edge of the chair. The olecranon is pushed distally past the humerus by the thumb of the physician while the other arm pulls distally along the axis of the forearm. **B:** Meyn's technique with patient lying prone on the table. (Reprinted from Meyn MA, Quigley TB. Reduction of posterior dislocation of the elbow by traction on the dangling arm. *Clin Orthop* 1974;103:106-107; with permission.)

Postreduction Care

Some type of immobilization, usually a posterior splint, is advocated by most investigators after successful closed reduction. The standard period of immobilization recommended is usually 3 weeks (55,56,75,88), although some have advocated early motion (84,85,108). Ninety degrees of elbow flexion appears to be the standard position of immobilization. O'Driscoll et al. (73) believed that if the elbow was stable to valgus stress with the forearm pronated that the anterior portion of the medial collateral ligament was intact and the patient could begin early motion.

Surgical Procedures

Open Reduction

Indications for primary open reduction are an inability to obtain a concentric closed reduction, an open dislocation, and a displaced osteochondral fracture.

Inadequate Closed Reduction. Carlioz and Abols (11) reported that 19 of 58 posterior dislocations required open reduction. In 13, the reduction was stable and the surgery was for the treatment of displaced fractures. In 6, open reduction of the joint was necessary: 2 each for an entrapped medial epicondyle, ulnar osteochondral fragment, and ligamentous fragment.

In adults with posterior elbow dislocations without concomitant fracture, those treated operatively for primary repair of ligaments had no better function or stability than those treated nonoperatively (47,48). The mean lack of elbow extension in both groups was 10 degrees. Similar results were reported by Josefsson et al. (45) in 28 children and adolescents with simple posterior dislocations treated nonoperatively. However, Durig et al. (18) recommended primary operative treatment of uncomplicated dislocations, because early surgery produced satisfactory functional results in all 10 of their patients. Cromak (14) reported full function in 14 children and adolescents treated by early operative repair.

Open Posterior Dislocations. Open dislocations usually have a high incidence of arterial injuries (34,50,55,57). For this reason, operative intervention usually is necessary for debridement and evaluation of the brachial artery.

Associated Fractures. The presence of a displaced fracture, such as the medial epicondyle, is a common indication for surgical intervention (11,23,102). Surgery for associated fractures produced slightly more excellent results than nonoperative treatment in the series of Carlioz and Abols (11). Similar results were reported by Wheeler and Linscheid (102). Fowles et al. (23), however, had poorer results in 9 children in whom the medial epicondyles were stabilized surgically. They recommended surgery only for children in whom the medial epicondyle is entrapped or significantly displaced after closed reduction. Repair of an associated medial epicondylar fracture also may improve elbow stability in athletes (87,108).

Postoperative Care

Immobilization after surgery depends on the procedure performed. After open reduction, management is similar to that after satisfactory closed reduction. The length of immobilization for fractures usually is 4 to 6 weeks.

AUTHOR'S PREFERRED METHOD OF TREATMENT

The “push-off” technique of reduction of an elbow dislocation is preferred in younger children, usually 9 years of age or less. In this age group, the child often can be seated comfortably in the parent's lap (Fig. 16-7). Hanging the arm over the back of the chair may provide some stabilization.

For the child 9 years of age or older and the young adolescent, the puller technique advocated by Parvin (75) is used (Fig. 16-6). The forearm must remain supinated during the process of reduction. Occasionally, it is necessary to hypersupinate the forearm to unlock the coronoid process and radial head before reduction. Closed reduction is done either with heavy sedation or general anesthesia. After reduction, radiographs are obtained to assess the adequacy of the reduction (Fig. 16-8). The elbow is immobilized in a posterior splint with the elbow flexed 90 degrees and the forearm in mid-pronation. This forearm position is chosen simply to allow the patient to be more functional in the splint.

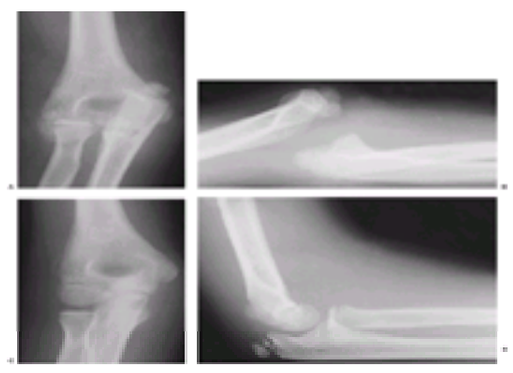

FIGURE 16-8. Closed reduction. **A:** Anteroposterior radiograph of a 9-year-old girl with a posterior dislocation of the right elbow. The proximal radius and ulna are superimposed on the distal humerus, and there is increased cubitus valgus. **B:** Lateral radiograph shows the proximal radius and ulna posterior to the distal humerus. **C:** Following closed reduction using a puller technique, there has been a concentric reduction. **D:** Lateral radiograph

Because the major complication of elbow dislocations is stiffness, the splint is removed in about 5 days and the patient begins active elbow motion. In 7 to 10 days, the patient can discard the splint and simply use a sling. The emphasis is on early active motion to prevent the stiffness that often occurs after this injury. Before reduction, it is important to emphasize to the parents that there may be some loss of motion, especially extension, regardless of the treatment. This is usually not of functional or cosmetic significance.

A careful neurologic examination must be done before and after the reduction with special attention to the median nerve. This same careful examination must be made at all follow-up evaluations.

Complications

Complications of posterior elbow dislocations can be divided into those occurring early and those occurring later. Early complications include neurologic and vascular injuries. Late complications include loss of motion, myositis ossificans, recurrent dislocations, radioulnar synostosis, and cubitus recurvatum. The special problems of chronic, unreduced dislocations are not considered complications of treatment.

Neurologic Injuries

In the combined series (55,71,83,85) of 317 patients, 32 patients (10%) had nerve symptoms after reduction. There was no breakdown as to the ages of the patients with the nerve injuries. Twenty-one injuries involved the ulnar nerve, seven the median nerve; in four patients, both the median and ulnar nerves were involved. Most were transient paresthesias with rapid recovery. Only one patient failed to recover fully (55). Carlioz and Abols (11) reported no neurologic injuries with 58 dislocations in children and adolescents, although two children had transient ulnar nerve symptoms.

Ulnar Nerve Lesions

There is an increased incidence of ulnar nerve injuries associated with elbow dislocations (11,13,24,55,101). There were 21 ulnar nerve injuries plus 4 combined ulnar and median nerve injuries in the combined series (55,71,83,85). Watson-Jones (101) described 16 nerve lesions in 97 elbow dislocations, 12 of which involved the ulnar nerve; 9 of these there were associated with medial epicondylar fracture. Galbraith and McCullough (24) found 6 ulnar nerve injuries in 187 elbow dislocations, with or without fractures, in their study of acute nerve injuries in closed elbow injuries. Four of these patients had medial epicondyle fractures and two had radial head fractures; all had posterior elbow dislocations. Linscheid and Wheeler (55) reported neurologic complications in 24 of 110 elbow disclocations, including 16 ulnar nerve injuries alone and 4 injuries to both the ulnar and medial nerves. They recommended ulnar nerve transposition if ulnar nerve symptoms were present in a patient undergoing open reduction and internal fixation of a displaced medial epicondylar fracture. Cotton (13) reported 10 children with posterior dislocations associated with medial epicondylar fractures and ulnar nerve neuropathy. Except for the one patient described by Linscheid and Wheeler (55), these reported ulnar nerve injuries were transient and resolved completely.

Radial Nerve Lesions

Watson-Jones (101) is the only investigator to report a radial nerve injury associated with an elbow dislocation. He described two patients in whom the symptoms rapidly resolved after reduction.

Median Nerve Lesions

The most serious neurologic injury involves the median nerve, which can be damaged directly by the dislocation or can be entrapped within the joint. Median nerve injuries occur most commonly in children 5 to 12 years of age. There were seven median and four median-ulnar nerve injuries (3%) in the combined series (55,71,83,85).

Types of Median Nerve Entrapment. Fourrier et al. (21) in 1977 delineated three types of medial nerve entrapment (Fig. 16-9):

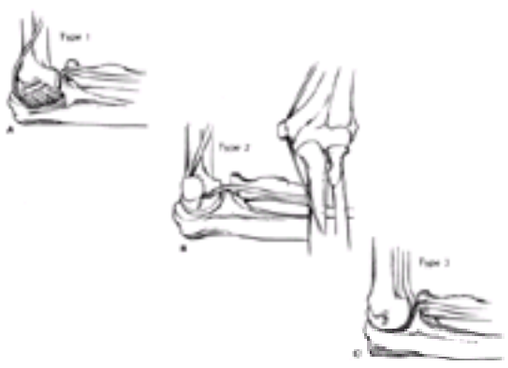

FIGURE 16-9. Median nerve entrapment. **A:** Type 1. Entrapment within the elbow joint with the median nerve coursing posterior to the distal humerus. **B:** Type 2. Entrapment of the nerve between the fracture surfaces of the medial epicondyle and the medial condyle. **C:** Type 3. Simple kinking of the nerve into the anterior portion of the elbow joint. (Redrawn from Hallett J. Entrapment of the median nerve after dislocation of the elbow. *J Bone Joint Surg* [Br] 1981;63:408-412; with permission.)

Type 1. Either avulsion of the medial epicondyle along with the superficial head of the pronator teres muscle or simple rupture of the muscle origins and ulnar collateral ligaments (Fig. 16-9A) allows the median nerve, with or without the brachial artery, to become posteriorly displaced. If the lateral displacement of the proximal radius and ulna is not corrected before reduction, the nerve is especially prone to being entrapped between the trochlea and the olecranon during the process of reduction. Hallett (29) demonstrated in cadavers that pronation of the forearm while the elbow is hyperextended, forces the median nerve posteriorly during the process of reduction, making it also vulnerable to entrapment. This type of entrapment has been reported frequently (4,7,8,16,21,27,63,78,80,94). Delay in diagnosis is common. The medial epicondyle is commonly fractured. In a few patients, the nerve was so severely damaged after being entrapped that resection of the injured portion with reanastomosis was necessary (7,27,63). Good recovery of function was reported.

If the nerve has been entrapped for a considerable period, the Matev sign may be present on the radiographs (63). This represents a depression on the posterior surface of the medial epicondylar ridge where the nerve has been pressed against the bone (Fig. 16-10) (4,16,27,29,78,80,94). This groove is represented radiographically by two sclerotic lines parallel to the nerve. This sign disappears when the pressure from the nerve has been released.

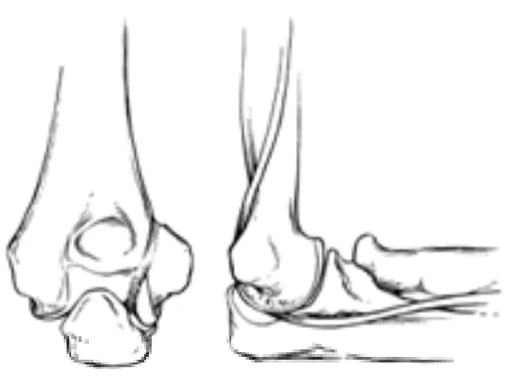

FIGURE 16-10. The Matev sign impingement of the median nerve against the posterior surface of the medial condyle produces a depression with sclerotic margins. (Redrawn from Matev I. A radiographic sign of entrapment of the median nerve in the elbow joint after posterior dislocation. *J Bone Joint Surg* [Br] 1976;58:353-355; with permission.)

Type 2. The nerve is entrapped between the fracture surfaces of the medial epicondyle and the distal humerus (Fig. 16-9B). The fracture heals and the nerve is surrounded by bone, forming a neoforamen (78,82,94). This may or may not be visible radiographically. The medial epicondyle is osteomized to free the nerve.

Type 3. The nerve is kinked and entrapped between the distal humerus and the olecranon (Fig. 16-9C). Only three injuries of this type have been reported (4,77,79). Resection and reanastomosis resulted in return of good function over 6 to 24 months.

Al Qattan et al. (2) described a fourth type of median nerve entrapment. In a 14-year-old boy the median nerve was trapped in a healed medial epicondylar fracture (type 2) in an anterior to posterior direction and then passed through the elbow in a posterior to anterior direction (type 1) 18 months after a posterior dislocation with a medial epicondylar fracture. The nerve was so severely damaged that it was resected and repaired with sural nerve grafts.

The combination of an associated fracture of the medial epicondyle and significant median nerve dysfunction was cited by Rao and Crawford (80) as an absolute indication for surgical exploration of the nerve because of the frequency of median nerve entrapment with fractures of the medial epicondyle (types 1 and 2). Magnetic resonance imaging may be helpful in defining the course of the median nerve if entrapment is suspected. Once the entrapped nerve is removed from the joint, neurologic function typically improves even if the nerve appears seriously damaged. Resection and reanastomosis rarely are necessary.

Arterial Injuries

Arterial injuries are common with posterior elbow dislocations in children and adolescents (28,34,35,38,50,57,61,76,86,105). Only eight vascular injuries (3%) were reported in the combined series (55,71,83,85). However, Carlioz and Abols (11) reported four patients with diminished radial pulses that resolved after reduction. Arterial injuries frequently are associated with open dislocations in which collateral circulation is disrupted (34,50,57,86), and they also have been reported in association with closed dislocations (28,35,38,105). Usually the brachial artery is ruptured (28,34,38,50,57,61), but it also can be thrombosed (105) as well as entrapped in the elbow joint (35,76,105). Pearce (76) reported an entrapped radial artery in which there was a high bifurcation of the brachial artery.

When there is a complete rupture, there usually is evidence of severe ischemia distally. Unfortunately, the presence of good capillary circulation to the hand or a Doppler pulse at the wrist does not always mean the artery is intact (28,38). Arteriograms usually are not necessary because the arterial injury is at the site of the dislocation. A new technique using intravenous digital angiography has been used to confirm complete obstruction of the brachial artery if there is clinical evidence of distal ischemia (38).

Treatment usually consists of relocation of displaced brachial arteries (35,105) and operative repair of those that are ruptured or severely damaged. Ligation of the ends has been done, especially if there was good capillary circulation distally (34,50), but this may predispose to late ischemic changes such as claudication and cold sensitivity. Most investigators recommend direct arterial repair or a vein graft (28,38,57,61,86). Louis et al. (57) recommended arterial repair because their cadaver studies demonstrated that a posterior elbow dislocation usually disrupted the collateral circulation necessary to maintain distal blood flow.

Loss of Motion

Almost all patients with elbow dislocations lose some range of elbow motion (11,23,45,47,48). This loss is less in children than in adults (45) usually only 5 to 10 degrees of extension, and rarely is of functional or cosmetic significance. However, this potential for loss of motion must be explained to the parents before reduction

and may be an indication for a supervised rehabilitation program.

Myositis Ossificans versus Heterotopic Calcification

True myositis ossificans should be differentiated from heterotopic calcification, which is a dystrophic process. Myositis ossificans involves ossification within the muscle sheath that can lead to a significant loss of range of motion of the elbow. Disruption of the brachialis muscle is believed to be a contributory factor (56). Fortunately, myositis ossificans is rare in children (45,97). Although heterotopic calcification in the ligaments and capsule of the elbow is common (45,83) it rarely results in loss of elbow function (Fig. 16-11).

FIGURE 16-11. Heterotopic calcification. **A:** An elbow that had been dislocated 2 months previously. There is heterotopic calcification in the ulnar collateral ligaments (*arrow*). **B:** Lateral view of the same elbow. Some true ossification has occurred where the brachialis inserts into the coronoid process (*arrow*)

Thompson and Garcia (97) found no myositis ossificans in 8 of 10 children 0 to 15 years of age with elbow injuries. The two children with myositis ossificans had supracondylar fractures. In Neviaser and Wickstrom's (71) eries of 115 patients, 10 had radiographic evidence of myositis ossificans; all, however, were asymptomatic. Only Roberts (83) differentiated true myositis ossificans from heterotopic calcification. In his series of 60 elbow dislocations, only 3 patients had true myositis ossificans. Linscheid and Wheeler (55) noted that the incidence of some type of heterotopic calcification was 28%, which was most common around the condyles. Only in 5 patients was it anterior to the capsule (which probably represented true myositis ossificans in the brachialis muscle). Four of these patients had some decrease in elbow function. Josefsson et al. (45) reported that 61% of 28 children with posterior dislocations had periarticular calcification, but this did not appear to be functionally significant.

Recurrent Posterior Dislocations

Recurrent posterior elbow dislocation is rare. It is discussed in detail in the next section. In the combined series of dislocations, only two (0.1%) recurrent dislocations were reported (55,71,83,85).

Radioulnar Synostosis

In dislocations with an associated fractures of the radial neck, the incidence of a secondary proximal radioulnar synostosis is increased (Fig. 16-12). This can occur regardless of whether the radial neck fracture is treated operatively or nonoperatively (8,11,73). Carlioz and Abols (11) reported a synostosis in one of three patients with a posterior elbow dislocation associated with radial neck fractures.

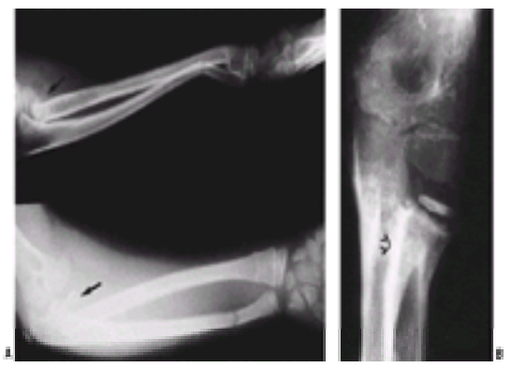

FIGURE 16-12. Radioulnar synostosis. **A:** Injury radiographs demonstrating a posterolateral dislocation associated with a type II proximal radius epiphyseal fracture (*arrow*). Open reduction of the proximal radial fracture was performed. **B:** Six months later, the patient developed a proximal radioulnar synostosis (*arrow*). (Courtesy of Ruben Pachero, M.D.)

Cubitus Recurvatum

Occasionally, a severe elbow dislocation results in significant tearing of the anterior capsule. As a result, after reduction, when all the stiffness created by the dislocation has subsided, the patient may have some hyperextension (cubitus recurvatum) of the elbow. This usually is minimally symptomatic.

Recurrent Posterior Elbow Dislocations

Although recurrent posterior elbow dislocations almost always involve adult patients (18,26,32,37,43,49,51,60,62,65,67,72,74,95,98,100,107,109) the initial dislocation has occurred before skeletal maturity. Approximately 80% of recurrent dislocations are in males. Three investigators have reported bilateral cases (49,67,81).

Diagnosis

Mechanism of Injury

The pathology of recurrent dislocation involves the collateral ligaments, capsular laxity, and bone defects.

Ligamentous and Capsular Laxity. Osborne and Cotterill (74) suggested that articular changes are secondary and that the primary defect is a failure of the posterolateral ligamentous and capsular structures to become reattached after reduction (Fig. 16-13). Posterior dislocations usually cause attenuation of the ulnar collateral ligaments, and this further contributes to the instability. With recurrent dislocations, the radial head impinges against the posterolateral margin of the capitellum, creating an osteochondral defect (Fig. 16-14).

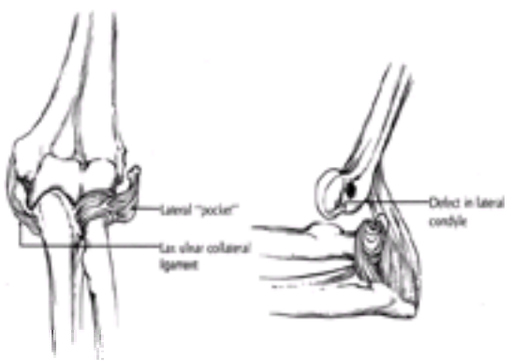

FIGURE 16-13. Pathology of recurrent dislocation. The three components that allow the elbow to dislocate: a lax ulnar collateral ligament, a pocket in the radial collateral ligament, and a defect in the lateral condyle. (Reprinted from Osborne G, Cotterill P. Recurrent dislocation of the elbow. *J Bone Joint Surg* [Br] 1966;48:340-346; with permission.)

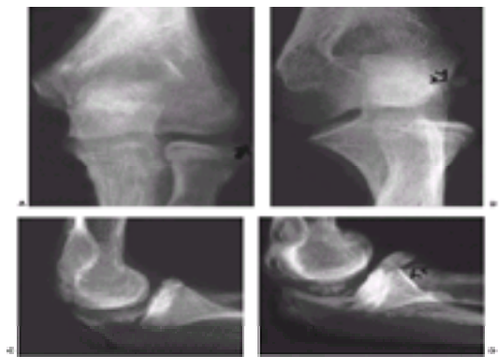

FIGURE 16-14. Pathologic changes of recurrent dislocation. **A:** Anteroposterior radiograph of a 13-year-old who had recurrent dislocations. An osteochondral fragment (*arrow*) is attached to the lateral ligament. **B:** An oblique radiograph shows the defect (*arrow*) in the posterolateral condylar surface. **C:** Radiographs of an 11-year-old after his first dislocation. **D:** One year later, after recurrent dislocation and subluxations, blunting of the radial head has developed (*arrow*). (Courtesy of Marvin E. Mumme, M.D.)

Osborne and Cotterill (74) attributed the failure of the capsule to reattach to the presence of a considerable amount of articular cartilage, which provides a poor surface for reattachment, and synovial fluid, which further inhibits healing. With recurrent dislocations, secondary changes tend to develop (Fig. 16-14). In addition to the defect in the capitellar articular surface, a similar defect develops in the anterior articular margin of the radial head. When these two defects appose each other, recurrence of the dislocation is more likely. Subsequent studies have confirmed these findings in almost all recurrent dislocations, especially in children (18,32,72,95,98,107).

O'Driscoll et al. (88) described posterolateral instability in five patients, including two children, in whom laxity of the ulnar part of the radial collateral ligament allowed a transitory rotary subluxation of the ulnohumeral joint and a secondary dislocation of the radiohumeral joint. Patients with posterolateral instability often describe a history of recurrent temporary dislocation of the elbow, but when examined exhibit no unusual clinical findings.

The instability is diagnosed with a posterolateral rotary instability test. In some patients posterolateral rotary instability can be detected only with the patient completely relaxed under general anesthesia. This test is performed by holding the arm over the head while applying proximal axial compression plus a valgus and supination force to the forearm with the elbow flexed to only 20 to 30 degrees (Fig. 16-15). O'Driscoll et al. reported that surgical repair of the lax ulnar portion of the radial collateral ligament eliminated the posterolateral rotary instability (72).

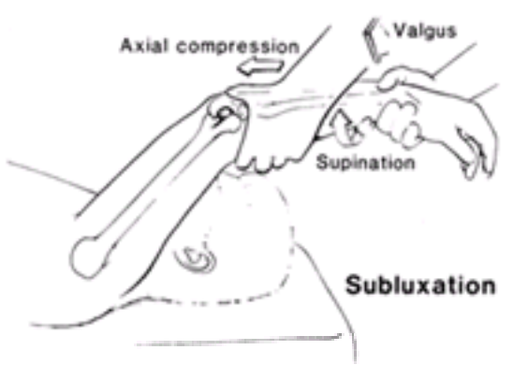

FIGURE 16-15. Posterolateral rotary instability. Posterolateral rotational instability is best demonstrated with the upper extremity over the radial head. The radial head can be subluxed or dislocated by applying a valgus and supination force to the forearm at the same time proximal axial compression is applied along the forearm. (Reprinted from O'Driscoll SW, Bell DF, Morrey BF. Posterolateral rotary instability of the elbow. *J Bone Joint Surg [Am]* 1991;73:441; with permission.)

Schwab et al. (87) described treatment of the laxity of the medial collateral ligament with advancement of the medial epicondyle proximally to tighten the medial collateral ligament.

Bone Defects. In addition to the previously described osteochondral defects in the capitellum and radial head, bone defects include a shallow semilunar notch resulting from a coronoid fossa process fracture or multiple recurrent dislocations. Osteochondral fragments in the elbow joint also can contribute to instability.

Treatment Options

Nonoperative

There appears to be only one report of successful nonsurgical management of recurrent elbow dislocations. Herring (37) used an orthosis that blocked the last 15 degrees of extension. After his patient wore this orthosis constantly for 2 years and with vigorous activities for another 6 months, there were no further dislocations, but the follow-up period was only 1 year. Beaty and Donati (5) emphasized that physical therapy and the use of an orthosis should be tried before surgery is considered.

Surgical Procedures

The treatment of recurrent posterior elbow dislocations is predominately surgical. Various surgical procedures have been described to correct bone and soft tissue abnormalities (Fig. 16-16).

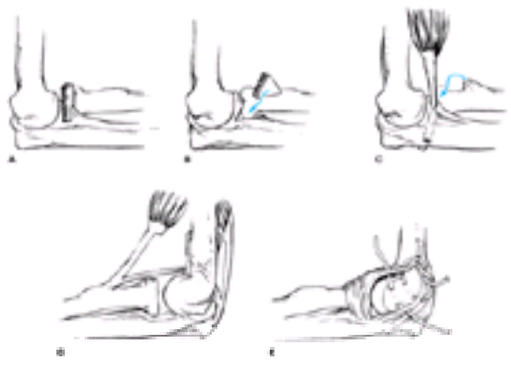

FIGURE 16-16. Surgical procedures for recurrent dislocation. **A:** Bone block. **B:** Coronoid osteotomy. **C:** Biceps tendon transfer. **D:** Cruciate ligament reconstruction. **E:** Lateral capsular reattachment of Osborne and Cotterill

Bone Procedures. These are directed more toward correcting dysplasia of the semilunar notch of the olecranon. Milch (67) inserted a boomerang-shaped bone block. Others (26,65,100) found that a simple bone block was all that was necessary (Fig. 16-16A). Mantle (62) increased the slope of the semilunar notch in two patients with an opening wedge osteotomy of the coronoid process (Fig. 16-16B).

Schwab et al. (87), believing the ulnar collateral ligament to be the mainstay of elbow stability, advocated tightening the medial side by osteotomizing the medial epicondyle and reattaching it proximally, but reported no results.

Soft Tissue Procedures. Reichenheim (81) and King (51) transferred the biceps tendon just distal to the coronoid process to reinforce it (Fig. 16-16C). Kapel (49) developed a cruciate ligament reconstruction in which distally based strips of the biceps and triceps tendon were passed through the distal humerus and sutured to the olecranon and coronoid process respectively (Fig. 16-16D). Beaty and Donati (5) modified this technique by transferring a central slip of the triceps through the humerus posterior to anterior and attaching it to the proximal ulna.

The most widely accepted technique is that described by Osborne and Cotterill (74), in which the lateral capsule is reattached to the posterolateral aspect of the capitellum with sutures passing through holes drilled in the bone (Fig. 16-16E). The joint should be inspected at surgery because osteocartilagenous loose bodies may be present (32,60,95). Since Osborne and Cotterill's (74) initial report of eight patients, successful use of this technique has been reported in numerous others (18,32,60,72,95,98,107). Zeier (109) and O'Driscoll et al. (72) reinforced the lateral repair with strips of fascia lata, triceps fascia, or palmaris longus tendon. Malkawi (60) transferred the ulnar nerve and reinforced the medial repair in a patient with ulnar neuropathy.

Posttreatment Care

Postoperatively, especially after the repair described by Osborne and Cotterill (74), the arm is immobilized in a long arm cast with the elbow flexed 90 degrees for approximately 4 weeks. Active range of motion exercises are then begun.

Complications

The major complication after correction of recurrent dislocations is loose osteocartilagenous fragments and destruction of the articular surface of the joint (Fig. 16-17). Loose fragments must be removed at initial surgery and later should they occur.

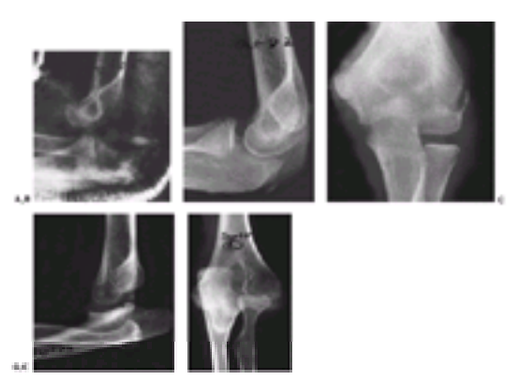

FIGURE 16-17. Effects of recurrent dislocation. This girl began to have recurrent dislocations of her elbow at age 9. **A:** The ease at which the elbow redislocates is shown in this radiograph. **B and C:** Radiographs taken at the beginning of episodes of dislocation. Her dislocation continued. **D and E:** Four years later the elbow demonstrated marked changes in its architecture. (Courtesy of David J. Mallams, M.D.)

Unreduced Posterior Elbow Dislocations

Untreated or neglected posterior dislocations of the elbow in children are extremely rare in North America. Most reported series are from other countries (1,22,52,59,69,89). In 1925, Speed (93) from the United States reported six, including four in children.

Diagnosis

Children with untreated dislocations typically have pain and limited mid-range of motion. Pathologically, there is subperiosteal new bone formation that produces a radiohumeral horn, myositis ossificans of the brachialis muscle, capsular contractures, shortening of the triceps muscle, contractures of the medial and lateral collateral ligaments, and tightening of the ulnar nerve (21,22,89). These factors have to be considered when planning treatment.

Treatment Options

Nonoperative

Closed reduction of dislocations recognized within 3 weeks of injury may be possible (1,22). If this fails or if the dislocation is of longer duration, open reduction is necessary.

Surgical Procedures

Open reduction through a posterior approach, as described by Speed (93), involves lengthening of the triceps muscle and release or transposition of the ulnar nerve (22,69,89). Others have advocated a posterolateral or medial and lateral incisions for better exposure (1,52). Satisfactory results usually cam be obtained if a stable concentric reduction is achieved within 3 months of the initial dislocation (1,52). Results decline thereafter but still may produce some improvement in function (22,69) (Fig. 16-18). Internal fixation of the elbow to maintain reduction is used for 2 to 4 weeks, followed by vigorous physical therapy (22,69). Two large Kirschner wires or

Steinmann pins may be used to stabilize the elbow and minimize the risk of intraarticular breakage.

FIGURE 16-18. Unreduced dislocation. **A:** Preoperative anteroposterior radiograph. The elbow sustained an injury 3 years before surgery. Elbow motion was extremely limited and painful. The lateral supracondylar ridge had been eroded by the radial head (*arrow*). **B:** Lateral radiograph. The posterior position of the olecranon is apparent. **C:** Anteroposterior radiograph 3 months postoperatively. Total elbow motion was 30 degrees, but there was less pain and more stability

Mahaisavariya et al. (59) reported decreased flexion contracture and better functional results in 34 patients with unreduced elbow dislocations 1 to 3 months after injury in whom the triceps tendon was not lengthened compared with 38 patients who had the triceps lengthened at surgery.

Congenital Elbow Dislocations

It must be remembered that a chronic elbow dislocation may be congenital. Because of the abnormal nature of these elbows, they are prone to injury. In addition, because of the relatively free range of motion of the elbow before injury, the child or parents may not have recognized that the elbow has been dislocated since birth.

The key to differentiating a congenital from an acute traumatic elbow dislocation is examination of the radiographic architecture of the articulating surfaces. In a congenitally dislocated elbow, there is marked atrophy of the humeral condyles and the semilunar notch of the olecranon (Fig. 16-19). However, these same changes can result from chronic recurrent dislocation after trauma, making the differentiation between congenital and traumatic difficult. Certainly, if other congenital anomalies are present or the child has an underlying syndrome, such as Ehlers-Danlos or Larsen's syndrome, the dislocation is likely to be congenital.

FIGURE 16-19. Congenital elbow dislocation. Lateral **(A)** and anteroposterior **(B)** radiographs of an elbow with congenital dislocation. The patient had sustained a minor injury. The fact that similar findings were seen in the opposite uninjured elbow confirms the congenital origin. (Courtesy of Earl A. Staple, M.D.)

Posteromedial Dislocation

Posteromedial elbow dislocations are rare. One patient described by Wilkins et al. (103) developed a recurrent dislocation. This 12-year-old boy had trochlear hypoplasia secondary to a very distal supracondylar fracture (Fig. 16-20). It was believed that hypoplasia of the trochlea contributed to the instability of the medial aspect of his elbow joint, predisposing him to recurrent dislocations. As he grew, his medial ligaments tightened, and subsequently he became asymptomatic.

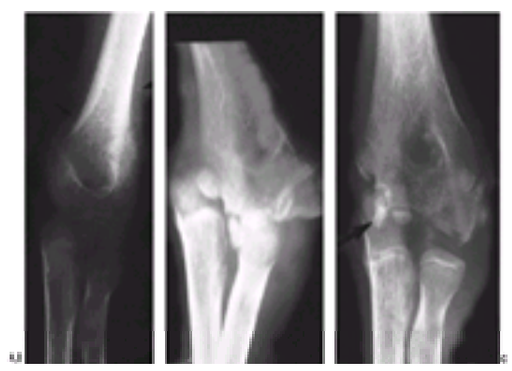

FIGURE 16-20. Posteromedial dislocation. **A:** At 6 years of age, this boy sustained what was thought to be a simple undisplaced but very distal supracondylar fracture. This radiograph taken 4 weeks after injury shows periosteal new bone formation along both supracondylar columns (*arrow*). **B:** Four years later, he began sustaining recurrent posteromedial dislocations. **C:** Radiograph after reduction, at that time, shows delayed development of the medial ossification center of the crista (*arrow*). It was thought that this hypoplastic trochlea contributed to his elbow instability. (Courtesy of Stephen A. Cord, M.D.)

ANTERIOR ELBOW DISLOCATIONS

Anterior elbow dislocations are also rare. Of the 317 elbows in the combined series (55,71,83,85), only five were anterior, for an incidence of slightly over 1%. They are associated with an increased incidence of complications, such as brachial artery disruption and associated fractures, compared with posterior dislocations (12,40,42,92,104,106).

Diagnosis

Mechanism of Injury

Anterior elbow dislocations usually are caused by a direct blow to the posterior aspect of the flexed elbow (40,106). However, hyperextension of the elbow also has

been implicated (104). Twisting of the forearm on the elbow commonly occurs.

Signs and Symptoms

The elbow is in extension with fullness in the antecubital fossa. Swelling usually is marked because of the soft-tissue disruption associated with this type of dislocation. There is severe pain with attempted motion. A careful neurovascular examination is mandatory.

Radiographic and Other Imaging Studies

Routine anteroposterior and lateral radiographs are diagnostic. In most cases, the proximal radius and ulna dislocate anteromedially rather than purely anteriorly (Fig. 16-21). Associated fractures are common. In children, the triceps insertion may be avulsed from the olecranon with a small piece of cortical bone (106). This fracture usually reattaches to the olecranon after reduction. Wilkerson (104) reported an anterior dislocation associated with a displaced olecranon fracture in a 7-year-old boy. Inoue and Horii (40) reported an 11-year-old girl with an anterior elbow dislocation with displaced fractures of the trochlea, capitellum, and lateral epicondyle. These were repaired with open reduction and internal fixation using Herbert bone screws.

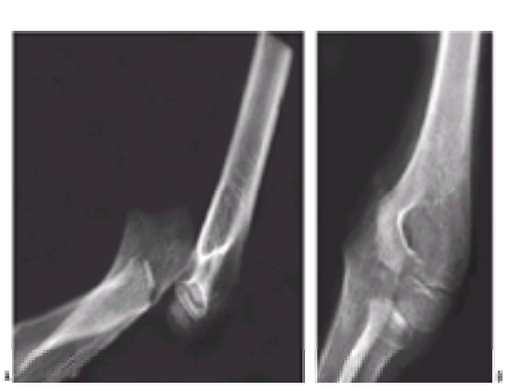

FIGURE 16-21. Anterior dislocation of the elbow. **A:** Initial lateral radiograph. The olecranon lies anterior to the distal humerus. **B:** Initial anteroposterior radiograph. The proximal ulna and radial head lie anteromedial, and the elbow carrying angle has drifted into varus. (Courtesy of Hilario Trevino, M.D.)

Treatment Options

Nonoperative: Closed Reduction

Reduction usually is accomplished by flexing the elbow and pushing the forearm proximally and downward at the same time (106). As for the posterior dislocations, a force must first be applied longitudinally along the axis of the humerus with the elbow semiflexed to overcome the forces of the biceps and triceps. The longitudinal force along the axis of the forearm is directed toward the elbow (Fig. 16-22). To make reduction easier, the distal humerus can be forced in an anterior direction by pushing on the posterior aspect of the distal arm.

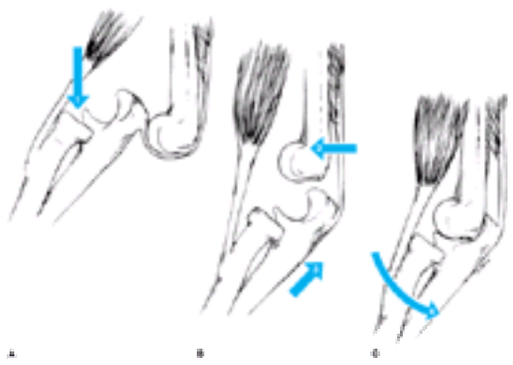

FIGURE 16-22. Reduction of anterior dislocation. **A:** With the elbow semiflexed, a longitudinal force is applied along the long axis of the humerus (*arrow 1*). Pulling distally on the forearm may be necessary to initially dislodge the olecranon. **B:** Once the olecranon is distal to the humerus, the distal humerus is pushed anteriorly (*arrow 2*) while a proximally directed force is applied along the long axis of the forearm (*arrow 3*). **C:** Finally, the elbow is immobilized in some extension (*arrow 4*).

Surgical Procedures

Surgery usually is not required unless the dislocation is open, the brachial artery injury is present, or there is an associated fracture that does not realign satisfactorily after closed reduction. Open reduction and internal fixation of the fracture may then be necessary (40,104).

Postreduction Care

Because most anterior dislocations occur in flexion, the elbow should be immobilized in some extension for 2 to 3 weeks, followed by active range of motion exercises. Early motion after open reduction and internal fixation of an associated olecranon fracture usually can be allowed (40,104).

AUTHOR'S PREFERRED METHOD OF TREATMENT

Closed reduction (Fig. 16-22) is the initial procedure of choice. A distal force must be applied in line with and parallel to the long axis of the humerus first. Once the length has been reestablished, a posteriorly directed force along the axis of the forearm is applied until the elbow is reduced.

Complications

There appears to be an increased incidence of brachial artery rupture or thrombosis associated with anterior elbow dislocations (42,92). When present, prompt arterial repair is necessary.

MEDIAL AND LATERAL ELBOW DISLOCATIONS

These are rare dislocations. Lateral dislocations, either incomplete or complete, are more common than medial dislocations. There are no recent reports of medial dislocations in children.

Diagnosis

Signs and Symptoms

In an incomplete lateral dislocation, the semilunar notch articulates with the captilulotrochlear groove and the radial head appears more prominent laterally. There may be reasonably free extension and flexion, so lateral dislocation may be overlooked. In a complete lateral dislocation, the olecranon is totally lateral to the capitellum. This gives the elbow a markedly widened appearance.

Radiographic and Other Imaging Studies

Anteroposterior and lateral radiographs of the elbow usually are diagnostic. On the lateral view the elbow may appear reduced.

Treatment Options

These rare dislocations are treated by closed reduction. A longitudinal force is applied along the axis of the humerus to distract the elbow, and then direct medial or lateral pressure (opposite the direction of the dislocation) is applied over the proximal forearm (Fig. 16-23).

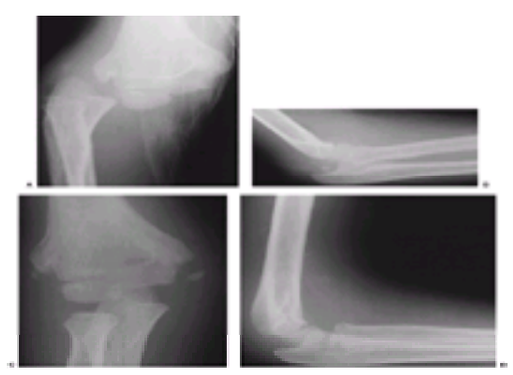

FIGURE 16-23. Lateral elbow dislocation. **A:** Initial anteroposterior radiograph in this 6-year-old with a lateral dislocation and displaced medial epicondyle fracture. **B:** Lateral radiograph shows slight posterior dislocation. **C and D:** Postreduction radiographs demonstrate anatomic reduction of the dislocation. The medial epicondyle is satisfactorily aligned.

DIVERGENT ELBOW DISLOCATION

Divergent dislocation represents a posterior elbow dislocation with disruption of the interosseous membrane between the proximal radius and ulna with the radial head displaced laterally and the proximal ulna medially (Fig. 16-24). These dislocations are extremely rare (3,9,17,20,33,39,64,70,88,91,99).

FIGURE 16-24. Medial-lateral divergent dislocation. **A:** Anteroposterior view demonstrating disruption of the proximal radioulnar joint with the radius lateral and the ulna medial. **B:** Lateral radiograph confirms that the radius and ulna are both posterior to the distal humerus. **C:** A radiograph taken 4 weeks after injury shows periosteal new bone formation (*arrows*), indicating where the soft tissues were extensively torn away from the proximal ulna.

Divergent dislocations usually are caused by high-energy trauma. Associated fractures of the radial neck, proximal ulna, and coronoid process are common (9,20,99). It has been speculated that, in addition to the hyperextension of the elbow that produces the dislocation, a strong proximally directed force is applied parallel to the long axis of the forearm, disrupting the annular ligament and interosseous membrane and allowing the divergence of the proximal radius and ulna.

Treatment Options

Nonoperative: Closed Reduction

Divergent dislocations are typically easily reduced via the closed method with general anesthesia (Fig. 16-24A). Reduction is achieved by applying longitudinal traction with the elbow semiextended and at the same time compressing the proximal radius and ulna together.

Surgical Procedures: Open Reduction

This is rarely indicated. There have been only two divergent dislocations reported that required open reduction (20,64). Closed reduction failed in one child (64), and the other had a displaced fracture of the proximal ulna (20).

Postreduction Care

After successful closed reduction, the elbow is immobilized in 90 degrees of flexion and the forearm in neutral for approximately 2 to 3 weeks. Active range of motion exercises are then begun. Most patients typically regain full elbow motion, including forearm pronation and supination.

PROXIMAL RADIOULNAR TRANSLOCATION

Translocation of the proximal radius and ulna is another extremely rare injury (9,10,19,25,31,41,58). It is commonly missed on the anteroposterior radiograph unless the proximal radius and ulna are noted to be completely reversed in relation to the distal humerus.

Translocations are believed to be caused by a fall onto the pronated hand with the elbow in full or nearly full extension, producing an axial force on the proximal radius. The anterior radial head dislocation occurs first, followed by the posterior dislocation. The radial head, depending on the degree of pronation, can be lodged in the coronoid fossa or dislocated posteriorly. More pronation allows the radial head to dislocate posteriorly beneath the trochlea. As a consequence, fractures of the radial head, radial neck, or coronoid process may occur (9,10,19,58). Isbister (41), however, believed the etiology may be iatrogenic: an inappropriate reduction

technique of the posterior dislocation.

Treatment Options

Nonoperative: Closed Reduction

Closed reduction with general anesthesia can be attempted but is usually unsuccessful (Fig. 16-25). MacSween (58) reported a successful closed reduction with the elbow flexed 100 degrees and the forearm fully supinated.

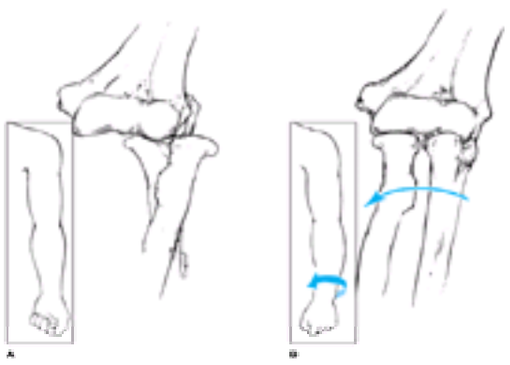

FIGURE 16-25. Proximal radioulnar translocation. **A:** Position of the proximal radius and ulna with a proximal radioulnar translocation. **B:** If the forearm is forced into pronation during reduction, the ulna may become lodged in the capitulotrochlear groove and the radius forced anterior to the trochlea. (Redrawn from Harvey S, Tchelebi H. Proximal radio-ulnar translocation. *J Bone Joint Surg* 1979;61:447-449; with permission.)

Surgical Procedures: Open Reduction

Most reported radioulnar translocations have required open reduction (9,10,19,25,31,41). Internal fixation also may be necessary for an associated displaced fracture. Harvey and Tchelebi (31) used an osteotomy of the proximal ulna to expose and reduce the radius. This was complicated by a postoperative ulnar nerve paralysis that recovered completely over 2 months.

Postreduction Care

After successful closed or open reduction, a long arm cast with the forearm in neutral position is worn approximately 4 weeks, followed by an active range of motion exercises. The presence of a fracture may prolong the immobilization. Mild residual loss of motion is a common sequela of proximal radioulnar translocation.

RADIAL HEAD DISLOCATION

Isolated traumatic dislocation of the radial head is an uncommon injury. Most reports have single case reports (113,121,124,136,140,143,145), but some small series have been reported (117,118,126,127,129,130,135,137,141,144,145 and 146,148,149). The diagnosis usually is missed initially.

In reports in which ages were given, the mean was 7 years. Vesely (146) combined the experience of the members of the Association of Bone and Joint Surgeons to accumulate 17 dislocations; 13 were anterior, 3 were lateral, and 1 was posterior. Two recurred.

Unusual Dislocation Patterns

Isolated radial head dislocations are variants of Monteggia lesions (118,123,126,127,129,133). Often, if the patient and the radiographs are carefully examined, an occult fracture of the olecranon or proximal ulna is discovered (127). The fracture may not be apparent until bowing of the proximal ulna or olecranon develops during the healing phase (118).

Lincoln and Mubarak (129) reviewed isolated anterior radial head dislocations in which there was no overt evidence of a fracture of the ulna. In each, there was subtle anterior bowing of the shaft of the ulna. They described this as the ulnar bow sign. Normally the dorsal margin of the ulna is a straight line (Fig. 16-26). Based on their findings, they suggested that the term *isolated radial head dislocation* was a misnomer and that these were actually variants of type I Monteggia injuries. Others have reported radial head dislocation in association with nondisplaced (greenstick or plastic deformation) fracture of the olecranon (122,127,130).

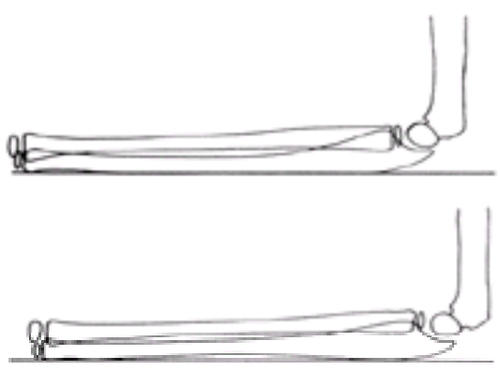

FIGURE 16-26. Ulnar bow sign. **A:** The normal posterior border of the ulna is represented by a straight line. **B:** In minimal type I Monteggia lesions, there is loss of this ulnar straight line with anterior bowing of the posterior border of the ulna and complete dislocation or partial subluxation of the radial head anteriorly. (Reprinted from Lincoln TL, Mubarak SH. “Isolated” traumatic radial-head dislocation. *J Pediatr Orthop* 1944;14:455; with permission.)

Because most of these injuries are occult Monteggia lesions, there is often subtle bowing of the ulna. In type I Monteggia lesions, the ulna demonstrates the typical ulnar bow sign in which the shaft of the ulna is bowed anteriorly and the radial head is dislocated anteriorly (Fig. 16-26). In type III Monteggia lesions, the proximal ulnar metaphysis or olecranon is bowed radially (laterally) and the radial head is dislocated anterolaterally. Late repair produces better results in anterior dislocations than in anterolateral dislocations (137).

Rare Causes

Cubitus Varus Deformity

Cubitus varus after a supracondylar fracture of the distal humerus has been shown by Abe et al. (110) to predispose to radial head dislocation. They described four dislocations that were chronic, recurrent, and precipitated by further injury. The radial head dislocated when the forearm was supinated and reduced when it was pronated. In addition to ligamentous repair, a supracondylar osteotomy was performed to correct the distal humerus deformity.

Osteochondritis Dissecans

Klekamp et al. (128) reported seven older children and adolescents with osteochondritis dissecans of the capitellum who developed instability of the radial head: five subluxations and two posterolateral dislocations. Treatment was based on the presence of loose bodies and the characteristics of the osteochondral defect.

Birth Trauma

This is an extremely rare mechanism of injury. Danielsson and Theander (121) reported an anterior dislocation, Schubert (140) an isolated anterolateral radial head dislocation, and Bayne and Rang (113) an anteromedial dislocation. Interestingly, all three infants were breech deliveries.

Diagnosis

Mechanism of Injury

The mechanism creating an isolated dislocation of the radial head appears to be the same as in Monteggia lesions (123,126,127,129,137). The only difference is that the olecranon and proximal ulna are not visibly fractured. The mechanism of injury of the various Monteggia lesions are discussed in Chapter 12.

In the 12-year-old reported by Stanley (143), he found an extreme degree of hyperextension of the elbow due to ligamentous laxity. He believed this laxity contributed significantly to the etiology. This finding has not been mentioned by other investigators, but most of these dislocations occur at around 7 years of age, when ligamentous laxity is at its peak (Fig. 16-23).

Wiley et al. (148) found in cadaver studies that anterior dislocations of the radial head could be produced only with great force. Dislocation required complete division of the anterior capsule and annular ligament, pronation, and application of an anterior force to the posterior aspect of the radial head. Tearing of the interosseous membrane sometimes occurred before the dislocation could be achieved.

Relationship to Congenital Dislocation of the Radial Head

It is important to be able to differentiate a congenital dislocation of the radial head that requires no treatment from an acute or chronic traumatically dislocated radial head that may require treatment. Congenital dislocations are commonly bilateral, posterior, and associated with other anomalies such as Ehlers-Danlos syndrome, but some are idiopathic (112,131,132,134,139). Because of the lack of significant disability, the parents often are unaware that their child has a congenital radial head dislocation. If the child sustains an injury to the elbow with subsequent pain and swelling, accurate radiographic interpretation may be difficult.

Isolated traumatic dislocations of the radial head in newborns have been documented (113,121,140). This gives credence to the theory that many congenital dislocations may actually have a traumatic etiology that was unrecognized.

Because most congenital dislocations are bilateral, it was initially thought that unilateral dislocations were probably traumatic in origin. However, Agnew and Davis (111) reported six patients with isolated unilateral dislocations in whom there had been no history of trauma and the presence of the dislocation had been recognized since early childhood. Thus, there is doubt whether all unilateral radial head dislocations are traumatic. Southmayd and Ehrlich (142) reported three children with symptomatic subluxations of the radial head, two of whom had unilateral involvement. It was uncertain whether there was a relationship with congenital dislocation of the radial head. Similarly, Bell et al. (114) reported congenital subluxations and dislocations of 34 elbows in 27 patients without other musculoskeletal anomalies; only 7 were bilateral.

Mardam-Bey and Ger (131) argued that if there were other congenital musculoskeletal abnormalities, if there was a positive family history of dislocated radial heads, or if the patient had bilateral dislocations, these were probably congenital in origin. The absence of early trauma alone is not a reliable criterion, because trauma may occur as an occult incident at an early age.

Signs and Symptoms

In an acute injury the elbow is swollen, motion is limited, and the radial head may or may not be palpable. In a chronic dislocation, the radial head usually is palpable and there is a lack of full flexion and extension. Pronation usually is full while supination is limited. In chronic dislocations there is typically some loss of pronation and flexion. The carrying angle may be increased and there may be valgus instability.

Radiographic and Other Imaging Studies

Routine radiographs demonstrate an isolated radial head dislocation, but distinguishing a traumatic from a congenital dislocation can be difficult. In a review of 50 patients with congenital dislocations of the radial head, Mardam-Bey and Ger (131) found the following radiographic characteristics in all their patients: relatively short ulna or long radius, hypoplastic or absent capitellum, partially defective trochlea, prominent ulnar epicondyle, dome-shaped radial head with long neck, and grooving of the distal humerus. Similar findings have been reported by McFarland (132) and Miura (134). Unfortunately, these same changes can be found in children with long-standing traumatic dislocations (112,118,120) (Fig. 16-27). When the radiographic findings described by Mardam-Bey and Ger (131) are seen, all that can be said with certainty is that the dislocation is long-standing. The congenital nature is determined by the presence of other factors.

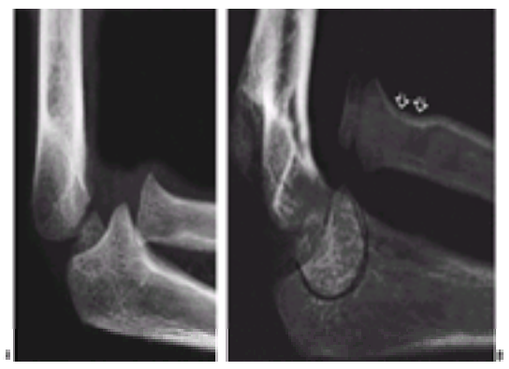

FIGURE 16-27. Progression of changes. **A:** Initial injury radiograph in a 5-year-old who sustained an acute minimally displaced anterior dislocation of the radial head. This dislocation was not appreciated initially. **B:** Three years later, the displacement had progressed and the radius had grown proximally. The radial neck also has become narrowed and elongated (*arrows*). These findings are similar to those described for a congenital dislocation of the radial head. (Courtesy of Charles T. Price, M.D.)

Arthrography

Arthrograms were advocated by Mizuno et al. (135) in the differentiation of congenital and traumatic dislocations. Their differentiation was based on whether the radial head was intraarticular or extraarticular. If the radial head remained within the intact but distended capsule, the dislocation was considered congenital. In 15 traumatic dislocations, the capsule was torn and the radial head was extraarticular.

Treatment Options

Nonoperative: Closed Reduction

Most acute radial head dislocations can be satisfactorily treated by closed reduction and immobilization (126,144,145 and 146,148,149), but nonoperative treatment is not appropriate for chronic radial head dislocations. Previously it was believed that dislocations older than 1 month should be left alone and possibly treated by radial head excision if the elbow became symptomatic (144). More recently, it has been recognized that chronic dislocations can be significantly improved by surgical reconstruction.

Surgical Procedures

Open Reduction

Neviaser and LeFevre (136) described an acute dislocation that required open reduction because the radial head was buttonholed through the capsule. Danielsson and Theander (121) reported an infant with an irreducible anterior dislocation of the radial head in which complete displacement of the annular ligament required division and then repair. If treatment is delayed for more than a week, open reduction may be necessary if a closed reduction is unsuccessful. Open reduction is universally necessary 3 weeks following injury. As long as 3 years after injury, open reduction with annular ligament reconstruction can produce good results (118,130,141). Techniques used for reconstruction are modifications of the procedure described by Bell Tawse (115). A more anatomic and physiologic reconstruction technique of the annular ligament using two holes drilled in the proximal ulna has been described by Seel and Peterson (141).

Ulnar Osteotomy

In addition to open reduction and reconstruction of the annular ligament, osteotomy of the proximal ulna sometimes is necessary to achieve reduction of the radial head (117,118,133,137), Bouyala et al. (117) reported the use of this technique in 15 patients, including 9 with isolated dislocations of the radial head. There were no redislocations, and all had improved elbow motion. Their technique is essentially the same as that used for chronic Monteggia lesions (115,116,119,137,138) McGuire and Myers (133) reported seven patients treated with open reduction and ulnar osteotomy without annular ligament reconstruction. The ulnar plate was contoured until the radial head rotated against the capitellum during a full range of pronation and supination. All patients regained full elbow motion. McGuire and Myers believed that redirecting the radial head to the capitellum resulted in stability. This is essentially what occurs when a Monteggia fracture is reduced closed. The annular ligament is torn, but does not require reconstruction for stability.

Complications can occur with the reconstruction technique of open reduction, annular ligament reconstruction, and ulnar osteotomy. Rodgers et al. (138) reported 14 complications in 7 patients undergoing these procedures. Ultimately, there were 3 good, 2 fair, and 2 poor results.

Radial Osteotomy

If the radial head was anterior and could be reduced closed by manually supinating the forearm, Futami et al. (124) achieved stability with a rotation osteotomy of the radius at mid-shaft. With the radial head reduced in maximum supination, the distal shaft segment was then rotated and fixed in pronation. This was thought to decrease the tension on the biceps, theorized to be one of the major deforming forces.

Radial Head Excision

Excision of the radial head in long-standing dislocations relieves discomfort but usually produces minimal improvement in motion (149). However, Hresko et al. (125) demonstrated significant improvement in motion in 27 elbows in 25 patients under 18 years of age who had radial head excision for a variety of conditions that caused stiff, painful radiocapitellar joints.

Postreduction Care

After successful closed reduction, the arm is immobilized in a long arm cast with the elbow flexed 90 degrees and the forearm in full supination for 3 to 6 weeks (126,144, 145 and 146). Supination decreases the pull of the biceps muscle and tenses the interosseous membrane. Weisman et al. (147) reported two children with late dislocations in whom there appeared to have been an elbow dislocations with spontaneous resolution. Dislocation occurred with the arm immobilized in 90 degrees of elbow flexion but without supination.

A similar immobilization position is used after open reduction, with or without an osteotomy. This is continued for approximately 6 weeks or until the osteotomy is healed.

AUTHOR'S PREFERRED METHOD OF TREATMENT

Most acute radial head dislocations can be treated by closed manipulation. The key to maintaining the reduction is to immobilize the elbow in hyperflexion (³120 degrees) (Fig. 16-28). The forearm is usually held in neutral rotation. The radius should always point toward the capitellum. Forearm supination can be increased to decrease the deforming force of the biceps brachii. To support the hyperextended elbow, a figure-of-eight cast, similar to the one used for supracondylar fractures, is used.

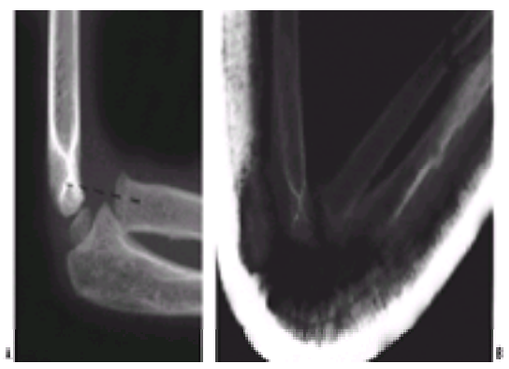

FIGURE 16-28. Closed reduction. **A:** Acute injury radiograph shows that the long axis of the radius (*dotted line*) passes proximal to the center of the capitellum, indicating a dislocation. **B:** After reduction, this relation has been reestablished and is maintained with the elbow immobilized in hyperflexion.

For long-standing post traumatic dislocations, I prefer open reduction and reconstruction of the annular ligament using a lateral strip of triceps tendon as a modification of the Bell Tawse (115) procedure popularized by Lloyd-Roberts and Bucknill (130) and others (Fig. 16-29) (116,118,119,137,141). I have no experience with the technique described by Seel and Peterson (141), although it appears to be an excellent alternative. The radiocapitellar joint can be stabilized with a small Steinmann pin rather than a Kirschner wire to decrease the risk of pin breakage.

FIGURE 16-29. Open reduction. **A:** Radiograph of a 5-year-old who had sustained an acute elbow injury 6 months previously. The radial head dislocation was not appreciated on the initial radiographs. **B:** After a Bell Tawse procedure, a Steinmann pin is used for fixation. The strap from the triceps fascia is passed through the olecranon (*arrow*). **C:** Six months after surgery, the reduction has been maintained.

Complications

Annular Ligament Calcification

Dystrophic calcification of the capsule and annular ligament after reduction of radial head dislocations is common (122,130,136,144). It appears as a semilunar calcification surrounding the radial head and may become evident as early as 2 weeks after injury. In most patients, this calcification spontaneously resolves. This localized, well-defined calcification is not to be confused with the diffuse pattern of myositis ossificans after elbow injuries.

Loss of Motion

Lloyd-Roberts and Bucknill suggested that untreated traumatic lesions result in a significant loss of elbow motion that can considerably decrease the power and dexterity of the extremity (130). Their patient had no distal radial ulnar subluxation and could do heavy labor without difficulty. He was also essentially pain free. Most patients with untreated radial head dislocations develop secondary cubitus valgus deformity and valgus instability when performing upper extremity weight-bearing activities (i.e., as in gymnastics).

ISOLATED DISLOCATIONS OF THE ULNA

Isolated dislocations of the ulna have been described in adults (see Chapter 22 in *Fractures in Adults*). However, there have been no known reports of this injury occurring in children.

SUBLUXATION OF THE RADIAL HEAD (PULLED ELBOW SYNDROME)

Subluxation of the head of the radius or pulled elbow is a common elbow injury in young children (150,152, 153 and 154, 156, 157 and 158,162,167,168, 172,173). The term *nursemaid's elbow* and other eponyms and synonyms have been used to describe this condition (161,171). The demographics associated with the subluxation of the radial head have been well described (150, 152, 153 and 154, 156, 157 and 158,162,167, 168, 172, 173). The mean age at injury is usually 2 to 3 years, with the youngest reported patient 2 months of age. It rarely occurs after 7 years of age. Sixty percent to 65% of the children affected are girls, and the left elbow is involved in approximately 70%. It is difficult to determine the actual incidence because many subluxations are treated in primary care physician's offices or resolve spontaneously before being seen by a physician.

Diagnosis

Mechanism of Injury

Longitudinal traction on the extended elbow is the usual mechanism of injury. Cadaver studies have shown that longitudinal traction on the extended elbow can produce a partial slippage of the annular ligament over the head of the radius and into the radiocapitellar joint, sometimes tearing the subannular membrane. Displacement of the annular ligament occurs most easily with the forearm in pronation. In this position the lateral edge of the radial head, which opposes the main portion of the annular ligament, is narrow and round at its margin (162,163). In supi- nation the lateral edge of the radial heal is wider and more square at its margin, thereby restricting slippage. McRae (164) demonstrated that forearm pronation maintains the displacement of the annular ligament.

Although the annular ligament slips proximally, it only partially covers the radial head. This anatomic finding has been confirmed in numerous cadaver experiments (163,164,171). Salter and Zaltz (171) found that if the annular ligament slipped over the equator of the radial head, the maximum anteroposterior diameter, the ligament could not be reduced to its original position. The two reports of surgical exploration of this injury in the acute stage confirmed this observation (171,176). After 5 years of age, the distal attachment of the annular ligament to the neck of the radius has strengthened sufficiently to prevent its tearing and subsequent displacement (171).

It was initially believed that the radial head diameter was less in children than in adults and this contributed to subluxation of the annular ligament. However, cadaver studies of infants, children, and adults have shown that the ratio of the head and neck diameters is essentially the same (169,171). Griffin (156) suggested that the lack of ossification of the proximal radial epiphysis in children less than 5 years of age made it more pliable, thereby facilitating slippage of the annular ligament.

Amire et al. (150) performed a controlled study comparing 30 normal children with 100 who had sustained subluxation of the radial head. They found an increased incidence of hypermobility or ligamentous laxity among children with pulled elbows. Also, there was increased incidence of hypermobility in one or both parents of the involved children compared with normals. It was these investigators' contention that hypermobility could be a factor predisposing children to this condition.

Thus, the most widely accepted mechanism today is that the injury occurs when the forearm is pronated, the elbow extended, and longitudinal traction is applied to the patient's wrist or hand (Fig. 16-30) (163,164,172). Such an injury typically occurs when a young child is lifted or swung by the forearm or when the child suddenly steps down from a step or off a curb while one of the parents is holding the hand or wrist. The investigator also has seen a number of children who, while falling backward, grab an object for support, thereby applying longitudinal traction across an extended, pronated elbow.

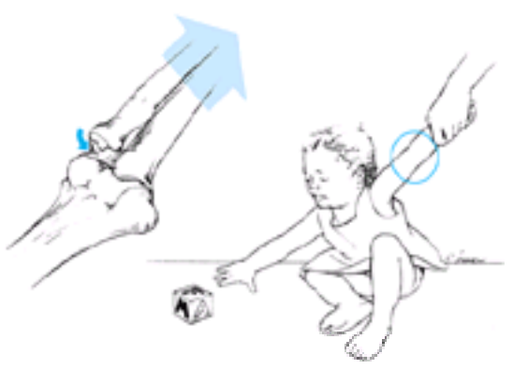

FIGURE 16-30. The injury most commonly occurs when a longitudinal pull is applied to the upper extremity. Usually the forearm is pronated. There is a partial tear in

the orbicular ligament, allowing it to subluxate into the radiocapitellar joint.

Unusual Mechanisms

Newman (166) reported that five of six infants under 6 months of age with a pulled elbow sustained the injury when rolling over in bed with the extended elbow trapped under the body. It was believed that this maneuver, especially if the infant was given a quick push to turn over by an older sibling or a parent, provided enough longitudinal traction to displace the annular ligament proximally.

Signs and Symptoms

The history is critical in making the diagnosis. There usually is an episode of a sudden longitudinal pull on the elbow of the young child. The initial pain usually subsides rapidly and the child does not appear to be in distress except that he or she is reluctant to use the involved extremity. The upper extremity is typically held at the side with the forearm pronated. A limited painless arc of flexion and extension may be present. However, any attempt to supinate the forearm produces pain. Although there is no evidence of an elbow effusion, local tenderness may be present over the radial head and annular ligament. In some patients the pain may be referred proximally to the shoulder or distally to the wrist (150,157).

Unfortunately, the classic history is not always present (153,167,168,170,172). In some studies 33% to 49% of patients had no history of a sudden longitudinal pull (170,172). There are several reasons why the history may not be characteristic: the parents are reluctant to give the true mechanism for fear they may be accused of child abuse, the injury can be sustained in a fall (153,170), or the injury was not observed by a reliable adult witness. Often, the child is crying and thus impossible to examine adequately until he or she has calmed down. In these nonclassic patients, other causes, such as occult fractures or early septic arthritis, must be carefully ruled out.

Radiographic and Other Imaging Studies

Results of anteroposterior and lateral radiograph usually are normal (152,153,156,158,163,168,171,172,174), but subtle abnormalities may be present. Normally, the line down the center of the proximal radial shaft should pass through the center of the ossification center of the capitellum (radiocapitellar line) (155,174). Frumkin (155) demonstrated that this did not occur in 3 infants with subluxation of the radial head. Careful review of the radiographs of children with true subluxation found that the line was more than 3 mm lateral to the center of the capitellum in almost 25% (174). To determine this subtle change requires a direct measurement on the radiograph. One problem is that these views often are taken with the forearm supinated and the subluxation is reduced when the technician forces the forearm into supination to position it for the radiograph. Bretland (151) found that if the best radiograph that can be obtained is an oblique with the forearm in pronation, radial head subluxation is the likely diagnosis.

Mehara and Bhan (165) reported a new radiologic sign of distal shift of the radius compared with the ulna. They found that the proximal radial length was altered in 21 of 25 patients (84%) with radial head subluxations. The normal relationships were restored after reduction.

Should radiographs be taken of every child before manipulation is attempted? If there is a classic history, the child is 5 years of age or younger, and the clinical findings strongly support the diagnosis, radiographs probably are not necessary (150,153,168,171,176). If, however, there is an atypical history or clinical examination, radiographs should be obtained before manipulation is attempted.

Arthrography

Matles and Eliopoulos (163) reported the use of arthrograms in some patients. Interposition of the annular ligament produces a defect between the radial head and the capitellum that is visible on arthrography (Fig. 16-31).

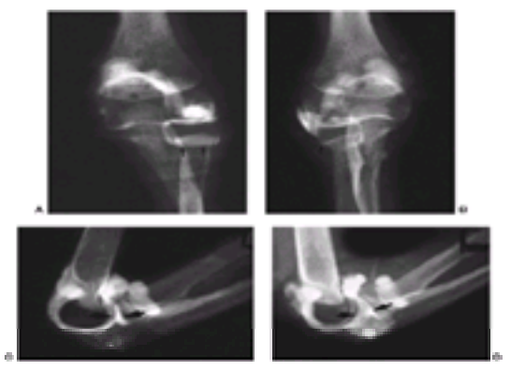

FIGURE 16-31. Irreducible annular ligament. **A:** Arthrogram of the normal uninjured left side shows a well-defined margin to the capsule and annular ligament at the radial neck (*arrows*). **B:** On the affected side, this margin has lost its sharp definition and the lateral aspect has migrated somewhat proximally. **C:** On the lateral radiograph of the normal elbow the radial head articulates directly with the capitellum (*arrows*) when the elbow is fully flexed. **D:** On the injured side there is some limitation to full flexion. At surgery, the gap between the two articular surfaces (*arrows*) was filled with the interposed annular ligament. (Courtesy of Robert M. Campbell, Jr., M.D.)

Ultrasonography

When the diagnosis is not evident, ultrasonography may be helpful (160,162). The diagnosis is made by demonstrating an increase in the echonegative area between the articular surfaces of the capitellum and the radial head (radiocapitellar distance). Kosuwon et al. (160) found that this distance is normally about 3.8 mm with forearm pronated. With a subluxated radial head, this measured 7.2 mm. A difference of 3 mm between the normal and affected sides, therefore, suggests radial head subluxation.

Treatment Options

Nonoperative: Closed Reduction

Almost all subluxations are correctable by closed reduction. This is usually best done by forearm supination (153,156,157,161,162,167,168,172,173). Some have recommended that supination be performed with the elbow flexed, and others have found that supination alone with the elbow extended can effect a reduction. In all patients, a snapping sensation can be both heard and palpated when the annular ligament reduces. Macias et al. (161) reported that hyperpronation was more successful than supination in a randomized study. Reduction was successful in 40 of 41 patients (98%) in the hyperpronation group, compared with 38 of 44 patients (86%) in the supination group. They concluded that the hyperpronation technique was more successful, required fewer attempts, and was often successful when supination failed.

Surgical Procedures: Open Reduction

This is rarely indicated. Even if untreated, most radial head subluxations reduce spontaneously. The only indication for surgery is a chronic symptomatic irreducible

subluxation (171,176). In these, the annular ligament must be partially transected to achieve reduction (Fig. 16-31).

Postreduction Care

After a successful closed reduction of a first time radial head subluxation, immobilization of the extremity is not necessary if the child is comfortable and using the arm normally. Salter and Zaltz (171) recommended the use of a sling, mainly to prevent the elbow from being pulled a second time. Kohlhaas and Roeder (159) recommended a T-shirt technique for flexed elbow stabilization in very young children. This provided adequate immobilization without the use of a sling by pinning the sleeve of the long sleeve T-shirt to the opposite chest.

Parent Education

After the reduction, it is important to explain to the parents the mechanism of injury and to emphasize the need to prevent longitudinal pulling on the upper extremities.

AUTHOR'S PREFERRED METHOD OF TREATMENT

First, it is important to try to elicit the classic history of the child having had a longitudinal force applied across the extended elbow. The entire extremity is then carefully examined. The characteristic focal tenderness should be pinpointed directly over the radial head. If there is clinical evidence of an elbow effusion, then radiographs of the upper extremity are obtained to assess for other injuries before manipulating the elbow.

Once the diagnosis of subluxation of the radial head is clearly established clinically, manipulation is performed. It is first explained to the parents there will be a brief episode of pain followed by complete or significant relief of the symptoms. The patient usually is seated on the parent's lap. The patient's forearm is grasped with the elbow semiflexed while the thumb of the surgeon's opposite hand is placed over the lateral aspect of the elbow. The forearm is first supinated. If this fails to produce the characteristic snap of reduction, then the elbow is flexed maximally until the snap occurs (Fig. 16-32). Just before reaching maximal flexion, there often is an increase in the resistance to flexion. At this point, a little extra pressure toward flexion must be applied, which usually produces the characteristic snap as the annular ligament suddenly returns to its normal position. If this fails, the hyperpronation technique of Macias et al. (161) is used.

FIGURE 16-32. Reduction technique, “nurse maid's” elbow. **Left:** The forearm is first supinated. **Right:** The elbow is then hyperflexed. The surgeon's thumb is placed laterally over the radial head to feel the characteristic snapping as the ligament is reduced.

What should be done if a definite snap or pop is not felt or if the patient fails to use the extremity after manipulation? If the subluxation has occurred more than 12 to 24 hours before the child is seen, there often is a mild secondary synovitis, and recovery may not be as dramatic. There also may be a small amount of blood in the elbow joint. The important fact to determine is whether the initial diagnosis was correct. This requires radiographs, if they were not taken before the manipulation, and a careful reexamination of the entire extremity. If the radiograph results are normal and the elbow can be fully flexed with free supination and pronation, the physician can be assured that the subluxated annular ligament has been reduced. In this circumstance, the patient's arm is placed in a splint or sling for a few days to one week and reexamined clinically first and radiographically if needed.

Complications

Unreduced Subluxations

There are no reports of long-term sequelae from unrecognized and unreduced subluxations. Almost all subluxations reduce spontaneously. The only problem seems to be the discomfort to the patient until the annular ligament reduces.

Recurrent Subluxations

The reported incidence of recurrent subluxation has varied from 5% to 39% (153,156,157,167,168,172,173,175). Children 2 years of age or younger appear to be at greatest risk for recurrence (172,176). Recurrent subluxations usually respond to the same manipulative procedure as the initial injury. They eventually cease after 4 to 5 years when the annular ligament strengthens. These recurrences do not lead to any long-term sequelae.

Recurrent subluxations are relatively common. After 2 or 3 episodes, the elbow is immobilized in a long arm cast for 1 to 2 weeks. This treatment seems to be effective because it allows healing of the soft tissues and decreases recurrent episodes.

George H. Thompson: Department of Orthopaedic Surgery, Case Western Reserve University, and Department of Pediatric Orthopaedics, Rainbow Babies and Children's Hospital, Cleveland, Ohio.

JOHN F. SARWARK

FRACTURES OF THE PROXIMAL HUMERUS

Fractures of the proximal humerus are relatively uncommon injuries of childhood, with an incidence of 1.2–4.4 per 1,000 per year (7,57,125), fewer than 5% of all pediatric fractures (40,43,56,57,88).

Fractures of the proximal humerus can be a common birth-related injury (61,101). As an infant is passing through the birth canal, the arm may be placed in a variety of awkward positions that will result in a separation through the physis of the proximal humerus (22,34,36,37,61,72,101). In older children, trauma, both direct and indirect, is the predominant cause of fractures in the proximal humerus. In this age group, these fractures can involve either the metaphysis, the physis, or both.

Because of the thick periosteum in this area and the proximity to the physis, fractures in this region have enormous potential to heal and remodel, perhaps more so than anywhere else in the body. Thus, proximal humeral fractures in children, in general, can be expected to heal without significant residual functional or cosmetic deficits.

Diagnosis

Mechanism of Injury

Birth Fractures

Fractures in the proximal humerus frequently occur during delivery (61,101). These fractures are generally believed to result from hyperextension or rotation of the arm during the passage through the birth canal (Fig. 17-1) (22,34,36,37,61,72,101). As might be expected, obstetric proximal humeral fractures occur most frequently during vaginal deliveries of infants with larger size or breech presentation (14,29,47,101). Prenatal size and presentation, however, have not been accurate predictive factors for these fractures, because proximal humeral fractures can and do occur during vaginal deliveries of infants of all sizes and weights (14,29,47).

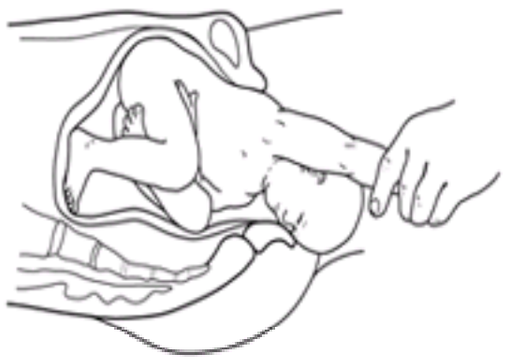

FIGURE 17-1. Hyperextension or rotation of the ipsilateral arm may result in a proximal humeral or physeal injury during birth.

Childhood/Adolescent Fractures

For older children, the mechanism of injury in most proximal humeral fractures is trauma. The trauma can be a direct blow to the shoulder area, especially to the posterior aspect (22,77,103) or indirect as in a fall onto an outstretched hand that transmits the force through the arm to the proximal humerus (2,9,47). Indirect trauma can result in forced or nonphysiologic positioning of the upper extremity, which in turn may cause a fracture of the proximal humerus. Specifically, six potential mechanisms of upper extremity positioning have been proposed to explain the resulting proximal humeral fractures: forced extension, forced flexion, forced extension with lateral or medial rotation, and forced flexion with lateral or medial rotation (123). Although trauma has been acknowledged as the most common mechanism of pediatric proximal humeral fractures, it is still controversial whether a fall or a direct blow is the more common etiology of the fracture.

Pediatric proximal humeral fractures often occur in children involved in motor vehicle accidents and sports (Fig. 17-2 and Fig. 17-3) (51). It has been estimated that approximately 50% of shoulder girdle fractures in children are related to sports and play activities (78). Athletic activities associated with proximal humeral fractures include contact sports, horseback riding (fall from horses), gymnastics (upper extremity impact and weight bearing), and baseball (repetitive throwing) (20,56,66,114,115).

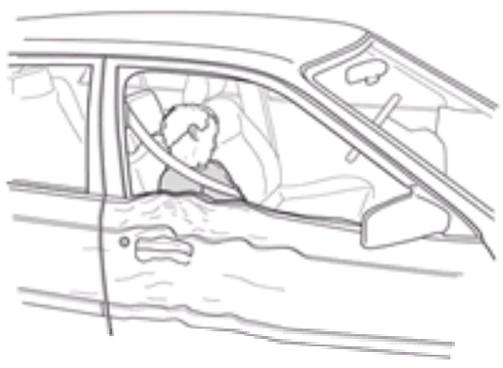

FIGURE 17-2. Motor vehicle crashes may result in proximal humeral fracture due to blunt trauma to the shoulder region.

FIGURE 17-3. Blunt trauma from contact sports may result in fracture of the proximal humerus in children.

Less often, pediatric proximal humeral fractures result from other illnesses such as malignant or benign tumors and pituitary gigantism (1,54,87,94). They also can be a complication of radiation therapy to the shoulder region (24). In addition, shoulder joint neuropathy secondary to Arnold-Chiari malformation, myelomeningocele, or syringomyelia has been implicated as an etiologic factor in proximal humeral fractures (5,67). An unknown percentage of pediatric proximal humeral fractures are [ol0]part of the injuries associated with child abuse (Fig. 17-4) (28). Because no clear fracture pattern in the proximal humerus is suggestive of abuse, an index of suspicion must remain high when evaluating infants or young children with humeral fractures (99).

FIGURE 17-4. Although the exact mechanism of injury may vary in child abuse, fracture of the proximal humerus may result from twisting at the elbow or forearm.

Signs and Symptoms

Clinical features of proximal humeral fractures in newborns may be subtle and not readily identified. For example, the infant may be irritable when lifted by the arms or when the involved upper extremity is moved. The infant may refuse to move the arm, giving the appearance of paralysis (i.e., pseudoparalysis). In addition to proximal humeral fractures, the differential diagnosis for such paralysis includes brachial plexus injury, septic shoulder, and clavicular fractures. Infants exhibiting upper

extremity paralysis also may be suffering from posterior humeral head dislocation (111).

Older children typically report a history consistent with a proximal humeral fracture. They often present with an obvious deformity in the anterior shoulder region and refuse to use the involved arm. Pain, swelling, and ecchymosis, to some degree, are invariably present, and the overall contour of the shoulder is altered in comparison with the contralateral uninjured shoulder.

Most children with displaced proximal humeral fracture hold the involved upper extremity in internal rotation to reduce the pull of the pectoralis major muscle on the distal fragment. With posterior fracture dislocations, children demonstrate limited and extremely painful external rotation. Some children with fractures of the greater tuberosity have an unusual presentation of luxatio erecta where the involved shoulder is positioned in extreme abduction (27). This position reduces the displacement across the fracture as the greater tuberosity is pulled superiorly by the supraspinatus muscle. The elbow is typically flexed in luxatio erecta, allowing the hand to be near or above the head (27,52). Because fractures of the lesser tuberosity will affect the function of the inserting subscapularis muscle, internal rotation with the shoulder in adduction and abduction with the shoulder in external rotation will be limited and painful (49,89,119).

Radiographic Studies

The proximal humeral epiphysis is not visible on plain radiographs until about 6 months of age (53,81), and plain radiographs are of limited value in evaluation of proximal humeral fractures in infants. On an anteroposterior (AP) radiograph, a change in the positional relationship between the proximal humeral metaphysis and the scapula and acromion often is visible. A comparison with the uninjured contralateral shoulder may reveal this alteration more clearly. A vanishing epiphysis sign also has been reported to describe posteriorly displaced transphyseal fractures of the proximal humerus (Fig. 17-5) (50,95). In comparison with the unaffected contralateral side, the epiphysis appears to vanish on an AP radiograph when it is displaced posteriorly. For complete evaluation of proximal humeral fractures in newborns and infants, ultrasonographic studies often are diagnostic and informative (11,41,116). Computed tomography (CT) also may be useful, especially for complex fractures with posterior dislocations (112).

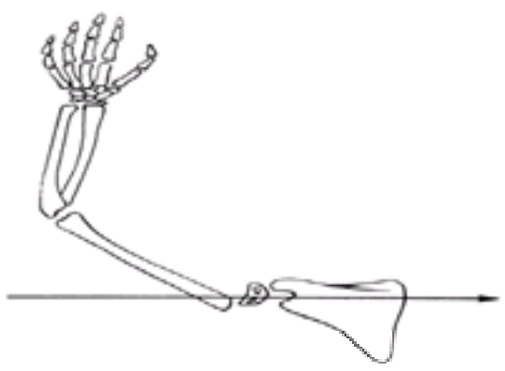

FIGURE 17-5. Vanishing epiphysis sign.

For evaluation of proximal humeral fractures in older children, two radiographs in perpendicular views can be diagnostic (108). Ideally, a true AP view of the shoulder and an axillary lateral view provide the most information about the fracture. Because some lesser tuberosity fractures may only be visible on an axillary lateral view, this radiograph should be included whenever possible (42). Often, however, an axillary lateral view is difficult to obtain in a child with an acutely fractured proximal humerus. In these instances, transthoracic axillary view or **Y** view radiographs can be obtained. An apical oblique view, an AP radiograph with the x-ray beam at 45 degrees of caudal tilt, also can provide significant information about the proximal humerus (102). In fact, some authors report that most shoulder trauma can be evaluated with AP and apical oblique radiographs and that a lateral view (axillary lateral or **Y** view) can be obtained if a humeral fracture is suspected (10).

When adequate radiographs cannot be obtained, CT is useful in evaluating proximal humeral fractures. CT may be especially useful in characterizing posterior fracture dislocations (33,119). If the child continues to complain of shoulder pain despite negative radiographic and CT results, an occult fracture must be ruled out. For this purpose, magnetic resonance imaging (MRI) is diagnostic (7,90,110). A bone scan also may be useful in such situations. However, due to the normally increased radionuclide uptake in the physis of the proximal humerus, a bone scan in this region may be difficult to interpret.

Classification

Fractures of the proximal humerus in the pediatric population are broadly categorized by their anatomic location. They may involve the physis, the metaphysis, the lesser tuberosity, or the greater tuberosity. In addition, the degree of fracture displacement plays an important role in the overall treatment option. Other fracture characteristics that must be evaluated include the presence or absence of open fractures, concomitant glenohumeral dislocations, and fracture stability.

Fractures involving the physis are classified according to the Salter-Harris classification (92) (Fig. 17-6). Salter-Harris type I injuries with fractures through the physis occur mostly in patients under 5 years of age (22,83). After 11 years of age, most fractures of the proximal humerus are Salter-Harris type II injuries, with the fracture line exiting through the metaphysis (12,22,83). Some Salter-Harris type II injuries are associated with an additional anterolateral bony fragment (12). Salter-Harris type III injuries with the fracture line exiting through the epiphysis rarely occur in the proximal humerus of children (22,83). The few reported such injuries occurred with and without concomitant glenohumeral dislocation (16,33,109,120,124). Salter-Harris type IV injuries involving both the metaphysis and the epiphysis of the proximal humerus have not been reported in children.

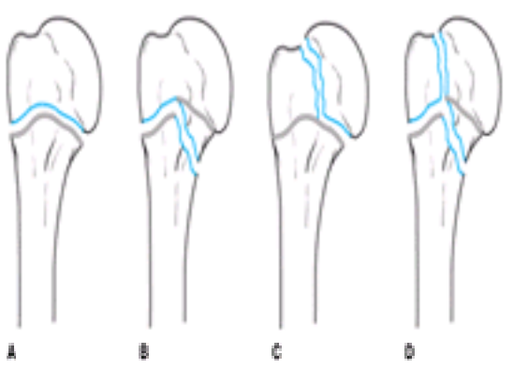

FIGURE 17-6. Physeal fractures of the proximal humerus.

Fractures of the metaphysis occur mostly in children 5 to 12 years of age (Fig. 17-7) and are categorized by their anatomic location and degree of displacement (22). The anatomic location is described in relation to the major deforming forces in the region, namely the insertions of the pectoralis major and the deltoid muscles. Presence or absence of other fractures in the [ol0]ipsilateral upper extremity also must be documented, because segmental fractures may require alternative treatments (46,71,82). Other isolated fractures of the proximal humerus may include the greater and the lesser tuberosities (27,49,52,89,121).

FIGURE 17-7. Healing undisplaced fracture of the proximal humerus in a 5-year-old child.

The degree of fracture displacement in the proximal humerus is classified with respect to the shaft diameter of the humerus (77). In grade I injuries, there is up to 5 mm of displacement. In grade II and III injuries, fractures are displaced by up to one third and two thirds of the humeral shaft diameter, respectively. Displacement of greater than two thirds of the shaft diameter, including total displacement, is classified as a grade IV injury. In addition to degree of displacement, fractures in this region may demonstrate angulation deformities. Although varus angulation is most common, fractures can be angulated in any direction.

In high-energy trauma, fractures of the proximal humerus may be associated with concomitant dislocations of the glenohumeral joint. The direction of the dislocation may be anterior, posterior, or inferior (16,27,28,33,52,80,117). A stress fracture of the metaphysis or a slipped epiphysis can be produced by chronic or repetitive trauma, such as repetitive throwing, gymnastics with humeral weight bearing, and localized radiation therapy (20,24,66,114,115). Because of the tremendous healing and remodeling potential in the pediatric proximal humerus, these injuries can be successfully treated with conservative nonsurgical therapy.

Surgical Anatomy

The proximal humeral ossification center cannot be seen on plain radiographs until about 6 months of age (53,81). In addition to the proximal humerus, both the greater and lesser tuberosities contain their own separate ossification centers. The ossification center for the greater tuberosity appears at around 1 to 3 years of age, while the ossification center for the lesser tuberosity takes form at 4 to 5 years of age (81,93). The two tuberosities coalesce at around 5 to 7 years of age and subsequently fuse with the humeral head at 7 to 13 years of age (81,93).

The proximal physis of the humerus continues to proliferate well into the teenage years and is ultimately responsible for approximately 80% of the overall humeral growth (8,85,86,105). Interestingly, longitudinal growth at the proximal humeral physis changes during development such that it is responsible for only 75% of humeral growth before age 2, but up to 90% of growth after age 11 (8,85,86). For girls, this growth continues until around 14 years of age, with subsequent fusion of the epiphysis to the shaft at 14 to 17 years of age (8,19,105). For boys, growth continues until about age 16, when closure of the physis begins (8,85,86). For most boys, the proximal humeral physis is closed by about 18 years of age (19).

The articular surface of the proximal humerus covers most of the medial aspect of the epiphysis as well as the proximal medial corner of the metaphysis (Fig. 17-8). The glenohumeral joint capsule surrounds the articular surface such that most of the medial epiphysis as well as the proximal medial corner of the metaphysis are intraarticular (Fig. 17-9). Conversely, a predominant proportion of the physis is extracapsular and remains susceptible to injury. The periosteum is quite strong in the posteromedial aspect of the proximal humerus, but the periosteum in the anterolateral aspect is relatively weak, occasionally allowing the fractured fragment to penetrate and prevent reduction (22).

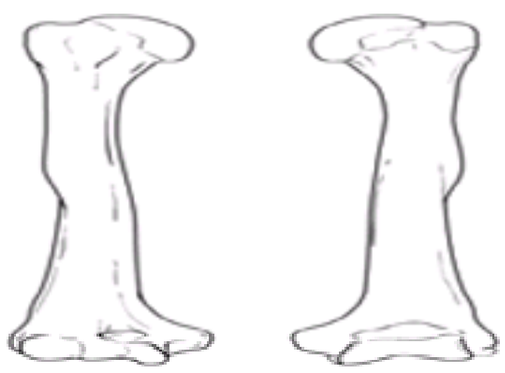

FIGURE 17-8. The articular surface of the proximal humerus.

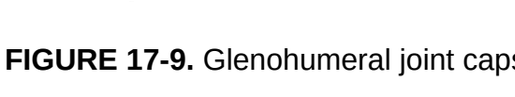

FIGURE 17-9. Glenohumeral joint capsule.

The proximal humerus is the site of insertion for a number of different muscles that can influence the pattern of fracture displacement. These muscles and their attachments form early during development and are grossly similar to those of an adult shoulder by the time of birth. The four muscles of the rotator cuff insert onto the epiphysis. The subscapularis muscle inserts on the anterior aspect of the epiphysis on the lesser tuberosity, whereas the teres minor, the infraspinatus, and the supraspinatus muscles insert onto the superior and posterior aspect of the epiphysis near the greater tuberosity (Fig. 17-10). In addition to the rotator cuff muscles, other muscular attachments that can cause fracture displacement are the deltoid and pectoralis major muscles. The deltoid muscle attaches in the lateral aspect of the humeral shaft, whereas the pectoralis major muscle attaches to the anteromedial aspect of the metaphysis.

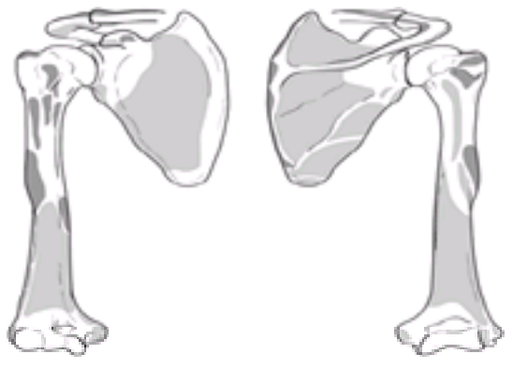

FIGURE 17-10. Origins and insertions of the cuff muscles in a child: subscapularis, teres minor, infraspinatus, and supraspinatus.

The vascular supply to the proximal humerus arises from the axillary artery. Distal to the pectoralis minor muscle, three different arterial branches arise from the axillary artery before it becomes the brachial artery to supply the upper extremity. One of these branches is the subscapular artery, which runs with the subscapular nerve to supply the rotator cuff muscles. The remaining two branches, the anterior and the posterior humeral circumflex arteries, supply the proximal humerus. Most of the humeral head vascularity is from the arcuate artery, which, in turn, is from the ascending branch of the anterior humeral circumflex artery (30,55). The posterior humeral circumflex artery is a less dominant vascular supplier of the proximal humerus, because it supplies a small portion of the greater tuberosity and a small portion in the posteroinferior portion of the humeral head (30) (Fig. 17-11).

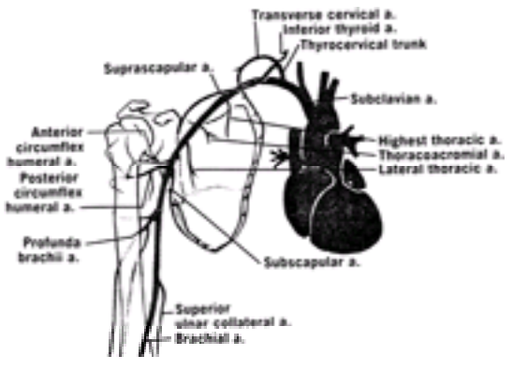

FIGURE 17-11. The arterial anatomy of the shoulder region.

The close proximity of the axillary nerve to the proximal humerus makes this neural structure susceptible to injury during fracture and fracture dislocations of the proximal humerus (4,27,117). The axillary nerve is a branch of the posterior cord of the brachial plexus. It traverses the anterior aspect of the subscapularis muscle before passing inferior to the glenohumeral joint to the posterior aspect of the proximal humerus (Fig. 17-12). The axillary nerve provides innervation to the deltoid muscle as well as a cutaneous sensory function over the lateral aspect of the deltoid cuff. Documentation of the normal function of this nerve before the initiation of treatment is essential.

FIGURE 17-12. Relationship of the brachial plexus and artery to the proximal humerus and the scapula.

Most fractures of the pediatric proximal humerus involve the physis (12,22,83). The extracapsular location of the proximal humeral physis makes this structure susceptible to injury. Physeal fractures are thought to occur through the zone of hypertrophy and spare the reserve as well as the proliferative cells in the physis (92). Therefore, children with Salter-Harris type I or II fractures still maintain excellent potential for longitudinal growth and remodeling in the proximal humerus (6,22).

In children 5 to 12 years of age, a significant proportion of proximal humeral fractures involve the metaphysis rather than the physis (22). This rather unexpected finding has been attributed to the rapid metaphyseal growth that occurs during this age, which, in turn, results in a relative structural weakness of the metaphysis (22).

Various muscular attachments to the proximal humerus contribute to the degree and the overall pattern of fracture displacement. With fractures of the physis (Salter-Harris types I, II, and III), the rotator cuff muscles displace the epiphysis into abduction, flexion, and slight external rotation, whereas the metaphysis is displaced anteriorly and medially by the pectoralis major muscle. With metaphyseal fractures proximal to the pectoralis major muscle, the proximal fragment is abducted, flexed, and externally rotated by the rotator cuff muscles. The deltoid muscle displaces the distal fragment proximally, whereas the pectoralis major muscle displaces the same fragment anteriorly and medially. If the fracture occurs between the insertions of the deltoid and the pectoralis major muscles, the proximal fragment is adducted by the pull of the pectoralis major muscle, and the distal fragment will be pulled proximally by the deltoid muscle. If the fracture occurs distal to the deltoid muscle insertion, the proximal fragment is abducted by the deltoid muscle and displaced anteriorly by the pectoralis major muscle. The distal fragment is pulled proximally and medially by the biceps and the triceps muscles (21).

Treatment Options

Because of their tremendous potential for healing and remodeling, fractures of the proximal humerus in children rarely require operative reduction and fixation (Table 17-1). This is especially true for obstetric proximal humeral fractures in infants. These fractures are quite amenable to gentle reduction with minimal or no anesthesia. If desired, the adequacy of the reduction can be evaluated via ultrasonography. With or without anatomic reduction, the affected upper extremity should then be immobilized to the body by using a safety pin to attach the shirt sleeve to the shirt (94). Proximal humeral fractures in this age group heal quite rapidly, typically within 2 to 3 weeks, and result in no residual functional or cosmetic deficits (22,36,47,62,101,122). Nondisplaced or minimally displaced proximal humeral fractures in older children also should be treated nonoperatively. Initial management of these fractures with sling-and-swathe immobilization (Fig. 17-13) followed by protected motion provides excellent long-term results (13,22,77).

	Immobilization	Operative Reduction/ Immobilization	Operative Reduction/ Internal Fixation
Birth fractures	X		
Chronic slipped proximal humeral epiphysis	X		
Metaphyseal fractures	X		
SH I before age 11 yr		X	
SH I after age 11 yr			X

TABLE 17-1. INTERVENTIONS FOR PROXIMAL HUMERUS FRACTURES

FIGURE 17-13. Sling and swathe for immobilization of proximal humeral fracture.

Initial management of displaced proximal humeral fractures may require reduction of the fracture before immobilization. Because the remodeling potential of the fracture decreases with the increasing age of the child, the degree of acceptable displacement and angulation also changes with the age of the child. Generally, relatively greater displacement and angulation can be accepted in younger children. For fractures in children under the age of 11, good to excellent long-term outcomes can be expected regardless of the fracture displacement (22,59,77,103). Grossly displaced or angulated proximal humeral fractures in children over 11 are managed with fracture reduction and sometimes with specialized immobilization (22,59,77,100). Various types of shoulder immobilization include sling-and-swathe, thoracobrachial bandage, hanging arm cast, shoulder spica cast, salute position shoulder spica cast, and “statue of liberty” cast (13,22,36,59,77).

Some investigators recommend reducing all grade III and grade IV fractures and immobilizing grade IV fractures in salute-position shoulder spica casts (77). Other investigators suggest gentle reduction of Salter-Harris type I and II fractures in children over 11 years of age, followed by immobilization with thoracobrachial bandage or shoulder spica casts or more likely percutaneous pinning (Fig. 17-14) (22). If a Salter-Harris type II fracture cannot be adequately reduced, Dameron and Reibel recommend treatment with a salute-position shoulder spica cast with the arm positioned in external rotation, abduction, and flexion (22). An acceptable reduction of proximal humeral fractures in children over 11 years of age has been proposed by some to be less than 50% displacement and 20 degrees of angulation (100). Regardless of the specific treatment options, nonoperative treatment of pediatric proximal humeral fractures has produced good to excellent results in all age groups (22,59,77,100).

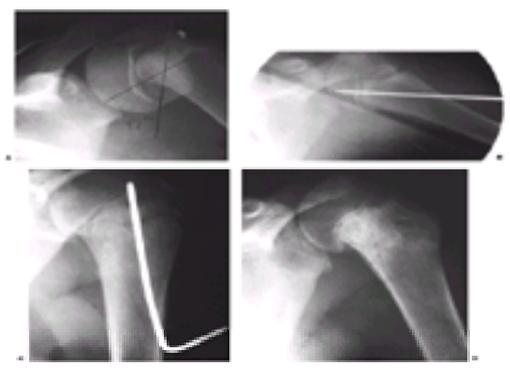

FIGURE 17-14. A: Salter-Harris I fracture of proximal humerus.

Multiple maneuvers exist for the reduction of pediatric proximal humeral fractures. Most fractures can be reduced by applying longitudinal traction to the arm while positioning it in abduction and flexion. If this maneuver does not sufficiently reduce the fracture, better reduction can be obtained by moderate abduction, flexion to 90 degrees, and external rotation (77). Alternatively, the fracture can be reduced by direct manual manipulation of the fragments while the arm is placed in marked abduction (~30 degrees), slight flexion (~30 degrees), and longitudinal traction (9,47,122). Despite significant efforts, however, some fractures cannot be adequately reduced because of a barrier in the fracture site. Anatomic structures that can prevent reduction of proximal humeral fractures include the periosteum, the periosteal cuff, the shoulder joint capsule, and the biceps tendon (26,44,60,62,118).

Because of the consistently good results of nonoperative treatment, indications for operative treatment of pediatric proximal humeral fractures are limited (18). Reported indications for operative interventions include open fractures, fractures associated with neurovascular injury, fractures associated with multiple trauma, displaced intraarticular fractures such as Salter-Harris type III fractures, irreducible fractures, and significantly displaced fractures in older adolescents (12,40,60,68,73,76,98,106,120).

AUTHOR'S PREFERRED METHOD OF TREATMENT

I manage most fractures of the proximal humeral physis nonoperatively. This includes undisplaced and most displaced physeal injuries of the proximal humerus. I prefer to percutaneously pin markedly displaced fractures involving the proximal humeral physis and metaphysis, particularly those in children over 12 years of age and then apply a shoulder immobilizer or Velpeau bandage (Fig. 17-15). Almost all metaphyseal fractures are treated nonoperatively with only a few requiring closed reduction. Because of the tremendous remodeling potential of metaphyseal fractures in children, displacements in bayonet apposition of up to 1 cm are acceptable. The rationale behind closed reduction and percutaneous pinning of proximal humeral physeal fractures is a more rapid return to normal active and passive range of motion. There is a minimally increased but acceptable risk of infection. In my opinion, this approach is more acceptable than leaving the fracture unreduced. My preference is to place the pin percutaneously through the metaphyseal fragment up into the physis as in pinning of a slipped capital femoral epiphysis in the hip (Fig. 17-14). After percutaneous pinning, the arm can be brought alongside the patient's body for more acceptable and more comfortable immobilization with a shoulder immobilizer. Alternatively, intramedullary fixation with flexible nails is an effective method (Fig. 17-16).

FIGURE 17-15. A: Anteroposterior radiograph of displaced fracture of the proximal humerus metaphysis with shortening with apparent inferior subluxation of the humeral head with respect to the glenoid.

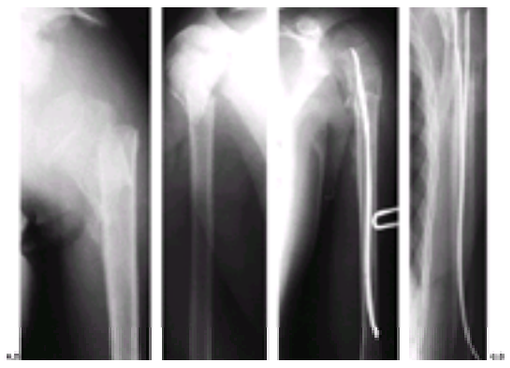

FIGURE 17-16. A: Anteroposterior radiograph of displaced, shortened fracture of the proximal humerus. **B:** Axillary image of same. **C:** Intramedullary fixation using retrograde technique. Note the satisfactory restoration of alignment. **D:** Postoperative lateral view.

Displaced fractures of the lesser tuberosity generally are treated with open reduction to restore the subscapularis tendon and anterior capsule. Lag screws or suture anchors are very useful in this region, particularly for smaller injuries.

Fractures of the greater tuberosity generally are associated with acute dislocations of the shoulder and are treated nonoperatively after following the closed reduction of the shoulder dislocation. Rarely, after closed reduction of the shoulder dislocation, the greater tuberosity fracture reduction is unacceptable, and an open approach to repair the tuberosity fracture along with the rotator cuff is required.

Fracture dislocations of the shoulder require closed reduction with appropriate anesthesia. If this is associated with a physeal injury, the physeal injury generally does not require further closed reduction or open reduction techniques. If the dislocation or fracture cannot be placed in an acceptable position, open reduction is generally done through an anterior or axillary approach to the proximal humerus.

Complications

Early Complications

Diagnosis of a proximal humeral fracture can be delayed in a child who is asymptomatic or minimally symptomatic. In children suffering from multiple traumas, the diagnosis can be delayed because of a low level of clinical suspicion. Even after the diagnosis of proximal humeral fracture is made, full evaluation and characterization of the fracture pattern can remain incomplete because of adequate radiographic studies. A high index of suspicion, thorough physical examination, and insistence on high-quality radiographs must all be present to ensure prompt diagnosis and treatment of proximal humeral fractures.

Neurologic injury to the brachial plexus can result from fractures and fracture–dislocations of the proximal humerus (4,23,27,117). Most nerve deficits can be diagnosed immediately because the clinical signs are readily apparent. Rarely, however, nerve deficits from proximal humeral fractures can evolve slowly and delay the diagnosis (23). Typically, these nerve deficits are transient, and full function can be expected to return in less than 6 months (45). If the neurologic deficit persists longer than 3 months, further evaluation with electromyography is warranted. If no evidence of nerve recovery or regeneration is present, nerve exploration, repair, and grafting can be considered (4,15). Salvage operations for permanent nerve deficits include proximal humeral osteotomy and muscle or tendon transfers (3,17,39,48,84).

Fractures of the proximal humerus in children also can be associated with other injuries, including rib fractures and pneumothorax (94). In adults, these fractures have been associated with disruptions and thrombosis of the axillary vessels as well (65,97,107,127). Operative fixation of proximal humeral fractures with pins and wires have been associated with hardware migrations that can be fatal (64,70). Therefore, serial radiographic monitoring of the hardware after shoulder operations is essential.

Late Complications

Humerus varus after trauma is a rare complication that typically affects neonates and children under 5 years of age (25,58,69,104,113). Children with humerus varus have a significant decrease in the humeral neck–shaft angle and shortening of the upper extremity. Although shoulder abduction may be moderately limited, most children with humerus varus have only mild functional deficits and do not require surgical correction of the deformity (25,58,69,113). If, however, active abduction and flexion are severely limited, corrective osteotomy of the proximal humerus can produce good results (32,104).

Hypertrophic scarring can occur after surgical reduction of proximal humeral fractures. When the scarring is present in the anterior shoulder region after an anterior deltopectoral incision, the cosmetic deformity may be significant and psychologically damaging, especially for girls (26,31). Therefore, many investigators have argued for the more cosmetically appealing axillary or anterior axillary incision (35,63).

Limb length inequality after proximal humeral fractures occurs more frequently in children treated with surgical intervention than in those treated nonoperatively (6,22,91). The inequality is not significantly affected by the quality of initial fracture reduction (6). The discrepancy may be more pronounced in older children (1–3 cm) (77). Despite this inequality, however, these children rarely develop any functional deficits to warrant surgical intervention. Full arrest of physeal growth after traumatic proximal humeral fractures is extremely uncommon (22). Although still quite rare, it does occur more frequently in children with pathologic fractures through unicameral bone cysts (38,75,79). If the functional or cosmetic deficit is significant, a limb-lengthening procedure may be of benefit for these children (96).

Osteonecrosis of the humeral head after proximal humeral fractures occurs frequently in adults, but is rare in children (74,126). Even after acute disruption of the vascular supply to the proximal humeral epiphysis, subsequent remodeling and revascularization may occur in children and lead to excellent clinical results (120). Similarly, glenohumeral subluxation after proximal humeral fractures is a rare complication in the pediatric population that typically results in good clinical outcomes (126). These children are best treated with a short period of immobilization followed by early physical therapy and rehabilitation (94).

FRACTURES OF THE SCAPULA

The unique anatomy of the scapula protects this bony structure from severe injury. The scapula has 17 different muscle attachments and is encased in multiple layers of muscle and other soft tissue structures. Due to this inherent protection, fractures and dislocations of the scapula are rare. In fact, it has been estimated that only 1% of all fractures involve the scapula (133,135). The significance of a scapular injury, however, is its disproportionately high association with major trauma. The high-energy traumas that cause scapular injuries also can result in significant injuries to other major organ systems (150,160,161). Therefore, all children with scapular fractures must be systematically evaluated to exclude other life-threatening injuries that require immediate medical attention and intervention.

Diagnosis

Mechanism of Injury

Glenoid

Fractures of the glenoid typically occur in a fall onto an upper extremity. This is believed to drive the humeral head onto the glenoid fossa, which, in turn, results in the fracture. Depending on the direction of the force, the fracture may only injure the rim of the glenoid or the entire glenoid fossa.

Scapula

Many fractures at other sites of the scapula are avulsion-type injuries from the various muscle attachments. Scapular fractures also can occur after a direct traumatic insult to the bone itself. These insults may be associated with other life-threatening injuries, such as hemothorax, pneumothorax, and cardiac contusions that require immediate medical attention (150,160). As with all other high-energy injuries, child abuse must be excluded as a cause for the scapular injury when no clear traumatic cause is evident (142).

Signs and Symptoms

Scapular fractures or dislocations, by themselves, do not pose an immediate danger to the patient. However, over 75% of all patients with scapular fractures have other injuries (128,139,157,160). In one reported series, the rate of mortality among patients with scapular fractures was over 14% (160). Therefore, before the scapular fracture is investigated, the child must be systematically examined for other, possibly life-threatening, injuries. A full trauma evaluation should be undertaken for head, chest, abdominal, and renal injuries. If available, a consultation with the trauma service would also be prudent. Conversely, fractures of the scapula should be sought in children with life-threatening trauma.

Orthopaedic evaluation for scapular fracture should include an examination for other bony deformities and extremity tenderness. Children with scapular fractures complain of significant pain and tenderness around the shoulder girdle and decline to move the affected arm. Localized edema may obscure the overall shoulder contour. A comparison with the contralateral shoulder often is helpful in determining this loss of contour. Because of the close proximity of the scapula to the axillary artery and the brachial plexus, fractures of the scapula often are associated with neurovascular injury (160) (Fig. 17-12). The ipsilateral arm must be carefully examined to document any arterial or neurologic deficits before the initiation of treatment. When injury to axillary or distal vasculature is suspected, an angiogram should be performed to examine the integrity of the vessels.

Radiographic Studies

Many scapular injuries are initially identified on the AP chest radiograph of a trauma series. An AP chest radiograph also may reveal scapulothoracic dissociation. This devastating injury should be suspected if the medial border of the scapula is displaced laterally, if there is a clavicular fracture with a large [chdisplacement, or if there is a complete acromioclavicular joint [chseparation with large displacement (155). Scapulothoracic dissociation typically occurs in patients with massive, direct trauma to the chest or proximal upper extremity and is highly associated with ipsilateral neurovascular injury (131,155).

When a scapular injury is suspected, AP and lateral view radiographs of the scapula should be immediately obtained because they are essential in characterizing the fracture. In addition to these, other views should be obtained to assess various fracture patterns. The Stryker notch view, for example, better reveals coracoid fractures, whereas the axillary lateral view is better suited to identify glenoid fractures. The axillary lateral view also is helpful in confirming the location of the humeral head on the glenoid. Because the three-dimensional structure of the scapula is complex, even high-quality radiographs may not provide all the details necessary to characterize the fracture. In such instances, CT with three-dimensional reconstructions may be required. CT also is essential in characterizing intraarticular injuries of the glenoid.

Accurate interpretation and assessment of scapular radiographs requires recognition and identification of developmental variations. Reported developmental variations of the scapula include Sprengel's anomaly, absent acromion, bipartite or tripartite acromion, bipartite coracoid, and coracoid duplication (129,140,148,156,158). Os acromiale, for example, is often mistakenly identified as a fracture. This variation occurs when the centers of ossification in the acromion fail to unite (129). s acromiale is present in 2.7% of the general population and is bilateral in 60% (145). Typically, os acromiale is located in the anterior and inferior aspect of the distal acromion and has a smooth and uniform appearance on radiographs. If, however, radiographic studies and clinical examination cannot distinguish between a fracture and a developmental variation, further evaluation with a bone scan may be indicated (141).

Classification

Multiple classification systems for scapular fractures have been reported. Many are descriptive and based primarily on the anatomic location. Ada and Miller, for example, classified scapular injuries into those of acromion, spine, coracoid, neck, glenoid, and body (128). In their series, fractures occurred most often in the body (35%), followed by the neck (27%). Fractures of the coracoid were least common (7%). Similarly, Thompson et al. (160) classified scapular fractures into the three broad anatomic locations: fractures of the glenoid and the glenoid neck, fractures of the acromion and the coracoid, and fractures of the body (Fig. 17-17). Other anatomic location–based scapular fracture classifications have been reported by Imatani (139) and Wilbur and Evans (161).

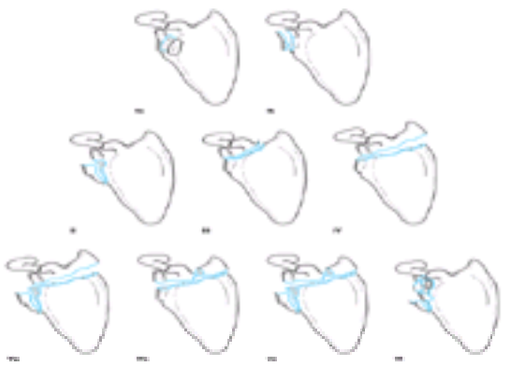

FIGURE 17-17. General classification of scapular/glenoid fractures.

The classification described below is also based on the anatomic location of the fracture, with additional subclassifications based on multiple reported studies (Fig. 17-17 and Table 17-2). It must be emphasized, however, that most of these studies are not specific for pediatric scapular fractures. Therefore, application of this classification system and its supportive studies to pediatric scapular fractures should be individualized to each child. The fracture should be adequately evaluated for its anatomic location, displacement, comminution, and articular involvement. In addition, ipsilateral neurovascular status, the overall status of the patient, and other concomitant injuries should be fully characterized.

TABLE 17-2. TREATMENT OF SCAPULAR FRACTURES

Fractures of the body and the spine of the scapula, which make up nearly 50% of all scapular fractures, are broadly categorized into those with and without displacement. Although isolated fracture of the scapular neck is believed to be a stable bony construct, ipsilateral fractures to both the scapular neck and the clavicle may lead to disruption of the suspensory mechanism of the shoulder (133,144). Therefore, fractures of the scapular neck are categorized into those with and without concomitant injury to the clavicle. For similar considerations, fractures of the coracoid process are categorized into those with and without concomitant injury to the acromioclavicular joint.

Fractures of the acromion are categorized into those with and without displacement. Displaced fractures are further subclassified based on the presence or absence of subacromial narrowing. Subacromial space narrowing may occur after inferior displacement of the acromion or after superior displacement of an ipsilateral glenoid fracture. When treated conservatively, these fracture patterns often lead to subacromial impingement in adults and result in decreased range of shoulder motion and increased shoulder pain (143). Although its applicability to acromial fractures in younger children is still debated, this finding significantly affects the treatment options for acromial fractures in older children.

Fractures of the glenoid typically occur when the humeral head is driven onto the glenoid fossa. Depending on the direction of the force applied to the humeral head, the fracture may involve the entire fossa or just the rim. If the entire fossa is involved, the fracture line may then exit in multiple locations about the scapula. Hence, fractures of the glenoid are classified into five distinct groups based on their anatomic location and course of the fracture. This system was initially proposed by Ideberg and later expanded by Goss (Fig. 17-18) (132,137,138). Type I fractures are isolated glenoid rim fractures, with Ia involving the anterior rim and Ib involving the posterior rim. Type II, III, and IV fractures are glenoid fractures with fracture lines exiting through lateral, superior, and medial aspects of the scapula, respectively. Type V fractures are various combinations of type II, III and IV fractures. Type Va, for example, is a combination of types II and IV. Type Vb is a combination of types III and IV, whereas type Vc is a combination of type II, III, and IV. Type VI fractures are comminuted fractures of the glenoid fossa. These various types of glenoid fractures are associated with distinct patterns of morbidity and treatment options.

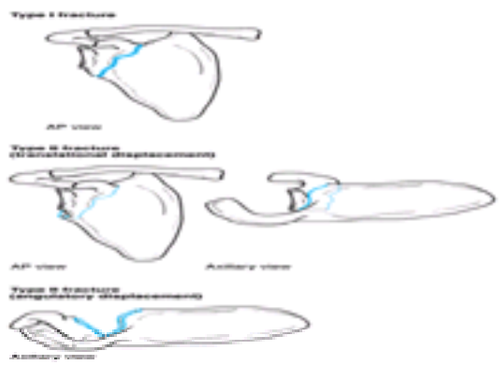

FIGURE 17-18. Classification of fractures of the glenoid neck.

Scapulothoracic dissociation occurs when all attachments or articulations between the thorax and the scapula are completely severed. When there is an ipsilateral neurovascular injury, it is sometimes referred to as a forequarter amputation. This is in contrast to scapulothoracic dislocation, where only the inferior scapulothoracic articulation is displaced (131). Although intrathoracic dissociations have been reported (153), scapulothoracic dissociations are typically laterally displaced. These injuries are categorized as open or closed with intact or compromised neurovascular status.

Surgical Anatomy

During development, the scapula forms in the first trimester of gestation. It first appears near the level of lower cervical spine, C4–C7, and then descends to its final position on the lateral aspect of the upper thorax during development. Most of the scapula is formed by intramembranous ossification. Numerous centers of ossification exist for the scapula: three for the body, two for the coracoid process, two to five for the acromion (129), and one for the glenoid. These ossification centers during childhood are often mistakenly identified as fractures. In some developmental anomalies, distinct ossification centers fail to fuse and persist into adulthood (148). These conditions are also frequently characterized as fractures. With few exceptions, however, a developmental variation and a fracture can be distinguished by clinical history, physical examination, and radiographic appearance.

In its final form, the scapula is roughly triangular and has a complex three-dimensional structure. It is responsible for linking the upper extremity to the axial skeleton (Fig. 17-19) and contains attachments to 17 distinct muscles. The anterior aspect of the scapular body is a relatively flat surface, most of which is covered by the subscapularis muscle. The posterior aspect of the scapula is divided into two fossae by the scapular spine. These superior and inferior scapula fossae are mostly covered by the supraspinatus and the infraspinatus muscles, respectively. The anteromedial border of the scapular body provides attachment to the serratus anterior muscle. The posteromedial border contains the attachment sites of the levator scapulae, rhomboideus major and minor, and latissimus dorsi muscles. The omohyoid muscle attaches to the superior aspect of the scapular body, whereas the teres minor and major muscles and the triceps muscle attach to the lateral border. The scapular spine provides attachments to the trapezius and deltoid muscles, and the long head of the biceps muscle originates from the superior rim of the glenoid. Finally, the pectoralis minor muscle, as well as the conjoined tendon of the coracobrachialis and short head of the biceps muscles, attach to the coracoid process.

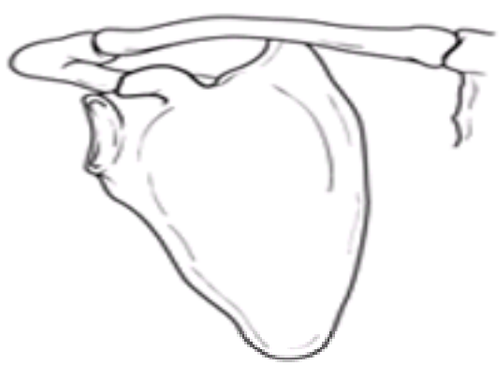

FIGURE 17-19. Relationship between the scapula, clavicle, and sternum.

In addition to these muscle attachments, the scapula participates in the formation of both glenohumeral and acromioclavicular joints. The glenohumeral joint is stabilized by multiple dynamic and static forces about the joint, which are discussed separately. The acromioclavicular joint is stabilized in part by the presence of two coracoclavicular ligaments that position the distal clavicle immediately medial to the acromion. The two ligaments are the conoid and the trapezoid ligaments, with the conoid being the more medial of the two.

In close proximity to the scapula are a number of neurovascular structures that can be injured during a scapular fracture. Most notable are the brachial plexus and the axillary artery, which course across the anterosuperior aspect of the scapula. They are immediately posterior and inferior to the tip of the coracoid process. Medial to the base of the coracoid process is the scapular notch with the overlying transverse scapular ligament. The suprascapular nerve and artery pass under and over the ligament, respectively, in the scapular notch and are susceptible to injury with nearby fractures. The axillary nerve travels within an intermuscular interval immediately inferior to the glenoid and is also susceptible to injury with displaced fractures of the glenoid neck (149).

Biomechanics

The scapula can protract, retract, abduct, and elevate. Its motion augments the movements about the glenohumeral joint, including abduction, flexion, and extension. In addition, with the clavicle, the scapula acts to link the axial skeleton to the upper extremity. It provides a scaffold from which the upper extremity suspends and articulates in order to function. Therefore, its structural integrity is essential to the proper functioning of the upper extremity.

A traumatic insult may cause fractures in multiple locations about the scapula, with one fracture influencing the stability of another. Goss solidified this idea and subsequently proposed the concept of a superior shoulder suspensory complex (SSSC) (133). The SSSC is a set of bony struts attached to a circular complex of structures at the lateral end of the scapula (Fig. 17-20). The superior and inferior bony struts are the middle clavicle and the lateral scapula body/spine, respectively. The circular complex is composed of acromioclavicular ligament, acromion, glenoid process, coracoid process, coracoclavicular ligament, and distal clavicle. As a whole, the SSSC is responsible for linking the upper extremity to the axial skeleton. Traumatic injury to any single component of the SSSC will likely result in a minimally displaced fracture, because the inherent stability of the circular complex is still intact. However, when multiple structures of the circular complex are injured, a double disruption to the circle occurs. This, in turn, results in significant instability and displacement at one or all of the fracture sites. Similarly, injury to one of the structures of the ring complex with a concomitant injury to a bony strut also may create an unstable construct. Goss therefore proposed that the treatment decisions for scapular injuries should be based on the maintenance of SSSC integrity (133).

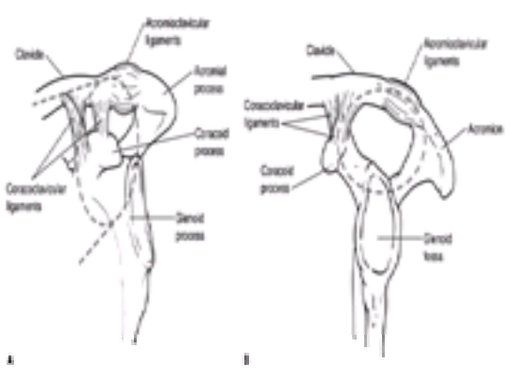

FIGURE 17-20. Superior shoulder suspensory complex.

Treatment Options

Isolated fractures of the scapular body do not affect the integrity of the SSSC (Table 17-2). In addition, because of the numerous muscle attachments, fractures of the scapular body are quite stable and can be treated conservatively. Conservative treatment of nondisplaced or minimally displaced scapular body fractures in adults is generally associated with excellent results; therefore, similar treatment is recommended for equivalent fractures in the pediatric population (139,154,157,162). In adults, scapular body fractures with significant displacement of more than 10 mm, however, resulted in unfavorable outcomes when treated conservatively (154). Unfortunately, a comparable study of pediatric scapular body fractures has not yet been reported, and ideal treatment can only be inferred.

Nondisplaced or mildly displaced scapular neck fractures without concomitant injury to the clavicle can be treated conservatively (146). In the presence of ipsilateral clavicular injury, however, surgical intervention generally is recommended to reestablish the SSSC (128,136,144,151). Recommendations vary as to whether open reduction and fixation of the clavicle is sufficient to stabilize the fracture (136) or whether the neck fracture also must be reduced in addition to the clavicle (144). For patients in whom surgical intervention is not possible, skeletal traction may be an acceptable option (130).

Fractures of the coracoid process typically occur at the base. Isolated fractures of the coracoid process usually are nondisplaced and can be treated conservatively with a sling and mobilization as tolerated. Displaced coracoid fractures occur with ipsilateral injury to the distal clavicle or the acromioclavicular joint. Most investigators favor open reduction and internal fixation of these fractures to restore the integrity of the SSSC (147,157,161). Displaced coracoid fractures near the suprascapular notch with injury to the suprascapular nerve also have been described, with some investigators arguing for early exploration (152).

Isolated fractures of the acromion in children are typically nondisplaced. In adults, acromial fractures with subacromial narrowing are associated with subsequent development of subacromial impingement when treated nonsurgically (143). Therefore, most investigators recommend open reduction and internal fixation for displaced acromial fractures where the subacromial space has been compromised (143). In addition, as described above, when fractures of the acromion occur with another disruption in the SSSC, the resulting deformity and instability may warrant operative fixation (133).

Fractures of the glenoid neck typically are nondisplaced unless other elements of the SSSC are disrupted. These fractures generally have excellent outcomes with nonsurgical treatment. Significant displacement or angulation, however, may limit glenohumeral motion (130,154). In adults, glenoid neck fractures with more than 10 mm of displacement or 40 degrees of angulation result in poor outcomes when treated without surgical reduction (128). Therefore, it is reasonable to infer that pediatric glenoid neck fractures with significant displacement or angulation also require surgical intervention. The indications for surgery, unfortunately, remain poorly defined and must be individualized to each child.

Treatment of glenoid rim fractures (types I and II) is based on the presence or absence of shoulder instability. Closed treatment of asymptomatic glenoid rim fractures rarely result in longterm morbidity (163). For glenoid rim fractures with resulting shoulder subluxation or instability, however, operative reduction and fixation are recommended to prevent permanent or recurrent dislocations. (130,134,135). In adults, shoulder instability occurred when the fracture was displaced more than 10 mm or when the fracture involved more than either 25% of the anterior or 33% of the posterior aspects of the glenoid (130). Anterior and posterior approaches to the glenoid generally are recommended for open reduction and internal fixation of anterior and posterior rim fractures, respectively (133).

Nondisplaced glenoid fossa fractures (types III–VI) also can be successfully treated nonsurgically (133). Displaced fractures, on the other hand, are associated with significant morbidity (pain, stiffness, and limited range of motion) when treated without surgical reduction. For glenoid fossa fractures, maximal acceptable intraarticular displacement is believed to be 5 mm (130,159). Again, lack of definitive studies prevent the formation of absolute indications for surgery in the pediatric population. In type IV glenoid fractures, where significant comminution is present, acceptable operative reduction and fixation may be difficult to achieve (133,138), and these fractures may be better treated with nonsurgical options (133,138). For open reduction and internal fixation of these fractures, a posterior approach

generally provides the most acceptable exposure (133).

Initial treatment of scapular dissociations generally focuses on stabilization and repair of the neurovascular injury. If the axillary artery and the brachial plexus are completely destroyed, an early amputation should be considered (155). For most patients including children, however, the limb is salvaged whenever possible. Immediate exploration of the brachial plexus is warranted when a concomitant vascular injury requires an operative repair. In the absence of a vascular injury, however, the brachial plexus need not be acutely explored. After a period of 4 to 6 weeks, the extent of the brachial plexus injury should be documented before any surgical reconstruction, including nerve repair or musculotendinous transfer (133,155). Immediate operative stabilization of an ipsilateral clavicular fracture generally is not necessary, unless the bony instability further compromises the integrity of the neurovascular structures.

AUTHOR'S PREFERRED TREATMENT

Most problems related to injuries of the scapula are not necessarily related to treatment but are more often related to failure to accurately evaluate associated major systems injuries (68). Therefore, once the patient is stabilized, the approach to the scapula or glenoid fractures can be more thoroughly undertaken. Fractures of the glenoid generally are treated with observation and follow-up, including a program of physical therapy and rehabilitation. For the rare displaced glenoid fracture, open reduction with internal fixation is recommended. This is generally performed via a deltopectoral approach, but posterior approaches to the scapula and glenoid may be useful in this particular injury.

Intrathoracic dislocation is rare. Most can be reduced by closed manipulative methods. In those associated with residual scapular deformity, an open approach may be required.

With scapulothoracic disassociation it is important to attend to the priorities of trauma care, including an appropriate and detailed neurovascular examination. Vascular consultation or evaluation may be required given the potential for massive injury to the brachial artery or plexus. In these instances, early or late amputation should be considered.

Complications

Late complications associated with scapular fractures generally involve improper functioning of the upper extremity. Displaced fractures of the scapular body and spine, for example, infrequently result in upper extremity weakness and pain with movement (128). Similarly, fractures of the acromion can result in pain and decreased range of upper extremity motion secondary to subacromial impingement (143). Displaced intraarticular fractures of the glenoid are associated with glenohumeral subluxation or dislocation, as well as early progression of degenerative arthritis (130,133,134 and 135).

Of special consideration are the concomitant injuries frequently associated with scapular fractures (128,139,157,160). Due to their proximity, the axillary and the suprascapular nerves may be injured in association with glenoid and coracoid fractures, respectively (149,152). In addition, the energy required to create scapular fractures likely results in other injuries, such as rib fractures, pneumothorax, and vascular avulsions. All or portions of the lower brachial plexus are susceptible to injury with scapulothoracic dissociations (131,155,158). This devastating injury also has been associated with the development of compartment syndrome in the upper arm (162).

FRACTURES OF THE CLAVICLE

The clavicle has the important function of linking the axial skeleton to the upper extremity (Fig. 17-19). It is an **S**-shaped bone whose medial end is connected to the axial skeleton through the sternoclavicular joint. The medial two thirds of the bone is in the shape of a tube, whereas the lateral end is flatter and is stabilized in its position by the two coracoclavicular ligaments (trapezoid and conoid). The lateral aspect of the clavicle takes part in the formation of the acromioclavicular joint, which, in effect, is connected to the upper extremity through the glenohumeral joint.

Through its joints, the sternoclavicular and the acromioclavicular, the clavicle contributes to the overall motion of the upper extremity. The clavicle can protract and retract (228). It also rotates and elevates to contribute to shoulder abduction (164,203,228). In addition, the clavicle provides the attachment site for the two predominant mobilizers of the upper extremity: the pectoralis major and the deltoid muscles. The integrity of the clavicle, therefore, is crucial to the optimal functioning of the entire upper extremity.

The clavicle is mostly subcutaneous throughout its span, being situated on the anterosuperior aspect of the thorax. Its structure is palpable and, in some cases, prominent in the upper thorax. Because of its subcutaneous location, it is one of the most frequently fractured bony structures in the body. In fact, it is the bone most commonly injured during labor and delivery, accounting for nearly 90% of all obstetrical fractures (179,189,250). In older children, clavicular fractures occur frequently, with the reported rates ranging between 8% and 15% of all pediatric fractures (216,219,232). Because of differences in the mechanism and rate of injury, prognosis, and treatment options, clavicular fractures are broadly categorized by their anatomic location: medial third, middle third, and distal third (Fig. 17-21). Most clavicular fractures occur at the middle third, with the reported rates ranging from 76% to 85% (226,232). The second most common site of clavicular injury is the distal third, with the reported rates between 10% and 21% (226,232,243,249). Fractures in the medial third of the clavicle are relatively uncommon and represent only 3% to 5% of all clavicular fractures (232,249).

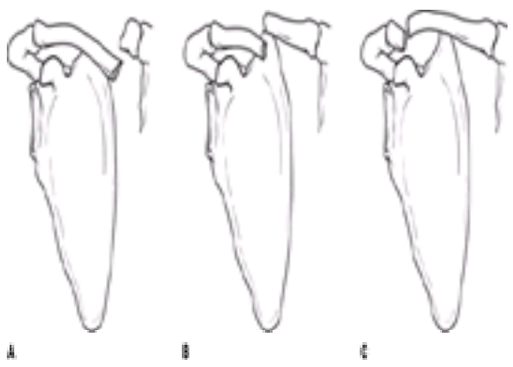

FIGURE 17-21. A: Fracture of the medial third of the clavicle. **B:** Fracture of the middle one third of the clavicle. **C:** Fracture of the lateral third of the clavicle.

Diagnosis

Mechanism of injury

The clavicle is the most common site of all obstetrical fractures, and clavicular fractures occur in 1% to 13% of all births (177,179,189,195,196,206,237,250,251,264). The incidence of obstetric clavicular fractures increases with larger fetuses and with decreasing experience of the obstetricians (179,206,218). In addition, deliveries involving the use of instruments or specialized obstetric maneuvers are more likely to result in a clavicular fracture (179,196,206,218). Therefore, it has been postulated that the fracture occurs as a result of excessive lateral to medial pressure on the shoulders during passage through the narrow birth canal. Accepting that this mechanism appears likely, it also must be noted, however, that the most clavicular fractures occur during deliveries of normal-sized to small fetuses with excellent obstetric care. Thus, it appears that obstetrical clavicle fractures are unavoidable consequences of some vaginal deliveries.

The most common mechanism of clavicular fractures in older children is a fall onto the shoulder (215,232,260). Other mechanisms include accidents where the traumatic insult is applied directly to the clavicle (260). Indirect applications of force, like falling onto an outstretched hand, are much less likely to result in clavicular

fractures (260).

A significant amount of energy can be directly applied to the clavicle during sports-related activities such as football or lacrosse. As expected, children participating in sports frequently sustain clavicular fractures as well as sternoclavicular and acromioclavicular joint dislocations (216,232). A large proportion of these injuries may be preventable with the use of protective equipment and adequate padding (258). Many children victimized by child abuse also present with clavicular fractures. Despite clinical suspicions, however, no clear pattern for isolated clavicular fractures has been associated with child abuse (201,214).

Signs and Symptoms

Clavicular fractures in newborn infants may be difficult to identify. In the acute stage, before stabilization of the fracture, infants with clavicular fractures may voluntarily splint or not move the affected arm to minimize discomfort (180,224). Frequently, this pseudoparalysis is mistaken for a brachial plexus injury, delaying the correct diagnosis. In order to reduce the pull of the sternocleidomastoid muscle across the fracture site, these infants will also turn their heads toward the side of the fracture. In addition, infants with acute clavicular fractures typically exhibit an asymmetric Moro reflex (242,254). Generalized edema is present, which prevents the palpation of normal clavicular margins (198). Often, the diagnosis may be suspected and later confirmed only after a mass is noticed over the affected clavicle. This mass represents a healing fracture callus that forms 7 to 10 days after the initial trauma. Therefore, by the time of such delay in diagnosis, the fracture has already stabilized to the extent that it causes little discomfort to the infant.

Clavicular fractures in older children typically are readily apparent and less difficult to diagnose. Children complain of moderate to severe pain around the area of the fracture and voluntarily immobilize and stop using the affected arm. Tenderness, ecchymosis, and edema, to some degree, are invariably present, and in fractures with large displacement, a bony prominence or deformity may be noted. Most children with clavicular fractures keep their heads turned to the side of the fracture in order to relax the sternocleidomastoid muscle (198). It must be cautioned that, on rare occasions, atlantoaxial subluxation and clavicular fracture may occur together. Attributing acute torticollis entirely to the clavicular fracture may delay the diagnosis of atlantoaxial subluxation, which can lead to the development of permanent atlantoaxial rotatory fixation (165).

Examination of children with either acromioclavicular or sternoclavicular joint injuries may produce crepitus and instability over the affected joint. Of special note are children with acute posterior dislocations of the sternoclavicular joint. Because of their proximity, structures of the mediastinum are susceptible to both compression and injury. Compressions of the great vessels, the esophagus, or the trachea can lead to serious and even life-threatening emergencies (193,267). Children with these injuries may complain of inability to speak, respire, or swallow. In addition, pulses in the ipsilateral upper extremity may be diminished or absent, and the neck veins may be distended. Because of the potentially life-threatening nature of this specific injury, every child with a suspected clavicular injury should be carefully evaluated for these signs and symptoms before the initiation of treatment.

Radiographic Studies

In all age groups, an AP radiograph is the standard study with which a clavicular fracture is initially evaluated. For neonates, however, ultrasonography has been a valuable supplement in establishing the diagnosis of clavicular fractures (199,212). Ultrasonography is particularly useful in detecting occult clavicular fractures as well as sternoclavicular joint dislocations in this early age group (199,241).

For older children, other radiographic studies may be necessary to supplement the AP radiograph in evaluating the clavicular fracture. For fractures in the middle third of the clavicle, several views may be beneficial: the cephalad-directed views, the apical oblique view, and the apical lordotic view. The cephalad-directed views are helpful in illustrating the degree of fracture displacement (Fig. 17-22). These views are taken with the x-ray beam 20 to 40 degrees cephalad to the clavicle (Fig. 17-23A). The apical oblique view is taken with the x-ray beam 45 degrees lateral to the axial axis of the body and 20 degrees cephalad to the clavicle. This view is better suited to identify fractures in the middle third of the clavicle, where significant curvature is present in the bone (265). The apical lordotic view is a perpendicular view of the anteroposterior radiograph. It is taken laterally with the shoulder abducted more than 130 degrees (Fig. 17-23B). This degree of shoulder abduction, however, can cause significant discomfort in children with acute clavicular fractures. Therefore, this radiographic view may be better suited for evaluating the healing of the clavicular fracture rather than for the initial assessment of the fracture (245).

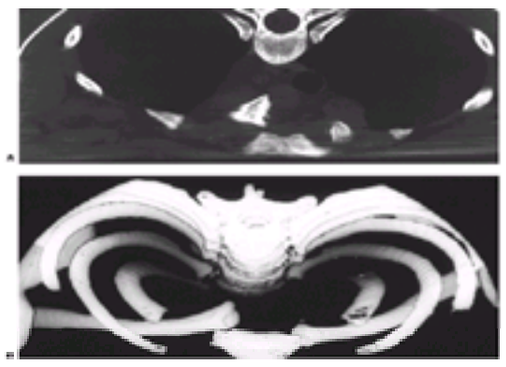

FIGURE 17-22. A: Computed tomography image of the clavicle showing posterior retrosternal dislocation of the medial end of the clavicle. **B:** Three-dimensional reconstruction of image shown in A.

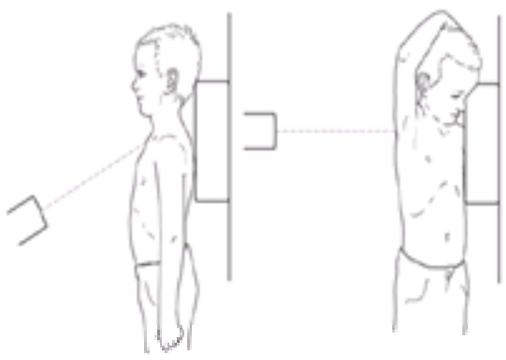

FIGURE 17-23. A: Cephalad-directed views. **B:** Apical lordotic view.

Fractures in the lateral aspect of the clavicle may require additional radiographic views for full assessment. In addition to the views mentioned above, an axillary lateral view is helpful in evaluating the fracture and its displacement. If the injury in this portion of the clavicle or the acromioclavicular joint is not obvious on the obtained radiographs, a radiographic stress view may provide more useful information. A radiographic stress view is an AP radiograph of the lateral clavicle with distraction on the ipsilateral upper extremity. Distraction can be achieved by asking the child to hold 5 to 10 pounds of weight with his or her hand or by simply having an assistant gently pull the arm downward. The stress view may demonstrate subtle injuries to the distal clavicle or the acromioclavicular joint. If there are concerns about the integrity of the acromioclavicular joint, computed tomography (CT scan) may be essential for full evaluation of the injury.

Fractures in the medial third of the clavicle, including sternoclavicular dislocation, are sometimes difficult to characterize even with the radiographic views mentioned above. The “serendipity” view, where a broad x-ray beam with 40 degrees of cephalic tilt projects both clavicles on the same film, is helpful for evaluating fractures in this portion of the clavicle (Fig. 17-24) (246). By comparing with the uninjured contralateral side, the location of injury and the degree of displacement often can be determined. The most rapid and effective study for evaluating injuries in the medial third of the clavicle, however, is CT. CT provides detailed information about the

morphology of the medial clavicle, the medial physis, the degree of displacement, and possible injury to the underlying intrathoracic structures. Therefore, CT is an essential part of the evaluation of injury to the medial end of the clavicle and is recommended for both acute and chronic injuries.

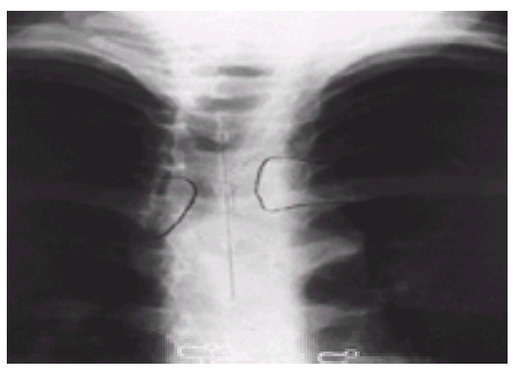

FIGURE 17-24. Serendipity view of the medial clavicle.

Classification

The most widely used classification for clavicular fractures, proposed by Allman, is based on the anatomic location of the fracture. (166) (Fig. 17-21). Type I fractures occur in the middle third of the clavicle and generally include all fractures lateral to the sternocleidomastoid muscle and medial to the coracoclavicular ligament. Type II fractures are in the distal clavicle, including and lateral to the coracoclavicular ligament. Type III fractures, which are relatively uncommon, are medial to the sternocleidomastoid muscle. Within this general framework, further classifications exist for injuries to the distal and medial ends of the clavicle.

Distal Clavicular Injuries

Distal clavicular injuries lateral to the coracoclavicular ligament and injuries to the acromioclavicular joint are categorized by a system proposed by Dameron and Rockwood (Fig. 17-25) (180). Although similar to the system for adult distal clavicular injuries, this classification system incorporates the observation that the distal clavicle displaces through a disruption in its periosteal sleeve rather than by true disruption of the coracoclavicular ligaments. It should be also noted that true acromioclavicular dislocations rarely occur in children. Most fractures in this region are either metaphyseal or physeal fractures (188,234). However, because distal clavicular epiphyseal ossification does not occur until age 18 or 19, these injuries may have the radiographic appearance of an acromioclavicular dislocation rather than a fracture (pseudodislocation) (188,234,261).

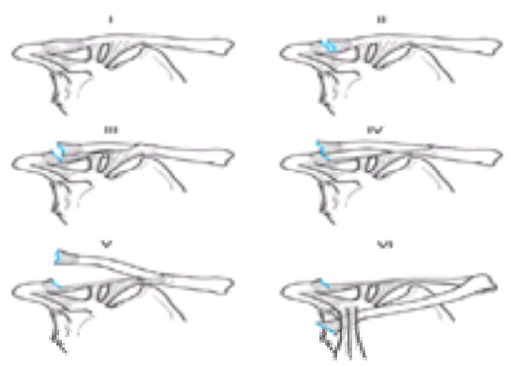

FIGURE 17-25. Dameron and Rockwood classification of distal/lateral fractures.

Type I distal clavicular injuries are caused by low-energy trauma and are characterized by mild strains of the acromioclavicular ligaments. There are no other soft tissue or bony abnormalities, and no gross changes are seen on radiographs. Type II injuries include complete disruptions of the acromioclavicular ligaments with mild damage to the superolateral aspect of the periosteal sleeve. Mild instability of the distal clavicle results, and minimal widening of the acromioclavicular joint may be seen on a radiograph. In type III injuries, complete disruptions of the acromioclavicular ligaments occur in addition to a large disruption in the periosteal sleeve. Noticeable superior displacement of the distal clavicle, with the coracoid–clavicle interval being 25% to 100% greater than the contralateral uninjured side, is seen on an AP radiograph (175,181). Similar soft tissue disruptions are seen in type IV injuries. The distal clavicle, however, is displaced posteriorly and is often imbedded in the trapezius muscle (169). Minimal changes may be noted on an AP radiograph, so an axillary lateral view is required to identify the posterior clavicular displacement. Type V injuries are similar to type III injuries. The difference lies in the fact that the superior aspect of the periosteal sleeve is completely disrupted in type V injuries. This allows subcutaneous displacement of the distal clavicle, occasionally splitting the deltoid and the trapezius muscles. On an AP radiograph, the coracoid–clavicle interval is more than 100% greater than the contralateral uninjured side. In type VI injuries, the distal clavicle is displaced inferiorly with its distal end located inferior to the coracoid process (194).

Medial Clavicular Injuries

The medial physis of the clavicle is the last physis in the body to close, and the fusion of this epiphysis to the shaft occurs as late as 23 to 25 years of age (208,239). The sternoclavicular ligaments attach primarily to the epiphysis, leaving the physis unprotected outside the capsule (214). Because of its unique anatomy, traumatic insults to the medial end of the clavicle in children typically result in fractures through the physis rather than dislocations through the sternoclavicular joint. Therefore, these injuries are categorized most appropriately in the Salter-Harris classification system (252). Most fractures at the medial end of the clavicle are Salter-Harris type I or II fractures. These fractures are further subdivided by the direction of the clavicular displacement, either anterior or posterior. Although anterior displacement of the clavicle occurs more frequently, more attention is given to fractures with posterior displacement due to the possibility of concomitant mediastinal injuries and potential emergent nature of the injury.

Surgical Anatomy

The clavicle appears early during embryonic development. By the 5th or 6th week of gestation, it begins ossification at two separate centers, medial and lateral (192,228,233). By the 7th or 8th week of gestation, its overall contour and shape are already formed (192). During childhood, approximately 80% of clavicular growth and lengthening occur at the medial physis (223,236). Despite this early ossification and growth, complete growth of the clavicle does not occur until early adulthood. The lateral physis continues to proliferate until 18 to 19 years of age, and the medial physis does not close until 23 to 25 years of age (238,239,261).

The distal clavicle articulates with the scapula through the acromioclavicular joint, a joint that lacks inherent structural stability. It is held together in part by the acromioclavicular ligaments, which are relatively weak secondary stabilizers. The primary stabilizers of the joint are the two coracoclavicular ligaments, the conoid and the trapezoid, which place the lateral end of the clavicle immediately next to the acromion. Although the distal clavicle and the coracoid process usually do not articulate, a coracoclavicular joint has been reported in adults (213). In children, the distal clavicle and the acromion are surrounded by thick periosteum that forms a protective tube around the bony structures. The coracoclavicular ligaments are attached to the periosteum on the inferior surface of the distal clavicle. Because these ligament attachments are stronger than the periosteum, displacement of the distal clavicle occurs through a disruption in the periosteum rather than by detachment of the ligaments. In fact, displacement of the distal clavicle through this periosteum in children has been likened to having “a banana being peeled out of its skin.” As mentioned above, the distal clavicular physis does not ossify until early adulthood (261). Therefore, fractures through the distal clavicular physis or metaphysis may

be mistakenly identified as acromioclavicular joint dislocations.

Medially, the clavicle articulates with the sternum and the first rib through the sternoclavicular joint. Similar to the acromioclavicular joint, this joint also lacks inherent structural stability. It is held together by a series of strong ligaments, including the intraarticular disc ligament, the anterior and posterior capsular ligaments, the interclavicular ligament, and the costoclavicular ligament (172). In children, the medial physis of the clavicle is still open, and the capsular ligaments attach primarily to the epiphysis (172,208,239). Therefore, injuries to the medial clavicle typically result in physeal fractures with the epiphysis attached to the sternum.

Along its course, the clavicle also serves as attachment sites for a number of different muscles. On its superior surface, the clavicular head of the sternocleidomastoid muscle is attached. On the posterior surface, the trapezius muscle is attached, whereas the pectoralis major and the deltoid muscles are attached on the anterior surface. Inferiorly, the clavicle provides attachment sites for the subclavius muscle as well as the clavipectoral fascia.

In addition to these muscle attachments, the clavicle provides protection to the subclavian vessels and the brachial plexus. These vital structures are located posterior to the clavicle, crossing the clavicle at the junction between the medial two thirds and lateral one third of the bone (Fig. 17-12). Due to this close proximity, the neurovascular status of the ipsilateral upper extremity may be jeopardized in children with displaced clavicular shaft fractures. In addition, as discussed above, posterior dislocation of the sternoclavicular joint can lead to compression or injuries of the great vessels within the mediastinum. Therefore, neurovascular status of the ipsilateral upper extremity must be documented before the initiation of treatment for any clavicular injury.

Biomechanics

The clavicle contributes significantly to the overall motion and optimal function of the upper extremity. In the anterior to posterior direction, the clavicle can protract and retract about 35 degrees (228). Laterally, it can rotate and elevate to contribute approximately 30 degrees to full shoulder abduction (164,203,228). The clavicle also provides the attachment sites for the major mobilizers of the upper arm in the pectoralis major and the deltoid muscles. Finally, together with the scapula, the distal clavicle forms the SSSC. As proposed by Goss, the SSSC provides a scaffold from which the upper extremity suspends and articulates in order to function (197).

Treatment Options

General Comments

Numerous methods of treating clavicular fractures have been described. In fact, it has been stated that over 200 methods of treatment exist (215). For most of these pediatric fractures, nonoperative treatment should be the prevailing rule rather than the exception. In addition, the importance of prevention cannot be overemphasized, because it is certainly the best of all the treatment options. Improved obstetrical care, use of adequate equipment and padding in contact sports, and updated safety equipment and conditions at child recreational facilities should lead to significant reductions in the incidence and complications of clavicle fractures.

Middle Third Fractures

Treatment of obstetrical clavicular fractures is always nonoperative. For most birth-related clavicular fractures, minimal or no treatment is recommended. If the infant appears to be in significant discomfort, the affected arm can be immobilized to the body for a short period of time, typically less than 2 weeks. Immobilization of the affected arm can be easily and effectively accomplished by using a safety pin to attach the long shirt sleeve to the shirt (211,221,253). The parents should be warned to not disturb the upper extremity by unnecessary excessive movements in the acute period. In addition, they should be informed that the infant will develop a noticeable mass over the fracture site which will typically resolve within 6 months (242).

Good to excellent results also can be expected from nonoperative treatment of most clavicle fractures in older children. A figure-of-eight splint is an acceptable method of nonoperative treatment and has been widely used with successful outcomes (207,230,242,255). It can be applied directly or after an attempt at closed reduction with retraction of the shoulders (235). In general, younger children do not require reduction of the fracture because their potential for remodeling is greater (235).

The figure-of-eight splint, unfortunately, can be uncomfortable for some children. In addition, inappropriate use of the splint, on rare occasions, can lead to a number of complications, including edema, compression of the axillary vessels, and brachial plexopathy (Fig. 17-26) (191,217,230). Use of a sling, on the other hand, is typically well tolerated by children and is not associated with any of these complications. Treatment of both nondisplaced and displaced clavicular fractures with a sling has shown remarkably good results. In fact, in comparison with a figure-of-eight splint, treatment of clavicular fractures with a sling resulted in similar final outcomes (167,207,259). Therefore, it appears that nonoperative treatment of middle third clavicular fractures with a simple sling can result in excellent outcomes without compromising the child's comfort.

FIGURE 17-26. A: Anteroposterior radiograph of comminuted clavicular fracture. **B:** Skin erosion over fracture fragment due to figure-of-eight splint.

Reported indications for operative treatment of clavicular fractures include severely displaced and irreducible fractures that threaten skin integrity, concomitant vascular injury requiring repair, irreducible compression of the subclavian vessels, compromise of the brachial plexus, and open fractures (202,204,229,240,268). In addition, as discussed separately in this chapter, concomitant displaced fractures in various regions of the scapula, including the acromion, the coracoid, and the scapular neck, may compromise the SSSC and require operative repair (197).

Distal Third Fractures

Injuries to the distal clavicle in the pediatric population typically are pseudodislocations of the acromioclavicular joint, with fractures through the metaphysis or the physis (186,234). The acromioclavicular joint and the coracoclavicular ligaments usually are undamaged, and most of the periosteal sleeve is intact. Therefore, exceptional potential for growth and remodeling exists for these fractures, allowing successful nonoperative treatment for most injuries to the distal clavicle.

Most investigators agree that undisplaced or minimally displaced injuries of the distal clavicle (types I, II, and III), should be treated without surgery (171,180,200,234,247). These injuries are managed with a sling or a figure-of-eight splint immobilization followed by early rehabilitation with range of motion exercises. Most children treated with nonoperative management demonstrate no significant long-term functional or cosmetic deficits.

The treatment of displaced types IV, V, and VI distal clavicle fractures remains controversial. Some investigators report that most children experience no functional deficits regardless of the method of treatment (171,200). Others report that distal clavicular injuries with either fixed or gross displacement should be treated with open reduction and internal fixation to prevent permanent deformity (168,175,180,182,188,200,234,248). One report suggested that although displaced distal clavicular injuries in children under 13 may be amenable to nonoperative treatment, those in children over 13 years of age should be treated with open reduction and internal

fixation (186).

Although no clear consensus exists for the treatment of grossly displaced distal clavicular fractures in children, as long as the integrity of the SSSC is maintained, it appears that neither nonoperative or operative management results in long-term deficit in the normal function of the shoulder. Treatment options, therefore, should be individualized for each child and his or her family based on their compliance as well as their acceptance of the possible cosmetic deformity.

Medial Third Clavicular Injuries

Most pediatric injuries in the medial clavicle are fractures through the physis. Similar to distal clavicular injuries, these fractures have vast potential for healing in an acceptable position, and subsequent remodeling and nonoperative management is appropriate.

Nondisplaced fractures of the medial physis do not require active intervention. Symptomatic treatment is all that is required for these stable fractures. In fact, nondisplaced fractures often are missed during initial examination and are only discovered after a mass is noted over the medial clavicle. The parents should be warned that the mass is a healing callus surrounding the fracture and that it should remodel and disappear in 4 to 8 months.

Most fractures with anterior displacement also should be treated without surgery. Open reduction and internal fixation of these injuries may lead to significant, and sometimes life-threatening, complications (178,190,223,224). Attempts at closed reduction, especially in younger children, are not required because these fractures will remodel and result in minimal or no residual deformity. The maneuver for the closed reduction requires applying longitudinal traction to the ipsilateral upper extremity while the shoulder is abducted to 90 degrees (253). Gentle posterior pressure also should be applied over the fracture to encourage reduction. After the reduction is accomplished, the clavicle should be immobilized with a figure-of-eight splint or cast (253).

Treatment of medial clavicular fractures with posterior dislocation requires immediate evaluation for the presence or absence of concomitant mediastinal injuries. If physical examination and radiographic evaluations do not reveal mediastinal injuries, these fractures are treated with a controlled closed reduction. The fractures can be expected to heal and remodel without any significant residual deformity or pain. If mediastinal structures are compromised or injured, immediate attempts at closed reduction are required. Under adequate anesthesia, the displaced medial clavicle is held manually or with a towel clip and manipulated anteriorly to reduce the fracture. This reduction maneuver should be performed while longitudinal traction is applied to the ipsilateral upper extremity (253). If closed reduction is unsuccessful, open reduction, with the assistance of a thoracic surgeon, may be required. Once reduced, these fractures typically are stable and require no internal fixation. Infrequently, however, some fractures may involve a physeal disruption of the medial border and require a suture repair. Immobilization with a figure-of-eight splint or cast for a short period of time should provide adequate environment for fracture healing.

AUTHOR'S PREFERRED METHOD OF TREATMENT

The approach to neonatal or birth injuries is one of diagnosis and reassurance and education of the parents. The family is told that a bump will develop over the fracture site and that the fracture will heal uneventfully. If the infant initially demonstrates discomfort with the fracture, the long arm sleeve of the infant's shirt can be pinned to the shirt for 7 to 10 days to provide adequate immobilization.

Older children who present to the emergency room generally have a significant level of pain and discomfort. I prefer to use a figure-of-eight harness to provide retraction of the shoulder, to gain length at the level of the fracture, and to reduce pain. With the use of the figure-of-eight harness, it is important to inspect the skin on weekly follow-ups for 3 weeks to assure that no unusual sharp bone fragments create any skin problems at the site of passage of the figure-of-eight harness over the fracture (Fig. 17-26). The parents are once again informed that the bone will take a couple of months to remodel and that there may be a bump for up to a year after the fracture.

The indications for operative management for clavicular fractures in children are rare and include fractures with the potential to develop both thickness loss over the apex of a fracture or a direct impingement of the clavicle on either the brachial plexus or subclavian vessel. Even with these fractures, gentle manipulation and closed reduction should be attempted. If open repair is done, the fractured clavicle generally can be placed into the periosteal sleeve and the periosteal sleeve can be repaired over the fractured clavicle without the need for additional internal fixation.

Most fractures of the medial end of the clavicle, with or without anterior displacement or posterior retrosternal dislocations, can be treated nonoperatively. Generally 3 to 6 weeks in a figure-of-eight harness or sling is adequate after stable reduction.

Anterior displacements of the medial end of the clavicle generally are associated with a physeal disruption and usually can be treated with closed reduction. Longitudinal traction is applied to the upper extremity with moderate abduction of the humerus and general pressure is applied over the scapuloclavicular joint. Persistent instability of the scapuloclavicular joint is acceptable in anterior displacements because of the significant potential for remodeling in this area. After 2 to 4 weeks of immobilization, a program of progressive rehabilitation can begin.

Posterior dislocations of the medial end at the clavicle of the sternoclavicular joint may be either pure dislocations or associated with a physeal disruption and may be acute life-threatening injuries. Most of these injuries can be treated successfully with closed reduction with general anesthesia and stand-by support of the cardiovascular service. The technique for the closed reduction is quite specific and involves the placement of a bolster in the midline along the level of the spine and spinous processes. Both humeri are adducted to the level of the chest, and anterior pressure is placed over the deltoid and humeral head toward the table with a downward pressure over both proximal humeri. This is generally sufficient to provide adequate retraction of the shoulder and restore the length of the clavicle at the level of the sternoclavicular joint. Further downward pressure to the level of the table provides a fulcrum force to reduce the medial end of the clavicle anteriorly into the sternoclavicular joint. Rarely a towel clip may be required. It is placed subcutaneously through the medial third of the clavicle to aid in the reduction process. Open reduction of the medial end of the sternoclavicular joint is indicated when closed reduction fails or results in an unstable retrosternal displacement. If the dislocation is unstable, generally repair of the capsule with a nonabsorbable suture through the capsule of the joint at the level of the sternum through holes drilled into the medial end of the clavicle is sufficient to provide anterior stability of the dislocation. Internal fixation is not recommended in this location.

Most injuries to the distal end of the clavicle in children and adolescents are treated nonoperatively. These fractures heal rapidly because of the early deposition of periosteal new bone and remodeling. Generally, patients can be treated with a sling and pain management with appropriate oral analgesics and ice to control swelling. Early range-of-motion therapy is recommended at approximately 10 days to 2 weeks. Clinical union is generally seen by 4 to 6 weeks.

For the rare type IV, V, or VI displaced distal clavicular injury, an open approach can be useful in replacing the distal clavicle in its periosteal sleeve, and repair of the periosteal sleeve may be sufficient to provide adequate fixation.

Complications

Implants and internal fixation devices for clavicular fractures have been associated with numerous complications, including hardware migration, infection, and nonunion (178,190,223,224,231,256,257). Although most of these complications can be adequately treated, some can have fatal results (178). Therefore, whenever possible, fixation of pediatric clavicular fractures should use minimal or no hardware.

Serious vascular injuries also have been described in association with clavicular fractures, including subclavian and axillary artery disruption, subclavian vessel compression, and arteriovenous fistula (170,202,209,227,262). In addition, displaced fractures of the medial clavicle may result in compression or injury of the great vessels within the mediastinum (193,267). Occasionally, these compressions can be relieved nonoperatively by reducing the fracture and eliminating the excessive pressure on the vessels (202,227). However, if nonoperative treatment does not alleviate the compression, operative reduction of the fracture and possible vascular repair may be required. Certainly, if the structural integrity of the vessels is compromised, operative repair by an experienced vascular or thoracic surgeon is necessary.

In addition to the compression of the great vessels, displaced medial clavicular fractures can result in compression of the trachea and esophagus, causing difficulty with respiration or swallowing (193,267). Clavicular fractures resulting from severe trauma can be associated with pneumothorax (185,225). Rarely, a pneumothorax results from obstretrical clavicular fractures (220).

Neurologic deficits of the brachial plexus have been reported in association with clavicular fractures. Brachial plexus palsy may present early or late after the traumatic insult, and occasionally requires operative reduction of the fracture (170,183,184,202,205). Rarely, such nerve deficits can result from inappropriate use of the figure-of-eight splints (217,230). Although permanent nerve deficits have been reported, most brachial plexus injuries resolve spontaneously (205,210).

Although malunions are frequent soon after fracture healing, most children experience no long-term deformities because of their tremendous potential for remodeling. Occasionally, however, significant deformities such as clavicular reduplication and cleidoscapular synostosis may require further intervention (234,244).

Clavicular pseudarthrosis may be congenital, traumatic, or pathologic (174,176,231,238,243,263,266), but most often it results from previous injuries. Clavicular pseudarthroses, especially congenital or embryonic types, often are completely asymptomatic and require no treatment. Operative indications for pseudarthrosis include unacceptable cosmetic deformity and pain (173,176,222,266). It must be noted, however, that operative repair with grafting and internal fixation of the pseudarthroses can result in other complications, such as pneumothorax, subclavian vessel damage, air embolism, and brachial plexus deficit (187).

FRACTURES OF THE HUMERAL SHAFT

Embryology and Development

The end of the embryonic period is marked by vascular invasion of the humerus at age 8 weeks. During the subsequent fetal period, the humerus resembles the adult bone in both form and muscular relationships (357,364). A bony collar is present very early with subsequent enchondral bone formation. The secondary ossification centers at the ends are not generally ossified radiographically until after birth (364).

Applied Anatomy

Osseous

The proximal metaphysis of the humerus is wider than the thinner, triangular shaft. Distally, this flattens and widens to form the condylar region of the elbow. The deltoid inserts into a protuberance midway down the shaft known as the deltoid tuberosity. Distal to the tuberosity, the muscular spinal groove wraps posteriorly around the humerus. The groove gives origin to the uppermost fibers of the brachialis. The periosteum of the humeral diaphysis is thick and provides good remodeling potential (327,331). The main vascular foramen is at mid-shaft, but accessory foramina are common—most enter the anterior surface usually below the main foramen, but many are posterior (308,364).

Nerves

The radial nerve ordinarily lies close to the inferior lip of the spiral groove but not directly in it (515). The profunda artery either accompanies the radial nerve or passes in a second narrower grove. The nerve is protected from the humerus by a layer of either the triceps or the brachialis until the lower margin of the spiral groove near the lateral intermuscular septum (515). The ulnar nerve passes from anterior to posterior just distal to the humeral mid-shaft. A well-formed arcade and internal brachial ligament may hold the ulnar nerve (395). This ligament is always posterior to the medial intermuscular septum and subsequently joins the medial intermuscular septum proximal to the medial epicondyle. A few patients with a modified arcade have only superficial fibers of the triceps medial head passing superficial to the ulnar nerve and none deep to the nerve, making the nerve very close to the bone and vulnerable during a fracture (395).

Muscles

Several major muscle attachments occur throughout the metaphyseal and diaphyseal regions of the humerus. The pectoralis major muscle inserts laterally and distal to the bicipital grove along the anterior aspect of the humerus. The latissimus dorsi and teres major insert on the upper medial aspect of the humerus medial to the bicipital groove. The deltoid courses from the clavicle, acromion, and scapular spine to insert over a broad area of the deltoid tuberosity. The coracobrachialis arises from the coracoid process and inserts on the anterior medial aspect of the humerus at the junction of the middle and lower thirds. The brachialis originates from the anterior humerus about midway down the shaft. Knowledge of these muscles and their directions is essential to understand fracture displacement and treatment (327,383).

Mechanisms of Injury

Birth Injuries

Humeral fractures are more common in breech presentations and with macrosomic infants. The most difficult position is when the child's arms have gone above the head with maneuvers to bring the arm down after version and extraction (423).

Child Abuse

Humeral fractures in child abuse represent 61% of all new fractures and 12% of all fractures (417,441). Shaw et al. (482), in a retrospective review of 34 humeral shaft fractures in children under 3 years of age, found that most occurred accidentally: only 6 were classified as caused by probable abuse. Child abuse must be part of the differential diagnosis in children with humeral diaphyseal fractures (441). The fractures may be spiral from a twisting injury or transverse from a direct blow.

Older Children

Older children sustain primarily transverse fractures from direct blows to the arm, frequently from falls, pedestrian/vehicle accidents, gunshot wounds, and machinery. Sports injuries are direct from contact sports or indirect from throwing. Throwing injuries occur as a stress injury from overuse or acutely during the throwing cycle from poor mechanics (269,303,359,363,366,381,415,490,493,502,514). A stress fracture also has been reported in an adolescent tennis player (458). Acute throwing fractures result from a sudden external rotation torque developed on the distal humerus with concomitant proximal internal rotation from the pectoralis major between the cocking and acceleration phases (339) as the shoulder external rotation and elbow flexion suddenly change to shoulder internal rotation and elbow extension. Humeral fractures may occur from arm wrestling in older adolescents (284,418,433). Many humeral fractures are pathologic through simple bone cysts or through dysplastic bones from osteogenesis imperfecta or fibrous dysplasia. Occasionally, pathologic fractures occur from benign or malignant tumors.

Classification

The simplest classification for humeral diaphyseal fractures describes the location (proximal third, middle third, or distal third, or the diaphyseal–metaphyseal junction), the pattern (spiral, short oblique, or transverse), the direction of displacement, and any tissue damage. Anatomically, the location is noted as proximal to the pectoralis major insertion, between the pectoralis major and deltoid insertions, below the deltoid insertion, or at the distal metaphyseal–diaphyseal junction (332). Humeral shaft fractures may be segmental, with fractures of the shaft and neck (492), or associated with shoulder dislocation (283). If they are associated with fractures of the ipsilateral forearm, they result in the so-called “floating elbow” (491).

The Association for the Study of Internal Fixation (AO-ASIF) has a classification for humeral shaft fractures (435), but it is not very applicable to most children's fractures, and like most classifications, it is subject to interobserver variability (393).

Incidence

Fractures of the humeral shaft represent 10% or less of humerus fractures in children (316,392,412) and 2% to 5.4% of all children's fractures (316,513). They are most common in children under 3 and over 12 years of age (285). The incidence is greater in children with more severe trauma (470). The incidence is 12 to 30 per 100,000 per year (404,513,518). Birth injuries to the humerus have a reported incidence ranging from 0.035% to 0.34% (306,423).

Signs and Symptoms

Evaluation of the Neonatal Shoulder

History

The infant who does not move the shoulder poses a diagnostic challenge. Establishing and evaluating a differential diagnosis is the first concern. By history, was the delivery normal? When was the problem noticed? Does the child move any part of the extremity? Was there a history of maternal gestational diabetes or of fetal macrosomia? Does the child nurse from each breast? A broad, useful differential diagnosis consists of clavicle fracture, proximal humeral physeal fracture, humeral shaft fracture, shoulder dislocation, brachial plexus palsy, septic shoulder, osteomyelitis, hemiplegia, and child abuse.

Examination

Initially, the child should be observed for spontaneous motion of the upper extremity. Is there any hand or elbow motion? Are there any areas of swelling, ecchymosis, or increased warmth? Does the child move the ipsilateral lower extremity? The clinician should carefully palpate each area of the upper extremity, starting with the clavicle and comparing it carefully with the opposite side for any change in soft tissue contour or tenderness. The upper arms and shoulders should then be examined, looking for any tenderness in the supraclavicular fossa. Lastly, the spine should be examined for tenderness or swelling.

Imaging Studies

Radiographs may be needed of the shoulder, clavicle, humerus, and cervical spine. Often the shoulder, clavicle and humerus can be seen on a single anteroposterior view of both upper extremities and the chest. Ultrasonography can be used to identify a fracture of the clavicle or the proximal humeral epiphysis, a shoulder dislocation, or a shoulder effusion. A computed tomography (CT) scan or arthrogram may be necessary. The radiographic findings for each fracture are discussed in the particular anatomic sections.

Birth Fractures of the Humerus

In the newborn, a humeral fracture can simulate a brachial plexus palsy with pseudoparalysis and an asymmetric Moro reflex. The fracture site is tender and may have swelling or ecchymosis. The diagnosis is confirmed by plain radiography (387,423).

Older Children

In older children, the diagnosis is usually evident with pain, swelling, and unwillingness to move the arm. The arm is often supported by the opposite hand and is held tightly to the body (Fig. 17-27). It is essential to perform a complete neurologic and vascular examination of the extremity before any treatment except emergency splinting.

FIGURE 17-27. A young patient with a humeral shaft fracture, holding the arm tightly to his side.

Children with torus or greenstick fractures may have localized tenderness but no deformity. In multiple-trauma victims, careful evaluation should be made of the arm because the diagnosis can be missed, especially if the patient is medically unstable (406). Humeral fractures should be sought in patients with massive upper extremity trauma.

Radiographic Findings

Birth fractures of the humerus are usually quite apparent on anteroposterior and lateral radiographs of the humerus. In older children, radiographs should be taken in both the anteroposterior and lateral planes to obtain two films perpendicular to each other. Most fractures are easily visualized on these radiographs. A true lateral view of the distal humerus is noted by superimposition of the posterior supracondylar ridges of the medial and lateral epicondyles (488). A supracondylar process of the humerus, when present, is best seen on an oblique radiograph showing the anterior medial aspect of the distal humerus.

Displaced fractures above the pectoralis major have marked abduction of the proximal fragment with external rotation by the rotator cuff attachment (327,332). The distal fragment is pulled proximally by the deltoid and medially by the pectoralis major. Displaced fractures between the pectoralis major and deltoid insertions show adduction of the proximal fragment from the pectoralis major and shortening by pull of the deltoid on the distal fragment. Fractures below the deltoid insertion have abduction of the long proximal fragment by the deltoid, but with shortening and medial displacement of the distal fragment by the pull of the biceps and triceps (332).

Pathologic bone may be evident (500). Simple bone cysts are a common cause of fractures. Periostitis or periosteal reaction of the humerus necessitates differentiating osteomyelitis or Ewing's sarcoma from a stress fracture; every effort must be made to identify a cortical fissure using other imaging techniques (275,299).

Holstein and Lewis described a short oblique fracture of the distal third of the humerus with potential radial nerve palsy after closed reduction (385). This has been called the Holstein-Lewis fracture.

Treatment

Birth Injuries

Neonatal humeral shaft fractures heal and remodel quite well, with 40% to 50% remodeling within 2 years (Fig. 17-28) (289). Reported treatments include a sling and swathe (384) or a traction device using the von Rosen splint (277). The primary potential complication of birth injuries is an internal rotation deformity. Therefore, the fracture is best stabilized by splinting the arm in extension. If the parents will be moving the child, the splinted arm can be bound to the chest with a soft wrap. Children with arthrogryposis and brachial plexus palsies are prone to internal rotation contractures of the shoulder; these can be exacerbated if the birth fracture's rotation is not controlled.

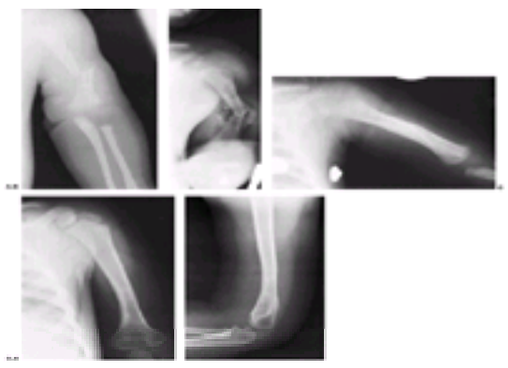

FIGURE 17-28. A: Fracture of the left humerus in a neonate that occurred during a difficult delivery. **B:** After 2 weeks of immobilization, clinical and radiographic union is evident, but with anterolateral angulation. **C:** At 2 months after injury, there is considerable remodeling. **D and E:** At 20 months, there is essentially complete remodeling of the fracture.

Stress Fractures

Virtually all nondisplaced stress injuries heal well with temporary rest and immobilization (269,337,359,363,415,458,493,503,514). They can displace if not treated (269). Displaced stress fractures should be treated like other humerus fractures.

Acceptable Alignment

Because the humerus is not a weight-bearing bone, it does not require the precise mechanical alignment of the lower extremity. The marked mobility of the shoulder also allows some axial and rotational deviation without functional problems. Severe internal rotation contractures can cause difficulties in some overhead activities such as ball throwing and facial hygiene. Varus of 20 to 30 degrees is necessary before becoming clinically apparent (Fig. 17-29) (332,397,457). Anterior bowing may be apparent with 20 degrees angulation (397). Functional impairment does not occur with 15 degrees or less of internal rotation deformity (332). Even adolescents can correct up to 30 degrees spontaneously (332). Beaty (285) gives guidelines based on the patient's age: children under 5 years of age tolerate 70 degrees angulation and total displacement, children 5 to 12 tolerate 40 to 70 degrees angulation, and children over 12 tolerate 40 degrees and 50% apposition. However, bayonet apposition is acceptable (292–294), with 1 to 2 cm of shortening well tolerated (Fig. 17-30). Clinical appearance is more important than radiographic alignment.

FIGURE 17-29. A and B: Radiographic appearance of a malunited humerus fracture showing 20 degrees of varus. **C and D:** The same patient with no deformity or disability, despite her thin extremities.

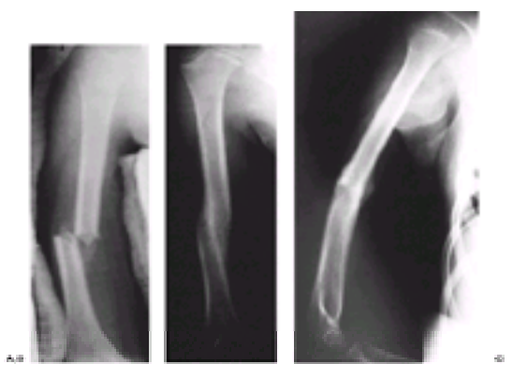

FIGURE 17-30. A: Humerus fracture allowed to heal in slight varus and bayonet apposition. **B and C:** The ultimate result, with essentially normal alignment.

Nonoperative Treatment

Nonoperative treatment often increases internal rotation by 3 to 12 degrees at the expense of external rotation (332). This rarely is a functional problem. Nonoperative methods include a sling and swathe, the U plaster, a hanging arm cast, a thoracobrachial cast or dressing, a coaptation splint or functional bracing, and traction.

Sling and Swathe

The simplest form of treatment for fractures is a sling and swathe. It is sufficient for patients with minimally displaced greenstick and torus fractures (375,457). Although this treatment may yield good results in displaced fractures (489), it can be quite difficult to control anterior angulation (386) and may be uncomfortable.

U Plaster-Sugartong

Böhler (292) described a U plaster similar to the sugartong splint used on forearms. Plaster of appropriate width for the upper arm is formed from over the shoulder along the lateral aspect of the arm, underneath the olecranon, and along the medial aspect of the arm to the axilla. Cotton webbing is placed between the plaster and the skin, and the plaster is secured using a wrap (Fig. 17-31). Results have been quite good (332), particularly in children (398). Holm (384) suggested applying benzoin before the cotton webbing and using a collar-and-cuff sling about the wrist. To prevent slippage, Shantharam (477) suggested applying the splint from the base of the neck, over the shoulder, and around to the axillary fold, with a strap securing the proximal end to the chest. The U plaster may not control alignment satisfactorily in more displaced fractures, which may require a thoracobrachial cast (293,384,457) or internal fixation. Böhler actually abandoned the immediate use of the U plaster for a thoracobrachial cast because of problems with early swelling (293,294)

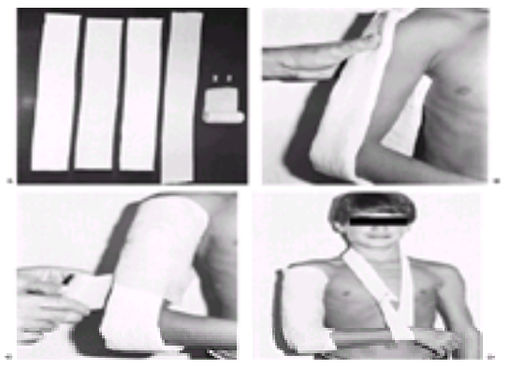

FIGURE 17-31. Coaptation splints with collar and cuff. **A:** The material used for a sugartong arm splint is two pieces of cast padding rolled out to the length of the plaster-of-paris splint and applied to each side of the splint after it is wet. The splint is then brought into the tubular stockinette of the same width but 4 inches longer than the splint. **B:** The plaster splint is applied to the arm from the axilla up to the tip of the acromion. **C:** As the plaster is setting, the splint is molded to the arm. An elastic bandage holds the splint in place. **D:** Stockinette is applied and attached to the wrist to form a collar-and-cuff sling.

Hanging Arm Cast

The hanging arm cast, described by Caldwell as a technique already in use (305), consists of a long arm cast with a sling around the neck tied to the cast along the forearm. The weight of the cast and arm provides longitudinal traction. The position of the sling is modified to correct anterior or posterior angulation and varus or valgus. Rotation is difficult to control. Stewart and Hundley suggested not using it in children under age 12 because children cannot keep their arms in a dependent position during sleep and often keep the arm supported rather than hanging while awake (495). However, excellent results are reported in patients under age 10 (516). This is probably due to the marked remodeling and potential for good results regardless of treatment in children. Possible complications of the hanging cast include inferior shoulder subluxation (516), decreased external rotation (320), and shoulder stiffness (279), but these are rarely significant in children.

Thoracobrachial Immobilization

Severely unstable fractures uncontrollable in a hanging cast or U plaster may necessitate extending the cast to the chest as a thoracobrachial cast or splint (293,294,384,386,457). Various types of thoracobrachial dressings are often described as a Velpeau, but technically this is incorrect: Velpeau described a thoracobrachial bandage with acute elbow flexion. If a thoracobrachial cast or splint is used for a grossly unstable fracture, usually only a few degrees of abduction is necessary (384). Distal diaphyseal fractures rarely require extension to the chest.

Functional Bracing

Functional bracing, as described by Sarmiento (473), has been quite effective in adults (280,340,354,371,408,432,437,445). It may be difficult to use in children because size differences require a customized brace for each patient or a large supply of braces; however, modern thermoplastics can keep this economical (Fig. 17-32) (286). A prefabricated brace is placed on the initial visit if possible or on subsequent visits after placement of a U plaster or sling and swathe at the initial evaluation (520). The patient must be followed closely and the splint tightened as needed. It should not be used in bedridden patients because of loss of gravity support (280). Sarmiento (270,473) noted difficulty in controlling anterior angulation and indicated that patients should not lean on the elbow. The results in adults may be functionally superior to those of the U plaster (481).

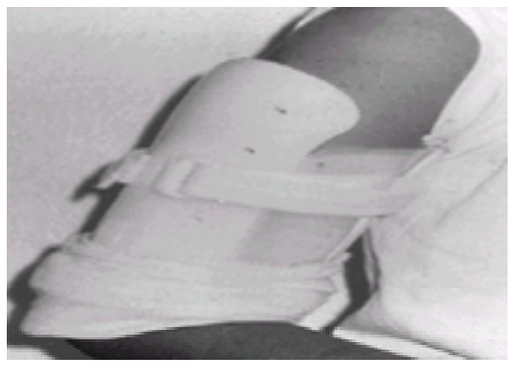

FIGURE 17-32. Light plastic functional braces are useful to maintain alignment and allow early restoration of motion, particularly in older children and adolescents.

Traction

Side-arm and overhead skin and skeletal forms of traction have been described (276,384,457,509). If olecranon skeletal traction is used, the AO method of an eye screw in the olecranon is less likely to produce ulnar nerve irritation than is a transolecranon pin (435,457). Excessive traction can lead to nonunion in adults (382) and elbow dislocation in children (376).

Operative Treatment

There are several surgical alternatives for humeral diaphyseal fractures: pinning, external fixation, intramedullary rodding, screw fixation, and compression plating. Biomechanically, interlocking rods are the stiffest in bending, and dynamic compression plating is stiffest in torsion. Flexible intramedullary rods are not as stiff as intact bone (379).

Open Reduction and Internal Reduction

Open reduction and internal reduction can be performed through either a posterior triceps-splitting approach [as advocated by the AO group (435,468)] or through an anterior lateral approach between the brachialis and brachioradialis with extension proximally between the deltoid and pectoralis (287,348). The normal 4.5-mm dynamic compression plate does not provide adequate stability for the adult humerus shaft. The broad 4.5-mm dynamic compression plate is designed to allow compact screw placement without causing excessive stress on the humerus (435). At least six cortices of screw fixation proximal and distal to the fracture site are needed. With either the anterolateral or posterior approach, the lateral intermuscular septum should be split in the distal third to release the radial nerve's tether. Interfragmentary lag screws should be used when possible. The plate should be slipped underneath the radial nerve and vessels and some muscle placed between the plate and the nerve. Multiple screws in oblique fractures without a compression plate are unsatisfactory in adults (468) but may be sufficient in children. Extensively comminuted fractures should be grafted with autologous cancellous bone.

Generally, the results are good (287,377,378,436,517,523), and plating is particularly advocated in multiple-trauma patients to facilitate nursing care and management of other injuries (287). Potential complications include radial nerve palsy, infection, delayed union, nonunion, and failure of fixation (523).

Intramedullary Rodding

Several types of intramedullary rods are available. Currently, there are no indications for reamed intramedullary nailing in children because of potential proximal

physeal damage and the small diaphyseal diameter. However, they may be used in older adolescents if the risk of physeal arrest is minimal and the canal has sufficient diameter (461). Reamed nailing has been reported in patients as young as 16 (326,328). The results are generally good (326,338,372,391,399,426,456,466,505,507,521), with a low risk of nonunion and infection (278).

Unreamed nails, such as Ender nails, Rush rods, or flexible titanium rods have been used primarily in adults. Nails or rods can be inserted via a posterior triceps-splitting approach through a hole just above the olecranon fossa. This can be useful for rapid management of fractures, including open fractures in patients with multiple trauma (303,315,323,335,373). Rods should not be inserted through the greater tuberosity in children (except under extenuating circumstances) because of the proximal humeral physis and the potential for shoulder impingement (421,467,494). Inserting these relatively large rods through the epicondyles results in a high incidence of nail back-out (373).

There are two techniques of using small, flexible, smooth wires. In the Hackethal technique (370), fluoroscopy is used with a tourniquet placed on the upper arm. A hole is made just proximal to the olecranon fossa using a triceps-splitting approach. Smooth, blunt-tipped Steinmann pins are placed up the canal of the humerus, progressively filling the canal with smaller and smaller pins as needed (Fig. 17-33). Results are generally good (313,336,341,380,430,446,522), although pin back-out can be a problem and care must be taken not to distract the fracture site. The rods should be bent 90 degrees at the cortical window (446). This technique may be useful for segmental and pathologic fractures (414).

FIGURE 17-33. The Hackethal technique involves multiple smooth pins placed up the humeral shaft through a cortical window just above the olecranon fossa. The pins are placed until the canal is filled.

The other technique consists of using small smooth rods or Steinmann pins placed through the epicondyles (413,431). The tips of the rods should be blunt and slightly bent. These are placed through the lateral epicondyle or through both the medial and lateral epicondyles. A hole is made in the epicondyle, and a blunt-tipped Steinmann pin is tapped up the diaphysis using a mallet or passed by hand, with a drill chuck holding the pin. The bend on the tip of the rods facilitates crossing the fracture site and manipulating the fracture reduction. A splint is necessary postoperatively. Alignment need be only within the tolerances for a closed reduction (Fig. 17-34).

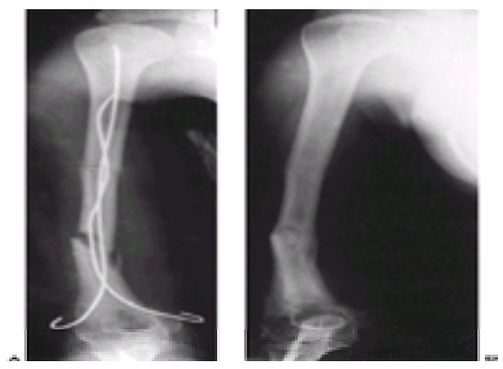

FIGURE 17-34. A: A segmental fracture difficult to align by nonoperative methods treated with two intramedullary smooth pins. **B:** Alignment need be only within the same tolerances as closed reduction.

External Fixation

Both unilateral and multiplanar external fixation are occasionally useful for humeral shaft fractures (276,333,394,396). External fixators are primarily useful for severe open fractures or as an alternative to internal fixation. In patients with open fractures, immediate external fixation with subsequent bone grafting yields good results (455,486). External fixation can be combined with internal fixation for immediate stability (325) for early rehabilitation. Severe open fractures with bone loss can be treated with primary shortening followed by callus distraction (469) to provide early soft tissue coverage and subsequent restoration of humeral length. Care must be taken during pin placement to avoid radial nerve injury. If screws are used, limited open screw placement can prevent this injury (455). Ring fixators may be useful for reconstructing the injured humerus (304,310,311,321,389,390,484,485).

Operative Versus Conservative Treatment

Because most humeral fractures are controllable nonoperatively, there are few surgical indications (288). Potential operative indications include open fractures, multiple trauma, bilateral injuries, arterial injuries, compartment syndromes, pathologic fractures, significant nerve injuries, inadequate closed reduction, and ipsilateral upper extremity injuries or paralysis.

Preadolescents can almost always be managed nonoperatively, except with severe soft tissue injury. If fracture reduction cannot obtain less than 30 degrees varus and 20 degrees anterior angulation in older children and adolescents—or more importantly, if the arm appears deformed—alternatives such as internal fixation, intramedullary rodding, external fixation, a thoracobrachial cast, or traction should be considered. Inadequate closed reduction is most common in obese patients and in thin women with large breasts (468). However, obesity tends to hide the deformity of the fracture, and large breasts are seldom encountered in children.

Open fractures may require fixation. Small, stable grade 1 wounds can still be managed using coaptation splints or other closed methods. Unstable open fractures should be stabilized with internal or external fixation to protect soft tissues (318,335,409,420,468,510).

Multiple-trauma victims are often best treated with internal or external fixation for more rapid mobilization (285,287,303,348,416,425). This is particularly true in patients with chest injuries, where thoracobrachial immobilization would compromise pulmonary care (335,416,420). Excellent results have been reported with external fixation (318,394,455,486), retrograde rodding using Ender nails or Rush rods (303), and internal fixation (287). In older adolescents, more rigid locked or unlocked intramedullary rodding can be used for patients requiring their upper extremities for mobility (348). However, this luxury does not exist for younger children.

Arterial injury and compartment syndromes requiring fasciotomy are potential indications for internal fixation (353,451,460,487). Continued fracture mobility can damage a vascular anastomosis (355,428,460,487), and fasciotomy can make the fracture less stable. Temporary vascular shunting before internal fixation allows the orthopaedist and the vascular surgeon to work under optimal conditions (317).

Most pathologic fractures in children, including those from malignancy (463), fibrous dysplasia (360,492), osteogenesis imperfecta, and simple bone cysts, can be

treated nonoperatively. Simple bone cysts are discussed later in the section on proximal humerus fractures. Occasionally, patients with osteogenesis imperfecta require intramedullary rodding using Bailey-Dubow rods. A report of a 6-year-old with progressive ossifying fibrodysplasia suggests that internal fixation may prevent stiffness after fractures in this condition (438). In fractures secondary to malignancy, intramedullary rodding is necessary if extensive cortical loss causes instability (322,326,411,421,504). Spontaneous fracture in a severely brain-injured or unresponsive cerebral palsy patient is best treated nonoperatively (508).

Ipsilateral injuries, particularly fractures of the proximal or distal humerus and of the forearm, can be difficult to control. In adults with a floating elbow, internal fixation of the humeral fracture provides optimal results (303,405,464). This is also true for supracondylar humeral fractures in children but is not documented in diaphyseal fractures (491). The floating elbow is often associated with other organ system injuries; nerve injury occurs in up to 50% of these patients (448).

Humeral shaft fractures with ipsilateral brachial plexus palsies in adults heal best with open reduction and internal fixation (300). The same is true with spinal cord injuries (358). Functional bracing is precluded in these patients because the muscles do not function. Because of the excellent healing potential in children, they may be treated nonoperatively if satisfactory alignment can be maintained. Older adolescents should be treated like adults.

Radial Nerve Palsies

Radial nerve palsies with humeral shaft fractures have been reported in children (Fig. 17-35) (314,420). Primary radial nerve palsies occur at the time of the fracture; secondary radial nerve palsies occur after manipulation of the fracture. Many clinicians recommend exploration of primary (270,329,356,385,401,403,435,443,450,465,501) and secondary radial nerve palsies (285,332,356,443,450,483,506,513). The incidence of concomitant radial nerve palsy with a humeral shaft fracture ranges from 2.4% to 20.6% (291,336,403,420,427,449,465,479,511) and has been reported in 4.4% of children's humeral shaft fractures (420). Most occur with middle and distal humeral shaft fractures, but they may occur with more proximal fractures as well (427). In explored primary radial nerve palsies, the incidence of complete nerve laceration is small (420,443,479,488,511). Commonly, the nerve is tented over the bone, trapped in the fracture site, or contused. The natural history is excellent, with recovery ranging from 78% to 100% (271,291,296,297,338,356,361,443,449,450,470,479,511). Therefore, many clinicians recommend observation rather than early exploration (291, 338,356,361,443,449,450,470,479,511). Open fractures resulting in severe soft tissue injury requiring debridement should have the radial nerve explored and tagged (499) or preferably repaired (349). More severe open fractures should be stabilized using either intramedullary rodding or internal or external fixation to provide good soft tissue for radial nerve recovery. Early repair of the nerve provides the best anatomic results (290). Bostman et al. (297) recommended exploration and internal fixation in patients with bayonet apposition because the abundant callus may endanger nerve recovery (297). The recommended waiting time before radial nerve exploration ranges from 8 weeks to 6 months (270,271,332,338,386,427,449,450,457,483,513). Nerve grafting up to 18 months after the injury can provide good function (290,347). Seddon suggested a physiologic time of allowing 1 mm per day after the 1 to 2 months of Wallerian degeneration and nerve growth through the neuroma (475). Nerves grow 1 to 3 mm per day (475,476,498), and this rate has been used clinically with good success (362,499).

FIGURE 17-35. Radial nerve palsy secondary to a humeral shaft fracture from a low-velocity gunshot wound.

In secondary radial nerve palsies, the surgeon may feel compelled to explore the nerve because he or she “caused” the radial nerve injury. However, natural history studies of observed secondary radial nerve palsies show recovery of 80% to 100% with nonoperative treatment (297,356). Secondary palsies occurring after manipulation may be observed (291,338,402,445,479). If the palsy occurs after a considerable time, the nerve is probably encased in callus and further investigation, including exploration, is warranted (342,496). Late presentation may result in an osseous foramen containing the nerve and requiring decompression (342).

AUTHORS' PREFERRED METHOD OF TREATMENT

Birth fractures have a very good prognosis for full recovery. To prevent an internal rotation contracture, I place the arm in either a U plaster or a plaster coaptation splint with the palm facing anteriorly. A soft wrap holds the arm to the body so the child can be carried. The splint can be removed in 2 weeks. On healing, the radiographic angulation can be quite worrisome to the parents. I like to show them radiographs of other infants with marked remodeling, and keep photographs handy for this purpose.

Most humeral diaphyseal fractures in children are treated nonoperatively. Torus fractures are treated with a commercial shoulder immobilizer or a sling. Greenstick fractures and displaced fractures in younger children are treated with a U plaster or a plaster coaptation splint; these are usually applied in the emergency department with mild sedation. I prefer general anesthesia if more manipulation is needed. A careful neurologic and vascular evaluation is performed before and after manipulation. I place a U plaster with Webril padding extending from over the deltoid, around the olecranon, and up to the axillary fold, and secure it with a gauze wrap followed by an elastic bandage. I have had similar results applying plaster coaptation splints on the medial and lateral aspects of the arm and rewrapping frequently with an elastic wrap. The patient is placed in a collar-and-cuff sling for forearm support. If alignment is unsatisfactory, a new splint is reapplied and molded.

In those rare fractures uncontrollable by closed means, I prefer smooth intramedullary rodding using two 2-mm rods placed retrograde through the epicondyles. For unstable fractures with extensive comminution, I prefer to use a unilateral external fixator, with small incisions made during screw placement to avoid the radial nerve. Open fractures are treated in a similar manner. Significant bone loss can be treated using bone transport techniques. I avoid plate fixation because it creates a stress riser, particularly in growing children. If a fracture occurs distal or proximal to the plate, it must be reexplored for plate removal, necessitating reexploration of the radial nerve and potential nerve damage. I observe both primary and early secondary radial nerve palsies, exploring them only after 1 to 2 months and growth of 1 mm per day if electromyography shows no return.

Rehabilitation

Patients treated with closed manipulation should be followed weekly for the first few weeks to ensure that alignment is maintained. The coaptation splint or long arm cast should be replaced as needed. Patients with radial nerve palsies must be instructed in finger motion to keep the fingers supple and prevent contractures. Noncompliance requires formal hand therapy or a radial nerve outrigger. Stiffness of the shoulder and elbow is uncommon in children, but pendulum exercises are started at 3 to 4 weeks in older children and adolescents. Some form of immobilization is generally continued for 6 weeks. Patients should not return to contact sports until there is adequate healing, and the family should be cautioned that refracture may occur during the first 6 months after injury.

Prognosis

The prognosis for healing and remodeling of humeral shaft fractures in children is excellent. Internal rotation deformity is usually minimal, and the outlook for radial nerve palsies is good. Loss of shoulder motion may occur but is more common in older patients (386).

Complications

Malunion

Malunion is uncommon in children's humeral diaphyseal fractures. Varus of 20 to 30 degrees can be accepted (Fig. 17-29) (299,332,343,457), but anterior bowing of 20 degrees may be apparent (397). An internal rotation deformity of 15 degrees causes no functional impairment (332). Most patients under 6 years of age grow out of angular deformities (386). Children 6 to 13 years of age may not, although some remodeling is possible even in adolescents (386,440). Obese patients are more prone to malunion, but they also hide their deformity better (468). Green and Gibbs (365) noted that the deformity visible on the anteroposterior and lateral radiographs is generally not the maximum deformity, which is the vector sum of the two deformities. This can be appreciated by obtaining a radiograph perpendicular to the plane of the deformity, similar to the Stagnara view for scoliosis.

Nonunion

Primarily a problem in adults and occasionally in older adolescents, there are few reports of humeral nonunion in children—one in a child with progeria at age 4 (351), four in children with osteogenesis imperfecta (355), and three from severe trauma (410). In adults, numerous treatments have been used successfully. These include reamed nails (319) and modified flexible nails (368,452). However, the best results appear to be from ASIF techniques with the broad dynamic compression plate and autogenous bone grafting (282,312,346,374,435,519). Currently, treatment in children and adolescents must be extrapolated from adult treatment. In general, the atrophic ends of the nonunion are taken back to bleeding surfaces and apposed, a compression plate is applied with fixation of at least six cortical screws proximally and distally, and bone grafting is performed (374). The Ilizarov technique also reportedly produces good results (275,304,310,389,390,484). Electrical stimulation also has been used with success (324,344,345,477,478,497). Children with dysplastic bone, such as those with osteogenesis imperfecta, are best treated with intramedullary rodding and bone grafting (355).

Nerve Palsies

Radial nerve palsies were discussed previously. They also may occur immediately after operative treatment (334), or may be delayed and occur many years after internal fixation (352). Ulnar nerve paralysis has been reported from entrapment of the nerve in the fracture site (395). A small percentage of people have an abnormal arcade of Struthers in which only superficial fibers of the triceps medial head pass superficial to the ulnar nerve and none pass deep to the nerve, making the nerve extremely close to the bone and vulnerable to an abduction extension mechanism of fracture, which opens the anterior medial aspect of the humerus (395). In about 10% of the population, the median nerve crosses posterior to the brachial artery rather than anterior, placing it closer to the humerus. Median nerve palsy has been reported from an apex anterior mid-diaphyseal fracture (422). After an easy fracture reduction, the median nerve was caught in the fracture between the coracobrachialis and brachialis muscles, where the nerve crossed anteriorly. Anterior interosseous nerve palsies have not been reported in fractures above the supracondylar region.

Compartment Syndrome

The fascia of the upper arm is not as strong as it is in the lower arm, making compartment syndrome less common. Mubarak and Carroll (434) reported a dorsal forearm compartment syndrome in a 9-year-old boy with a humerus shaft fracture. Gupta and Sharma (367) reported on an adult with a triceps compartment syndrome from a middle third minimally displaced fracture; this fracture did not disrupt the intercompartmental boundaries.

Vascular Injuries

Vascular injuries require a high index of suspicion and rapid treatment (301,334,424,429). The fracture should be stabilized sufficiently to prevent disruption of the vascular repair.

Infection

Infections have been reported in patients undergoing surgery. They have not been reported in closed fractures of the humerus in children, but have been reported in closed fractures elsewhere (307,512).

Loss of Motion

Loss of shoulder and elbow motion is more common in older patients (272,386). The joint affected is usually the one closest to the fracture site.

Limb-Length Discrepancy

Overgrowth after humeral fracture occurs in about 81% of patients but is generally minimal (<1 cm) (375). Some generalized stimulus to the extremity is evident, with overgrowth of the carpals as well (474). In patients with limb-length discrepancy of 3 cm or more at maturity, lengthening may be indicated (330,447). Unilateral or ring fixators may be used with Ilizarov's principles (310,311).

Other Complications

Uncommon complications include reflex sympathetic dystrophy (350) and fat embolism (400). Late refracture may occur from retained internal fixation (298).

DISTAL HUMERAL DIAPHYSEAL FRACTURES

Little has been written about distal humeral diaphyseal or metaphyseal–diaphyseal junction fractures, which are much less common than supracondylar humeral fractures. Fractures in this region should not be confused with supracondylar humeral fractures. The distal diaphysis is more triangular and the periosteum is thinner than in the supracondylar region (327,331), making these fractures generally less stable than supracondylar fractures. The cortical bone also heals more slowly than metaphyseal bone, requiring longer immobilization. The mobile wad, anconeus, and flexor pronator mass originate off the epicondyles; the biceps, brachialis, and triceps all insert distally. Therefore, forearm position greatly affects the fracture position. Because the brachial artery is tethered by the lacertus fibrosus, injury to the artery is more likely than with more proximal fractures.

Etiology

Distal humeral diaphyseal–metaphyseal junction fractures may be caused by transverse or longitudinal loading, torsion, or moments generated by the forearm about the elbow. They are more often caused by direct blows and twisting rather than ulnar leverage in the olecranon fossa. The diagnosis, made on plain radiographs, must be differentiated from a supracondylar humerus fracture.

Classification

Most distal humeral diaphyseal fractures are transverse, spiral, or short oblique. Occasionally, an oblique or spiral fracture extends distally toward or beyond the epicondyles (Fig. 17-36). The description must include the direction of displacement, the neurologic and vascular status, and the degree of comminution. Medial column comminution predisposes to varus malunion.

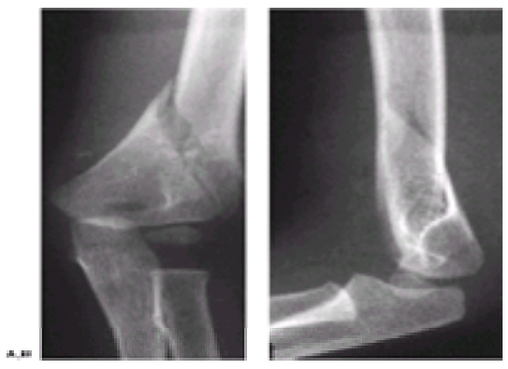

FIGURE 17-36. A and B: Distal humeral diaphyseal fracture extending to the epicondyles. This fracture was treated by casting with the forearm in pronation.

Treatment

Nonoperative

Closed treatment usually is possible because acute flexion of the elbow, with potential vascular compromise, is not required to maintain reduction. These fractures tend toward varus malunion (Fig. 17-37) (302), which may be cosmetically unacceptable, particularly in more distal fractures. With 20% or less of humeral growth occurring distally (295,453,454), significant remodeling may not occur. Because of the proximity to the epicondyles with their muscular origins, supination and pronation affect fracture reduction. If one cortex is open, then the muscles originating on that side should be tightened to reduce the fracture (274). Because of the varus tendency, this is usually by pronation (292,294,487). However, this is best checked radiographically (Fig. 17-38 and Fig. 17-39).

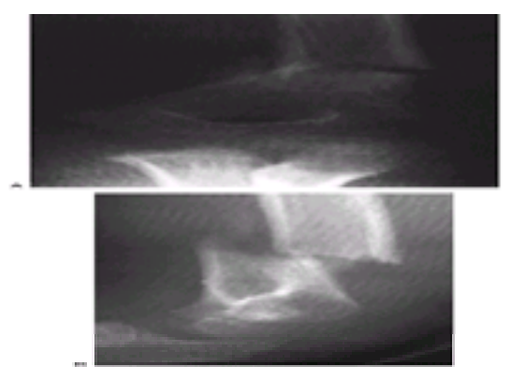

FIGURE 17-37. A and B: Radiographs showing the tendency of distal humeral diaphyseal fractures toward varus malunion. This fracture required remanipulation.

FIGURE 17-38. Influence of forearm rotation. Pronation **(A and B)** of the forearm produces a valgus angulation at the fracture site (*arrows*). Supination **(C and D)** creates a varus angulation (*arrows*).

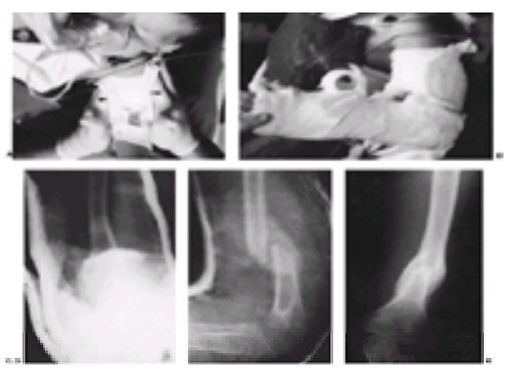

FIGURE 17-39. The same patient shown in Fig. 17-38. **A:** The humeral coaptation splint is molded (*arrows*) with the forearm in neutral. **B:** A second forearm coaptation splint is added, and the extremity is suspended with a loop. **C:** Radiographs show satisfactory linear alignment. **D and E:** The fracture healed in bayonet apposition but with satisfactory alignment.

Operative

Unstable fractures may require fixation (302,457) and possibly open reduction. Closed reduction and percutaneous pinning should be performed in a similar fashion to supracondylar humerus fractures. However, because the fracture is more proximal, it is difficult to get the pins into the diaphysis without crossing them at the fracture site (Fig. 17-40). Attempts should be made to pass the wires in intramedullary fashion up the lateral or medial and lateral columns separately to provide stability (Fig. 17-41) (457). This can be done by drilling the wires, but it is easier to create a starting site at the epicondyles and pass blunt-tipped wires up the columns. Holding the wires with a drill chuck helps, too. Because of the bony anatomy and the ulnar nerve, lateral wires are easier to place, particularly in younger children (Fig. 17-42). Alternatively, the fracture can be managed with skeletal traction until callus forms; then either a U plaster splint or a long-arm cast can be applied (Fig. 17-43). Brug and colleagues report the best results with flexible intramedullary rodding (302).

FIGURE 17-40. A and B: Distal humeral diaphyseal fracture in an 18-month-old child treated with closed reduction and percutaneous pinning **(C)**. The pins cross at the fracture site with decreased stability and some loss of position **D and E:** The ultimate outcome was good.

FIGURE 17-41. Ideally, pin fixation for distal humeral diaphyseal–metaphyseal junction fractures involves pins placed in intramedullary fashion up the medial and lateral columns.

FIGURE 17-42. Segmental distal humeral diaphyseal and supracondylar fracture in a 4-year-old boy. **A and B:** Both fractures could not be controlled by closed means.

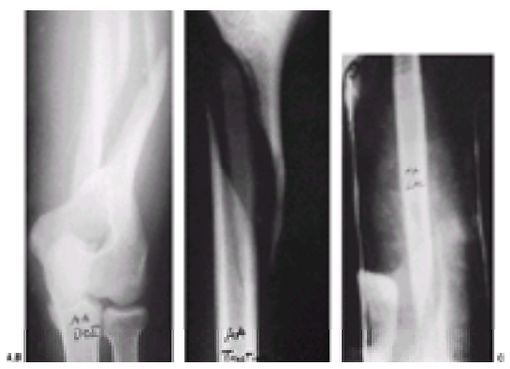

FIGURE 17-43. A comminuted distal humeral metaphyseal–diaphyseal fracture in a 14-year-old boy. Injury films **(A)** show multiple fragments in the metaphyseal–diaphyseal area. **(B)** The patient was placed in traction for 2 weeks until callus appeared and then was transferred to a long arm cast **(C)**.

AUTHORS' PREFERRED METHOD OF TREATMENT

For distal humeral diaphyseal–metaphyseal junction fractures, I prefer closed treatment. Nondisplaced fractures are treated with a long arm cast split to allow for swelling. A double sugartong splint is used if swelling is severe. I reduce displaced fractures under general anesthesia. Because supination and pronation of the forearm can affect the position, I use the image intensifier to determine the position best for maintaining the reduction; this is usually pronation. If the reduction obtained is unstable and cannot be held with a cast, I do not hesitate to treat it by percutaneous pinning, with small Steinmann pins placed through the medial and lateral epicondyles and up their respective columns, keeping the pins as divergent as possible at the fracture site or with lateral column pins. It is helpful to introduce them through the epicondyle and then tap rather than drill them up the column to prevent convergence at the fracture site. The pins are removed once good callus forms.

SUPRACONDYLAR PROCESS FRACTURES

Anatomy

Occasionally, a proboscis-like supracondylar process extends from a few centimeters above the medial epicondyle. The incidence of this process ranges from 0.1% to 2.7%, with the lower percentages in blacks and the higher percentages in whites (281,419,439). The process extends obliquely downward and may be connected with the medial epicondyle by a tough fibrous band (281,309,394,419,439). Frequently, the foramen formed between the fibrous band and the humerus is traversed by the median nerve and the brachial artery. They may be entrapped by a fracture. Anomalous attachments of the coracobrachialis and the pronator teres may occur on the process (Fig. 17-44) (369,399).

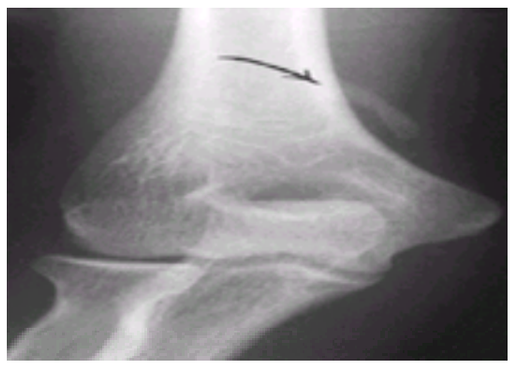

FIGURE 17-44. Radiographic appearance of a supracondylar process (*arrow*).

Etiology

Supracondylar process fractures are the result of direct blows. There are no reports of avulsion from the anomalous muscle attachments.

Classification

Supracondylar process fractures are classified as displaced or nondisplaced, with notation of median nerve or brachial artery compromise.

Treatment

Supracondylar process fractures have been reported in children (399) and usually are caused by direct blows to the distal humeral area. They may be quite painful and result in compression of the brachial artery or median nerve (281,309,369,399,419). The process is best seen on oblique views (439). If there are no symptoms of median nerve or brachial artery compression, they are treated by elevation, ice, and temporary immobilization for comfort. However, if a painful nonunion or neurovascular symptoms develop, the fragment should be excised (439). Fractures with neurologic signs or symptoms are treated by fragment excision and nerve and artery decompression.

GLENOHUMERAL SUBLUXATION AND DISLOCATION

Dislocation of the glenohumeral joint in children is rare. None of the ancient writings of Hippocrates (460–375 B.C.), Galen (A.D. 131–201), and Paul of Aegena (A.D. 625–690) made specific mention of this injury in children (601). Most textbooks that address children's shoulder problems do not even discuss dislocations of the glenohumeral joint, and others barely touch on the subject (533,599,600,607,610,615). A review of the literature would suggest that glenohumeral dislocations in children less than 12 are rare. Although several case reports have been presented, no large series of this entity are available (564,566,579,614). Rowe, in his 1956 review of 500 dislocated shoulders (604), found that only 8 patients were under 10 years of age. In this same series, 99 patients were 10 to 20 years of age, but no details on skeletal maturity were given (603,604). Rockwood reported a series of 44 patients with shoulder dislocations, predominantly adolescents (601). Many articles have been published on adolescent patients without discussing their skeletal maturity (548,557,586,591). As the child reaches adolescence, the incidence of shoulder instability increases, but in the skeletally immature patient, this injury can still be considered rare. Marans et al. (585) in 1992 presented a series of 21 patients with open physes from two major trauma centers.

Anatomy

Developmental anatomy was discussed in the section on fractures of the proximal humerus. The glenohumeral joint consists of the articulation between the large convex humeral head and the relatively flat glenoid fossa. This joint is anatomically suited to accommodate the wide range of motion necessary to perform upper extremity function. To accomplish this range of motion, very little bony constraint is inherent in this joint. The articular surface area and radius of curvature of the humeral head are about three times the size of the relatively flat glenoid surface. Although the glenoid fossa is deepened by the labrum, the mismatch in the surface area and the radius of curvature explains the lack of joint stability.

The primary constraint for the joint is the capsular/ligamentous complex. The capsule on its inner surface is reinforced by thickened areas known as the anterior glenohumeral ligaments. This complex capsular/ligamentous structure must provide stability against abnormal translation while allowing a wide range of motion. With the arm abducted, the inferior capsule is highly redundant. The most important ligament is the anteroinferior glenohumeral ligament, located within the inferior redundant area. It is mechanically designed to tighten as the arm is abducted and externally rotated, much like the effect of wringing out a washcloth. This structure becomes the primary site of pathology in anterior shoulder instability, either when the anteroinferior glenohumeral ligament attachment to the glenoid and labrum is stripped from the anterior neck of the glenoid or as these ligaments are disrupted in substance (Fig. 17-45). Disruption of the capsular labral attachment is known as a Perthes' or Bankart's lesion.

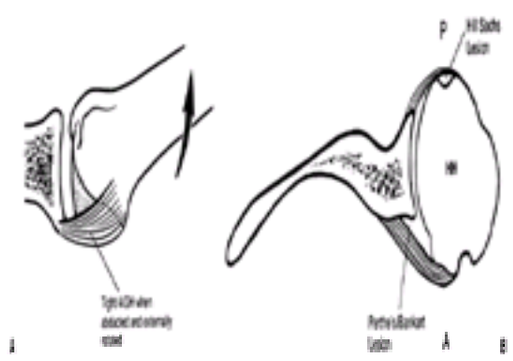

FIGURE 17-45. A: The tight anteroinferior glenohumeral ligament complex with the arm abducted and externally rotated. This ligament sling is the primary restraint against anterior instability of the shoulder. **B:** A cross-section in the transverse plane through the glenohumeral joint demonstrates the common lesions associated with anterior instability of the shoulder: Hill-Sachs lesion, Perthes-Bankart lesion, and redundant anteroinferior glenohumeral ligaments. *A,*anterior; *P,*posterior; *HH,* humeral head.

The humeral attachment of the capsule of the glenohumeral joint is along the anatomic neck of the humerus except medially, where the attachment is more distal along the shaft. The physis, therefore, lies in an extracapsular position except on the medial side. As in most pediatric joint injuries, the strong capsular attachment to the epiphysis makes failure through the physis a much more common injury than true capsular/ligamentous injury (542,574,611). Therefore, fracture through the physis is more common than a dislocation in the skeletally immature patient.

The rotator cuff tendons consist of the subscapularis, supraspinatus, infraspinatus, and teres minor muscles. These muscle–tendon units surround the joint anteriorly, superiorly, and posteriorly. They serve an important function as dynamic secondary stabilizers of the joint by forming a force-couple with the large shoulder muscles (deltoid, pectoralis major, and latissimus dorsi). As the glenohumeral joint moves through its range of motion, the cuff provides a dynamic stabilizing effect, preventing excessive translation of the humeral head on the glenoid. This is important when addressing rehabilitation for the prevention of recurrent glenohumeral dislocation.

Mechanism of Injury

Traumatic Dislocations

Anterior dislocations of the shoulder are most common in this category. Significant evidence of trauma should be present to assign patients to this grouping, as compared with the relatively minor trauma in the atraumatic group. The mechanism of injury is similar to that observed in the adult. A force applied to the outstretched hand that forces the arm and shoulder into an abducted, externally rotated position is the primary mechanism. The humeral head is levered out of the glenoid process anteriorly, with the head lodging against the anterior neck of the glenoid. This occurs commonly in contact sports, falls, fights, and motor vehicle accidents (531,567,592).

Traumatic posterior dislocations are much less common. In most series of posterior dislocations in all age groups, they represent only 2% to 4% of all dislocations. The history is one of violent trauma with the arm in a position of flexion, internal rotation, and adduction. This can occur in falls and in motor vehicle accidents as the arm braces the body against impact. The other common mechanisms that produce posterior dislocations include convulsions and electroshock. In these cases, the shoulder is dislocated posteriorly by the violent contraction of the shoulder internal rotators, which in most cases are stronger than the shoulder external rotators. The history of the injury and a high index of suspicion are necessary to avoid missing a posterior dislocation (546,547,563,596,612).

In neonates, pseudodislocation of the shoulder can occur (561). This problem represents traumatic epiphyseal separation of the proximal humerus, which is certainly much more common than a true traumatic dislocation of the shoulder in this age group. Most true traumatic dislocations of the shoulder in the neonatal period occur in babies with underlying birth trauma to the brachial plexus or central nervous system.

Laskin and Sedlin (577) reported on a 3-month-old infant with Erb-Duchenne palsy who sustained a traumatic luxatio erecta of the shoulder during a planned shoulder manipulation. Posterior dislocation of the shoulder also can occur as a secondary traumatic phenomenon in unrecognized brachial plexus injury of the upper trunk at delivery (527,580,617,618). Green and Wheelhouse (558) reported a dislocation in a 7.5-month-old infant that was secondary to a septic brain injury.

Atraumatic Dislocations

Atraumatic shoulder instability is more common in children and adolescents than is readily recognized. The child who presents with shoulder dislocation without a clear-cut significant history of trauma should arouse suspicion that atraumatic instability may be present. These patients have inherent joint laxity that allows the shoulder to be dislocated either voluntarily or involuntarily as the result of a minimally traumatic event (Fig. 17-46) (536). Throwing, hitting an overhead tennis shot, or pushing the body up when in bed does not constitute significant trauma. A high index of suspicion should be maintained with this kind of history. In the voluntary dislocator, conscious selective firing of muscles while antagonists are inhibited, combined with arm positioning, allows the shoulder to dislocate. A key to the diagnosis is that atraumatic instability, whether voluntary or involuntary, is not associated with much pain. Even if reduction is necessary, the pain usually disappears rapidly. In most instances, spontaneous reduction occurs without manipulation (601).

FIGURE 17-46. Congenital laxity of the left shoulder in a 4-year-old boy who is totally asymptomatic and has a full range of motion of the left shoulder. **A:** With abduction and extension, the head subluxates anteriorly and inferiorly. **B:** An anteroposterior radiograph shows some lateral displacement of the humeral head. **C:** With overhead elevation, the humeral head is noted to displace anteriorly, laterally, and inferiorly. (Courtesy of Don Jones, M.D.)

Other causes of atraumatic shoulder instability, in addition to multidirectional joint laxity, include Ehlers-Danlos syndrome, congenital absence of the glenoid, deformities of the proximal end of the humerus, and emotional and psychiatric instability. True congenital dislocations of the shoulder are most commonly associated with developmental defects and multiple congenital abnormalities (537,540,555,559,598). Arthrogryposis, neglected septic arthritis, and neurologic defects also have been implicated in atraumatic dislocations in the young child (527,557,558,565,609,617).

Classification

Etiology of Instability

1. Traumatic dislocations
   a. Primary trauma to the shoulder itself
   b. Secondary to birth trauma of the brachial plexus or central nervous system.
2. Atraumatic dislocations—voluntary or involuntary
   a. Congenital abnormalities or deficiencies of bone or soft tissue
   b. Hereditary joint laxity problems, such as Ehlers-Danlos syndrome
   c. Developmental joint laxity problems
   d. Emotional and psychiatric disturbances

Because of the rarity of this injury, no consensus exists as to a classification scheme in children and adolescents. In adults, shoulder instability can be classified as to direction, degree, and chronicity. Two basic schemes have been used to classify other dislocations in children and adolescents; the more common is based on the direction or location of the dislocation. This scheme is useful in describing the clinical and radiographic features of the injury, but it does not address the underlying pathology in children (601).

Direction of Instability

Therefore, a second classification scheme describing the etiology of the dislocation is also useful when considering treatment options for this injury in children. This second system is similar to that used for adults but takes into account congenital and developmental problems unique to children. As discussed later in the section on treatment of this problem, accurate classification is important in selecting the appropriate conservative versus surgical options (526,542,597).

There are four directions of dislocation: anterior, posterior, multidirectional, and inferior (luxatio erecta). As with shoulder dislocations in adults, anterior dislocation in children is the most common, constituting at least 90% of glenohumeral dislocations (Fig. 17-47). Several isolated reports of posterior dislocation in children and adolescents have been documented, but posterior dislocation is rare in children, as in adults (534,553,566,587). Multidirectional luxatio of the shoulder has been well described as a distinct clinical entity by Burkhead and Rockwood (535), O'Driscoll and Evans (548), and Rockwood (601,602). Luxatio erecta or inferior locked dislocations are uncommon but have been reported in children (554,577,589).

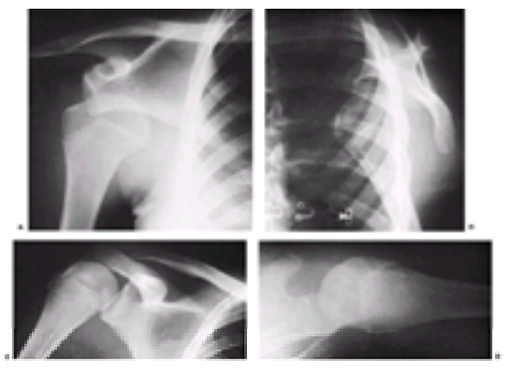

FIGURE 17-47. Anterior dislocation of the right shoulder in a 15-year-old girl. **A:** Note the typical subcoracoid position on the anteroposterior film. **B:** On a true scapular lateral film, note the anterior displacement of the humeral head. **C:** Postreduction film demonstrates a Hill-Sachs compression fracture in the posterolateral aspect of the humeral head. **D:** On the postreduction axillary film, note the posterolateral compression fracture of the humeral head.

Degree of Instability

The degree of instability can be classified as a subluxation or a dislocation. A subluxation is an incomplete dislocation characterized by pain, a feeling of slipping, or a dead feeling in the arm. A complete dislocation of the humeral head out of the glenoid fossa is characterized by a displacement and locking of the head on the rim of the glenoid.

Chronicity of Instability

The chronicity of instability can be classified as acute, recurrent, or chronic. A single episode of instability can be described as an acute injury. As in the skeletally mature patient, an acute injury can lead to a recurrent instability, depending on the damage to the ligament and bony restraints of the joint. A chronic instability exists when an acute dislocation is not reduced, and is usually associated with congenital dislocations.

Signs and Symptoms

Traumatic Dislocations

The patient with a traumatic anterior dislocation presents with a painful, swollen shoulder. Obvious deformity is present, with a prominent acromion and the lateral upper arm flattened. The arm is often supported by the opposite hand and held in an abducted and externally rotated position. Despite swelling, the humeral head can usually be palpated in a position anterior to the glenoid.

Careful examination of the neurologic and vascular status is necessary. The axillary nerve is the most commonly injured with anterior dislocation, and special attention to its function is necessary on examination (532). The sensory distribution of the axillary nerve is along the upper lateral arm; the motor innervation is to the deltoid and teres minor muscles. Light touch is adequate for sensory testing in the upper arm region. An easy way to test deltoid function is to support the involved elbow in one hand while using the opposite hand to grab the muscle belly of the deltoid. The patient is asked to abduct the arm against resistance for about 1 inch so that deltoid firing is initiated. This examination confirms the status of the axillary nerve (Fig. 17-48).

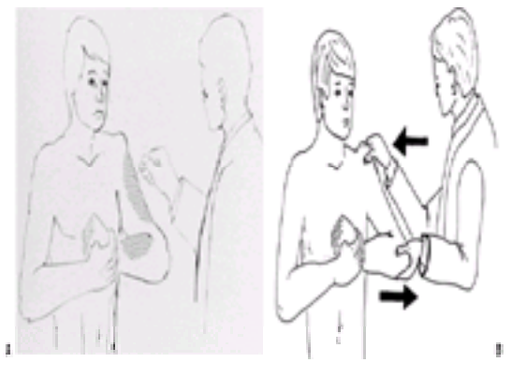

FIGURE 17-48. A: Sensory distribution for the axillary nerve important in anterior dislocation. **B:** Deltoid muscle can be tested in acute anterior dislocation by grabbing the muscle belly with the right hand while supporting the elbow with the left. The patient then can actively contract the deltoid by pushing the elbow against the examiner's hand while the examiner feels the muscle contraction.

In recurrent anterior dislocation or subluxation, the arm is well located with an overall normal appearance of the shoulder. The shoulder demonstrates a full range of motion, although the cocking position is avoided. The apprehension test with the arm abducted above 90 degrees is positive. This is a key finding in the diagnosis of recurrent anterior instability.

Traumatic posterior dislocation is, again, much less common than anterior dislocation. The patient presents with flattening of the anterior aspect of the shoulder and posterior fullness. The arm is held at the side, with the forearm internally rotated across the chest. The patient resists any attempt at motion. A hallmark of posterior dislocation is the lack of shoulder external rotation and inability to supinate the forearm. These findings are difficult to elicit in the acute situation. It is advantageous to examine the shoulder with the patient seated so that the examiner can visualize the shoulders from above. This view accentuates the posterior fullness and anterior flattening often present. The neurovascular status should be closely checked. A history of convulsion or electrical shock should raise a high index of suspicion for posterior dislocation.

In neonates, traumatic separation of the upper humeral physis, the so-called pseudodislocation of the shoulder, can exactly mimic an anterior dislocation. The child is irritable and often holds the arm abducted and externally rotated. There is resistance to any type of motion. Deformity in dislocation or pseudodislocation in the neonate is usually absent or subtle.

Atraumatic Dislocations

The most notable finding in patients with atraumatic shoulder instability is the relative lack of pain associated with the subluxation or dislocation. Even in cases of involuntary atraumatic dislocation, the minor pain associated with the dislocation itself subsides rapidly after reduction. Episodes of atraumatic subluxation and dislocation occur much more frequently than traumatic dislocations, and in almost all cases spontaneous reduction is the rule.

On clinical examination, there is evidence of multiple joint laxity (594). Also, multidirectional laxity or instability of the opposite shoulder is usually present (548,549,601,602). Characteristics of multiple joint laxity include hyperextension at the elbows, knees, and metacarpophalangeal joints. Not uncommonly, striae of the skin are present, and skin hyperelasticity is a noted characteristic of Ehlers-Danlos syndrome. Multidirectional laxity of the shoulder is characterized by a positive sulcus sign and significant translation on an anterior and posterior drawer test.

The sulcus sign is a dimpling of the skin below the acromion when manual longitudinal traction is applied to the arm (Fig. 17-49). This produces an inferior

subluxation of the humeral head away from the acromion that enlarges the subacromial space and causes dimpling of the skin. The drawer or shift and load test is performed with the examiner seated behind the patient. The scapula is stabilized with one hand and forearm while the humeral head is manually translated anteriorly and posteriorly by the examiner's opposite hand (Fig. 17-50). Although some translation within the glenohumeral joint is expected in all patients, those with multidirectional laxity demonstrate translation of greater than 5 mm anteriorly and posteriorly from a neutral position.

FIGURE 17-49. Dramatic demonstration of inferior subluxation of the glenohumeral joint in a patient with multidirectional instability. The clinical correlate is the sulcus sign.

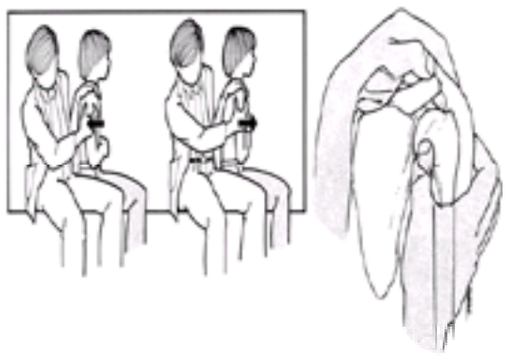

FIGURE 17-50. Drawer test. This technique is used to subluxate the shoulder manually both anteriorly and posteriorly to demonstrate multidirectional laxity.

In atraumatic dislocation, the shoulder often dislocates anteriorly, posteriorly, or inferiorly. The most common direction of dislocation in voluntary instability is posterior or inferior. The patient who can voluntarily dislocate the shoulder can force the humeral head posteriorly by contracting the anterior deltoid and internal rotators while inhibiting the antagonistic muscles (Fig. 17-51). The elbow is positioned in horizontal adduction, and the head is dislocated. The arm can then be abducted and, often with an audible clunk, the shoulder reduces. Once again, the hallmark is lack of pain with the dislocation (543,550,573,578,584,605,608).

FIGURE 17-51. Voluntary anterior dislocation of the right shoulder in an 8-year-old boy. **A:** The patient voluntarily has dislocated the right shoulder anteriorly. **B:** The shoulder voluntarily reduced. The patient explained that he was taught to do this by an older brother who also had voluntary dislocation of the shoulders.

Radiographic Findings

Children and adolescents with open growth plates have a low incidence of true traumatic dislocation of the shoulder. Traumatic lesions on plain radiographs are similar to those found in adults (Fig. 17-52). On the anteroposterior or internally rotated views of the proximal humerus, the Hill-Sachs compression lesion on the posterolateral aspect of the humeral head is commonly found. This injury to the proximal humerus occurs as the humeral head is impacted against the anterior rim of the glenoid during a dislocation (Fig. 17-53). Bony injury to the anterior glenoid rim can occur with dislocation as well. A variable degree of injury from small avulsion-type fragments to substantial bony fractures can occur. These anterior glenoid rim injuries are best seen as a double density on the anteroposterior view of the shoulder or as a separate fragment on the axillary and West Point lateral views. The West Point lateral view projects the anteroinferior glenoid rim and most clearly shows this lesion when it is present. In traumatic posterior dislocation, the reverse Hill-Sachs lesion can be seen on the anterior part of the humeral head in conjunction with a possible fracture of the posterior rim of the glenoid.

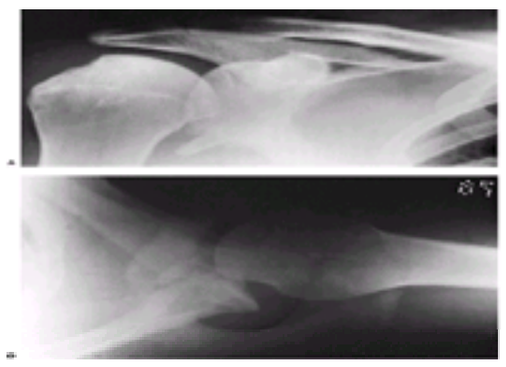

FIGURE 17-52. Traumatic anterior dislocation of the right shoulder in a 15-year-old boy. **A:** On the anteroposterior view, note the Hill-Sachs lesion as well as the anteroinferior bony fragment off the glenoid rim. **B:** Axillary radiograph made with the arm in 90 degrees of abduction demonstrates the anterior subluxation as well as the deficiency of the anterior glenoid rim.

FIGURE 17-53. Anterior shoulder dislocation in a skeletally immature adolescent patient. **A:** Anteroposterior radiograph demonstrates the common appearance of an anterior dislocation of the shoulder. **B:** Postreduction anteroposterior radiograph of the shoulder shows a large posterolateral compression fracture of the humeral head or Hill-Sachs lesion.

In cases of traumatic subluxation of the shoulder in which the diagnosis may be unclear clinically, an arthrogram with CT scan or tomograms can sometimes better delineate the extent of capsular stripping from the anterior glenoid rim. More recently, saline arthrograms and magnetic resonance imaging have enhanced our ability to define the degree of injury to the labrum, capsule, and articular surfaces (560,602). CT scanning and magnetic resonance imaging have been useful for analyzing the significance of fractures of the glenoid rim (Fig. 17-54 and Fig. 17-55). In addition, the size of the reverse Hill-Sachs lesion of the humeral head in posterior dislocations is best analyzed with a CT scan (576,616).

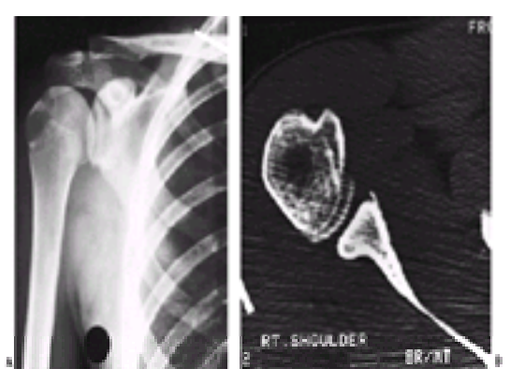

FIGURE 17-54. A: Anteroposterior radiograph of a 14-year-old boy with recurrent anterior subluxation. Notice the presence of a Hill-Sachs compression fracture on the humeral head and a subtle double density at the anteroinferior glenoid rim. **B:** Computed tomography scan shows this to be an avulsion-type bony injury of the anterior glenoid.

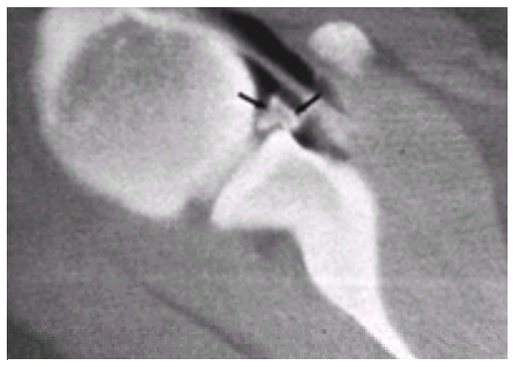

FIGURE 17-55. Magnetic resonance imaging scan in a patient with recurrent anterior instability of the shoulder. The arrows demonstrate a calcified bony Bankart's lesion.

With atraumatic dislocations in patients who do not have congenital or developmental defects, radiographs are usually normal. The most common defects seen on radiographs with atraumatic dislocations are congenital aplasia or absence of the glenoid. In patients with multidirectional laxity and atraumatic dislocation, stress radiographs can usually demonstrate instability in anterior, posterior, and inferior directions. The inferior component of multidirectional instability can be demonstrated by applying weights to the arm in an anteroposterior film. This shows the humeral head subluxating in its relation to the glenoid (571).

Treatment

Traumatic Instability

The literature on the specific treatment of shoulder instability in children is limited (526,538,600,610). Most clinicians make treatment recommendations for patients of all age groups (524,525,530,531,545,572). Therefore, most of the data presented in this section are extrapolated from the adult and adolescent literature, as well as from the experience of Dameron and Rockwood (542).

Acute Dislocation

Patients with an acute dislocation of the shoulder should undergo closed reduction by one of the standard, accepted techniques. For anterior dislocation, many reduction techniques have been described. Most clinicians prefer light sedation with intravenous or intramuscular injection. The traction/countertraction method appears to be the most gentle. A sheet placed in the axilla of the affected shoulder passes above and below the patient so that countertraction can be applied to the body while longitudinal traction in line with the deformity is applied to the arm. Steady, continuous traction fatigues the muscles that lock the dislocation, and eventually reduction is accomplished by disimpacting the humerus from the glenoid. The Stimson maneuver is equally effective. The patient is placed prone on the examining table, with a weight applied to the affected arm. Both methods are gentle and effective (591). Success with gentle scapular manipulation has been reported by Kothari and Dronen (575) and McNamara (588) as a safe, effective way to reduce the dislocation.

The Steel maneuver in most cases requires no anesthesia (personal communication, J. Steel, 1975). With the patient supine on the examining table, the examiner supports the elbow in one hand while supporting the forearm and wrist in the other. The arm is gently abducted above 90 degrees and slowly externally rotated. With the arm held above 90 degrees of abduction, it is then gently adducted while further external rotation is applied. As reduction occurs, the arm can be taken down into adduction and internal rotation across the chest. Often, reduction is not even felt by the patient or physician. Caution is always used with any type of manipulative reduction, and the procedure is certainly not as safe as gentle traction/countertraction or the Stimson maneuver. Prereduction and postreduction radiographs are required to document fractures and to demonstrate the direction of dislocation. Preoperative and postoperative detailed neurologic examinations are indicated as well.

Postreduction immobilization is another highly debated point. The adult literature suggests that the period of immobilization may not be truly important in predicting recurrent dislocations. A sling or sling and swathe with the arm internally rotated is the most common method of immobilization (525,544).

Closed reduction for acute posterior dislocations is somewhat similar to that for anterior dislocations. Traction/countertraction is the most effective. Traction is applied in line with the deformity, and the humeral head is gently lifted back into its normal relationship with the glenoid. Most clinicians agree that immobilization should be with the arm in neutral rotation or slight external rotation at the shoulder. This may require the use of a spica cast or modified shoulder spica cast, as described by Dameron and Rockwood (542).

Recurrent Dislocation

The true incidence of recurrent dislocation after traumatic shoulder dislocation in children is difficult to assess because of the rarity of the injury and the variety of reports in the literature (556,569). In 1963, Rowe (603) reported a 100% incidence of recurrence in children 1 to 10 years of age with anterior dislocation. He also reported a 94% incidence of recurrence in adolescents and young adults (ages 11–20) (603). Elbaum et al. (551) reported a recurrence rate of 71% in 9 pediatric patients with traumatic anterior dislocations. The average age was 9 years. After reduction, they were immobilized for 3 weeks and then were treated with rehabilitation. However, Rockwood (601) reported a recurrence rate of only 50% in a series of adolescents and young adults 13.8 to 15.8 years of age. Hovelius et al. (569) reported a 47% recurrence rate in patients less than 20 years of age. In a 10-year follow-up study, Hovelius et al. (568) found that recurrent dislocation necessitating operative treatment had developed in 34% of shoulders in patients who were 12 to 22 years of age at the time of initial dislocation, compared with 28% in patients who were 23 to 29 and 9% in patients who were 30 to 40 years old. The type and duration of the initial treatment had no effect on the rate of recurrence. Vermeiren et al. (613) reported a recurrence rate of 68% in patients under 20 years of age. They reported a better prognosis if the dislocation was associated with a fracture of the joint. Heck (564) reported a case of traumatic anterior dislocation in a 7-year-old boy who remained stable at a 5-year follow-up (Fig. 11-56). Endo et al. (552) reported no recurrence in 2 patients, ages 3 and 9, with traumatic anterior dislocation. However, the follow-up was only 2 years in the 3-year-old and 1 year in the 9-year-old. Wagner and Lyne (614) reported an 80% recurrence rate in 10 patients with clearly open proximal humeral epiphyses. Marans et al. (585) reported the fate of traumatic anterior dislocations of the shoulder in 21 children (15 boys, 6 girls) in what may be the largest documented series to date. All the children had one or more documented anterior dislocations after the initial injury. Some of the children had been immobilized in a sling and swathe for 6 weeks. The literature reflects that the natural history of shoulder dislocations in adolescents and young adults demonstrates recurrence rates for dislocation of 50% to 90% despite the treatment program used after the initial dislocation.

FIGURE 17-56. Traumatic anterior subluxation of the left shoulder in a 7-year-old boy. **A:** Anteroposterior film of the left shoulder does not reveal any striking abnormality. **B:** An axillary film shows that the humeral head is subluxated away from the glenoid fossa. **C:** Anteroposterior film of the left shoulder after manual reduction. (*Courtesy of Charles C. Heck.*)

Multiple surgical procedures have been described for the treatment of anterior shoulder instability. Once again, specific results for procedures such as the Putti-Platt, Bankart, and Magnuson-Stack have not been documented for children. Barry and associates (530) described the effective use of the coracoid transfer for recurrent anterior instability in adolescents. Capsular procedures that specifically address the capsular pathology have been described by Neer and Foster (595), Jobe (581), and Rockwood and associates (602), but results in children's dislocations were not documented. Goldberg and colleagues (557) have reported on the use of arthroscopic techniques for capsular repair in adolescents.

Atraumatic Instability

Treatment of patients with atraumatic dislocations of the shoulder appears more difficult than treatment for true traumatic dislocations. Emphasis should be placed on careful diagnosis in these cases. Specific congenital bony or neurologic deficits should be recognized. The sequelae of Ehlers-Danlos syndrome or other collagen deficiency syndromes should be noted.

In patients with multidirectional laxity and voluntary or involuntary dislocations, a significant history of trauma is usually lacking. These patients have minimal pain associated with the dislocation and on clinical examination usually have other signs of multidirectional laxity of the opposite shoulder. Most of these dislocations reduce spontaneously and are associated with little pain. Rowe et al. (605), Neer (594), and Burkhead and Rockwood (535,601,602) have described the use of a vigorous rehabilitation program involving strengthening of the rotator cuff as the treatment of choice for these patients. Most patients who do not have significant emotional and psychiatric problems are successful in improving their shoulder stability with such a program.

Most clinicians would agree that surgical intervention is considered only if a strict 6- to 12-month rehabilitation program fails. Routine shoulder reconstructions involving subscapularis shortening, including the Magnuson-Stack and Putti-Platt procedures, or “bone blocks” such as the Bristow are not sufficient for preventing future instability. Neer and Foster (595) described the inferior capsular shift reconstruction specifically for patients with multidirectional laxity of the shoulder with atraumatic instability. This procedure attempts to eliminate the overall capsular laxity and is used only after rehabilitation has failed. Huber and Gerber (570) reported on 25 consecutive children with 36 involved shoulders with voluntary subluxation of the shoulder. The children managed by “skillful neglect” had a satisfactory outcome, but only 50% of those treated with an operative procedure to prevent later degenerative arthritis had good results. They concluded that voluntary subluxation of the shoulder has a favorable result and that there is no indication for surgery with this problem in children.

AUTHORS' PREFERRED METHOD OF TREATMENT

The most important problem in dealing with shoulder dislocations in children is to establish whether the dislocation is truly traumatic or atraumatic in nature. This is accomplished by obtaining a careful history of the mechanism of injury and performing a physical examination designed to elicit evidence of multidirectional instability of the opposite shoulder, generalized joint laxity, or a congenital or developmental problem. Care should be taken to identify the voluntary dislocator, who should be treated nonoperatively in essentially all cases.

In the acute traumatic dislocation, whether anterior or posterior, gentle closed reduction should be performed. Prereduction and postreduction radiographs are taken, and a thorough neurologic and vascular examination is performed. The traction/countertraction method under light sedation or a gentle manipulative reduction should be used. For an anterior traumatic dislocation, we immobilize the shoulder in internal rotation for 4 weeks. For a posterior dislocation, the shoulder is immobilized for 4 weeks in a commercial splint or modified spica cast with the shoulder in neutral rotation. After this period of immobilization, a rehabilitation program stressing rotator cuff strengthening is instituted.

As discussed, the recurrence rate after a traumatic anterior dislocation is 50% or higher. Although we hesitate to intervene surgically after the initial dislocation, the patient and parents should be counseled that the recurrence rate is high and that the rehabilitation program may fail. With a second dislocation, the diagnosis of recurrent dislocation is established and surgical intervention is indicated. We use the capsular shift procedure as described by Rockwood and associates (602). (This technique is described in detail in Vol. I of *Fractures in Adults*.) If present, the Bankart's or Perthes' lesion is repaired anatomically to the anterior glenoid rim.

Capsular shift is then performed to tighten the anteroinferior capsule.

A 6-month course of rehabilitation follows surgical intervention. For the first month, pendulums and gentle elevation exercises are performed. The shoulder is protected in a sling, especially at night. The second and third months are used to regain range of motion, including protected external rotation. This procedure is designed to address the pathology without limiting motion. The fourth through sixth months are used for a progressive strengthening program, which includes strengthening of the rotator cuff and deltoid. At 6 months, the reconstruction is mature enough to release the child to a full activity level.

For atraumatic dislocation, reduction can be accomplished if necessary after an acute dislocation in a fashion similar to that described for traumatic dislocations. Again, attention should be focused on confirming the diagnosis of atraumatic dislocation. Patients with voluntary dislocation and their families should be counseled that the dislocations can be harmful to the joint and should be discouraged.

Patients with atraumatic instability should be treated with a vigorous rehabilitation program. Only in the face of recurrence after 6 to 12 months of supervised rehabilitation should surgical intervention be considered. Great care should be taken to exclude the voluntary dislocator as a surgical candidate. Psychiatric evaluation is instituted if necessary. A capsular procedure as described by Neer or the capsular shift technique described by Rockwood can be used to eliminate laxity of the joint capsule in a circumferential manner (594,601,602). Surgical management of the atraumatic dislocator is difficult and requires meticulous attention to detail during both the surgical procedure and the postoperative rehabilitation program.

Rehabilitation

The importance of an extensive rehabilitation program for instability about the shoulder for both traumatic and atraumatic problems has been emphasized (525,542). Specific exercises are used to strengthen the rotator cuff and deltoid muscles. The scapular stabilizers are also strengthened. Three-inch wide strips of rubber (Therabands) are used to strengthen the cuff and deltoid muscles; Theratubes are used later if necessary. The rehabilitation program is detailed in Volume I of this series (*Fractures in Adults*).

The amount of weight varies depending on the extent of the problem as well as the patient's age, size, and baseline strength. Exercises are performed four to six times a day. After basic strengthening has been accomplished, isokinetic exercises using the flexion/extension plane and the internal and external rotation plane are effective for maximizing endurance and strength in the shoulder girdle musculature.

Complications

There is little information in the literature about the success rate of surgical reconstruction of the shoulder for recurrent dislocation in children. As discussed, traumatic dislocation in a child or adolescent can progress to recurrent dislocation in 50% to 100% of cases. Rockwood and colleagues have shown that more than 85% of atraumatic dislocators can be managed with a vigorous rehabilitation program and do not require surgery (535,601,602). Surgical treatment of these problems in children could be expected to have a success rate at least equal to that in adults. Greater than 90% success in stopping traumatic dislocations would be expected with surgical reconstruction (524,530,572).

Complications of surgical reconstruction of the shoulder have included recurrent dislocation, recurrent subluxation, painfully restricted motion, problems with metal impingement or loosening about the shoulder, and neurologic injury. Perhaps the most common problem associated with the standard reconstructions about the shoulder that include subscapularis tendon-shortening procedures (Magnuson-Stack and Putti-Platt) has been loss of external rotation. This loss in adults has been associated in some patients with a more rapid progression to glenohumeral arthritis (562,583).

Procedures that use metallic implants about the shoulder, including the Bristow and the DuToit stapling procedures, have been associated with complications of metal impingement on the humeral head or encroachment on the articular surface. Both problems can lead to pain and eventual arthritic change (528,533,549,619).

The axillary nerve is the one most commonly injured with shoulder dislocation. Fortunately, most axillary nerve injuries associated with dislocations are neurapraxic, and function returns with time and observation. In the event of complete axillary nerve palsy, significant disability can exist due to the lack of deltoid function (529,532,539,541,551,582).

Morrison and Egan (593) reported an axillary artery and a brachial plexus injury in a luxatio erecta dislocation in an 11-year-old child. The artery was rejoined with a vein graft and the brachial plexus injury fully recovered.

Young Kwon and John F. Sarwark: Division of Pediatric Orthopaedic Surgery, Children's Memorial Hospital, Chicago, Illinois.

CERVICAL SPINE INJURIES IN CHILDREN

W. C. WARNER, JR.

Injuries to the cervical spine in children are uncommon, accounting for only 1% of pediatric fractures and 2% of all spinal injuries (4,69,70,89,107,122,139,159,173). McGrory et al. (107) estimated that the incidence of pediatric cervical spine injuries was 7.41 in 100,000 per year. However, this low incidence of cervical spine injuries in children may be misleading because some injuries are not detected or detected only at autopsy. Aufdermaur (8) examined the autopsied spines of 12 juveniles who had spinal injuries. Clinically and radiologically, a fracture was suggested in only 1, but all 12 had cartilage end plates that were separated from the vertebral bodies in the zone of columnar and calcified cartilage similar to a Salter I fracture. Only radiographs at autopsy showed the disruption, represented by a small gap or apparent widening of the intervertebral space (8).

Pediatric cervical spine fractures differ from those in adults not only in pattern but in cause, incidence, and treatment (113). Most cervical spine injuries in children under 11 years of age occur in the upper cervical spine, unlike in older children, adolescents, and adults, in whom fractures occur more commonly in the lower cervical spine (55,69,89,139). Upper cervical spine injuries are more predominant in young children because of the unique anatomic and biomechanical properties of the immature cervical spine. The immature spine is hypermobile because of ligamentous laxity, and the facet joints are more horizontally oriented. These horizontally oriented facets give less resistance to forward translation than the more vertically oriented facets in adults. This, combined with a young child's relatively large head, changes the fulcrum of neck motion to the upper cervical spine. Because a child's musculature is not as developed as an adult's, the cervical spine has less support during injury. As the anatomic and biomechanical aspects of the spine change with maturity, so do the level and type of injuries seen.

In younger children, most of the injuries are fractures through the vertebral end plates or synchondroses or ligamentous injuries. In adolescents, vertebral body fractures or fracture–dislocations involving the lower cervical spine are more common and have the characteristics of adult cervical spine injuries (Table 18-1).

TABLE 18-1. LOCATION OF INJURIES BY AGE

Neurologic deficits occur infrequently with pediatric cervical fractures, and when a partial deficit is present, the prognosis is better in children than in adults (13,47). Complete neurologic deficits, however, tend to remain complete regardless of whether they occur in children or adults. This may reflect the magnitude of injury that caused the complete neurologic lesion. Orenstein et al. (119,120) found that deaths from cervical spine injuries or associated injuries occur most commonly in children 8 years of age or younger. Nitecki and Moir (115) found that the younger the age and the higher the level of injury, the more likely the injury was to be fatal, again reflecting the severity of the initial injury and explaining the increased incidence of death (72,115,119).

Spinal cord injury without radiographic abnormalities (SCIWORA) has been found with increased frequency in children and may be related to the relative hypermobility of a child's spine (see later section on SCIWORA). Depending on the age at the time of injury and the level of spinal cord injury, other problems that may occur in children are the development of spinal deformities and lower extremity problems, such as contractures and progressive subluxation or dislocation of the hip joint.

ANATOMY

Understanding the normal growth and development of the cervical spine is essential when treating a child with a suspected cervical spine injury (130). This will allow the physician to differentiate normal physes or synchondroses from pathologic fractures or ligamentous disruptions and will alert the physician to any possible

congenital anomalies that may be mistaken for a fracture.

Upper Cervical Spine

At birth the atlas is composed of three ossification centers, one for the body and one for each of the neural arches (Fig. 18-1). The ossification center for the anterior arch is present in approximately 20% of individuals at birth, appearing in the remainder during the first year of life. Occasionally, the anterior arch is bifid, and the body may be formed from two centers or may fail to completely appear. The posterior arches usually close by 3 years of age. Occasionally, the posterior synchondrosis between the two halves of the neural arch fail to fuse and result in a bifid arch. This common variation must be considered during any surgical dissection in this region. The neurocentral synchondroses that link the neural arches to the body are best seen on an open-mouth odontoid view. These synchondroses close by 7 years of age and should not be mistaken for fractures (30). The canal of the atlas is large to allow for the amount of rotation that occurs at this joint as well as some forward translation (31). The vertebral arteries are about 2 cm from the midline and run in a groove on the superior surface of the atlas. This must be remembered during lateral dissection at the occipital cervical junction. The ring of C1 reaches about normal adult size by four years of age. Therefore arthrodesis after 4 years of age should not cause spinal canal stenosis (Fig. 18-2).

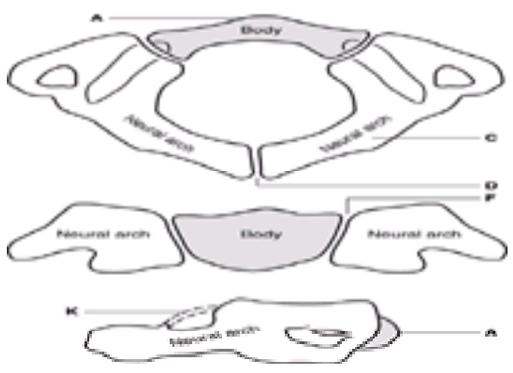

FIGURE 18-1. Diagram of C1 (atlas). The body **(A)** is not ossified at birth, and its ossification center appears during the 1st year of life. The body may fail to develop, and forward extension of neural arches **(C)** may take its place. Neural arches appear bilaterally about the 7th week **(D)**, and the most anterior portion of the superior articulating surface is usually formed by the body. Synchondrosis of spinous processes unite by the 3rd year. Union may rarely be preceded by the appearance of the secondary center within the synchondrosis. Neurocentral synchondrosis **(F)** fuses about the 7th year. The ligament surrounding the superior vertebral notch **(K)** may ossify, especially in later life. (Reprinted from Bailey DK. Normal cervical spine in infants and children. *Radiology* 1952;59 : 713=714; with permission.)

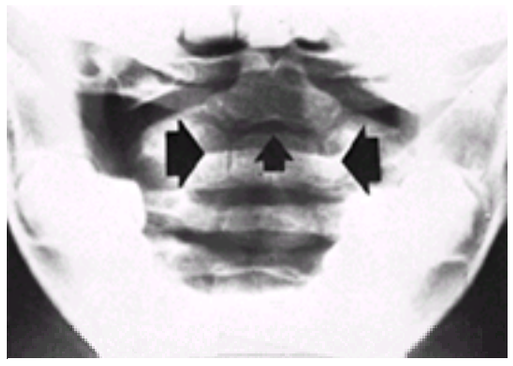

FIGURE 18-2. The epiphysis at the base of the odontoid process is shown by the small arrow. This is well below the level of the superior articular facet of the axis. The synchondroses between the body of the axis and the neural arches are shown by the large arrows. Just above this are the synchondroses between the odontoid process and the neural arches. The odontoid process, therefore, surmounts the body of the axis and is sandwiched between the neural arches. The physis and synchondroses combine to form the letter arches. (Reprinted from Fielding JW. Selective observations on the cervical spine in child. In: Ahstrom JP Jr, ed. *Current practice in orthopaedic surgery.* Vol. 5. St. Louis: CV Mosby, 1973; with permission.)

Occipitalization or assimilation of the atlas occurs when the first cervical vertebra fails to segment from the skull. This may lead to basilar impression and narrowing of the foramen magnum. This anomaly can increase a child's susceptibility to spinal cord injury or vertebral artery compromise caused by trauma. Vertebral artery compromise also can occur in patients with occipitalization from skull traction, resulting in brainstem ischemia (14).

The axis develops from at least four separate ossification centers: one for the dens, one for the body, and two for the neural arches (Fig. 18-3). Between the odontoid and the body of the axis is a synchondrosis or vestigial disk space that often is mistaken for a fracture line. This synchondrosis runs well below the level of the articular processes of the axis and usually fuses at about 6 to 7 years of age, although it may persist as a sclerotic line until 11 years of age (31). The most common odontoid fracture pattern in adults and adolescents is transverse and at the level of the articular processes. This fracture should not be confused with the normal synchondrosis, which is more cup shaped, with the transverse portion below the level of the articular processes in the body of the axis. After 6 to 7 years of age, the synchondrosis should not be present on an open-mouth odontoid view. A fracture should be considered if a lucent line is present after 7 years of age. The neural arches of C2 fuse at 3 to 6 years of age. These are seen as vertical lucent lines on the open-mouth odontoid view. Occasionally, the tip of the odontoid is V shaped (dens bicornum) or a small separate summit ossification center may be present at the tip of the odontoid (ossiculum terminale) (Fig. 18-4).

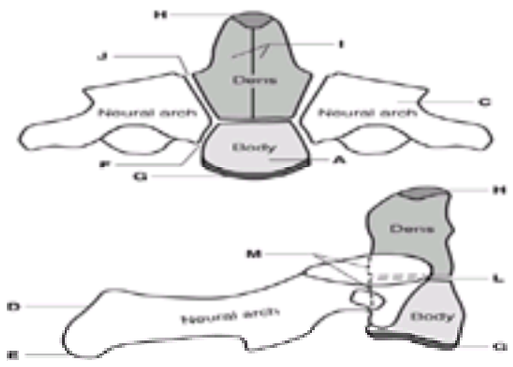

FIGURE 18-3. Diagram of C2 (axis). The body **(A)** in which one center (occasionally two) appears by the 5th fetal month. Neural arches **(C)** appear bilaterally by the 7th fetal month. Neural arches fuse **(D)** posteriorly by the 2nd or 3rd year. Bifid tip **(E)** of spinous process (occasionally a secondary center is present in each tip). Neurocentral synchondrosis **(F)** fuses at 3 to 6 years. The inferior epiphyseal ring **(G)** appears at puberty and fuses at about 25 years of age. The summit ossification center **(H)** for the odontoid appears at 3 to 6 years and fuses with the odontoid by 12 years. Odontoid (dens) **(I)**. Two separate centers appear by the 5th fetal month and fuse with each other by the 7th fetal month. Synchondrosis between the odontoid and neural arch **(I)** fuses at 3 to 6 years. Synchondrosis between the odontoid and body **(L)** fuses at 3 to 6 years. Posterior surface of the body and odontoid **(M)**. (Reprinted from Bailey DK. Normal cervical spine in infants and children. *Radiology* 1952;59 : 713-714; with permission.)

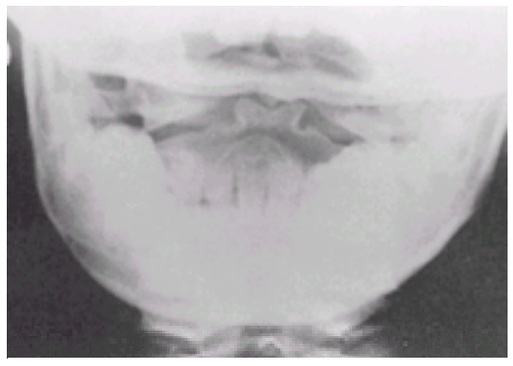

FIGURE 18-4. Anteroposterior open-mouth odontoid view demonstrating V-shaped dens bicornis and ossiculum terminale. (Reprinted from Warner WC. Cervical spine anomalies. In: Canale ST, Beaty JH, eds. *Operative pediatric orthopedics,* 2nd ed. St. Louis: CV Mosby, 1995; with permission.)

The arterial blood supply to the odontoid is derived from the vertebral and carotid arteries. The anterior and posterior ascending arteries arise from the vertebral artery at the level of C3 and ascend anteriorly and posteriorly to the odontoid, meeting superiorly to form an apical arcade. These arteries supply small penetrating branches to the body of the axis and the odontoid process. The internal carotid artery gives off cleft perforators that supply the superior portion of the odontoid. This peculiar arrangement of arteries and vessels is necessary for embryologic development and anatomic function of the odontoid. The synchondrosis prevents direct vascularization of the odontoid from C2, and vascularization from the blood supply of C1 is not possible because the synovial joint cavity surrounds the odontoid. The formation of an os odontoideum after cervical trauma may be related to this peculiar blood supply (Fig. 18-5).

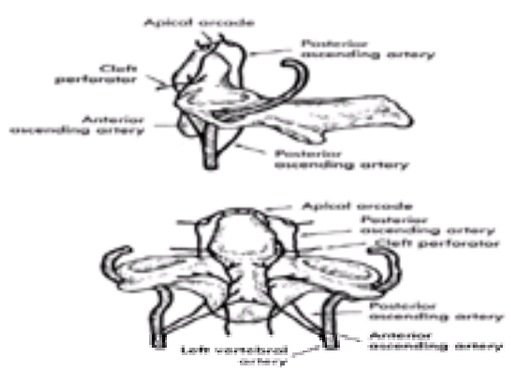

FIGURE 18-5. Blood supply to odontoid: posterior and anterior ascending arteries and apical arcade. (Reprinted from Schiff DC, Parke WW. The arterial supply of the odontoid process. *J Bone Joint Surg [Am]* 1973;55 : 1450-1464; with permission.)

Lower Cervical Spine

The third and seventh cervical vertebrae share a similar ossification pattern: a single ossification center for the vertebral body and an ossification center for each neural arch (Fig. 18-6). The neural arch fuses posteriorly between the second and third years, and the neurocentral synchondroses between the neural arches and the vertebral body fuse by 3 to 6 years of age. These vertebrae are normally wedge shaped until 7 to 8 years of age (31,96,133). The vertebral bodies, neural arches, and pedicles enlarge by periosteal appositional growth, similar to that seen in long bones. By 8 to 10 years of age, a child's spine usually reaches near adult size and characteristics. There are 5 secondary ossification centers that can remain open until 25 years of age (96). These include one each for the spinous processes, transverse processes, and the ring apophyses about the vertebral end plates. These should not be confused with fractures.

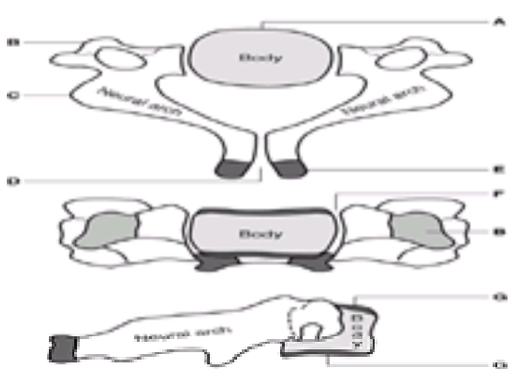

FIGURE 18-6. Diagram of typical cervical vertebrae, C3 to C7. The body **(A)** appears by the 5th fetal month. The anterior (costal) portion of the transverse process **(B)** may develop from a separate center that appears by the 6th fetal month and joins the arch by the 6th year. Neural arches **(C)** appear by the 7th to 9th fetal week. Synchondrosis between spinous processes **(D)** usually unites by the 2nd or 3rd year. Secondary centers for bifid spine **(E)** appear at puberty and unite with spinous process at 25 years. Neurocentral synchondrosis **(F)** fuses at 3 to 6 years. Superior and inferior epiphyseal rings **(G)** appear at puberty and unite with the body at about 25 years. The seventh cervical vertebra differs slightly because of a long, powerful, nonbifid spinous process. (Reprinted from Bailey DK. Normal cervical spine in infants and children. *Radiology* 1952;59 : 713-714; with permission.)

The superior and inferior end plates are firmly bound to the adjacent disk. The junction between the vertebral body and the end plate is similar to a physis of a long bone. The vertebral body is analogous to the metaphysis, and the end plate to the physis, where longitudinal growth occurs. The junction between the vertebral body and the end plate has been demonstrated to be weaker than the adjacent vertebral body or disk, which can result in a fracture at the end plate in the area of columnar and calcified cartilage of the growth zone, similar to a Salter I fracture of a long bone (8). The inferior end plate may be more susceptible to this injury than the superior end plate because of the mechanical protection afforded by the developing uncinate processes (17,87).

The facet joints of the cervical spine change in orientation with age. The angle of the C1–C2 facet is 55 degrees in the newborn and increases to 70 degrees at maturity. In the lower cervical spine, the angle of the facet joints is 30 degrees at birth and 60 to 70 degrees at maturity. This may explain why the pediatric cervical spine may be more susceptible to injury from the increased motion or translation allowed by the facet joint orientation.

Increased ligamentous laxity in young children allows a greater degree of spinal mobility. Flexion and extension of the spine at C2–3 is 50% greater in children between the ages of 3 and 8 years than in adults. The level of the greatest mobility in the cervical spine descends with increasing age. Between 3 and 8 years of age the most mobile segment is C3–C4; from ages 9 to 11 years, C4–C5 is the most mobile segment, and from ages 12 to 15 years C5–C6 is the most mobile segment (34,125). This explains the tendency for craniocervical injuries in the young children.

Several anomalies of the cervical spine may influence treatment recommendations. The atlas can fail to segment from the skull, a condition called occipitalization of the atlas, and can lead to narrowing of the foramen magnum, neurologic symptoms, and increased stresses to the atlantoaxial articulation, which often causes instability. The association of occipitalization of the atlas and congenital fusion of C2 and C3 is likely to lead to atlantoaxial instability. Failure of fusion of the posterior

arc of C1 is not uncommon and should be sought before performing any surgical procedure that involves C1. Wedge-shaped vertebrae, bifid vertebrae, or a combination of these also can occur. Klippel-Feil syndrome consists of the classic triad of a short neck, low posterior hairline, and severe restriction of motion of the neck from fusion of the cervical vertebrae (77,91). Congenital fusion of the cervical spine may predispose a child to injury from trauma by concentrating stresses in the remaining mobile segments.

Hensinger et al. (76) reported congenital anomalies of the odontoid process, including aplasia (complete absence), hypoplasia (partial absence in which there is a stubby piece at the base of the odontoid located above the C1 articulation), and os odontoideum. Os odontoideum consists of a separate ossicle of the odontoid with no connection to the body of C2. The cause may be traumatic in nature (76). These anomalies of the odontoid also may predispose a child to injury or instability.

HISTORY

Most cervical spine injuries in young children occur from falls, motor vehicle accidents, or pedestrian–vehicle accidents (36,107). In young children a fall from less than 5 feet can cause a cervical spine injury (144). Infants are at risk for cervical spine injury from lack of head control. Other causes of cervical spine injury in infants are child abuse and obstetric trauma (Table 18-1) (30,153,162). In teenagers injuries from sports and motor vehicle accidents are more common (107,166). At Children's Hospital in Boston, cervical spine injuries from unsupervised diving exceeded those occurring in organized athletics over the past 20 years. Haffner et al. (70) have reported an increased frequency of spinal injuries from gunshot wounds in teenagers.

Obtaining an adequate history and physical examination from an injured child may require more time, patience, and effort by the treating physician. An adequate history and physical examination may not be obtained on the initial examination, and repeated examination may be necessary.

SYMPTOMS

Children with cervical spine injuries have various signs and symptoms. Neck pain or localized tenderness of the cervical spine is the most common presenting symptom and should alert the physician to proceed with further diagnostic workup. The patient also may have more subtle complaints, such as headaches, occipital pain radiating to the shoulders, limited range of motion, torticollis, bowel or bladder symptoms, seizures, or a snapping sensation in the neck. In newborns, any unexplained respiratory distress, delayed motor response, hypotonia, or hypertonia should be evaluated. Occasionally, a patient may be unresponsive, so the spine must be protected until appropriate spine clearance has been obtained. Head or facial trauma, loss of consciousness, or high-speed motor vehicle accident are indications for evaluation of the cervical spine. Sometimes after multiple trauma, the only sign of a cervical spine injury is difficulty weaning from assisted ventilation. Often this is associated with a closed head injury. This can mislead the treating physician into believing that the difficulty in weaning from the ventilator is due to the head injury, and an associated cervical spine injury may be overlooked. Positive neurologic findings may be present despite a normal-appearing radiograph, a condition called SCIWORA, and should alert the treating physician to a possible occult cervical spine injury (83,122,164,169).

EVALUATION

Examination of an injured child should begin with inspection for associated head or facial trauma. Abrasions and bruising about the neck that can be caused by direct trauma or from the shoulder harness of a seat belt may be clues to an underlying cervical spine injury (Fig. 18-7) (58,66,82,99). An unconscious patient should be treated as if a cervical spine injury is present until proved otherwise (Fig. 18-8). The spine should be palpated for tenderness, muscle spasm, and alignment of the vertebrae. The spinous processes of C2 and C3 should be prominent and easily palpable. Anterior examination of the cervical spine may be difficult in a child. The cricoid cartilage is at the C5–C6 level and can be used as an anatomic landmark. The entire spine should be palpated and examined, because 20% of patients with cervical spine injuries have injuries at multiple levels (158). A thorough neurologic examination of both the upper and lower extremities should be performed, including strength, sensation, reflexes, and proprioception. An adequate neurologic examination may not be possible initially, and repeated examinations may be necessary. Extremity weakness or subtle sensory losses may not be apparent initially and may be found only on repeated examinations. Rectal sphincter tone and perianal sensation also should be evaluated. If the child is awake and cooperative, flexion, extension, rotation, and lateral tilt can be performed and correlated with pain. However, this should not be performed if the child is not cooperative or is unresponsive and only after initial screening radiographs have been evaluated.

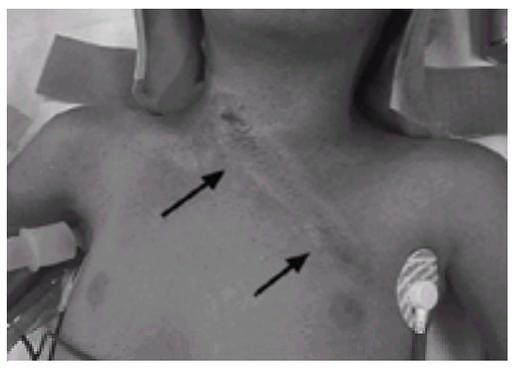

FIGURE 18-7. Clinical photograph of a patient with cervical spine injury, resulting from impact with the shoulder harness of a seat belt. Note location of skin contusions from the seat belt.

FIGURE 18-8. Clinical photograph demonstrating a soft tissue injury that can occur from impact with a shoulder harness of a seat belt and air bag inflation.

RADIOGRAPHIC EVALUATION

Plain Radiographs

When cervical spine injury is suspected, radiographs of the cervical spine are indicated. There is still no consensus on whether routine radiographs of the cervical spine should be obtained in every pediatric trauma patient. Some studies have shown that without associated facial trauma or specific physical findings that suggest cervical spine injury, routine cervical radiographs produce a low yield in pediatric trauma (42,95,133). Rachesky et al. (133) attempted to identify which injured children required cervical spine radiographs. They reviewed a large series of patients, of whom 1.2% had documented cervical spine injuries and concluded that cervical spine radiographs were indicated if the child had a complaint of neck pain, or if head or facial trauma associated with a motor vehicle accident were present. Despite these studies, the burden is still on the treating physician to rule out cervical spine injuries. Initial plain films should include a lateral cervical spine, open-mouth odontoid view, and an anteroposterior cervical spine. Oblique radiographs may be obtained if abnormalities are present on initial radiographs, or the treating physician suspects a cervical spine injury by history or examination. If the patient is medically unstable, then a cross-table lateral radiograph is sufficient until

the patient's condition permits a complete evaluation. Significant false-negative rates of 23% to 26% for single cross-table lateral radiographs have been reported, emphasizing the need for a complete radiographic evaluation of suspected cervical spine injuries (9,148). Lateral flexion and extension views can be obtained, but only with careful supervision and only after static films have not shown any obvious abnormalities. The child must be alert and cooperative, so it may not be possible to obtain these studies in a young, frightened child.

Evaluation of cervical spine radiographs should proceed systematically and should include evaluation of anterior and posterior vertebral body alignment, interspinous distance, and spinolaminar line. The absence of cervical lordosis on a lateral film may be a normal finding in children and does not necessarily indicate a cervical spine injury (31). The prevertebral soft tissue space should be evaluated for increased swelling. An increase in the prevertebral soft tissue space may be a subtle finding of possible ligamentous or bony injury. This soft tissue space may be altered by inspiration, crying, and infection, but a measurement of less than 6 mm at C3 is considered normal.

The interpretation of the plain films requires knowledge of normal spine variations. This is particularly true with the neurocentral synchondrosis and growth plates. Knowing when these should be present and when they should not is important so that they are not mistaken for an occult fracture (Table 18-2).

Avulsion fracture
Apical ossification center of the odontoid
Secondary ossification centers at the tips of the transverse and spinous processes
Fracture
Persistence of the synchondrosis at the base of the odontoid
Apparent anterior wedging of a young child's vertebral body
Normal posterior angulation of the odontoid seen in 4% of normal children
Instability
Pseudosubluxation of C2–C3
Incomplete ossification, especially of the odontoid process, with apparent superior subluxation of the anterior arch of C1
Absence of the ossification center of the anterior arch of C1 in the first year of life may suggest posterior displacement of C1 on the odontoid
Increase in the atlanto-dens interval of up to 4.5 mm
Miscellaneous
Physiologic variations in the width of the prevertebral soft tissue due to crying misinterpreted as swelling due to edema or hemorrhage
Overlying structures such as ears, braided hair, teeth, or hyoid bone. Plastic rivets used in modern emergency cervical immobilization collars can simulate fracture line
Horizontally placed facets in the younger child, creating the illusion of a pillar fracture
Congenital anomalies such as os odontoideum, spina bifida, and congenital fusion or hemivertebrae

TABLE 18-2. NORMAL OSSIFICATION CENTERS AND ANOMALIES FREQUENTLY CONFUSED WITH INJURY

Radiographic Evaluation of Specific Areas of the Spine

Atlantooccipital Junction

The atlantooccipital interval is the most difficult to assess because of the lack of discreet and reproducible landmarks on radiographs. The occipital condyles should rest within the depressions of the facets of the atlas. The interval between the occipital condyles and the superior margin of the facet joints of the atlas should be approximately 3 mm, and if the interval is more than 5 mm, an atlantooccipital disruption may be present (43,125). The interval between the basion (the anterior cortical margin of the foramen magnum) and the tip of the dens should be less than 12 mm (25). Another measurement to evaluate the atlantooccipital junction is the Powers ratio, which assesses the relative position of the skull base to the atlas (Fig. 18-9). A line drawn from the basion to the anterior cortex of the posterior arch of C1 is measured, and this distance is divided by the distance of a line drawn from the opisthion (the posterior cortical margin of the foramen magnum) to the posterior cortex of the anterior arch of C1. A normal value should be less than 1 and more than 0.7. A value of more than 1 suggests anterior subluxation of the atlantooccipital joint. A value of less than 0.7 suggests posterior subluxation of the atlantooccipital joint. However, the basion is not always visible on plain radiographs. The Wackenheim line, which is drawn along the posterior aspect of the clivus, probably is the most easily identified line to determine disruption of the atlantooccipital joint (Fig. 18-10) (108). If the line does not intersect the tip of the odontoid tangentially and if this line is displaced anteriorly or posteriorly, disruption or increased laxity about the atlantooccipital joint should be suspected. Other lines such as the McGregor, McCrae, and Chamberlain are not as useful in the evaluation of trauma but have been useful for identifying congenital anomalies with regard to basilar impression.

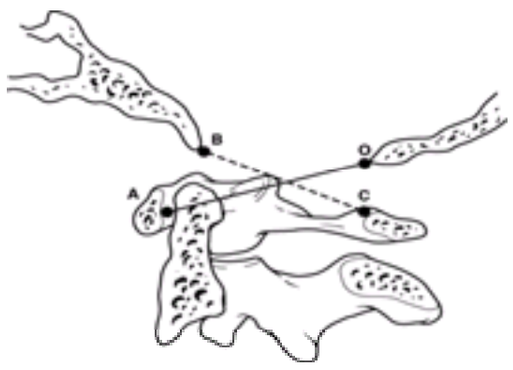

FIGURE 18-9. The Powers ratio is determined by drawing a line from the basion *(B)* to the posterior arch of the atlas (*C*) and a second line from the opisthion (*O*) to the anterior arch of the atlas (*A*). The length of the line BC is divided by the length of the line OA, producing the Powers ratio. (Reprinted from Lebwohl NH, Eismont FJ. Cervical spine injuries in children. In: Weinstein SL, ed. *The pediatric spine: principles and practice.* New York: Raven, 1994; with permission.)

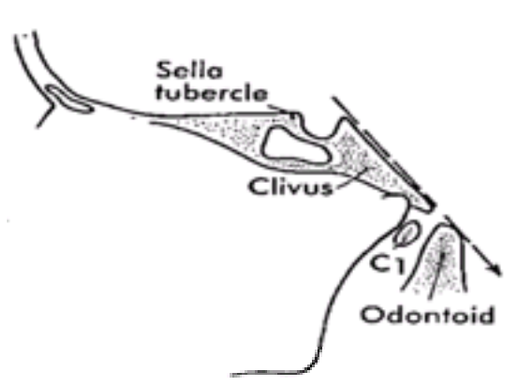

FIGURE 18-10. Drawing of Wackenheim clivus-canal line. This line is drawn along the clivus into the cervical spinal canal and should pass just posterior to the tip of the odontoid. (Reprinted from Menezes AH, Ryken TC. Craniovertebral junction abnormalities. In: Weinstein SL, ed. *The pediatric spine: principles and practice.* New York: Raven, 1994; with permission.)

Atlantoaxial Joint

Evaluation of the atlantoaxial joint should consist of measurement of the atlanto-dens interval and the space available for the spinal cord (Fig. 18-11). Steel reported that the space at the atlantoaxial joint can be divided into thirds: one third is taken up by the odontoid, one third by the spinal cord, and one third is space that is available for the cord (160). Up to 4.5 mm is considered a normal atlanto-dens interval in a child, because the unossified cartilage of the odontoid apparently increases the atlanto-dens interval. Also in children, extension gives the appearance of subluxation of the anterior portion of the atlas over the unossified dens on the

lateral view. This usually is a pseudosubluxation and does not represent true instability (Fig. 18-12) (31,40,51,53).

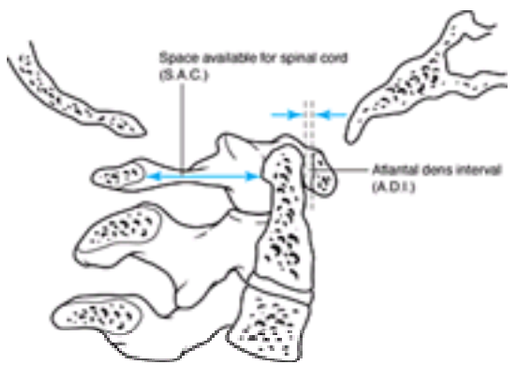

FIGURE 18-11. Sagittal views of the atlantoaxial joint demonstrating the atlanto-dens interval (*ADI*). The space available for the cord (*SAC*) is the distance between the posterior aspect of the odontoid and the posterior ring of C1. (Reprinted from Hensinger RN, Fielding JW. The cervical spine. Upper Cervical Spine

Anterior displacement of one vertebral body on another may indicate a bony or ligamentous injury, but anterior displacement of as much as 3 mm at one level may be a normal finding in the upper cervical spine of a child. This pseudosubluxation is most common at C2–C3 and at C3–C4. The anterior displacement should only be present when the radiographs are taken in flexion, and this displacement will reduce in extension. As an aid in deciding if subluxation is physiologic or pathologic, Swischuk and Rowe (161) and Von Torklus and Gehle (168) described a line drawn from the anterior cortex of the spinous process of C1 to the spinous process of C3 (Fig. 18-13). If the anterior cortex of the C2 spinous process misses this line by more than 3 mm, a true subluxation should be suspected. Also when evaluating instability caused by posterior soft tissue injuries, widening between C1 and C2 of more than 10 mm between the spinous processes is indicative of a soft tissue or ligamentous injury (2).

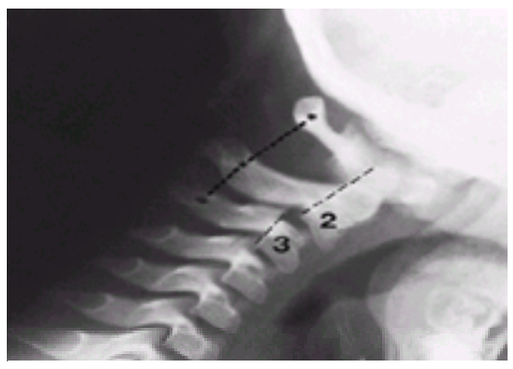

FIGURE 18-13. Pseudosubluxation of C2 on C3. Hypermobility is common in children under the age of 8 years. Specific measurements of the movement of the vertebral bodies (*thin dotted line*) are unreliable, whereas the relationship with the posterior elements (*thick dotted line*) is more consistent. In flexion, the posterior arch of C2 normally aligns itself in a straight-line fashion with C1 and C3. Note the relative horizontal nature of the facet joints, which allows greater mobility. (Reprinted from Swischuk LE. Anterior displacement of C2 in children: physiologic or pathoslogic? A helpful differentiating line. *Radiology* 1977;122 : 759-763; with permission.)

Lower Cervical Spine

Evaluation of the lower cervical spine on a lateral radiograph should include examination of the alignment of the spinous processes, the spinal laminar line, the posterior vertebral body line, and the anterior vertebral body line (Fig. 18-14). These should all be smooth curves with no step-offs or vertebral body translation. Loss of normal cervical lordosis may indicate spasm from a cervical injury but often is a normal finding in a child (169). Naidich's law states that at any level the interspinous distance may be one and a half times greater than the interspinous distance of the level above or the level below. A greater ratio indicates injury. Evaluation of a lateral cervical spine radiograph should include the bony anatomy as well as the soft tissue spaces. Changes in the soft tissue space may warn the physician of an underlying cervical spine injury when no abnormalities of the vertebrae or vertebral alignment are noted on plain radiographs. The normal retropharyngeal soft tissue space should be less than 6 mm at C3, and the retrotracheal space should be less than 14 mm at C6. Any increased widening may be indicative of an occult bony or ligamentous injury. Adran and Kemp (1) showed that the width of this soft tissue shadow may be markedly increased in a crying child because the pharynx is attached to the hyoid bone and any action displacing it forward artificially increases the width of this shadow. Therefore, radiographs must be taken with the patient at rest or during quiet respiration.

Special Imaging Studies

Special studies often are indicated for evaluation of pediatric cervical spine trauma. Most cervical spine injuries can be detected by routine plain radiographs (5). Flexion and extension plain radiographs often are needed to determine if any instability is present. Tomography, computed tomography (CT) scanning, CT myelography, magnetic resonance imaging (MRI), bone scanning, and cineradiography are useful adjunctive studies in the evaluation of cervical spine trauma. Of these, CT scanning to detect occult fractures is the most valuable in the trauma unit setting.

Dynamic Studies

Useful tools in evaluating pediatric cervical spine problems are dynamic flexion and extension radiographs taken from a lateral view, although cineradiography occasionally may be necessary. Static lateral films should always be viewed before performing flexion and extension views. From the static radiographs the physician may suspect a cervical spine injury but the lateral flexion and extension views usually will determine the presence of any instability.

Again, it must be emphasized that these dynamic studies should only be performed under the direct supervision of the treating physician and only in a cooperative patient. Cineradiography allows evaluation of flexion and extension and rotation and tilt; however, it requires a high radiation dose and now is used only in rare cases. CT scanning and MRI have generally replaced cineradiography in the definition of cervical spine injuries in children.

Tomography can aid in identifying injuries that are not seen well on plain radiographs. Sagittal, coronal, and three-dimensional reconstructions from CT scanning can give similar information. Most of the information obtained from tomography can now be obtained with CT reconstruction views, which not only shows information in the axial plane, but also shows better detail of any fractures or bony lesions. Flexion and extension views are possible with CT scanning to evaluate any occult instability. Sagittal, coronal, or three-dimensional reconstruction views can be obtained to help identify fractures or instability patterns at sites that are not easily seen on plain radiographs. This is most useful in evaluating the lateral masses and occipital condyles for fractures and fracture–dislocations. One should take care when placing the child into a CT scanner so that the head is not inadvertently placed in flexion because of the large size of a child's head relative to the body. If this is not taken into account, the neck will be placed in flexion and potentially could increase displacement of an occult fracture. Often children under 4 years of age require sedation for CT scanning.

Magnetic resonance imaging has become a useful diagnostic study to evaluate both soft tissue or ligamentous injury and SCIWORA. MRI gives both bone and soft tissue information, but it is most useful in evaluating the spinal cord for occult injuries and soft tissue for occult swelling, edema, or ligamentous injuries. Closkey et al. described this as a useful tool for detecting cervical spine injuries in head-injured or unconscious patients when flexion and extension views cannot be safely obtained (32).

Myelography is useful in detecting abnormalities in the spinal canal but has largely been replaced by MRI (Fig. 18-15).

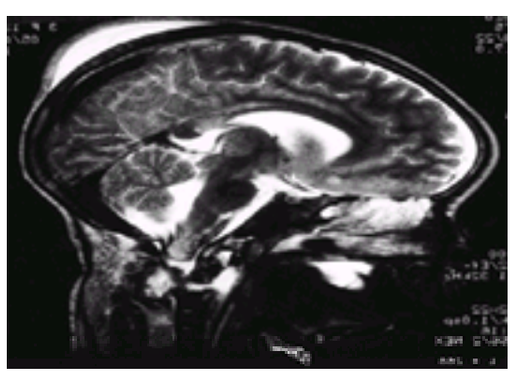

FIGURE 18-15. Magnetic resonance imaging depicts a ligament tear.

Another special study is arteriography, which is used to evaluate the vertebral arteries, especially in upper cervical spine trauma in young children. An MRI-enhanced technique can now be used to evaluate the vertebral arteries for injury and is not as invasive as arteriography. Therefore, cineradiography, myelography, and arteriography have been replaced by CT and MRI, which show better detail.

INITIAL MANAGEMENT OF CERVICAL SPINE INJURIES

Care must be taken to immobilize the cervical spine to prevent damage to the spinal cord, especially while extracting an injured child from an automobile or during transportation. Various devices can be used to immobilize the cervical spine during extraction but should consist of splintage of the head and neck to the thorax. Any immobilization device must allow access to the patient's oropharynx and the anterior region of the neck for emergency intubation or tracheostomy if necessary.

For transportation the child should be placed on a backboard. However, as Herzenberg et al. (79) have pointed out, the standard backboard used for adults is unsuitable for young children. Because the head of a young child is disproportionately large compared with the body, when placed on a standard board, the child's cervical spine is in flexion. This can translate the cervical spine forward into unstable fracture patterns. Herzenberg et al. (79) reported on 10 children under 7 years of age whose cervical spine had anterior angulation or translation on radiographs when placed on a standard backboard. They recommend a backboard with a recess so that the head can be lowered into it to obtain a neutral position of the cervical spine. This also can be accomplished with a split mattress technique, in which the body is supported by two mattresses, and the head is supported by one. Children under 6 years of age should be immobilized using a split mattress technique or a spine board with an occipital recess (Fig. 18-16 and Fig. 18-17) (79). One problem with this immobilization protocol, however, is that it tends to reduce displaced fractures and makes recognition of the injury more difficult, especially end plate fractures, which are similar to Salter I fractures in that when reduced the fracture line cannot be seen (Fig. 18-18) (78).

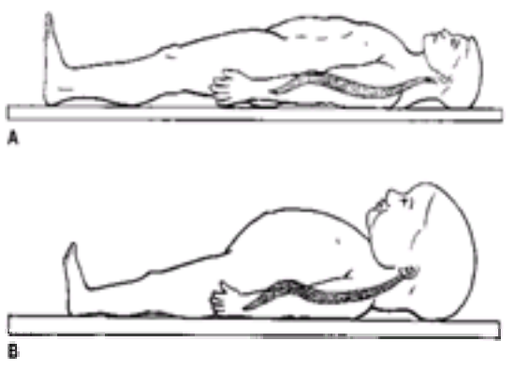

FIGURE 18-16. A: Adult immobilized on a standard backboard. **B:** Young child on a standard backboard. The relatively large head forces the neck into a kyphotic position. (Reprinted from Herzenberg JE, Hensinger RN, Dedrick DK, et al. Emergency transport and positioning of young children who have an injury of the cervical spine. The standard backboard may be hazardous. *J Bone Joint Surg [Am]* 1989;71 : 15-22; with permission.)

Emergency transport and positioning of young children who have an injury of the cervical spine: the standard backboard may be hazardous. *J Bone Joint Surg [Am]* 1989;71 : 15-22; with permission.)

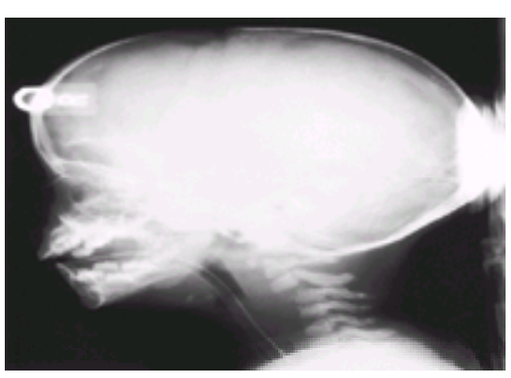

FIGURE 18-18. Lateral radiograph demonstrating anterior displacement of a fracture resulting from improper immobilization of a child on a flat spine board without an occipital recess.

If a child needs to be placed in a halo body jacket, this head–trunk relationship also should be remembered so that the cervical spine is not in flexion.

A large variety of pediatric cervical stabilization devices are available, including rigid cervical collars made out of plastic or soft foam (37,110). The rigid cervical collars give better immobilization than soft foam collars, but they may cause problems from pressure and often proper fitting may be difficult. Even the best immobilization allows 17 degrees of flexion, 19 degrees of extension, 4 degrees of rotation, and 6 degrees of lateral motion (110). Huerta et al. (84) recommended that these devices be supplemented with tape and sand bags on either side of the head to limit the amount of spinal motion to 3 degrees in any direction. If resuscitation is required, further displacement of an unstable cervical injury is a potential risk. A study of four patients with unstable cervical injuries who failed to be resuscitated in the emergency room showed that axial traction during the emergency treatment actually increased the deformity (15). Skull tongs and halo devices can be used in young children for immobilization (68), but care must be taken regarding the amount of pressure that can be used for the Crutchfield tongs or halo pins. There are special pediatric pin sets for the Crutchfield tongs, and if a halo device is used, then multiple pins at a lower torque are recommended.

Minerva cast immobilization is an effective means of immobilizing the cervical spine, but to place a well-fitted cast on a young child requires some attention to detail. Custom-made orthoses also can be used and have the advantages of easier care and adjustability. The disadvantage is that they do not immobilize the cervical spine as well as a properly applied Minerva cast (Fig. 18-19). Thermoplastic materials also may cause significant skin problems from excoriation secondary to the plastic and contact dermatitis (Fig. 18-20).

FIGURE 18-19. A 3-year-old with a fracture of the odontoid immobilized in a Minerva cast.

FIGURE 18-20. A: A child immobilized in a SOMI brace. **B:** Note the rash secondary to contact dermatitis.

The halo device, introduced by Perry and Nickel (126) in 1959, provides immobilization of an unstable cervical spine and also can be used for traction in certain situations. The halo device can be used to immobilize the injured cervical spine in children, but the complications seen with the use of a halo device are much more frequent in children than in adults (11,44). Dormans et al. (44) reported a 68% complication rate with the use of halo immobilization in children, most commonly pin site infection and pin loosening. Other complications were dural penetration, supraorbital nerve injury, and pin site scars that were considered by the family to be objectionable. Despite this high complication rate, all patients were able to wear the halo until fracture healing or fusion occurred (45). A prefabricated halo vest has been used with good results in adults, and these vests can be easily fitted, but in children proper fit rarely is achieved and a halo cast or custom-molded halo vest is needed to obtain adequate fit and immobilization. If a cast or custom-fitted vest is not used, the head will be fixed in the halo and unwanted movement will take place in the vest (Fig. 18-21, Fig. 18-22 and Fig. 18-23).

FIGURE 18-21. Child immobilized in halo brace after occipital cervical arthrodesis.

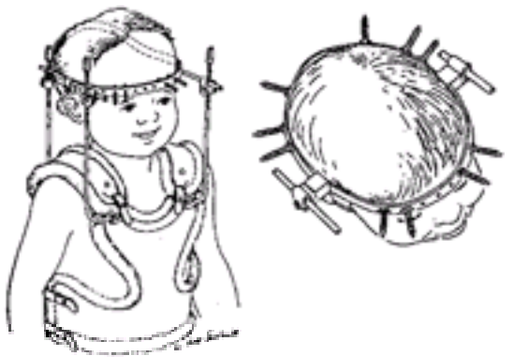

FIGURE 18-22. A: Custom halo vest and light superstructure. **B:** In the multiple-pin, low-torque technique, 10 pins are used for an infant halo ring attachment. Usually, 4 pins are placed anteriorly, avoiding the temporal area, and the remaining 6 pins are placed in the occipital area. (Reprinted from Mubarak SJ, Camp JF, Fuletich W, et al. Halo application in the infant. *J Pediatr Orthop* 1989;9:612–614; with permission.)

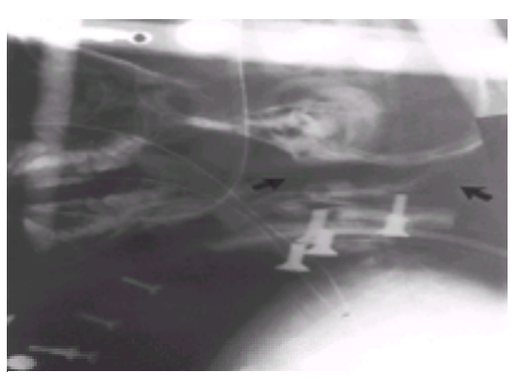

FIGURE 18-23. Patient with an atlantooccipital dislocation in a halo brace. Note the improper fitting of the vest and space between the vest and chest wall. This allows for significant displacement of atlantooccipital dislocation in the halo brace.

Mubarak et al. (112) recommended the following steps in the fabrication of a custom halo for a child: (a) the size and configuration of the head are obtained with the use of a flexible lead wire placed around the head; (b) the halo ring is fabricated by constructing a ring 2 cm larger in diameter than the wire model; (c) a plaster mold of the trunk is obtained for the manufacture of a custom bivalved polypropylene vest; and (d) linear measurements are made to ensure appropriate length of the superstructure.

Computed tomography scanning before halo application may help determine bone structure and skull thickness and aid in planning pin placement to avoid a suture line, congenital malformations, and sites that may be prone to pin penetration because of skull thickness. Skull thickness in children varies greatly up to 6 years of age (97) and increases between the ages of 10 and 16 years, after which time it is similar to that in adults. Letts found that a 2-mm skull could be completely penetrated with a 160-pound load, which is below the recommended torque pressure for adult skulls.

Mubarak et al. (112) recommended the use of multiple pins at lower torque pressures in infants and children. Eight to ten pins can be used and tightened to 2 to 4 inch-pounds, depending on the child's age. The use of multiple pins allows significantly less torque pressure. Although this technique is useful, skull development is an important factor to consider in halo application in patients under 2 years of age. The halo probably should not be used in children under 18 months of age: cranial suture interdigitation may be incomplete and fontanels may be open anteriorly in children under 18 months of age and posteriorly in children under 6 months of age. If

a halo is used in patients under 18 months of age, there is the potential for displacement through the unfused suture lines.

Technique of Halo Application

Once constructed, the halo ring is applied with the patient under general anesthesia. In older children and adolescents, local anesthesia can be used. The patient is placed supine, and the head is supported by an assistant or a cupped metal extension that cradles the head. If a metal extension is used, care should be taken not to place the neck in flexion and to maintain the proper relationship of the head and neck with the trunk. The immediate areas of pin insertion are shaved and the skin is prepared with antiseptic solution. Selected areas in the skin and the periosteum are infiltrated with local anesthetic. With the help of an assistant and an application device, the halo is held around the patient's head. The halo is held below the area of greatest diameter of the skull, just above the eyebrows, and about 1 cm above the tips of the ears. The pin sites are carefully selected so that the pins enter the skull as nearly perpendicular as possible. The best position for the anterior pins is in the anterolateral aspect of the skull, above the lateral two thirds of the orbit, and below the greatest circumference of the skull; this area is a relatively safe zone. This will avoid injury to the supraorbital and supratrochlear nerves. Care should be taken to avoid the temporalis muscle because penetration of this muscle by the halo pin can be painful and may impede mandibular motion during mastication or talking; the bone in this area also is very thin, and pin loosening is likely.

The posterior pins are placed directly diagonal from the anterior pins, if possible, and inferior to the equator of the skull. The pins are introduced through the halo and the two diagonally opposed pins are tightened simultaneously. It is important that the patient's eyes are closed while the pins are tightened to ensure that the forehead skin is not anchored in such a way as to prevent the eyelids from closing after application of the halo.

In an infant or young child, 10 pins are inserted to finger tightness or 2 inch-pounds anterolaterally and posteriorly. If the skull thickness is of great concern, finger tightness only should be used to prevent penetrating the skull. In slightly older children, 2 inch-pounds of torque should be used. In adolescents near skeletal maturity whose skull thickness is nearly that of an adult (as determined by CT scan) torque pressure can be increased to as much as 6 to 8 inch-pounds. The pins are secured to the halo with the appropriate lock nuts or set screws. A custom polypropylene vest or cast is applied as well as the superstructure after the halo ring and pins are in place.

The pins should be cleaned daily at the skin interface with hydrogen peroxide or a small amount of povidone-iodine solution. The pins are tightened again 48 hours after application. If a pin becomes loose after halo application, it can be retightened as long as resistance is met. If no resistance is met, the pin should be removed and another pin inserted at another site. Superficial infections about the pin site can be treated with oral antibiotics and continued pin site care. If the cellulitis persists or an abscess forms, then the pins should be removed. Dural puncture can occur from the halo pins. When this occurs the pin should be removed and prophylactic antibiotics should be given. The dural tear usually heals in 4 to 5 days, at which time the antibiotics can be discontinued.

SPINAL CORD INJURY WITHOUT RADIOGRAPHIC ABNORMALITIES

Spinal cord injury without radiographic abnormalities, a syndrome first brought to the attention of the medical community by Pang and Wilberger (122), is unique to children. This condition is defined as a spinal cord injury in a patient with no visible fracture or dislocation on plain radiographs, tomograms, or CT scans.

A complete or incomplete spinal cord lesion may be present, and the injury usually results from severe flexion or distraction to the cervical spine. SCIWORA is believed to occur because the spinal column (vertebrae and disk space) in children is more elastic than the spinal cord and can undergo considerable deformation without being disrupted (26). The spinal column can elongate up to 2 inches without disruption, whereas the spinal cord ruptures with only one fourth of an inch of elongation.

Spinal cord injury without radiographic abnormalities also may represent an ischemic injury in some patients, although most are believed to be due to a distraction-type injury in which the spinal cord has not tolerated the degree of distraction but the bony ligamentous elements have not failed. Aufdermaur suggested another possibility (8): a fracture through a pediatric vertebral end plate reduces spontaneously (much like a Salter I fracture), giving a normal radiographic appearance, although the initial displacement could have caused spinal cord injury.

Spinal cord injury without radiographic abnormalities is more common in children under 8 years of age than in older children (122,124,139,169). Predisposing factors that may explain the increased frequency of SCIWORA in younger children are cervical spine hypermobility, ligamentous laxity, and an immature vascular supply to the spinal cord. The reported incidence of this condition varies from 7% to 66% of patients with cervical spine injuries (Sullivan's incidence of SCIWORA was 5% to 67%) (121,122,175).

Delayed onset of neurologic symptoms have been reported in as many as 52% of patients in some series (122,139). Pang and Pollock reported 15 patients who had delayed paralysis after their injury (121). Nine had transient warning signs such as paresthesia or subjective paralysis. In all patients with delayed onset of paralysis, the spine had not been immobilized after the initial trauma and all were neurologically normal before the second event. This underlines the importance of diligent immobilization of a suspected spinal cord injury in a child. Approximately half of the young children with SCIWORA in reported series had complete spinal cord injuries, whereas the older children usually had incomplete neurologic deficit injuries that involved the subaxial cervical spine (6,8,69,139).

Careful radiographic evaluation is helpful in the workup of these patients, but MRI will show a spinal cord lesion that often is some distance from the vertebral column injury. As many as 5% to 10% of children with spinal cord injuries have normal radiographic results (69,75).

SPINAL CORD INJURY IN CHILDREN

Spinal cord injuries are still rare in children. Rang reviewed spinal injuries at the Toronto Hospital for Sick Children over 15 years and found that children constituted a small percentage of the patients with acquired quadriplegia or paraplegia (134). He found that paraplegia was three times more common than quadriplegia. When a spinal cord injury is suspected, the neurologic examination must be complete and meticulous and may take several examinations of sensory and motor function. If an acute spinal cord injury is documented by examination, the administration of methylprednisolone within the first 8 hours after injury has been shown to improve the chances of neurologic recovery (18, 19, 20 and 21). Methylprednisolone in the treatment of acute spinal cord injuries has been shown to improve motor and sensory recovery when evaluated 6 weeks and 6 months postinjury (20); however, this positive effect on neurologic recovery is limited to those treated within the first 8 hours of injury. The initial loading dose of methylprednisolone is 30 mg/kg body weight. If the loading dose is given within 3 hours after injury, then a maintenance infusion of 5.4 mg/kg is given for 24 hours after injury. If the loading dose is given between 3 and 8 hours after injury, then a maintenance infusion of 5.4 mg/kg is given for 48 hours after injury. Methylprednisolone decreases edema, has an antiinflammatory effect, and protects the cell membranes from scavenging oxygen free radicals (18, 19, 20 and 21).

In several series (18, 19, 20 and 21) there was a slight increase in the incidence of wound infections, but no significant increase in gastrointestinal bleeding. All of these studies involved patients 13 years or older, so no documentation of the efficacy in young children exists. A combination of methylprednisolone and GM1 ganglioside is being studied for its possible beneficial effect on an injured spinal cord (61, 62, 63 and 64). GM1 is a complex acidlike lipid found at high levels in the cell membrane of the central nervous system that is thought to have a neuroprotective and neurofunctional restorative potential. Early studies have shown that patients given both drugs have had improved recovery over those who had received just methylprednisolone.

Once spinal cord injury is documented, routine care includes prophylaxis for stress ulcers, routine skin care to prevent pressure sores, and initial Foley catheterization followed by intermittent catheterization and a bowel training program. With incomplete lesions, children have a better chance than adults for useful recovery. Hadley et al. (69) noted that 89% of pediatric patients with incomplete spinal cord lesions improved, whereas only 20% of patients with complete injuries had evidence of significant recovery. Laminectomy has not been beneficial and can be harmful (151,174) because it increases instability in the cervical spine. For example, it can cause a swan neck deformity or progressive kyphotic deformity (104,154). The risk of spinal deformity after spinal cord injury has been investigated by several researchers (10,12,27,49,90,104). Mayfield et al. (104) found that patients who had a spinal cord injury before their growth spurt all developed spinal deformities, 80% of which were progressive. Ninety-three percent developed scoliosis, 57% developed kyphosis, and 18% lordosis. Sixty-one percent of these patients required spinal arthrodesis for stabilization of their curves. Orthotic management usually is unsuccessful, but in some patients it delays the age at which arthrodesis is necessary. Lower extremity deformities also may occur, such as subluxations and dislocations about the hip. Pelvic obliquity can be a significant problem and may result in pressure sores and difficulty in seating in a wheelchair.

NEONATAL INJURY

Spinal column injury and spinal cord injury can occur during birth, especially during a breech delivery (117,163). Injuries associated with breech delivery usually are in the lower cervical spine or upper thoracic spine and are thought to result from traction, whereas injuries associated with cephalic delivery usually occur in the upper cervical spine and are thought to result from rotation. It is unclear whether cesarean section reduces spinal injury in neonates (100); however, Bresnan and Abroms (22) noted that neck hyperextension *in utero* (star-gazing fetus) in breech presentations is likely to result in an estimated 25% spinal cord injury with vaginal delivery and can be prevented by delivering via cesarean section.

Distraction type injuries to the upper cervical spine have been reported in infants in forward-facing car seats. Because infants have poor head control and muscular development, if placed in a forward facing car seat and a sudden deceleration occurs, the infant's head continues forward while the remainder of the body is strapped in the car seat, resulting in a distraction-type injury (66).

Neuromuscular control of the cervical spine in neonates and infants is underdeveloped, and a normal infant cannot adequately support his or her head until about 3 months of age. Infants, therefore, cannot protect their spines against excessive forces that may occur during delivery or during the months after birth. Skeletal injuries from obstetric trauma are probably under-reported because the infantile spine is largely cartilaginous and difficult to evaluate radiographically, especially if the injury is through the cartilage or cartilage–bone interface (8). A cervical spine lesion should be considered in an infant who is floppy at birth, especially after a difficult delivery. Flaccid paralysis with areflexia usually is followed by a typical pattern of hyperreflexia once spinal cord shock is over. Brachial plexus palsies also warrant cervical spine radiographs. MRI can sometimes be helpful in this diagnosis.

Shulman et al. (153) found atlantooccipital and axial dislocations at autopsy, and Tawbin (163) found a 10% incidence of brain and spinal injuries at autopsy.

Treatment of the neonatal cervical spine is nonoperative and should consist of careful realignment and positioning of the child on a bed with neck support or a custom cervical thoracic orthosis. Healing of bony injuries is usually rapid and complete (159).

Caffey (30) in 1974 and Swischuk (162) in 1969 described a child abuse syndrome called the shaken infant syndrome. Children have weak and immature neck musculature and cannot support their heads when they are subjected to whiplash stresses. Intercranial and interocular hemorrhages can occur. This injury can result in death or cerebral injury with retardation and permanent visual and hearing defects. Fractures of the spinal column and spinal cord injuries can occur after the violent shaking of the child. Swischuk reported a spinal cord injury in a 2-year-old that was the result of violent shaking that produced a cervical fracture dislocation that spontaneously reduced (162).

OCCIPITAL CONDYLAR FRACTURE

Occipital condylar fractures are rare, and their diagnosis requires a high index of suspicion, especially in patients who are unconscious or have a closed head injury or cranial nerve injury. CT with multiplanar reconstruction usually is necessary to establish the diagnosis. Three types of occipital condylar fractures have been described: type I, impaction fracture; type II, basilar skull fracture extending into the condyle; and type III, avulsion fractures. An avulsion fracture is the only type of occipital condylar fracture that is unstable. Type I injuries are the result of axial compression. Type II injuries occur after a direct blow. Both type I and II occipital condylar fractures can be treated with a cervical orthosis. Type III or avulsion fractures require halo immobilization or occipitocervical arthrodesis (3).

ATLANTOOCCIPITAL INSTABILITY

Atlantooccipital dislocation was once thought to be a rare fatal injury found only at the time of autopsy (Fig. 18-24) (8,16,24,153). This injury is now being recognized more often, and children are surviving (44,123,158). This increase in the survival rate may be due to increased awareness and improved emergency care with resuscitation and spinal immobilization by emergency personnel. Atlantooccipital dislocation occurs in sudden deceleration accidents, such as motor vehicle or pedestrian–vehicle accidents. The head is thrown forward, and this may cause sudden craniovertebral separation.

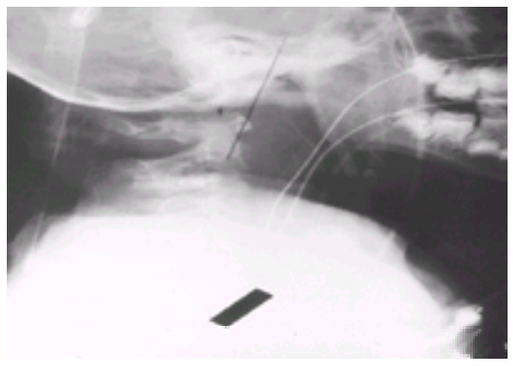

FIGURE 18-24. Patient with atlantooccipital dislocation. Note the forward displacement of the Wackenheim line and the significant anterior soft issue swelling.

The atlantooccipital joint is a condylar joint that has little inherent bony stability. Stability is provided by the ligaments about the joint. The primary stabilizers are the paired alar ligaments and the tectorial membrane (a continuation of the posterior longitudinal ligament). In children, this articulation is not as well formed as in adults and it is less cup shaped. Therefore, there is less resistance to translational forces (8,16,24,25,153).

Diagnosis may be difficult, because atlantooccipital dislocation is a ligamentous injury. Although patients with this injury have a history of trauma, some may have no neurologic findings. Others, however, may have symptoms such as cranial nerve injury, vomiting, headache, torticollis, or motor or sensory deficits (24,29,33,74,81,123). Brainstem symptoms, such as ataxia and vertigo, may be caused by vertebrobasilar vascular insufficiency. Unexplained weakness or difficulty in weaning off a ventilator after a closed head injury may be a sign of this injury.

The treating physician must be aware of radiographic findings associated with atlantooccipital dislocation. A significant amount of anterior soft tissue swelling usually is present.

Radiographic findings that aid in the diagnosis of atlantooccipital dislocation are the Wackenheim line, Powers ratio, dens–basion interval, and occipital condylar distance. The Wackenheim line is drawn along the clivus and should intersect tangentially the tip of the odontoid. A shift anterior or posterior of this line represents either an anterior or posterior displacement of the occiput on the atlas (Fig. 18-25). This line is probably the most helpful because it is reproducible and easy to identify on a lateral radiograph. The Powers ratio is determined by drawing a line from the basion to the posterior arch of the atlas and a second line from the opisthion to the anterior arch of the atlas. The length of line BC is divided by the length of the line OA, producing the Powers ratio. A ratio of more than 1.0 is diagnostic of anterior atlantooccipital dislocation. A ratio of less than 0.7 is diagnostic of posterior atlantooccipital dislocation. Values between 1.0 and 0.7 are considered normal. Another radiographic measurement is the dens–basion interval. If the interval measures more than 1.2 cm, then disruption of the atlantooccipital joint has occurred (25,129). Donahue et al. (43) described an occipital condylar facet distance of more than 5 mm from the occipital condyle to the C1 facet as indicative of atlantooccipital injury. They recommended measuring this distance from five reference points along the occipital condyle and the C1 facet (Fig. 18-26).

FIGURE 18-25. Craniovertebral dislocation. **A:** Lateral view shows extensive soft tissue swelling. The distance between the basion and the dens is 2.4 cm (*arrows*) (normal is <1 cm). **B:** Line drawing made to demonstrate the abnormal relationship between the occiput and the upper cervical spine. FIGURE 18-26. Atlantooccipital joint measurement points 1 through 5 demonstrated on normal cross-table lateral skull radiograph in an 8-year-old **(A)** and a 14-year-old **(B)**. (Reprinted from Kaufman RA, Carroll CD, Buncher CR. Atlantooccipital junction: standards for measurement in normal children. *AJNR* 1987;8:995–999; with permission.)

Magnetic resonance imaging also is useful in diagnosing atlantooccipital dislocation by showing soft tissue edema and ligament injury or disruption.

OPERATIVE TREATMENT

Because atlantooccipital dislocation is a ligamentous injury, nonoperative treatment usually is unsuccessful. Although Georgopoulos et al. (65) did report successful halo stabilization, immobilization in a halo should be used with caution: if the vest or cast portion is not fitted properly, displacement can increase (Fig. 18-27). Traction should be avoided for the same reason. Surgical stabilization is the recommended treatment (99). Posterior arthrodesis can be performed *in situ,* with wire fixation or fixation with a contoured Luque rod and wires. If the C1–C2 articulation is stable, arthrodesis should be only from the occiput to C1 so that C1–C2 motion is preserved (157). Some researchers have expressed reservations about the chance of obtaining fusion in the narrow atlantooccipital interval and have recommended arthrodesis from the occiput to C2. If stability of the C1–C2 articulation is questionable, arthrodesis should extend to C2 (106).

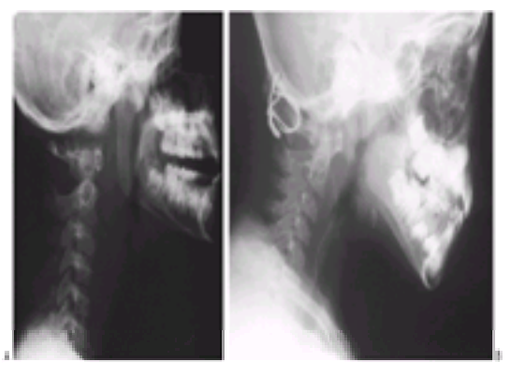

FIGURE 18-27. A: Lateral radiograph of a patient with atlantooccipital dislocation. Note the increase in the facet condylar distance. **B:** Lateral radiograph after occipital C1 arthrodesis.

For a patient who presents very late with an unreduced dislocation, an *in situ* arthrodesis is recommended. DiBenedetto and Lee (41) recommended arthrodesis *in situ* with a suboccipital craniectomy to relieve posterior impingement.

Instability at the atlantooccipital joint is increased in patients with Down's syndrome as well as those with a high cervical arthrodesis below the axis. These patients may be at risk of developing chronic instability patterns and are at higher risk of having instability after trauma.

Occiput to C2 Arthrodesis

Arthrodesis without Internal Fixation

In younger children in whom the posterior elements are absent at C1 or separation is extensive in the bifid part of C1 posteriorly, posterior cervical arthrodesis from the occiput to C2 with iliac crest bone graft is performed using a periosteal flap from the occiput to provide an osteogenic tissue layer for the bone graft (Fig. 18-28) (93).

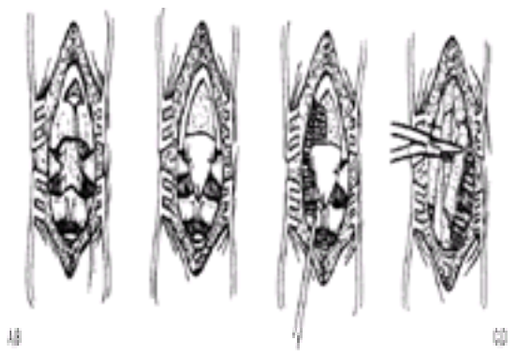

FIGURE 18-28. Technique of occipitocervical arthrodesis used when posterior arch of C1 is absent. **A:** Exposure of the occiput, atlas, and axis. **B:** Reflection of periosteal flap to cover defect in atlas. **C:** Decortication of exposed vertebral elements. **D:** Placement of autogenous cancellous iliac bone grafts. (Redrawn from Koop SE, Winter RB, Lonstein JE. The surgical treatment of instability of the upper part of the cervical spine in children and adolescents. *J Bone Joint Surg [Am]* 1984;66:403; with permission.)

A halo is applied after the patient is anesthetized, endotracheal intubation is obtained, and all anesthesia lines are in place. For younger children, 6 to 10 pins with lower pressure torque are used in the halo (Fig. 18-21); in older children, 4 pins can be used.

A radiograph is obtained to evaluate the position of the head and cervical spine in the prone position with the halo in place. The radiograph also aids in identifying landmarks and levels, although once the skin incision is made, the occiput and spinous processes can be palpated.

A straight posterior incision is made from the occiput to about C3, with care not to expose below C2 to avoid extension of the fusion to lower levels. An epinephrine and lidocaine solution is injected into the cutaneous and subcutaneous tissues to help control local skin and subcutaneous bleeding. The incision is deepened in the midline to the spinous processes of C2. Once identified, the level of the posterior elements of C1 or the dura is more easily found.

After C2 is identified, subperiosteal dissection is carried proximally. Extraperiosteal dissection is used to approach the occiput (Fig. 18-28A). The dura is not completely exposed; if possible, any fat or ligamentous tissue present is left intact. The interspinous ligaments also should be left intact.

The occipital periosteum is mobilized by making a triangular incision directly on the posterior skull, with the apex posteriorly and the broad base over the foramen magnum region. A flap of 3 or 4 cm at the base can be created. With subperiosteal elevation, the periosteum can be reflected from the occiput to the spinous processes of C2 (Fig. 18-28B). The apex of the flap is sutured to the spinous process of C2 and is attached laterally to any posterior elements that are present at C1 or other lateral soft tissues. After the periosteum is secured to the bone and any rudimentary C1 ring is exposed subperiosteally, a power bur is used to decorticate the occiput and any exposed portions of C1 and C2 (Fig. 18-28C).

Iliac crest bone graft is harvested, and struts of iliac bone are placed across the area on the periosteal flap (Fig. 18-28D). No internal fixation is used other than sutures to secure the periosteum. The wound is closed in a routine fashion, and a body jacket or cast is applied and attached to the halo. The halo cast is worn until radiographs show adequate posterior arthrodesis, usually in 8 to 12 weeks.

Arthrodesis with Triple-Wire Fixation

In older adolescents in whom the posterior elements of C1 and C2 are intact, a triple-wire technique, as described by Wertheim and Bohlman (171), can be used (Fig. 18-29). The wires are passed through the outer table of the skull at the occipital protuberance. Because the transverse and superior sagittal sinuses are cephalad to the protuberance, they are not endangered by wire passage.

FIGURE 18-29. Technique of occipitocervical arthrodesis used in older adolescents with intact posterior elements of C1 and C2. **A:** A bur is used to create a ridge in the external occipital protuberance, and then a hole is made in the ridge. **B:** Wires are passed through the outer table of the occiput, under the arch of the atlas, and through the spinous process of the axis. **C:** Corticocancellous bone grafts are placed on the wires. **D:** Wires are tightened to secure grafts in place. (Redrawn from Wertheim SB, Bohlman HH. Occipitocervical fusion: indications, technique, and long-term results. *J Bone Joint Surg [Am]* 1987;69:833; with permission.)

Stability of the spine is obtained preoperatively with cranial skeletal traction with the patient on a turning frame or cerebellar head rest. The patient is placed prone, and a lateral radiograph is obtained to document proper alignment. The subcutaneous tissues are injected with an epinephrine solution (1 : 500,000). A midline incision is made extending from the external occipital protruberance to the spine of the third cervical vertebra. The paraspinous muscles are sharply dissected subperiosteally with a scalpel, and a periosteal elevator is used to expose the occiput and cervical laminae, with special care to stay in the midline to avoid the paramedian venous plexus. At a point 2 cm above the rim of the foramen magnum, a high-speed diamond bur is used to create a trough on either side of the protuberance, making a ridge in the center (Fig. 18-29A). A towel clip is used to make a hole in this ridge through only the outer table of bone. A 20-gauge wire is looped through the hole and around the ridge, then another 20-gauge wire is looped around the arch of the atlas. A third wire is passed through a hole drilled in the base of the spinous process of the axis and around this structure, giving three separate wires to secure the bone grafts on each side of the spine (Fig. 18-29B).

A thick, slightly curved graft of corticocancellous bone of premeasured length and width is removed from the posterior iliac crest. The graft is divided horizontally into two pieces, and three holes are drilled into each graft (Fig. 18-29C). The occiput is decorticated and the grafts are anchored in place with the wires on both sides of the spine (Fig. 18-29D). Additional cancellous bone is packed around and between the two grafts. The wound is closed in layers over suction drains.

Either a rigid cervical orthosis or a halo cast is worn for 6 to 15 weeks, followed by a soft collar that is worn for an additional 6 weeks.

Occipitocervical Arthrodesis

The positioning of the patient and the procedure are performed with the patient under general anesthesia and with monitoring of the somatosensory-evoked potentials (Fig. 18-30). A halo ring is applied initially with the patient supine. Subsequently, the patient is carefully placed in the prone position, the halo is secured to the operating table with a halo-positioning device, and the alignment of the occiput and the cervical spine is confirmed with a lateral radiograph. The midline is exposed from the occiput to the second or third cervical vertebra. Particular care is taken to limit the lateral dissection to avoid damaging the vertebral arteries.

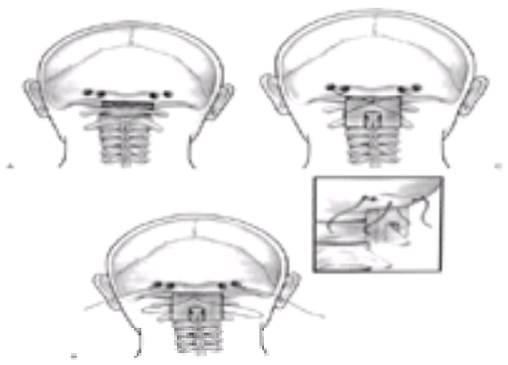

FIGURE 18-30. Occipitocervical arthrodesis. **A:** Four bur holes are placed into the occiput in transverse alignment, with two on each side of the midline, leaving a 1-cm osseous bridge between the 2 holes of each pair. A trough is fashioned into the base of the occiput. **B:** 16- or 18-gauge Luque wires are passed through the bur holes and looped on themselves. Wisconsin button wires are passed through the base of the spinous process of either the second or third cervical vertebra. The graft is positioned into the occipital trough and spinous process of the cervical vertebra at the caudal extent of the arthrodesis. The graft is locked into place by the precise contouring of the bone. **C:** The wires are crossed, twisted, and cut. The extension of the cervical spine can be controlled by positioning of the head with the halo frame, by adjustment of the size and shape of the bone graft, and to a lesser extent by tightening of the wires. (Reprinted from Dormans JP, Drummond DS, Sutton LN, et al. Occipitocervical arthrodesis in children. *J Bone Joint Surg [Am]* 1995;77:1234–1240; with permission.)

In patients who need decompression because of cervical stenosis or for removal of a tumor, the arch of the first or second cervical vertebra (or both) is removed, with or without removal of a portion of the occipital bone to enlarge the foramen magnum.

Four holes, aligned transversely, with two on each side of the midline, are made with a high-speed drill through both cortices of the occiput, leaving a 1-cm osseous bridge between the two holes of each pair. The holes are placed caudal to the transverse sinuses. A trough is fashioned into the base of the occiput to accept the cephalad end of the bone graft. A corticocancellous graft is obtained from the iliac crest and is shaped into a rectangle, with a notch created in the inferior base to fit around the spinous process of the second or third cervical vertebra. The caudal extent of the intended arthrodesis (the second or third cervical vertebra) is determined by the presence or absence of a previous laminectomy, congenital anomalies, or the level of the instability. On each side, a looped 16- or 18-gauge Luque wire is passed through the bur holes and looped on itself. Wisconsin button wires (Zimmer, Warsaw, Indiana) are passed through the base of the spinous process of either the second or the third cervical vertebra. The wire that is going into the left arm of the graft is passed through the spinous process from right to left. The graft is placed into the occipital trough superiorly and about the spinous process of the vertebra that is to be at the caudal level of the arthrodesis (the second or third cervical vertebrae). The graft is precisely contoured so that it fits securely into the occipital trough and around the inferior spinous process before the wires are tightened. The wires are subsequently crossed, twisted, and cut. An intraoperative radiograph is made at this point to assess the position of the graft and the wires as well as the alignment of the occiput and the cephalad cervical vertebrae. Extension of the cervical spine can be controlled by positioning of the head with the halo frame, by adjustment of the size and shape of the graft, and to a lesser extent by appropriate tightening of the wires.

Occipitocervical Arthrodesis with Contoured Rod and Segmental Wire

Occipitocervical arthrodesis using a contoured rod and segmental wire has the advantage of achieving immediate stability of the occipitocervical junction (Fig. 18-31). This allows the patient to be in a cervical collar after surgery, avoiding the need for halo immobilization.

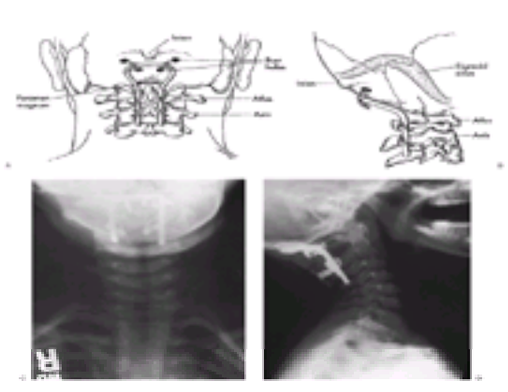

FIGURE 18-31. A–D: Occipitocervical arthrodesis using a contoured rod and segmental wire or cable fixation. (**A** and **B** reprinted from Warner WC. Pediatric cervical spine. In: Canale ST, ed. *Campbell's operative orthopaedics.* St. Louis: Mosby Yearbook, 1998; with permission.)

The base of the occiput and the spinous processes of the upper cervical vertebrae are approached through a longitudinal midline incision, which extends deep within the relatively avascular intermuscular septum. The entire field is exposed subperiosteally. A template of the intended shape of the stainless steel rod is made with the appropriate length of Luque wire. Two bur holes are made on each side, about 2 cm lateral to the midline and 2.5 cm above the foramen magnum. Care should be taken to avoid the transverse and sigmoid sinus when making these bur holes. At least 10 mm of intact cortical bone should be left between the bur holes to ensure solid fixation. Luque wires or Songer cables are passed in an extradural plane through the two bur holes on each side of the midline. The wires or cables are passed sublaminar in the upper cervical spine. The rod is bent to match the template; this usually will have a head–neck angle of about 135 degrees and slight cervical lordosis. A Bend Meister (Sofamor/Danek, Memphis, Tennessee, U.S.A.) may be helpful in bending the rod. The wires or cables are secured to the rod. The spine and occiput are decorticated and autogenous cancellous bone grafting is performed.

FRACTURES OF THE ATLAS

Fracture of the ring of C1 (Jefferson fracture) is not a common injury in children (15,86,102,109,114,136,165). This injury is caused by an axial load applied to the head. The force is transmitted through the occipital condyles to the lateral masses of C1, causing a disruption in the ring of C1, usually in two places, with fractures occurring both in the anterior and posterior rings. In children an isolated single fracture of the ring can occur with the remaining fracture hinging on a synchondrosis. This is an important distinction in children because often fractures occur through a normal synchondrosis and there can be plastic deformation of the ring. This distinction can be seen on plain radiographs, with fractures appearing through what appears to be normal physes. As the lateral masses separate, the transverse ligament may be ruptured or avulsed, resulting in C1 and C2 instability (109). If the two lateral masses are widened more than 7 mm beyond the borders of the axis on an anteroposterior radiograph, then an injury to the transverse ligament is presumed. Injury to the transverse ligament may be from a rupture of the ligament or an avulsion of the ligament attachment to C1. Jefferson fractures may be evident on plain radiographs, but CT scans are superior at demonstrating this injury. CT scans also may be used to follow the progress of healing.

Treatment consists of immobilization in an orthosis [Philadelphia collar or sternal occipital mandibular immobilizer (SOMI)], Minerva cast, or halo brace. If there is excessive widening (>7 mm), halo traction followed by halo brace or cast immobilization is recommended. Surgery rarely is necessary to stabilize these fractures (Fig. 18-32).

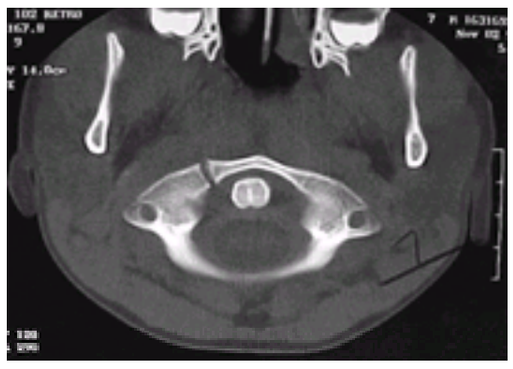

FIGURE 18-32. Radiograph of an atlas fracture.

ATLANTOAXIAL INJURIES

Odontoid Fractures

Odontoid fractures are one of the most common fractures of the cervical spine in children (107), occurring at an average age of 4 years (45,146). The unique feature of odontoid fractures in children is that the fracture most commonly occurs through the synchondrosis of C2 distally at the base of the odontoid. This synchondrosis is a cartilage line at the base of the odontoid and looks like a physeal or Salter I injury.

A fracture of the odontoid usually is associated with head trauma from a motor vehicle accident or a fall from a height, although it also can occur after trivial head trauma. Radiographs should be obtained in any child complaining of neck pain. Clinically, the child will complain of neck pain and resist attempts to extend the neck. Odent et al. (118) reported that 8 of 15 odontoid fractures in children were the result of motor vehicle accidents, with the child fastened in a forward-facing seat. The sudden deceleration of the body as it is strapped into the car seat while the head continues to travel forward causes this fracture.

Most odontoid injuries are anteriorly displaced and usually have an intact anterior periosteal sleeve that provides some stability to the fracture when immobilized in extension and allows excellent healing of the fracture (7,137,142,149). Growth disturbances are uncommon after this type of fracture. This synchondrosis normally closes at about 3 to 6 years of age and adds little to the longitudinal growth of C2.

Most often the diagnosis can be ascertained by viewing the plain radiographs. Anteroposterior radiographs usually appear normal, and the diagnosis must be made from lateral radiographs because displacement of the odontoid usually occurs anteriorly. Plain radiographs sometimes can be misleading when the fracture occurs through the synchondrosis and has spontaneously reduced. When this occurs the fracture has the appearance of a nondisplaced Salter I fracture. CT scans with three-dimensional reconstruction views may be needed to fully delineate the injury (150). MRI also may be useful in nondisplaced fractures by detecting edema around the injured area, indicating that a fracture may have occurred. Dynamic flexion and extension views to demonstrate instability may be obtained in a cooperative child if a nondisplaced fracture is suspected.

Odontoid fractures in children generally heal uneventfully and rarely have complications. Neurologic deficits rarely have been reported after this injury, except by Odent et al., who described neurologic injuries in 8 of 15 patients, although most were stretch injuries to the spinal cord at the cervical thoracic junction and not at the level of the odontoid fracture.

Treatment of odontoid fractures is by closed reduction (usually extension or slight hyperextension of the neck), although complete reduction of the translation is not necessary. At least 50% apposition should be obtained to provide adequate cervical alignment, then the patient should be immobilized in a Minerva or halo cast or custom orthosis. This fracture will heal in about 6 to 8 weeks. After bony healing, stability should be documented by flexion/extension lateral radiographs. Once the Minerva cast or halo is removed, a soft collar is worn for 1 to 2 weeks. If an adequate reduction cannot be obtained by recumbency and hyperextension, then head halter or halo traction is needed. Rarely, manipulation under general anesthesia is needed for irreducible fractures (Fig. 18-33). Surgery with internal fixation rarely has been reported, due to the good results that are achieved with conservative treatment in children (57,67,130,135,141).

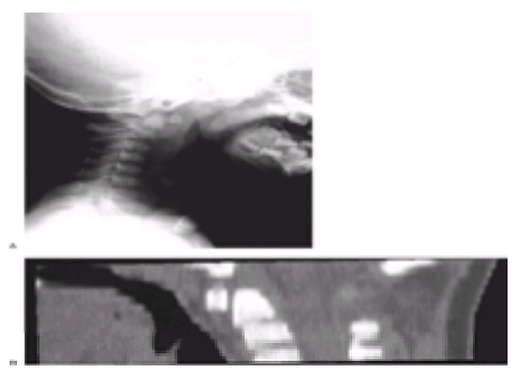

FIGURE 18-33. A and B: Lateral radiograph and CT reconstruction view of odontoid fracture through the synchondrosis of C2. Note the anterior displacement.

Os Odontoideum

Os odontoideum consists of a round ossicle that is separated from the axis by a transverse gap, which leaves the apical segment without support. Fielding et al. (51,53) suggested that this was an unrecognized fracture at the base of the odontoid. Some studies have documented normal radiographs of the dens with abnormal radiographs after trivial trauma. This can be explained by a distraction force being applied by the alar ligaments, which pulls the tip of the fractured odontoid away from the base and produces a nonunion.

The presentation of an os odontoideum can be variable. Signs and symptoms can range from a minor to a frank compressive myelopathy or vertebral artery compression. Presenting symptoms may be neck pain, torticollis, or headaches caused by local irritation of the atlantoaxial joint. Neurologic symptoms can be transient or episodic after trauma to complete myelopathy caused by cord compression (46). Symptoms may consist of weakness and loss of balance with upper motor neuron signs, although upper motor neuron signs may be completely absent. Proprioceptive and sphincter dysfunction also are common.

Os odontoideum usually can be diagnosed on routine cervical spine radiographs, which include an open mouth odontoid view (Fig. 18-34). Lateral flexion and extension views should be obtained to determine if any instability is present. With os odontoideum there is a space between the body of the axis and a bony ossicle. The free ossicle of the os odontoideum usually is half the size of a normal odontoid and is oval or round with smooth sclerotic borders. The space differs from that of an acute fracture in which the space is thin and irregular instead of wide and smooth. The amount of instability should be documented on lateral flexion and extension plain radiographs that allow measurement of both the anterior and posterior displacement of the atlas on the axis. Because the ossicle is fixed to the anterior arch of C1 and moves with the anterior arch of C1 both in flexion and extension, measurement of the relationship of C1 to the free ossicle is of little value because they move as a unit. A more meaningful measurement is made by projecting lines superiorly from the body of the axis to a line projected inferiorly from the posterior border of the anterior arch of the atlas. This gives more information as to the stability of C1–C2. Another measurement that is very helpful is space available for the cord, which is the distance from the back of the dens to the anterior border of the posterior arch of C1.

FIGURE 18-34. Lateral radiograph **(A)** and open-mouth odontoid radiograph **(B)** demonstrating os odontoideum. (Reprinted from Warner WC. Pediatric cervical spine. In: Canale ST, ed. *Campbell's operative orthopaedics.* St. Louis: Mosby Year Book, 1999:2817; with permission.)

Recommended treatment is posterior arthrodesis of C1 to C2. Before arthrodesis is attempted, the integrity of the arch of C1 must be documented by CT scan. Incomplete development of the posterior arch of C1 is uncommon but has been reported to occur with increased frequency in patients with os odontoideum. This may necessitate an occipital to C2 arthrodesis for stability. If a C1–C2 arthrodesis is performed, one must be careful not to overreduce the odontoid and cause posterior translation. Care also must be taken in positioning the neck at the time of arthrodesis and when tightening the wires if a Gallie or Brooks arthrodesis is performed to prevent posterior translation (Fig. 18-35 and Fig. 18-36).

FIGURE 18-35. Posterior translation of atlas after C1–C2 posterior arthrodesis.

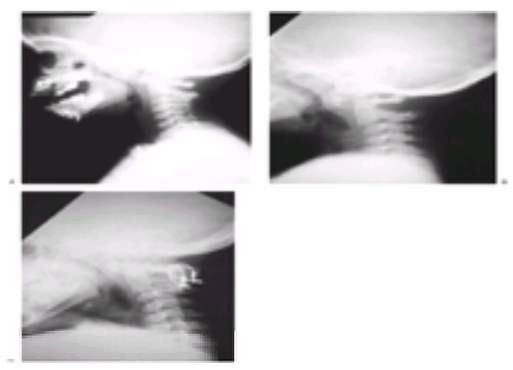

FIGURE 18-36. A: Lateral radiograph of traumatic C1–C2 instability. **B:** Note the increase in the atlanto-dens interval. **C:** Lateral radiograph after C1–C2 posterior arthrodesis.

Traumatic Ligamentous Disruption

The transverse ligament is the primary stabilizer of an intact odontoid against forward displacement. Secondary stabilizers consist of the apical and alar ligaments, which arise from the tip of the odontoid and pass to the base of the skull. These also stabilize the atlantooccipital joint indirectly (80). The normal distance from the anterior cortex of the dens to the posterior cortex of the anterior ring of C1 is 3 mm in adults and 4.5 mm in children. In children if the distance is more than 4.5 mm, disruption of the transverse ligament is presumed. The spinal canal at C1 is large compared with other cervical segments and accommodates a large degree of rotation and some degree of pathologic displacement without compromising the spinal cord. Steel has expressed this as a rule of thirds. The spinal canal at C1 is occupied equally by the spinal cord, odontoid, and a free space, which provides a buffer zone to prevent neurologic injury. Steel found that anterior displacement of the atlas that exceeds a distance equal to the width of the odontoid may place the spinal cord at risk (160).

Acute rupture of the transverse ligament is rare and reportedly occurs in fewer than 10% of pediatric cervical spine injuries (98,107). However, avulsion of the attachment of the transverse ligament to C1 is more common.

A patient with disruption of the transverse ligament usually has a history of cervical spine trauma and complains of neck pain, often with notable muscle spasms. Diagnosis is confirmed on lateral radiographs that demonstrate an increased atlanto-dens interval. An active flexion view may be required to demonstrate instability in cooperative patients with unexplained neck pain or neurologic findings. CT scans are useful to demonstrate avulsion of the transverse ligament from its origins to the bony ring of C1.

Although rarely used, conservative treatment of acute transverse ligament injuries has been reported. For acute injuries, reduction in extension is recommended followed by surgical stabilization of C1 and C2 and immobilization for 8 to 12 weeks in a Minerva cast, a halo brace, or cervical orthosis. Flexion and extension views should be obtained after stabilization to document stability.

OPERATIVE TREATMENT

Atlantoaxial Arthrodesis

Technique of Brooks and Jenkins

The supine patient is intubated in the supine position while still on a stretcher, and is then placed prone on the operating table, with the head supported by traction; the head-thorax relationship is maintained at all times during turning (23) (Fig. 18-37). A lateral cervical spine radiograph is obtained to ensure proper alignment before surgery. The skin is prepared and draped in a sterile fashion and a solution of epinephrine (1 : 500,000) is injected intradermally to aid hemostasis.

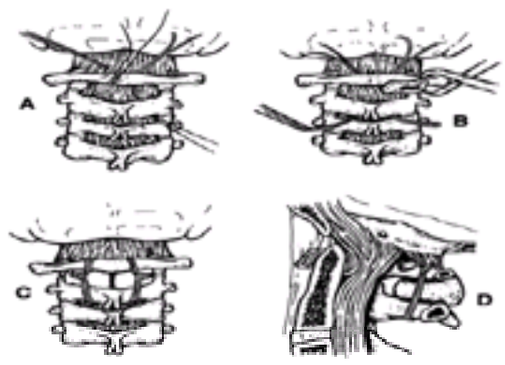

FIGURE 18-37. Technique of atlantoaxial arthrodesis (Brooks-Jenkins). **A:** Wires are inserted under the atlas and axis. **B:** Full-thickness bone grafts from the iliac crest are placed between the arch of the atlas and the lamina of the axis. **C and D:** The wires are tightened over the graft and twisted on each side. (Redrawn from Brooks AL, Jenkins EB. Atlantoaxial arthrodesis by the wedge compression method. *J Bone Joint Surg [Am]* 1978;60:279; with permission.)

C1 and C2 are exposed through a midline incision. Using an aneurysm needle, a mersiline suture is passed from cephalad to caudad on each side of the midline under the arch of the atlas and then beneath the lamina of C2. These serve as guides to introduce two doubled 20-gauge wires. The size of the wire used varies depending on the size and age of the patient. Two full-thickness bone grafts approximately 1.25 × 3.5 cm are harvested from the iliac crest and beveled so that the apex of the graft fits in the interval between the arch of the atlas and the lamina of the axis. Notches are fashioned in the upper and lower cortical surfaces to hold the circumferential wires and prevent them from slipping. The doubled wires are tightened over the graft and twisted on each side. The wound is irrigated and closed in layers over suction drains.

Technique of Gallie

The supine patient is intubated while on a stretcher (59) (Fig. 18-38). The prone patient then is placed on the operating table with the head supported by traction, maintaining the head–thorax relationship during turning. A lateral cervical spine radiograph is obtained to ensure proper alignment before surgery. The skin is prepared and draped in a sterile fashion, and a solution of epinephrine (1 : 500,000) is injected intradermally to aid hemostasis.

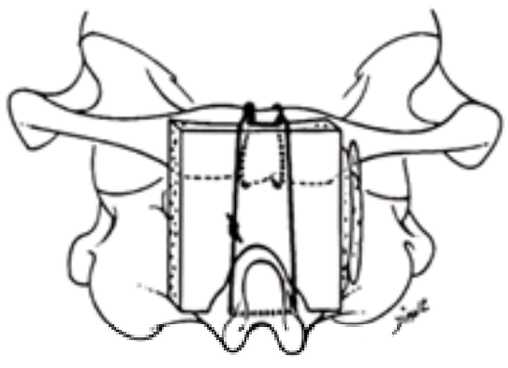

FIGURE 18-38. Wires are passed under the lamina of the atlas and through the spine of the axis and tied over the graft. This method is used most frequently. (Reprinted from Fielding JW, Hawkins RJ, Ratzan SA. *J Bone Joint Surg [Am]* 1976;58:400; with permission.)

A midline incision is made from the lower occiput to the level of the lower end of the fusion, extending deeply within the relatively avascular midline structures, the intermuscular septum, or ligamentum nuchae. Care should be taken not to expose any more than the area to be fused to decrease the chance of spontaneous extension of the fusion. By subperiosteal dissection, the posterior arch of the atlas and the lamina of C2 are exposed. The muscular and ligamentous attachments from C2 are removed with a curet. Care should be taken to dissect laterally along the atlas to prevent injury to the vertebral arteries and vertebral venous plexus that lie on the superior aspect of the ring of C1, less than 2 cm lateral to the midline. The upper surface of C1 is exposed no farther laterally than 1.5 cm from the midline in adults and 1 cm in children. Decortication of C1 and C2 generally is not necessary. From below, a wire loop of appropriate size is passed upward under the arch of the atlas either directly or with the aid of a mersiline suture. The mersiline suture can be passed with an aneurysm needle. The free ends of the wire are passed through the loop, grasping the arch of C1 in the loop.

A corticocancellous graft is taken from the iliac crest and placed against the lamina of C2 and the arch of C1 beneath the wire. One end of the wire is passed through the spinous process of C2, and the wire is twisted on itself to secure the graft in place. The wound is irrigated and closed in layers with suction drainage tubes.

Atlantoaxial Instability Associated with Congenital Anomalies and Syndromes

Although acute atlantoaxial instability in children is rare, chronic atlantoaxial instability occurs in certain conditions such as juvenile rheumatoid arthritis, Reiter's syndrome, Down's syndrome, and Larsen's syndrome. Bone dysplasia—such as Morquio's polysaccharidosis, spondyloepiphyseal dysplasia, and Kniest's syndrome—also may be associated with atlantoaxial instability, as well as os odontoideum, Klippel-Feil syndrome, and occipitalization of the atlas (28,73,75,92,94,111).

Certain cranial facial malformations have high incidences of associated anomalies of the cervical spine, such as Apert's syndrome, hemifacial microsomy, and Goldenhar's syndrome (152). Treatment recommendations are individualized based on the natural history of the disorder and future risk to the patient. Although there is little literature on cervical spine instability in each of these syndromes, there has been considerable interest in the incidence and treatment of atlantoaxial instability in children with Down's syndrome (35,38,131,132,167).

Some Down's syndrome patients have C1–C2 instability of more than 5 mm. The Committee on Sports Medicine of the American Academy of Pediatrics issued a policy statement (35) asserting that Down's syndrome patients with 5 to 6 mm of instability should be restricted from participating in sports that carry a risk of stress to the head and neck. The Special Olympics organization has placed even greater restrictions on particular sports (156). Davidson found that neurologic signs were more predictive of impending dislocation than the radiologic criteria. Nearly all the patients with actual dislocations that he reviewed had at least several weeks of readily detectable physical signs before dislocation occurred (38).

Surgical stabilization is indicated for patients with translation of more than 10 mm. In patients with less than 10 mm of translation and a neurologic deficit or history of neurologic symptoms, surgical stabilization also may be indicated. Once surgical stabilization is needed, the treating physician must understand the increased risk of complications (i.e., pseudarthrosis) in this patient population. Segal et al. (145) reported a high complication rate after posterior arthrodesis of the cervical spine in patients who have Down's syndrome. Six of ten patients developed resorption of the bone graft and associated pseudarthrosis. Other complications in this patient population after attempted posterior arthrodesis were wound infection, dehiscence of the operative site, instability of adjacent motion segments, and neurologic sequelae (152).

Atlantoaxial Rotatory Subluxation

Atlantoaxial rotatory subluxation is a common cause of childhood torticollis. This condition is known by several names such as rotatory dislocation, rotatory displacement, rotatory subluxation, and rotatory fixation. Atlantoaxial rotatory subluxation probably is the most accepted term used, except for long-standing cases (3

months), which are called rotatory fixation.

A significant amount of motion occurs at the atlantoaxial joint; half of the rotation of the cervical spine occurs there. Through this range of motion at the C1–C2 articulation, some children develop atlantoaxial rotatory subluxation. The two most common causes are trauma and infection; the most common cause is an upper respiratory infection (Grisel's syndrome) (172). Subluxation also can occur after a retropharyngeal abscess, tonsillectomy, pharyngeoplasty, or trivial trauma. There is free blood flow between the veins and lymphatics draining the pharynx and the periodontoid plexus (124). Any inflammation of these structures can lead to attenuation of the synovial capsule or transverse ligament or both, with resulting instability. Another potential etiologic factor is the shape of the superior facets of the axis in children. Kawabe (88) demonstrated that the facets are smaller and more steeply inclined in children than in adults. A meniscus-like synovial fold was found between C1 and C2 that could prohibit reduction after displacement has occurred.

Classification

Fielding and Hawkins (54) classified atlantoaxial rotatory displacements into four types based on direction and degree of rotation and translation (Fig. 18-39). Type 1 is a unilateral facet subluxation with an intact transverse ligament. This is the most common and benign type. Type 2 is a unilateral facet subluxation with anterior displacement of 3 to 5 mm. The unilateral anterior displacement of one of the lateral masses may indicate an incompetent transverse ligament with potential instability. Type 3 is bilateral anterior facet displacement with more than 5 mm of anterior displacement. This type is associated with deficiencies of the transverse and secondary ligaments, which can result in significant narrowing of the space available for the cord at the atlantoaxial level. Type 4 is an unusual type in which the atlas is displaced posteriorly. This usually is associated with a deficient dens. Although types 3 and 4 are rare, neurologic involvement may be present or instantaneous death can occur. Both types must be managed with great care.

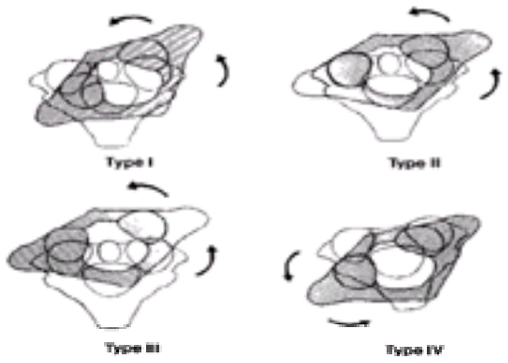

FIGURE 18-39. Classification of rotary displacement. (Reprinted from Fielding JW, Hawkins RJ. Atlantoaxial rotary fixation. *J Bone Joint Surg [Am]* 1977;59:37; with permission.)

Signs and Symptoms

Clinical findings include neck pain, headache, and a cock-robin position of rotating to one side as well as lateral flexion to the other (Fig. 18-40). When rotatory subluxation is acute, the child resists attempts to move the head and has pain with any attempts at correction. Usually they are able to make the deformity worse but are not able to correct it. Associated muscle spasms of the sternocleidomastoid muscle occur predominantly on the side of the long sternocleidomastoid muscle in an attempt to correct the deformity. If the deformity becomes fixed, the pain subsides but the torticollis and the decreased range of motion will persist (52). If rotatory fixation has been present for a long time in a small child, plagiocephaly sometimes can be noted. Neurologic abnormalities are extremely rare, although a few cases have been reported.

FIGURE 18-40. Child with rotary subluxation of C1 on C2. Note the direction of head tilt and rotation of the neck.

Radiographic Findings

Adequate radiographs may be difficult to obtain because of the associated torticollis and difficulty in positioning the head and neck. Anteroposterior and open mouth odontoid views should be taken with the shoulders flat and the head in as neutral a position as possible (101). Lateral masses that have rotated forward appear wider and closer to the midline, whereas the opposite lateral mass appears narrower and farther away from the midline on this view. One of the facet joints may be obscured because of apparent overlapping. The distance between the lateral mass and the dens also will be asymmetric. On the lateral view, the lateral facet appears anterior and usually appears wedge shaped instead of the normal oval shape. The posterior arches of the atlas may fail to superimpose because of head tilt, giving the appearance of fusion of C1 to the occiput (occipitalization). Flexion and extension lateral views are recommended to exclude instability.

Cineradiography has been used for the evaluation of atlantoaxial rotatory subluxation (50,54,80). This technique is limited in the acute stage, because pain restricts the motion necessary for a satisfactory study. With atlantoaxial rotatory fixation, cineradiography may be helpful in confirming the diagnosis by demonstrating that the atlas and axis are rotating as a unit. However, this technique requires high radiation exposure and generally has been replaced by CT scanning (7,45,54,60,128). CT should be performed with the head and body positioned as close to neutral as possible. This will show a superimposition of C1 on C2 in a rotated position and will allow the degree and amount of malrotation to be quantified. Some researchers have recommended dynamic CT scans taken with the patient looking to the right and the left to diagnose rotatory fixation (127). Three-dimensional CT scans also are helpful in identifying rotatory subluxation (140). MRI is of little value in this condition unless there are neurologic findings (Fig. 18-41).

Differential Diagnoses

Differential diagnoses include torticollis caused by ophthalmologic problems, sternocleidomastoid tightness from muscular torticollis, brainstem or posterior fossa tumors or abnormalities, congenital vertebral anomalies, and infections of the vertebral column.

Treatment

Treatment depends on the duration of the symptoms (127). Many patients probably never receive medical treatment, because symptoms may be mild and the subluxation may reduce spontaneously over a few days before medical attention is sought. If rotatory subluxation has been present for a week or less, a soft collar, anti-inflammatory medication, and exercise program are indicated. If this fails to produce improvement and the symptoms persist for more than a week, head halter traction should be initiated. This can be done either at home or in the hospital, depending on the social situation and the severity of symptoms. Muscle relaxants and analgesics also may be needed. Phillips and Hensinger (127) found that if rotatory subluxation was present for less than 1 month, head halter traction and bed rest were usually sufficient to relieve symptoms. If the subluxation is present for longer than a month, successful reduction is not very likely (29). However, halo traction can still be used to try to reduce the subluxation. The halo allows increased traction weight to be applied without interfering with opening of the jaw or causing skin pressure on the mandible. While the traction is being applied, active rotation to the right and left should be encouraged. Once the atlantoaxial rotatory subluxation has been reduced, motion has been restored, and the reduction is documented by CT scan, the patient is maintained in a halo vest for 6 weeks. If reduction cannot be maintained, posterior atlantoaxial arthrodesis is recommended. Even though internal rotation and alignment of the atlas and axis may not be restored, successful fusion should result in the appearance of normal head alignment by relieving the muscle spasms that occurred in response to the malrotation. Posterior arthrodesis also is recommended if any signs of instability or neurologic deficits secondary to the subluxation are present, if the deformity has been present for more than 3 months or if conservative treatment of 6 weeks of immobilization has failed.

Hangman's Fracture

Bilateral spondylolisthesis of C2, or hangman's fractures, also may occur in children (170). The mechanism of injury is forced hyperextension. Most reports of this injury have been in children under the age of 2 years (48,56,128,138). This injury probably occurs more frequently in this age group because of the disproportionately large head, poor muscle control, and hypermobility. The possibility of child abuse also must be considered. Patients present with neck pain and resist any movement of the head and neck. There should be a positive history of trauma (Fig. 18-42).

FIGURE 18-42. Lateral radiograph of patient with traumatic C2 spondylolisthesis (Hangman's fracture).

Radiographs reveal a lucency anterior to the pedicles of the axis, usually with some forward subluxation of C2 on C3. One must be sure this is a fracture and not a persistent synchondrosis of the axis. Matthews et al. (103), Nordstrom et al. (116), and Smith et al. (155) have reported similar cases of persistent synchondrosis of the axis. CT scans showed the defect to be at the level of the neurocentral chondrosis. Later films showed ossification within the synchondrosis gap.

Treatment should be symptomatic with immobilization in a Minerva cast, halo, or cervical orthosis for 8 to 12 weeks. Traction is not needed to reduce this fracture and may even produce potentially dangerous distraction. Pizzutillo et al. (128) reported that four of five patients healed with immobilization. If union does not occur, posterior arthrodesis or anterior arthrodesis can be performed to stabilize this fracture.

SUBAXIAL INJURIES

Fractures and dislocations involving C3 through C7 are rare in children and infants (85,87,105,151) and usually occur in teenagers or older children. Lower cervical spine injuries in children as opposed to those in adults can occur through the cartilaginous end plate (39). The end plate may break completely through the cartilaginous portion (Salter type I) or may exit through the bony edge (Salter type II). Usually the inferior end plate fractures because of the protective effect of the uncinate processes of the superior end plate (8).

Posterior Ligamentous Disruption

Posterior ligamentous disruption can occur with a flexion or distraction injury to the cervical spine. The patient usually has point tenderness at the injury site and complains of neck pain. Initial radiographs may be normal except for loss of normal cervical lordosis. This may be a normal finding in young children, but should be evaluated for possible ligamentous injury in an adolescent. Widening of the posterior interspinous distance is suggestive of this injury. MRI may be helpful in documenting ligamentous damage.

With posterior ligamentous disruption, gradual displacement of one segment on the other can occur, and secondary adaptive changes in the growing spine may make reduction difficult. Posterior ligamentous injuries should be protected with an extension orthosis, and patients should be followed closely for the development of instability. If signs of instability are present, then a posterior arthrodesis should be performed.

Compression Fractures

Compression fractures, the most common fractures of the subaxial spine in children, are caused by flexion and axial loading that results in loss of vertebral body height. This can be detected on a lateral radiograph. Because vertebral disks in children are more resilient than the vertebral bodies, the bone is more likely to be injured. Compression fractures are stable injuries and heal in children in 3 to 6 weeks. Many compression fractures may be overlooked because of the normal wedge shape of the vertebral bodies in young children. Immobilization in a cervical collar is recommended for 3 to 6 weeks. Flexion and extension films to confirm stability should be obtained 2 to 4 weeks after injury. In children under 8 years of age, the vertebral body may reconstitute itself with growth, although Schwarz et al. (143) reported that kyphosis of more than 20 degrees may not correct with growth. Associated injuries can include anterior teardrop, laminar, and spinous process fractures.

Unilateral and Bilateral Facet Dislocations

Unilateral facet dislocations and bilateral facet dislocations are the second most common injuries in the subaxial spine in children. Most occur in adolescents and are similar to adult injuries. The diagnosis usually can be made on anteroposterior and lateral radiographs. In children the so-called perched facet is a true dislocation. The cartilaginous components are overlapped and locked. On the radiograph, the facet appears perched because the overlapped cartilage cannot be seen. Unilateral facet dislocation is treated with traction and reduction. If reduction cannot be easily obtained, open reduction and arthrodesis are indicated. Complete bilateral facet dislocation, although rare, is more unstable and has a higher incidence of neurologic deficit (Fig. 18-43). Treatment consists of reduction and stabilization with a posterior arthrodesis.

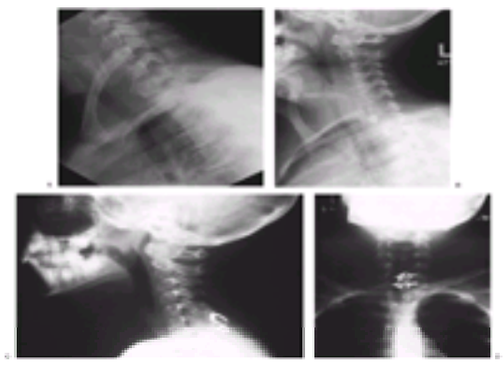

FIGURE 18-43. A and B: Lateral radiograph of a patient with so-called perched facets, demonstrating a facet dislocation. **C and D:** Lateral and anteroposterior radiograph after reduction and posterior arthrodesis.

Burst Fractures

Although rare, burst fractures can occur in children. These injuries are caused by an axial load. Radiographic evaluation should consist of anteroposterior and lateral views. CT scans aid in detecting any spinal canal compromise from retropulsed fracture fragments and occult laminar fractures. If no neurologic deficit or significant canal compromise is present, then treatment consists of traction followed by halo immobilization. Anterior arthrodesis rarely is recommended in pediatric patients except in the rare patient with a burst fracture and significant canal compromise (147). Anterior arthrodesis destroys the anterior growth potential; as posterior growth continues, a kyphotic deformity may occur (Fig. 18-44).

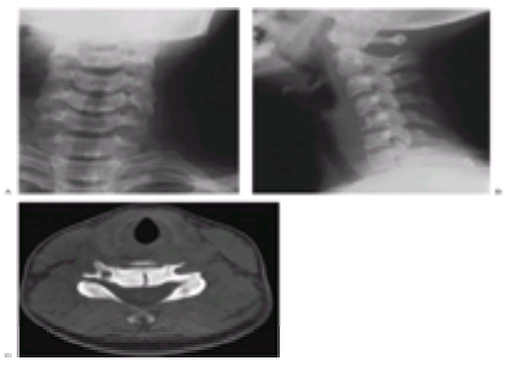

FIGURE 18-44. A, B, and C: Anteroposterior and lateral radiograph and CT scan of patient with a minimally displaced burst fracture of C5.

Spondylolysis and Spondylolisthesis

Spondylolysis and spondylolisthesis of C2 through C6 have been reported. These injuries can occur from either a hyperextension or flexion axial loading injury. Associated anterosuperior avulsion or compression fractures of the vertebral body may occur. The diagnosis usually is made on plain radiographs that show a fracture line through the pedicles. Oblique views may be necessary to better identify the fracture line. CT scanning may be useful in differentiating an acute fracture from a normal synchondrosis. Treatment consists of immobilization in a cervical orthosis or halo brace. Surgical stabilization is recommended only for truly unstable fractures or nonunions. Neurologic involvement is rare.

OPERATIVE TREATMENT

Posterior Arthrodesis

General anesthesia is administered with the patient supine (Fig. 18-45). The patient is turned prone on the operating table, with care taken to maintain traction and proper alignment of the head and neck. The head may be positioned in a head rest or maintained in skeletal traction. Radiographs are obtained to confirm adequate alignment of the vertebrae and to localize the vertebrae to be exposed. Extension of the fusion mass can occur when extra vertebrae or spinous processes are exposed in the cervical spine. A midline incision is made over the chosen spinous processes, and the spinous process and lamina are exposed subperiosteally to the facet joints. If the spinous process is large enough, a hole is made in the base of the spinous process with a towel clip or Lewin clamp. An 18-gauge wire is passed through this hole, looped over the spinous process, and passed through the hole again. A similar hole is made in the base of the spinous process of the inferior vertebra to be fused, and the wire is passed through this vertebra. The wire is then passed through this hole, looped under the inferior aspect of the spinous process, and then passed back through the same hole. The wire is tightened and corticocancellous bone grafts are placed along the exposed lamina and spinous processes. The wound is closed in layers. If the spinous process is too small to pass wires, then an *in situ* arthrodesis can be performed and external immobilization used.

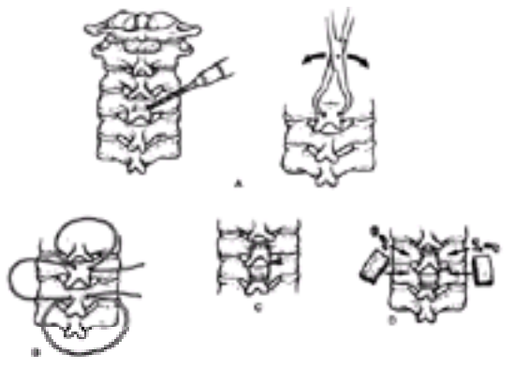

FIGURE 18-45. Technique of posterior arthrodesis in subaxial spine levels C3–C7. **A:** A hole is made in the spinous process of the vertebrae to be fused. **B:** An 18-gauge wire is passed through both holes and around the spinous processes. **C:** The wire is tightened. **D:** Corticocancellous bone grafts are placed. (Redrawn from Murphy MJ, Southwick WO. Posterior approaches and fusions. In: Cervical Spine Research Society. *The cervical spine.* Philadelphia: JB Lippincott, 1983; with permission.)

Hall et al. (71) used a 16-gauge wire and threaded Kirschner wires. The threaded Kirschner wires are passed through the bases of the spinous processes of the vertebrae to be fused. This is followed by a figure-of-eight wiring with a 16-gauge wire (Fig. 18-46). After tightening the wire about the Kirschner wires, strips of corticocancellous and cancellous bone are packed over the posterior arches of the vertebrae to be fused.

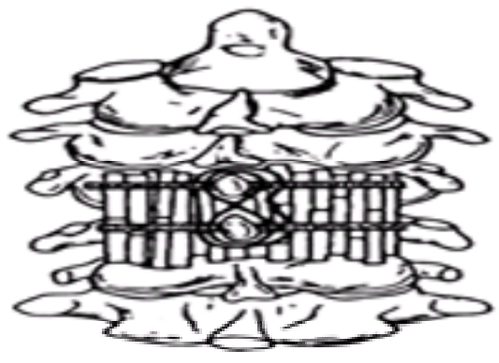

FIGURE 18-46. Alternative fixation method for posterior arthrodesis of C3–C7. A 16-gauge wire is placed in a figure-of-eight pattern around two threaded Kirschner wires passed through the bases of the spinous processes of the vertebrae to be fused. FRACTURES OF THE THORACIC AND LUMBAR SPINE

RANDALL T. LODER
ROBERT N. HENSINGER

Pediatric spinal fractures represent 2% to 5% of all spinal injuries (49,71). Most spinal fractures in children occur in the cervical spine, but severe and seriously disabling injuries do occur in the thoracolumbar spine. Fractures of the thoracic and lumbar spine are rare in children compared with their frequency in adults. The actual incidence of thoracolumbar spinal injuries, however, may be twice that reported; statistics are skewed toward more severe injuries because many patients with mild injuries are never admitted to a hospital (5,71).

The location of the fracture and the mechanism of injury vary with the age of the child. Neonates are more prone to cervical injuries than to dorsal or lumbar injuries (74). Thoracolumbar spinal fractures in infants may be caused by child abuse, whereas children in the first decade of life usually sustain these injuries from motor vehicle accidents, either as a pedestrian or passenger, or from falls from heights (23,49,53,62). Thoracolumbar spinal fractures in children over 10 years of age typically occur in sports and recreational activities (such as tobogganing and bicycling), as well as motor vehicle accidents (57,70,71,102,124). Injuries from gunshot wounds also are increasing in frequency.

ANATOMY

Certain anatomic features in children that influence the radiographic appearance of the spine, as well as the type of fractures, include an increased cartilage–bone ratio, the presence of secondary ossification centers, and soft tissue hyperelasticity. In infancy and early childhood, the vertebral bodies are largely cartilaginous, and the intervertebral disk spaces appear radiographically to be larger than they are (Fig. 19-1). With maturation the ossification center of the centrum enlarges and the cartilage–bone ratio reverses.

FIGURE 19-1. The radiograph of a normal spine in a 10-week-old infant. The superior and inferior vertebral end plates and vertebral apophysis are cartilaginous. Thus, the apparent widening of the intervertebral spaces is relative to the ossific portion of the vertebrae. The anterior and posterior notching of the walls of the vertebral body are due to normal vascular channels and may be confused with fracture.

In infants, horizontal conical shadows of lessened density extend inward from both the anterior and posterior walls of the vertebral bodies and can be confused with a fracture (Fig. 19-1) (138). The posterior indentation represents the foramen for the posterior arteries and veins in the vertebral wall; it is present in all vertebrae and at all ages. The more noticeable anterior conical shadow represents a large sinusoidal space within the vertebra. This anterior notch usually disappears by 1 year of age with ossification of the anterior and lateral walls of the vertebral bodies.

The vertebral apophyses are secondary centers of ossification that develop in the cartilaginous end plates at the superior and inferior surfaces of the vertebral bodies. Because they are thicker at the periphery than at the center, they appear as rings during early ossification and are called ring apophyses. These apophyses, equivalent to the epiphyses of long bones, are separated from the vertebral bodies by narrow cartilaginous physes. Equal superior and inferior vertical growth of the vertebral bodies occurs at these physes. The vertebral physes appear radiographically between the ages of 8 and 12 years and may be confused with avulsion fractures before they fuse with the vertebral bodies by approximately 21 years of age.

In children, the elasticity of the disks and vertebral bodies far exceeds that of the neural elements. In the cervical spine, the vertebral column can be stretched up to 2 inches without disruption, whereas the spinal cord tolerates only 1/4 inch. This elasticity partially accounts for the occurrence of spinal cord injury without radiographic abnormality (SCIWORA) in younger children (9,71,99,147). By the age of 10 years, the mechanical and anatomic characteristics of the bony thoracolumbar spine approach that of an adult, and fracture patterns become the same.

CLASSIFICATION AND MECHANISM OF INJURY

The three main mechanisms of thoracolumbar spinal fractures are flexion with or without compression, distraction, and shear. Pure compression may cause slipping of the vertebral apophysis, which occurs only in adolescents.

Flexion

Hyperflexion injuries with compression are more common than distraction, shear, or subluxation–dislocation injuries (62,63). In immature spines, the intact disks are more resistant to vertical compression than are the vertebral bodies. During compression, the vertebral body collapses before the normal disk fails. Because of this, few children have posterior herniated disks, and herniation occurs only with significant loading injuries such as weight-lifting and gymnastics or repetitive trauma (30). Herniated disks associated with intervertebral disk calcification have been rarely reported (84,103).

When a vertebra is slowly vertically loaded, the major distortion is a bulge in the vertebral end plate, with only a slight change of the annulus and no alteration in the shape of the nucleus pulposus (112). The bulging of the end plate forces blood out of the cancellous bone, which normally is a shock-absorbing mechanism. With further compression, the end plate fractures, nuclear material ruptures into the vertebral body, and the two vertebrae move closer (Fig. 19-2). If the spine is already flexed when compression is applied, as in tobogganing, the blood is already squeezed out of the vertebral body, the shock-absorbing properties are decreased, and less force is required to injure the spine (Fig. 19-3) (57).

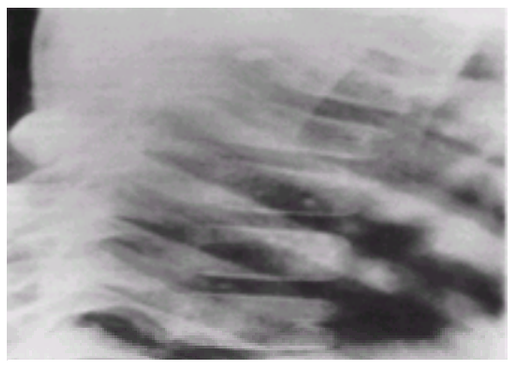

FIGURE 19-2. Radiograph of a 5-year-old girl who sustained compression fractures of three vertebrae from a sledding accident. Note reversal of the normally convex end plate, as well as breaking and wedging of the bodies. Overlapping of the spongiosum may appear as increased density. The child was asymptomatic within 6 weeks, and complete restitution of vertebral height can be expected.

FIGURE 19-3. The radiograph of a 15-year-old girl who sustained an injury to the vertebral body from tobogganing, with fracture of the apophyseal ring (*arrow*) and displacement anteriorly.

In older children, the nucleus pulposus is no longer fluid, and compression forces are transmitted through the annulus, resulting in either tearing of the annulus with a diffuse collapse of the vertebral body due to buckling of its sides or a marginal plateau fracture (112). Stronger compression forces applied more rapidly may cause a bursting type of injury, similar to that in adults (Fig. 19-4).

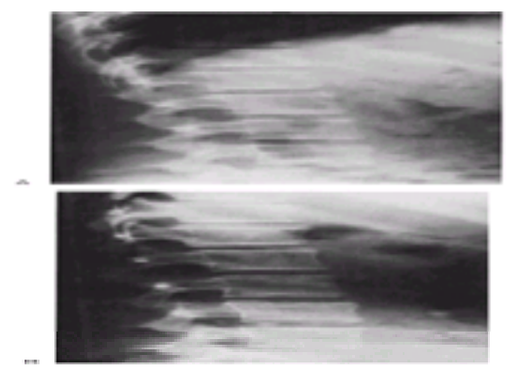

FIGURE 19-4. A: The radiograph of a 15-year-old girl who was involved in a motor vehicle accident, sustaining multiple compression fractures, wedging of L1, and anterior buckling of L4 and L5. **B:** The same patient 6 months later. There is persistence of disk space narrowing at T12 to L1. Complete remodeling of this injury is not expected, because she is near the end of skeletal growth. She was treated conservatively and is asymptomatic.

The vertebral disks of children are more elastic than those of adults, and transmit compression forces as a wave through multiple levels (63,70,112). This is reflected by the clinical fact that multiple compression fractures, usually in the mid-thoracic to mid-lumbar area (49,53,63), are more common in children (Fig. 19-2) than in adults (49,53,63).

Chance fractures, described by Chance in 1948 (25), were more clearly defined by Smith and Kaufer (123) as a lumbar spinal injury associated with seat belts. Forward flexion over the belt produces distraction of the posterior vertebral elements and anterior compression, leading to disruption of the interspinous ligaments, ligamentum flavum, and facet capsules. This injury, previously uncommon in children, is increasing with the more frequent use of lap belts because of child restraint laws (6,66). The middle and anterior columns may fail through either soft tissues (posterior longitudinal ligament and disk) or bone (vertebral body or end plate). If the fulcrum of rotation is slightly posterior to the anterior margin of the vertebral body, there may be a slight component of vertebral body compression anteriorly. More commonly, however, the fulcrum point is anterior to the vertebral body and the anterior elements fail in distraction.

Pediatric Chance fractures are of four types (Fig. 19-5) (118). A reverse Chance fracture (a hyperextension injury) also has been described in infants and children (38,91), rarely with entrapment of bowel (113). A fracture through the posterior elements alone without lumbar body fracture also has been reported in children and adults (1).

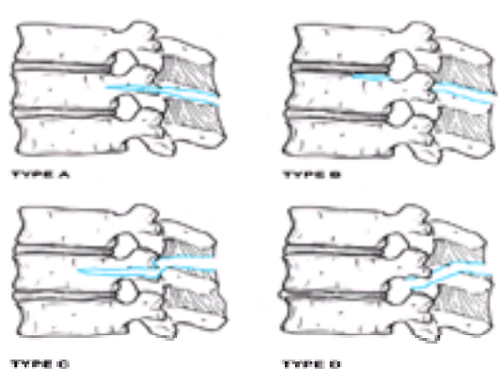

FIGURE 19-5. Seat-belt fracture patterns in skeletally immature children. Type A is a bony disruption of the posterior column extending just into the middle column. Type B is an avulsion of the posterior elements with facet joint disruption or fracture and extension into the apophysis of the vertebral body. Type C is a posterior ligamentous disruption with a fracture line entering the vertebra close to the pars interarticularis and extending into the middle column. Type D is a posterior ligamentous disruption with a fracture line traversing the lamina and extending into the apophysis of the adjacent vertebral body. (Adapted from Rumball K, Jarris J. Seat-belt injuries of the spine in young children. *J Bone Joint Surg [Br]* 1992;74:571–574; with permission.)

Distraction and Shear

In children with violent injuries, such as those sustained from being hit by a car, thoracolumbar spine injuries are caused primarily by shear forces (7). The vertebrae typically fracture through the end plate apophyses (Fig. 19-6). These injuries also may be associated with flexion and rotation, which leads to shearing and often traumatic spondylolisthesis (Fig. 19-7).

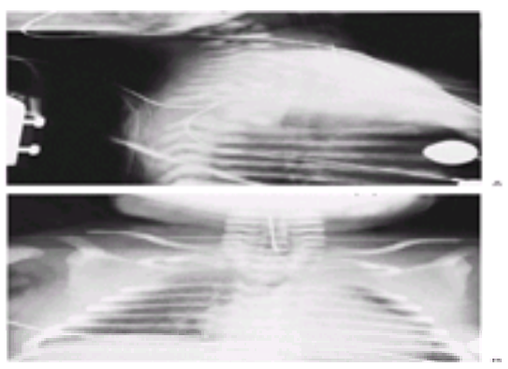

FIGURE 19-6. The radiograph of a newborn with complete disruption at T3–T4. The child was a breech delivery with cephalopelvic disproportion, leading to a difficult extraction. **A:** Anteroposterior view. **B:** Lateral view, demonstrating that the fracture extended through the cartilage end plate. The child is completely paraplegic at the T3–T4 level and has paralysis of the right hemidiaphragm.

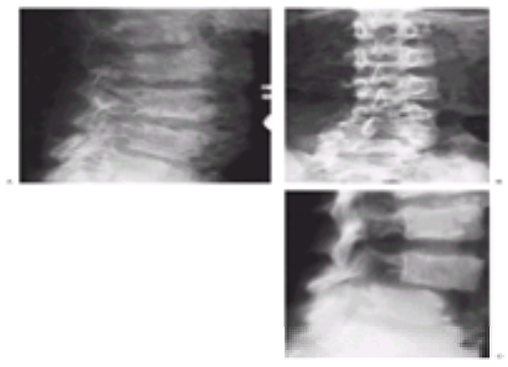

FIGURE 19-7. The radiograph of a 13-year-old Boy Scout who sustained this lumbar fracture when a tree fell directly across his back during a severe thunderstorm. **A:** The anteroposterior view demonstrates a shear-type injury with a fracture–dislocation of L4 to L5 lamina. **B:** The lateral view demonstrates a traumatic spondylolysis at the L4–L5 level. **C:** Lateral tomograms demonstrated severe disruption of the pedicle and facet.

Compression (Slipping of the Vertebral Apophysis)

Slipping of the vertebral apophysis usually occurs in adolescent boys, with traumatic displacement of a lumbar vertebral ring apophysis into the spinal canal and associated disk protrusion (35,126,132). These injuries typically arise from the posterior inferior rim of L4 and less commonly from the inferior rim of L3 or L5. The age and circumstances under which this injury occurs are analogous to those in patients with slipped capital femoral epiphysis (22), which suggests that the vertebral end plate is more susceptible to shear forces during the period of rapid growth. Both chronic and acute forms have been described, and the problem is often erroneously diagnosed as a herniated disk because of the similarity of symptoms (35,126). Many patients (38%) with slipped vertebral apophyses also have lumbar Scheuermann's disease (35), perhaps because the preexisting marginal Schmorl's node weakens the edge and leads to a slip of the apophysis (126).

Slipping of the apophysis can be classified into three types according to radiographic appearance (Fig. 19-8) (132):

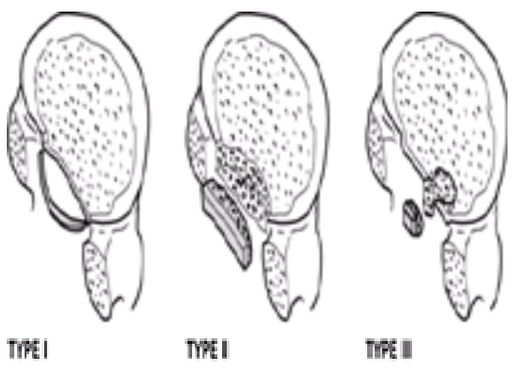

FIGURE 19-8. Schematic representation of the three types of avulsion fractures. In type I **(left)**, an arcuate fragment is found, but no osseous defect is seen at the posterior rim of the vertebral body. Type II **(middle)** is an avulsion fracture of the posterior rim of the vertebral body that includes a rim of bone. The fragment is not arcuate, and it is thicker than in type I. The sharply avulsed osseous edge is recognized on computed tomography. Type III **(right)** is a localized fracture posterior to an irregularity of the cartilage end plate. The osseous defect anterior to the fragment, as depicted on computed tomography, is larger than the fragment. (Adapted from Takata K, Inoue S-I, Takahashi K, et al. Fracture of the posterior margin of a lumbar vertebral body. *J Bone Joint Surg [Am]* 1988;70:589–594; with permission.)

Type I: Separation of the posterior rim of the involved vertebra. A calcified arc is seen on computed tomography (CT) scan with no evidence of associated large bony fracture. This type is most common in children 11 to 13 years of age.

Type II: Avulsion fracture of part of the vertebral body, annular rim, and cartilage. This type is most common in adolescents and young adults 13 to 18 years of age.

Type III: More localized injury that includes smaller posterior irregularities of the cartilaginous end plate. This is most common in young adults over the age of 18 years.

A type IV injury spans the entire length and breadth of the posterior vertebral margin between the end plates (37).

SIGNS AND SYMPTOMS

In a child who is awake and cooperative, complaints of pain may point to spinal injury. In older children, pain and tenderness of the spine usually are present, and inability to walk and muscle spasms often are present with unstable spinal injuries. In a child with polytrauma, a significant vertebral fracture may be overlooked (80). Innocuous-appearing fractures of the lumbar or thoracic transverse processes are often associated with serious abdominal injury (20%) to the spleen and liver, pelvis, urinary tract, or chest (2,61,109,119,129,130,144); 50% to 90% of children with lap belt injuries have intraabdominal injuries (6,44,118), most commonly small bowel ruptures and traumatic pancreatitis. Some researchers (48,118) have reported that abdominal injuries are so severe as to dominate the early clinical picture and result in late detection of spinal fractures. Marked soft tissue swelling, bruising, and tenderness along the posterior spinal area are signs that a spinal fracture may have occurred. Ecchymosis in a lap belt distribution should alert the clinician to the possibility of a Chance fracture (Fig. 19-9) (122).

FIGURE 19-9. An abdominal contusion from a lap belt, or the “seat belt sign.” (Reproduced from Jarvis JG. Seat belt fractures. In: Letts RM, ed. *Management of pediatric fractures.* New York: Churchill Livingstone, 1994; with permission.)

Slipping of the vertebral apophysis typically is caused by a traumatic incident such as weight lifting, gymnastics, or shoveling (22). Acute slipping produces signs and symptoms similar to those of a central herniated nucleus pulposus, including neurologic findings such as muscle weakness, absent reflexes, and positive straight-leg raising (126). Late findings are similar to those of spinal stenosis.

Spinal Cord and Root Injury

The most serious diagnostic error is failure to recognize complete or partial paralysis. Neurologic evaluation of a frightened, hurt, uncooperative child is difficult. Gross flexion or reflex withdrawal of the limbs may mimic voluntary movement. Stimulation and handling of the child may produce crying, leading to a false assumption that sensation is intact. Serial observations over time may be necessary to determine the patient's true neurologic status.

Birth injuries to the spinal cord should be suspected in a floppy infant or a child with a nonprogressive neurologic lesion after a difficult delivery. The single most important finding is the demonstration of a sensory level. Somatosensory-evoked potentials may be helpful (11).

Nine percent to 15% of all spinal cord injuries occur in children and are twice as frequent in boys as in girls (33,62,71). Boys 10 to 15 years of age are at greatest risk for spinal cord injury (33). Young children usually have injuries at the cervicothoracic junction that result in more severe neurologic injury, but they also have more potential for recovery than do older children. Adolescents with thoracolumbar fractures are more likely to have transient or incomplete neurologic deficits that resolve or improve (49).

Delayed onset of paraplegia (2 hours to 4 days) may indicate a vascular insult to the spinal cord (26). The injury is typically at the mid-portion of the thoracic spine (watershed area) and usually is associated with a blow to the chest or abdomen, resulting in shock or profound hypotension from internal injuries. This generally results in complete and permanent paraplegia.

In older children, vertebral fractures are the most frequent cause of neurologic injury (83%) (71). Fracture–dislocations at the thoracolumbar junction are the most common injuries (36%), with the remainder between T4 and L2 (49,62,63,71). The risk of neurologic injury increases with canal narrowing: spinal canal stenosis of 35% at T11–T12, 45% at L1, and 55% at L2 and below are significant factors for neurologic impairment (52).

Recent evidence about burst fractures has suggested that the degree of neurologic injury correlates primarily with the energy of the injury, with no correlation to the amount of osseous or canal disruption. This suggests that the neurologic injury occurs at the time of trauma rather than as a result of pressure in the canal due to remaining osseous fragments (81). Further investigation is necessary to clarify the contributions of canal stenosis and the energy of the injury in the etiology of neurologic damage from thoracolumbar spine fractures.

Spinal cord injury without radiographic abnormality has been reported to occur in 5% to 55% of all pediatric spinal cord injuries, usually in children under 10 years of age (9,43,49,71,76,99,100,117,147). The immature, elastic spine is much more deformable than that of an adult. Momentary displacement from external forces can endanger the spinal cord without causing radiographic disruption of bone or ligaments. Four major factors are believed to be involved: hyperextension, flexion, distraction, and spinal cord ischemia from direct cord contusion or vascular insufficiency (82). The neurologic deficit ranges from complete cord transection to partial cord deficits; the cervical and thoracic areas are almost equally involved (33). Neurologic loss is more often complete in younger children (birth to 8 years of age), in whom thoracic lesions tend to be neurologically complete more often (92%) than in adolescents (50%). Lumbar lesions are rare and tend to be incomplete in all age groups (33). By definition, no disruption, malalignment, or other bony abnormalities are seen on plain radiographs. Physiologic disruption of the spinal cord is not necessarily associated with anatomic disruption. The exact pathoanatomy is not truly known. Magnetic resonance imaging (MRI) is most useful to study the cord and disk–ligament complexes and correlates with clinical outcome (45). The outcome for patients with SCIWORA is primarily determined by the initial neurologic status. Approximately 25% have late deterioration of neurologic function.

Treatment is controversial. Pang (99) recommended brace immobilization for 3 months, but in his series, no child had instability at initial evaluation and only one child later developed instability demonstrated by flexion–extension radiographs (99). Without documented radiographic instability, the biomechanical usefulness of brace immobilization is questionable, although Pang suggests that bracing treats “incipient instability.” In children, normal stability is seldom regained after ligamentous spinal injuries are allowed to heal with simple immobilization, and spinal fusion usually is needed. It seems unlikely that SCIWORA would behave differently regarding instability, incipient or otherwise. Regardless of whether brace immobilization is used or not, close follow-up of neurologic function is necessary. Any sign of instability on flexion–extension radiographs after 3 months of bracing is an indication for surgical stabilization.

Neurologic injuries are uncommon with Chance fractures, although in one series 3 of 10 children had paraplegia (118). This may be related to the higher center of gravity in children that results in an increased moment arm and greater distraction of the neurologic structures.

RADIOGRAPHIC FINDINGS

The radiographic appearance of a spinal injury depends on the force and mechanism of injury. Compression can cause changes ranging from slight flattening of the normally convex end plates to frank wedging of the vertebrae. A zone of increased density in the vertebral body may overlap the trabecular bone (53,61). Damage to multiple vertebrae is usually present (the maximum reported number is 11), but clinically observable kyphosis is uncommon unless there is a fracture–dislocation (53). True fracture lines are seldom seen in prepubertal children. Avulsed vertebral corners, common in adults, are rare in children (43). If the amount of force is significant, the end plate ruptures and the disk is extruded into the vertebral body, forming a Schmorl's node, typically in the lower thoracic and upper lumbar vertebrae (10).

Adult fracture patterns, such as subluxation or fracture–dislocation, which are uncommon in children (Fig. 19-10), are more common in adolescents (Fig. 19-11). As in adults, CT scans and sagittal reconstructions are more accurate than plain x-rays in detecting posterior arch fractures (Fig. 19-12) and retropulsed bone with spinal canal narrowing (15,42). The CT cuts must be at right angles to the vertebral bodies or the lesion will be confused with a pseudofracture (15). In children with slipped vertebral apophyses, CT scanning (35,126) shows a small bony fragment (the edge of the vertebral end plate) within the spinal canal (Fig. 19-13). MRI shows a large anterior extradural impression (or rarely even a complete block) from the slipped apophysis and protruded disk (22,115).

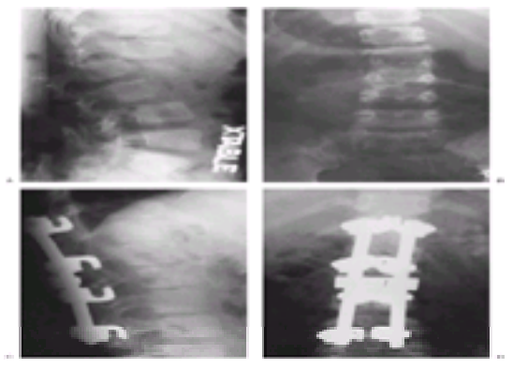

FIGURE 19-10. This 7-year-old boy was a restrained passenger involved in a motor vehicle accident and sustained a fracture–dislocation at L1–L2. **A:** Lateral. **B:** Anteroposterior. There was a complete absence of neurologic function below L1 on admission. He underwent open reduction and internal fixation that night with instrumentation and fusion from T10 to L3. **C:** Lateral. **D:** Anteroposterior. At follow-up some 3 years later, he has significant motor recovery, with motor strength being 4/5 psoas, quadriceps, and hamstring; 3/5 triceps surae; 2/5 extensor hallicus longus; and 1/5 tibialis anterior. He is ambulatory with ankle–foot orthoses. (Courtesy of Gregory Graziano, M.D.)

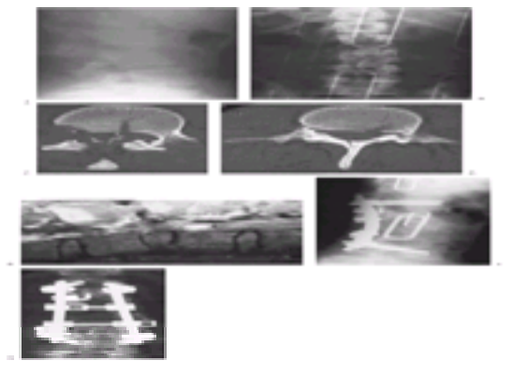

FIGURE 19-11. This 16-year-old girl was involved in a motor vehicle accident, sustaining a fracture–dislocation at L2–L3 with complete loss of neurologic function. The initial radiographs [lateral **(A)** and anteroposterior **(B)**] demonstrate a fracture with significant kyphosis at L2–L3. Also note that the fracture involving the posterior elements of L3 extends inferiorly nearly into L4. This created a very unstable situation, and the clinician elected to proceed with instrumentation and fusion. The preoperative computed tomography scan shows a three-column injury **(C)**. Also note the L3 laminar fractures **(D)**. The preoperative magnetic resonance image (T2-weighted) shows an area of increased signal (*arrow*), representing acute cord edema, as well as an area of decreased signal (*arrowhead*), representing acute intraspinal hemorrhage **(E)**. At surgery, hooks could not be placed on the lamina of L3 due to fracture, as noted on the preoperative computed tomography scan. For this reason, the clinician elected to proceed with instrumentation from L1 to L4 using pedicle screws. Due to the marked disruption and instability noted at the time of posterior spinal fusion, the clinician also elected to perform an anterior fusion from L2 to L4. The postoperative radiographs are shown [lateral **(F)** and anteroposterior **(G)**]. (Courtesy of Frances Farley, M.D.)

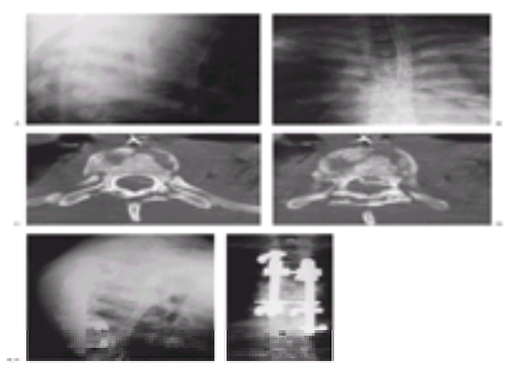

FIGURE 19-12. This 17-year-old girl was an unrestrained passenger in a school bus involved in a motor vehicle accident. The rear tire blew out at a speed of 70 mph, causing the bus to roll over several times. She was unconscious for a short period of time, but on arrival in the emergency department she complained of chest pain. Physical examination was pertinent for a sternal contusion, a nontender spine, and a normal neurologic examination of the lower extremities. Chest and spine radiographs demonstrated a fracture of T5. The lateral radiograph demonstrates a marked compression of T5 and kyphosis at T5–T6 **(A)**. The anteroposterior radiograph demonstrates a compression of T5, with pedicular widening **(B)**. The computed tomographic scan shows fractures of the laminae **(C)**, along with retropulsion of bone into the canal **(D)**. Due to the kyphosis, retropulsion of bone, and three-column injury, a posterior spinal fusion with distraction instrumentation was performed. Radiographs 1 year after surgery demonstrate correction of the kyphosis [lateral **(E)**] with a normal frontal alignment [anteroposterior **(F)**].

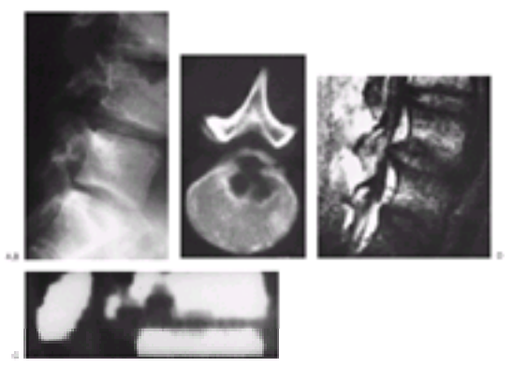

FIGURE 19-13. Slipped vertebral apophysis in a 15-year-old with back pain, hamstring tightness, and symptoms suggestive of spinal stenosis. **A:** Lateral radiograph at the lumbosacral junction demonstrates a Schmorl's node and bony changes in the posterior portion of the apophysis of L4. **B:** The computed tomography scan demonstrates a Schmorl's node formation and a fracture of the apophysis with subluxation into the spinal canal. **C:** The computed tomography scan reconstruction of the same lesion. **D:** Magnetic resonance imaging demonstrates slipping of the vertebral apophysis as well as the intervertebral disk, with encroachment of the spinal canal.

Chance fractures in children usually are in the mid-lumbar spine (L1–L3) instead of the thoracolumbar junction as in adults. Routine lateral radiographs are best for making the diagnosis (Fig. 19-14) and should be obtained in any child believed to have abdominal injury caused by a seat belt (139). Avulsion of spinous processes often extends over several vertebral levels, often with anterior compression fractures. CT scans typically do not demonstrate this injury because the cuts are in the same plane as the horizontal fracture–dislocations but can provide further information about the presence of intracanal bony fragments or injury to the osseous posterior arch. If injury to the gastrointestinal tract is suspected, appropriate imaging should be performed.

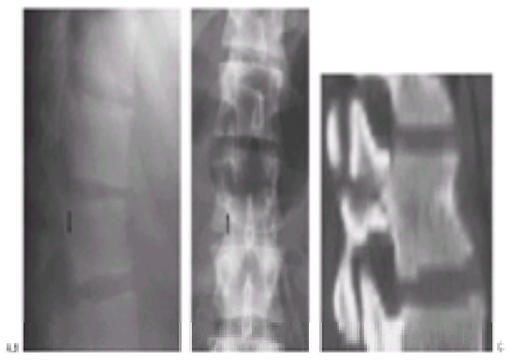

FIGURE 19-14. This 17-year-old boy was involved in a motor vehicle accident sustaining a bony Chance fracture. **A:** The lateral spine radiograph shows the fracture line (*arrow*) through the posterior elements and the vertebral body. **B:** The anteroposterior radiograph also shows the fracture and gap through the posterior elements (*arrow*). **C:** The sagittal reconstruction from the computed tomography scan clearly shows the fracture line through the posterior elements.

Magnetic resonance imaging is better than CT scanning or myelography for evaluation of spinal cord or cauda equina injuries in children (13,16,69,133), and obviates the need for intrathecal injection of contrast dye that is necessary for a myelogram. However, false-negative and false-positive MRI results may occur. The presence of spinal instrumentation is not a contraindication to the MRI scan. Three types of MRI patterns are seen on T2-weighted images of acute spinal cord injuries. Type I is a decreased signal consistent with acute intraspinal hemorrhage, type II is a bright signal consistent with acute cord edema, and type III is a mixed signal of central hypointensity and peripheral hyperintensity, consistent with contusion. Patients with type I patterns rarely have improvement in Frankel grade, whereas those with types II and III patterns frequently improve at least one Frankel grade (13).

TREATMENT

Spinal Cord and Root Injury

The second National Acute Spinal Cord Injury study published in 1990 (18) recommended that methylprednisolone be given within the first 8 hours of injury to improve neurologic recovery. Unfortunately, the youngest patient in that study was 13 years old, so the outcome of these recommendations in younger children is unknown. The follow-up study (19) further defined the doses and time intervals, but here again the youngest patient in that study was 14 years old. Nevertheless, we do recommend the administration of methylprednisolone in patients with acute, blunt spinal cord injuries. The initial loading dose is 30 mg/kg body weight. If the loading dose is given within 3 hours after injury, then a maintenance infusion of 5.4 mk/kg is given for 24 hours after injury; if the loading dose is given 3 to 8 hours after injury, then a maintenance infusion of 5.4 mk/kg is given for 48 hours after injury. It must be remembered that these recommendations were developed for those who had sustained blunt trauma. There is some evidence that the administration of methylprednisolone in penetrating spinal cord injury may actually impair recovery of neurologic function (107). Finally, the administration of methylprednisolone is associated with a higher complication rate, especially pneumonia and sepsis (19,41), but without an increase in mortality (19).

Fracture Treatment

Permanent disk space narrowing and spontaneous interbody fusion are uncommon after spinal injuries in children, because the healthy intervertebral disks typically transmit forces to the vertebral bodies (65). This, along with the presence of the rib cage in the thoracic spine, makes a stronger case for nonoperative treatment of spinal injuries in children than in adults. Approximately two thirds of spinal fractures in children are stable.

Flexion Injuries

Simple compression fractures heal quickly with little tendency for further progression. Symptomatic treatment with a short period of bed rest or immobilization with a cast or orthosis usually is sufficient for mild injuries. In studies comparing casting with bed rest, the type of treatment did not affect the outcome, and most children were asymptomatic in 1 to 2 weeks (62,63,88). Posterior tenderness in the area of the fracture occasionally persists but usually does not pose any serious problem (62). Symptoms may persist for some time after end plate fracture and disk herniation into the vertebral body but usually resolve with conservative treatment.

The brace used for treatment of a flexion injury (compression fracture) can be of two types. The first is a Jewitt brace made of a metal frame with a sternal and pubic anterior pad and a posterior vertebral pad. The lateral screw connection is used to secure and adjust the brace. The second type is a polypropelene “clamshell” brace with Velcro closure and foam lining. The brace is molded to fit the patient, and the anterior shell contacts the sternum and pubis to prevent kyphosis.

If hyperextension is required, it can be best obtained in a cast with extension across the hip joint to a “pantaloon,” if extension of the lower lumbar spine is required. A Risser table or adapted spica table is needed to apply these body casts.

Chance Fractures

If the injury is truly bony in all columns, closed reduction with reconstitution of lordosis and cast immobilization are appropriate. If the injury is ligamentous, operative reduction with fusion is indicated, because ligamentous disruptions do not heal without instability. Glassman et al. (46) reported that brace treatment failed only in patients with an initial kyphosis of more than 20 degrees, and they advocate immobilization if kyphosis is less than 20 degrees. In their series, all children with successful brace treatment had a decrease in kyphosis over time because the potential for anterior growth remained. When operative treatment is required, the type of fixation depends on the age of the child. In small children, simple interspinous wiring can be supplemented by postoperative cast immobilization. In adolescents, standard compression instrumentation can be used.

OPERATIVE TREATMENT

Interspinous Process Wiring of Ligamentous Chance (Lap-Belt) Injury

Anesthesia is induced with the patient supine, and appropriate spinal cord monitoring leads are placed. The child is then carefully log-rolled prone onto rolls on a standard operating table. Suspension-type frames (such as the Hall-Relton frame) should not be used because this may allow excessive lumbar sag in an already unstable spine and possibly increase neurologic damage. The legs and distal lumbar spine should be placed directly over the break of the operating table to allow some extension of the legs and distal lumbar spine during the reduction maneuver.

The entire spine and iliac crests are prepared and draped in standard fashion. A posterior midline incision is made over the injured vertebral levels. Often the gap between the spinous processes is easily palpable or ecchymosis is seen. If the level cannot be localized clinically, an intraoperative lateral radiograph should be taken before the incision is made (Fig. 19-15A). Dissection is carried sharply down to the level of the thoracolumbar fascia. Dissection must be executed carefully because the injury causes severe disruption of the thoracolumbar fascia and paravertebral musculature. Incising the subcutaneous fat alone often makes the dura visible through the disrupted area.

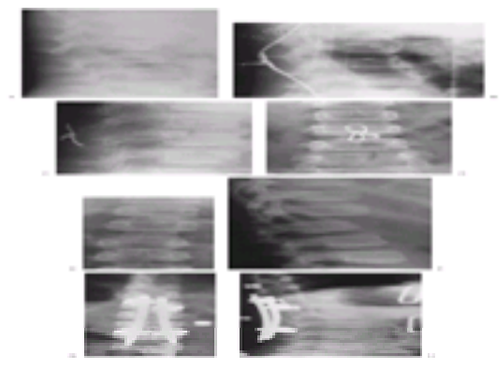

FIGURE 19-15. Chance fracture. **A–E:** This 5-year-old girl was a back-seat passenger involved in a motor vehicle accident at a high rate of speed. She wore a seat belt and sustained a type B Chance fracture. The lateral radiograph intraoperatively obtained for localization of the level for purposes of incision placement **(A)**. Note the overlying marker. At L2–L3 note the increased disk space posteriorly with kyphosis and interspinous distance widening, as well as the avulsion fractures of the spinous processes of L1 and L2. The intraoperative lateral radiograph after interspinous wiring, confirming reduction of the kyphosis, interspinous widening, and facet joints **(B)**. Lateral **(C)** and anteroposterior **(D)** radiographs 9 months later showing maintenance of the reduction and a solid fusion mass. **E–H:** This 9-year-old child was a restrained passenger in a motor vehicle crash and sustained a type B Chance fracture [anteroposterior **(E)** and lateral **(F)**], which was also associated with a small element of shear, as noted by the slight lateral and more obvious posterior displacement of L1 on L2. He was completely hemiparetic. He underwent a posterior compression type of instrumentation [anteroposterior **(G)** lateral **(H)**]. Two months later, he had complete neurologic recovery. (**E–H** courtesy of William Warner, Jr., M.D.)

When the thoracolumbar fascia is reached, the paravertebral muscles are carefully elevated subperiosteally from the spinous processes of the two disrupted vertebrae. The laminae and disrupted facet joints are exposed by careful lateral dissection. Only the injured levels should be exposed to prevent fusion of uninvolved levels or iatrogenic instability. The interspinous ligaments connecting the disrupted vertebrae to the normal cranial and caudal vertebrae should not be removed or violated in any way (removing these ligaments can create an iatrogenic ligamentous instability at the uninjured levels). Normal facet joints also must not be violated. Large hematomas are often encountered during this portion of the procedure; frequent use of warm saline irrigation with careful dissection allows safe exposure of the disrupted facet joints. Small pieces of bone avulsed from the spinous processes and a completely torn ligamentum flavum are often encountered in the disrupted area. The disrupted ligamentum flavum is carefully removed without violating the dura. Here again, frequent and copious use of warm saline irrigation will make the dissection easier by lysing the hematoma and elevating tissues off the dura. The disrupted and frayed facet capsules are removed, as well as any bony fragments in the area of the facets that might prevent anatomic reduction.

A gradual and gentle reduction is begun by grasping the separated spinous processes with towel clips and gradually reducing the kyphosis. The reduction of the disrupted facets is evaluated by visual inspection. Spinal cord-evoked potentials must be carefully monitored during the reduction maneuver. Reduction often can be facilitated by extending the leg portion of the table and bringing the distal lumbar fragment into lordosis. With small awls or towel clips, holes are made at the bases of the spinous processes of the two disrupted vertebrae. The holes should be carefully placed to ensure that the dural sac is not penetrated. A figure-of-eight wire is passed through the holes. The wire is tightened and a lateral radiograph is taken to confirm reduction, using both the facet joints and interspinous distance to confirm anatomic reduction (Fig. 19-15B). If the reduction is not adequate, the wire is further tightened until an anatomic reduction is achieved. The wire is then cut and bent. The articular cartilage of the facet joints is destroyed at the level of the fusion, and an autogenous bone graft is placed at the levels to be fused. To minimize the risk of stenosis, either a local fat graft or gelatin sponge is placed over the exposed dural sac before the bone graft is placed.

If the spinous processes are too small to place the wire through drill holes, the wire can be placed around the spinous processes. With a small Kerrison rongeur, a small trough is made in the base of the spinous process, superiorly at the superior vertebrae and inferiorly at the inferior vertebra. The interspinous ligaments connecting the disrupted vertebrae to the normal cranial and caudal vertebrae should not be removed or violated in any way. The spinous processes are then wired together in a figure-of-eight fashion by placing the wire in the troughs in the spinous processes.

After routine closure, the child is carefully rolled supine and a pantaloon spica cast is applied, with care to maintain lumbar lordosis. Radiographs are taken after the cast has hardened, and then the child is awakened.

OPERATIVE TREATMENT

Compression Instrumentation of Ligamentous Chance (Lap-Belt) Injury

In an older child or adolescent, compression instrumentation can be used (Fig. 19-15C), usually obviating the need for postoperative cast immobilization. The same intraoperative positioning and exposure as for interspinous wiring are used. After removal of the disrupted and frayed facet capsules, ligamentum flavum, and bone fragments in the area of the facets, instrumentation is begun. A claw-type construct is made using two laminar hooks (one on the right and one on the left of the spinous process) in a downgoing fashion over the lamina at the most superior level, and two laminar hooks (again one on the right and one on the left of the spinous process) in an upgoing fashion over the lamina at the most inferior level. If the superior hooks are at the level of the spinal cord or conus, the right and left hooks can be placed at successive laminar levels instead of at the same level to minimize the decrease in intracanal space owing to the sublaminar hooks. Again, the interspinous ligaments connecting the disrupted vertebrae to the normal cranial and caudal vertebrae should not be removed or violated in any way. If the instrumentation is of the Cotrel-Dubousset type, all the hooks should be closed.

Rods of appropriate length are measured and inserted into the hooks. Gradual compression is applied, alternately compressing right and left sides. The adequacy of reduction of the disrupted facets is evaluated by visual inspection. Spinal cord-evoked potentials are carefully monitored during the reduction maneuver. A lateral radiograph is taken to confirm reduction, using both the facet joints and interspinous distance to verify anatomic reduction (Fig. 19-15E). After confirmation of reduction, the hooks are firmly tightened onto the rods, and a fusion is performed as previously described. When possible, crosslinking should be used between the two rods.

After routine closure, the patient is carefully rolled supine and radiographs are taken to confirm maintenance of the reduction and instrumentation position. Depending on the degree of intraoperative stability and compliance of the patient, either no immobilization or a thoracolumbosacral orthosis is used.

Distraction and Shear Injuries

Unstable injuries, such as vertebral subluxation or fracture–dislocation, should be reduced (21,63,65,88). The child should be placed on a turning frame or at complete bed rest with log rolling until the acute symptoms subside, and then operative reduction and fixation should be performed. In children with neurologic injury, the fracture should be reduced promptly, especially if the neurologic injury involves the conus medullaris and nerve roots. Children with burst fractures that result in kyphosis and spinal canal narrowing of more than 25% are at risk of further canal compromise, and early correction and decompression should be considered (21).

These adult fracture patterns usually occur in adolescents. Spontaneous interbody fusion seldom occurs; clinicians should not rely on such fusion to provide long-term stability (63,88). The spinal canal and vertebral elements are the same size as in adults, and adult instrumentation is used for reduction and stabilization (Fig. 19-11 and Fig. 19-12). All instrumentation must be accompanied by posterior spinal fusion at least one level above and below the level or levels of injury. In older children with severe neurologic deficits, extending the fusion to the sacrum to prevent late onset of paralytic scoliosis is rarely advocated (76).

Some injuries that are stable in adults may be progressive in children. Severe crushing of the vertebral body and end plate (burst fractures), with or without disruption of the posterior supporting ligaments or laminectomy, is analogous to a Salter-Harris type IV injury of the vertebral apophysis. Growth arrest leads to progressive kyphosis (88). Early recognition, reduction, stabilization, and fusion prevent late deformity and neurologic compromise.

The indications for immediate surgical decompression (49) are the same as in adults: an open wound and progressive neurologic deficit in an incomplete spinal cord

injury. Reduction of an unstable fracture–dislocation is a relative indication. Laminectomy is seldom helpful, especially in children without bony injury (49,65). It accentuates an already unstable condition, which may lead to progressive deformity (146) such as kyphosis, which is difficult to manage (72,76). If laminectomy is necessary, it should be accompanied by a short segment fusion.

Slipped Vertebral Apophysis

Surgical treatment is nearly always needed. Laminectomy and decompression with removal of the bony ridge and disk give excellent results (22,126). Disk removal alone is not sufficient to relieve the nerve root impingement (22).

PROGNOSIS AND COMPLICATIONS

Growth Arrest

Progression of the vertebral body deformity is uncommon in children, unless the injury is unstable, such as a fracture–dislocation, or a neurologic deficit is present. The vertebral bodies have great potential for restoration because of the stimulation of vertebral growth and overgrowth (53,63). In children who are under 10 years of age or have a Risser sign of 0 or 1 at the time of injury (106), the vertebral body tends to return to its normal shape, even after multiple compression fractures, and kyphosis is uncommon (62,63,65,69,70,71). However, complete reconstitution is possible only if the nucleus pulposus does not protrude into the vertebra (62). The vertebral end plate is the area of active growth, and if it is damaged, little subsequent correction of the deformity will occur. The undamaged adjacent vertebra usually compensates for asymmetric growth of a damaged vertebra, especially in the thoracolumbar area, and significant scoliosis seldom occurs (62). Spontaneous interbody fusion is rare in children; the interposed, undamaged, intervertebral disk is thought to block this process (63,71,112).

Spinal Cord and Root Injury

The most devastating complication of thoracolumbar spinal injuries is paraplegia. A child with a spinal cord injury has the same problems as an adult with spinal cord injury: increased susceptibility to long bone fractures, hip dislocation, pressure sores, joint contractures, and genitourinary complications (9). In addition, a child is likely to develop progressive spinal deformity (scoliosis, kyphosis, and lordosis) (Fig. 19-16) (9). For many children, the original vertebral injury often is overshadowed by the severity of these late spinal deformities (9). Scoliosis erodes the ability to sit easily, and in young children pelvic obliquity may lead to subluxation of the hip and ischial pressure sores (72,76).

FIGURE 19-16. The radiograph of a 9-year-old girl who sustained a motor vehicle accident and polytrauma. There were no radiographic vertebral fractures, but she was a complete paraplegic at T10, believed to be due to a vascular injury and hypotension. **A:** The anteroposterior radiograph at 11 years of age demonstrates a mild collapsing type of scoliosis. **B:** By 13 years and 9 months of age, the curve had increased to 50 degrees despite aggressive orthotic management. This scoliosis required surgical instrumentation and fusion.

In children (girls under 12 and boys under 14 years of age), the incidence of progressive spinal deformity after traumatic paraplegia is 86% to 100% (9,86). The onset of curvature has been reported to occur in children as young as 3 years (9). The fracture seldom determines the direction of curvature; rather, most children develop a long paralytic thoracolumbar curve thought to be caused by the influence of gravity and the uneven forces of spasticity (72). A long thoracolumbar kyphosis reverses the normal lumbar lordosis (76,86). Increased lumbar lordosis is less common (18%) and usually is associated with hip flexion contractures in an ambulatory patient (72,86). Progression of the spinal curvature is directly related to the age of the child, the degree of spasticity, and the level of the lesion (76,86). Children with more proximal injuries are more likely to have a progressive deformity than are those injured at or below the level of the conus medullaris (9).

In adolescents who are near skeletal maturity at the time of injury, spinal deformity is more often caused by the fracture–dislocation itself (86). Progressive kyphosis and pain at the fracture site are common (42%), especially after laminectomy (72,86). If the kyphosis is progressive, long-term neurologic sequelae may develop, with further loss of function from tenting of the neural structures over the kyphos. This is another reason for early surgical stabilization of these fractures in adolescents (86).

Treatment of scoliosis should be initiated soon after the injury, before a severe curve develops. Total-contact underarm plastic orthoses have been helpful in at least temporarily controlling the collapsing paralytic curve. Treatment recommendations are similar to those for idiopathic scoliosis. Curves of less than 40 to 45 degrees may be controlled by bracing, or at least surgery can be delayed until further spinal growth has occurred and the child is of optimal age (74,76). For curves of more than 45 to 50 degrees, surgical stabilization should be performed. In one series (86), 68% of children required surgical correction. Children with severe or rigid curves may require anterior release with or without halo-wheelchair traction. Segmental instrumentation, such as Harrington or Luque rods with sublaminar wiring, or the newer rotational systems (such as Cotrel-Dubousset) are used, along with arthrodesis. The child should be quickly mobilized after surgery to avoid the problems associated with long periods of bed rest (such as pneumonia and decubiti in insensate areas).

With the advent of MRI, the “rare” posttraumatic syringomyelia is being discovered with increasing frequency (13). Symptoms can develop many years after injury (4.5 years average), even as late as 15 years (141). Pain is the initial symptom in over half of the children, followed by progressive neurologic loss as demonstrated by sweating below the level of the original lesion, loss of motor function, and changes in the deep tendon reflexes (141). The best method to detect syringomyelia is MRI, and some researchers have recommended that an initial baseline MRI be obtained to make later detection of syringomyelia easier (13,83).

Other Spinal Injuries

The fractures discussed in the preceding sections are acute traumatic injuries. Fractures or fracture-like conditions of the thoracic and lumbar spine in children can result from causes other than acute trauma, including repetitive stress, systemic disease that creates pathologic bone, societal mechanisms of trauma (such as child abuse and gunshot wounds), spondylolysis and spondylolisthesis, and lumbar and dorsolumbar Scheuermann's disease.

Stress Fractures

Stress fractures (31) are caused by abnormal or repetitive loading of normal bone. They typically occur in young active individuals, most often in the metatarsals and tibia in children. Grier et al. (47) reported stress fractures of the sacrum in two children, both of whom had pelvic pain and positive FABER (flexion, abduction, external rotation) tests. A bone scan can be used to localize the pain, and the diagnosis is confirmed by CT scanning. Treatment is nonoperative.

Systemic Diseases

Spontaneous collapse of a single vertebral body, especially in a child between the ages of 2 and 6 years (96), suggests the possibility of an eosinophilic granuloma (Fig. 19-17). Usually there is complete collapse of the body (vertebra plana), and the lytic appearance typical of this lesion in other areas of the skeleton is rarely

seen. The intervertebral disk is not affected. An adjacent soft tissue mass is uncommon and, if present, suggests an infectious process (such as tuberculosis or a bacterial process) or Ewing's sarcoma, instead of eosinophilic granuloma. The prognosis is excellent, with some reconstitution of the height of the vertebral body and little residual deformity. However, complete reconstitution rarely occurs.

FIGURE 19-17. The lateral radiograph of a girl 2 years and 1 month of age with eosinophilic granuloma of T12. Note the vertebra plana with maintenance of the disk space height.

Multiple vertebral collapse is common in patients with Gaucher's disease, mucopolysaccharidoses, leukemia, and neuroblastoma (4,40,89,108). he abnormal cells displace the normal bone-forming elements, and the vertebra becomes structurally weak and collapses with minor trauma. Usually these children have visceral as well as skeletal involvement at other sites. A bone scan and skeletal survey should be obtained to identify these other sites. Typical symptoms are persistent pain in the region of the collapse. Neurologic complications are rare. In children with leukemia the peripheral leukocyte count may be normal despite vertebral involvement and collapse (89).

In patients with Gaucher's disease, the bone-forming elements are replaced by an infiltrate of glucocerebroside-containing reticulum cells. One or more vertebrae may collapse, but a gibbus is rare (Fig. 19-18). The mucopolysaccharidoses, chondrodystrophies, and lipidoses are similar to Gaucher's disease, with cellular storage of an abnormal metabolite and structural weakness. Vertebral changes are typically first noted at the thoracolumbar junction, with anterior herniation of the nucleus pulposus, and appear on radiographs as a “beaking” of the vertebral body (Fig. 19-19). Depending on the severity of the disease, the process may involve the entire spine (4).

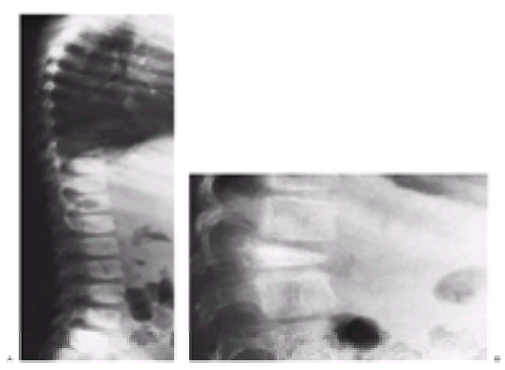

FIGURE 19-18. Gaucher's disease. The illness is progressive with increased storage of the abnormal metabolite and structural weakening of the vertebral elements. **A:** Normal appearance of the thoracolumbar spine at 5 years of age. **B:** At 8 years of age a spontaneous compression fracture of L1 has occurred. The patient sustained many similar fractures until her death 3 years later.

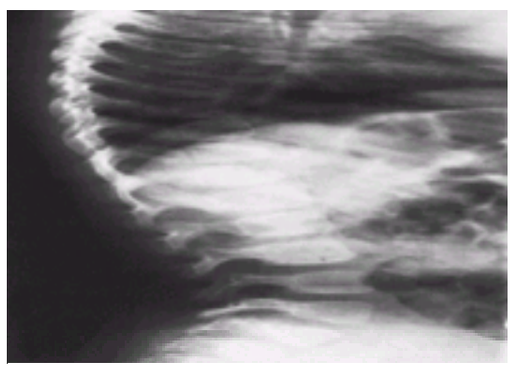

FIGURE 19-19. The lateral radiograph of a 13-month-old infant evaluated for delay in motor milestones and subluxation of the hips. Note the beaking of the T12 vertebral body. This finding is compatible with storage diseases such as mucopolysaccharidoses, mucolipidoses, or hypothyroidism. In this situation, further clinical and laboratory investigation is required. This particular child was diagnosed with Hurler's syndrome on the basis of laboratory studies.

Serial compression fractures are common in patients with osteogenesis imperfecta (Fig. 19-20). However, these children usually have the typical stigmata, such as long bone fragility, extremity deformity, and blue sclera. Progressive spinal deformities of scoliosis and kyphosis are common in severely involved children. Compression fractures with kyphosis also can be caused by certain conditions associated with systemic osteoporosis, such as cystic fibrosis, or as a consequence of treatment, such as corticosteroid-induced osteoporosis in children with severe juvenile rheumatoid arthritis (114,137).

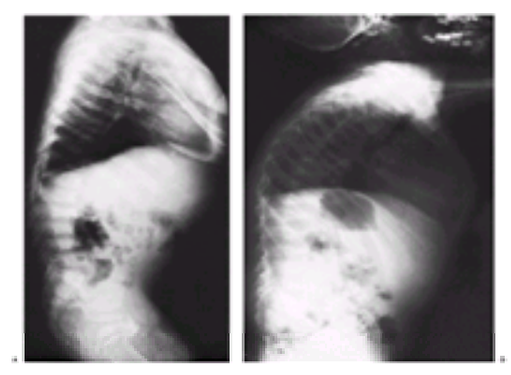

FIGURE 19-20. Compression fractures seen in osteogenesis imperfecta. **A:** The lateral radiograph of the spine at 3 years of age with compression fractures of the lumbar vertebrae. **B:** At age 7, compression fractures of every vertebrae, with narrowing of the vertebral body and apparent increase of the intervertebral disk spaces

representing disks that have retained their normal elasticity.

Compression fractures also occur in patients with idiopathic juvenile osteoporosis (Fig. 19-21), an unusual acquired systemic condition characterized by profound osteoporosis in otherwise normal prepubertal children, typically between the ages of 8 and 15 years (68). The condition may be confused with osteogenesis imperfecta; however, it is of limited duration, usually 1 to 4 years, and is followed by nearly normal restoration of the skeleton. Osteoporosis is evident radiologically, and fractures occur with minimal trauma. There is no family history, and patients do not have the blue sclera, wormian bone skull changes, or poor teeth characteristic of osteogenesis imperfecta (68). Initial complaints are usually related to the spine, and if the condition is recognized, early treatment with a Milwaukee brace improves the appearance and reduces the amount of kyphosis and residual deformity. An even rarer osteoporosis is associated with heparin use, and compression fractures rarely occur in children with severe cardiac disease that requires long-term heparin treatment to prevent thromboembolic phenomena (Fig. 19-22).

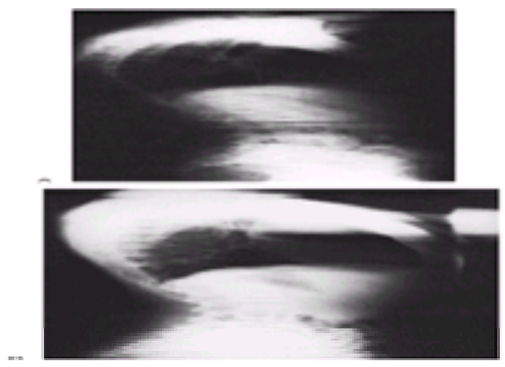

FIGURE 19-21. Idiopathic juvenile osteoporosis. This is a systemic condition characterized by the onset of osteoporosis in an otherwise normal prepubertal child, typically between the ages of 8 and 15. **A:** The patient has sustained multiple spontaneous compression fractures with considerable kyphosis and deformity of the vertebrae. **B:** Early treatment with a Milwaukee brace improved his appearance and reduced the degree of kyphosis and residual deformity.

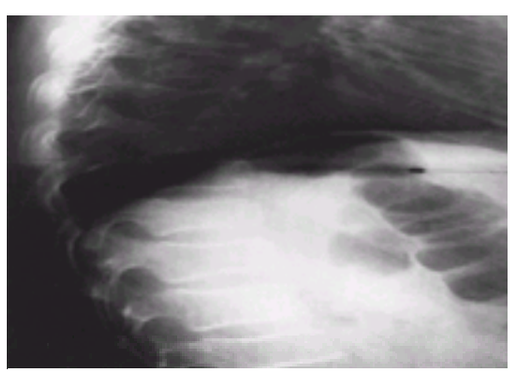

FIGURE 19-22. The lateral radiograph of a 15-year-old boy on long-term subcutaneous heparin anticoagulation for a congenital cardiac condition. Note the osteopenia of the vertebrae, the central compression fractures of the vertebral bodies, and the preservation of the intervertebral disk height.

Spinal Fractures Caused by Child Abuse or Gunshot Wounds

Vertebral injuries caused by child abuse are less common than injuries of the extremities (131). Spinal injuries are usually caused by hyperflexion and may be simple compression of the vertebral bodies, avulsion of the secondary centers of ossification of the spinous processes, or, less frequently, herniation of the nucleus pulposus into the vertebral body. Fracture–dislocations (Fig. 19-23) or kyphosis secondary to severe disruptions are rare, (27,34,73,131), although there are striking examples of T12–L1 subluxation–dislocation with complete paraplegia from spanking (32,110). These are actually Salter-Harris type I fractures of the vertebral centrum from the cartilaginous end plate and may mimic a central nervous system tumor (24). There are no radiographic vertebral changes specific for the battered child syndrome. Kleinman and Marks (73) found three main patterns: (a) compression, usually no more than 25% of the anterior half of the vertebral body; (b) fracture of the anterosuperior aspect of the vertebral body with extension into the anterior aspect of the end plate; and (c) combined lesions. Similarly, the classic corner fractures of the long bones are present in only 15% of abused children. A high index of suspicion is more helpful than a specific radiographic finding. The children may exhibit other signs of neglect, such as poor nutrition and poor hygiene.

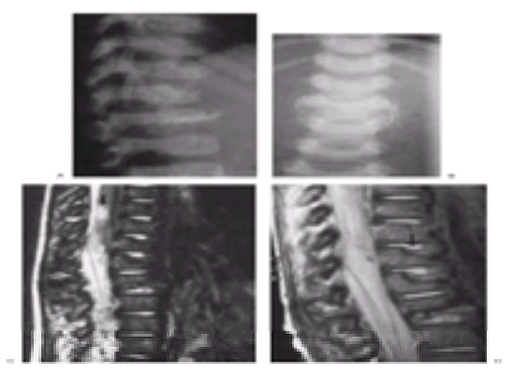

FIGURE 19-23. The radiographs of a 10-month-old girl with paraplegia from a thoracolumbar fracture due to child abuse. The child presented to the emergency department with “acute onset” paraplegia. A skeletal survey also discovered healing clavicle and rib fractures, consistent with abuse. After investigation by the Department of Social Services, the father was criminally prosecuted and subsequently incarcerated. **A:** The lateral radiograph shows anterosuperior Schmorl's nodes at T12 to L2, as well as compression of the vertebral body of L2. There is callus formation at the inferior aspect of the L2 vertebral body. Note that the disk height is relatively preserved. **B:** The anteroposterior radiograph shows callus between L2 and L3 and compression of L2. **C:** The magnetic resonance image (T2-weighted) shows an area of increased signal intensity, representing cord edema (*arrow*). **D:** The magnetic resonance image (T1-weighted) shows the protrusion of the intervertebral disk into the anterior margin of the vertebra (*arrow*) with its associated compression of the body. Note the multiple levels of disk disruption and vertebral body compression.

Spinal injuries caused by gunshot wounds are increasing in frequency. At Rancho Los Amigos Medical Center, between 1985 and 1989, gunshot wounds in children accounted for the same number of spinal cord injuries as did motor vehicle accidents (38% each). Before 1970, gunshot wounds accounted for only 6% of spinal injuries (50). Laminectomy does not affect the outcome of patients with complete lesions and is detrimental to those with incomplete lesions (127), resulting in cerebrospinal fluid fistulas, infection, and late instability. Thus, laminectomy is rarely needed (28,127), and the only indication for surgery is a progressive neurologic deficit (54). One exception may be a motor lesion between T12 and L4, where one series showed a significantly better motor recovery after bullet removal (140).

Spondylolysis and Spondylolisthesis

Spondylolysis occurs in approximately 5% of the general population. Its origin is controversial, with data supporting both developmental and congenital origins. Congenital deficiency of the sacrum and lack of integrity of the posterior structures, on a genetic basis, may predispose to spondylolysis. Developmental factors such as trauma, posture, or certain repetitive activities may cause a stress fracture of the pars interarticularis.

Spondylolysis occurs in children after walking age. It is rare in children younger than 5 years of age and has been reported in only one infant (17). It is most common in children aged 7 or 8 years, suggesting that trauma is a prominent factor in the etiology (8,143). Spondylolysis can only be produced by forced hyperextension, and laboratory tests indicate that a high degree of force is required (60). Although minor trauma is common (50% of males and 25% of females) and often initiates the onset of symptoms, seldom is the injury severe (56). Rather, the onset of symptoms coincides closely with the adolescent growth spurt (135).

Spondylolysis at L5–S1 is often categorized as a congenital anomaly of the spine. Although there is no supporting embryologic or anatomic evidence for this designation, several findings favor a congenital origin. A high rate of occurrence among family members and certain ethnic groups has been reported by numerous researchers, with an incidence of 27% to 69% in near relatives versus an expected frequency of 4% to 8% in the general population (145). There are also racial and sex differences, with the lowest incidence in black females and the highest (6.4%) in white males. Persons with spondylolysis have an increased incidence of sacral spina bifida (28% to 42%) and congenital lack of development of the proximal sacrum and superior sacral facets (145).

Substantial documentation supports the theory that spondylolysis represents a stress fracture of the pars interarticularis (77,143). Some researchers have postulated that lumbar lordosis is accentuated by the normal hip flexion contractures of childhood, focusing the force of weight bearing on the pars interarticularis and leading to gradual disruption (75). Anatomic studies suggest that shear stresses are greater on the pars interarticularis when the spine is extended (75,77). In children, the pars interarticularis is thin, the neural arch has not reached its maximal strength, and the intervertebral disk is less resistant to shear (29). A fatigue fracture can occur at physiologic loads during cyclic flexion–extension motion of the lumbar spine (77). These stresses may be further accentuated by lateral flexion movements on the extended spine, as may occur during a back walk-over in gymnastics (75,77). Spondylolysis is four times more frequent (11%) in female gymnasts than in other girls of the same age (64); many initially have normal radiographic results and later develop spondylolysis. Recent evidence has demonstrated the presence of synovial pseudarthroses at the site of the spondylolysis, which also communicates with the facet joint just superior to it. This suggests that stress fractures of the pars intertarticularis due to repetitive trauma fail to heal because of the presence of synovial fluid from a nearby facet joint; this eventually results in a spondylolysis (121).

Acute spondylolysis has been reported in soldiers who carry heavy backpacks or perform exercises to which they are unaccustomed (143). In many, the defect healed with conservative treatment, whereas others developed pseudarthrosis, persistent symptoms, and the typical radiographic appearance of spondylolysis. An increased frequency of spondylolysis has been noted in teenagers with thoracolumbar Scheuermann's disease, a condition believed to be caused by excessive and repetitive mechanical loading on the immature spine (98). Similarly, thoracolumbar kyphosis is often associated with a compensatory increase in lumbar lordosis. Those performing heavy physical work, such as weight-lifters, lumberjacks, and football lineman, also have been reported to be more at risk for spondylolysis (79).

Signs and Symptoms

Although spondylolysis commonly occurs in late childhood or early adolescence, symptoms are relatively uncommon in children and rarely are severe enough to require medical attention during the teenage years (39,55). In a prospective longitudinal survey, only 13% of children known to have spondylolysis developed symptoms before 18 years of age (39). In the occasional child who develops symptoms, the onset usually coincides with the adolescent growth spurt (56,120).

Although pain is the major complaint in adults, most children and adolescents do not have pain and seek medical attention only because of a postural deformity or gait abnormality caused by hamstring tightness. Pain generally is localized to the low back and, to a lesser extent, the posterior buttocks and thighs (56,120). Symptoms usually are initiated or aggravated by strenuous activity of the spine common to oarsmen, gymnasts, divers, hockey players, tennis players, and baseball pitchers. A combination of these factors are present when too much weight is used by weight-lifters performing the military press, when incorrect technique is used by gymnasts, and when swimmers or runners make too rapid advances. Symptoms usually are decreased by rest and limitation of activities (56,64,77).

Physical examination may demonstrate some tenderness to palpation in the low back. There may be some splinting, guarding, and restriction of side-to-side motion in the low back, especially if onset of the condition is acute. If hamstring tightness is present, forward flexion of the hips is markedly restricted. Eighty percent of symptomatic patients have hamstring tightness (so-called spasm), and this has been attributed to nerve root irritation; however, no objective evidence supports this contention (8,105,135). Hamstring tightness is seldom accompanied by neurologic signs (8,120)

Children, unlike adults, seldom have objective signs of nerve root compression, such as motor weakness, reflex change, or sensory deficit (135). Examination, however, should include a careful search for sacral anesthesia and bladder dysfunction. Similarly, children with spondylolysis rarely have myelographic evidence of disk protrusion or evidence of herniation at surgical exploration (56,135).

Radiographic Findings

If the radiolucent defect in the pars interarticularis is large (Fig. 19-24), it can be seen on nearly all radiographs of the lumbar spine. If the defect is unilateral, as it is in 20% of patients, or is not accompanied by spondylolisthesis, special imaging techniques may be required (78,85).

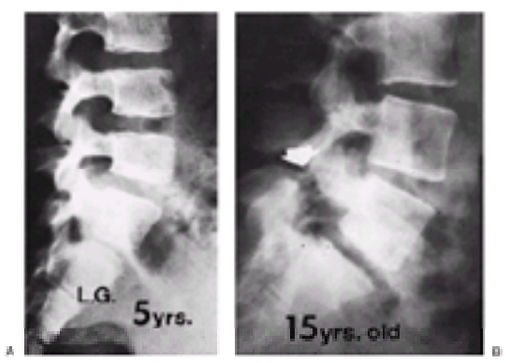

FIGURE 19-24. A: The radiograph of a 5-year-old girl with normal appearance of the lumbosacral junction. **B:** The same person at age 15. Spondylolysis and grade I spondylolisthesis have developed in the interim with symptoms referable to the low back. Spondylolysis in children occurs after walking age, but rarely before 5 years, and more commonly at 7 or 8 years. Onset of symptoms coincides closely with the adolescent growth spurt.

Oblique views show this area in relief and apart from overlying bony elements; the diagnosis is missed in 20% of young patients if oblique views are not obtained (78). The “Scotty dog” of Lachapele, with the defect appearing at the terrier's neck, is a helpful visual aid to those inexperienced with oblique radiographs (Fig. 19-25). In an acute injury, the gap is narrow with irregular edges, whereas in a long-standing lesion, the edges are smooth and rounded, suggesting a pseudarthrosis (Fig. 19-26). The width of the gap depends on the amount of bone resorption after the fracture and the degree of spondylolisthesis.

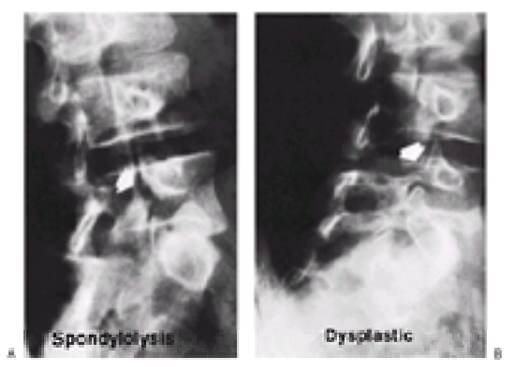

FIGURE 19-25. A: Pars interarticularis defect, or spondylolysis, as seen on an oblique view (*arrow*), typically found with the isthmic type of spondylolisthesis. **B:** Similar oblique view of a patient with dysplastic (congenital) spondylolisthesis, demonstrating elongation and attenuation of the pars interarticularis, perhaps a prespondylolytic defect, and may represent a stress or fatigue fracture of the pars intrarticularis.

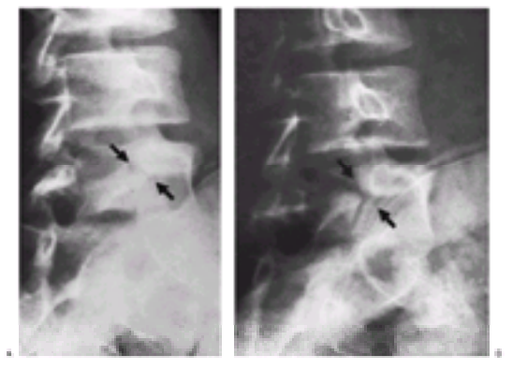

FIGURE 19-26. The radiograph of a 13-year-old boy who felt a snap in the low back during a swimming race turn. **A:** Spondylolysis of the pars interarticularis is seen (*arrow*). The narrow, irregular appearance suggests recent injury. **B:** Despite cast immobilization, the fracture did not heal. The appearance 6 months later demonstrates blunting of the bone ends and widening of the gap. However, the patient was asymptomatic.

Less commonly, symptomatic children (26%–35%) have poorly developed or dysplastic (Wiltse type I) posterior structures (55,142). Because of anomalous development, the posterior facets appear to subluxate on the sacral facets. In children with dysplastic posterior structures, rather than a gap or defect in the pars interarticularis, the facets appear to subluxate and the pars interarticularis may become attenuated like pulled taffy. This has been called the “greyhound” of Hensinger (56); a defect may later appear in the center. This may be a different manifestation of the same disease process, because both lesions are present in members of the same family (145), suggesting that the spondylolytic type represents an acute stress fracture of the pars interarticularis and the dysplastic or elongated type represents a chronic stress reaction with gradual attenuation of the pars.

Deficiency of the posterior elements is common in patients with spondylolysis. Easily observable defects, such as dysraphic or malformed laminae, have been reported in 32% to 94% of these patients, and, if discovered on routine lumbosacral views, should prompt a more detailed radiographic investigation (145). CT scanning is rarely indicated in acute fracture of the pars interarticularis because a combination of bone scanning and oblique x-rays is more reliable in detecting the lesion (116). Spondylolysis at L4 or L3 is difficult to diagnose with CT scans because the plane of scanning is parallel to the fracture (116). MRI should be considered if the patient's symptoms or neurologic signs do not resolve with bed rest, or if bladder or bowel dysfunction or perineal hypesthesia is present.

When the diagnosis is suspected clinically but cannot be confirmed radiographically (especially in the stress reaction stage before fracture), a bone scan will be helpful, especially a single photon emission CT scan (12,85). Small, partial, or unilateral fractures can be overlooked on x-rays, but bone scans demonstrate an area of increased bone turnover caused by healing of the fracture. Bone scanning may demonstrate increased uptake in patients with only 5 to 7 days of symptoms (101,136). Later, up to 1 year after onset of symptoms, bone scanning is helpful to distinguish between patients with an established nonunion (cold bone scan) and those in whom healing is still progressing (hot bone scan) and who may benefit from immobilization (77,136). Bone scanning is not recommended in patients whose symptoms are of more than 1 year's duration or who are asymptomatic (136), unless a bone tumor (such as osteoid osteoma), infection, or malignancy is suspected.

Bone scanning is especially helpful in young athletes whose activities are highly associated with spondylolysis, such as gymnastics (64). Early detection of the stress reaction allows early treatment, which can shorten the recovery period. Bone scanning also can be used to evaluate recovery and determine when an athlete can return to competition (64).

Treatment

In some children and adolescents, the spondylolytic defect may heal with 3 to 6 months' casting or bracing (thoracolumbosacral orthosis) if there is an acute, clearly documented onset with injury (135,136,143) or if the lesion is early in its course (93). Healing is more likely with unilateral defects than bilateral defects. A bone scan may be helpful to differentiate a continuing process from one of a long duration (77).

In children in whom the spondylolysis is of long duration, healing is unlikely, but symptoms usually respond to conservative measures (56). Restriction of vigorous activities and back and abdominal strengthening exercises usually are successful in controlling mild backache and hamstring tightness (55). Patients with more severe or persistent complaints may require bed rest, cast or brace immobilization, and nonnarcotic analgesics (128). Hamstring tightness is an excellent clinical guide to the success or failure of the treatment. Most children have complete relief of symptoms or only minimal discomfort at long-term follow-up (135).

Any child or adolescent with symptoms caused by spondylolysis, especially those under 10 years of age, should be closely followed for progression to spondylolisthesis (143). We do not advise those with asymptomatic spondylolysis or those with minimal symptoms to restrict their activities; 7.2% of asymptomatic young men 18 to 30 years of age have pars defects and relatively few have persistent symptoms (92). Progression is unlikely with competitive sports activities (94). Thus, limitation of activity in a growing child does not seem justified (55). It must be emphasized that spondylolysis is rarely symptomatic in adolescence, and caution is advisable in treating a child whose symptoms do not respond to bed rest or who has objective neurologic findings. In this situation, MRI and possibly electromyography should be considered.

A small percentage of young persons with spondylolysis do not respond to conservative measures or are unwilling to curtail their activities and may require surgical stabilization. If surgery is necessary, a posterolateral fusion from L5 to S1 with autogenous bone graft usually is sufficient. If spondylolisthesis is of grade III or greater, the fusion usually is extended to L4 (56). Nachemson (95) reported solid healing of the defect after bone grafting and intertransverse process fusion.

In patients with small defects (6–7 mm) and only slight spondylolisthesis, a variety of techniques have been described for direct reduction of the defect, including wiring of the transverse process or placement of a screw across the pars, coupled with a bone graft (such as in a pseudarthrosis repair) (20,36,97,104). These procedures usually are recommended for older adolescents and young adults (<30 years of age) with minimal displacement and degenerative change (95,97). The best candidates for this method of treatment are those with defects between L1 and L4 or those with multiple defects. This is an attractive alternative to the traditional transverse process fusion because it repairs the defect at one vertebral level rather than involving a second nonaffected vertebrae (20,104). In properly selected patients, 80% to 90% obtain a solid fusion with good to excellent results. In children, the Gill procedure or laminectomy should never be performed without an associated fusion because removal of the posterior elements may lead to increased instability and spondylolisthesis.

A rare type of spondylolisthesis, acute spondylolytic spondylolisthesis, has been described (58). This injury is caused by high-energy trauma and is an unstable spinal

injury, similar to a fracture–dislocation, usually in the pars interarticularis of L5. The so-called traumatic spondylolisthesis (type IV) is caused by a fracture in areas of the bony hook other than the pars interarticularis, differentiating these two acute types of spondylolistheses. The deformity typically progresses, and some patients develop neurologic compromise. Because of their instability, high risk of progression, and possibility of developing neurologic compromise, these injuries should be treated operatively. Grade I deformities can be adequately treated with posterior arthrodesis; more severe deformities may require both anterior and posterior arthrodeses because of the greater disruption of secondary ligamentous restraints (58).

Lumbar and Thoracolumbar Scheuermann's Disease

Scheuermann's disease is a common cause of thoracic kyphosis and is seldom painful. Children present with cosmetic concerns and are subsequently found to have the characteristic vertebral changes. Sorenson's radiographic criterion of three or more adjacent vertebrae wedged more than 5 degrees (125) confirms the diagnosis. End plate irregularity, Schmorl's node formation, and narrowing of the disk space are common but are not in themselves diagnostic. Thoracic Scheuermann's disease is typically limited to the thoracic vertebrae, spontaneous in onset, and due to hereditary influences. Lumbar or thoracolumbar osteochondritis is less common but is more often accompanied by pain (14,46,139). Several researchers suggest that the lumbar vertebral changes are the result of trauma (14,46,139). Lumbar or thoracolumbar Scheuermann's disease primarily affects adolescents (13–17 years of age) and is accompanied by a period of moderately severe pain with activity. Patients usually have a history of acute back strain or injury (14,46,87). Wassmann noted that the condition was eight times more common in “lads from the country” (139), and others have reported that the lumbar vertebral changes often are associated with hard physical labor before the age of 16, suggesting that the maturing end plate and vertebral body are more vulnerable to increased mechanical strain during this period of rapid growth (14,46,139). Hafner (51) coined the term *apprentice kyphosis,* or *kyphosis muscularis,* and he found that it occurred more commonly in boys (2:1) between the ages of 15 and 17 years, during the growth spurt. Micheli (90) found similar lumbar changes in young athletes and suggested that the cause was a localized stress injury to the vertebral physes.

The apophyseal ossification centers first appear in the lower thoracic region at approximately 9 years of age and fuse with the vertebral bodies between the ages of 17 and 22 years. The ring is thinner in the middle than in the periphery. Increasing the pressure in the intervertebral disk forces it through the center of the end plate and into cancellous bone of the vertebral body (Fig. 19-27) (67). The mechanism is analogous to the production of Schmorl's nodes and is accompanied by narrowing of the disk space (59,67,111). Similarly, metabolic and neoplastic diseases that lead to structural weakening of the bone are often associated with Schmorl's node formation (111). Marginal Schmorl's nodes are more often associated with trauma, and central nodes are more frequent and consistent with thoracic Scheuermann's disease (3). In experimental models, heavy lifting, especially when seated and bending forward, increased the intranuclear pressures to the lower end of the range necessary to produce fracture through a normal vertebral end plate (Fig. 19-28) (67). Flexion–extension motion of the spine, as in rowers, weight lifters, and gymnasts, can produce these same forces (Fig. 19-29) (90).

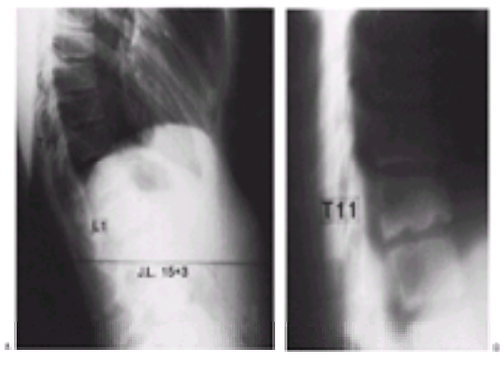

FIGURE 19-27. Radiographs of a 15-year-old boy with persistent back pain in the mid-lumbar region following a weight-lifting program. **A:** The routine lateral view suggests mild end plate changes. **B:** A lateral tomogram demonstrates Schmorl's node formation and end plate irregularity of T11. Subtle changes on routine films may belie significant end plate changes or disk protrusion into the vertebral body.

FIGURE 19-28. A: Acute herniated Schmorl's node in a 15-year-old weight lifter with back pain and nodes at L2, L3, and L4. **B:** Eight months later there has been continued growth of the vertebrae without progressive deformity. **C:** At 21 years of age the sites of the Schmorl's nodes are still seen, although they appear smaller. The minimal wedging at L2 has not changed in the preceding 6 years.

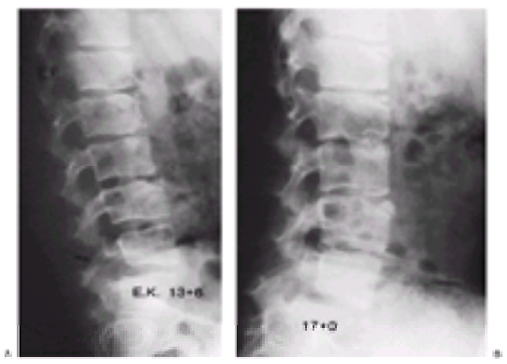

FIGURE 19-29. A: Radiographs of a 13-year-old boy who sustained vertebral end plate changes at several levels while playing football. Note the associated spondylolysis (*arrow*) and mild spondylolisthesis. The patient's discomfort responded satisfactorily to bracing. **B:** The radiographs at age 17 years demonstrate the continued free fragment appearance of the vertebral apophysis at several levels and persistence of Schmorl's nodes.

Back pain may be present from 2 to 6 months and is increased with activity, accentuated by forward flexion, and relieved by rest (14,46). Conservative treatment such as bracing usually is sufficient (67,125). Occasionally, bed rest or plaster immobilization is required. There are no reports of children needing surgery for symptoms, and only a few have required correction for deformity. The vertebral changes progress slowly toward healing during the time of remaining growth. Schmorl's node formation and disk space narrowing generally persist (Fig. 19-28 and Fig. 19-30) (87). The apophyseal fragment at the anterior margin of the vertebral body seldom heals.

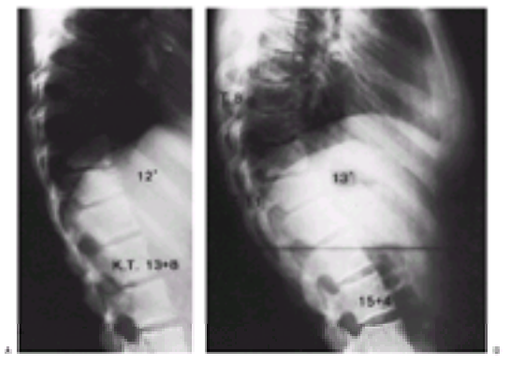

FIGURE 19-30. A: Radiographs of a 13-year-old girl who sustained anterior compression of the L1 vertebra during gymnastics, with 12 degrees of wedging. She had persistent discomfort over several months that responded to bracing. **B:** At 15 years of age she was asymptomatic; there has been no remodeling of the deformity.

The kyphotic deformity may progress because of the anterior deformation of the vertebral bodies from the original injury or because of increased pressure on the anterior margin with cessation of growth in that region. The kyphosis generally is not severe and seldom requires any specific treatment. For severe deformity in a skeletally immature patient with kyphosis exceeding 50 to 60 degrees, a Milwaukee brace is recommended (Fig. 19-31). Surgery is rarely needed.

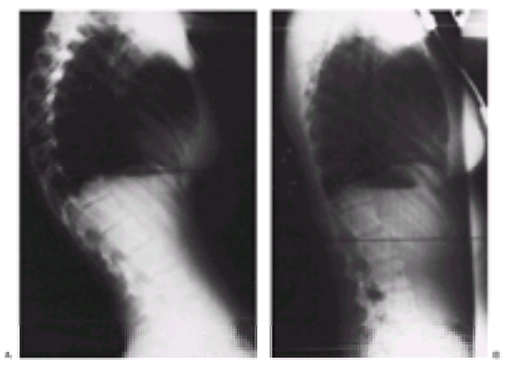

FIGURE 19-31. Radiographs of a 15-year-old girl with persistent back pain and deformity following gymnastics. **A:** Vertebral end plate changes, Schmorl's node, and gibbus at the thoracolumbar junction. **B:** Treatment with the Milwaukee brace improved alignment by reducing the deformity.

FRACTURES OF THE PELVIS

S. TERRANCE CANALE
JAMES H. BEATY

Pelvic fractures constitute only 1% to 3% of all fractures in children. The most important aspect of treatment of these fractures is the realization that such a fracture is an indication that significant trauma has occurred and other injuries to neurovascular structures, abdominal viscera, the genitourinary system, and the musculoskeletal system also may have occurred. Fractures of the pelvis and spine are associated with the longest hospital stays, the most admissions to the intensive care unit, and the highest rates of mortality in patients with multiple injuries (9,60). When a fracture of a child's pelvis is seen on an initial radiograph, it should be an indication that associated life-threatening soft tissue injuries may be present, and the treatment of these injuries should take priority over management of the fracture. Mortality rates in children with pelvic fractures have been reported to be as high as 25% (49), but more recent series report mortality rates of 2% to 12% (18,27,33,52,61,63). In 1,254 patients with pelvic fractures, Ismail et al. (27) reported an overall mortality rate of 5% for children and 17% for adults. In children, fracture-related exsanguination was the cause of death in only 0.3%, whereas 3.4% of deaths in adults were due to pelvic fracture exsanguination.

DIAGNOSIS

Mechanisms of Injury

Most pelvic fractures in children are caused by vehicular accidents. From Rang's early reports (50) to more recent series (3,4,5,14,27,30,33,40,52,54,61), 70% to 90% of reported pelvic fractures in children were caused by traffic accidents. Most often the injured child is a pedestrian struck by a car. Avulsion injuries usually occur in athletic activities, especially gymnastics, track, and soccer. Child abuse is a rare etiology (34,44).

Signs and Symptoms

The evaluation of a child with a suspected pelvic fracture begins with a thorough history and physical examination. Often a child with a pelvic fracture has concomitant multiple injuries about the head, chest, abdomen, and genitourinary tract, and these other injuries take precedence concerning operative intervention to stabilize the child's condition. The pelvic fracture itself often has low priority in the critical care of a child with polytrauma.

The examination of the pelvic area begins with a visual inspection. Areas of contusion, abrasion, laceration, ecchymosis, or hematoma, especially in the perineal and pelvic areas, should be recorded.

Landmarks such as the anterior superior iliac spine, crest of the ilium, sacroiliac joints, and symphysis pubis should be palpated. Exerting posterior pressure on the anterior superior iliac crest produces pain at the fracture site as the pelvic ring is opened. Compressing the pelvic ring at the iliac crest from the lateral to the medial direction also causes pain, and crepitation may be felt if a pelvic fracture is present. Pressure downward on the symphysis pubis and posteriorly on the sacroiliac joints causes pain and motion if there is a fracture in the pelvic ring. The range of motion of the extremities, especially of the hip joint, should be determined. Occasionally, pain in the inguinal area is noted during flexion and extension of the hip if there is a pelvic fracture.

Associated Injuries

Because most pelvic fractures in children result from high-velocity trauma, injuries other than the pelvic fracture usually are present. Of the 43 children with pelvic fractures reported by Blasier et al. (3), 25 (58%) had associated injuries, most often multiple fractures, closed head injuries, and spine injuries. The incidence of concomitant injuries increases with the severity of the pelvic fracture. Bond et al. (5) noted that the location and number of pelvic fractures were strongly associated with probability of abdominal injury: 1% for isolated pubic fractures, 15% for iliac or sacral fractures, and 60% for multiple fractures of the pelvic ring. Poole et al. (47) suggested that the outcomes of patients with pelvic fractures were determined by the associated injuries rather than by the pelvic fracture.

As in adults, retroperitoneal hemorrhage is the most serious life-threatening complication in children with unstable pelvic ring disruptions. Marked cephalad displacement of the hemipelvis can injure the superior and inferior gluteal arteries at the sciatic notch. Injury of the iliac or femoral artery is uncommon except with open fractures involving the anterior pelvic ring (60). McIntyre et al. (33) correlated the risk of life-threatening hemorrhage to pelvic fracture complexity. Patients with bilateral anterior and posterior fractures required transfusions significantly more often than those with other types of fractures. Ultrasonography or peritoneal lavage help rule out intraabdominal injury.

Hematuria has been reported in from 34% to 57% of children with pelvic fractures, usually without any significant urinary tract injury. When hematuria is accompanied by an inability to void, blood at the urethral meatus, or abnormality of the prostate, genitourinary consultation should be obtained. Most urologic injuries occur with fractures of the anterior pelvic ring (60). The reported incidence of genitourinary injuries (bladder or urethral rupture, vaginal or scrotal tear, kidney injury) averages approximately 5%.

Children with pelvic fractures are more likely to have head injuries than are adults with pelvic fractures. Rieger and Brug (52) reported head injuries ranging from mild concussion to brain death in 48% of their 54 patients, and other series have reported closed head injuries in approximately 30% of patients (30,33,61). Although injury to the brain has a higher priority and needs more immediate attention than fractures in a child with polytrauma, inadequately treated pelvic fractures can result in permanent disability and should be treated with expectation of full neurologic recovery.

Pelvic fractures with posterior displacement of the hemipelvis or iliac wing can damage the lumbosacral plexus, as well as the sciatic, femoral, and obturator nerves. Neurologic examination of the lower extremities should be routine, and documentation of any neurologic deficit is essential.

Fractures of other bones are present in approximately half of children with pelvic fractures (30,33,52,54,61). The most frequently fractured bones are the femur, tibia, and fibula. Vazquez and Garcia (63), in a study of 79 children with pelvic fractures, found that the presence of any additional fracture was a significant indication that head or abdominal injury also was present and that transfusion would be required in the first 24 hours after injury. Death, thoracic injuries, and patients requiring laparotomy or an additional nonorthopaedic procedure were twice as frequent in the group with additional fractures as in the group with pelvic fractures only. Vazquez and Garcia (63) suggested that this easily identifiable risk factor can help identify patients who may benefit from early transfer to a regional pediatric trauma center.

Radiographic Studies and Other Imaging

All too often in an emergency situation, the child's well-being is jeopardized in one of the least desirable emergency areas of the hospital, the radiology department. Radiographs should be obtained only after the patient is stabilized. Rarely do radiographs on an emergency basis help the physician stabilize the child. Once the patient is clinically stable, only pertinent radiographs should be ordered by the physician in charge. If special views are necessary, then the physician ordering these films should be in attendance. Scout views of the skull, chest, abdomen, pelvis, and long bones should be procured quickly.

In a child with a pelvic fracture, unless there is a significant fracture–dislocation, multiple radiographic views can be deferred. When the child is stable, multiple views of the pelvis should be taken (29). With the patient supine, the pelvis has a normal tilt of 25 degrees posteriorly. Thus, taking only an anteroposterior film of the pelvis gives, in reality, an oblique projection, which, as in radiographs of other long bones, is not the most desirable view. As an aid to diagnosis, a 25-degree caudad (inlet) view reveals the amount of internal or external rotation deformity or the amount of displacement. Also useful in determining the amount of rotation in the anteroposterior plane is the 35-degree cephalad (outlet) view. The pelvis can be tilted into internal and external rotation to determine fractures of the acetabulum and pelvic outlet. A description of these views recommended by Judet is given in Chapter 35 of *Fractures in Adults* (Volume 2 of this series). Comparison views of the contralateral apophysis may be helpful in evaluating avulsion fractures.

Computed tomography (CT) scanning helps determine the presence of fractures and any disruption or incongruity of the sacroiliac joint, sacrum, or acetabulum. Newer, rapid CT scanners can obtain a full pelvic scan in the initial evaluation. Three-dimensional CT images show more clearly superior or inferior displacement of the hemipelvis if a pelvic ring injury is present and help define the degree and direction of any acetabular displacement or rotational deformity (20,35). Magnetic resonance imaging (MRI) has the same benefits and also can delineate soft tissue injuries in the pelvis (35). Occasionally, a radioisotopic bone scan is useful for evaluating nondisplaced fractures and the rare stress fracture (58,59).

CLASSIFICATION

Quinby (49) and Rang (50) classified pelvic fractures in children into three categories: uncomplicated fractures, fractures with visceral injuries requiring surgical exploration, and fractures associated with immediate, massive hemorrhage. The prognostic importance of this classification is apparent, and it is useful with regard to the patient's ultimate outcome; however, its emphasis, as it should be in an emergency situation, is on associated soft tissue injuries rather than on the pelvic fracture itself. Watts (64) classified pediatric pelvic fractures according to the severity of skeletal injury: (a) avulsion, such as epiphysiolysis (caused by violent muscular activity); (b) fracture of the pelvic ring (crushing injury), stable or unstable; and (c) acetabular fracture (associated with hip dislocation). Torode and Zieg (61), in a retrospective analysis of 141 children with pelvic fractures, also classified the injuries based on the severity of the fracture; their classification does not include acetabular fractures (Fig. 20-1, Table 20-1). Tile (59) modified Pennal's classification of pelvic fractures in adults to include three types based on mechanism of injury: anteroposterior compression, lateral compression, and vertical shear (Table 20-2). This classification system has been incorporated into the Orthopaedic Trauma Association classification, which also consists of three main types: A, lesion sparing (or with no displacement of) posterior arch; B, incomplete disruption of posterior arch, partially stable; and C, complete disruption of posterior arch, unstable (Table 20-3). Numerous subtypes also are included. This detailed system is described in the chapter on pelvic fractures in adults in *Fractures in Adults* (Volume 2, Chapter 35). Silber and Flynn (55) reviewed radiographs of 133 children and adolescents with pelvic fractures and classified them into two groups: immature (all physes open) and mature (closed triradiate cartilage). They suggested that in the immature group, management should focus primarily on associated injuries, and in the mature group adult pelvic fracture classifications and principles are appropriate.

I. Avulsion fractures
II. Iliac wing fractures
  IIa. Separation of the iliac apophysis
  IIb. Fracture of the bony iliac wing
III. Simple ring fractures
  IIIa. Fractures of the pubis and disruption of the pubic symphysis; the posterior structures remain stable
  IIIb. Fractures involving the acetabulum, without a concomitant ring fracture
IV. Fractures producing an unstable segment (ring disruption fracture)
  IVa. "Straddle" fractures, characterized by bilateral inferior and superior pubic rami fractures
  IVb. Fractures involving the anterior pubic rami or pubic symphysis and the posterior elements (e.g., sacroiliac joint, sacral ala)
  IVc. Fractures that create an unstable segment between the anterior ring of the pelvis and the acetabulum

FIGURE 20-1. Torode and Zieg classification of pelvic fractures in children. Type I, avulsion fractures; type II, iliac wing fractures; type III, simple ring fractures; type IV, ring disruption fractures.

This multitude of classification systems makes comparison of incidence, results, and complications difficult among studies using different systems. Many recent studies of children's pelvic fractures in the literature use the Torode and Zieg (61) or Tile (2,59) classifications, or both, but the most basic classification—stable or unstable fracture—in general is the most useful information for making treatment decisions. Most pelvic fractures in children are stable injuries.

APPLIED ANATOMY

There are several important anatomic differences between the pelvis of a child and that of an adult (Table 20-4). First, a child's pelvis is more malleable because of the nature of the bone itself, the increased elasticity of the joints, and the ability of the more cartilaginous structures to absorb energy (43). Second, the elasticity of the joints may allow significant displacement and resultant fracture in only one area rather than the traditional concept of a mandatory “double break” in the ring for a displaced fracture (43,50). Third, avulsion fractures of an apophysis occur more often in children and adolescents than in adults because of the inherent weakness of cartilage compared with bone; fractures of the acetabulum into the triradiate cartilage also occur more often for the same reason (50,64). Fourth, fractures through physeal cartilage in children can ultimately cause growth arrest, leg-length discrepancy, and faulty development (e.g., a fracture through the triradiate cartilage with resultant “bony bar” formation and ultimately a deficient acetabulum) (1,21).

	Individual	Single Break	Double Break	Acetabulum
Campbell Clinic Series (104 Patients)[a]				
	Avulsion: 13.4%	Two ipsilateral rami:	Straddle: 3%	Small fragment: 0.7%
	Pubis or ischium: 33.6%	8.2%	Malgaigne: 8.2%	Linear fractures (stable): 6%
	Wing of ilium: 18%	Symphysis pubis: 3%	Severe, multiple:	Linear fractures (unstable): 6
	Sacrum or coccyx: 1.3%	Sacroiliac joint: 0.7%	0.7%	Secondary to central
	Total: 68.3%	Total: 11.9%	Total: 11.9%	dislocation: 3%
				Total: 9.7%
Comparison with Other Series				
Dunn[b] (115 patients)		70% (stable)	30% (unstable)	Not included
Pohler[b] (186 patients)	10%	39%	27%	24%
Rosoff (84 patients)	60.5%	2.5%	32%	5%
Hall, Klassen, Ottolngui[c] (204 patients)	24.5%	18.6%	31.9%	7.8% (17.2% acetabulum and pelvis)

TABLE 20-4. DISTRIBUTION OF PELVIC FRACTURES IN CHILDREN

Ossification Centers

The pelvis in a child consists of three primary ossification centers: the ilium, ischium, and pubis. The three centers meet at the triradiate cartilage and fuse at approximately 16 to 18 years of age (43) (Fig. 20-2). The pubis and ischium fuse inferiorly at the pubic rami at 6 or 7 years of age. Occasionally, at approximately the time of fusion of the ischium to the pubis, an asymptomatic mass, the ischiopubic synchondrosis, is noted radiographically in this area. The child should be treated expectantly, and this should not be confused with a fracture of the pelvis.

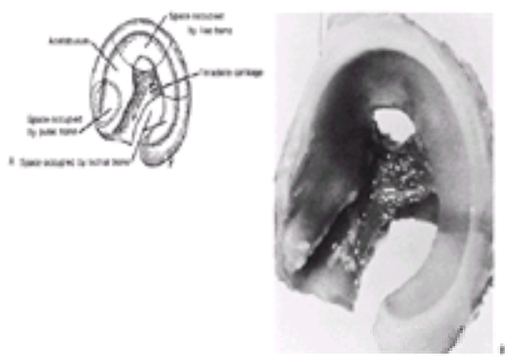

FIGURE 20-2. A: Triradiate–acetabular cartilage complex viewed from the lateral side, showing the sites occupied by the iliac, ischial, and pubic bones. **B:** Normal acetabular cartilage complex of a 1-day-old infant. The ilium, ischium, and pubis have been removed with a curet. The lateral view shows the cup-shaped acetabulum. (From Ponseti IV. Growth and development of the acetabulum in the normal child. *J Bone Joint Surg Am* 1978;60:575–585; with permission.)

The secondary centers of ossification include the iliac crest, ischial apophysis, anterior inferior iliac spine, pubic tubercle, angle of the pubis, ischial spine, and lateral

wing of the sacrum. The iliac crest is first seen at 13 to 15 years and fuses at 15 to 17 years of age. The secondary ossification of the ischium is first seen at 15 to 17 years and fuses at 19 years of age, although fusion may be as late as 25 years of age. A center of ossification may be present at the anterior inferior iliac spine at approximately 14 years, fusing at 16 years of age (43,64). These secondary centers of ossification and the age of appearance and fusion are described so they will not be confused with avulsion fractures.

The acetabulum contains the physes of the ilium, ischium, and pubis that merge to become the triradiate cartilage. Interstitial growth in the triradiate part of the cartilage complex causes the acetabulum to expand during growth and causes the pubis, ischium, and ilium to enlarge as well. The concavity of the acetabulum develops in response to the presence of a spherical femoral head. The depth of the acetabulum increases during development as the result of interstitial growth in the acetabular cartilage, of appositional growth of the periphery of this cartilage, and of periosteal new bone formation at the acetabular margin (48). At puberty, three secondary centers of ossification appear in the hyaline cartilage surrounding the acetabular cavity. The *os acetabuli,* which is the epiphysis of the pubis, forms the anterior wall of the acetabulum. The epiphysis of the ilium, the *acetabular epiphysis,* (48,64) forms a large part of the superior wall of the acetabulum. The small secondary center of the ischium is rarely seen. The os acetabuli, the largest part, starts to develop at approximately 8 years of age and forms a significant part of the anterior wall of the acetabulum; it unites with the pubis at approximately 18 years of age. The acetabular epiphysis develops in the iliac acetabular cartilage at approximately 8 years and fuses with the ilium at 18 years of age, forming a substantial part of the superior acetabular joint surface (Fig. 20-3). The *secondary center of the ischium,* the smallest of the three, develops in the ischial acetabular cartilage at approximately the ninth year, unites with the ischium at 17 years, and contributes very little to acetabular development. These secondary centers should not be confused with avulsion fractures or loose bodies in the hip joint.

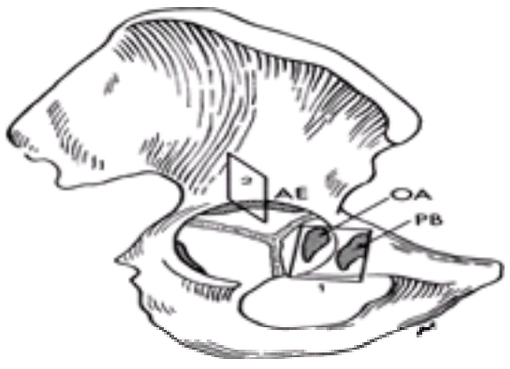

FIGURE 20-3. Right innominate bone of an adolescent. The os acetabuli (OA) is shown within the acetabular cartilage adjoining the public bone (PB); the acetabular epiphysis (AE), within the acetabular cartilage adjoining the iliac bone; and another small epiphysis (not labeled), within the acetabular cartilage adjoining the ischium **(left)**. (From Ponseti IV. Growth and development of the acetabulum in the normal child. *J Bone Joint Surg Am* 1978;60:575–585; with permission.)

AVULSION FRACTURES

Avulsion fractures of the pelvis usually occur in adolescents or young adults participating in sports (13,19,51) and usually are caused by powerful contraction of the attached muscle, although they can result from chronic repetitive traction on a developing apophysis, without acute trauma (13,19). The sartorius muscle attaches to the anterior superior iliac spine, the direct head of the rectus femoris to the anterior inferior iliac spine, and the hamstrings and adductors to the ischial tuberosity.

Of 91 pelvic avulsion fractures reported in 4 series (17,37,53,57), 38% were ischial avulsions, 32% were avulsions of the anterior superior iliac spine, and 18% were avulsions of the anterior inferior iliac spine (Fig. 20-4). Avulsions of the iliac crest (3%) and the lesser trochanter of the femur (9%) accounted for the rest.

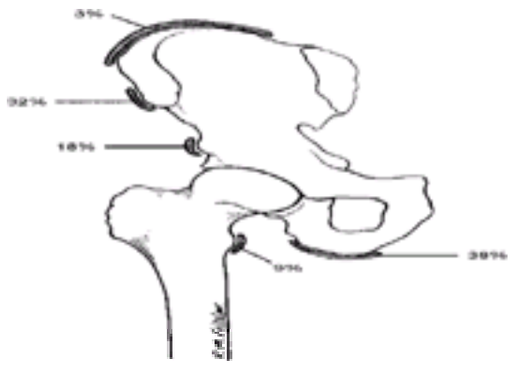

FIGURE 20-4. Location of pelvic avulsion fractures in four series. (Modified from Ferbach SK, Wilkinson RH. Avulsion injuries to the pelvis and proximal femur. *Am J Radiol* 1981;137:581–584; with permission.)

Mechanism of Injury

Overpull of the sartorius muscle, especially with the hip in extension and the knee flexed, can result in avulsion fracture of the anterior superior iliac spine. Avulsion of the anterior inferior iliac spine can be caused by excessive exertion on the direct head of the rectus femoris muscle, which has its origin at the inferior iliac spine. Maximal exertion of the muscle occurs when the hip is hyperextended and the knee is flexed. This injury occurs most frequently in sports that involve kicking (e.g., soccer, rugby, football) and is much less common than avulsion of the anterior superior iliac spine, possibly because the anterior inferior iliac spine apophysis fuses earlier than the anterior superior iliac spine. Avulsion fractures of the ischial tuberosity can occur with maximal exertion by the hamstring muscles at their origin (38). These injuries occur most often in adolescents and young adults during sports, especially gymnastics, football, and track.

Diagnosis

Symptoms usually include localized swelling and tenderness about the site of the avulsion fracture. Motion is limited, and pain may be mild or marked. In patients with chronic avulsions caused by repetitive activity, pain and limitation of motion usually are gradually progressive. In patients with ischial avulsions, pain at the ischial tuberosity can be elicited by flexing the hip and extending the knee. In this position, if the hip is moved into abduction, more pain is elicited. Patients also may have pain while sitting or moving on the involved tuberosity.

In patients with anterior superior iliac spine avulsions, radiographs show slight displacement of the apophysis (Fig. 20-5). In patients with anterior inferior iliac spine avulsions, radiographs show minimal distal displacement of the fragment. Further displacement is probably prevented because this is a conjoined tendon, and the reflected head of the rectus femoris muscle is intact. Contralateral views can be obtained and compared to ensure that this fragment is not actually a secondary center of ossification, either the os acetabuli or acetabular epiphysis (Fig. 20-6). With ischial tuberosity avulsions, radiographs reveal a large fragment displaced distally compared with the opposite ischial tuberosity (Fig. 20-7). Significant displacement is resisted by the intact sacrotuberous ligament.

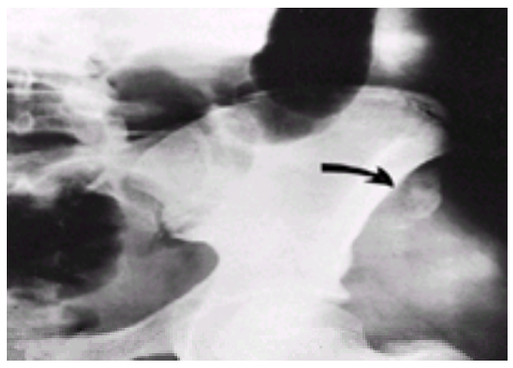

FIGURE 20-5. Displaced fracture of the anterosuperior iliac spine.

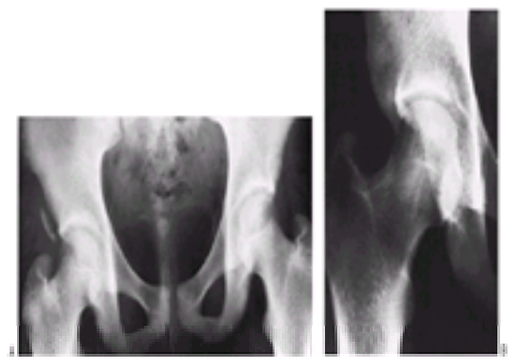

FIGURE 20-6. A: Anteroposterior radiograph of an anterior inferior iliac spine fracture with displacement. **B:** Three-year follow-up shows union with no displacement and no pain.

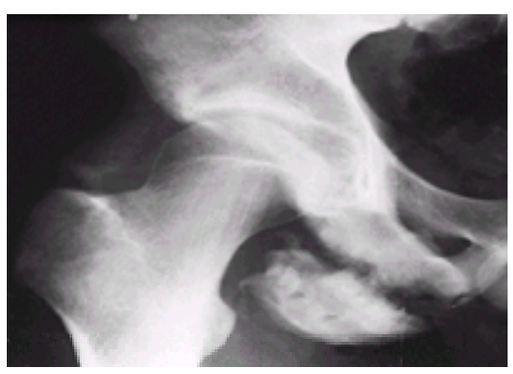

FIGURE 20-7. Large ischial tuberosity fracture.

Because these avulsion fractures occur primarily through secondary centers of ossification before the center is fused with the pelvis, primarily in adolescents and young adults 14 to 25 years of age (64), comparison views of the contralateral apophysis should be taken to ensure that what appears to be an avulsion fracture is not in reality a normal adolescent anatomic variant. The exuberant callus formation can occasionally mimic an osteosarcoma. Recognition of initial deformity and fracture pattern is important to avoid unnecessary evaluation, such as CT and radionuclide scans, and inappropriate treatment.

Treatment and Prognosis

Usually, the only treatment necessary is a short period of rest with positioning of the hip to lessen stretch on the involved muscle and subsequent guarded weight bearing on crutches for 2 weeks or more. Fernbach and Wilkinson (17) found no decrease in athletic ability in their 20 patients treated conservatively, and they recommended surgery only for symptomatic nonunions. Although operative treatment has not been proven to improve results, Gordon et al. (20) recommended open reduction of all “widely displaced” avulsion fractures and fixation with a threaded Kirschner wire or lag screw, depending on the size of the fragment. Lynch and Renström (32) also recommended open reduction and internal fixation of large fragments displaced more than 2 cm.

Excessive callus formation after healing, especially of ischial avulsions, may be painful and impair sports activities (Fig. 20-8), occasionally requiring excision of the callus formation and the apophysis. Sundar and Carty (57), at 44-month follow-up of sports-related avulsion pelvic fractures in 24 adolescents, found that 8 of 12 patients with ischial avulsions had significant limitation of athletic ability, and 5 had persistent symptoms. Of the 12 patients with avulsions of the anterior superior or anterior inferior iliac spine, 11 recovered completely and returned to active competition. Two of our patients with ischial tuberosity avulsions had chronic pain and disability that resolved after excision of the ischial apophysis; both returned to athletic competition and were pain free at 5-year follow-up.

FIGURE 20-8. Ischial tuberosity fracture at time of fracture **(A)** and at 6-month follow-up **(B),** showing abundant callus formation.

FRACTURES OF THE PUBIS OR ISCHIUM

In children, pelvic rami fractures usually are caused by high-velocity trauma and have a significant number of associated injuries. In our series of pelvic fractures, of 45 pubic and ischial fractures, 38 were caused by vehicular accidents, most in either pedestrians or passengers in automobiles. Reed (51) reported that 45% of the pelvic fractures in the children in his series were rami fractures, and we noted a 33.6% incidence. Rieger and Brug (52) reported 20 (37%) “simple ring fractures” in their series of 54 pelvic fractures in children, and McIntyre et al. (33) reported that 23 (40%) of 57 pelvic fractures were “type I” (unilateral anterior) fractures. Single

ramus fractures are more common than multiple rami fractures, and the superior ramus is fractured more often than the inferior ramus (7,16,51,61) (Fig. 20-9).

FIGURE 20-9. A: Stable superior pubic ramus fracture. The patient was allowed full weight bearing at 4 weeks postfracture. **B:** He was asymptomatic and radiography showed early callus formation.

In patients with isolated pubic fractures, clinical examination reveals pain and possible crepitus at the fracture site; however, there should be little or no motion on deep palpation. Inlet and outlet radiographic views or CT scanning are helpful in determining if any other pelvic fractures are present. If there is a significant displacement of the pubic rami, a second fracture through the pelvic ring should be suspected, although because of the plasticity of bone and elasticity of the symphysis and sacroiliac joints in children, more displacement can be expected than in adults with the same injury. Bed rest until pain subsides, followed by progressive weight bearing, usually is sufficient treatment.

Fractures of the Body of the Ischium

Fracture of the body of the ischium near the acetabulum is extremely rare in children. The fracture occurs from external force to the ischium, most commonly in a fall from a considerable height. The fracture usually is minimally displaced, and treatment consists of bed rest and progressive weight bearing (Fig. 20-10).

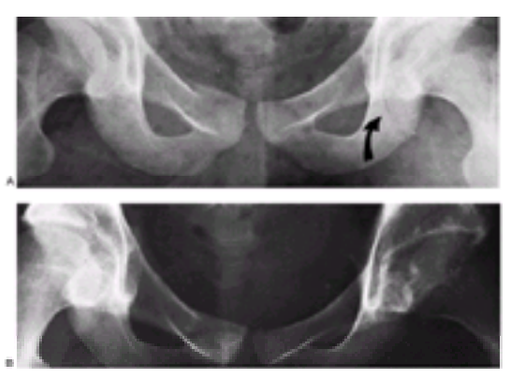

FIGURE 20-10. Nondisplaced fracture through the left ischium and contralateral superior pubic ramus fracture **(A).** Follow-up radiograph shows mild displacement and incongruity of the acetabulum and complete healing of the superior pubic ramus fracture **(B).** Either displacement of the fracture fragments or premature closure of the triradiate cartilage could have contributed to the incongruity of the femoral head in the acetabulum.

Stress Fractures of the Pubis or Ischium

Stress fractures are rare in small children, but they do occur in adolescents and young adults from chronic, repetitive stress to a bony area, and during the last trimester of pregnancy. Stress fractures of the pubis are likewise uncommon, but a small series of stress fractures, primarily in the inferior pubic rami, has been reported. Chronic symptoms and pain increased by stress may be noted in the inferior pubic area. Radiographs may show no evidence of a fracture for as long as 4 to 6 weeks, and then only faint callus formation may be visible; however, a technetium bone scan may reveal increased uptake (26), indicating a stress fracture, 3 to 4 weeks before changes on radiography. Treatment should consist of discontinuing the activity causing the repetitive stress to the area, and guarded weight bearing on crutches for 4 to 6 weeks.

At approximately the time of fusion of the ischiopubic ossification centers (age 6 to 7 years), the ischiopubic synchondrosis has been noted on radiographs and may persist for 2 to 3 years (10,64). Radiographs of the ischiopubic junction are, at best, difficult to interpret and may be misinterpreted as a fracture. Caffey (10) noted this radiographically in 57% of his pediatric patients at approximately 7 years of age. Quite often, the synchondrosis is bilateral (40%). An asymptomatic synchondrosis in a child 6 to 10 years of age should be treated as a variant of normal development (Van Neck's disease) (62). If it causes pain in a child older than 10 years of age, a fracture should be suspected and treated as such (Fig. 20-11).

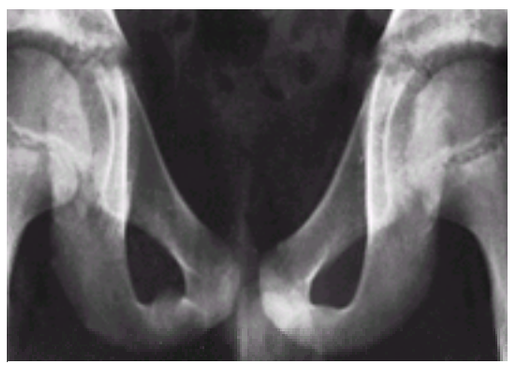

FIGURE 20-11. A: Posterior hip dislocation in a 5-year-old girl. **B:** Nonconcentric reduction. Note widened joint space on left compared with right hip. Posterior open reduction revealed infolded labrum and a flap of capsule.

Fractures of the Wing of the Ilium (Duverney Fracture)

Direct trauma may cause a fracture of the wing of the ilium, but isolated iliac wing fractures are relatively rare. Reed (51) reported an incidence of 12% in children with fractures of the pelvis. Rieger and Burg (52) reported iliac wing fractures in only 3 (5.6%) of their 54 patients, and McIntyre et al. (33) reported only 7 (1.2%) in 57 fractures. However, this fracture can occur with other fractures of the pelvis, and the incidence may be slightly misleading: for example, in our series of 24 fractures of the wing of the ilium in children, only 11 were isolated fractures.

Displacement of the fracture usually occurs laterally, but it can occur medially or proximally. Severe displacement is prevented by preservation of some of the

attachments of the abdominal muscles and the hip abductors. Pain is located over the wing of the ilium, and motion at the fracture site also may be noted. A painful Trendelenburg gait may be present because of spasm of the hip abductor muscles.

A fracture of the wing of the ilium may be overlooked on an underexposed radiograph of the pelvis where the ilium is poorly seen as a large area of radiolucency. Use of a “hot light” is helpful in making the diagnosis (Fig. 20-12).

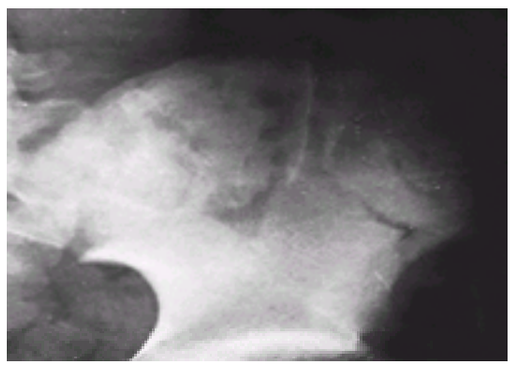

FIGURE 20-12. Minimally displaced fracture of the left iliac wing.

Treatment of an iliac wing fracture usually is dictated by the associated injuries. Bed rest in a comfortable position, usually with the leg abducted, is all that is necessary for treatment of the fracture itself. This should be followed by partial weight bearing on crutches until the symptoms are completely resolved. Regardless of the amount of comminution or displacement, these fractures usually unite without complications or sequelae (Fig. 20-13).

FIGURE 20-13. A: Severely comminuted fracture of the left iliac wing. **B:** Radiograph at 3-month follow-up shows fracture healed with displacement, but the patient was asymptomatic.

FRACTURES OF THE SACRUM

Sacral fractures constitute a small portion of pelvic fractures in children. Rieger and Brug (52) reported 2 sacral fractures and 7 sacroiliac fracture–dislocations in their 54 patients. Our series of pelvic fractures in children included two patients with sacral fractures (4%), 15 and 17 years of age. Sacral fractures may be slightly more common than reported, but because they are obscured by the bony pelvis and soft tissue shadows of the abdominal viscera, and because they are rarely displaced, they may be overlooked (Fig. 20-14). These fractures are significant because they may damage the sacral nerves, resulting in loss of bladder and bowel function.

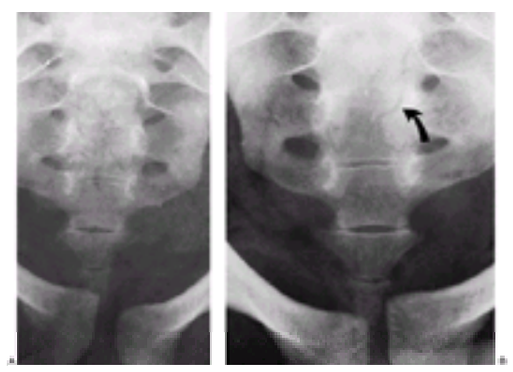

FIGURE 20-14. A: Radiograph suggesting comminuted nondisplaced linear sacral fracture on the left. **B:** At 6-week follow-up, radiograph shows definite evidence of linear sacral fracture.

Sacral fractures are best diagnosed clinically. Pain and swelling may be present, usually over the lower part of the sacrum. Rectal examination causes pain anterior to the sacrum. Occasionally, the fracture fragments may be felt. Repeated bimanual rectal examination with attempts at reduction should be avoided because a tear in the rectum may occur.

The fractures are difficult to see on radiographs. The fracture can be oblique, but most are transverse with minimal displacement and occur through a sacral foramen, which is the weakest part of the body of the sacrum. Minimal offset of the foramen or offset of the lateral edge of the body of the sacrum is an indication of sacral fracture. Lateral views are helpful only if there is anterior displacement, which is rare. A 35-degree caudad view of the pelvis may reveal a fracture of the body of the sacrum. CT scans may be useful for determining the amount of anterior displacement, if any, in these fractures (Fig. 20-15).

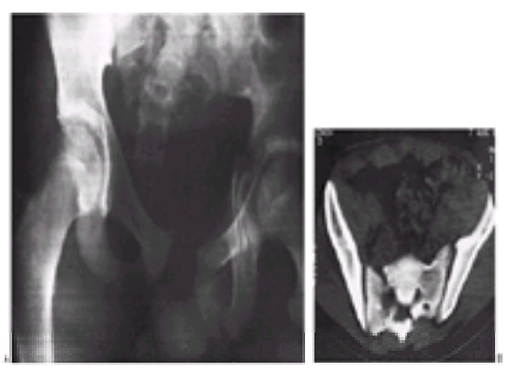

FIGURE 20-15. A: A 15-year-old boy with an obvious fracture of the left acetabulum and symphysis pubis diastasis, and a questionable and ill-defined sacral fracture. **B:** Computed tomography scan reveals a comminuted displaced sacral fracture.

FRACTURES OF THE COCCYX

Significant soft tissue injury to the coccyx makes it difficult to determine on radiograph if a coccygeal fracture has occurred, especially in a child. However, historically, trauma to the coccyx is often refractory to treatment. For this reason, if clinical symptoms are sufficient, an injury to this area in a child should be considered a fracture regardless of whether a fracture can be seen on radiographs.

Coccygeal fractures are not included in most large series of fractures of the pelvis in adults and children, although the coccyx is part of the pelvis. Of our nine patients with coccygeal fractures, in eight the mechanism of injury was similar to that in adults: a direct fall onto the buttocks in the sitting position. There were no associated injuries with these nine fractures. Clinically, there was immediate, severe pain in the area of the coccyx in all patients. Pain on defecation may be present as well as pain on rectal examination. Because radiographic identification is difficult, the diagnosis should be made clinically by digital rectal examination. Exquisite pain may be elicited, and an abnormal mobility of the coccygeal fragments may be noted. Acute symptoms may abate at 1 to 2 weeks, but in our patients symptoms while sitting persisted for an average of 4 weeks.

Lateral radiographs of the coccyx with the hips flexed maximally may reveal the fracture (Fig. 20-16). The coccyx may appear to be acutely angulated as a variant of normal, and a fracture may not be seen, or the normal acute angulation may be interpreted as a fracture or dislocation.

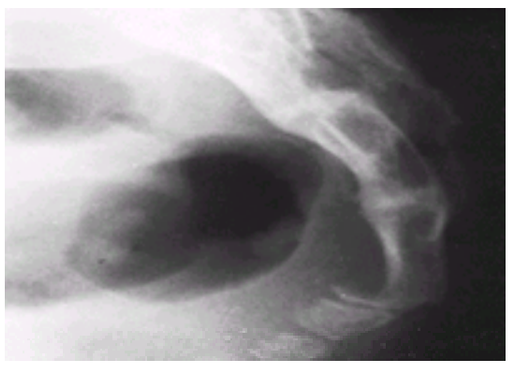

FIGURE 20-16. Lateral radiograph with the hips maximally flexed reveals displaced coccygeal fracture in a 14-year-old boy.

In all nine of our patients, the fracture was identified. Treatment consisted of an inflated doughnut cushion in three patients, decreased activity in three patients, and no treatment in three patients. The longest period of active treatment was 6 weeks (average, 4 weeks). Unlike adults with trauma to the coccyx, none of these children had prolonged impairment or psychological overtones.

FRACTURES OF TWO IPSILATERAL RAMI

Fractures of the pubic rami, which are more common than any other pelvic fracture in children, may be stable bilateral fractures or ipsilateral fractures of the superior and inferior rami. Ipsilateral fractures, although stable, may produce an increased incidence of associated injuries to abdominal viscera, especially the bladder (16).

Considerable force is necessary to cause this fracture pattern, and other associated fractures should be expected. A general evaluation should be followed by examination of the pelvis and lower extremities, with special attention to abrasions, contusions, lacerations, and ecchymosis about the pelvis. Palpation reveals discomfort anteriorly, and crepitus at the fracture site may be noted.

Various methods of treatment have been advocated for adults, such as bed rest, lower limb traction, and pelvic sling. However, in children, the fracture almost always unites with adequate remodeling of even the most displaced fractures. For this reason, short-term bed rest followed by progressive weight bearing on crutches on the involved side is all that is necessary (Fig. 20-17).

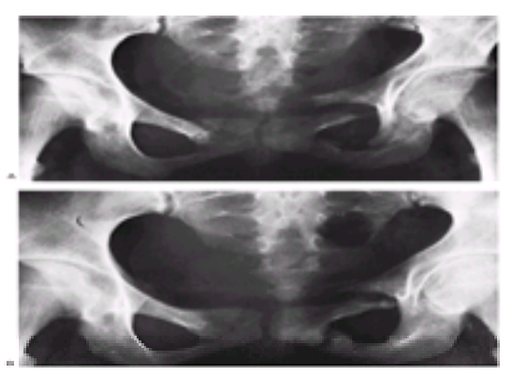

FIGURE 20-17. A: Ipsilateral left pubic rami fractures with a contralateral right superior rami fracture. **B:** At 2-year follow-up, nonunion of the ipsilateral rami fractures is evident, but the patient is asymptomatic.

FRACTURES NEAR OR SUBLUXATION OF THE SYMPHYSIS PUBIS

Isolated injuries in the symphysis pubis area are rare, primarily because they usually occur in association with disruption of posterior structures such as the sacroiliac joint. Although significant force appears to be necessary to disrupt or fracture the symphysis pubis, isolated disruption of the symphysis can occur (64). Usually, there is some normal elasticity at the symphysis in adults (0.5 mm in men, 1.5 mm in women), and there is probably even more in children, depending on skeletal maturity.

Clinically, exquisite pain is present anteriorly at the symphysis; the legs are externally rotated and often pain is worse in the supine position than in the side-lying position (64). Motion of the hips in flexion, abduction, external rotation, and extension is restricted and painful (fabere sign).

Radiographs may reveal subluxation and widening of the symphysis pubis, as if opening a book. Offset may be superior, inferior, anterior, or posterior (Fig. 20-18). Furthermore, a fracture near or into the symphysis may produce an equivalent subluxation of the symphysis pubis (Fig. 20-19). Because of the variable normal separation of the symphysis in children of different ages, the amount of traumatic separation may be difficult to evaluate. Watts (64) suggested radiographs with and without lateral compression of the pelvis. More than 1 cm of difference in the width of the symphysis pubis between the two views suggests a symphysis pubis separation.

FIGURE 20-18. Mild symphysis pubis subluxation with superior displacement. At 4-year follow-up, the patient is asymptomatic.

FIGURE 20-19. Fracture adjacent to the symphysis pubis with equivalent symphysis pubis separation.

We saw a child with anterior pubic pain and obvious widening of the symphysis pubis after a moving vehicle accident. On radiographs, it appeared that the child had an isolated disruption of the symphysis pubis; however, when an adequate history was obtained and physical examination was performed, it was apparent that the child had been treated for exstrophy of the bladder with congenital widening of the symphysis. The lesson learned should be obvious: “If all else fails, examine the patient.”

Treatment of isolated fractures or subluxations of the symphysis pubis should consist of bed rest, usually in a side-lying position, especially if other injuries are present. Unilateral Buck's traction may relieve pain, but it rarely improves alignment of the fracture or subluxation. Application of a spica cast in the lateral position with lateral compression may also reduce the displacement and decrease hospitalization (64)

FRACTURES NEAR OR SUBLUXATION OF THE SACROILIAC JOINT

Fractures near or subluxation of the sacroiliac joint are rare, isolated injuries, probably even less common than isolated fractures at the weaker symphysis pubis. More commonly, disruption of the sacroiliac joint occurs with fractures or dislocations of the anterior portion of the pelvis, causing an unstable injury of the pelvis. Sacroiliac dislocations differ from those in adults in several ways. In children, fractures tend to be incomplete because of partial tearing of the anterior sacroiliac ligaments and the thick posterior periosteum (43). A subchondral fracture through structurally weak zones of cartilage may leave the sacroiliac joint intact (15). Associated vascular and neurologic injuries are common (23).

Subluxation or fracture of the sacroiliac joint should be suspected with high-velocity trauma and injury to the posterior aspect of the pelvis near the sacroiliac joint. In patients with these injuries, the fabere sign is markedly positive on the ipsilateral side (15,23). Comparison views of both sacroiliac joints should be carefully evaluated to determine any asymmetry of the wings of the ilium with more separation at the sacroiliac joint (Fig. 20-20). Any offset of the distal articular surface of the sacrum and ilium on radiography is an indication of sacroiliac joint disruption. Oblique views for comparison of both sacroiliac joints often are beneficial. Because of the rarity of this subluxation or fracture, multiple views, including inlet and outlet views, and axial CT scan may be necessary to ensure that there is no anterior fracture (Fig. 20-21).

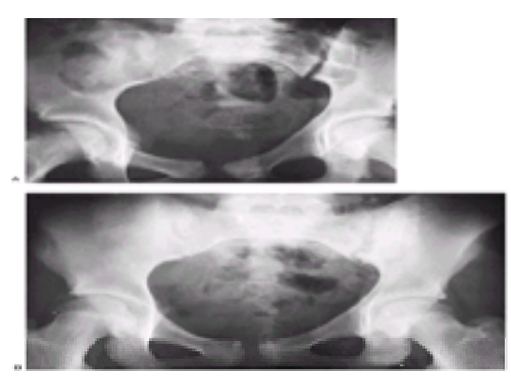

FIGURE 20-20. Separation of the left sacroiliac joint with asymmetry of the wings of the ilium. **A:** Careful scrutiny of the radiograph reveals contralateral pubic rami fractures. **B:** At 2-year follow-up, the sacroiliac joint is slightly wide, but the patient is asymptomatic.

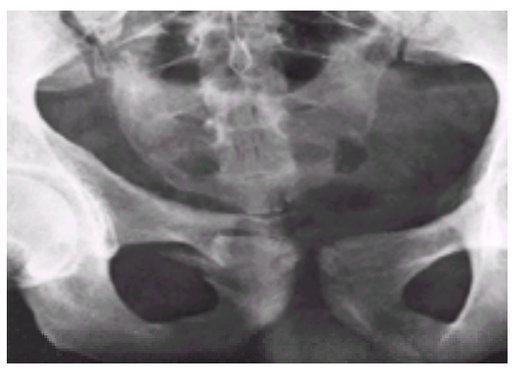

FIGURE 20-21. Fracture of the superior pubic ramus; occult fractures of the ipsilateral sacrum and the sacroiliac joint at the distal articular surface also are present.

Bed rest and guarded weight bearing on crutches is probably all the treatment needed for isolated subluxations or fractures. Heeg and Klasen (23) reported sacroiliac joint dislocations in 18 children, 10 of whom had extensive degloving injuries of the posterior pelvis. Ten were treated nonoperatively, six with open reduction and internal fixation, one with open reduction but no internal fixation, and one with external fixation. Disabling long-term symptoms persisted from incomplete neurologic recovery in six.

UNSTABLE FRACTURE PATTERNS

Unstable pelvic fracture combinations usually are of three types:

- Double vertical pubic rami fractures (straddle or floating fractures) or dislocations of the pubis that occur as an anterior double break in the pelvic ring anteriorly
- Double fractures in the pelvic ring anteriorly and posteriorly, through the bony pelvis, sacroiliac joint, or symphysis pubis (Malgaigne fractures)
- Multiple crushing injuries that produce at least two severely comminuted fractures in the pelvic ring

Bilateral Fractures of the Inferior and Superior Pubic Rami

Bilateral fractures of both the inferior and superior pubic rami (straddle fractures) cause a floating anterior arch of the pelvic ring that is inherently unstable (Fig. 20-22), as does dislocation of the symphysis pubis with fractures of both ipsilateral pubic rami. This fracture pattern frequently is associated with bladder or urethra disruption.

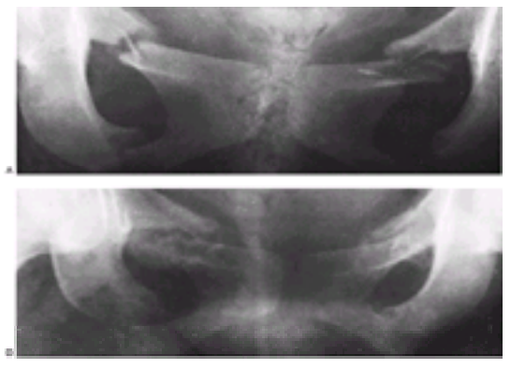

FIGURE 20-22. A: Classic example of a straddle fracture in a 16-year-old girl. **B:** At 6 weeks after injury, abundant callus formation is present and the fractures have healed.

Bilateral fractures of the inferior and superior pubic rami can occur in a fall while straddling a hard object or by lateral compression on the pelvis. The floating fragment usually is displaced superiorly, being pulled in this direction by the rectus abdominis muscles (64). Radiographically, an inlet view most accurately determines the amount of true displacement of the floating fragment.

In a child, regardless of the amount of displacement, the fracture should heal and remodeling can be expected. Because this fracture does not involve the weight-bearing portion of the pelvis, it does not cause leg-length discrepancy. Skeletal traction is unnecessary, and a pelvic sling is contraindicated because of the possibility that compression will cause medial displacement of the ilium (64).

Treatment should consist simply of bed rest in the semi-Fowler position with flexion of the hips to relax the abdominal musculature. If the fracture was caused by lateral compression forces, the lateral decubitus position is contraindicated for fear of medial displacement of the ilium.

Complex Fracture Patterns

Fractures and dislocations of the posterior arch (posterior to the acetabulum) combined with anterior ipsilateral or contralateral fractures or dislocations of the anterior arch [Malgaigne (36) fractures; Fig. 20-23] result in instability of the hemipelvis and acetabulum. These unstable fractures are associated with retroperitoneal and intraperitoneal bleeding. Bilateral anterior and posterior fractures are the most likely fracture pattern to cause severe hemorrhage. Initial treatment usually involves replacement of blood volume and stabilization of the child's overall condition before treatment of the pelvic fractures (60).

FIGURE 20-23. An unusual Malgaigne fracture; fracture extends through the ilium into the sacroiliac joint with ipsilateral pubic rami fractures.

Three mechanisms of injury have been implicated in these fractures and fracture–dislocations: anteroposterior compression forces, lateral compression forces, and, with the hip fixed in extension and abduction, indirect forces transmitted proximally along the femoral shaft.

Aside from the physical signs usually associated with pelvic fractures, leg-length discrepancy and asymmetry of the pelvis also may be present because of the displacement of the hemipelvis. If the measured distance from the umbilicus to the medial malleolus is unequal for the two extremities, and the distance from the anterior superior iliac spine to the medial malleolus is the same, pelvic obliquity or displacement is present rather than true leg-length discrepancy. Inlet and outlet radiographic views and CT scanning reveal the amount of pelvic displacement.

Numerous treatment regimens have been successful, depending on the type of fracture and the amount of displacement. For fractures with mild displacement, bed rest in the lateral recumbent position may be all that is necessary. If lateral displacement is severe, closed manipulation in the lateral decubitus position and spica casting can be used, as described in Chapter 35 in Volume 2 of this series. If the displacement is cephalad only, skeletal traction or even skin traction can be used in a small child. Occasionally, manipulation under anesthesia may be required. After successful manipulation of the fragments, traction on the involved side can be used to maintain the reduction. Open or percutaneous external fixation of the pelvis with pins incorporated in a distraction or compression device has been advocated to allow accurate reduction of the fracture or dislocation, early ambulation (non-weight bearing), and decreased pain secondary to instability.

Schwarz et al. (54), in a long-term (2 to 25 years) follow-up of 17 children with nonoperatively treated unstable pelvic fractures, reported unsatisfactory results in 8 due to pelvic asymmetry. They emphasized that reduction of pelvic ring fractures should be as anatomic as possible because healing in malposition causes poor results.

Nierenberg et al. (42), however, reported excellent or good results after conservative treatment of 20 unstable pelvic fractures in children despite radiographic evidence of deformity. They suggested that treatment guidelines for unstable pelvic fractures are not the same for children as for adults, and recommended that external or internal fixation should be used only when conservative methods fail.

Operative treatment of pelvic fractures in children is not routinely recommended (3) because (a) exsanguinating hemorrhage is unusual in children, so operative pelvic stabilization to control bleeding rarely is necessary (3,41); (b) pseudarthrosis is rare in children and fixation is not necessary to promote healing (51); (c) the thick periosteum in children tends to help stabilize the fracture, so surgery usually is not necessary to obtain stability (51); (d) prolonged immobilization usually is not necessary for fracture healing (42); (e) significant remodeling can occur in skeletally immature patients (18) (Fig. 20-24); and (f) long-term morbidity after pelvic fracture is rare in children (18,41). Operative fixation may be indicated to facilitate wound treatment in open fractures, control hemorrhage during resuscitation, allow patient mobility and make nursing care easier, prevent deformity in severely displaced fractures that may not heal or adequately remodel, improve overall patient care in patients with polytrauma, minimize risk of growth disruption, or restore articular congruity.

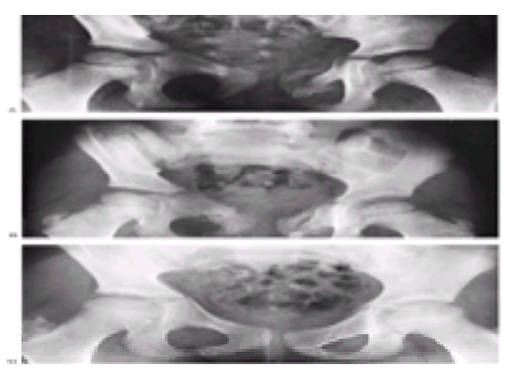

FIGURE 20-24. A: A 6-year-old child with a Malgaigne fracture with right sacroiliac joint displacement and multiple (four) pubic rami fractures. **B:** Four weeks after injury. **C:** At 5-year follow-up, complete remodeling is present.

Keshishyan et al. (29) advocated external fixation of complex pelvic fractures, especially in children with polytrauma, and Gordon et al. (20) suggested external fixation or open reduction and internal fixation in children older than 8 years of age because hip spica casting is poorly tolerated in older children. Stiletto et al. (56) reported good results after open reduction and internal fixation of unstable pelvic fracture in two toddlers. AO small-fragment instrumentation was used in both. These surgeons recommended protection in a spica cast for 6 to 8 weeks, with removal of the implants at that time. Occasionally, open reduction and internal fixation of severely malaligned fractures may be indicated. However, because of the potential surgical complications, open reduction of pelvic fractures in children should not be undertaken casually by the inexperienced surgeon.

AUTHORS' PREFERRED TREATMENT

Treatment is more likely to be conservative in younger children and operative in juveniles and adolescents. For toddlers, we prefer to use bed rest and distal femoral skeletal traction on the displaced side of the hemipelvis. The younger the child, the more likely that traction will be adequate treatment and the pelvis will remodel. Open reduction and internal fixation rarely are required in a young child unless severe (>3 cm) displacement of the sacroiliac joint cannot be corrected with traction. Combining open reduction and internal fixation with external fixation may be necessary in a child older than 8 to 10 years of age with an unstable fracture and severe polytrauma (Fig. 20-25). The technical principles are identical to those used for unstable pelvic fractures in adults (see Chapter 35, Volume 2). In older adolescents, treatment should follow the guidelines for the treatment of adult fractures (see Chapter 35, Volume 2), including a combination of internal and external fixation for fracture stabilization and early mobilization.

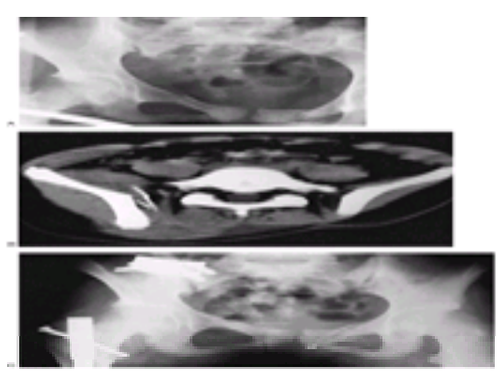

FIGURE 20-25. A: Multiple trauma in this 12-year-old child included three fractures of the pubic rami, disruption and fracture of the sacroiliac joint on the right, and a femoral shaft fracture on the right. **B:** Computed tomography scan shows fracture of the ilium and disruption of the sacroiliac joint. **C:** After open reduction and internal fixation of the sacroiliac joint and closed intramedullary nailing of the femoral shaft fracture. Note femoral nail inserted through the greater trochanter.

Severe Multiple or Open Fractures

In patients with crushing injuries, distortion of the pelvis is severe and, in addition to multiple breaks in the pelvic ring, apparent or occult fractures of the sacrum may be present, with or without neurologic involvement. Massive hemorrhage is common, and only rarely does a child survive this major insult (39,64). The patient is usually in hypovolemic shock, and emergency measures outlined previously in this chapter may be necessary.

Although total disruption of the pelvis is apparent on radiographs, usually one hemipelvis is partially intact. In general, each complex fracture needs a special treatment regimen; however, the treatment outlined for unstable fracture patterns usually can align the pelvis. Treatment may have to be by trial and error, with serial radiographs and CT scans to evaluate the progress of realignment.

The patient should be stable without evidence of a drop in blood volume before any operative intervention, either closed or open external fixation or open reduction, is undertaken.

These severe multiple fractures about the pelvis are important because the mobile fracture fragments may penetrate visceral organs (e.g., the bladder or abdominal viscera), lacerate the abdominal vascular tree, or cause neurologic involvement (Fig. 20-26). These acute injuries should take precedence over realignment of the pelvic architecture, although if possible during emergency surgery such as a laparotomy, pelvic stabilization should be achieved quickly with a combination of internal and external fixation as needed while the patient is under general anesthesia. In particular, the application of an external fixator may decrease blood loss by stabilizing mobile, bleeding bone fragments (1,58,59).

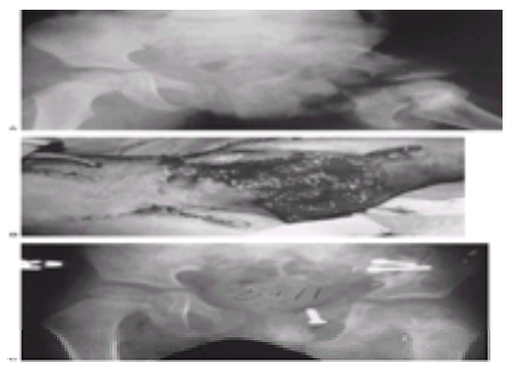

FIGURE 20-26. A and B: Complex open type IIIC pelvic fracture in a 3-year-old boy. Vascular (femoral artery and vein) and neurologic injuries also were present. Multiple debridements were required, as were colostomy and vesicostomy. The fractures of the wing of the ilium and pubic rami were fixed with small screws. **C:** One year after injury. (Courtesy of Dr. Gerry Clancy, Children's Hospital, Denver, CO.)

Open pelvic fractures are rare in children. Mosheiff et al. (40) reported that 13% of 116 pediatric pelvic fractures seen over a 12-year period were open injuries. Fourteen of the 15 children were struck by motor vehicles and one sustained a gunshot wound. Five children with stable fractures were treated nonoperatively, and 10 with unstable fractures were treated with external fixation (5), internal fixation (2), or combined external and internal fixation (3). Three of the children died because of uncontrollable hemorrhage (two patients) and chest injury (one patient). Eleven of the 12 surviving children had deep wound infection or sepsis, and 3 had premature physeal closure. Mosheiff et al. (40) emphasized that the treatment of the soft tissue injuries depends on stabilization of the pelvis and that external fixation alone is insufficient for most open pelvic fractures.

ACETABULAR FRACTURES

Acetabular fractures constitute only 1% to 15% of pelvic fractures in children, making them very uncommon. The mechanism of injury of acetabular fractures in children is similar to that in adults: the fracture occurs from a force transmitted through the femoral head. The position of the leg with respect to the pelvis and the location of the impact determine the fracture pattern; the magnitude of the force determines the severity of the fracture or fracture–dislocation. Patients with high-energy injuries usually have major associated injuries, whereas isolated acetabular fractures can occur from low-energy forces.

Classification

Watts (64) described a classification of acetabular fractures in children that consisted of four types: (a) small fragments that most often occur with dislocation of the hip, (b) linear fractures that occur in association with pelvic fractures without displacement and usually are stable, (c) linear fractures with hip joint instability, and (d) fractures secondary to central fracture–dislocation of the hip. More recently, however, acetabular fractures in both adults and children usually are classified by the system of Letournel and Judet (28,31). A more comprehensive classification is based on the AO comprehensive fractures classification, which groups all fractures into A, B, and C types with increasing severity. Type A acetabular fractures involve a single wall or column; type B fractures involve both columns (transverse or T-types) and a portion of the dome remains attached to the intact ilium; and type C fractures involve both columns and separate the dome fragment from the axial skeleton by a fracture through the ilium. Both of these classification systems are discussed in more detail in Chapter 35, Volume 2 of this series *(Fractures in Adults).*

Radiographic Evaluation

Anteroposterior and lateral views may not adequately show the amount of displacement of acetabular fragments after fracture. Inlet, outlet, and 45-degree oblique (Judet) views often are necessary to appreciate the amount of displacement. CT scanning can be used to determine the amount of acetabular displacement (Fig. 20-27) and to determine if any retained fragments in the acetabulum are preventing an accurate concentric reduction (11). Three-dimensional CT reconstructions can give an excellent view of the overall fracture pattern, but often underestimate minimally displaced fractures.

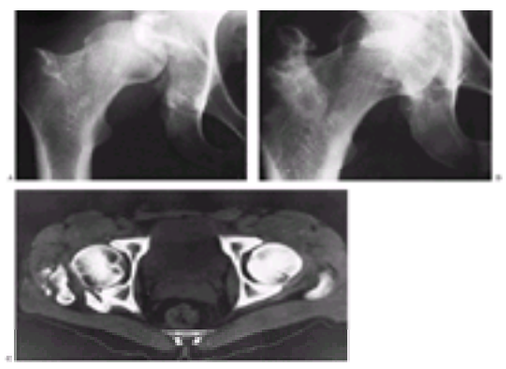

FIGURE 20-27. A: Traumatic dislocation with a small acetabular fragment. **B:** After reduction, a small fragment is visible, but it is not impeding hip congruity or function. **C:** At 12 weeks after injury, computed tomography scan reveals that the fragment is from the posterior acetabulum, with mild displacement of the acetabulum posteriorly.

After reduction of a hip dislocation, radiographs of both hips should be carefully compared to ensure that the reduction is not incongruous. Subtle signs of an incongruous reduction with retained osseous or cartilaginous fragments, an inverted limbus, or entrapped soft tissues include minimal widening of the joint (without traction applied) and asymmetry of Shenton's line compared with the opposite hip (11) (Fig. 20-28). If there is any doubt about the concentricity of the reduction, CT or MRI is indicated.

FIGURE 20-28. A: Posterior hip dislocation in a 5-year-old girl. **B:** Nonconcentric reduction. Note widened joint space on left compared with right hip. Posterior open reduction revealed infolded labrum and a flap of capsule.

Treatment

The aim of treatment for acetabular fractures in children is the same as for adults: to restore joint congruity and hip stability. Treatment guidelines in general follow those for adults. Bed rest or non–weight-bearing ambulation with crutches can be used for nondisplaced or minimally (£1 mm) displaced fractures. Because weight-bearing forces must not be transmitted across the fracture, crutch ambulation is appropriate only for older children who can be relied on to avoid putting weight on the injured limb. Non-weight bearing usually is continued for 6 to 8 weeks. In younger children, this may be shortened to 5 or 6 weeks, and in adolescents (older than 12 years of age), partial weight bearing should be continued for 3 to 4 more weeks. For fractures in which displacement can be reduced to less than 2 mm, skeletal traction with a traction pin in the distal femur can be used. Because traction must be maintained for 5 to 6 weeks, this option usually is not feasible in older children or adolescents.

Gordon et al. (20) recommended accurate reduction and internal fixation of any displaced acetabular fracture in a child. They noted that the presence of incomplete fractures and plastic deformation may make accurate reduction difficult or impossible; they recommended that incomplete fractures be completed and that osteotomies of the pubis, ilium, or ischium be made if necessary for accurate reduction of the acetabulum. In children with open physes, all periacetabular metallic implants should be removed 6 to 18 months after surgery.

Improved outcomes with early (<24 hours) fixation of acetabular fractures in adults has been reported (46), and Gordon et al. (20) noted that early fixation is especially important to prevent malunion in young patients in whom healing is rapid.

In addition, anatomic alignment of the triradiate cartilage should be obtained in children. Linear growth of the acetabulum occurs by interstitial growth in the triradiate part of the cartilage complex, causing the pubis, ischium, and ilium to enlarge. The depth of concavity of the acetabulum is in response to the presence of a spherical femoral head and increases during development as a result of interstitial growth in the acetabular cartilage. Cessation of growth of all or part of the triradiate cartilage occurring secondary to fracture may result in a dysplastic acetabulum.

Acetabular dysplasia secondary to growth arrest (bony bridge) of the triradiate cartilage has been reported after trauma to the acetabulum (Fig. 20-29). Heeg et al. (22,24,25) reported acetabular deformity and subluxation of the hip in two of three patients with premature fusion of the triradiate cartilage. Peterson and Robertson (45) reported formation of a physeal osseous bar in a 7-year-old boy 2 years after fracture of the lateral portion of the superior ramus at the junction with the triradiate cartilage. After excision of the osseous bridge, the physis remained open. Although the injured physis closed earlier than the contralateral side, there was only a slight increase in the thickness of the acetabular wall and lateral displacement of the femoral head. Peterson and Robertson emphasized that early recognition and treatment are essential, before premature closure of the entire physis and development of permanent osseous deformity.

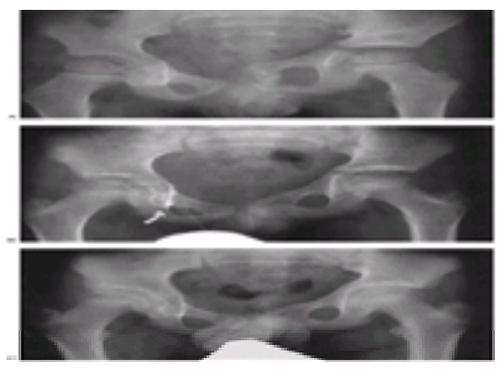

FIGURE 20-29. A: Fractures of the left superior and inferior pubic rami and the left ilium with injury to the right triradiate cartilage in a 5-year-old boy. **B:** Three years after injury, the pubic rami fractures are healed and remodeling has occurred, but acetabular dysplasia, widening of the “teardrop,” and mild subluxation are evident in the right hip. **C:** At 15 years of age, the sequelae of the mild triradiate cartilage injury are still apparent, but he is not symptomatic.

Bucholz et al. (8) noted two main patterns of physeal disturbance in nine patients with triradiate cartilage injury: a Salter-Harris type I or II injury, which had a favorable prognosis for continued normal acetabular growth, and a Salter-Harris type V crush injury, which had a poor prognosis with premature closure of the triradiate cartilage caused by formation of a medial osseous bridge (Fig. 20-30). In either pattern, the prognosis depended on the child's age at the time of injury. In young children, especially those younger than 10 years of age, acetabular growth abnormality was common and resulted in a dysplastic acetabulum. By the time of skeletal maturity, disparate growth increased the incongruity of the hip joint and led to progressive subluxation. These researchers found that acetabular reconstruction was frequently necessary to correct the gradual subluxation of the femoral head.

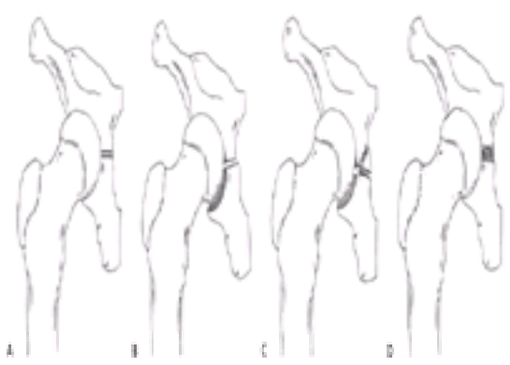

FIGURE 20-30. Types of triradiate cartilage fractures. **A:** Normal triradiate cartilage. **B:** Salter-Harris type I fracture. **C:** Salter-Harris type II fracture. **D:** Salter-Harris type V (compression) fracture. Surgical Treatment

The surgical approach varies according to the pattern of the fracture and the direction of the displacement as determined on the preoperative radiographs and CT scans (20) (Table 20-5). Fractures of the posterior wall or posterior column can be approached through a Kocher-Langenbeck approach with the patient either in the lateral decubitus position (isolated posterior wall fracture) or supine (associated posterior column fracture). Anterior column injuries can be approached through an ilioinguinal approach. Some transverse fractures may require an extended iliofemoral approach, but this is rare in children (12). The extended lateral approaches, which include the extended iliofemoral and triradiate approaches, should be avoided as much as possible because of the risk of devascularization of the ileum and heterotopic bone formation (21).

The surgeon should be familiar with Judet's (29) treatise on the operative reduction of acetabular fractures and with Letournel's works before performing this surgery. For smaller children and smaller fragments, Watts (64) recommended threaded Kirschner wires for reduction. In larger children, cannulated screws may aid in reduction and provide secure fixation (Fig. 20-31). Small-fragment reconstruction plates, appropriately contoured, also can be used. Gordon et al. (20) described the addition of a small (two- or three-hole) “hook plate” for small or comminuted fragments (Fig. 20-32). Because operative procedures about the hip may be necessary later, the hardware in a child may be removed in this situa- tion.

Fracture Type	Exposure
Anterior column or wall	Ilioinguinal
Posterior column or wall	Kocher-Langenbeck
Transverse	Ilioinguinal (or extended lateral)
T-shaped	Ilioinguinal and Kocher-Langenbeck (or extended lateral)
Anterior column and posterior hemitransverse	Ilioinguinal
Both columns	Ilioinguinal (or extended lateral)

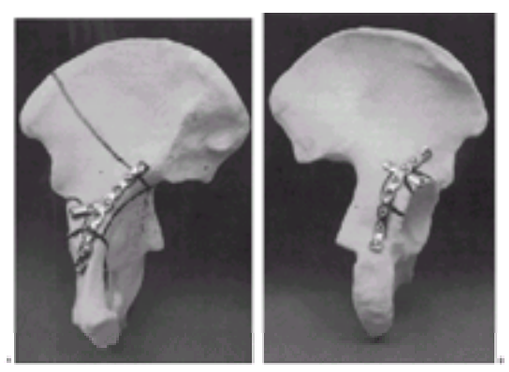

FIGURE 20-32. A: Anterior column plate and additional anterior wall "hook" plate. **B:** Posterior wall buttress plate and hook plate. (From Gordon RG, Karpik K, Mears DC. Techniques of operative reduction and fixation of pediatric and adolescent pelvic fractures. *Oper Tech Orthop* 1995;5:95–114; with permission.)

Brown et al. (6) described the use of CT image-guided fixation of acetabular fractures in 10 patients, including bilateral posterior wall fractures in a 14-year-old girl. They cite as advantages of image-guided surgery reduced operating time (approximately 20% reduction), less extensive surgical dissection, reduced fluoroscopic time, and compatibility with traditional fixation techniques. Most important, it allows accurate and safe placement of screws and pins for acetabular fixation.

Postoperative Management

Small children can be immobilized in a spica cast for 6 weeks. If radiographs show adequate healing at that time, the cast is removed and free mobility is allowed. In an older child with stable fixation, crutches are used for protected weight bearing for 6 to 8 weeks. If radiographs show satisfactory healing, weight bearing is progressed as tolerated. Return to vigorous activities, especially competitive sports, is delayed for at least 6 months.

COMPLICATIONS

Because of the remodeling potential in young children, loss of reduction and malunion usually are not problems. Reported complications include premature triradiate cartilage closure, avascular necrosis, traumatic arthritis, sciatic nerve palsy, heterotopic myositis ossificans about the acetabulum and pelvis after acetabular fractures (Fig. 20-33), and pelvic asymmetry at long-term follow-up of female patients. Because this asymmetry may cause maternal dystocia during childbearing, pelvimetry is recommended before pregnancy. Rieger and Brug (52) reported one female patient who required cesarean section because of ossification of the symphysis pubis after nonoperative treatment of an open-book fracture. Schwarz et al. (54) reported leg-length discrepancies of 1 to 5 cm in 10 of 17 patients after nonoperative treatment of unstable pelvic fractures; 5 complained of low back pain at long-term follow-up. Nine of 10 patients with lumbar scoliosis also had low back pain.

FRACTURES AND TRAUMATIC DISLOCATIONS OF THE HIP IN CHILDREN

R. DALE BLASIER
LAURIE O. HUGHES

FRACTURES OF THE HIP

Fractures of the head and neck of the femur in children are exceedingly rare, accounting for fewer than 1% of all pediatric fractures (24). In comparison, the prevalence of fractures of the hip in children is less than 1% of that in adults. Therefore, most orthopaedic surgeons will treat only a few such fractures in a lifetime (16).

The pattern of fracture and thus the classification in children differ from those in adults. Because of the weak proximal femoral physis, a transphyseal separation can occur in children. Transcervical and cervicotrochanteric fractures have an extremely high risk for avascular necrosis (AVN) and coxa vara compared with their adult counterparts. Intertrochanteric fractures are mechanically similar in both groups, although in children involvement of the greater trochanteric apophysis can result in premature closure.

The proximal femoral physis is at risk in hip fracture and has obvious implications for fracture care and prognosis. If the proximal physis is damaged, coxa vara or coxa breva may develop with further growth regardless of fracture alignment. Conversely, if the greater trochanter apophysis fuses prematurely as a result of trauma, coxa valga may develop (4).

Although hip fractures in children can generally be expected to heal, their importance lies in the frequency and severity of complications, including AVN, coxa vara, premature physeal closure, limb length discrepancy and occasionally nonunion. Because the hip is developing in the growing child, deformities can progress with age.

Diagnosis

Mechanism of Injury

Hip fractures in children can be caused by axial loading, torsion, hyperabduction, or a direct blow to the hip. Almost all hip fractures in children are caused by severe, high-energy trauma. This is in marked contrast to hip fractures in the elderly, in whom minor torsional forces acting on osteoporotic bone cause most hip fractures. The proximal femur in children, except for the proximal femoral physis, is extremely strong, and high-energy forces, such as from moving vehicle accidents and high falls, are necessary to cause fracture (9).

Examination

Clinical examination usually reveals pain in the hip and a shortened, externally rotated extremity. With a nondisplaced or stress fracture of the femoral neck, the patient may be able to bear weight with a limp and may only demonstrate hip or knee pain with extremes of range of motion, especially internal rotation. A good quality anteroposterior pelvic radiograph will provide a comparison view of the opposite hip if a displaced fracture is suspected. A cross-table lateral radiograph should be considered to avoid further displacement and unnecessary discomfort to the patient from an attempt at a frog-leg lateral view. Any break or offset of the bony trabeculae near Ward's triangle is evidence of a nondisplaced or impacted fracture.

Not all fractures can be detected on plain radiographs early. Special studies may be required to reveal an occult fracture. A radioisotopic bone scan 48 hours after the onset of symptoms may show increased uptake at the fracture site. The typical magnetic resonance imaging (MRI) appearance of a fracture is a linear black line (low signal) on all sequences surrounded by a high signal band of bone marrow edema and hemorrhage. The low signal represents trabecular impaction. MRI may detect an occult hip fracture within the first 24 hours after injury (17).

In a patient with posttraumatic hip pain without evidence of a fracture, other diagnoses must be considered, including synovitis, hemarthrosis, and infection. A complete blood count, erythrocyte sedimentation rate, C-reactive protein, and temperature are helpful. Ultrasonography can be used to detect fluid in the joint. If necessary, aspiration should be performed. A bloody aspirate establishes the diagnosis of fracture, whereas a serous or suppurative aspirate suggests synovitis or infection, respectively. In children under 5 years of age, developmental coxa vara can be confused with an old hip fracture (4).

Classification

Pediatric hip fractures are classified by the method of Delbet. Its simplicity and uniformity allow accurate description and reporting of results of each fracture by type. Type I is a transepiphyseal separation, with (type IA) or without (type IB) dislocation of the femoral head from the acetabulum. Type II is a transcervical fracture. Type III is a cervicotrochanteric fracture. Type IV is an intertrochanteric fracture (8) (Fig. 21-1). Subtrochanteric fractures are not included in this classification and are discussed in Chapter 22.

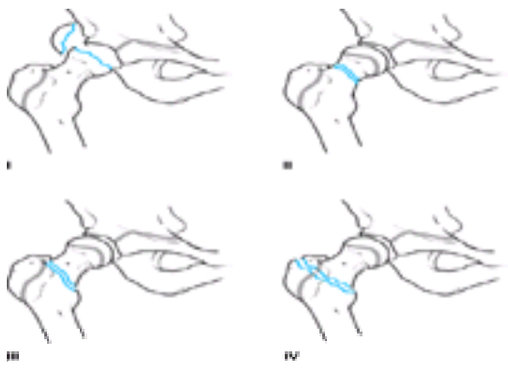

FIGURE 21-1. Delbet classification of hip fractures in children. *I,* transepiphyseal, with or without dislocation from the acetabulum; *II,* transcervical; *III,* cervicotrochanteric; and *IV,* intertrochanteric.

Type I

Transphyseal fractures occur through the proximal femoral physis (Fig. 21-2). Such fractures are rare, constituting 8% of femoral neck fractures in children (16). True transphyseal fractures tend to occur in young children after high-energy trauma (5,12) and are different from unstable slipped capital femoral epiphyses of the preadolescent, which probably occur as a result of a subtle endocrinopathy. In the absence of a history of significant trauma in a young child, battered child syndrome should be suspected (28). Rarely, this injury occurs during a difficult delivery or attempted closed reduction of a traumatic dislocation of the hip in adolescents (16). Approximately half of type I fractures are associated with a dislocation of the capital femoral epiphysis. In such cases, the outcome is dismal because of AVN and premature physeal closure in virtually 100% of patients (5,12).

FIGURE 21-2. Type I transphyseal fracture of the left proximal femur in a 3-year-old patient with spina bifida. Superior translation of the metaphysis with the head remaining in the acetabulum is typical of a type IA fracture.

Type I fractures in children under 2 or 3 years of age have a better prognosis than in older children. AVN is unlikely, although coxa vara, coxa breva, and premature physeal closure can cause subsequent leg length discrepancy (18,23).

Type II

Transcervical fractures account for 46% of fractures of the head and neck of the femur in children (16). In three large series, 77% of all type II fractures were displaced (16). Nondisplaced fractures have a better prognosis and a lower rate of AVN than displaced fractures, regardless of treatment (5,24). The risk of AVN is thought by most investigators to be directly related to the initial displacement of the fracture, although a few have hypothesized an intraarticular hemarthrosis with tamponade (5,16) as the etiology of vascular impairment.

Type III

Cervicotrochanteric fractures are, by definition, located at or above the anterior intertrochanteric line and are the second most common type of hip fracture in children, comprising about 34% of fractures (16). The incidence of AVN is 20% to 30%, and, as in type II fractures, the risk of AVN is directly related to the degree of displacement at the time of injury (16). Premature physeal closure occurs in 25% of patients and coxa vara in 14% (16). Displaced type III fractures are similar to type II fractures in regard to the development of complications. Nondisplaced type III fractures have a much lower complication rate than displaced fractures.

Type IV

Intertrochanteric fractures account for only 12% of fractures of the head and neck of the femur in children (16). This fracture has the lowest complication rate of all four types. Nonunion and AVN after this fracture are exceedingly rare. Coxa vara and premature physeal closure have rarely been reported (5,16,19,24,25).

Unusual Fracture Patterns

Type I fracture in a neonate deserves special attention. This injury is exceedingly rare, and, because the femoral head is not visible on plain radiographs, the index of suspicion must be high. An affected infant holds the extremity flexed, abducted, and externally rotated. A strong suspicion, pseudoparalysis, and shortening are keys to the diagnosis. The differential diagnosis includes septic arthritis and hip dislocation. Plain radiographs may be of assistance, but ultrasonography is useful if the diagnosis remains in doubt. Plain radiographs may show a high riding proximal femoral metaphysis on the involved side, resembling a dislocation. Ultrasonography shows the cartilaginous head in the acetabulum with dissociation from the femoral shaft. The diagnosis can be missed if there is no history of trauma (such as in child abuse) or if there is an ipsilateral fracture of the femoral shaft (1).

Stress fractures are caused by repetitive injury and result in hip or knee pain and a limp. Pain associated with long distance running, marching, or a recent increase in physical activity is suggestive of stress fracture. Close scrutiny of high-quality radiographs may identify sclerosis, cortical thickening, or new bone formation. Undisplaced fractures may appear as faint radiolucencies (Fig. 21-3).

FIGURE 21-3. A: This 5-year-old boy jumped off his bunk bed and subsequently complained of right hip pain and limp. Anteroposterior radiography yielded normal findings. **B:** Careful examination of the frog-leg lateral radiograph revealed a nondisplaced femoral neck fracture. Symptoms resolved after 4 weeks in a spica cast.

An acute unstable slipped capital femoral epiphysis may be confused with an acute type I fracture of the proximal femur; however, a slipped capital femoral epiphysis is caused by an underlying abnormality of the physis and occurs after trivial trauma, usually in preadolescents, whereas type I fractures usually occur in young children.

Fracture after minor trauma suggests weakened bone. Intrinsic bone disease, tumors, cysts, and infections may weaken the bone. If the trauma is significant, but the history is not consistent, nonaccidental trauma must always be considered (2,28).

It is easy to miss hip fractures that are overshadowed by more dramatic or painful injuries. Radiographs of the proximal femur should be examined carefully in patients with femoral shaft fractures because ipsilateral fracture or dislocation of the hip is not unusual (1).

Surgical and Applied Anatomy

Ossification of the femur begins in the 7th fetal week (12). In early childhood, only a single proximal femoral physis exists (Fig. 21-4A and Fig. 21-4B). During the first year of life, the medial portion of this physis grows faster than the lateral, creating an elongated femoral neck by 1 year of age (Fig. 21-4C). The capital femoral epiphysis begins to ossify at approximately 4 months in girls and 5 to 6 months in boys. The ossification center of the trochanteric apophysis appears at 4 years in boys and girls (16) (Fig. 21-4D). The proximal femoral physis is responsible for the metaphyseal growth in the femoral neck, whereas the trochanteric apophysis contributes to the appositional growth of the greater trochanter and less to the metaphyseal growth of the femur (20) (Fig. 21-5). Fusion of the proximal femoral and trochanteric physes occurs at about the age of 14 in girls and 16 in boys (15). The confluence of the greater trochanteric physis with the capital femoral physis along the superior femoral neck (Fig. 21-4E) and the unique vascular supply to the capital femoral epiphysis make the immature hip vulnerable to growth derangement and subsequent deformity after a fracture.

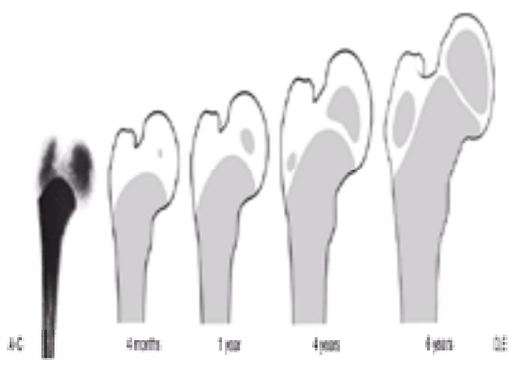

FIGURE 21-4. The transformation of the preplate to separate growth zones for the femoral head and greater trochanter. The diagram shows development of the epiphyseal nucleus in the proximal end of the femur. **A:** Radiograph of the proximal end of the femur of a stillborn female, weight 325 g. **B–E:** Drawings made on the basis of radiographs. FIGURE 21-5. Drawing of a frontal section through the upper end of the femur of a 14-week-old pig injected 8 weeks previously with tetracycline (50 mg/kg). Diagram depicts the contribution of the capital femoral physis and greater trochanteric physis to new bone formation. (Reprinted from Edgren W. Coxa plana. A clinical and radiological investigation with particular reference to the importance of the metaphyseal changes for the final shape of the proximal part of the femur. *Acta Orthop Scand* 1965;84(suppl):24; with permission.)

Vascular Anatomy

Because of the frequency and sequelae of AVN of the hip in children, the blood supply has been studied extensively (7,23,29,30). Postmortem injection and microangiographic studies have provided clues to the vascular changes with age. These observations are enumerated as follows:

1. The vessels of the ligamentum teres are of virtually no importance. They contribute little blood supply to the femoral head until age 8, and then only about 20% as an adult.
2. At birth, the branches of the medial and lateral circumflex arteries (metaphyseal vessels) traversing the femoral neck predominately supply the femoral head. These arteries gradually diminish in size as the cartilaginous physis develops and forms a barrier that prevents penetration of these vessels into the femoral head. This metaphyseal blood supply is virtually nonexistent by age 4.
3. When the metaphyseal vessels diminish, the lateral epiphyseal vessels predominate and the femoral head is primarily supplied by these vessels, which bypass the physeal barrier.
4. Ogden noted that the lateral epiphyseal vessels consist of two branches, the posterosuperior and posteroinferior branches of the medial circumflex artery (Fig. 21-6). At the level of the intertrochanteric groove, the medial circumflex artery branches into a retinacular arterial system (the posterosuperior and posteroinferior arteries). These arteries penetrate the capsule and traverse proximally (covered by the retinacular folds) along the neck of the femur to supply the femoral head peripherally and proximally to the physis.

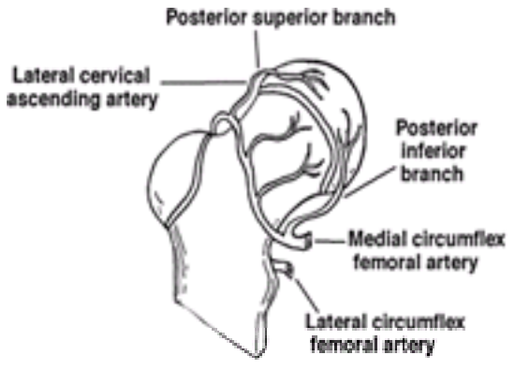

FIGURE 21-6. Arterial supply of the proximal femur. The capital femoral epiphysis and physis are supplied by the medial circumflex artery through two retinacular vessel systems: the posterosuperior and posteroinferior. The lateral circumflex artery supplies the greater trochanter and the lateral portion of the proximal femoral physis and a small area of the anteromedial metaphysis.

5. Capsulotomy does not damage the blood supply to the femoral head, but violation of the intertrochanteric notch or the lateral ascending cervical vessels may render the head avascular.
6. At about 3 to 4 years of age, the lateral posterosuperior vessels appear to predominate and supply the entire anterior lateral portion of the capital femoral epiphysis.
7. The posteroinferior and posterosuperior arteries persist throughout life and supply the femoral head.
8. The multiple small vessels of the young coalesce with age to a limited number of larger vessels. As a result, damage to a single vessel can have serious consequences; for example, occlusion of the posterosuperior branch of the medial circumflex artery can cause AVN of the anterior lateral portion of the femoral head (4).

Soft Tissue Anatomy

The hip joint is enclosed by a thick fibrous capsule. Tense hemarthrosis after intracapsular fracture may tamponade the ascending cervical vessels and may have implications in the development of AVN. The hip joint is surrounded on all sides by a protective cuff of musculature. Open hip fracture is rare. In the absence of associated hip dislocation, neurovascular injuries are rare after hip fracture and are more likely to occur during surgery.

The lateral femoral cutaneous nerve lies in the interval between the tensor and sartorius muscles and supplies sensation to the lateral thigh. This nerve must be identified and preserved during an anterolateral approach to the hip. The femoral neurovascular bundle is separated from the anterior hip joint by the iliopsoas. Thus, any retractor placed on the anterior acetabular rim should be carefully placed deep to the iliopsoas to protect the femoral bundle. Inferior and medial to the hip capsule, coursing from the deep femoral artery toward the posterior hip joint, is the medial femoral circumflex artery. Placement of a distal Hohmann retractor too deeply can tear this artery, and control of the bleeding may be difficult.

The sciatic nerve emerges from the sciatic notch beneath the piriformis and courses superficial to the external rotators and the quadratus medial to the greater trochanter. The nerve is rarely seen at hip fracture surgery, but placement of a Hohmann retractor dorsally and distally, simultaneous with external rotation of the leg, can damage it.

Treatment

Type I

Fracture treatment is based on the age of the child and fracture stability after reduction. In toddlers under 2 years of age with nondisplaced or minimally displaced fractures, simple spica cast immobilization is likely to be successful. Because the fracture tends to displace into varus and external rotation, the limb should be casted in mild abduction and neutral rotation to prevent displacement. Displaced fractures in toddlers should be reduced closed by gentle traction, abduction, and internal rotation. If the fracture “locks on” and is stable, casting without fixation is indicated. If the fracture is not stable, it should be fixed with small smooth pins that access the femoral neck and cross the physis. If casting without fixation is done, repeat radiographs should be taken within days to look for displacement because the likelihood of successful repeat reduction decreases rapidly with time and healing in a young child (Fig. 21-7).

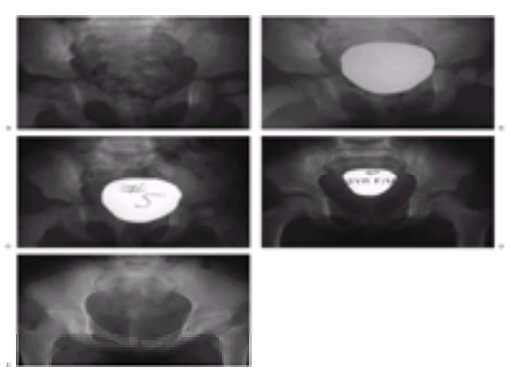

FIGURE 21-7. A: A 16-month-old boy with a type I fracture of the left hip. Note widening of the left femoral physis. **B:** Lateral radiograph at injury. Instability of the physis is apparent. **C:** Anteroposterior radiograph after 1 month in spica cast. **D:** At 2 years postinjury, the patient has mild coxa valga and coxa breva. **E:** At 10 years postinjury, coxa breva secondary to premature physeal closure is evident. Note the overgrowth of the greater trochanter.

Older children should always have operative fixation even if the fracture is undisplaced because the complications of late displacement may be great. Smooth pins can be used in young children, but cannulated screws are better for older, larger children. Fixation should cross the physis into the capital femoral epiphysis. Irreducibility mandates an open reduction and internal fixation. Postoperative spica cast immobilization is mandatory in all but the oldest and most reliable adolescents. Fixation may be removed shortly after fracture healing (8–12 weeks) to enable further growth in younger patients.

Closed reduction of type IB fracture–dislocations should be attempted, with immediate open reduction if unsuccessful. Internal fixation is mandatory. The surgical approach should be from the side to which the head is dislocated, generally posterolateral. Parents must be advised in advance about the risk of AVN.

Type II and Type III

Displaced neck fractures should always be treated with anatomic reduction and stable internal fixation to minimize the risk of late complications. In two large series, the prevalences of coxa vara and nonunion were high in displaced transcervical fractures treated with immobilization but without internal fixation (5,19). Much lower prevalences of these two complications have been documented in patients treated with anatomic closed or open reduction and internal fixation (5).

Internal fixation is also recommended by most investigators for nondisplaced transcervical fractures (16), because the risk of late displacement in such fractures far outweighs the risk of percutaneous screw fixation, especially in young children (3). Nondisplaced type II fractures in children under 5 years of age can be managed with spica casting and close follow-up (10,19), but fixation remains preferable. Even then, close follow-up is necessary to prevent varus displacement in the cast.

Gentle closed reduction of displaced fractures is accomplished with the use of longitudinal traction, abduction, and internal rotation. Open reduction is frequently

necessary for displaced fractures and should be performed via a Watson-Jones surgical approach.

Internal fixation with cannulated screws is performed through a small lateral incision. Three screws should be placed if possible. One screw should be placed low along the calcar, and two above, spaced as widely as possible (3). Occasionally, the small size of the child's femoral neck will accommodate only two screws. Care should be taken to minimize drill holes in the subtrochanteric region because they increase the risk of subtrochanteric fracture. If possible, screws should be inserted short of the physis in type III fractures; however, if physeal penetration is necessary for purchase, it must be done (Fig. 21-8 and Fig. 21-9). The risks of premature physeal closure and trochanteric overgrowth are much less than those of nonunion, pin breakage, and AVN. Treatment of the fracture is the first priority, and any subsequent growth disturbance and leg length discrepancy (LLD) are secondary.

TABLE cellSpacing=0 cellPadding=0 align=left border=0 hspace="10" vspace="5">

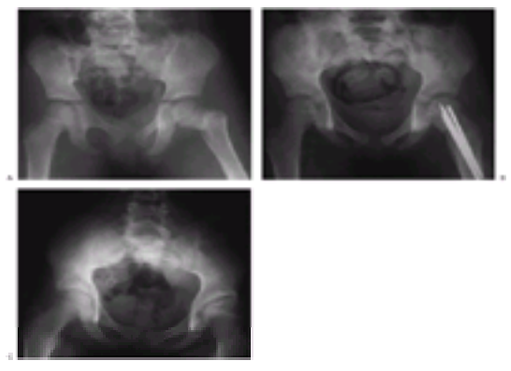

FIGURE 21-8. A: A girl 4 years and 4 months of age with a type II fracture of the left femoral neck. Anteroposterior pelvis film at presentation shows a displaced femoral neck fracture. **B:** Three weeks postinjury. Smooth pins were chosen to minimize the risk of physeal damage. **C:** Six years after fracture. Mild coxa valga is evident, possibly from damage to the growth zone on the superior femoral neck in this young child.

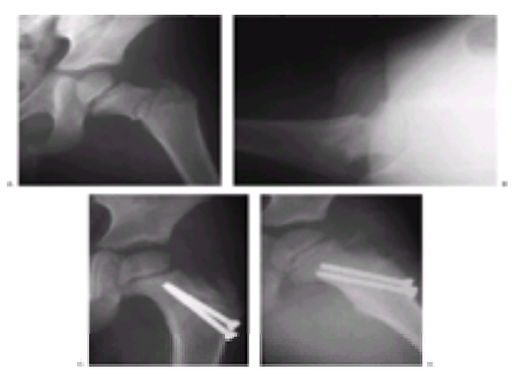

FIGURE 21-9. A: This boy 4 years and 9 months of age sustained a type III femoral neck fracture in a motor vehicle accident. **B:** Lateral radiograph at presentation. **C:** Three months after anatomic open reduction and internal fixation with two screws, sparing the physis. **D:** Lateral radiograph on the same date.

Nondisplaced cervicotrochanteric fractures can be treated adequately in an abduction one and one-half spica cast with close follow-up (16). Displaced cervicotrochanteric fractures have been shown to have a complication rate similar to that for type II fractures and should be treated similarly. Fixation generally does not need to cross the physis in type III fractures.

In a more distal cervicotrochanteric fracture, especially in a child over 5 years of age, a pediatric hip compression screw can be used for more secure fixation. Consideration may be given to capsulotomy or aspiration of the joint to eliminate tense hemarthrosis at the time of surgery. Spica casting is routine, except in older reliable children. Hardware removal at 6 to 12 months after fracture union will avoid bony overgrowth of the hardware.

Type IV

Good results can be expected after closed treatment of most intertrochanteric fractures, regardless of displacement. Traction and spica cast immobilization are effective (16). Failure to maintain adequate reduction and polytrauma are indications for internal fixation. Children old enough to use crutches or those with multiple injuries can be treated with open reduction and internal fixation (Fig. 21-10 and Fig. 21-11). A pediatric hip screw provides the most rigid internal fixation for this purpose.

FIGURE 21-10. A: A girl 3 years and 7 months of age with type IV intertrochanteric right femur fracture. **B:** Three months after fixation with a pediatric sliding hip screw.

FIGURE 21-11. A: A 14-year-old boy who fell from a tree swing sustained this nondisplaced left intertrochanteric hip fracture. **B:** Lateral radiograph shows the long

spiral fracture line. **C:** Three months postfixation with an adult sliding hip screw.

Surgical Procedures

When an operation is indicated, several factors must be evaluated before the method of internal fixation and the operative procedure are selected (Table 21-1). Perhaps the most important consideration is the age of the patient. For discussion, three age-groups have been established arbitrarily: infantile (younger than three years), juvenile (three to eight years), and adolescent (older than eight years).

Anterolateral approach
Age 0–3 yr—smooth pins, 5/64-inch or 3/32-inch
Age 3–8 yr—cannulated 4.5-mm screws
Age 8+ yr—6.9 or 7.3-mm cannulated screws
Type IV fractures
  <8 yr—pedi hip compression screw
  >8 yr—adult hip compression screw
Always predrill and tap before inserting screws
Avoid crossing physis if possible, but cross physis if necessary for stability
Age <10 yr—hip spica for 6–12 wk

TABLE 21-1. SURGICAL TIPS AND PEARLS FOR FRACTURES IN CHILDREN

For younger and smaller patients, the operation should be done on a radiolucent operating table rather than on a fracture table, which is more appropriate for older and larger adolescents.

For internal fixation of types I, II, and III fractures of the femoral neck, smooth pins may be used in infants; cannulated 4.0-millimeter screws, in children; and cannulated 6.5-millimeter screws, in adolescents. For fixation of type-IV fractures, pediatric-size hip-compression screws should be used in children and adult-size hip-compression screws, in adolescents.

A hip-spica cast should supplement internal fixation in all patients who are less than ten years old. Fractures of the neck of the femur in children who are twelve years old or more are treated in a manner similar to that used in adults: no postoperative cast is used and early walking with crutches is encouraged. For patients who are between the ages of ten and twelve years, the necessity for a postoperative cast is less clear-cut. If stability of the fracture fixation is questionable, or if compliance of the patient is doubtful, a hip-spica cast should be used.

Because the femoral bone in children is harder than the osteoporotic bone in elderly patients, pre-drilling and pre-tapping are necessary for insertion of all screws.

Finally, growth of the femur and the contribution of the proximal femoral physis are important; however, this physeal contribution to growth is only 13 per cent of the entire extremity, or three to four millimeters per year on the average. Once the decision for internal fixation of a fracture of the head or neck of the femur is made, stable fixation of the fracture is a higher priority than preservation of the physis. If stability is questionable, the internal fixation device should extend into the femoral head for rigid, stable fixation, regardless of the type of fracture or the age of the child.

Anterolateral Approach

If closed reduction is successful, a 5- to 4.5-cm lateral incision is made distal to the greater trochanter apophysis for insertion of pins or cannulated screws. An anterior approach through the Watson-Jones interval is often used for open reduction. A lateral incision is made over the proximal femur, slightly anterior to the greater trochanter (Fig. 21-12A). The fascia lata is incised longitudinally (Fig. 21-12B). The innervation of the tensor muscle by the superior gluteal nerve is 2 to 5 cm above the greater trochanter and care should be taken not to damage this innervation. The tensor muscle is reflected anteriorly. The interval between the gluteus medius and the tensor muscles will be used (Fig. 21-12C). The plane is developed between the muscles and the underlying hip capsule. If necessary, the anteriormost fibers of the gluteus medius tendon can be detached from the trochanter for wider exposure. After clearing the anterior hip capsule, longitudinal capsulotomy is made along the anterosuperior femoral neck. A transverse incision may be added superiorly for wider visualization (Fig. 21-12D).

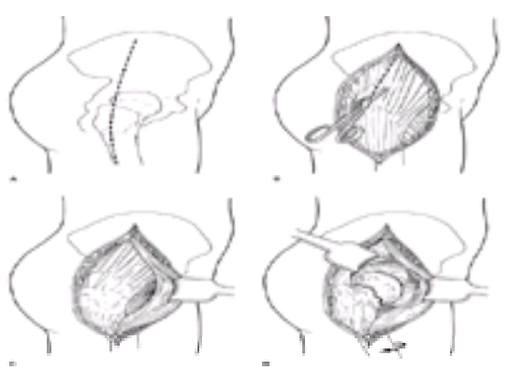

FIGURE 21-12. Watson-Jones lateral approach to the hip joint for open reduction of femoral neck fractures in children. **A:** Skin incision. **B:** Interval between gluteus medius and tensor fasciae. **C:** Dissection carried proximally. **D:** Completed exposure.

Alternatively, a bikini approach can be used through the Smith-Petersen interval. Care should be taken to identify and protect the lateral femoral cutaneous nerve. The sartorius and rectus muscles can be detached to expose the hip capsule. Medial and inferior retractors should be carefully placed to avoid damage to the femoral neurovascular bundle and medial femoral circumflex artery, respectively. Care must be taken not to violate the intertrochanteric notch and the lateral ascending vessels.

Under direct vision, the fracture is reduced and guidewires are passed from the lateral aspect of the proximal femur up the neck perpendicular to the fracture. Wires are passed either through the incision or percutaneously if a bikini approach is used. Smooth wires can be used as definitive fixation in toddlers or as guides for drilling if cannulated screws are used. The choice of internal fixation should consider the child's size and age. For internal fixation of types I, II, and III fractures, smooth pins are appropriate in children under 3 years of age, cannulated 4.5-mm screws in children 3 to 8 years of age, and 6.5-mm cannulated screws in children over 8 years of age. For fixation of type IV fractures, simple screw fixation is inappropriate. A pediatric-size hip compression screw is appropriate in patients under 8 years of age, and an adult-size hip compression screw may be used in older children and adolescents. Because the femoral neck in children is denser and harder than the osteoporotic bone in elderly patients, predrilling and tapping are necessary before the insertion of screws.

Postoperative Fracture Care

Hip spica casting is used after internal fixation in most patients under 10 years of age. The cast should remain in place for 6 to 12 weeks depending on age. For children over 12 years of age, no postoperative cast is used, and early walking with crutches is encouraged, as in adults. For children 10 to 12 years of age, the use of a postoperative cast depends on the stability of fracture fixation and the patient's compliance. If either is in doubt, a single hip spica cast is used. Formal rehabilitation usually is unnecessary unless there is a severe persistent limp, which may be due to abductor weakness. Stiffness rarely is a problem in the absence of AVN.

Complications

Avascular Necrosis

Avascular necrosis is the most serious and frequent complication of hip fractures in children. Its overall prevalence is approximately 30% based on nine series in the literature (6,16,22). It is the primary cause of poor results after fractures of the hip in children. The risk of AVN is related to the extent of initial displacement of the fracture and to the damage to the blood supply at injury. The risk of AVN is highest after displaced type IB, type II, and type III fractures (16) (Fig. 21-13). Although prompt reduction of displaced fractures may be of some benefit, its worth has not been proven. Increased intraarticular pressure caused by fracture hematoma may be related to AVN after intracapsular fracture, and evacuation of this hemarthrosis may decrease the AVN rate (16,22,27). Aspirating the hematoma from the hip capsule may decrease the intracapsular pressure and increase blood flow to the femoral head (6,22) or may have no effect (16,21). If a child is going to have an anesthetic for treatment of a fracture, aspiration of the hematoma can easily be accomplished. Open reduction results in capsular evacuation at capsulotomy, or a small capsulotomy can be made if a straight lateral incision is used after unsuccessful closed reduction.

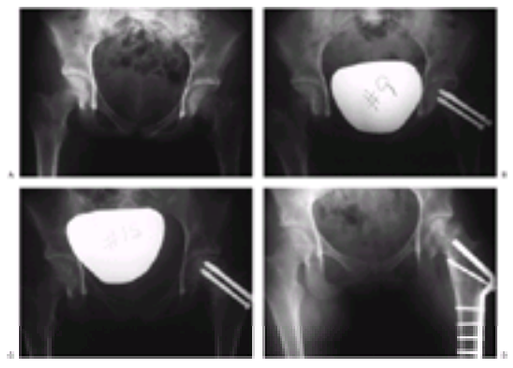

FIGURE 21-13. A: A 14-year-old girl with a type II fracture of the left femoral neck. **B:** After fixation with three cannulated screws. **C:** Seven months after injury. Avascular necrosis with collapse of the superolateral portion of the femoral head. **D:** After treatment with valgus osteotomy.

Avascular necrosis has been classified by Ratliff as follows: type I, involvement of the whole head; type II, partial involvement of the head; and type III, an area of AVN from the fracture line to the physis (24) (Fig. 21-14). Type I is the most severe and most common form and has the poorest prognosis. Type I probably results from damage to all of the lateral epiphyseal vessels, type II from localized damage to one or more of the lateral epiphyseal vessels near their insertion into the anterolateral aspect of the femoral head, and type III from damage to the superior metaphyseal vessels. Type III is rare but has a good prognosis (24).

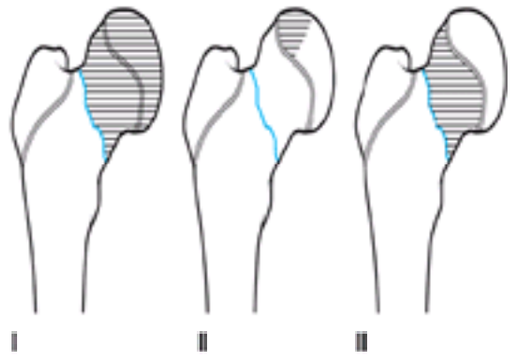

FIGURE 21-14. Three types of avascular necrosis. (Reprinted from Ratliff AHC. Fractures of the neck of the femur in children. *J Bone Joint Surg [Br]* 1962;44:528; with permission.)

Avascular necrosis causes pain and limitation of motion. As early as 6 weeks after injury, plain radiographs may reveal decreased density of the femoral head with widening of the joint space. Fragmentation and collapse of the femoral head occur late. Technetium bone scanning with pinhole collimation may show decreased uptake in the involved femoral head early in the course of AVN. With revascularization, changes may be variable. Signs and symptoms of AVN usually develop within the first year after injury, but sometimes as late as 2 years (16,25). Patients should be followed with plain radiographs for at least 2 years after fracture to rule out late onset of AVN. MRI reveals AVN within a few days of injury (see the subsection on Avascular Necrosis later under Hip Dislocations in Children). If MRI does not reveal AVN within 6 weeks of injury, it is unlikely to develop. The long-term results of AVN are poor in over 60% of patients (5,10,13). There is no clearly effective treatment for posttraumatic AVN in children (16,25). Older children (>10 years of age) tend to have worse outcomes than younger children. Ongoing investigative research includes the role of core decompression, vascularized fibular grafting, and the trapdoor procedure. Results of the procedures in few reported patients must ultimately be compared with the natural healing of untreated AVN. Remodeling can occur over many years and is more likely in younger children than in older ones. Degenerative arthrosis in older children is generally irreversible. Valgus intertrochanteric osteotomy may improve coxa vara and leg length discrepancy if there is reasonable congruence in adduction of the hip preoperatively (Fig. 21-15).

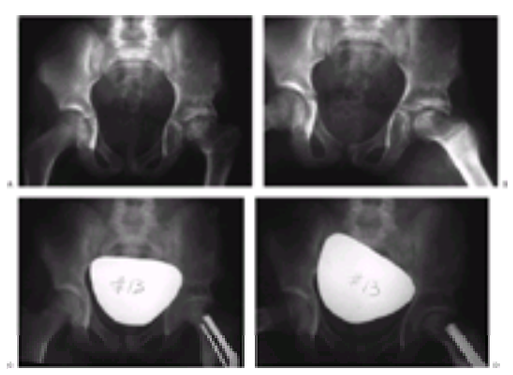

FIGURE 21-15. A: A girl 9 years and 4 months of age with Ratliff type I avascular necrosis of the femoral head. **B:** Lateral radiograph on the same date. The patient has had a previous acetabular osteotomy for containment. **C:** Two years after valgus osteotomy. **D:** Lateral radiograph on same date. Note that some remodeling of the femoral head has occurred.

Coxa Vara

The prevalence of coxa vara has been reported to be approximately 20% to 30% in nine series (16), although it is significantly lower in series in which internal fixation was used after reduction of displaced fractures (5). Coxa vara may be caused by malunion, AVN, premature physeal closure, or a combination of these problems (Fig. 21-16). Severe coxa vara raises the greater trochanter in relation to the femoral head, causing shortening of the extremity and mechanical disadvantage of the abductors. The result is an abductor lurch. If the child is over 8 years of age, the neck shaft angle is 110 degrees or less, and coxa vara has been persistent for more than 2 years, subtrochanteric valgus osteotomy may be considered to restore limb length and abductor strength (16).

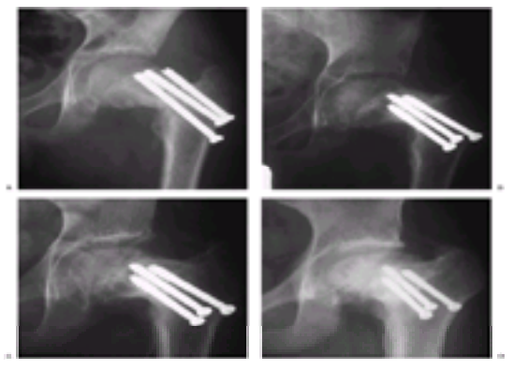

FIGURE 21-16. A: A 12-year-old boy with a type III left hip fracture. Poor pin placement and varus malposition are evident. **B:** The fracture united in mild varus after hardware revision. **C:** Fourteen months after injury. Collapse of the weight-bearing segment is evident (Ratliff type II avascular necrosis). **D:** Six years postinjury. Coxa breva and trochanteric overgrowth are seen secondary to avascular necrosis, malunion, and premature physeal closure.

Premature Physeal Closure

Premature physeal closure has occurred after approximately 28% of fractures (16). The risk of premature physeal closure increases with penetration by fixation devices or when AVN is present. It is most frequent in patients who have type II or III AVN (24,25) (Fig. 21-16).

The capital femoral physis contributes only 13% of the growth of the entire extremity and normally closes earlier than most of the other physes in the lower extremity. As a result, shortening due to premature physeal closure is not significant except in very young children (16,18). Treatment for leg length discrepancy is only indicated for significant discrepancy (2.5 cm or more projected at maturity) (16). Rarely, trochanteric epiphysiodesis may be used in progressive coxa vara.

Nonunion

Nonunion occurs infrequently, with an overall incidence of 7% of hip fractures in children (16). Nonunion is a complication of femoral neck fracture and is not generally seen after type I or type IV fractures. The primary cause of nonunion is failure to obtain or maintain an anatomic reduction (5,16). After femoral neck fracture in a child, pain should be gone and bridging new bone should be seen at the fracture site by 3 months after injury. A computed tomography (CT) scan may be helpful to look for bridging bone. If no or minimal healing is seen by 3 months, the diagnosis of nonunion is established. Nonunion should be treated operatively as soon as possible. Either rigid internal fixation or subtrochanteric valgus osteotomy should be performed to allow compression across the fracture (Fig. 21-17). Because the approach necessary for bone grafting is extensive, it should be reserved for recalcitrant cases. Internal fixation should extend across the site of the nonunion, and spica cast immobilization should be used in all but the most mature and cooperative adolescents.

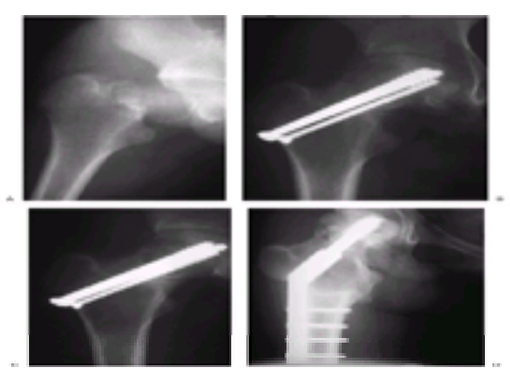

FIGURE 21-17. A: A 15-year-old girl with a markedly displaced type II femoral neck fracture. **B:** She underwent open reduction and internal fixation with two 7.3-mm cannulated screws and one 4.5-mm cannulated screw. Primary bone grafting of a large defect in the superior neck also was performed. **C:** Radiograph at 5 months showing a persistent fracture line. **D:** Six weeks after valgus intertrochanteric osteotomy. The fracture is healing.

Other Complications

Infection is uncommon after hip fractures in children. The reported incidence of 1% (5,19,24) is consistent with the expected infection rate in any closed fracture treated surgically with open reduction and internal fixation.

Chondrolysis is exceedingly rare and has been reported only in one series at a rate of 50% (13). Care must be taken to avoid persistent placement of hardware into the joint, which can cause this condition.

Stress Fractures

Stress fractures of the femoral neck are unusual in children. Only 13 cases have been reported in the English-language literature. The rarity of such fractures underscores the need for a high index of suspicion when a child has unexplained hip pain, because early diagnosis and treatment are essential to avoid complete fracture with displacement.

Mechanism

Stress fractures of the femoral neck in children result from repetitive cyclic loading of the hip, such as that produced by a new or increased activity. A recent increase in the repetitive activity is highly suggestive of the diagnosis. Long distance running, trampoline use, and scooter use are examples of such activities. Underlying metabolic disorders that weaken the bone may predispose to stress fracture. In adolescent female athletes, amenorrhea, anorexia nervosa, and osteoporosis have been implicated in the development of stress fractures of the femoral neck (14).

The usual presentation is that of progressive hip or groin pain with or without a limp. The pain may be perceived in the thigh or knee, and the pain may not be so severe as to preclude the offending activity. In the absence of displacement, examination typically reveals slight limitation of hip motion with increased pain, especially with internal rotation. Usually, plain radiographs reveal the fracture, but in the first 4 to 6 weeks after presentation, plain films may be negative. If there are no changes

or only linear sclerosis, bone scan will help identify the fracture. MRI has been documented as a sensitive test for undisplaced fractures of the femoral neck because impaction of the bony trabeculae appears on both T1 and T2 images as a linear black signal (21). If a sclerotic lesion is seen on plain radiographs, the differential diagnosis should include osteoid osteoma, chronic sclerosing osteomyelitis, bone infarct, and osteosarcoma. Other causes of hip pain, including slipped capital femoral epiphysis, Legg-Calve-Perthes disease, infection, avulsion injuries of the pelvis, and eosinophilic granuloma should be considered. Stress fracture unrelieved by rest or treatment may progress with activity to complete fracture with displacement (26). For this reason, prompt diagnosis and treatment are important.

Classification

Devas classified femoral neck stress fractures into two types: compression fractures and tension fractures. The compression type appears as reactive bone formation on the inferior cortex without cortical disruption. This type rarely becomes completely displaced but may collapse into a mild varus deformity (11). Compression types have recently been reported to progress to complete fracture without early treatment (26). The tension type is a transverse fracture line appearing on the superior portion of the femoral neck (11). This type is inherently unstable because the fracture line is perpendicular to the lines of tension and fractures heal best under compression. Tension stress fractures have not been reported in children but may occur in the skeletally mature teenager (26).

Treatment

Compression type fractures generally can be treated with a period of non–weight bearing on crutches. Partial weight bearing can be allowed at 6 weeks and full weight bearing at 12 weeks if pain is resolved and there is radiographic evidence of healing. In small or uncooperative children, spica casting may be necessary. Displacement into varus, however minimal, mandates internal fixation. Tension fractures are at high risk for displacement and should be treated with *in situ* compression fixation using cannulated screws (Fig. 21-18).

FIGURE 21-18. Treatment algorithm for hip pain in children and adolescents with a history and physical examination compatible with a stress fracture. (Reprinted from St. Pierre P, Staheli LT, Smith JB, et al. Femoral neck stress fractures in children and adolescents. *J Pediatr Orthop* 1995;15:470–473.

Complications

Coxa vara is the most common complication of untreated compression type fractures. Acute displacement of this type also has been described. Once displaced, the stress fracture is subject to all the complications of type II and type III displaced femoral neck fractures.

HIP DISLOCATIONS IN CHILDREN

Hip dislocations in children are relatively uncommon. They can occur in young children under age 5 as a result of seemingly trivial trauma (32,37,43,46,51). The child's acetabulum at that age is primarily soft pliable cartilage, and there is generalized ligamentous laxity that allows hip dislocation. Dislocations in older children usually require significant trauma because the acetabulum is bony and less resilient and the ligaments are stiffer (37,43,46,51). Most hip dislocations in children can be reduced easily and will heal satisfactorily (46,51), although the possibility of late problems exists (50). Difficulties after hip dislocation can include neurovascular injury, concomitant fracture, irreducibility, nonconcentric reduction, AVN, coxa magna, arthrosis, and recurrent dislocation.

Diagnosis

The mechanism of injury dictates the direction of hip dislocation. Posterior dislocations are the most common (32,50,51) and generally occur when a force is applied to the leg with the hip flexed. Anterior dislocations generally occur through a combination of external rotation and abduction.

The affected child has pain and inability to ambulate. Children sometimes feel the pain in the knee rather than in the hip (Fig. 21-19). The hallmark of the clinical diagnosis of dislocation of the hip is abnormal positioning of the limb, which is not seen in fracture of the femur. With posterior dislocation, the thigh tends to be flexed, adducted, and internally rotated. The greater trochanter is proximal to its normal position, and the femoral head is often palpable in the gluteal region. If the hip is dislocated anteriorly, the extremity is generally extended, abducted, and externally rotated. Posterior dislocations of the femoral head can damage the sciatic nerve, and function of this nerve should be specifically tested after injury. Anterior dislocations can damage the femoral neurovascular bundle, and femoral nerve function and perfusion of the limb should be assessed.

FIGURE 21-19. A: Not all children have severe pain with dislocation. An 8-year-old complained of pain and had difficulty walking after wrestling. Because of knee pain, a knee immobilizer was placed at an outside facility. **B:** The leg length discrepancy had gone unnoticed. **C:** The thigh was markedly shortened on the dislocated right side. **D:** Closed reduction was easily achieved under anesthesia. Thigh length was restored. She made an unremarkable recovery.

Plain radiographs usually confirm the diagnosis. Radiographs should be examined for fracture of the acetabular rim and proximal femur, which may be associated with dislocation. Ipsilateral femoral fracture has been described in a few patients (50). CT scanning is useful for evaluating the acetabulum and may be useful in localizing intraarticular bony fragments after reduction (44) (Fig. 21-20). The identification of nonbony fragments is difficult by CT without the use of concomitant arthrography (44). MRI is useful for evaluating soft tissues that may be interposed between the femoral head and acetabulum. MRI is especially helpful in nonconcentric reductions when the initial direction of dislocation is unknown. Soft tissue injury will dictate the surgical approach.

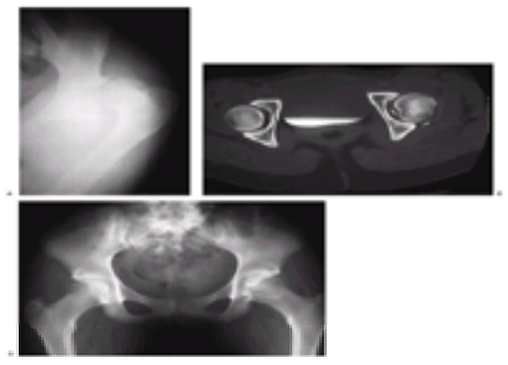

FIGURE 21-20. A: A girl 13 years and 11 months of age sustained a left posterior hip dislocation in a motor vehicle accident. **B:** Computed tomography scan after reduction showed intraarticular bony fragments. **C:** At open reduction and capsulorrhaphy, the bony fragments were removed. Suture anchors were used to reattach capsule to bone. Ten months postinjury, there is no sign of avascular necrosis. Heterotopic ossification is seen.

Spontaneous reduction may occur after hip dislocation (47), and the diagnosis will be missed if it is not considered. The presence of air in the hip joint, which may be detectable on CT scan of the pelvis, is evidence that a hip dislocation has occurred (36). Dislocation and spontaneous reduction with interposed tissue can occur and lead to late arthropathy if untreated (47). Widening of the joint space on plain radiographs suggests the diagnosis. In patients with hip pain, a history of trauma, and widening of the joint space, consideration should be given to MRI or arthrography to rule out dislocation with spontaneous relocation incarcerating soft tissue. If incarcerated soft tissues or osseous cartilage fragments are found, open reduction is required to obtain concentric reduction of the hip.

Classification

Hip dislocations in children generally are classified as anterior or posterior depending on where the femoral head lies after dislocation. Posterior dislocations are much more common than anterior dislocations and tend to occur as a result of an axial force on the femur applied toward the hip with the hip in flexion. Dashboard injury is a frequent cause. The limb assumes a position of shortening, internal rotation, and adduction (Fig. 21-21).

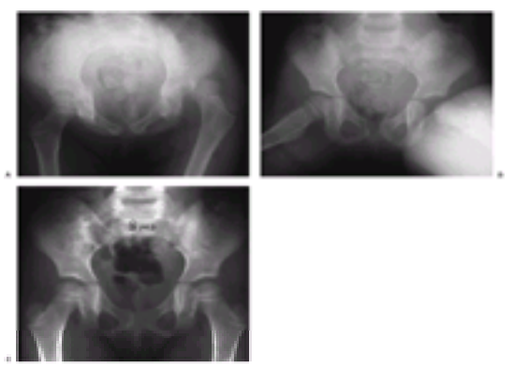

FIGURE 21-21. A: A girl 4 years and 7 months of age presented with a posterior dislocation of the left hip. **B:** Frog-leg lateral radiograph at injury is shown. **C:** Eight months after successful closed reduction, radiographic appearance is normal.

Anterior dislocations can occur superiorly or inferiorly and result from forced abduction and external rotation. In extension, the hip tends to dislocate anteriorly and superiorly. The limb appears shortened, the thigh is positioned in external rotation and extension and the femoral head is palpable in the groin. If the hip dislocates with the leg flexed, the femoral head tends to dislocate inferiorly. The leg is held in abduction, external rotation, and flexion, and the femoral head is palpable near the obturator foramen (Fig. 21-22).

FIGURE 21-22. A: An 11-year-old girl sustained anterior inferior dislocation of the hip. **B:** Immediate closed reduction was concentric.

Fracture–dislocation of the hip involving the femoral head or the acetabulum is much more unusual in children than in adults. Older adolescents may sustain adult-type fracture–dislocations of the hip, and these are best classified by the methods of Thompson and Epstein and of Pipkin.

Unusual Fracture Patterns Associated with Hip Dislocation

There are several pitfalls in the diagnosis of hip dislocations in children. It is always important to look for associated fractures. In older children, it is important to evaluate the posterior rim of the acetabulum after posterior dislocation to rule out fracture (Fig. 21-23). Fractures at other sites in the femur must be considered. It is important to obtain radiographs that show the entire femur to rule out ipsilateral fracture. Fractures of the femoral head are distinctly unusual in children, but separation of the capital femoral epiphysis and femoral neck fracture have been reported in association with dislocation of the hip.

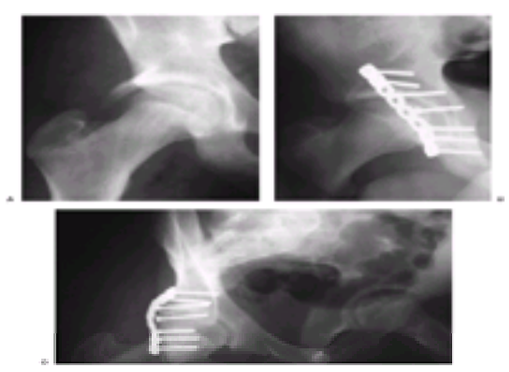

FIGURE 21-23. A: A 12-year-old boy was tackled from behind in football. The right hip was dislocated. Reduction was easily achieved, but the hip was unstable posteriorly as a result of fracture of the posterior rim of the acetabulum. **B:** The fracture and capsule were fixed via a posterior approach. **C:** Oblique view shows reconstitution of the posterior rim.

Another pitfall is the possibility of spontaneous relocation of a dislocation of the hip. Failure to appreciate the presence of hip dislocation may lead to inadequate treatment. If soft tissue has been interposed in the hip joint, chronic arthropathy may result. In a child with posttraumatic hip pain without obvious deformity, the possibility of dislocation–relocation must be considered. Radiographs should be obtained to rule out joint space widening and undisplaced fracture.

Another consideration after reduction of hip dislocations is interposed tissue. After reduction, hemarthrosis may initially cause the hip joint to appear slightly wide (49). With time, the hip should seat and the increased iliofemoral distance should subside (Fig. 21-24). If it fails to appear concentric after a few days, the possibility of interposed soft tissue must be considered (39,43,47,52).

FIGURE 21-24. A: A boy 10 years and 3 months of age sustained an anterior dislocation of the hip in football. **B:** The hip was easily reduced. The joint space was initially widened, probably due to hemarthrosis but normalized in a few days. **C:** At 4 months postinjury, the radiographic appearance was normal.

Surgical and Applied Anatomy

The hip joint is highly specialized. Although capable of bearing body weight, the hip still provides a tremendous range of motion, surpassed only by the range of motion of the shoulder. The architecture of the hip joint is highly specialized and is centered on the spherical femoral head, which resides in the bony acetabulum. The relatively narrow femoral neck increases the range of motion possible at the hip joint in flexion, extension, abduction, and circumduction. A larger diameter neck would impinge on the acetabular rim at extremes of motion.

Containment of the hip joint is assured by several factors. The bony socket physically constrains the femoral head and is further deepened by the surrounding fibrocartilaginous acetabu- lar labrum. In young children, the socket and labrum are largely cartilaginous and flexible. In older children, a larger proportion of the socket and rim is hard bone. Intimate contact between the cartilaginous surfaces of the round head and the socket, in the presence of joint fluid, provides a suction fit. In an intact joint, considerable force is required to disrupt this union. The strong fibrous joint capsule further contains the hip joint. The capsule is flexible enough to allow excellent range of motion, but secure enough to maintain the hip reduced except for extreme circumstances. The ligamentum teres does not provide any stability to the hip. The muscles that span the hip joint further provide active extrinsic stability by maintaining constant tension across the hip joint, which pushes the head into the acetabulum. These muscles, which provide the power for standing and locomotion, act around the fulcrum centered at the hip. Efficient transmission of muscle forces requires hip stability.

In order for the hip to dislocate, considerable force or mechanical advantage is required to overcome these restraints. The capsule must be torn or stretched. This will be deformed or disrupted at the time of dislocation. The ligamentum teres is likely to be torn, but this does not appear to result in any long-term sequelae.

Treatment Options

The immediate goal in the treatment of a dislocated hip is to obtain concentric reduction as soon as practically possible. Generally, closed reduction should be attempted initially. Successful closed reduction can be achieved with intravenous or intramuscular sedation in the emergency room in many patients (49). Complete muscle relaxation is required for others, and this is best provided in the operating room with a general anesthetic. Open reduction is indicated if closed reduction is unsuccessful or incomplete.

Several methods of closed reduction have been described. Stimson described a maneuver for reduction of posterior dislocation of the hip. It is also referred to as the gravity method of Stimson. In this method, the patient is placed prone with the lower limbs hanging over the edge of a table. Two persons are required to perform this maneuver. An assistant stabilizes the pelvis by applying pressure downward from above. The manipulator holds the affected knee and hip flexed 90 degrees and applies gentle downward pressure in an attempt to bring the posteriorly dislocated head over the posterior rim of the acetabulum and back into the socket. Gentle internal and external rotation may assist in the reduction.

Allis described a maneuver in which the patient is placed supine and the reducing surgeon stands above the patient. For this reason, either the patient must be placed on the floor or the surgeon must climb onto the operating table. The knee is flexed to relax the hamstrings. While an assistant stabilizes the pelvis, the surgeon applies longitudinal traction along the axis of the femur and gently manipulates the femoral head over the rim of the acetabulum and back into the socket.

Bigelow described a manipulative reduction in which the patient lies supine and an assistant provides downward pressure on the pelvis. The surgeon grasps the ipsilateral limb at the ankle with one hand, puts the opposite forearm behind the knee, and applies longitudinal traction in the axis of the femur. Internal rotation, adduction, and flexion of 90 degrees or more take the tension off the *Y* ligament and allow the surgeon to bring the femoral head to the level of the acetabulum, posteriorly. The femoral head is then levered into the acetabulum by abducting, externally rotating, and extending the hip. This is a more forceful maneuver than the others and may cause damage to the articular surfaces of hip or even fracture the femoral neck, so it should be used with great caution.

A technique called the reverse Bigelow maneuver can be used for anterior dislocation. In this technique, the hip is held in partial flexion and abduction. One of two reduction methods may be used. The first is a lifting method in which a firm jerk is applied to the thigh, which may result in reduction. If that fails, traction is applied in the line of the thigh and the hip is then sharply internally rotated, adducted, and extended. This manipulative method may result in reduction but also risks fracture of the femoral neck.

With any type of dislocation, traction along the axis of the thigh coupled with gentle manipulation of the hip often effects reduction after satisfactory relaxation of the surrounding muscles.

If satisfactory closed reduction cannot be obtained using reasonable measures, it is appropriate to proceed with open reduction to remove any obstructing soft tissues.

Surgical Procedures

Open reduction of a posterior dislocation should be performed through a posterolateral approach. The patient is positioned in the lateral decubitus position with the

dislocated side upward. The incision is centered on and just posterior to the greater trochanter and goes up into the buttock. Generally a straight incision can be made with the hip flexed approximately 90 degrees. Once the gluteal fascia lata is incised, the femoral head can be palpated beneath or within the substance of the gluteus maximus muscle. The fibers of the gluteus maximus can then be divided by blunt dissection, exposing the femoral head. The path of dislocation is followed through the short external rotator muscles and capsule down to the acetabulum. The sciatic nerve lies on the short external rotators and should be inspected. It may be necessary to detach the short external rotators in order to see inside the joint capsule.

Anterior dislocations should be approached through an anterior approach. This can be done through a bikini incision that uses the interval between sartorius and tensor fascia lata. The deep dissection follows the defect created by the femoral head down to the level of the acetabulum.

At the time of open reduction, the femoral head should be inspected for damage, scuffing, or fracturing. Before reduction, the acetabulum should be inspected and palpated for similar damage. Any intraarticular fragments should be removed. The labrum and capsule should be inspected for repairable tears. Labral fragments that cannot be securely replaced should be excised, but repair should be attempted. Frequently, the labrum or hip capsule is entrapped in the joint. The femoral head should be dislocated and any interposed soft tissue extracted. The labrum or capsule may be tied for ease in removal. Obstacles to reduction should be teased out of the way and the traumatic defect enlarged if necessary. The hip joint is then reduced under direct vision. Radiographs should be taken to confirm concentric reduction. If the joint appears slightly widened, repeat investigation must rule out interposed tissue. Slight widening may be due to fluid in the hip joint and this should settle out over the next few days. The capsule is repaired if possible. Closure is routine.

Open fractures should be treated with immediate irrigation and debridement. The surgical incision should incorporate and enlarge the traumatic wound. Inspection should proceed as detailed above. Capsular repair should be attempted if the hip joint is not contaminated. The wound should be left open or should be well drained to prevent invasive infection. As in all open fractures, intravenous antibiotics should be administered and repeat wound care performed as needed.

Postreduction Care

After reduction, treatment should be symptomatic. Generally a short period of recumbency, until the pain subsides, can be followed by return to ambulation with crutches if necessary. Bed rest, spica casting, skin traction, and non–weight bearing have not been proven to be beneficial (43,50,51). After open reduction with substantial capsulorrhaphy, immobilization or a spica cast may be indicated for a period of 6 weeks to allow capsular healing. Physical therapy is not routinely necessary. Return to full activities is encouraged.

Complications

Most hip dislocations in children will be treated and resolved without sequelae. Complications are rare.

Vascular Injury

Impingement on the femoral neurovascular bundle has been described after anterior hip dislocation in children, and this may occur in 25% of patients (50). If there is femoral artery occlusion, the hip should be relocated as soon as possible to remove the offending pressure from the femoral vessels. If relocation of the hip fails to restore perfusion, immediate exploration of the femoral vessels by a vascular surgeon is indicated.

Nerve Injury

The sciatic nerve may be damaged after a posterior dislocation of the hip in 2% to 13% of patients (35,50,51). Usually the nerve is directly compressed by the femoral head. The treatment is expedient relocation of the hip. Nerve function returns spontaneously in most patients (35,43). The nerve does not need to be explored unless open reduction is required for other reasons. If sciatic nerve function is demonstrated to be intact and is lost during the reduction maneuver, the nerve should be explored to ensure that it has not displaced into the joint. Other nerves around the hip joint rarely are injured at dislocation. Treatment is generally expectant unless laceration or incarceration is suspected. If so, exploration is indicated.

Avascular Necrosis

Avascular necrosis occurs in about 10% of hip dislocations in children (40,50). Prompt relocation of the hip, especially within 24 hours, may decrease the incidence of this complication (37,50). The risk of AVN is probably related to the severity of initial trauma (50). The cause is unknown. It may result from damage to ascending vessels or increased intracapsular pressure (49). The type of postreduction care has not been shown to influence the rate of AVN.

Early technetium bone scanning detects AVN as an area of decreased uptake. This is best seen on pinhole collimated images. After a few weeks, with the onset of revascularization and reossification, the uptake may appear normal or even increased.

Magnetic resonance imaging detects avascularity of the capital femoral epiphysis as loss of signal on T1-weighted images (48). Findings on T2-weighted images are abnormal but of variable signal intensity.

After hip dislocation, routine screening for AVN by bone scan or MRI cannot be strongly recommended for several reasons. Even if a perfusion defect is detected, there is no known treatment that will reverse it. Secondly, MRI may be falsely negative if performed within a few days of injury (48). Furthermore, hips with abnormal bone scan and MRI weeks after injury may not develop symptomatic AVN. In fact, a large proportion of perfusion defects seen on MRI spontaneously resolve after several months (41,48).

If hips are followed by serial radiographs for AVN, it is recommended that they be studied for at least 2 years after dislocation because radiographic changes may appear late (32). If MRI yields normal findings 4 to 6 weeks after injury, no further study is necessary because the risk of developing symptomatic AVN is miniscule (48).

If AVN develops, pain, loss of motion, and deformity of the femoral head are likely (31). AVN in a young child resembles Perthes' disease and may be treated like Perthes' disease (31). Priorities are to maintain mobility and containment of the femoral head to maximize congruity after resolution. AVN in older children should be treated as in adults and may require hip fusion, osteotomy, or reconstruction, as discussed following femoral neck fractures.

Recurrent Dislocation

Recurrence after traumatic hip dislocation is rare but occurs most frequently after posterior dislocation in children under 8 years of age (33,38) or in children with known hyperlaxity (Down's syndrome, Ehlers-Danlos disease). The incidence is estimated at no more than 3% (46). At surgical exploration of these hips, recurrence has been found to result from either laxity or a defect in the capsule (33). Recurrence can be quite disabling and in the long term may result in damage to the articular surfaces due to scuffing. Arthrography is recommended to identify a capsular defect or redundancy (33). Prolonged spica casting (at least 3 months) may stop recurrence (53), but exploration with capsulorrhaphy is a more rapid and reliable solution (33,38,53). In older children, recurrent dislocation can occur as a result of a bony defect in the posterior rim of the acetabulum similar to that in adults and may require posterior acetabular reconstruction.

Chondrolysis

Chondrolysis has been reported after hip dislocation in up to 6% of children (40,43,45,46) and probably occurs as a result of articular damage at the time of dislocation. Chondrolysis cannot be reversed by medical means, and treatment should be symptomatic. Antiinflammatory medicines and weight-relieving devices should be used as needed. If the joint fails to reconstitute, fusion or reconstruction should be considered.

Coxa Magna

Coxa magna occasionally occurs after hip dislocation. The reported incidence ranges from 0% to 47% (40,45,46). It is believed to occur as a result of posttraumatic

hyperemia (46). In most children, this condition is asymptomatic and does not require any treatment (46). There is no intervention that will prevent coxa magna.

Late Presentation

Not all hip dislocations in children cause severe or incapacitating symptoms. Ambulation may even be possible (Fig. 21-19). As a result, treatment may be delayed or the diagnosis missed, and shortening of the limb and contracture are well-established, making reduction difficult. Prolonged heavy traction will sometimes effect reduction (42). Preoperative traction, extensive soft tissue release, or primary femoral shortening should be considered if open reduction is required. Open reduction will likely be difficult and will not always be successful. Even if the hip stays reduced, progressive arthropathy may lead to a stiff and painful hip. The likelihood of a good result decreases with the duration of dislocation.

Interposed Soft Tissue

Interposed tissues may cause nonconcentric reduction or result in complete failure of closed reduction. Muscle, bone, articular cartilage and labrum have been implicated (34,37,39,43,52). CT arthrography or MRI provides information on obstacles to complete reduction and the direction of the initial dislocation (39,52). Open reduction generally is necessary to clear impeding tissues from the joint (34,39,43,46,52). Untreated nonconcentric reduction may lead to permanent degenerative arthropathy (47).

FEMORAL SHAFT FRACTURES

JAMES R. KASSER
JAMES H. BEATY

Femoral shaft fractures, including subtrochanteric and supracondylar fractures, represent approximately 1.6% of all bony injuries in children. The male:female ratio of femoral fracture is 2.6:1 with a bimodal distribution (10,12,17). The first peak occurs in early childhood, the second in mid-adolescence. A review of the Maryland Hospital Discharge Database by Hinton et al. (14) confirmed the bimodal distribution with peak incidences at 2 and 12 years of age. The annual rate of femoral shaft fracture in children was 1 per 5,000. In Switzerland, the incidence of pediatric femoral shaft fracture is 1 per 2,000 per year (5).

Although femoral shaft fractures are dramatic and disabling injuries, both to the patient and the family, most unite rapidly without significant complications or sequelae. Not many years ago, traction and casting were standard treatment or all femoral shaft fractures in children, and femoral fractures ranked high in duration of hospitalization for a single diagnosis (13). More recently, a variety of therapeutic alternatives, such as external fixation, compression plating, and flexible or locked intramedullary nailing, have become available to help decrease impairment, increase convenience, and decrease cost of care.

ANATOMY

Children's bone changes from primarily weak woven bone to stronger lamellar bone through remodeling during childhood (26). Strength also is increased by a change in geometry (Fig. 22-1). The increasing diameter and area of bone result in a markedly increased area moment of inertia, leading to marked increase in strength. This progressive increase in bone strength helps explain the bimodal distribution of femoral fractures. In early childhood, the femur is relatively weak and breaks under load conditions reached in normal play. In adolescence, high-velocity trauma is required to reach the stresses necessary for fracture.

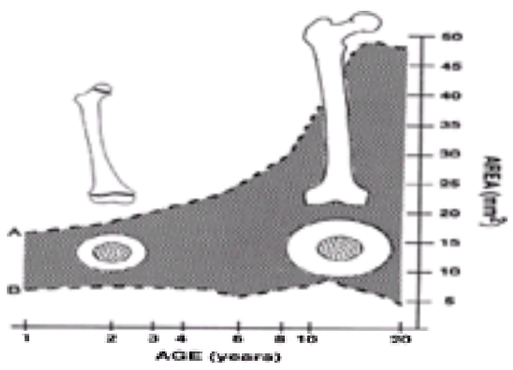

FIGURE 22-1. The shaded area represents cortical thickness by age group. This rapid increase in cortical thickness may contribute to the diminishing incidence of femoral fractures during late childhood. (Redrawn from Netter FH. *The Ciba collection of medical illustrations.* Vol. 8. Musculoskeletal system. Part I. Anatomy, physiology, and metabolic disorders. Summit, NJ: Ciba-Geigy, 1987; with permission.)

MECHANISM OF INJURY

The etiology of femoral fractures in children varies with the age of the child. In children younger than walking age, up to 80% of femoral fractures may be caused by abuse (1,11,27); in children under 4 years of age, up to 30% of femoral fractures may be caused by abuse. Blakemore et al. (3) reported that in 42 children 1 to 5 years of age who had femoral fractures, a history of a fall was present in 34. Although the history was considered suspicious for intentional injury in 14 patients, only 1 patient had a documented abuse-related injury. Older children are unlikely to have a femoral shaft fracture caused by abuse, because their bone is sufficiently strong to tolerate forceful blows or is able to resist torque without fracture. In older children, femoral fractures are most likely to be caused by high-energy injuries, such as motor vehicle accidents, which account for over 90% of femoral fractures in this age group (9,12,20). Gunshot wounds are an increasingly common cause of femoral fractures.

Pathologic femoral fractures are relatively rare in children, but they may occur because of generalized osteopenia in infants or young children with osteogenesis imperfecta. A femoral fracture in a young child with no history suggestive of abuse or significant trauma should suggest the possibility of osteogenesis imperfecta (19). Radiologic evaluation is often insufficient to diagnose osteogenesis imperfecta, and skin biopsy, collagen analysis, and bone biopsy may be required to make a definitive diagnosis. Generalized osteopenia also may accompany neurologic diseases, such as cerebral palsy or myelomeningocele, leading to fracture with minor trauma in osteopenic bone (10,16,25). Pathologic fractures may occur in patients with neoplasms, most often benign lesions such as nonossifying fibroma, aneurysmal bone cyst, unicameral cyst, or eosinophilic granuloma. Pathologic femoral fractures rarely occur in patients with osteosarcoma or Ewing's sarcoma (Fig. 22-2).

FIGURE 22-2. A: Femoral fracture through a poorly demarcated, mixed, osteoblastic, osteolytic lesion—an osteosarcoma. **B:** Sclerotic borders of this lesion in the distal femur are typical of a pathologic fracture through a nonossifying fibroma.

Stress fractures may occur in any location in the femoral shaft (6,15,22). Most occur in adolescents involved in sports activity, such as football, lacrosse, and track. Although uncommon (4% of all stress fractures in children), femoral shaft stress fracture should be considered in a child with thigh pain because an unrecognized stress fracture may progress to a displaced femoral fracture. As the number of young children involved in athletics increases, stress fractures will become more frequent (4). Bilateral femoral stress fractures were reported in a rollerblade enthusiast, reflecting a departure from the traditional sports recognized as being related to this injury (28).

An unusual femoral fracture reported in infants is a greenstick fracture of the medial distal femoral metaphysis that occurs when the parent falls on a child who is straddling the parent's hip. It is important to recognize this fracture because it occurs in infants at an age when abuse is the leading cause of femoral fracture. The fracture is caused by bending of the femur, which produces a compression injury to the medial cortex. This injury is not consistent with abuse and may confirm a parent's description of a fall as the cause.

DIAGNOSIS

Most patients with femoral shaft fractures are unable to walk and are in extreme pain with an obvious fracture. The diagnosis is more difficult in patients with multiple trauma or head injury, and in nonambulatory, severely disabled children. A physical examination usually is sufficient to document the presence of a femoral fracture. Swelling, instability, crepitance, and tenderness usually are present. In patients lacking sensation (myelomeningocele), swelling and redness may simulate infection.

The entire child must be carefully examined. Hypotension rarely results from an isolated femoral fracture. Waddell's triad of femoral fracture, intraabdominal or intrathoracic injury, and head injury are associated with high-velocity automobile injuries. Multiple trauma with head injury may dictate a change in management of the femoral shaft fracture (20,23).

The hemodynamic significance of femoral fracture has been studied recently by two groups (8,21). Hematocrit levels below 30% rarely occurred in the absence of multiple system injury. Hemodynamic instability was always associated with multisystem injury. A declining hematocrit should not be attributed to closed femoral fracture until other sources of blood loss have been eliminated (8,21).

RADIOGRAPHIC FINDINGS

Radiographic evaluation should include the entire femur, as well as the hip and knee, because injury of the adjacent joints is common. Femoral shaft fractures may occur with intertrochanteric fractures of the hip, fractures of the femoral neck, and dislocation of the upper end of the femur (2,7). Distal femoral fractures may be associated with physeal injury about the knee, knee ligament injury, meniscal tears (29), and tibial fractures (18).

Plain radiographs generally are sufficient for making the diagnosis. Bone scanning and magnetic resonance imaging (MRI) occasionally may be helpful in the diagnosis of small buckle fractures in limping children or stress fractures but usually are not necessary. Comminution or nondisplaced “butterfly” fragments, second fractures, joint dislocations, and pathologic lesions should be considered.

Roach and Hoschl (24) described diffuse uptake of radionuclide tracer throughout an entire femoral shaft in an 18-month-old child. This is significant because it demonstrates that radionuclide uptake may not be limited to the isolated area of the fracture but may involve the entire shaft of the bone in a very young child. A similar finding has been shown in plastic deformation of the forearm in young children.

CLASSIFICATION

Femoral fractures are classified as (a) transverse, spiral, or oblique; (b) comminuted or noncomminuted; and (c) open or closed. Open fractures are classified according to Gustilo's system (13). The presence or absence of vascular and neurologic injury is documented and is part of the description of the fracture. The most common femoral fracture in children (over 50%) is a simple transverse, closed, noncomminuted injury.

The level of the fracture (Fig. 22-3) leads to characteristic displacement of the fragments based on the attached muscles. With subtrochanteric fractures, the proximal fragment lies in abduction, flexion, and external rotation. The pull of the gastrocnemius on the distal fragment in a supracondylar fracture produces an extension deformity, which may make the femur difficult to align.

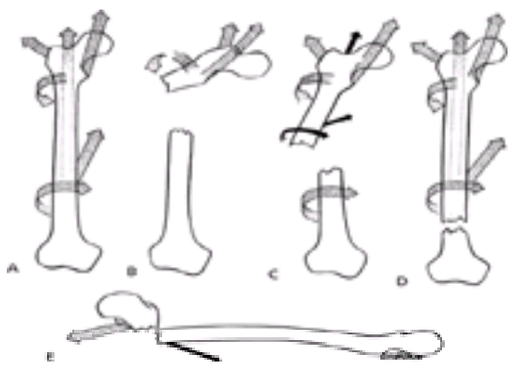

FIGURE 22-3. The relationship of fracture level and position of the proximal fragment. **A:** In the resting unfractured state, the position of the femur is relatively neutral due to balanced muscle pull. **B:** In proximal shaft fractures the proximal fragment assumes a position of flexion (iliopsoas), abduction (abductor muscle group), and lateral rotation (short external rotators). **C:** In mid-shaft fractures the effect is less extreme because there is compensation by the adductors and extensor attachments on the proximal fragment. **D:** Distal shaft fractures produce little alteration in the proximal fragment position because most muscles are attached to the same fragment providing balance. **E:** Supracondylar fractures often assume a position of hyperextension of the distal fragment due to the pull of the gastrocnemius.

TREATMENT

Treatment of femoral shaft fractures in children is age dependent, with considerable overlap between age groups (Table 22-1). The child's size and bone age also must be considered, as well as the cause of the injury. Whether the femoral fracture is an isolated injury or part of polytrauma influences treatment choices. Economic concerns, the family's ability to care for a child in a spica cast or external fixator, and the advantages and disadvantages of any operative procedure also are important factors. In adolescents, the psychologic implications of treatment should be considered. Prolonged hospitalization alters the ado- lescent's self-image and interrupts social and educational development. Especially in older children, the disadvantages of nonoperative treatment—time in traction or a cast, economic and social impact on the family—must be carefully weighed against the potential complications of a surgical procedure: infection, refracture after removal of fixation, neurologic injury, limb shortening or overgrowth, and avascular necrosis of the femoral head.

Age	Treatment
Birth to 24 mo	Pavlik harness (newborn to 6 mo) Immediate spica cast Traction → spica cast
24 mo to 5 yr	Immediate spica cast Traction → spica cast External fixation (rare) Flexible intramedullary rod (rare)
6–11 yr	Traction → spica cast Flexible intramedullary rod Compression plate External fixation
12 yr to maturity	Flexible intramedullary rod Compression plate Locked intramedullary rod External fixation

Treatment choices are influenced by polytrauma (vs. an isolated femoral shaft fracture) or open fractures with soft tissue trauma.

TABLE 22-1. TREATMENT OPTIONS FOR FEMORAL SHAFT FRACTURES IN CHILDREN AND ADOLESCENTS

The comparative economics of nonoperative and operative treatment of femoral shaft fractures have been evaluated by several researchers, but no clear consensus has been reached. Reeves et al. (57) reported that the cost of nonoperative treatment was 46% higher than that of operative treatment, even considering the necessity for a second surgical procedure for implant removal. Newton and Mubarak (53) analyzed the financial aspects of femoral shaft fracture treatment in 58 children and adolescents and determined that total charges were lowest for those treated with early spica casting and highest for those treated with skeletal traction or intramedullary nailing. Similarly, Coyte et al. (35) found the cost of surgical treatment (external fixation) to exceed that of early spica casting in all cases. Stans and Morrissy (65), in evaluating the cost of treating femoral fractures in children 6 to 16 years of age, found that all surgical treatments cost approximately the same. This cost was three times that of early spica cast management and essentially equivalent to traction, followed by spica cast. In all cost studies related to femoral fracture, the determinants of increased cost are (a) cost of fixation device, (b) cost of the operating room, and (c) cost of hospital days for recovery. Nork and Hoffinger (55) showed that hospital profit was highest in the traction group, despite charges being equivalent to the surgical group, because the actual hospital resources required were significantly less. In a study by Yandow et al. (70) comparing cost of traction to immediate spica in young children, equivalent results occurred with 83% greater charges in the traction group. Certainly, cost is a factor, but it should not be the overriding consideration in discussions of treatment options with the family.

In infants, newborn to 6 months of age, femoral fractures usually are reasonably stable because of thick periosteum. For stable proximal or mid-shaft femoral fractures, simple splinting or a Pavlik harness is all that is required. For unstable fractures in infancy, a simple splint can be tried, but usually the femur cannot be adequately treated in this manner. We have found that a Pavlik harness with a wrap around the thigh, as described by Wilkins, is beneficial. For femoral fractures with excessive shortening (>1–2 cm) or angulation (>30 degrees), spica casting may be required. Traction rarely is necessary in this age group.

In children 6 months to 6 years of age, immediate or early spica casting is the treatment of choice for femoral fractures with less than 2 cm of initial shortening (Fig. 22-4). Femoral fractures with more than 2 cm of initial shortening or marked instability and fractures that cannot be reduced with immediate spica casting require 3 to 10 days of skin or skeletal traction. Skeletal stabilization by external fixation generally is reserved for children with open fractures or multiple trauma. Intramedullary rodding is used in children with metabolic bone disease that predisposes to fracture or after multiple fractures, such as in osteogenesis imperfecta. Larger children in whom reduction cannot be maintained with a spica cast occasionally may benefit from flexible intramedullary rodding or traction.

FIGURE 22-4. A: Three weeks after immediate spica casting of isolated femoral shaft fracture in 3-year-old child. **B:** Three months after injury, fracture is healed in good position.

Treatment of femoral fractures in children 6 to 11 years of age is highly controversial. For stable, minimally displaced fractures, immediate spica casting usually produces satisfactory results; however, in large children with unstable comminuted fractures, traction followed by application of a cast brace or spica cast may be necessary. Because of the cost and the social problems that may accompany management of a child in a spica cast, enthusiasm for skeletal fixation has increased in recent years. Skeletal fixation frequently is used in children with multiple trauma, head injury, vascular compromise, floating knee injuries, or multiple fractures. Treatment options should be discussed with the parents before choosing the method of fracture fixation, even for isolated fractures.

Enthusiasm for treatment that decreases hospital stay has led to the use of external fixation and flexible intramedullary nails in children 6 years of age through maturity. Compression plating has been reintroduced as a technique with low risks and significant benefit in the management of pediatric femoral fractures. Even home traction has been recommended as a low-cost alternative for management with satisfactory outcome. In older children and adolescents, antegrade rodding has been recommended as a standard procedure, but the recognized risks of avascular necrosis and growth disturbance have led to limited use of this as a standard technique.

Pavlik Harness

In a newborn with a femoral fracture, one is faced with a very small child, a thick periosteum, and a remarkable remodeling potential. Stannard, Christensen, and Wilkins (64) popularized the use of the Pavlik harness for the treatment of this fracture. This treatment is ideal for a proximal or mid-shaft femur fracture that occurs as a birth-related injury. In a newborn infant in whom a femoral fracture is noted in the intensive care unit or nursery, simple padding or immobilization of the femoral with a soft splint can be tried. For a stable fracture, this approach may be sufficient and will allow intravenous access to the feet if needed. If the fracture remains angulated, a Pavlik harness can be applied with the hip in moderate flexion and abduction. This often helps align the distal fragment with the proximal fragment (Fig. 22-5). Reduction can be aided by a wrap around the thigh if greater stability is needed. The reduction is easily evaluated in the sagittal plane with a lateral radiograph, but evaluation of angulation in the coronal plane (varus-valgus) is more difficult because of hyperflexion. Stannard et al. (64) reported acceptable alignment in all patients with less than 1 cm of shortening. In fractures occurring in infancy, management may include evaluation for underlying metabolic bone abnormality or abuse. Once these have been ruled out, a stable fracture should be managed using a simple splint. Unstable fractures should be managed using a Pavlik harness and a small wrap around the thigh, with immediate spica or traction reserved for the rare fracture that cannot be managed with simpler means because of failure to align the

fracture or excessive shortening.

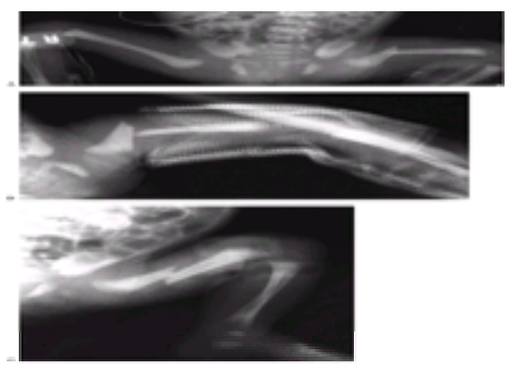

FIGURE 22-5. A: This infant had a birth-related left femoral fracture. **B:** An anterior-posterior splint was used but ended at the fracture site, only increasing the angulation. **C:** A Pavlik harness reduces the fracture by flexing the distal fragment.

Immediate Spica Casting

Immediate spica casting, popularized by Irani et al. (46) and Staheli et al. (62), is indicated for isolated femoral shaft fractures in children under 6 years of age unless (a) shortening of more than 2 cm is present, (b) massive swelling of the thigh is noted, or (c) associated injuries are present. Its primary advantages are simplicity, low cost, and generally good results based on leg length equality, healing time, and motion (38,45).

Hughes et al. (42) evaluated 23 children ranging in age from 2 through 10 years who had femoral fractures treated with immediate spica casting to determine the impact of treatment on the patients and their families. The greatest problems encountered by the family in caring for a child in a spica cast were transportation, cast intolerance by the child, and keeping the child clean. Although most children did not attend school while in the cast, no child was required to repeat a grade and no permanent psychological effects were reported by the parents. The researchers found that overall treatment in a spica cast was much easier for families of preschool children than for those with school-age children: healing time was faster, younger children were lighter, time until independent walking was shorter, and families of younger children had more preexisting care arrangements for them. They recommended counseling and planning with the family before cast application if possible.

Illgen et al. (44), in a series of 114 isolated femoral fractures in children under 6 years of age, found that 90 degree/90 degree (90/90) spica casting was successful in 86% without cast change or wedging, based on tolerance of shortening less than 1.5 cm and angulation less than 10 degrees. Of the 20 patients requiring spica change, only 2 healed with unacceptable position (>2 cm of leg length discrepancy). One of these overgrew by 1.5 cm and the other was lost to follow-up. Illgen et al. used an immediate spica regardless of initial shortening and placed the child in traction only if unacceptable shortening occurred. Shortening requiring spica cast change was associated with a knee flexion angle of less than 50 degrees. Similar excellent results have been reported by Czertak and Hennrikus (36) using the 90/90 spica cast.

Thompson et al. (67) described the telescope test in which patients were examined with fluoroscopy at the time of reduction and casting. If more than 3 cm of shortening could be demonstrated with gentle axial compression, traction was used rather than immediate spica casting. By using the telescope test, these researchers decreased unacceptable results (>2.5 cm of shortening) from 18% to 5%.

Martinez et al. (47) reported excessive shortening and angular deformity in 26 of 51 patients after immediate spica casting, especially in comminuted fractures. Although shortening and angulation can occur in a spica cast, excessive deformity can be detected with weekly radiologic and clinical evaluations during the first 2 to 3 weeks after injury. Minimal shortening is acceptable but should not exceed 2 cm (Fig. 22-6). This is best measured on a lateral radiograph taken through the cast. If follow-up radiographs reveal significant varus (>10 degrees) or anterior angulation (>30 degrees), the cast may be wedged. However, Weiss et al. (69) noted that wedging of 90/90 spica casts can cause peroneal nerve palsy, especially during correction of valgus angulation. For unacceptable position, the fracture can be manipulated and a new cast applied, or the cast can be removed and the patient placed in traction to regain or maintain length (Fig. 22-7). Angular deformity of up to 15 degrees in the coronal plane and up to 30 degrees in the sagittal plane may be acceptable, depending on the patient's age (Table 22-2). Finally, if shortening exceeds 2 cm, traction or an external fixator can be used.

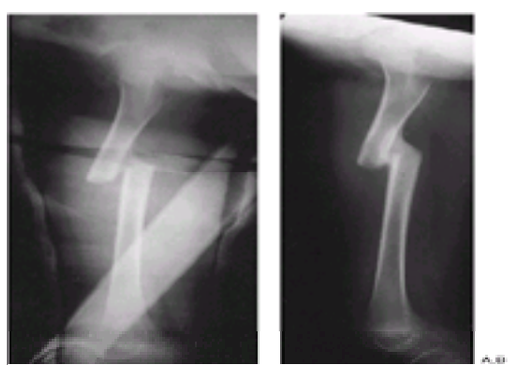

FIGURE 22-6. A: Immediate spica casting of isolated femoral shaft fracture in an 8-year-old child; shortening on initial radiograph was 2 cm. **B:** Four months after injury, shortening of 2 cm is seen with this healed fracture.

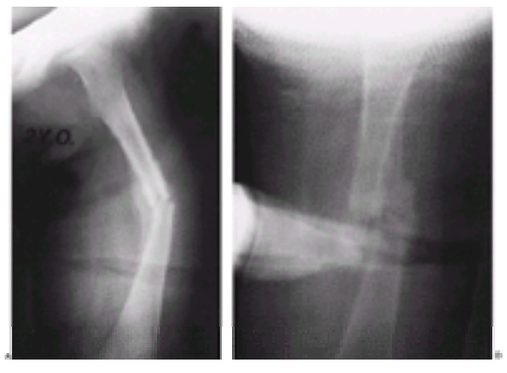

FIGURE 22-7. A: Unacceptable position of fracture in spica cast in a 2-year-old child. **B:** With manipulation, application of a new spica cast, and cast wedging, this angulation is corrected.

Age	Varus/ Valgus (degrees)	Anterior/ Posterior (degrees)	Shortening (mm)
Birth to 2 yr	30	30	15
2–5 yr	15	20	20
6–10 yr	10	15	15
11 yr to maturity	5	10	10

TABLE 22-2. ACCEPTABLE ANGULATION

Shortening and angulation occur most often in fractures associated with polytrauma and those with loss of the periosteal sleeve (9,10). Fry et al. (10) found that 50% (12 of 23) of closed femoral shaft fractures caused by high-energy trauma in children under 10 years of age required repeat reduction or other treatment to correct excessive shortening or angulation that occurred after initial reduction; only 8% (2 of 24) of low-energy fractures required repeat closed reduction.

The position of the hips and knees in the spica cast is controversial. Spica cast application with the hip and knee extended and the bottom of the foot cut out to prevent excessive shortening has been described (49). Varying the amounts of hip and knee flexion in the spica cast based on the position of the fracture also has been recommended: the more proximal the fracture, the more flexed the hip should be (62).

An alternative to the standard hip-knee extended spica is the 90/90 spica cast or the sitting spica cast (48,50). A sitting spica cast (Fig. 22-8), with the hips and knees set in about 90 degrees of flexion, is the easiest and perhaps the most effective cast for femoral fractures in preschool-aged children, unless the fracture cannot be maintained in this position. The child is placed in a sitting position with the legs abducted about 30 degrees on either side. The synthetic material used for the cast gives it sufficient strength so that no bar is required between the legs. This not only allows the child to be carried on the parent's hip but also aids in toiletry needs, making bedpans unnecessary. Also, the child can sit upright during the day and can attend school in a wheelchair.

FIGURE 22-8. A 90 degree/90 degree spica cast allows a small child to be carried on the parent's hip. The child can be placed in a sitting position in a chair or on the toilet in this type of cast.

Spica Cast Application: Technique

The child is taken to the operating room or plaster room where anesthesia or sedation is administered. A short leg cast is applied with the foot in neutral position (Fig. 22-9A). Extra padding and a felt pad are placed in the area of the popliteal fossa. The cast is then extended to a long leg cast with the knee held in 90 degrees of flexion (Fig. 22-9B). Because most diaphyseal fractures tend to fall into varus angulation while in a spica cast, a valgus mold is necessary (Fig. 22-9C). The patient is then placed on a spica table, supporting the weight of the legs with manual traction, and the remainder of the cast is applied with the hips in 90 degrees of flexion and 30 degrees of abduction, holding the fracture out to length (Fig. 22-9D). The leg should be placed in 15 degrees of external rotation to align the distal fragment with the external rotation of the proximal fragment. After the spica cast is in place, anteroposterior (AP) and lateral radiographs are obtained to ensure that length and angular and rotational alignment are maintained.

FIGURE 22-9. Application of a 90 degree/90 degree spica cast. **A:** Generous padding is applied over the foot, and a pad is placed on the popliteal fossa to prevent injury to the peroneal nerve and popliteal vessels. **B:** A long leg cast is applied with the knee flexed 90 degrees. **C:** A mold is placed over the apex of the fracture, generally correcting a varus deformity into slight valgus. **D:** Using a standard spica table, a one-and-a-half spica cast is applied with the hip flexed 90 degrees and abducted 30 degrees.

Gortex liners can be used to decrease the skin problems of diaper rash and superficial infection. This has been beneficial and has justified the cost of a Gortex liner. If angulation of more than acceptable limits occurs, the cast should be changed with manipulation in the operating room. Casts can be wedged for less than 15 degrees of angulation. If shortening of more than 2 cm is documented, the child should be treated either with cast change, traction, or conversion to external fixation with lengthening. When conversion to external fixation is required, we recommend osteoclasis at the time of the application of the external fixator with slow lengthening over a period of several weeks (1 mm per day) to reestablish acceptable length (Fig. 22-10).

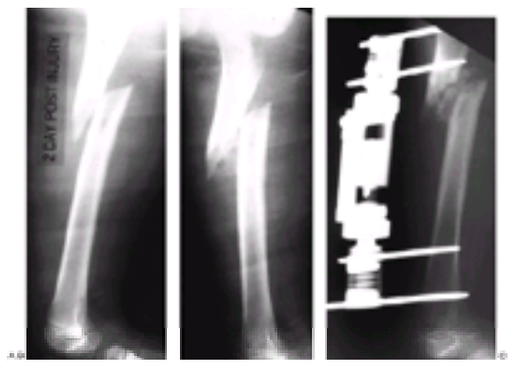

FIGURE 22-10. A: This 8-year-old child with a femur fracture was treated with an immediate spica cast. **B:** After 3 weeks of immobilization, unacceptable shortening (2.2 cm) was noted. **C:** Closed osteoclysis and lengthening with an external fixation device resolved the problem with length achieved by callus distraction.

Generally, the spica cast is worn for 4 to 8 weeks, depending on the age of the child and the severity of the soft tissue damage accompanying the fracture. After the cast has been removed, management should include skin care in young children and crutch-assisted or walker-assisted ambulation in older children. Ambulation is accomplished with weight bearing as tolerated. Stiff knees and weak hamstrings and quadriceps should be identified after the child begins to walk, and a physical therapy program should be started if needed. Long-term follow-up for leg length evaluation, range of motion, and quadriceps weakness should be maintained.

An alternative to extend the use of early spica cast treatment into an older age group and unstable fractures is the incorporation of a supracondylar traction pin into the spica cast. In a series reported by Sahin et al. (60), this technique was demonstrated to be effective in children 1 to 10 years of age. The clinicians accepted no more than 15 mm of shortening at the time of spica cast application, and obtained satisfactory results in all patients.

Traction and Casting

Since as early as the eighteenth century, traction has been used for management of femoral fractures. The French used the Hippocratic method of traction and coaptation splinting in extension. The English, influenced by Pott (56), treated patients on their side with the hip and knee flexed. In 1861, Buck (32) introduced simple horizontal traction. Vertical overhead traction with the hip flexed 90 degrees and the knee straight was introduced by Bryant in 1873 (31,33), but this often resulted in vascular insufficiency (Fig. 22-11) (54), and it is now rarely used for treatment of femoral fractures, except occasionally in infants under 2 years of age and weighing less than 20 pounds. However, even in this infantile age group, split Russell's traction (58) or immediate spica casting is preferable. Modified Bryant's traction, in which the knee is flexed 45 degrees, increases the safety of overhead skin traction (39). Gallows traction also has been used (41).

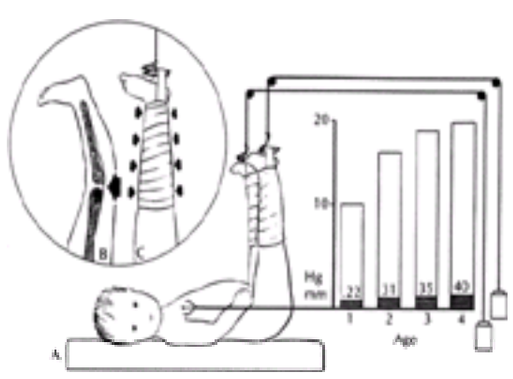

FIGURE 22-11. Adverse effect on limb circulation by overhead traction as detailed by Nicholson. **A:** Incremental increase in hydrostatic pressure necessary for limb perfusion due to increasing limb length. **B:** Hyperextension of the knee occurs if the infant moves to the foot of the bed, stretching the popliteal artery. **C:** Extrinsic compression of wrapping to maintain traction tapes aggravates the problem. Any or all of these factors contribute to the risk of overhead traction. (Redrawn from Nicholson J, Foster R, Heath R. Bryant's traction: a provocative cause of circulatory complications. *JAMA* 1955;157:4118; with permission.)

The indications for skin or skeletal traction include (a) unstable femoral fracture in a child under 6 years of age with more than 2 to 3 cm of shortening, (b) femoral fracture that fails to maintain proper length and alignment in a spica cast in a child under 6 years of age, and (c) femoral fracture in a child 6 to 11 years of age, without multiple fractures, head trauma, or severe soft tissue or vascular injuries, who is able to cooperate with a period of bed rest and spica cast immobilization and whose family prefers no surgery. The limit of skin traction is the interface between skin and tape or skin and foam traction boot. Skin complications, such as slough and blistering, usually occur when more than 5 pounds of traction is applied. When more than 5 pounds of traction is required, or simply for ease in patient management, skeletal traction can be used to maintain alignment (30).

Skeletal traction also can be used in adolescents with comminuted proximal femoral shaft and intertrochanteric fractures in whom secure fixation cannot be obtained without risk of vascular compromise to the proximal femur. In general, however, skeletal traction is not recommended for children 12 years of age or older because of significant incidences of shortening and angular malunion.

The distal femur is the location of choice for a traction pin (30,37,59). Although proximal tibial traction pins have been recommended by some clinicians (43), growth arrest in the proximal tibial physis and subsequent recurvatum deformity have been associated with their use (Fig. 22-12). Also, knee ligament and meniscal injuries that sometimes accompany femoral fractures are aggravated by the chronic pull of traction across the knee. The rare indication for a tibial traction pin is a child in whom fracture configuration or skin problems prevent placement of a femoral traction wire and in whom no knee injury is present.

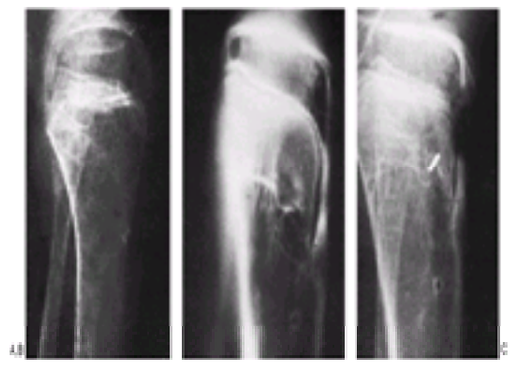

FIGURE 22-12. Tibial epiphyseal injury in association with tibial pin traction treatment for a femoral fracture. A 14-year-old boy sustained a femoral fracture that was treated by tibial skeletal traction. Two years later the fracture was well healed but 2.5 cm short. A recurvatum deformity of the same side was apparent. **A:** An apparent fusion of the tibial tubercle. **B:** The bridge was confirmed by tomography. **C:** Bridge resection was performed with free fat interposition. A marker was placed to facilitate subsequent evaluation of growth. A tibial pin, if used, should be inserted posterior to the anterior aspect of the tibial tubercle.

In a group of 45 patients with femoral fractures, Stanitski et al. (63) calculated the radiation dose received by the patient while in traction. The average dose before casting was 0.699 rad. Although this is a significant radiation exposure, it was not excessive compared to that received by patients managed with other methods of treatment, particularly when intraoperative exposures are considered. However, radiation exposure during treatment must be considered.

Femoral Traction Pin Insertion: Technique

After preparation of the thigh circumferentially from the knee to the mid-thigh, the limb is draped in a sterile manner. The knee is held in the position in which it will remain during traction; that is, if 90/90 traction is being used, the traction pin should be inserted with the knee bent 90 degrees (Fig. 22-13A). The patient either should be sedated and the wound treated with a local anesthetic or general anesthesia should be given before the traction pin is inserted (Fig. 22-13B). The location of pin insertion is one finger breadth above the patella with the knee extended or just above the flare of the distal femur (Fig. 22-13C). A small puncture wound is made over the medial side of the femur (Fig. 22-13D). A medial-to-lateral approach is used so that the traction pin does not migrate into the area of the femoral artery that runs through Hunter's canal on the medial side of the femur. A traction pin between 3/32 inch and 1/8 inch is chosen depending on the size of the child. The pin is placed parallel to the joint surface (30) to help maintain alignment while in traction. After the pin protrudes through the lateral cortex of the femur, a small incision is made over the tip of the pin. The pin is then driven far enough through the skin to allow fixation with a traction bow (Fig. 22-13F). If 90/90 traction is used, a short leg cast is laced with a ring through its mid-portion to support the leg. Alternatively, a sling to support the calf may be used. If a sling is used, heelcord stretching should be performed while in traction.

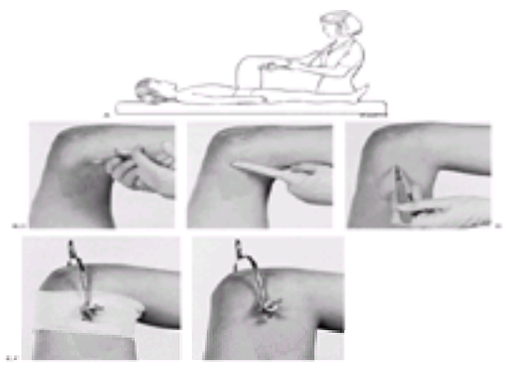

FIGURE 22-13. Insertion of femoral skeletal traction pin. **A:** The limb is held in the 90 degree/90 degree position by an assistant. **B:** A site just superior to the adductor tubercle is surgically prepared, both medially and laterally. **C:** Local anesthesia is applied in the skin and periosteum on both sides of the limb. **D:** The skin is penetrated with a scalpel. **E:** A threaded Steinmann pin is introduced at the level 1 cm proximal to the adductor tubercle. **F:** Dressing and traction bow in place.

After the skeletal traction pin has been placed in the distal femur, traction is applied in a 90/90 position (the hip and knee flexed 90 degrees) (Fig. 22-14) or in an oblique position (the hip flexed 20–60 degrees). If the oblique position is chosen, a Thomas splint or sling is necessary to support the leg. The fracture may be allowed to begin healing in traction, and radiographs should be obtained once or twice a week to monitor alignment and length. In a child under 10 years of age, the ideal fracture position in traction should be up to 1 cm of shortening and slight valgus alignment to counteract the tendency to fall into varus in the cast and the eventual overgrowth that may occur (average 0.9 cm). If this method is used for adolescents (11 years or older), normal length should be maintained.

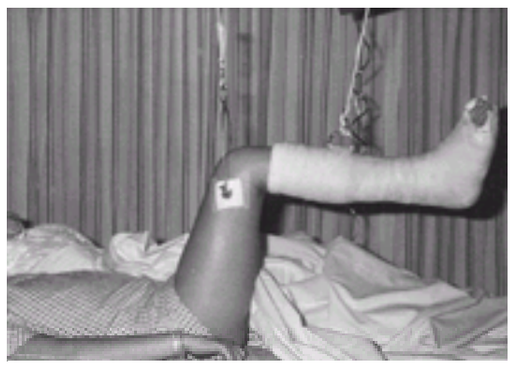

FIGURE 22-14. In 90 degree/90 degree traction, a femoral pin is used and the lower leg and foot are supported with a short leg cast or a sling.

Technique Tips

Threaded pins, although more difficult to remove, are preferable to smooth pins because of their secure fixation within the bone without side-to-side movement; however, they have a slightly higher incidence of skin interface complications.

Aronson et al. (30) found that obliquely placed femoral traction pins were associated with an increased incidence of varus or valgus angulation. Pins for skeletal traction should be placed parallel to the axis of the knee joint, and in children over 11 years of age the fracture should be reduced without shortening.

Postoperative Care

Prolonged traction of 3 weeks or more followed by knee immobilization in a spica cast is well tolerated by young children. In children over 12 years of age or in children weighing over 100 pounds, maintaining the knee in 90 degrees of flexion for a prolonged period of time may lead to knee stiffness and a difficult period of rehabilitation (43). Cast braces, either with a traction pin or after a period of traction, allow early knee motion. Polycentric hinges, fiberglass rods, or hinge cables should be used to prevent malalignment between the cast brace and the knee that restricts motion.

Alternatives for treatment after traction application include (a) a 2- to 3-week period of traction until callus formation is apparent and the fracture is stable before pin removal and application of a spica cast or cast brace (32,34,49,52,61); (b) early incorporation of a traction pin into a spica cast; and (c) incorporation of a traction pin into a cast brace with intermittent traction to maintain length until callus formation is present (40). Each of these methods has advantages, costs, and risks, and a clear “best method” cannot be identified.

Results of Traction and Casting

In a study by Gross et al. (40), 72 children with femoral fractures were treated with early cast brace/traction management. In this technique, a traction pin is placed in the distal femur and then incorporated in a cast brace. The traction pin is left long enough to be used for maintaining traction while the patient is in the cast brace or traction is applied directly to the cast. The patient is allowed to ambulate in the cast brace starting 3 days after application. Radiographs are taken of the fracture in the cast brace to document that excessive shortening is not occurring. The patient then is returned to traction in the cast brace until satisfactory callus is present to prevent shortening or angular deformity with weight bearing. The technique was not effective in older adolescents with mid-shaft fractures but achieved excellent results in children 5 to 12 years of age. The average hospital stay was 17 days.

Complications of Traction and Casting

Comparative studies and retrospective reviews have demonstrated unsatisfactory results in a small, yet significant, percentage of patients treated with skeletal traction (43,57,97,102). It is clear that traction remains an excellent method of treatment of femoral shaft fractures in children under 12 years of age, but other methods are easier or more convenient with the same outcome.

External Fixation

External fixation of femoral shaft fractures offers a fast convenient method to align and hold the fractured femur. It is the method of choice when severe soft tissue injury is present and may be considered in any patient where traditional closed methods of management are not appropriate (104). In head-injured or multiply injured patients and those with open fractures, external fixation offers an excellent method of management. Wagner was an early advocate of monolateral frame fixation and developed an external fixation and lengthening device. Aronson and Tursky (71) in 1987 reported their early experience with 44 femoral fractures treated with primary external fixation and early weight bearing. Most patients returned to school by 4 weeks after fracture and had full knee motion by 6 weeks after the fixator was removed. In this early study, end-on alignment was the goal and overgrowth was minimal. Following early enthusiasm for the use of external devices, the 1990s saw some waning interest in their use because of complications with pin track infections, scarring, and refracture. With other methods of skeletal fixation such as flexible intramedullary rodding , the use of external fixation devices for primary treatment of femoral fractures has declined.

Bar-On et al. (72) compared external fixation with flexible intramedullary rodding in a prospective randomized study. They found that the early postoperative course was similar but that the time to return to school and to resume full activity was less with intramedullary fixation. Muscle strength was better in the flexible intramedullary fixation group at 14 months after fracture. Parental satisfaction was also significantly better in the flexible intramedullary rodding group. Bar-On et al. (72) recommended that external fixation be reserved for open or severely comminuted fractures.

Fixator Design

The design of external fixator frames is important in determining the end result. In general, circular fixation devices are rarely, if ever, indicated for femoral fractures. External fixation should be performed using a monolateral or cantelever type system. The monolateral devices are of two types (Fig. 22-15). The AO system, in which pins can be placed at any point along a bar with a special clamp holding the pins at a right angle to the bar, has been in common use (Fig. 22-16). The advantage of this system is that the stability of fixation is increased if the two pins on each side of the fracture are spread widely with one pin close to the fracture and one quite distant from it. A second longitudinal rod can be added to this system to increase its rigidity. A second type of external fixation system has pin clamps at the end of a telescopic tube. The pin clamps provide easy application, but the stability of the fixation device is decreased because the pins are widely separated from the fracture. The pin clamps may be constrained to rotation only (Wagner) or attached with a universal joint to the barrel of the device (Orthofix) (Fig. 22-17). The telescoping barrel provides lengthening or dynamization, and the universal joints provide adjustment. Sola, Schoenecker, and Gordon (119) found that results were improved significantly by adding an auxiliary pin to the standard Orthofix type frame, providing better fixation near the fracture site. They reviewed 38 fractures in 37 children 5 to 18 years of age. Six of 22 femurs treated without auxiliary pins required remanipulations for loss of reduction, whereas only 1 of the 16 frames with an auxiliary pin required remanipulation. Although these researchers provided auxiliary pin fixation by attaching a pin to the barrel of the external fixator with methylmethacrylate, other methods of intermediate pin fixation are available at this time.

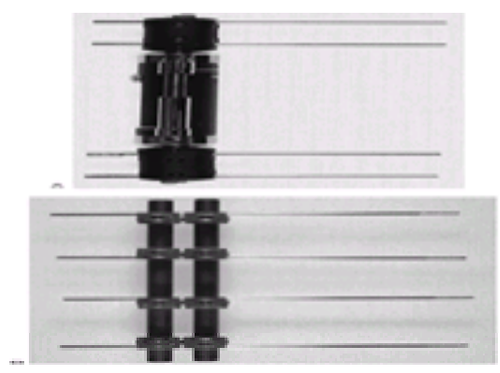

FIGURE 22-15. Monolateral external fixation devices have **(A)** fixed end clamps with universal joints (Orthofix type) or **(B)** pins that can be secured at various positions on a simple rod that positions close to and distant from the fracture site (AO), achieving greater stability of fracture fixation.

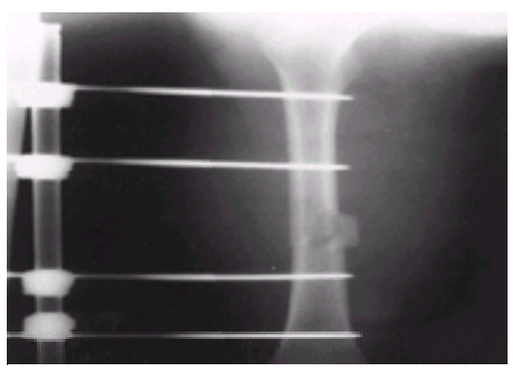

FIGURE 22-16. Application of AO external fixator. The most proximal and distal pins are placed a few centimeters from the fracture site to improve frame stability.

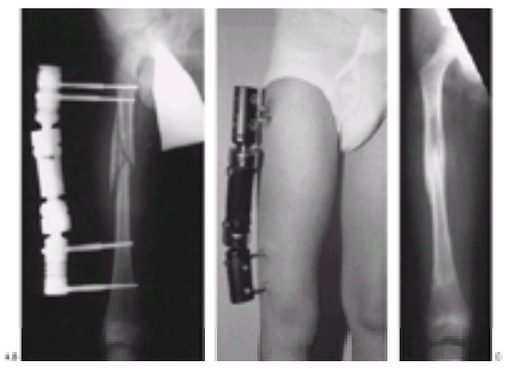

FIGURE 22-17. A: Two weeks after unilateral external fixation of a comminuted femoral shaft fracture in an 8-year-old child. **B:** Clinical photograph of external fixator in place. **C:** Four months after fracture, immediately after removal of the external fixator, fracture has healed in good position.

A new variation of external fixation device, the Orthofix device, uses a bar with pin clamps and intermediary fixation. The sliding clamps allow auxiliary pin fixation near the fracture site, as well as distal pin fixation. Dynamization is allowed with this device as well. Series reporting experience with this treatment of femoral

fractures are not yet available, and because enthusiasm currently is shifting toward flexible intermedullary rodding, large series treated with this device may not be routinely reported.

Another technical development in external fixation has been the use of hydroxyapatite-coated pins. The pin–bone interface was a problem with loosening with some devices. The strength of the pin–bone interface with hydroxyapatite-coated pins appears to be somewhat better, although large series with this device have not yet been reported.

Price and others have anecdotally recommended application of a frame with a more flexible construct. Pins are more closely clustered and placed farther from the fracture site, and the frame itself is placed more laterally away from the femur, which does not need to be anatomically reduced.

Unilateral Frame Application: Technique

Preoperative planning is mandatory. Fracture lines indicative of comminution must be recognized. There must be room between the trochanteric and the distal femoral physes for the device chosen.

After appropriate anesthesia, the leg is prepared and the patient is placed on a radiolucent table or a fracture table, depending on the preference of the surgeon and the size of the child. Either the fracture table or Fluoro table works well. We make the decision based on the size of the patient and the ease with which reduction can be obtained, as well as the help available. In general, a fracture table facilitates reduction and application of the external fixator.

First we try to reduce the fracture both in length and alignment. If the fracture is open, it should be irrigated and debrided before application of the external fixation device. With the fracture maximally aligned, fixation is begun. The minimal and maximal length constraints characteristic of all external fixation systems must be kept in mind. The angular adjustment intrinsic to the fixation device needs to be determined. If a universal joint at the end of the Orthofix device only allows for 15 degrees of angular correction, one cannot expect 40 degrees of adjustment after application of the device. Rotation in general is constrained with all external fixation systems once the first pins are placed. That is, if parallel pins are placed with the fracture in 40 degrees of malrotation, a 40 degree malalignment will exist. Rotational correction must be obtained before placing the pins in the proximal and distal shafts of the femur.

Application of the fixator is similar no matter what device is chosen (Fig. 22-18). One pin is placed proximally in the shaft, and another pin is placed distally perpendicular to the long axis of the shaft. Alignment is always to the long axis of the shaft rather than to the joint surface. Rotation should be checked before the second pin is placed because it constrains rotation but not angulation or length. After pins are correctly placed, all fixation nuts are secured and sterile dressings are applied to pins.

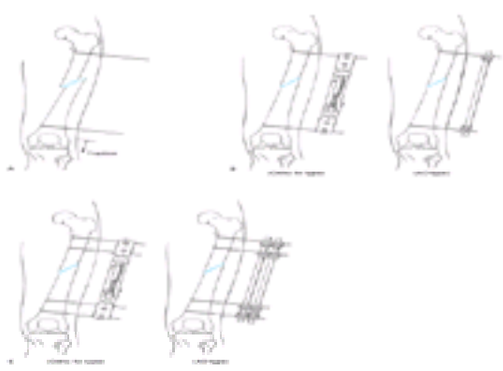

FIGURE 22-18. Technique of external fixation. **A:** With traction applied and provisional reduction of the fracture obtained, the proximal and distal pins are placed perpendicular to the long axis of the bone, being certain that rotational alignment is satisfactory. **B:** Provisional fixation is obtained by attaching the external fixation device with single pins in place. **C:** The second pin is added proximal and distal, providing secure fixation.

Technique Tips

Pin sizes vary with manufacturers, as do drill sizes. In general the pins are placed through predrilled holes to avoid thermal necrosis of bone. Sharp drills should be used. The manufacturer's recommendation for drill and screw sizes should be checked before starting the procedure. At least two pins should be placed proximally and two distally. An intermediate pin may be beneficial.

Postoperative Care

Pin care is critical, and avoiding tension at the skin–pin interface is beneficial. Large pin sites are cleaned with peroxide daily. Showering is allowed once the wound is stable and there is no communication between the pin and the fracture hematoma. Antibiotics are used liberally because pin site infections are common and easily resolved with antibiotic treatment, usually cephalosporin. The external fixation device remains until the fracture is healed. Dynamization is performed before removal, allowing the bone to be stressed to full body weight. The device should not be removed until three or four cortices demonstrate bridging bone continuous on AP and lateral radiographs, typically 3 to 4 months after injury.

Complications of External Fixation

The most common complication of external fixation is pin track infection, which has been reported to occur in up to 72% of patients (111). This complication generally is mild and easily treated with oral antibiotics and local pin site care. Sola et al. (119) reported a decreased number of pin track infections after changing their pin care protocol from cleansing with peroxide to simply having the patient shower daily. Superficial infections should be treated aggressively with pin track releases and antibiotics. Deep infections are rare, but if present, drainage and antibiotic therapy are mandatory. Any skin tenting over the pins should be released at the time of application or at follow-up.

In a study of complications of external fixators for femoral fractures, Gregory et al. (91) reported a 30% major complication rate and a 107% minor complication rate. Among the major complications were five refractures or fractures through pin sites. Skaggs et al. (117), in reviewing the use of external fixation devices for femoral fractures at Los Angeles Children's Hospital, found a 12% rate of secondary fractures in 66 patients. Multivariate linear regression analysis showed no correlation between the incidence of refracture and the fracture pattern, percentage of bone contact after fixator application, type of external fixator used, or dynamization of the fracture. A statistically significant association was found beteen the number of cortices demonstrating bridging callus on both the AP and lateral views at the time of fixator removal and refracture. Fractures with fewer than three cortices with bridging callus had a 33% risk of refracture, whereas those with three or four cortices showing bridging callus had only a 4% rate of refracture. Other reports in the literature with smaller numbers, but still substantial experience, document refracture rates as high as 20% with more significant complications (84,92,99,113,115,117).

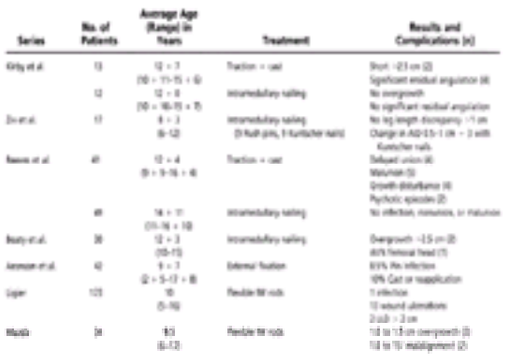
In 1997, in a follow-up of the original article by Aronson and Tursky (71), Blasier et al. (76) reported 139 femoral fractures treated with external fixation between 1984 and 1993. The average age at treatment was 8.9 years, and the average time to healing was 11.4 weeks. Only 18 patients had definitive radiographic follow-up, with 15 patients demonstrating overgrowth averaging 8.7 mm. In the series of Blasier et al., pin track infection was common, and there was a 2% incidence of fracture after removal of the device.

Although joint stiffness has been noted in some patients treated with external fixation, it is relatively uncommon in children with femoral fractures unless major soft tissue injury is present (85).

Intramedullary Fixation

Since the introduction of intramedullary fixation of femoral fractures, enthusiasm for this form of internal fixation has varied but generally increased. Although a number of techniques have been described over the years, the modifications introduced by Winquist et al. (126) and Ligier et al. (105) were significant. In the 1970s, Winquist et al. (126) developed techniques for closed intramedullary rodding and indirect methods of fixation with reamed and locked fixation devices. In the 1970s and 1980s, Ligier et al. (105) introduced a dual flexible rod system that provided internal fixation of fractures with an indirect reduction method leading to less fracture stability but accelerated healing.

By the late 1980s, techniques of antegrade rodding had been refined, and enthusiasm grew for using this procedure in younger patients. The publication by Ligier et al. (105) in 1988 of a group of patients treated with flexible intramedullary rodding seemed contrary to the tendencies toward more rigid and more secure fixation. With reports of avascular necrosis of the proximal femur by Beaty (73) and others beginning in the early 1990s, flexible rodding (either antegrade or retrograde) for femoral fractures has grown in favor over locked intramedullary nails. The relative safety of the technique combined with its simplicity have led to its greater acceptance. Comparative studies by Reeves et al. (57) and Kirby et al. (102) as well as retrospective reviews of traction and casting, suggest that femoral fractures in adolescents are better treated with intramedullary fixation (40,80,84, 89,97,102,105,122,126,128) than with traditional traction and casting (Table 22-3).



Series	No. of Patients	Average Age (Range) in Years	Treatment	Results and Complications (n)
Kirby et al.	13	12 + 7 (10 + 11-15 + 6)	Traction + cast	Short <2.5 cm (2) Significant residual angulation (4)
	12	12 + 8 (10 + 10-15 + 7)	Intramedullary nailing	No overgrowth No significant residual angulation
	13	9 + 3 (6-12)	Intramedullary nailing (3 Rush pins, 1 Kuntscher nail)	No leg length discrepancy >1 cm Change in ADI 0.5-1 cm > 2 with Kuntscher nails
Reeves et al.	41	12 + 4 (9 + 9-16 + 4)	Traction + cast	Delayed union (4) Malunion (5) Growth disturbance (4) Psychotic episodes (2)
	49	14 + 1 (11-16 + 10)	Intramedullary nailing	No infection, nonunion, or malunion

TABLE 22-3. RESULTS OF TREATMENT OF FEMORAL SHAFT FRACTURES IN ADOLESCENTS

Flexible Intramedullary Rod Fixation

Flexible intramedullary nailing of pediatric femoral fracture either with stainless steel (Ender) or titanium (Nancy) rods can be performed either antegrade or retrograde. The benefit of elastic internal fixation is that a healthy environment for fracture healing with some motion leads to increased callus formation. Properly used, flexible intramedullary rods provide sufficient stability in the fracture so that a cast is not needed, but they lack the rigidity of an external fixation device, which inhibits fracture healing. This lack of rigidity and inability to lock the flexible rods may predispose to deformity either with angular or axial deviation in unstable fractures. The lack of rigidity also may create an environment in which muscle spasm and postoperative pain become more of a problem than with traditional rigid intramedullary fixation devices.

Elastic nailing of femoral fractures carries with it a few controversies: (a) straight versus bent rods, (b) titanium versus steel, (c) immobilization versus no immobilization postoperatively, and (d) antegrade versus retrograde insertion.

Mechanical testing of femoral fracture fixation systems showed that the greatest rigidity is provided by an external fixation device and the least by flexible intramedullary rodding (B. Snyder, personal communication). Stainless-steel rods are stronger than titanium in bending tests. Stainless-steel rods have greater intrinsic strength and therefore are not as dependent on the opposing bend technique. The elastic nature of the titanium rods allows axial deviation with return to normal alignment. In 56 patients with femoral fractures stabilized with flexible titanium rods, Flynn (87) reported 4 with angular malalignment of more than 10 degrees. These angular deviations tended to occur in fractures toward the end of the bone rather than in diaphyseal fractures.

There is no series comparing titanium to stainless-steel rods in a randomized fashion, but both types of rods have high success rates when judged by rates of malunion, which are less than 5% in most series. Gregory et al. (92) compared the use of flexible rods (Ender) with rigid antegrade nailing and found that both techniques produced satisfactory outcomes but flexible rods required much less operative and fluoroscopy time with similar patient satisfaction and outcome.

Bourdelet (97) compared retrograde and antegrade (ascending and descending) flexible intramedullary rodding in a group of 73 femoral fractures. Treatment was not randomized, but the subtrochanteric insertion site was preferred because there were fewer knee symptoms and earlier patient independence with the antegrade insertion technique. The insertion site used by Bourdelet was just below the level of the trochanter proximally with a standard medial and lateral distal insertion site. An antegrade transtrochanteric approach was recommended by Carey and Calpin (82), who reported excellent results in 25 patients without growth arrest of the upper femur and no avascular necrosis. Satisfactory alignment and fracture healing were obtained in all patients.

Retrograde intramedullary rodding with Ender rods or titanium rods has been reported by Ligier et al. (105), Mann et al. (106), Heinrich et al. (95), Herscovici et al. (98), and others (82,100,109). Heinrich et al. (95) recommended a 3.5-mm Ender nail in children 6 to 10 years of age and a 4.0-mm nail in children over 10 years of age. Ligier and Metaizeau (105) used titanium rods ranging from 3 to 4 mm inserted primarily in a retrograde fashion. Heinrich et al. recommended flexible intramedullary nails for fixation of diaphyseal femoral fractures in children with multiple system injury, head injury, spasticity, or multiple long-bone fractures. After early success in this selected group of patients, they expanded the use of flexible intramedullary rods to include isolated fractures in any patient over 6 years of age with a femoral fracture and parents willing to accept the risk of the surgical treatment. External immobilization with casts was rapidly discontinued in their series.

Fixation with Flexible Intramedullary Rods: Technique

Preoperative Planning

Patients in whom this method of fixation is appropriate are those between the ages of 5 and 16 with noncomminuted femoral fractures. With unstable femoral fracture patterns, considerable experience is required to achieve satisfactory outcome with flexible intramedullary nailing. Postoperative cast immobilization or postoperative use of an external support device to supplement the internal flexible rod has been of value in unstable fractures.

In evaluating the radiograph, fracture lines that propagate beyond the obvious fracture should be noted (Fig. 22-19). Involvement of the distal metaphyseal region is a relative contraindication to this technique. The width of the canal is measured at the narrowest point in the diaphysis on both the AP and lateral view (Fig. 22-20), and this number is divided by 2. This represents the maximal diameter rod that can be used, and generally a rod at least 0.5 to 1 mm smaller than this radius should be used. Therefore, if the medullary canal measures 8 mm, a 3.0- to 3.5-mm rod probably should be used.

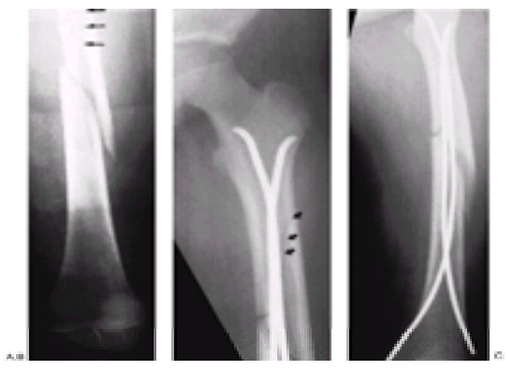

FIGURE 22-19. A: The initial anteroposterior radiography of the 8-year-old child shows an oblique femoral fracture, but there is also a nondisplaced butterfly fragment (*arrows*). **B:** Flexible rods may be used in such a case, being careful not to displace the fragment and **(C)** burying the rods deep in the proximal femoral metaphysis to provide satisfactory fixation.

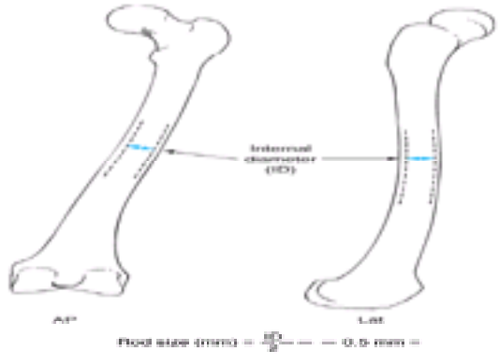

FIGURE 22-20. To determine the size of titanium flexible rods to be used, measure the diaphyseal internal diameter on both the anteroposterior and lateral views, divide by 2, and subtract 0.5 mm. Use the smaller of the number obtained from the anteroposterior and lateral views. AO rods range from 2.0 to 4.0 mm in diameter, in 0.5-mm increments.

The procedure can be performed either on a fracture table or on a fluoroscopy table, but reduction must be documented with fluoroscopy before insertion of the rods. The procedure is described with the use of a fracture table, but in small children (<80 pounds), we find this easier to do without a fracture table. The procedure has been described with AO titanium elastic rods, but other devices are available and can be used with slight variations in procedure.

Rod Bending

The distance from the top of the inserted rod to the level of the fracture site is measured, and a gentle 30-degree bend is placed in the nail with the apex at what will be the level of the fracture. Next the rod tip is bent to facilitate placement, and to allow the rod to bounce off the opposite cortex at the time of insertion. This also facilitates spreading of the rods in the proximal metaphysis, either in the femoral neck or in the greater trochanter. Some surgeons prefer to avoid the second bend at the level of the fracture and use these rods as straight rods, much as in traditional intramedullary fixation. Although not consistent with the recommendation of Lascombes, satisfactory results have been achieved with this technique, especially with the stronger stainless-steel rods. The rods used generally are 3.0 to 4.0 mm in diameter, depending on the size of the bone and the child. Two rods of the same size should be used, and varying sizes should be avoided.

The technique of elastic fixation of femoral fractures as described by Ligier et al. (105) requires that a bend be placed in the mid-portion of the rod at the level of the fracture site. This produces a spring effect (Fig. 22-21) that adds to the rigidity of the fracture fixation. The spread of the rods in opposite directions provides a “prestressed” fixation, which increases resistance to bending. The opposite bends of the two rods at the level of the fracture significantly increase resistance to varus and valgus stress, as well as torsion.

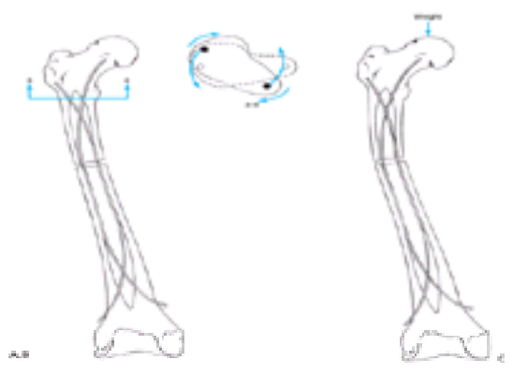

FIGURE 22-21. A: Stability from flexible rods comes from proper technique. **B:** Torsional stability results from divergence of the rods in the metaphysis. **C:** Resistance to sagittal and coronal bending results from spreading of the prebent rods through the diaphysis, as well as the size and material properties of the rods. Elastic rods return to their predetermined alignment when loaded unless plastic deformation occurs.

Retrograde Insertion

After the child is placed on the fracture table, the leg is prepared and draped with the thigh (hip to knee) exposed (Fig. 22-22). The image intensifier is used to localize the placement of skin incisions by viewing the distal femur in the AP and lateral planes. Incisions are made on the medial and lateral side distal to the insertion site in the bone. The top of the 3-cm incision should be at or just distal to the level of the insertion site, which is about 2.5 to 3 cm proximal to the distal femoral physis (Fig. 22-23). A 4.5-mm drill bit or awl is used to make a cortical hole in the bone.

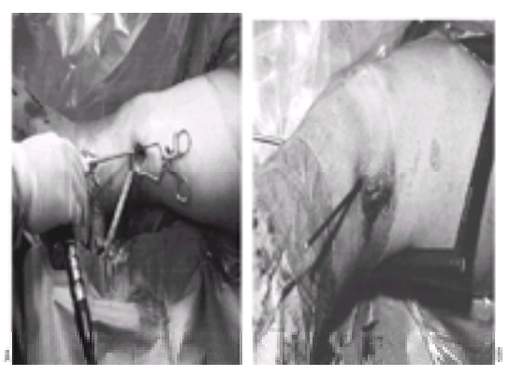

FIGURE 22-22. A: In children weighing more than 80 pounds, the fracture table may be used to provide traction and reduction of a femoral fracture. The leg is draped free, allowing medial and lateral rods to be placed. **B:** A radiolucent reduction bar may be beneficial to reduce angular deformity when passing the rods.

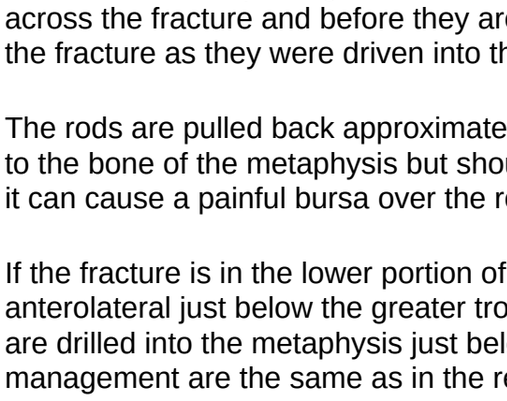

FIGURE 22-23. Retrograde insertion. **A:** The rods are inserted through a distal cortical hole 4.5 mm in diameter made either with a drill or an awl 2.5 cm above the physis. **B:** Rods are advanced to the level of the fracture site by rotating (reciprocally) or pounding with an inserter and mallet. The fracture is reduced and one rod is driven across the fracture site 3 to 5 cm. **C:** Then the second rod is driven into the proximal fragment.

Rods are inserted from the medial and lateral side and driven up to the level of the fracture. The distal femoral metaphysis is opened using a drill or awl at a point 2.5 cm proximal to the distal femoral physis. The drill is then inclined 10 degrees anteriorly and steeply angled in the frontal plane to facilitate passage of the nail through the dense pediatric metaphyseal bone. Upon insertion the rod glances off the cortex as it advances toward the fracture site. Both medial and lateral rods are inserted to the level of the fracture. At this point the fracture is reduced using longitudinal traction, as well as a fracture reduction tool (Fig. 22-22B). This tool is radiolucent and holds the unstable femoral fracture in the appropriate position to allow fixation. After the first rod is driven across the fracture, approximately 2 to 3 cm, the second rod is driven across the fracture. The two rods then are driven into the proximal end of the femur with one driven toward the femoral neck and the other toward the greater trochanter. When placing the second rod across the fracture site and rotating it, care must be taken not to wind one rod around the other. After the rods are driven across the fracture and before they are seated, fluoroscopy is used to confirm satisfactory reduction of the fracture and to ensure that the rods have not comminuted the fracture as they were driven into the proximal fragment.

The rods are pulled back approximately 2 cm, the end of each rod is cut, and the rods are driven back securely into the femur. The end of the rod should lie adjacent to the bone of the metaphysis but should be at least 1 cm distal to the insertion hole to allow ease in later removal. Bending the rod ends should be avoided because it can cause a painful bursa over the rod end.

If the fracture is in the lower portion of the femur and perhaps even if it is diaphyseal, a proximal insertion site should be considered. The insertion site may be anterolateral just below the greater trochanter or through the lateral border of the trochanter. Through a skin incision at the level of the trochanter, two 4.5-mm holes are drilled into the metaphysis just below the apophysis and connected with a rongeur. The rods are inserted antegrade. The sizing of the rods and postoperative management are the same as in the retrograde technique.

Technique Tips

Mazda et al. (109) emphasized that for insertion of titanium elastic nails, the nails have to be bent into an even curve over the entire length, and the summit of the curve has to be at the level of the fracture or very close to it in comminuted fractures. The depth of curvature should be about three times the diameter of the femoral canal. Flynn et al. (87) also stressed the importance of contouring both nails with similar gentle curvatures, choosing nails that are 40% of the narrowest diaphyseal diameter, and using medial and lateral starting points that are at the same level in the metaphysis.

Postoperative Management

For unstable long oblique fractures or comminuted fractures, immobilization with a cast or traction may be of benefit. To decrease knee pain and quadriceps spasm, we have found the use of a knee immobilizer to be beneficial in the early postoperative course. Physical therapy with touchdown weight bearing should begin as soon as the patient is comfortable. Gentle knee exercises and quadriceps strengthening can be begun, but there should be no aggressive passive motion of the knee, which increases the motion at the fracture site and increases quadriceps spasm. Postoperative knee motion does return to normal, but this requires time. Full weight bearing generally is tolerated by 6 weeks.

The rod may be removed 6 to 12 months after injury when the fracture is fully healed, usually as an outpatient procedure.

Complications of Flexible Intramedullary Nailing

Complications are relatively infrequent after flexible intramedullary nailing. In 308 fractures reported in six studies (72,81,86,96,105,108), no nonunions, infections, or occurrences of avascular necrosis were reported. Approximately 12% of patients had malunions, most often mild valgus or varus deformities, and approximately 3% had clinically significant leg length discrepancies from either overgrowth or shortening. Mazda et al. (108) pointed out a technique-related complication that occurred in 10 of their 34 patients: rods were left too long and caused painful bursae and limited knee flexion. All 10 patients had the nails removed 2 to 5 months after surgery. In a multicenter study that included 58 femoral fractures stabilized with titanium elastic nails, irritation of the soft tissue near the knee by the nail tip occurred in 4 patients (7%), leading to a deeper infection in 2 patients. This study also reported one refracture after premature nail removal, leading to a recommendation that nail removal be delayed until callus is solid and the fracture line is no longer visible.

Rigid Intramedullary Rod Fixation

Problems with angular malalignment and maintenance of length can be avoided with the use of rigid intramedullary fixation. Interlocking proximally and distally to maintain length and rotational alignment in unstable fractures, as in adults, appears to be of benefit to some adolescents (74,78,93). Beaty et al. (73) reported the use of interlocking intramedullary nails for the treatment of 31 femoral shaft fractures in 30 patients 10 to 15 years of age. All fractures united, and the average leg length discrepancy was 0.51 cm. No angular or rotational malunions occurred. All nails were removed at an average of 14 months after injury; no refracture or femoral neck fracture occurred after nail removal. One case of avascular necrosis of the femoral head occurred, which was thought to be secondary to injury to the ascending cervical artery during nail insertion. A poll of the members of the Pediatric Orthopaedic Society disclosed 14 patients with avascular necrosis in approximately 1,600 femoral fractures. Despite the use of a “safe” transtrochanteric insertion site for antegrade femoral rodding, a case of avascular necrosis has been reported. Buford et al. (79) showed in their MRI study of hips after antegrade rodding that subclinical avascular necrosis may be present. Antegrade rodding through the trochanter or the upper end of the femur appears to be associated with a risk of avascular necrosis in children with open physes, regardless of chronologic age.

Reamed antegrade nailing in children under 12 years of age is not recommended because of proximal femoral growth abnormalities (163), the risk of avascular necrosis of the femoral head (56,73,110,121), the size of the proximal femur, and the relative success of other treatment methods. However, Maruenda-Paulino et al. (107) reported good results using 9-mm Kuntscher rods in children 7 to 12 years of age, and Beaty et al. (73) reported the use of newer pediatric “intermediate” interlocking nails for femoral canals with diameters as small as 8 mm. In children 12 to 17 years of age, antegrade locked transtrochanteric fixation may occasionally be indicated for an unstable fracture in a large adolescent.

Open fractures in older adolescents can be effectively treated with intramedullary rodding, either as delayed or primary treatment, including those caused by gunshot wounds and high-velocity injuries (75,123). Antegrade intramedullary rod insertion maintains length, prevents angular malunion and nonunion, and allows the patient

to be rapidly mobilized and discharged from the hospital. However, other techniques with fewer potential risks should be considered.

Antegrade Intramedullary Nailing: Technique

The child is placed either supine or in the lateral decubitus position on a fracture table. The upper end of the femur is approached through a 5-cm longitudinal incision proximal to the greater trochanter and in line with the femoral shaft. The skin incision can be precisely placed after localization on both the AP and lateral views. The gluteus maximus muscle is spread, and the gluteus medius muscle identified. The rod should be inserted through the gluteus medius muscle insertion in the tip of the trochanter, because posterior dissection may place the vasculature proximally at risk for injury. Identifying the piriformis fossa with vigorous dissection and placement of anterior and posterior retractors to the femoral neck also may cause injury to the lateral ascending cervical artery and should be avoided. Dissection should be limited to the lateral aspect of the greater trochanter and not into the piriformis fossa. This prevents dissection near the origin of the lateral ascending cervical artery medial to the piriformis fossa.

A threaded-tip guidewire is inserted into the proximal edge of the greater trochanter, followed by reaming with a 9-mm reamer (Fig. 22-24). A ball-tip guidewire then can be inserted into the proximal femur. No dissection should be performed medial or posterior to the insertion site. The ball-tip guidewire is driven across the fracture site and into the distal fragment to a level just proximal to the distal femoral physis. Progressive reaming is performed before a reamed rod or a nonreamed rod is chosen. The smallest rod that maintains contact with the femoral cortices is used (generally 8 or 9 mm) and is locked proximally and distally. Only one distal locking screw is necessary, but two can be used (66). Rods that have an expanded proximal cross-section should be avoided. The proximal end of the nail should be left slightly long (up to 1 cm) to make later removal easier.

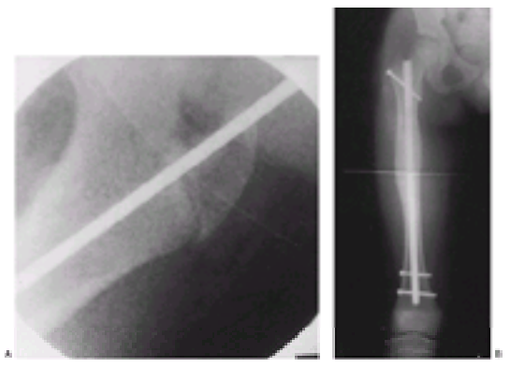

FIGURE 22-24. Antegrade insertion of intramedullary nail. **A:** Guidewire is placed at the medial edge of the greater trochanter, piercing the gluteus medius muscle and avoiding posterior insertion. **B:** Three months after fixation of a femoral shaft fracture in an 11-year-old child with multiple trauma and a closed head injury. A 9-mm pediatric locked intramedullary nail was used.

Technique Tips

Dissection should be limited to the tip of the greater trochanter, without extending to the capsule or mid-portion of the femoral neck. Leaving the proximal end of the nail up to 1 cm long makes later removal easier.

Postoperative Management

Nails can be removed 9 to 18 months after radiographic union to prevent bony overgrowth over the proximal tip of the nail. Dynamization with removal of the proximal or distal screw generally is not necessary.

Complications of Locked Intramedullary Nailing

Although good results have been reported with this technique and patient satisfaction is high, problems with proximal femoral growth, avascular necrosis, and leg length discrepancy cannot be ignored.

In a series of intramedullary nailing of 31 fractures, Beaty et al. (73) reported one patient with segmental avascular necrosis of the femoral head (Fig. 22-25), which was not seen radiographically until 15 months after injury. Kaweblum et al. (101) reported a patient with avascular necrosis of the proximal femoral epiphysis after a greater trochanteric fracture, suggesting that the blood supply to the proximal femur may have been compromised by vascular disruption at the level of the greater trochanter during rod insertion. Other researchers have reported single patients with avascular necrosis of the femoral head after intramedullary nailing (110,112,121). Chung (82) noted the absence of transphyseal vessels to the proximal femoral epiphysis and demonstrated that the singular lateral ascending cervical artery predominantly supplies blood to the capital femoral epiphysis (Fig. 22-26). He stated that all of the epiphyseal and metaphyseal branches of the lateral ascending cervical artery originate from a single stem that crosses the capsule at the trochanteric notch. Because the space between the trochanter and the femoral head is extremely narrow in children under 8 years of age, this single artery is vulnerable to injury and appears to be so until skeletal maturity, regardless of chronologic age.

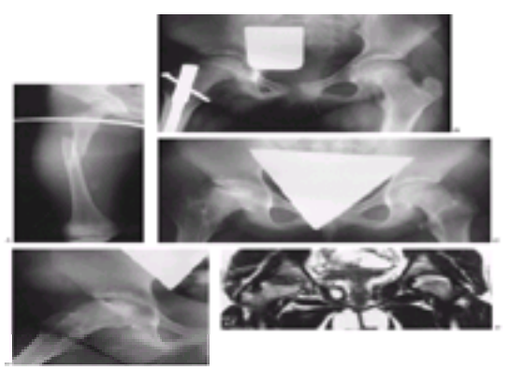

FIGURE 22-25. A: Isolated femoral shaft fracture in 11½-year-old child. **B:** One month after fixation with an intramedullary nail, femoral head appears normal. **C:** Eight months after injury, fracture is healed; note early signs of avascular necrosis of right femoral head. **D:** Fifteen months after injury, segmental avascular necrosis of the femoral head is evident on radiographs. **E:** Magnetic resonance image shows extent of avascular necrosis of right femoral head. (D reprinted from Beaty JH, Austin SM, Warner WC, et al. Interlocking intramedullary nailing of femoral-shaft fractures in adolescents: preliminary results and complications. *J Pediatr Orthop* 1994;14:178–183; with permission.)

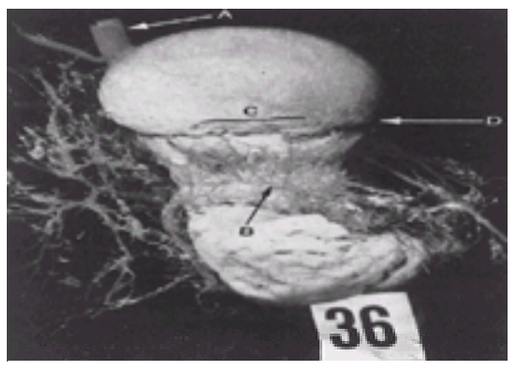

FIGURE 22-26. The single ascending cervical artery (*A*) is the predominant blood supply to the femoral head. The vessel is at risk during antegrade insertion of an intramedullary rod. (Reprinted from Chung S. The arterial supply of the developing proximal end of the femur. *J Bone Joint Surg [Am]* 1976;58:961; with permission.)

Townsend and Hoffinger (124) reported no avascular necrosis in 34 patients in whom a trochanteric tip starting point was used.

Skak et al. (118), in a long-term study of 52 children and adolescents with femoral fractures treated with plating and intramedullary rodding, found that excessive overgrowth was less common with nailing than with plating. Three patients had moderate valgus deformities of the hip and one had late arthrosis after intramedullary rodding despite using a transtrochanteric approach. Skak et al. (118) concluded that open physes were a contraindication to antegrade rodding even with a transtrochanteric approach. Thometz and Handen (121) also documented an association between avascular necrosis and antegrade rodding in an adolescent.

Growth abnormality in the proximal femur may occur with arrest of the greater trochanteric physis. Although most growth from the greater trochanter after 8 years of age is appositional, Raney et al. (163) reported five patients who developed coxa valga and mild hip subluxation from trochanteric physeal arrest after antegrade nailing. These patients ranged in age from 9 to 13 years, suggesting that even in older children greater trochanteric physeal arrest occasionally can produce clinical problems. Beaty et al. (73) reported two patients with overgrowth of more than 2.5 cm that required epiphysiodesis because of leg length discrepancy.

The proximal femoral physis is a continuous cartilaginous plate between the greater trochanter and the proximal femur in young children. Interference with the physis may result in atrophy of the femoral neck, placing the child at a small risk for subsequent femoral neck fracture (116). Antegrade rodding with reaming of a large defect also may result in growth disturbance in the proximal femur as well as femoral neck fracture (Fig. 22-27). Beaty et al. (73) reported no “thinning” of the femoral neck in their patients, which they attributed to an older patient group (10–15 years of age) and design changes in the femoral nail that allowed a decrease in the cross-sectional diameter of the proximal portion to 10 mm.

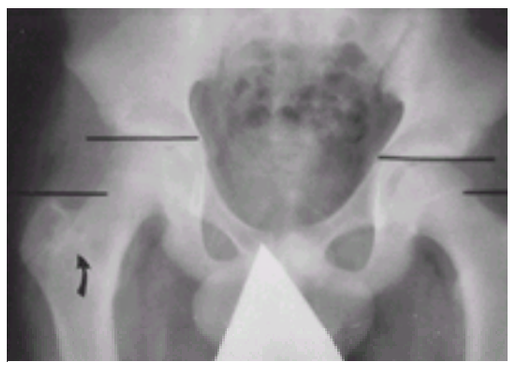

FIGURE 22-27. Fifteen-year-old boy 3 years after intramedullary nailing of the right femur. Acetabular to trochanter distance increased by 1.5 cm; note partial trochanteric epiphysiodesis (*arrow*) with mild overgrowth of the femoral neck. (Reprinted from Beaty JH, Austin SM, Warner WC, et al. Interlocking intramedullary nailing of femoral-shaft fractures in adolescents: preliminary results and complications. *Pediatr Orthop* 1994;14:178–183; with permission.)

Open Reduction and Internal Fixation with Plate and Screws

Ward et al. (125), Kregor et al. (103), Fyodorov et al. (88), and Hansen (94) recommended this form of treatment in selected femoral fractures. Ward et al. (125) reported the use of AO compression plates for the treatment of femoral shaft fractures in 25 children 6 to 16 years of age, 22 of whom had associated fractures or multisystem injuries. Follow-up was available for 24 patients, 23 of whom (96%) had healed fractures at an average of 11 weeks. According to these investigators, plate fixation offers the advantages of anatomic reduction, ease of insertion, simplified nursing care, rapid mobilization without casting, and applicability to any size femoral shaft. Disadvantages of plate fixation include the long incision necessary and the risks of plate breakage and stress fracture after plate removal. They recommend plate fixation only for children under 11 years of age with closed-head injuries or multiple trauma. All the patients reported by Kregor et al. (103) had multiple trauma, and this form of treatment was selected to stabilize the femoral fracture quickly and mobilize the patient. Fyodorov et al. (88) reviewed 21 patients in whom 4.5-mm DCP plates were used for fixation. Patients were kept non–weight bearing on crutches for 8 weeks. There were two plate breakages requiring revision and one requiring spica casting to achieve healing. Modern techniques of femoral plating (114) with maintenance of the periosteum may lead to greater acceptance of this method of management.

Pathologic fractures, especially in the distal femoral metaphysis, create larger areas of bone loss that can be treated with plate fixation and immediate bone grafting to avoid protracted periods of traction and immobilization (Fig. 22-28).

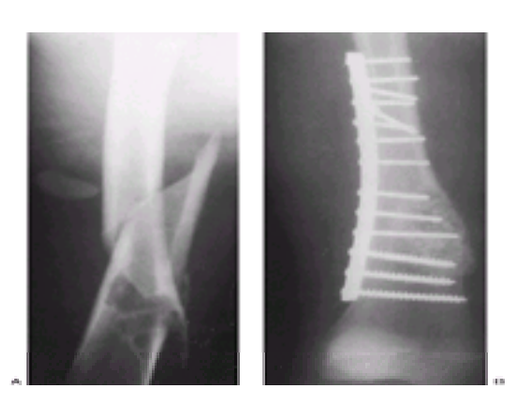

FIGURE 22-28. A: Pathologic fracture (nonossifying fibroma) of the femoral diaphysis. **B:** Plate fixation at the time of biopsy and bone grafting.

Technique

In a sterile operating room environment after general anesthesia has been given, the patient is placed on a radiolucent operating table and the entire extremity is prepared and draped. The femur is approached laterally. The vastus lateralis is retracted anteriorly to expose the femur. Soft tissue attachment to the bone is

preserved to the extent possible. Fragments are lagged into place and secured with a dynamic compression plate. A 4.5-mm or larger compression plate is used in children (Fig. 22-29). If the fracture is at either end of the bone, leaving insufficient bone for cortical fixation, fully threaded cancellous screws add to the stability of fixation and are preferable to either cortical or partially threaded cancellous screws. Both interfragmentary compression and dynamic compression techniques can be used to achieve stability and anatomic alignment.

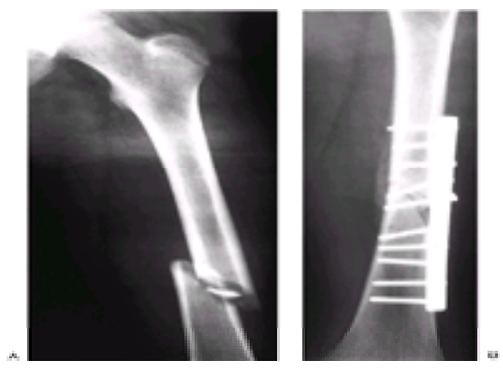

FIGURE 22-29. A: This oblique mid-shaft femoral fracture with some comminution in a 200-pound male occurred after an automobile accident. **B:** Stable fixation with plate and lag screw construction is highly successful and carries no risk of avascular necrosis.

Technique Tips

Soft tissue stripping should be limited, and three screws should be used proximal and distal to the fracture site.

Postoperative Management

Protected weight bearing is progressed to weight bearing to tolerance. Active range of motion of the hip and knee is encouraged.

Complications of Plate Fixation

Extensive dissection and periosteal stripping during plate application may lead to overgrowth. Overgrowth was not a significant problem in the series of Kregor et al. (103), with an average increase in length of 0.9 cm (range 0.5–1.5 cm), but Ward et al. (125) reported several patients with considerable overgrowth (approximately 1 inch), and Hansen (94) reported overgrowth of an inch in a 12-year-old boy, suggesting that overgrowth is possible in children over 10 years of age. More data are necessary on this issue to make a definitive statement.

Fyodorov, Sturm, and Robertson (88) reported hardware failure in 2 of 23 femoral shaft fractures treated with dynamic compression plating. One was treated with revision plating and the other with spica cast; both fractures healed uneventfully. No other complications were noted in their patients.

Refracture is rare, and whether bone atrophy under a plate is caused by stress shielding or by avascularity of the cortex is unknown. Although still somewhat controversial, the plate and screws are generally removed at 1 year after fracture to avoid fracture at the end of the plate.

Quadriceps strength after plate fixation appears not to be compromised, (147) relative to intramedullary fixation or cast immobilization.

AUTHORS' PREFERRED METHOD OF TREATMENT

For stable femoral fractures in children under 6 months of age, we use a posterior splint or Pavlik harness. If the fracture is unstable, usually the proximal fragment is flexed and a Pavlik harness is the ideal device for reducing and holding the fracture. The use of a Pavlik harness requires an attentive and compliant caregiver. Traction with a spica cast occasionally is needed in this group. Abuse and metabolic bone disease must be considered in an infant with a femoral fracture.

In children 6 months to 6 years of age, an immediate spica cast with Gortex liner is almost always the treatment of choice. If length or alignment cannot be maintained in an immediate spica cast, traction followed by casting can be used. We usually use a distal femoral traction pin and place the child in a 90/90 or oblique position in the bed for traction. It is of note, however, that over 95% of young children with femoral fractures can be managed with immediate spicas with a low complication rate and low cost. In children with multiple trauma, either flexible intramedullary rodding or external fixation is chosen, based on the fracture anatomy and the soft tissue injury.

In children 6 to 12 years of age, flexible intramedullary rodding is frequently used, most often with retrograde insertion. External fixation is used for unstable fracture patterns, comminuted fractures, and fractures with severe soft tissue injury. Immediate spica casts may be used for the most stable fractures in this age group. In children 12 years to maturity, we use flexible intramedullary rods as our treatment of choice. In a patient with an unstable fracture configuration, we would use either a plate or an antegrade rod, recognizing the low but significant risk of avascular necrosis of the femoral head. Plating is preferable for subtrochanteric and supracondylar fractures of the femur, whereas intramedullary nails are ideal for mid-shaft fractures. If antegrade rodding is chosen, a transtrochanteric approach is used. New methods are under development for fixation, using an infratrochanteric approach with a locked type of flexible rod, but such devices are not available yet.

COMPLICATIONS OF FEMORAL SHAFT FRACTURES

Leg Length Discrepancy

The most common sequela after femoral shaft fractures in children is leg length discrepancy. The fractured femur may be initially short from overriding of the fragments at union; growth acceleration occurs to “make up” the difference, but often this acceleration continues and overgrowth occurs. The potential for growth stimulation from femoral fractures has long been recognized, but the exact cause of this phenomenon is still unknown. Growth acceleration has been attributed to age, sex, fracture type, fracture level, handedness, and the amount of overriding of the fracture fragments. Age seems to be the most constant factor, but fractures in the proximal third of the femur and oblique comminuted fractures also have been associated with relatively greater growth acceleration. According to Staheli (170), in patients over 10 years of age, shortening is more likely; in patients 2 to 10 years of age, overgrowth is more likely, especially if traction has been used.

Shortening

Because the average overgrowth after femoral fracture is approximately 1.5 cm, shortening of 2 to 3 cm in the cast is the maximal acceptable amount. The maximal acceptable shortening depends on the age of the child; for example, in a 6-year-old child, 2.5 cm may be acceptable, whereas only 1 to 2 cm should be accepted in a 14-year-old approaching skeletal maturity. In patients 2 to 10 years of age with more than 3 cm of shortening after immediate spica casting, the cast is removed, traction is reapplied until acceptable length is obtained, and then a new cast is applied. For early shortening of more than 3 cm in a patient 11 or 12 years old, a reinstitution of traction and reapplication of the cast also may be appropriate. If, however, the shortening is unacceptable at 6 weeks after fracture, the decision must be made as to whether osteoclasis and distraction with external fixation is preferable to a later limb equalization procedure (lengthening or shortening). The trend is to correct the shortening immediately with external fixation if possible.

Overgrowth

Overgrowth after femoral fracture is common in children 2 to 10 years of age. The average overgrowth is 0.9 cm, with a range of 0.4 to 2.5 cm (169). Overgrowth

occurs whether the fracture is short, at length, or overpulled in traction at the time of healing. In general, overgrowth occurs most rapidly during the first 2 years after fracture and to a much lesser degree for the next year or so (148).

Truesdell (173) first reported the phenomenon of overgrowth in 1921, and many researchers since have verified the existence of growth stimulation after fracture (129,130,131,132,138,139,142,145,158,159). The relationship of the location of the fracture to growth is somewhat controversial. Staheli (170) and Malkawi (154) reported that overgrowth was greatest if the fracture occurred in the proximal third of the femur, whereas Henry (151) stated that the most overgrowth occurred in fractures in the distal third of the femur. Other investigators have found no relationship between fracture location and growth stimulation (145,151,164); Shapiro's data (169) support the lack of relationship. The relationship between fracture type and overgrowth also is controversial. In general, most researchers believe that no specific relationship exists between fracture type and overgrowth, but some have reported overgrowth to be more frequent after spiral, oblique, and comminuted fractures associated with greater trauma.

Angular Deformity

Some degree of angular deformity is frequent after femoral shaft fractures in children, but this usually remodels with growth. Angular remodeling occurs at the site of fracture with appositional new bone formation in the concavity of the long bone. Differential physeal growth also occurs in response to diaphyseal angular deformity. Wallace and Hoffman (176) stated that 74% of the remodeling that occurs is physeal, and appositional remodeling at the fracture site occurs to a much lesser degree. However, this appears to be somewhat age dependent. It is clear that angular remodeling occurs best in the direction of motion at the adjacent joint (176). That is, anterior and posterior remodeling in the femur occurs rapidly and with little residual deformity. In contrast, remodeling of a varus or valgus deformity occurs more slowly. The differential physeal growth in a varus or valgus direction in the distal femur causes compensatory deformity, which is usually insignificant. In severe varus bowing, however, a hypoplastic lateral condyle results, which may cause a distal femoral valgus deformity if the varus bow is corrected (Fig. 22-30).

FIGURE 22-30. Long-standing varus deformity in the femoral shaft may lead to hypoplasia of the lateral condyle and a compensatory distal femoral valgus deformity after correction of the varus of the shaft.

Guidelines for acceptable alignment vary widely. The range of acceptable anterior and posterior angulation varies from 30 to 40 degrees in children up to 2 years of age to 10 degrees in older children and adolescents (Fig. 22-31) (157). The range of acceptable varus and valgus angulation also becomes smaller with age. Varus angulation in infants and children should be between 10 and 15 degrees, although greater degrees of angulation may have a satisfactory outcome. Acceptable valgus angulation is 20 to 30 degrees in infants, 15 to 20 degrees in children up to 5 years of age, and 10 degrees in older children and adolescents. The muscle mass of the femur generally hides femoral deformity from direct observation. The acceptability of femoral deformity, in general, is a direct function of the degree of difficulty in changing the deformity and the appearance of the leg.

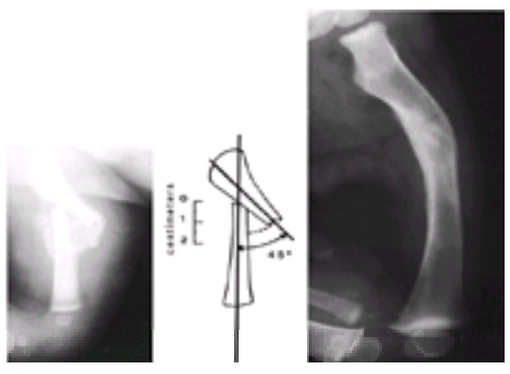

FIGURE 22-31. Remodeling potential of the femur during infancy. This infant sustained a femoral fracture during a breech delivery and was placed in a spica cast but with insufficient flexion of the hip. **Left:** At 3 weeks union is evident with about 45 degrees of angulation in the sagittal plane and 1.5 cm of overriding. **Center:** Line drawing demonstrating true angulation. **Right:** Twelve months later the anterior angulation has reduced to a level such that it was not apparent to the family, and the shortening has reduced to less than 1 cm.

Late development of genu recurvatum deformity of the proximal tibia after femoral shaft fracture has been most often reported as a complication of traction pin or wire placement through or near the anterior aspect of the proximal tibial physis, excessive traction, pin track infection, or prolonged cast immobilization (68). However, proximal tibial growth arrest may complicate femoral shaft fracture, presumably as a result of occult injury (152). Femoral pins are preferred for traction, but if tibial pins are required, the proximal anterior tibial physis must be avoided (51). Femoral traction pins should be placed one or two finger breadths proximal to the superior pole of the patella to avoid the distal femoral physis.

If significant angular deformity is present after fracture union, corrective osteotomy should be delayed for at least a year unless the deformity is severe enough to impair function. This will allow determination of remodeling potential before deciding that surgical correction is necessary. The ideal osteotomy corrects the deformity at the site of fracture. In juvenile patients, however, metaphyseal osteotomy of the proximal or distal femur may be necessary. In adolescents with mid-shaft deformities, diaphyseal osteotomy and fixation with an interlocking intramedullary nail are preferable.

Rotational Deformity

According to Verbeek (174), rotational deformities of 10 degrees to more than 30 degrees occur in one third of children after conservative treatment of femoral shaft fractures. Malkawi et al. (158) found asymptomatic rotational deformities of less than 10 degrees in two thirds of their 31 patients. Torsional deformity usually is expressed as increased femoral anteversion on the fractured side compared with the opposite side, as demonstrated by anteversion views; a difference of more than 10 degrees has been the criterion of significant deformity. However, Brouwer et al. (136) challenged this criterion, citing differences of 0 to 15 degrees in a control group of 100 normal volunteers. The accuracy of measurements from plain radiographs also has been disputed, and Norbeck et al. suggested the use of computed tomographic (CT) scanning for greater accuracy.

Rotational remodeling in childhood femoral fractures is another controversy in the search for criteria on which to base therapeutic judgments. According to Davids (143) and Braten et al. (135), up to 25 degrees of rotational malalignment at the time of healing of femoral fractures appears to be well tolerated in children. In their patients with more than 25 degrees of rotational malalignment, however, deformity caused clinical complaints. Davids found no spontaneous correction in his study of malunions based on CT measurements, but the length of follow-up is insufficient to state that no rotational remodeling occurs. Brouwer et al. (136) and others

(133,149,162,174) reported slow rotational correction over time.

Certainly, in older adolescents, no significant rotational remodeling will occur. In infants and juveniles, some rotational deformity can be accepted (146), because either true rotational remodeling occurs or functional adaptation allows resumption of normal gait. Up to 30 degrees of angular malrotation in the femur should result in no functional impairment unless there is preexisting rotational malalignment. The goal, however, should be to reduce a rotational deformity to 10 degrees, based on alignment of the proximal and distal femur radiographically, interpretation of skin and soft tissue envelope alignment, and correct positioning within a cast, based on the muscle pull on the proximal fragment. The distal fragment should be lined up with the position of the proximal fragment determined by the muscles inserted upon it (Fig. 22-3).

Delayed Union

Delayed union of femoral shaft fractures is uncommon in children. The time to fracture union in most children is rapid and age dependent. In children under 5 years of age, healing usually occurs in 4 to 6 weeks. In children 5 to 10 years of age, fracture healing is somewhat slower, requiring 8 to 10 weeks. Throughout adolescence, the time to healing continues to lengthen. By the age of 15 years, the mean time to healing is about 13 weeks, with a range from 10 to 15 weeks (Fig. 22-32). The rate of healing also is related to soft tissue injury and type of treatment. Application of an external fixation device appears to delay callus formation and slow the rate of healing.

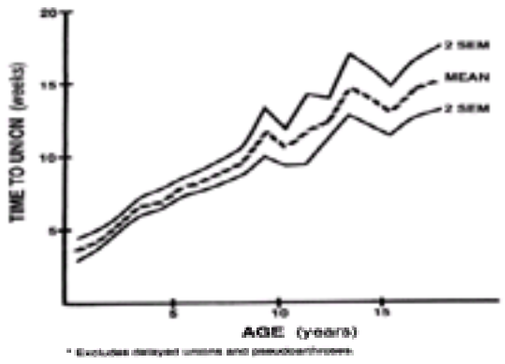

FIGURE 22-32. Time required for union of femoral shaft fractures in childhood and adolescence. (Redrawn from Skak SV, Jensen TT. Femoral shaft fracture in 265 children. *Acta Orthop Scand* 1988;59:704–707; with permission.)

Bone grafting and internal fixation with either a compression plate or locked intramedullary nail is the usual treatment for delayed union in older children and adolescents. Delayed union of a femoral fracture treated with casting in a child 1 to 6 years of age is probably best treated by continuing cast immobilization until bridging callus forms or (rarely) by additional bone grafting.

Nonunion

Nonunions of pediatric femoral fractures are rare (156). They tend to occur in adolescents, in infected fractures, or in fractures with segmental bone loss or severe soft tissue loss. Most nonunions in children are of tibial fractures; femoral fractures account for only 15% of nonunions in children. Even in segmental fractures with bone loss, young children may have sufficient osteogenic potential to fill in a significant fracture gap (Fig. 22-33) (160). For the rare femoral shaft nonunion in a child 5 to 10 years of age, bone grafting and plate-and-screw fixation have been traditional treatment methods, but more recently insertion of an interlocking intramedullary nail and bone grafting have been preferred, especially in children over 10 to 12 years of age.

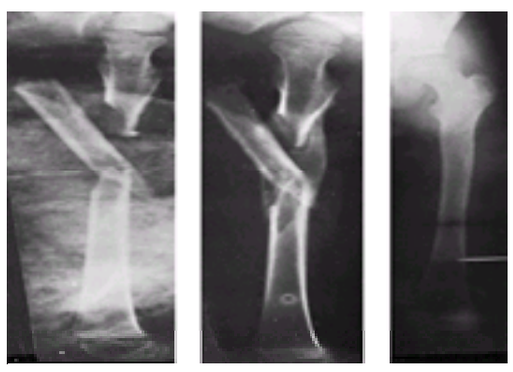

FIGURE 22-33. The effectiveness of remodeling of the femur in a child. **Left:** Comminuted fracture in an 8-year-old child managed with a femoral pin incorporated in a spica cast. The mid-fragment is markedly angulated. **Center:** Fracture after union 12 weeks later with filling in of the defect and early absorption of the protruding fragment. **Right:** Appearance at age 12 with only a minimal degree of irregularity of the upper femur remaining.

Robertson et al. (166) reported the use of external fixators in 11 open femoral fractures. The time to union was delayed, but a satisfactory outcome occurred without subsequent procedures. This supports the belief that the rates of delayed union and nonunion are low in pediatric femoral fractures, because open fractures would have the highest rates of delayed union.

Muscle Weakness

Weakness after femoral fracture has been described in the hip abductor musculature, quadriceps, and hamstrings, but persistent weakness in some or all of these muscle groups seldom causes a clinical problem. Hennrikus et al. (150) found that quadriceps strength was decreased in 30% of his patients and 18% had a significant decrease demonstrated by a one-leg hop test. Thigh atrophy of 1 cm was present in 42% of patients. These deficits appeared to be primarily related to the degree of initial displacement of the fracture. Finsen et al. (147) found hamstring and quadriceps deficits in patients with femoral shaft fractures treated with either rods or plates.

Damholt and Zdravkovic (141) documented quadriceps weakness in approximately one third of patients with femoral fractures, and Viljanto et al. (175) reported that this weakness was present whether patients were treated operatively or nonoperatively. Biyani (134) found that hip abductor weakness was related to ipsilateral fracture magnitude, long intramedullary rods, and, to a lesser degree, heterotopic ossification from intramedullary rodding.

Injury to the quadriceps muscle probably occurs at the time of femoral fracture, and long-term muscle deficits may persist in some patients regardless of treatment. Severe scarring and contracture of the quadriceps occasionally require quadricepsplasty (154).

Infection

Infection may rarely complicate a closed femoral shaft fracture, with hematogenous seeding of the hematoma and subsequent osteomyelitis. Fever is commonly associated with femoral fractures during the first week after injury (171), but persistent fever or fever that spikes exceedingly high may be an indication of infection.

Pin-track infections occasionally occur with the use of skeletal traction, but most are superficial infections that resolve with local wound care and antibiotic therapy. Occasionally, however, the infections may lead to osteomyelitis of the femoral metaphysis or a ring sequestrum that requires surgical debridement.

Neurovascular Injury

Nerve and vascular injuries are uncommon with femoral fractures in children (140,144,153,167). An estimated 1.3% of femoral fractures in children are accompanied by vascular injury (140,144,153,167), such as intimal tears, total disruptions, or injuries resulting in the formation of pseudoaneurysms (168). Vascular injury occurs most frequently with displaced Salter-Harris physeal fractures of the distal femur or distal metaphyseal fractures. If arteriography indicates that vascular repair is necessary after femoral shaft fracture, open reduction and internal fixation or external fixation of the fracture are recommended. Secondary limb ischemia also has been reported after the use of both skin and skeletal traction. Documentation of peripheral pulses at the time of presentation, as well as throughout treatment, is necessary.

Nerve abnormalities reported with femoral fractures in children include those caused by direct trauma to the sciatic or femoral nerve at the time of fracture and injuries to the peroneal nerve during treatment. Weiss et al. (69) reported peroneal nerve palsies in 4 of 110 children with femoral fractures treated with early 90/90 hip spica casting. They recommended extending the initial short leg portion of the cast above the knee to decrease tension on the peroneal nerve.

Riew et al. (165) reported 8 nerve palsies in 35 consecutive patients treated with locked intramedullary rodding. The nerve injuries were associated with delay in treatment, preoperative shortening, and boot traction. Resolution occurred in less than one week in 6 of 8 patients.

The natural history of peroneal nerve injury with femoral shaft fractures in children seems to be spontaneous correction. In infants, however, the development of an early contracture of the Achilles tendon is more likely. Because of the rapid growth in younger children, this contracture can develop quite early; and if peroneal nerve injury is suspected, the extremity should be braced until the peroneal nerve recovers. If peroneal, femoral, or sciatic nerve deficit is present at initial evaluation of a closed fracture, no exploration is indicated. If a nerve deficit occurs during reduction or treatment, the nerve should be explored. Persistent nerve loss without recovery over a 4- to 6-month period is an indication for exploration.

Compartment Syndrome

Compartment syndromes of the thigh musculature are rare, but have been reported in patients with massive thigh swelling after femoral fracture and in patients treated with intramedullary rod fixation (161). If massive swelling of thigh musculature occurs and pain is out of proportion to that expected from a femoral fracture, compartment pressure measurements should be obtained and decompression by fasciotomy should be considered. It is probable that some patients with quadriceps fibrosis (164) and quadriceps weakness (150,172) after femoral fracture had intracompartmental pressure phenomenon. Vascular insufficiency related to Bryant's traction may produce signs of compartment syndrome with muscle ischemia (137). Janzing (155) reported the occurrence of compartment syndrome using skin traction for treatment of femoral fractures. Skin traction has been associated with compartment syndrome in the lower leg in both the fractured and nonfractured side. The association of compartment syndrome with Bryant's traction is well recognized. It is important to realize that in a traumatized limb, circumferential traction needs to be monitored closely and is contraindicated in the multiply injured or head-injured child.

SPECIAL FRACTURES OF THE FEMORAL SHAFT

Metaphyseal (Subtrochanteric and Supracondylar) Fractures

Subtrochanteric fractures can be treated in traction, followed by either a cast brace or single spica cast (Fig. 22-34) (177). Sponseller (181) reported satisfactory results with conservative treatment of subtrochanteric fractures in children. Internal fixation with plate and screw devices also can produce satisfactory results (179). Intramedullary fixation of subtrochanteric fractures in children is generally not indicated. In adolescents, there is insufficient experience with this fracture to determine at what age intramedullary fixation with a reconstruction-type nail and an angled transfixion screw into the femoral neck is indicated. Antegrade intramedullary nail systems place significant holes in the upper femoral neck and should be avoided. Unlike subtrochanteric fractures in adults, nonunions are rare in children with any treatment method.

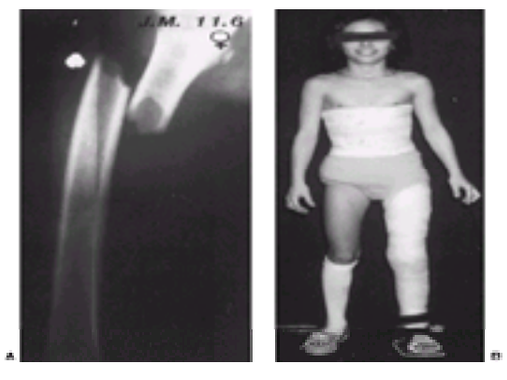

FIGURE 22-34. Subtrochanteric fractures **(A)** may be treated with traction followed by a one-legged ambulatory spica cast **(B)**.

With the admonition against intramedullary fixation in children with open physes combined with the fact that nonunions are rare, our recommendation is for traction followed by spica casting in young children up to approximately age 5 or 6, with plate and screw fixation in older children. The method of plate and screw fixation may be either a straight plate with angled screws in the proximal fragment (Fig. 22-35) or hip screw configuration systems appropriately sized to a small child.

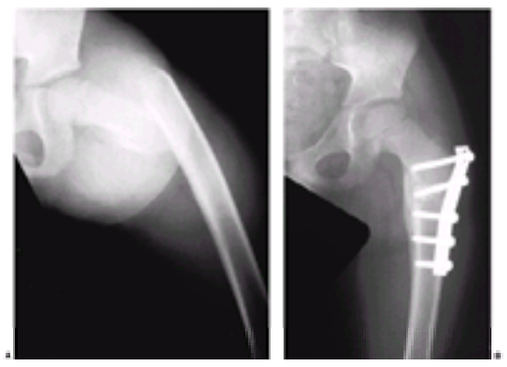

FIGURE 22-35. A: This 6-year-old boy sustained a subtrochanteric fracture of the femur. **B:** He was treated with plate and screw fixation supplemented with a spica cast.

The traction technique should be that of 90/90 traction in which the distal fragment is flexed to align with the proximal fragment and spica cast treatment may be either in an ambulatory one-legged spica cast or a flexed hip/flexed knee spica cast, depending on the fracture and healing.

Supracondylar fractures are difficult to treat because the gastrocnemius muscle inserts just above the femoral condyles and pulls the distal fragment into a position of extension (178), making alignment difficult (Fig. 22-3). The traditional methods of casting and single-pin traction may be satisfactory (Fig. 22-36). If alignment cannot be achieved using these methods, however, open reduction and internal fixation or combined epiphyseal-metaphyseal traction can be used. Generally, internal fixation is preferable, either with plates and fully threaded cancellous screws if there is sufficient metaphyseal length to allow this or with crossed smooth Kirschner wires transfixing the fracture from the epiphysis to the metaphysis, as described for distal femoral physeal separations (180). If there is sufficient metaphyseal length, antegrade flexible rods can be used.

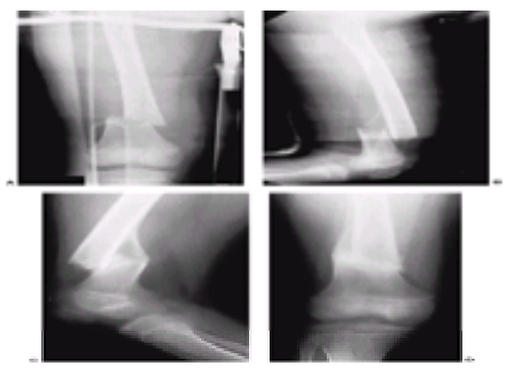

FIGURE 22-36. A: This 6-year-old patient sustained an unstable supracondylar fracture of the femur. **B:** The fracture was managed with immediate spica casting with the knee in 90 degrees of flexion, mandatory in such a case to prevent posterior angulation. **C:** Bayonet apposition is acceptable in a child this age.

Open Femoral Fractures

Open femoral fractures are uncommon in children because of the large soft tissue compartment around the femur. Proper wound care, debridement, stabilization, and antibiotic therapy are required to reduce the chance of infection (178).

External fixation of open femoral shaft fractures simplifies wound care and allows early mobilization. The configuration of the external fixator is determined by the child's size and the fracture pattern. Generally, monolateral half-pin frames are satisfactory, but thin-wire circular frames may be necessary if bone loss is extensive. External fixation provides good fracture control, but as always, family cooperation is required to manage pin and fixator care.

Plate fixation also allows early mobilization, as well as anatomic reduction of the femoral fracture. Wound care and treatment of other injuries are made easier in children with multiple trauma. However, this is an invasive technique with the potential for infection and additional injury to the already traumatized soft tissues in the area of the fracture. In emergency situations, plate fixation can be used for Gustilo-Anderson type I and II fractures; type III fractures in older adolescents are better suited for external fixation or intramedullary nailing. Plate breakage can occur if bone grafting is not used for severe medial cortex comminution.

In older adolescents, plating or flexible intramedullary nailing is especially useful. Closed nailing after irrigation and drainage of the fracture allows early mobilization and easy wound care in patients with Gustilo-Anderson type I, II, IIIA, and IIIB injuries, but the risk of avascular necrosis must be recognized.

Femoral Fractures in Patients with Metabolic or Neuromuscular Disorders

For patients with osteogenesis imperfecta who have potential for ambulation, surgical treatment with Rush or Bailey-Dubow rods is recommended for repeated fractures or angular deformity. Cast immobilization is usually avoided in patients with myelomeningocele or cerebral palsy because of the frequency of osteoporosis and refracture in these patients. If possible, existing leg braces are modified for treatment of the femoral fracture. In nonambulatory patients, a simple pillow splint is used.

Floating Knee Injuries

These rare injuries occur when ipsilateral fractures of the femoral and tibial shafts leave the knee joint “floating” without distal or proximal bony attachments (Fig. 22-37A). They are high-velocity injuries, usually resulting from collision between a child pedestrian or cyclist and a motor vehicle. Most children with floating knee injuries have multiple trauma, including severe soft tissue damage, open fractures, and often head injuries.

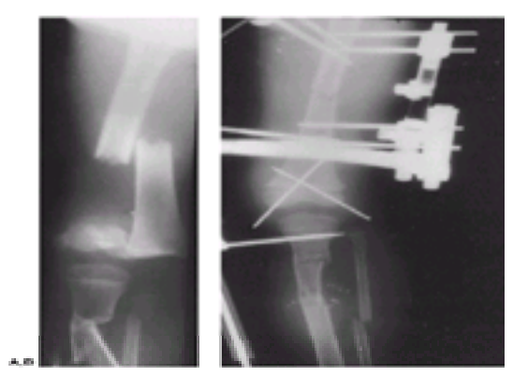

FIGURE 22-37. A: Floating knee injury in a 4-year-old girl: femoral shaft fracture, displaced physeal fracture of the distal femur, and open (type IIIB) proximal tibial fracture. **B:** After external fixation of femoral shaft fracture, closed reduction and percutaneous pinning of the distal femoral physeal fracture, and external fixation of the open tibial fracture; a free-flap was required for skin coverage.

In general, at least one of the fractures, usually the tibia, should be fixed. The femoral fracture can usually then be treated by the most appropriate option. If both fractures are open, external fixation of both the tibial and femoral fractures may be appropriate. If immediate mobilization is necessary, fixation of both fractures with external fixation, intramedullary nails, compression plates, or any combination of these may be indicated (Fig. 22-37B).

Letts and Vincent (18) described five patterns of ipsilateral tibial and femoral fractures and made treatment recommendations based on those patterns (Fig. 22-38). Because of the high prevalence of complications after closed treatment, Bohn and Durbin recommended open or closed reduction and internal fixation of the femoral fracture in older children. In children under 10 years of age, these investigators recommend 90/90 femoral pin traction for 4 weeks, followed by 1-½ spica casting until fracture union. The tibial fracture was immobilized in a below-knee cast during the traction. Bohn and Durbin listed four situations in which operative stabilization of the femoral fracture is indicated: (a) a child with severe head trauma with signs of posturing, (b) an adolescent near skeletal maturity, (c) a child with severe soft tissue injury, and (d) an inability to obtain acceptable closed reduction. Stabilization of the tibial fracture by external fixation is indicated if satisfactory closed reduction cannot be obtained or maintained and for open fractures with severe soft tissue injury, regardless of the age of the child.

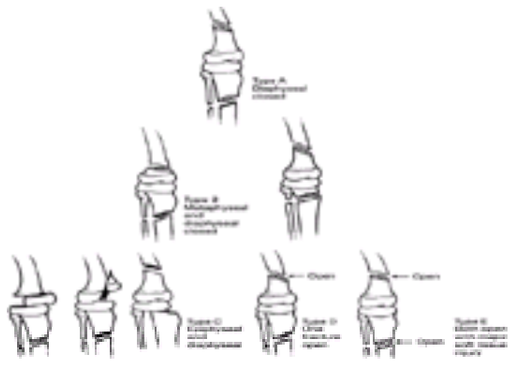

FIGURE 22-38. Classification of floating knee injuries in children. (Redrawn from Letts M, Vincent N, Gouw G. The “floating knee” in children. *J Bone Joint Surg [Br]* 1986;68:442; with permission.)

Letts and Vincent (18) reported that maintaining adequate reduction by traction was difficult in children over 12 years of age and that complications were more frequent in children treated by traction alone. Complications in their patients treated by traction alone included pin track infection, osteomyelitis, limitation of knee motion, malunion, and leg length discrepancies of 1.5 cm or more. Bohn and Durbin reported that of 19 patients with floating knee injuries, at long-term follow-up 11 had limb length discrepancy secondary to either overgrowth of the bone after the fracture or premature closure of the ipsilateral physis (7 patients), genu valgum associated with fracture of the proximal tibial metaphysis (3 patients), or physeal arrest (1 patient). Four patients had late diagnoses of ligamentous laxity of the knee that required operation. Other complications included peroneal nerve palsy, infection, nonunion, malunion, and refracture.

FRACTURES AND DISLOCATIONS ABOUT THE KNEE

PAUL D. SPONSELLER
CARL L. STANITSKI

PART I: EXTRAARTICULAR FRACTURES

Fractures involving the physes around the knee are far from “routine” injuries because they have a significant risk of growth disturbance, which can result in shortening or angulation, or both. Vascular injury occasionally occurs, especially with proximal tibial injuries, and nerves and ligaments also may be damaged.

DISTAL FEMORAL EPIPHYSEAL FRACTURES

Historical Review

The cause of a distal femoral epiphyseal fracture can help deter- mine the method of treatment and identify potential problems. In hyperextension fractures, the epiphysis is displaced anteriorly and the metaphysis is displaced into the popliteal fossa, making neurovascular injury possible. Reduction often is unstable because ligamentotaxis rarely is effective. Extreme knee flexion may be required to tighten the anterior soft tissue hinge. Varus–valgus fractures (Fig. 23-1) result from an abduction or adduction force, and the posterior periosteal hinge is intact. In either type of fracture, reduction should be precise because any residual varus or valgus about the knee in older children has limited remodeling potential.

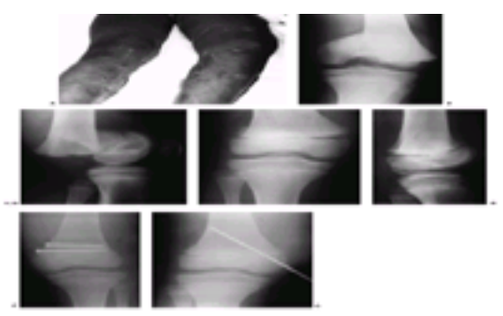

FIGURE 23-1. Appearance at presentation of an 11-year-old boy who was hit by a car from the front on the right side, sustaining a fracture-nseparation of both distal femoral epiphyses **(A).** There was apex-posterior angulation of both sides, with varus angulation on the left side **(B and C)** and valgus on the right **(D and E).** Both sides were treated by closed reduction, with stabilization using cannulated screws on the left **(F)** and a percutaneous smooth pin on the right **(G)**.

Many clinical studies of distal femoral physeal fractures report high incidences of growth disturbance, resulting in asymmetry of length or angulation, or both (6,63,77). Growth disturbance is caused by bony bridging resulting from direct physeal trauma or from lack of anatomic reduction of the physis. Several authors have shown that the likelihood of physeal disturbance is greater with significant (>50% of the width of the physis) initial displacement of the fracture (42,54,78). The complex contour of the physis makes it possible for shearing of the fracture line to occur across several zones of the physis at a microscopic level, even in fracture patterns that are typically considered to be benign, such as Salter-Harris type I and II injuries.

Although it has been thought that knee ligament injury does not occur with fracture through the distal femoral physis, Bertin and Goble (7) found that 14 of 29 patients with physeal injuries about the knee had ligamentous instability at follow-up. Brone and Wroble (15) reported three patients with Salter-Harris type III fractures of the femoral condyle associated with anterior cruciate ligament (ACL) tears, and found two more reported in the literature. All were near skeletal maturity. An awareness of this possibility and a careful examination will allow timely treatment of ligamentous injury.

Distal femoral physeal injuries account for 1% to 6% of all physeal injuries (Table 23-1) and for fewer than 1% of all fractures in children. They are much less common than physeal injuries of the ankle or upper extremity. Most are Salter-Harris type II injuries. Although separations through the cartilaginous physis would seem to be more likely than fractures through the hard cortical bone of the femoral shaft, the physis is protected by its large surface area and its undulating shape.

TABLE 23-1. COMPARTIVE INCIDENCE OF EPIPHYSEAL SEPARATIONS IN THE LOWER EXTREMITIES

In 1898, Hutchinson and Barnard (36) published one of the earliest reports of this injury. The results were dismal: of 58 patients with distal femoral physeal injuries, 22 required amputation and 10 died. The worst results were in patients with hyperextension injuries that caused popliteal ischemia and uncontrollable infection. Also in 1898, Poland (61) reported 114 patients with injuries to the distal femoral epiphysis, 24 of them boys whose legs were caught in the spokes of a moving carriage wheel as they swung themselves up over the tailgate. With the anterior thigh stopped against the wagon bed, the lower leg was hyperextended by the revolving wheel. The result was often an open injury with neurovascular compromise. Appropriately, separation of the distal femoral epiphysis came to be known as the *wagon-wheel injury* by the end of the 19th century.

After the beginning of the 20th century, little was written about injuries to the distal femoral epiphysis until Aitken and Magill's 1952 report of 15 patients (2). Ten of the 15 separations occurred in patients 13 to 17 years of age; all 10 were football injuries. Only 1 of the 15 patients had a hyperextension injury so common in the days of Hutchinson and Poland. Aitken and Magill wrote, “The horse and wagon has been replaced by the football field as the source of this type of injury.”

In 1960, Neer (51) reviewed 2,368 epiphyseal fractures and found that only 1% involved the distal femur. Seven patients (25%) had resultant growth disturbance. He related the severity of initial displacement to early physeal closure. Neer thought that delayed closure resulted from injury to the epiphyseal artery. In 1962, Bassett and Goldner (4) reported 25 patients with distal femoral physeal injuries, 40% of whom experienced significant shortening or angular deformity.

In 1973, Roberts (64) reported 100 patients with injuries to the distal femoral epiphysis. Two thirds of the separations resulted from sports. Of 50 patients followed an average of 7 years, 11 had shortening of more than 2.5 cm. Of the entire group of 100 fractures, no vascular injury was documented, and only 1 patient had an associated nerve injury (a transient peroneal deficit).

In 1974, in a retrospective review of 20 patients with separation of the distal femoral epiphysis, Stephens et al. (76) found a positive correlation between the severity of injury and premature closure of the physis. Substantial shortening developed in five patients despite satisfactory reduction. Growth inhibition usually was evident by 6 months after injury. Because six of their patients who had shortening had Salter-Harris type I or II injuries, the authors questioned the prognostic significance of the Salter-Harris classification as it pertained to separations of the distal femoral epiphysis.

In 1983, Riseborough et al. (63) in a follow-up study of 66 distal femoral separations reported that 17 patients subsequently underwent osteotomy for angular deformity. They identified a pattern of central growth arrest that supported Brashear's hypothesis (12–14) of damage to the germinal cells from the grinding of the central ridges on the proximal surface of the epiphysis as it displaced with injury.

In 1995, Thomson et al. (78) reported 30 fractures of the distal femoral physis and found that many displaced fractures lost reduction when immobilized in a cast. They recommended internal fixation of displaced fractures.

From one century to the next, the clinical presentation of distal femoral epiphyseal separation has changed considerably. The 19th-century surgeon most often found anterior displacement of the epiphysis from forced hyperextension, an open injury, neurovascular compromise, and, later, life-threatening infection. The 21st-century orthopaedic surgeon usually is presented with a closed injury, with displacement in either the coronal or sagittal plane, caused by either a motor vehicle accident or an athletic injury. Currently, the main concern is premature closure of the physis leading to progressive angulation or shortening, or both.

Surgical Anatomy

The epiphysis of the distal femur is larger and grows more rapidly than any other epiphysis in the lower extremity. It develops from a single ossific nucleus. It is the first epiphysis to ossify and the last to fuse. From birth to skeletal maturity, the distal femoral physis contributes 70% of the growth of the femur and 37% of the growth of the lower extremity. The annual rate of growth is approximately $^{3}/_{8}$ in. or 9 mm. The growth rate slows at a mean skeletal age of 13 years in girls and 15 years in boys (3,31).

Bony Anatomy

Immediately above the medial border of the medial condyle, the metaphysis of the distal femur widens sharply to the adductor tubercle. In contrast, the metaphysis flares minimally on the lateral side to produce the lateral epicondyle. A line tangential to the distal surfaces of the two condyles (the joint line) is approximately horizontal in an upright stance. The longitudinal axis of the diaphysis of the femur inclines medially downward, with an angle of 9 degrees from vertical. The mechanical axis of the femur, formed by a line between the centers of the hip and knee joints, is 3 degrees from vertical (Fig. 23-2).

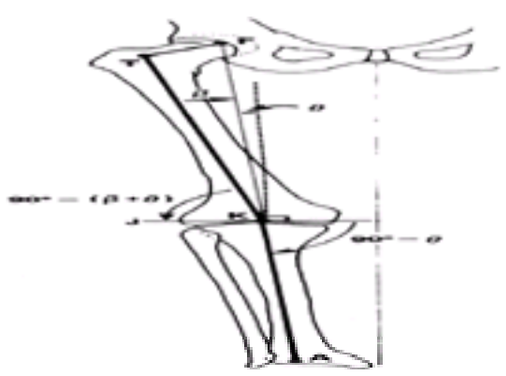

FIGURE 23-2. Relation between anatomic and mechanical axes of lower extremity and joint line. Normal value for theta is 3 degrees and for beta 6 degrees. (From Krackow KA. *Adv Orthop Surg* 1983;69-88; with permission.)

Viewed from behind, the condyles are separated by a deep intercondylar notch. In the coronal plane, the medial condyle has a larger cross section; in the transverse plane, the lateral condyle is larger.

A large part of the surface of the distal femoral epiphysis is covered by cartilage for articulation with the proximal tibia and patella. The anterior or patellar surface has a shallow midline concavity to accommodate the longitudinal ridge on the undersurface of the patella. The distal or tibial surface of each condyle extends on either side of the intercondylar notch far around onto the posterior surface. Here, the articular cartilage nearly reaches the posterior margin of the physis. Sometimes, there is a shallow horizontal groove on the articular surface of each condyle, marking the border between the patellar and tibial surfaces. This groove is more constant on the lateral condyle.

The contour of the distal femoral physis undulates from side to side, as well as from front to back. Although less pronounced in humans than in some animals, there is a distinctly quadrupedal configuration. On the distal surface of the metaphysis, facing the physis, a midline groove from anterior to posterior lies just above the intercondylar notch. A similar central groove is present in the midline from the medial to the lateral margins. The intersecting grooves divide the distal surface of the metaphysis into four mamillary processes. The corresponding proximal surface of the epiphysis has four valleys. The interdigitating configuration between the distal surface of the metaphysis and the proximal surface of the epiphysis may help to resist shear and torsion. When subject to trauma, however, the epiphyseal ridges may grind against the metaphyseal projections as a displaced separation occurs. In this way, germinal cells in the deeper layers of the intervening cartilaginous physis may be damaged. Brashear (12,13) has shown this to occur experimentally in simulated separations of the distal epiphyses in rat femora.

Soft Tissue Anatomy

The distal femoral physis is completely extraarticular. Medially and laterally, the physis is exactly at the level of the epicondyles, which serve as a landmark for it. Anteriorly and posteriorly, the synovial membrane and joint capsule of the knee attach to the femoral epiphysis close to the perimeter of the distal femoral physis.

Anteriorly, the suprapatellar pouch balloons up over the anterior surface of the metaphysis. On the medial and lateral surfaces of the epiphysis, the proximal attachment of the synovium and capsule is separated from the physis by the insertions of the collateral ligaments.

The strong posterior capsule, as well as all major supporting ligaments of the knee, are attached to the epiphysis of the femur distal to the physis. Both cruciate ligaments originate in the upward-sloping roof of the intercondylar notch distal to the physis. Compression and tension forces can be transmitted across the extended knee to the epiphysis of the femur by taut ligaments (57).

The medial head of the gastrocnemius and the plantaris muscles originate from the popliteal surface of the distal femoral metaphysis proximal to the physis. There is some difference of opinion among anatomists (11,29,30), as to whether the lateral head of the gastrocnemius originates from the metaphysis or the epiphysis. Muscle pull would not seem to be as much of a factor as the pull of the ligaments in the initial displacement of the epiphysis at the time of injury. Posterior displacement or angulation is not common, in contrast to displaced supracondylar femoral fractures. Also in contrast, separation of the distal femoral epiphysis with posterior displacement can be reduced and held by the extended knee, with the tightened gastrocnemius acting as an internal splint against the posterior aspect of the epiphysis (2).

Vascular Anatomy

The popliteal artery is close to the posterior surface of the distal femur: only a thin layer of fat separates the artery from the popliteal surface of the metaphysis. Directly above the femoral condyles, the superior geniculate arteries pass medially and laterally to lie between the femoral metaphysis and the overlying muscles. The terminal branches of the superior geniculate arteries enter the distal femoral epiphysis near the medial and lateral epicondyles. As the popliteal artery continues distally, it lies on the posterior capsule of the knee joint between the femoral condyles. At this level, the middle geniculate artery branches directly forward to enter the posterior aspect of the distal femoral epiphysis. The popliteal artery and its branches are vulnerable to injury from the distal femoral metaphysis at the time of hyperextension injury. An intimal tear of the artery is possible. It is unlikely that the distal femoral epiphysis would be completely shorn of its blood supply because of the rich anastomosis supplied, in part, by the superior geniculate branches.

Above the popliteal space, the sciatic nerve divides into the peroneal and tibial nerves. The peroneal nerve descends posteriorly between the biceps femoris muscle and the lateral head of the gastrocnemius muscle to a point just distal to the head of the fibula. The nerve is subject to stretch if the distal femoral epiphysis is tilted into varus or rotated medially. Moreover, the superficial course of the peroneal nerve makes it vulnerable to direct pressure on the posterolateral aspect of the knee.

Mechanism of Injury

The pattern of injury is determined by the direction of applied force as well as any other superimposed compressive or distraction loads. The epiphysis may be subject to distraction by a lateral force to the distal femur against a fixed foot, or by hyperextending the lower leg against a fixed thigh. An example of the former injury is a football player whose foot is fixed to the ground by his cleated shoe and who is hit from the side by another player. The classic example of the hyperextending mechanism is, as mentioned earlier, a boy who catches his lower leg in the spokes of a revolving wheel. A more modern example is a child descending on a trampoline while it is recoiling from another child (41). Both compression and distraction forces may be imposed simultaneously on the physis at the time of injury. Physeal separation begins on the tension side and ends with an oblique fracture through the metaphysis on the compression side (a Salter-Harris type II injury) (68). On the tension side, the cartilaginous matrix is more vulnerable to distraction or avulsion force. On the compression side, the osseous matrix of the metaphysis is more vulnerable to shear failure from loading.

Separation of the distal femoral epiphysis also can be caused by a direct blow. The anterior surface of the epiphysis may be struck when a patient falls forward on a bent knee. One reported distal femoral physeal separation was in a 14-year-old boy who struck his knee on the door frame as he galloped his horse through a barn (35).

Specific mechanisms of injury in recent clinical reviews are summarized in Table 23-2. In one series, all but 2 of 15 children hit by automobiles were 6 to 12 years of age. In contrast, separations from sports injuries usually occur between 10 and 19 years of age.

	Neer[a]	Bassett[b]	Roberts[c]	Stephens[d]	Total
Sports injury	5	4	64	8	81 (49%)
Hit by automobile	9	8	15	10	42 (25%)
Falls	3	3	12	1	19 (12%)
Auto accident	—	3	5	1	9 (5%)
Other	4	7	4	—	15 (9%)

TABLE 23-2. MECHANISM OF INJURY IN CLINICAL REVIEWS OF SEPARATION OF THE DISTAL FEMORAL EPIPHYSIS

Unusual mechanisms or underlying conditions also may cause distal femoral physeal injuries (4,73,74,77,80). Unilateral or bilateral separations can occur from birth injury (16). Separation of this epiphysis also has been noted in infants with arthrogryposis multiplex congenita, presumably occurring as stiff knees are passively manipulated (26). Epiphyseal separation also is a risk of manipulating a stiff knee in a normal child (71). Separations of the distal femoral epiphysis may occur in association with osteomyelitis, leukemia, hemophilia, osteosarcoma, and myelomeningocele (27,75,82). Rodgers et al. (66) reported four chronic physeal fractures of the distal femur in patients with myelomeningocele; they attributed them to chronic stress to a poorly sensate limb. Kumar et al. (39) noted that physeal injuries in children with myelomeningocele may heal more slowly than metaphyseal fractures and may require splinting or casting for a longer period. Separation through a normal physis has been reported in children with congenital absence of pain (53).

Classification

Separations of the distal femoral epiphysis have been classified according to the pattern of fracture, the direction of displacement, or the mechanism of injury. Each has specific implications (Table 23-3). The Salter-Harris classification (68) is useful for description and treatment planning. The direction and degree of displacement may help predict the type and severity of complications. Mechanisms of injury, as well as the implications of growth disturbance, vary with the patient's age.

Parameter	Implications
Anatomic	Directs method of stabilization, if displaced (does not strongly predict growth disturbance)
Salter I–IV (II most common)	
Displacement	Predicts risk of neurovascular injury
Medial	
Lateral	
Anterior	
Posterior	
Age	Predicts severity of growth disturbance—infantile and juvenile have risk of greatest disturbance
Infantile	
Juvenile	
Adolescent	

TABLE 23-3. CLASSIFICATION OF DISTAL FEMORAL EPIPHYSEAL FRACTURES: PARAMETERS AND IMPLICATIONS

Classification by Fracture Pattern

The Salter-Harris type I pattern is a separation through the distal femoral physis, without fracture through the adjacent epiphysis or metaphysis. It occurs in newborns with birth injury and in adolescents, often as a nondisplaced separation. Either may go undetected. Sometimes the diagnosis is made only in retrospect, when subperiosteal new bone formation occurs along the adjacent metaphysis. If displacement is present, it is usually in the sagittal plane. Growth disturbance may occur after Salter-Harris type I distal femoral injuries, contrary to the usual expectations for Salter-Harris type I fractures.

The Salter-Harris type II pattern, characterized by an oblique extension of the fracture across one corner of the adjacent metaphysis, is the most common type of separation at the distal femur and usually occurs in adolescents. Displacement usually is toward the side of the metaphyseal fragment (Fig. 23-3). The incidence of premature growth arrest, even with satisfactory reduction, is significant. If asymmetric growth follows a type II separation, the portion of the physis underneath the metaphyseal fracture usually is spared (78). Therefore, if the metaphyseal fracture is medial, deformity is more likely to be valgus than varus. If the metaphyseal fracture is lateral, varus angulation is more likely. The size of the metaphyseal fragment is proportional to the amount of compression force at the time of injury.

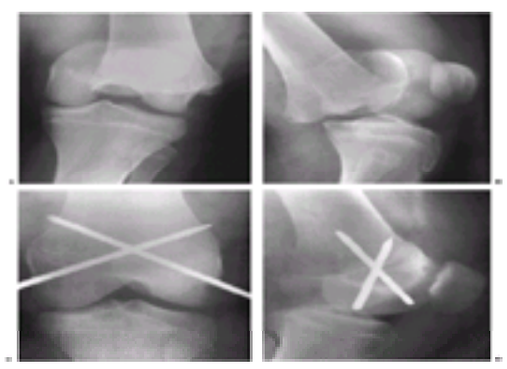

FIGURE 23-3. A and B: Anteriorly and medially displaced Salter-Harris type II fracture of the distal femoral epiphysis in a 16-year-old football player struck on the outside of the left knee. **C and D:** After closed reduction and percutaneous fixation with crossed Kirschner wires.

A Salter-Harris type III injury consists of a partial separation of the physis, with a vertical fracture line extending from the physis down to the articular surface of the epiphysis (Fig. 23-4). The vertical fracture line is usually in line with the intercondylar notch. Salter-Harris type III injuries most often are caused by valgus stress in sports and usually involve the medial condyle. The fracture may be nondisplaced and detected only with a stress radiograph. If displaced, reduction usually is unstable and requires internal fixation. A displaced type III fracture may cause incongruity of the joint surface, especially of the patellofemoral articulation. Hemarthrosis occurs from direct bleeding into the joint from the articular fracture.

FIGURE 23-4. A: Minimally displaced Salter-Harris type III fracture–separation of the distal femoral epiphysis in a 15-year-old football player hit from the front on the left knee. **B:** Fifteen years after injury.

Salter-Harris type IV injuries of the distal femur are uncommon. A sagittal fracture line extends from the metaphyseal cortex down across the physis and enters the articular surface of the epiphysis. Even slight displacement of the fracture fragment may produce growth disturbance from formation of a bony bridge from the displaced epiphysis to the metaphysis. Therefore, anatomic reduction and internal fixation are advised.

Salter-Harris type V injuries (without fracture) are rare. Most commonly, the diagnosis is made in retrospect at the time of evaluation for premature growth arrest and limb-length discrepancy or angular deformity.

Even less common is an avulsion injury to the edge of the physis. A small fragment, including a portion of the perichondrium and underlying bone, may be torn off when the proximal attachment of the collateral ligament is avulsed. This uncommon injury may also lead to localized premature growth arrest and progressive angular deformity (34). The bony bridge usually is small, localized, and surgically accessible, and excision is appropriate.

A triplane fracture infrequently occurs in the distal femur. Computed tomographic (CT) scans with three-dimensional modeling may be helpful in identifying and analyzing (44) this injury.

Classification by Displacement

Anterior displacement of the epiphysis results from hyperextension of the knee. The extension force on the distal femur is transmitted through the posterior capsule of the knee joint. The mechanism is similar to that of knee dislocations in adults. There is an increased risk of neurovascular injury (77).

Posterior displacement of the epiphysis on the femur is uncommon. It has been reported in birth injuries and in older children struck on the front of the flexed knee. Reduction is obtained and maintained by extending the knee.

Medial/lateral displacement currently is most common, usually with an associated fracture of the adjacent metaphysis (Salter-Harris type II).

Classification According to Age

Separations of the distal femoral epiphysis in infants may be associated with breech birth or child abuse (64) (Fig. 23-5). Most are Salter-Harris type I injuries. Clinically differentiating between an epiphyseal separation and hematogenous osteomyelitis may be difficult. Ultrasonography may be used to confirm fracture. Older children and preadolescents usually are injured in high-energy accidents such as a fall or being hit by a vehicle. Associated musculoskeletal and visceral injuries are common in this group.

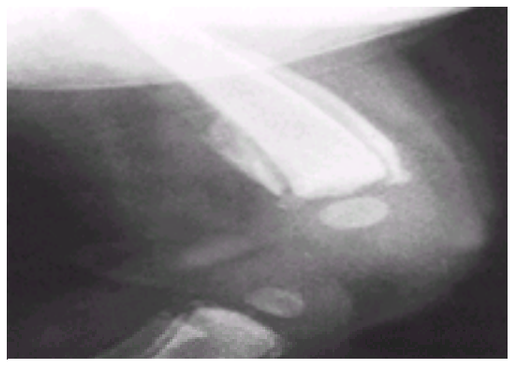

FIGURE 23-5. Lateral radiograph of a swollen knee in a 3-month-old girl who reportedly fell out of her crib 8 days earlier. Subperiosteal ossification along the distal femoral shaft indicates separation of the distal femoral epiphysis. Note evidence of fracture–separation of the proximal tibial epiphysis as well. Final diagnosis: abused child.

In most recent reviews, approximately two thirds of distal femoral epiphyseal separations occur in adolescents, often from contact sports (45,51,64). The most common patterns are Salter-Harris types I and II. The potential for growth disturbance is lowest in this group (Fig. 23-6).

FIGURE 23-6. A: The initial anteroposterior radiograph of a 12-year-boy who sustained an injury to the left knee while playing football shows widening of the lateral aspect of the distal femoral physis. **B:** With continued play, a second injury was sustained with anterior displacement of the distal femoral epiphysis. **C:** Open reduction and fixation with crossed Kirschner wires was necessary because of late presentation of injury. **D:** At follow-up, early closure of the distal femoral physis is apparent. (Courtesy of Stephen Cope, MD, Mobile, Alabama.)

Signs and Symptoms

Physical Findings

The patient usually cannot walk or bear weight on the injured limb immediately after sustaining a displaced separation of the distal femoral epiphysis. However, with a nondisplaced separation, such as in athletic injuries, the patient may be able to walk. He or she may have felt a “pop” at the injury and presumed a ligament tear. Effusion of the knee and soft tissue swelling develop rapidly. Abrasion or laceration of the overlying soft tissues may be a clue to the mechanism of injury or to an open fracture.

If the secondary hamstring spasm can be relaxed, instability just above the knee joint may be felt. Complete separation of the epiphysis and tear of adjacent ligaments can occur simultaneously. A soft end point or crepitus may accompany the abnormal motion after separation of the physis. Crepitus sometimes is absent because the periosteum is interposed between the metaphysis and the epiphysis. Abnormal laxity in a patient with negative radiographs may be caused by a nondisplaced physeal injury rather than by a ligamentous tear. If the diagnosis of physeal injury is confirmed radiographically, further stress or displacement of the epiphysis should be minimized.

It sometimes is possible to localize tenderness to the level of the physis, which is at approximately the same level as the upper pole of the patella and the adductor tubercle, both of which can be used as reference points. In Salter-Harris type III and IV fractures, tenderness is greater on the involved side of the distal femur.

Separation of the distal femoral epiphysis usually is accompanied by effusion of the knee joint. This is logical in Salter-Harris type III and IV separations, in which the articular surface is fractured. The hemarthrosis associated with other patterns of separation may be caused by bleeding through the synovial suprapatellar pouch. The knee may feel tense to palpation. Aspiration nearly always produces sanguineous fluid. Extravasation of blood into the soft tissues of the distal thigh and popliteal fossa produces ecchymosis that becomes apparent within 72 hours after injury.

Direction of Displacement

Most commonly, displacement of the epiphysis occurs in the coronal plane, producing varus or valgus deformity. The protruding end of the metaphysis can be palpated through the distal portion of the vastus medialis with valgus injuries, or through the vastus lateralis with varus injuries.

With anterior displacement, the patella, riding forward on the femoral epiphysis, becomes extremely prominent. There is a palpable depression across the anterior thigh just proximal to the patella, and fullness in the popliteal fossa is produced by posterior displacement of the distal end of the metaphysis. Posterior protrusion of the metaphysis may put pressure on the popliteal artery, so that pulsations become palpable in the subcutaneous region of the popliteal fossa. Anterior displacement of the distal femoral epiphysis may be indicated by prominence of the adductor tubercle, which is displaced with the epiphysis anterior to the metaphysis.

With posterior displacement of the distal femoral epiphysis, the distal end of the metaphysis is prominent on the anterior aspect of the distal thigh directly above the patella, and the epiphysis can be felt as a palpable fullness in the popliteal fossa. Whatever the direction of displacement, the patella and femoral condyles remain in line with the proximal tibia, a point useful in differentiating epiphyseal separation from dislocation of the knee.

Polytrauma

With an open injury, the distal end of the metaphysis may cause a transverse laceration, most often in the lateral portion of the popliteal fossa. The apex of the protruding metaphysis is denuded of periosteum.

Whenever a diagnosis of epiphyseal separation is suspected, careful neurovascular examination of the lower leg and foot should be done, including pulses, color, temperature, capillary refill, and motor and sensory status. The extremity may become cyanotic if venous return is impaired. The use of the Doppler flow meter may be helpful in evaluating circulation distal to the injury. Compartmental pressure recordings should be obtained if there are clinical findings of compartment syndrome (50). If the separation occurred in a vehicular accident, associated injuries may be present (4).

Radiographic Findings

Because the physis normally is radiolucent, injury is diagnosed by displacement, widening, or adjacent bony disruption (54). However, a nondisplaced Salter-Harris type I or III fracture without separation can be easily overlooked. Oblique views of the distal femur may reveal an occult fracture through the epiphysis or metaphysis. Stress views should be considered if multiple plain films are negative in a patient with an effusion or tenderness localized to the physis (Fig. 23-7).

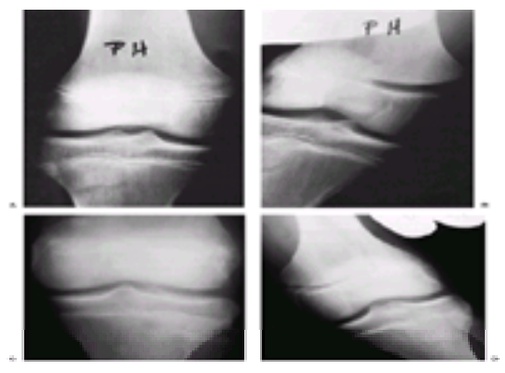

FIGURE 23-7. A 14-year-old football player sustained a knee injury when he was tackled. **A:** The initial anteroposterior radiograph shows no fracture or separation. **B:** Anteroposterior valgus-stress radiograph reveals separation of the distal femoral epiphysis. **C and D:** Another example, age 16: such injuries may occur even when the physes are nearly closed.

In a Salter-Harris type II injury, the most common pattern, a fracture line extends from the radiolucent physis obliquely through the distal femoral metaphysis. The metaphyseal fracture line and spared segment of physis outline a triangular fragment of bone that remains in position relative to the epiphysis. The size of the metaphyseal triangle tends to be larger if displacement has occurred in the coronal plane.

A vertical fracture line extending from the articular surface of the distal femoral epiphysis into the radiolucent physis is diagnostic of a Salter-Harris type III fracture. Usually, the epiphyseal fracture line is best seen on an anteroposterior view because it is oriented in the sagittal plane. The degree of displacement in this fracture pattern may be difficult to measure unless the radiographic projection is precisely in line with the plane of fracture. If the fracture pattern requires further definition to determine treatment, multiple oblique views or CT scanning may be helpful to demonstrate the fracture plane or measure the gap in the articular surface of the femoral portion of the patellofemoral joint. Less commonly, the vertical fracture extends through the articular surface in the weight-bearing portion of the femoral condyle. If the weight-bearing surface is involved, it is even more important to determine the degree of displacement.

A fracture line extending from the epiphyseal surface across the physis and up through the metaphysis is characteristic of a Salter-Harris type IV injury. Even 1 to 2 mm of displacement is significant (21). Occasionally, the pattern of fracture separation may be difficult to outline. If needed, CT can be useful.

Anterior or posterior displacement of the epiphysis is best appreciated on the lateral projection. The anteriorly displaced epiphysis usually is tilted so that the distal articular surface faces anteriorly. The posteriorly displaced epiphysis is rotated so that the distal articular surface faces the popliteal fossa.

Separation of the distal femoral epiphysis in an infant is difficult to see on initial radiographs unless there is displacement because only the center of the epiphysis is ossified at birth. This ossicle should be in line with the axis of the femoral shaft on both anteroposterior and lateral views (17,18). Comparative views of the opposite knee may be helpful. Magnetic resonance imaging (MRI), ultrasonography, or arthrography of the knee may help to identify a separation of the relatively unossified femoral epiphysis.

Stress views are indicated when the initial radiographic appearance is negative but the history and physical signs suggest epiphyseal separation. Stress radiographs may be falsely negative if there is associated muscle spasm. Adequate analgesia relaxes muscle spasm and helps protect the physis from further injury during examination. Some traction should be applied to the lower leg as the knee is angulated for radiographic examination. Smith (72) reported two 15-year-old boys injured on the football field for whom the diagnosis of distal femoral epiphyseal separation could be made only on stress views.

The radiolucent line representing the physis on the anteroposterior projection is approximately 3 mm thick until adolescence. Diminution of the distance between the line of provisional calcification at the lower edge of the metaphysis and the bony plate on the upper border of the epiphysis suggests a compression injury to the physis, especially if reinforced by the clinical findings. Neer (51) pointed out that radiographic signs of premature closure usually become evident within 6 months after injury.

Treatment—Overview

The objectives of treatment of separation of the distal femoral epiphysis are to obtain and maintain satisfactory reduction, to regain a functional range of motion of the knee joint, to regain normal strength of the quadriceps and hamstring muscles, and to avoid further damage to the physis.

Anatomic reduction of a displaced separation of the distal femoral epiphysis is desirable, and the closer the patient is to skeletal maturity, the greater the need for exact realignment. Blount (8) pointed out that residual varus or valgus deformity after reduction usually does not remodel with further growth. Reduction of displacement in the sagittal plane may be slightly less precise. Sharrard (70) stated that angulation of up to 15 degrees with apex anterior or posterior is well tolerated. Blount wrote that a child younger than 10 years of age with posterior angulation of less than 20 degrees will not have permanent genu recurvatum, and the deformity remodels with growth. The remodeling potential in infants is so great that considerable displacement can be accepted. Burman and Langsam (16) reported good results in displaced birth fractures that were merely splinted. Most infants can be treated by supportive traction or splinting, no matter how great the displacement.

Closed reduction usually can be performed in older children up to 10 days after injury. Böhler (9) reported successful reduction 12 days after injury, and Patterson (57) reported successful reduction in a 9-year-old girl 11 days after injury.

Closed reduction may fail for a number of reasons, making open reduction necessary. A Salter-Harris type I or II separation may be irreducible by closed methods because of interposed soft tissue, usually a flap of torn periosteum or muscle that curls up inside the fracture cleft. Displaced Salter-Harris type III or IV separations almost always require open reduction and internal fixation to minimize disruption of the articular surface and decrease the likelihood of premature growth arrest. In an open injury, open reduction and fixation may be accomplished at the time of wound debridement.

Although growth may be adversely affected by the injury itself, further damage to the physis should be avoided during diagnostic stress radiography, closed reduction, or open reduction. The use of general anesthesia decreases the forces across the physis. Kurlander (40) reported a patient in whom the popliteal artery was injured at the time of closed reduction. Salter et al. (67) stated that it is better to accept a less-than-perfect reduction and do a corrective osteotomy later than to cause further damage by rough handling.

Thomson et al. (78) showed that significantly displaced physeal fractures of the distal femur had a better outcome if they were internally fixed. Whenever possible, fixation devices are placed to avoid crossing the physis. In Salter-Harris type III separations, pins or screws may be placed transversely through the epiphysis. In Salter-Harris type II or IV separations, pins or screws are placed transversely through the metaphysis, engaging the triangular fragment if it is large enough (2 to 3 cm tall; Fig. 23-8). If traversing the physis is unavoidable, smooth, small-diameter pins are used.

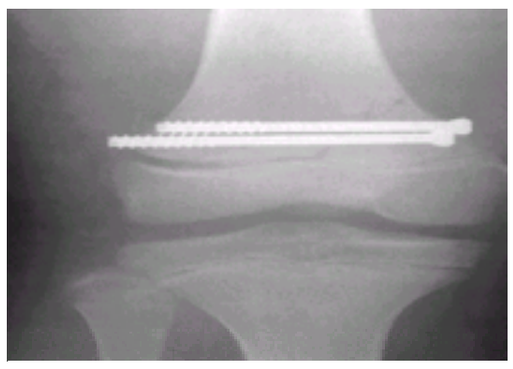

FIGURE 23-8. Previously reduced Salter-Harris type II fracture of the distal femoral epiphysis in a 13-year-old boy. After reduction, two 6.5-mm cannulated screws were inserted through the large medial metaphyseal fragment for fixation.

External fixation rarely is indicated for the treatment of physeal injuries about the knee because of the danger of secondary knee joint infection (79).

At the time of initial evaluation and treatment planning, the short- and long-term problems and complications are explained to the patient and parents. The need for long-term follow-up is stressed from the beginning of treatment. The family is better able to comprehend these facts if they are presented from the beginning.

Nonoperative or Conservative Treatment

Immobilization

A nondisplaced separation is immobilized to prevent displacement and relieve pain. If there is tense effusion of the knee joint, aspiration under sterile precautions may be done. A well-molded long leg cast is applied with the knee in approximately 15 to 20 degrees of flexion. The forces that caused the injury should be reversed and the intact periosteal hinge tightened. Thus, if the metaphyseal fragment of a nondisplaced Salter-Harris type II separation is on the lateral side of the metaphysis, the cast is applied with three-point molding into slight varus. If the metaphyseal fragment is medial, the cast is molded into slight valgus. Alternative methods of immobilization include a Jones dressing, posterior splint, cylinder cast from high thigh to supramalleolar level, or, most often, a single hip spica cast. The more secure form of immobilization should be used if the patient is obese or of uncertain reliability. It must be stressed that there is a high chance of loss of reduction if a displaced fracture is reduced and not internally fixed (78). Radiographs are made 1 week after immobilization to ensure that displacement has not occurred.

Isometric exercises are started as soon as symptoms permit. Straight-leg raises usually are possible approximately a week after injury. Ambulation on crutches with touchdown gait is continued for 3 to 6 weeks after injury. By 4 to 8 weeks after injury, depending on the patient's age, the cast is removed or converted to a removable posterior splint. Thereafter, active range-of-motion exercises are done twice daily until normal strength and knee motion are regained. Return to athletic activities may be permitted when symptoms are resolved, knee range of motion is normal, and quadriceps mass is symmetric with the opposite side. Even with a nondisplaced fracture, growth inhibition may be caused by a compression force at the time of injury, and the patient should be followed for at least 6 months and preferably for 12 to 24 months.

Closed Reduction and Fixation

The technique of closed reduction depends on the direction and degree of displacement of the epiphysis (Fig. 23-9). General anesthesia often is indicated to decrease associated muscle spasm and diminish the risk of further injury to the physis. Joint aspiration may precede manipulation. Keeping in mind the intact tether of periosteum on the side to which the epiphysis is displaced, the first maneuver increases the deformity slightly with traction. The proximal edge of the displaced epiphysis can then be brought to the edge of the metaphysis on the same side of the periosteal tether. Reduction is then completed by realignment of the angular deformity. Grinding of the physeal cartilage against the metaphysis is thereby avoided. The sequence of events is to pull, tip, and close the separation. The maneuver should be 90% traction and 10% leverage.

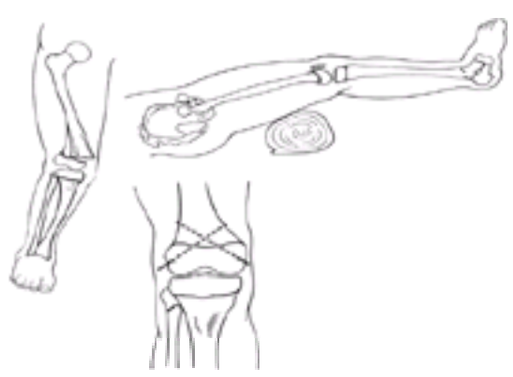

FIGURE 23-9. Closed reduction and stabilization of a Salter-Harris type I or II fracture. **A:** With medial or lateral displacement, traction is applied longitudinally along the axis of the deformity to bring the fragments out to length. **B:** For anterior displacement, the reduction can be done with the patient prone or supine. Length is gained first; then, using a large bolster as a fulcrum, a flexion moment is added. **C:** Fixation is with smooth 3-mm pins in most adolescents; the angle must be oblique so that the pins cross proximal to the physis. Pins should engage the far cortex and may be cut off under the skin.

Medial or Lateral Displacement. To reduce either medial or lateral displacement of the epiphysis, the patient is placed supine. The leg is grasped with the knee in extension and the hip in slight flexion. The thigh is fixed by an assistant. Moderate longitudinal traction is exerted by a handhold on the leg above the ankle. If the displacement of the epiphysis is medial, varus is increased gently and cautiously to avoid stretching the peroneal nerve. With one hand holding traction on the leg, the palm of the other hand is placed against the concave surface of the angulated distal femur. The epiphysis is pushed toward the metaphysis as the leg is realigned with the thigh. Once reduction is obtained, longitudinal traction is released. If traction on the leg is precluded by an associated injury to the femur or a tear of a knee joint ligament, a pin can be inserted transversely across the proximal tibia to be used as a handle in the maneuver. Usually, however, these associated injuries increase the risk of loss of reduction and are indications for primary internal fixation in adolescents. The reduction is checked by anteroposterior and lateral radiographs. A long leg cast or hip spica cast is then applied, with the knee in slight flexion. External immobilization is continued for 5 to 6 weeks. Thereafter, the care is similar to that for a nondisplaced separation.

Anterior Displacement. Anterior displacement of the epiphysis can be reduced with the patient either supine (82) or prone (62,68). Hutchinson and Barnard (36) showed that reduction of this displacement could be more easily and surely obtained by applying traction to the leg with the knee flexed. With the patient supine, the hip is flexed approximately 60 degrees and the thigh is fixed by an assistant. Longitudinal traction is applied, with the knee in partial flexion. Downward pressure on the epiphysis is exerted manually. With continuing traction on the leg, the knee is flexed 45 to 90 degrees. Prone reduction requires fewer assistants. If the surgeon chooses to perform the reduction with the patient prone, traction is applied to the limb, an assistant pushes down on the posterior aspect of the thigh, and the knee is flexed further until approximately 110 degrees of flexion is reached. This sequence is similar to that for reduction of a supracondylar humerus fracture of the elbow.

After reduction of an anteriorly displaced epiphysis, it is important to check the pulses in the foot and ankle. Flexion of a swollen knee to beyond 90 degrees may compromise the popliteal vessels. The position is maintained by temporary splinting while images are obtained. If reduction is adequate, the knee is immobilized in flexion by a long leg or hip spica cast. Bellin (5) and Griswold (32) noted difficulty regaining extension of the knee after prolonged immobilization in flexion. Two weeks after injury, the cast is changed or modified so that the knee can be brought out to 45 degrees flexion. It is important to increase the range of extension gradually

during the 6- to 8-week period of immobilization.

Pin Fixation. The larger the metaphyseal fragment and the greater the displacement, the less stable the closed reduction. If reduction of the anterior displacement is unstable, percutaneous pin fixation is recommended. An image intensifier may be used. If the metaphyseal fragment is large enough, threaded pins or screws can be directed transversely across the metaphysis after reduction (Fig. 23-10). In the absence of a substantial metaphyseal fragment, smooth pins are directed through the side of each condyle to cross in the metaphysis proximal to the central third of the physis. The closer the pins are to crossing at the fracture site, the less stable they are. To make the pins cross at a point proximal to the fracture site, they should come in at a “high” angle, less than 45 degrees to the long axis of the femur. The pins are cut off under the skin before application of the cast, with the knee in slight flexion. Infection is frequent if pins in this region are left out through the skin for a long time.

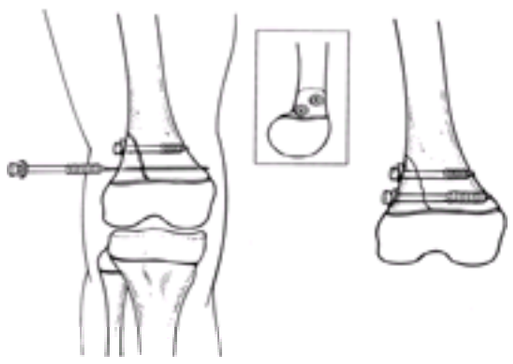

FIGURE 23-10. Reduction and percutaneous screw fixation of Salter-Harris type II fracture with a large metaphyseal fragment. **A:** Cannulated screws are placed closer to the physis than to the fracture line. Two screws may be placed anterior and posterior to each other. A washer helps increase compression. **B:** After both screws are in place, reduction should be maintained when pressure is removed. If deformity recurs, the metaphyseal fragment may be unstable or the periosteum may be infolded on the contralateral side.

Posterior Displacement. To reduce posterior displacement of the distal femoral epiphysis, the patient is placed supine. The surgeon grasps the leg and exerts downward longitudinal traction while the knee is held partly flexed. Longitudinal traction is continued as the leg is brought up to extend the knee. An assistant pulls up directly under the distal femoral epiphysis with one hand and pushes down on the distal metaphysis of the femur with the other. Heller (33) advised placing a pin transversely distal to the tibial tubercle. Upward pull on the tibial pin is continued while applying longitudinal traction to the leg. Aitken and Magill (2) pointed out that reduction of this type of separation was best maintained by leaving the knee in extension. The medial head of the gastrocnemius originates from the metaphysis proximal to the distal femoral physis and acts as an internal splint when held taut against the posterior aspect of the epiphysis by the extended position of the knee. Burman and Langsam (16) advised immobilization without reduction for posterior displacement in a newborn after breech delivery. They reported that adequate remodeling occurred, even with severe displacement.

Operative Treatment

Open Reduction of Physeal Fractures

Open reduction is indicated for displaced Salter-Harris type III or IV fractures, for all other types in which satisfactory alignment cannot be obtained by closed means, or when associated injuries mandate it (i.e., a “floating knee” or ligament injury). A tourniquet around the proximal thigh may be used for temporary hemostasis if it is placed proximally enough to avoid binding the thigh muscles under the inflated tourniquet.

For an irreducible Salter-Harris type II separation in the coronal plane, a longitudinal incision is centered over the palpable, prominent end of the metaphysis. The approach from this direction gives direct exposure of any obstacles to reduction and avoids disruption of the periosteal hinge. If the displacement of the epiphysis is lateral, the metaphysis protrudes medially under the distal portion of the vastus medialis. If the displacement of the epiphysis is medial, the metaphysis protrudes laterally under the distal edge of the vastus lateralis. If the displacement is anterior, the procedure is done with the patient prone. After incision of the deep fascia, dissection is continued, extending the plane of injury bluntly by spreading the muscle fibers to expose the end of the metaphysis. Irrigation and careful removal of clotted blood permit better inspection of the separation. An interposed flap of periosteum may be identified between the epiphysis and metaphysis. The periosteal flap is gently pulled out of the separation with forceps or a large skin hook. Special care is taken to avoid any additional damage to the physis covering the proximal surface of the epiphysis. Once the muscle and periosteal flap are removed, reduction is carried out by gentle realignment. To avoid damage to the physis, instruments should not be placed in the physeal interval. Again, for unstable or irreducible fractures, percutaneous pinning is indicated to stabilize the fracture (56) (Fig. 23-11). After closure of the wound, a long leg or hip spica cast is applied.

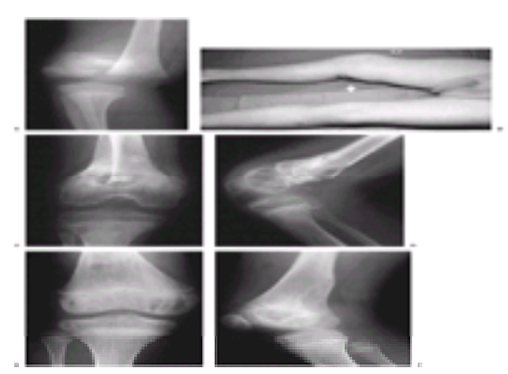

FIGURE 23-11. A: Completely displaced Salter-Harris type II fracture of the distal femur in a 6-year-old girl whose foot was on the back of the driver's headrest when the automobile in which she was riding was involved in an accident. **B:** Ecchymosis in the popliteal fossa and anterior displacement of the distal femur are evident. Clinical examination revealed absence of peroneal nerve function and a cold, pulseless foot. The fracture was irreducible by closed methods and required open reduction, internal fixation, and repair of a popliteal artery laceration. **C and D:** Three months after injury; note incomplete reduction, 25 degrees of posterior angulation, and abundant callus formation about the fracture. **E and F:** Four years after injury; note remodeling about the distal femur with normal growth of the distal femoral physis.

For open reduction and internal fixation of a Salter-Harris type III or IV separation, an anteromedial or anterolateral longitudinal incision is used (Fig. 23-12). The anterior physeal and articular margins of the fracture are exposed. If the fracture is nondisplaced, percutaneous cannulated screw fixation is indicated. In displaced fractures, arthrotomy allows inspection of the articular surface of the epiphysis. Reduction is checked by noting the apposition of the articular surfaces, the physeal line anteriorly, and the fracture pattern (Fig. 23-12, arrows) and can be confirmed with fluoroscopy. Provisional stabilization is obtained with Kirschner guidewires. When reduction is accomplished, threaded pins or screws are directed transversely across the epiphysis in Salter-Harris type III separations (Fig. 23-13), or across the metaphysis and epiphysis in Salter-Harris type IV injuries (Fig. 23-14). If crossing the physis with fixation is unavoidable, smooth pins or wires should be used. Fixation pins usually are introduced through stab wounds adjacent to the incision. The pins are cut off beneath the skin. After reduction and fixation are checked by intraoperative radiographs, the knee joint is thoroughly irrigated and inspected for other fractures and ligament disruption. After surgery, the reduction is protected by a long leg or hip spica cast.

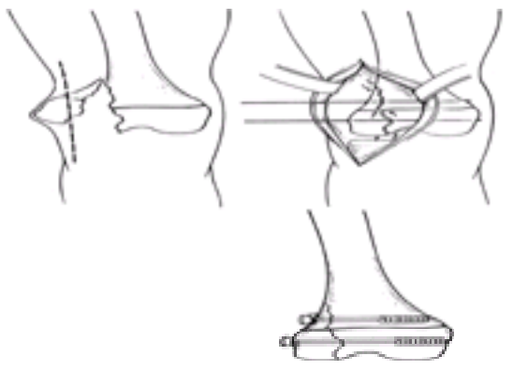

FIGURE 23-12. Open reduction of displaced lateral Salter-Harris type IV fracture of the distal femur. **A:** Longitudinal skin incision. **B:** Provisional stabilization with Kirschner wires. Cortex, physis, and joint surfaces are aligned *(arrows).* **C:** Fixation screws are inserted parallel to the physis.

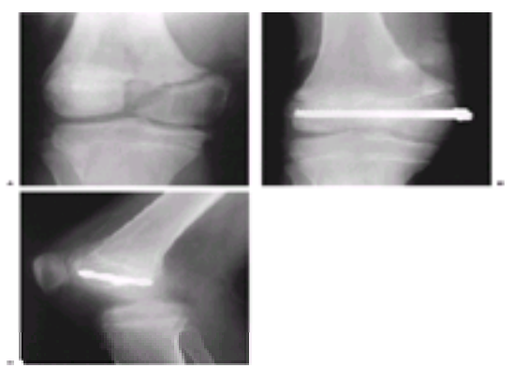

FIGURE 23-13. A: *Salter-Harris type III fracture–separation of the distal femur.* Note the vertical fracture line extending from the physis distally into the intercondylar notch with displacement. **B:** After reduction and fixation with two compression screws extending transversely across the epiphyseal fragments. Note closure and healing of the vertical fracture line in the epiphysis, with restoration of the articular surface. **C:** Placement of screws in the epiphysis distal to the physis and proximal to the articular cartilage.

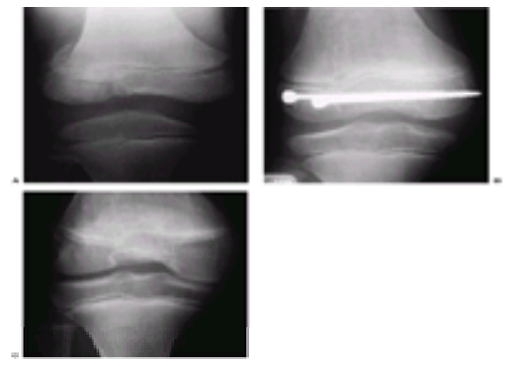

FIGURE 23-14. A: *Salter-Harris type IV fracture of the distal femur in a 7-year-old boy who was struck by a car.* The fracture plane was complex and it was significantly displaced. **B:** Two years after open reduction and internal fixation, growth was maintained, although flexion was limited to 110 degrees. **C:** Six years later, limb lengths and angulation were equal.

If an associated collateral ligament injury is found, it can be repaired at the time of open reduction. Internal fixation is used to allow early mobilization and rehabilitation of both the physeal separation and the ligamentous injury.

If vascular repair is indicated, a posterior modified S-shaped incision or posteromedial incision is used to follow the course of the femoral artery (Fig. 23-15). Care should be taken during incision because the vessel may be superficial beneath the skin. The hamstring tendons may be "bowstrung" around the femoral metaphysis. The artery may be in spasm, occluded by intimal tear, or torn. After the vascular structures are identified, the fracture is reduced and stabilized before vascular repair.

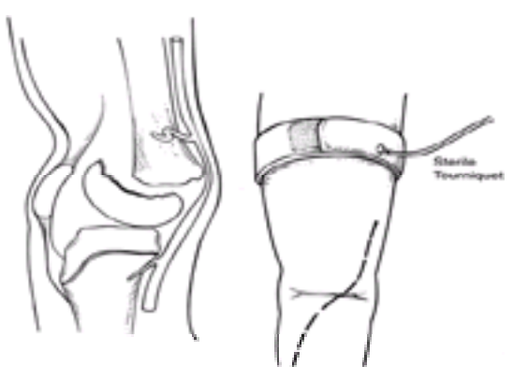

FIGURE 23-15. Open reduction of distal femoral fracture with vascular repair. **A:** Lateral view showing site of vascular injury. **B:** Modified S-shaped incision follows the course of the femoral artery.

Open separations of the distal femoral epiphysis usually are caused by hyperextension, with anterior displacement of the epiphysis. A wound may be present in the popliteal fossa, overlying the posterior protruding end of the metaphysis. The patient is placed prone with the knee slightly flexed and the skin is thoroughly irrigated and debrided. The wound is enlarged to allow inspection of the contents of the popliteal fossa. Muscle or periosteum or both may be interposed in the fracture site. Because the patient is prone, reduction is obtained by bringing the leg up against downward pressure on the distal end of the femoral shaft, while maintaining longitudinal traction. Internal fixation is used to stabilize the fracture, especially if vascular or ligamentous repair is to be done. The wound is packed open, and the knee immobilized in slight flexion with a long leg or hip spica cast. Rarely, if extensive soft tissue reconstruction is required, an external fixator spanning the knee may be considered to facilitate dressing changes and soft tissue reconstruction.

AUTHOR'S PREFERRED METHOD OF TREATMENT

Nondisplaced fractures are treated with above-the-knee cast immobilization for 4 to 6 weeks. For displaced Salter-Harris type I or II fractures, we perform gentle

closed reduction with the patient under general anesthesia, using traction and gentle manipulation. Extreme flexion should not be necessary to maintain reduction and should be avoided to prevent injury to vascular structures. In children younger than 10 years of age, as much as 20 degrees of posterior angulation is acceptable, but in patients closer to adolescence, we accept only minimal anteroposterior angulation and no more than 5 degrees of varus–valgus angulation.

If the displacement is anterior, we perform the reduction with the patient supine. An assistant holds the thigh with the hip partly flexed over a bolster. The surgeon grasps the leg from behind the calf with one hand and pulls down in line with the thigh as he or she tries to tip and close the epiphysis against the metaphysis with the other hand. We check for pulses after this maneuver. For all but minimally displaced and completely stable fractures, we use internal fixation with percutaneous pins or screws. Smooth pins $^{5}/_{64}$ or $^{3}/_{32}$ in.) are placed so that they cross in the metaphysis, proximal to the fracture, to prevent the epiphysis from rotating at the fracture site. In an adolescent with a large (2 to 3 cm high) triangular metaphyseal spike (Thurston-Holland fragment), we insert two cannulated 4.0- or 6.5-mm screws transversely to fix the spike to the metaphysis without crossing the physis. An above-the-knee cast is applied with the knee in 5 to 10 degrees of flexion.

We prefer open anatomic reduction for all displaced type III and IV fractures to prevent the formation of a bony bar, which causes limb-length discrepancy and angular deformity. The fracture line, the physis, and the joint surface are observed to confirm anatomic reduction (Fig. 23-16). Cannulated screws are then inserted with either an open technique or percutaneously with the aid of image intensification.

On the lateral view, the screws appear to be protruding anteriorly in the distal femoral epiphysis, but they actually are buried in articular cartilage. (Courtesy of Dr. William C. Warner, Jr, Campbell Clinic, Memphis, Tennessee.)

Open fractures or fractures caused by massive penetrating trauma require meticulous debridement. We try to save and stabilize any viable fragments of epiphysis or articular surface, but totally free fragments are removed. Debridement is repeated as necessary, usually at 48 hours, and soft tissue coverage is accomplished as soon as feasible.

Postreduction Care

Ambulation on crutches usually is possible within a few days. At 1 week after reduction, the patient returns for radiographs taken through the cast. If displacement has occurred, it is not too late to obtain reduction by remanipulation. If reduction is maintained, straight-leg exercises are begun four times daily. At 4 weeks after injury, the patient returns for radiographs. If subperiosteal new bone formation is present adjacent to the metaphysis, the cast is bivalved, and the posterior portion may then be removed twice daily for active muscle-strengthening and range-of-motion exercises, done both supine and prone. The splint may be reapplied for ambulation with crutches. Partial weight bearing is gradually increased. At 6 to 8 weeks after injury, and at regular intervals thereafter, the patient returns for reexamination to evaluate healing, range of knee motion, and the strength of thigh muscles. When range of motion and thigh muscle strength are fully recovered, the patient may return to normal activities. At 6 months after injury, alignment, leg length, and gait are evaluated with comparative radiographs of the lower extremities. If alignment, leg length, and gait are within normal limits, the patient is dismissed from routine care but is counseled to return for evaluation of growth 12 and 24 months after injury.

Prognosis

The prognosis for separation of the distal femoral epiphysis usually is good. Over two thirds of the patients with this injury are healthy adolescents (64). With appropriate treatment, they return to normal activities within 4 to 6 months. Although as many as a third of patients may sustain some damage to the physis at the time of injury, they usually are close enough to the end of growth to make shortening or angulation insignificant. For younger children with more remaining growth, the potential for angular and length deformity is significant.

The outlook for newborns with separations sustained at the time of delivery in general is good. Remodeling occurs rapidly. If part of the physis is damaged, however, the consequence is major deformity (a rare event). In some patients, nearly normal growth continues for a decade until the adolescent growth spurt makes a growth disturbance obvious (25).

Complications

Early complications of separations of the distal femoral epiphysis may include injury to the popliteal artery, neurapraxia of the peroneal nerve, associated ligamentous injury, and recurrent displacement of the epiphysis (Table 23-4). Complications that occur later include angular deformity, leg-length discrepancy, stiffness, quadriceps weakness, and persistent instability of the knee. Delayed union or nonunion is rarely a problem, except in patients with an underlying neuropathy such as meningomyelocele. Avascular necrosis of the epiphysis has not been reported after distal femoral physeal injuries, in contrast to proximal femoral physeal injuries. The reported incidences of complications in five clinical reviews are summarized in Table 23-5.

Pitfall	Preventive Strategy
Missed diagnosis	Consider undisplaced physeal injury in athletes with tenderness at physis or laxity on stress Careful physical examination of polytrauma patients for tenderness, or consider bone scan if unresponsive
Vascular impairment	Check pulses, temperature, muscle function; angiogram if abnormal
Peroneal nerve injury	Avoid excessive stretch through traction or excessive varus stress at reduction
Redisplacement	Apply spica cast if needed; internally fix if displaced or unstable; early follow-up to allow correction (within 1 week after injury)
Knee joint instability	Check ligaments when fracture stabilized or healed; tailor treatment to age and activity
Progressive angulation	Minimize trauma at reduction; magnetic resonance imaging may help to make earliest diagnosis; follow-up at 6 months after trauma to detect growth disturbances

TABLE 23-5. INCIDENCE OF COMPLICATIONS AFTER SEPARATION OF THE DISTAL FEMORAL EPIPHYSIS IN CLINICAL REVIEWS

Vascular Impairment

Intimal tear and thrombosis in the popliteal artery may be caused by trauma from the distal end of the metaphysis when the epiphysis is displaced anteriorly with a hyperextension injury (41,45). The current incidence of vascular injury is approximately 1%. A single vascular deficit occurred in each of two reviews (51,76). In another four reviews, there were no vascular injuries (2,45,64).

Neer (51) found vascular insufficiency in 1 of 21 patients with displaced separations of the lower femoral epiphysis; this was promptly relieved by reduction of the separation. Bassett and Goldner (4) reported on a patient with arterial spasm associated with displacement in the sagittal plane. At the time of initial examination, shortly after injury, the foot was pale and cold. Pulses were not palpable. After reduction, the color improved and the pulses returned. There were no sequelae to the temporary vascular occlusion.

If vascular impingement occurs but is relieved by prompt reduction of the displaced epiphysis, the patient must be observed for 48 to 72 hours to rule out an intimal tear with thrombosis. Vascular impairment may develop slowly from increasing compartmental pressure. If the patient has inordinate persistent pain, with a cool and pale foot, a femoral arteriogram and compartment pressure measurement should be considered, even if peripheral pulses are present. An arteriogram is not indicated for routine, closed hyperextension epiphyseal displacements, as long as the clinical examination is negative after reduction (38,81). In a patient with an acute fracture with vascular injury, in whom the foot is pale, cool, and nonviable, popliteal artery exploration is indicated after fracture reduction and stabilization. Arteriography is not mandatory for an isolated vascular injury because the site of the lesion is known and can be addressed at the time of re- duction. If there is an associated fracture of the pelvis or femoral shaft, arteriography may be necessary to localize the vascular injury.

Peroneal Nerve Injury

The peroneal nerve is the only nerve injured with any appreciable frequency in this type of fracture. It may be stretched by anterior or medial displacement of the epiphysis.

Lombardo and Harvey (45) reported a patient with an associated peroneal nerve palsy that resolved spontaneously over 6 months. Stephens et al. (76) reported two patients with peroneal nerve palsies who recovered completely. Both were adolescents with Salter-Harris type II separations. Roberts (64) found one patient with neurapraxia of the peroneal nerve associated with medial displacement of a Salter-Harris type II separation. The separation was satisfactorily reduced by closed means, and the nerve injury spontaneously resolved in several months.

Peroneal nerve injury is reported to occur in approximately 3% of separations of the distal femoral epiphysis. It rarely requires treatment other than reduction of the separation. The exception to this is a transected nerve in association with an open injury, which may be treated with repair or grafting. Persistent neurologic deficit after 3 to 6 months warrants electromyographic examination. If the conduction time is prolonged and fibrillation or denervation is present in distal muscles, exploration and microneural reanastomosis or resection of any neuroma may be indicated.

Recurrent Displacement

Separation of the distal femoral epiphysis may be quite unstable after reduction. Bassett and Goldner (4) found that 10 of 25 patients had loss of reduction after the initial manipulation. Thomson (78) found that 6 of 30 had either an unacceptable reduction or loss of reduction. After reduction of anterior displacement, the epiphysis may tilt forward again as swelling subsides. On the other hand, immobilization in extension stabilizes reduction of posterior or mediolateral displacement. Aitken and Magill (2) pointed out that the gastrocnemius acts as a strap against the posterior aspect of the distal femoral epiphysis when the knee is extended. If reduction is lost so that a second manipulation is required, internal fixation should be used.

Knee Joint Instability

Symptomatic knee joint instability may persist after the epiphyseal separation has healed. This finding at follow-up implies concomitant injury to knee ligaments, often unappreciated at the time of initial management of the epiphyseal separation. Aitken and Magill (2) found that four of nine patients had “some evidence of relaxation of the anterior cruciate ligament.” In the 20 patients reviewed by Stephens et al. (76), 5 had persistent instability of the knee. Lombardo and Harvey (45) found knee laxity in 8 of 34 patients. Brone and Wroble (15) found three ACL tears associated with Salter-Harris type III fractures of the medial femoral condyle.

Bertin and Goble (7) found that 6 of 16 patients seen in follow-up for distal femoral physeal fractures had positive anterior drawer and Lachman tests; 1 patient had laxity to valgus stress. They surmised that during injury, knee ligaments stretch in series just before fracture–separation of the adjacent cartilaginous physis. They emphasized the importance of early diagnosis of associated ligament injury. If there is no meniscal injury, a rehabilitation program is indicated initially. If there is a reparable meniscal tear, cruciate reconstruction at the time of meniscal repair after physeal healing may be indicated, depending on the patient's age and activity level.

Progressive Angulation

Progressive angulation after separation of the distal femoral epiphysis usually is caused by asymmetric growth (1,8,60) from either trauma to the physis at the initial injury (Salter-Harris type I or II) or physeal offset with bony bar formation after healing (28) (Salter-Harris type III or IV; Fig. 23-17). Occasionally, progressive angulation follows nonphyseal fractures (Fig. 23-18), in which an associated Salter-Harris type V physeal injury presumably was not noted (34). The risk of angular disturbance is highest in juveniles. If the growth defect is secondary to a persistently displaced Salter-Harris type IV injury, evidence of bony union is present between the displaced epiphysis and the metaphysis across the fracture line.

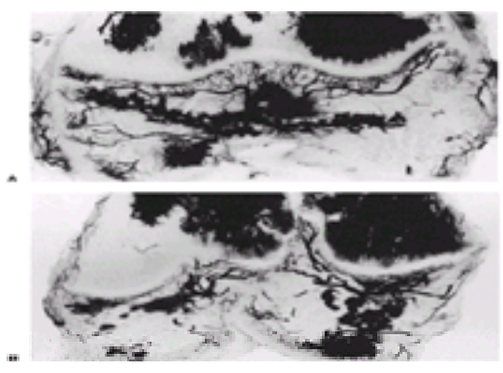

FIGURE 23-17. Mechanism of physeal bar formation after Salter-Harris type III and IV fractures. Physeal vessels that normally are distal **(A)** may anastomose with metaphyseal vessels because of vertical translation after Salter-Harris type IV fracture **(B).** (From Gomes LSM, Volpon JB. Experimental physeal fracture separations treated with rigid internal fixation. *J Bone Joint Surg Am* 1993;75:1756–1764; with permission.)

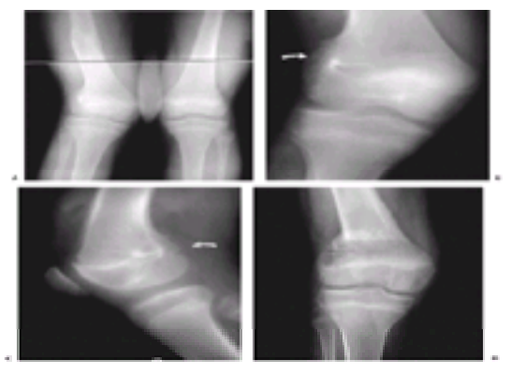

FIGURE 23-18. A: Genu valgum deformity of the right knee in a 14-year-old boy who sustained a right femoral shaft fracture at 10 years of age. **B and C:** Anteroposterior and lateral tomograms demonstrate bony bar formation in the posterior and lateral aspects of the distal femoral epiphysis. **D:** After distal femoral supracondylar osteotomy and bony bar resection of the distal femur.

If the separation is a Salter-Harris type II injury, the physis distal to the triangular metaphyseal fragment usually is spared. The localized area of growth inhibition occurs in that portion of the physis not protected by the metaphyseal fragment. If progressive angulation occurs after a Salter-Harris type II separation with lateral displacement, the subsequent deformity usually is varus. Conversely, if a Salter-Harris type II separation occurs with initial medial displacement, the subsequent deformity often is valgus.

If a localized area of premature arrest constitutes less than 25% to 30% of the total area of the physis and if at least 2 years of growth remain, excision of the bony bridge should be considered (65). The bridge can be accurately defined by MRI, but the study must be ordered with attention called to the physis, rather than to the knee itself. The characteristics of partially bound water in physeal cartilage are distinct from those of free synovial fluid, and excellent contrast can be obtained with proper planning. The surgeon should request proton-density sequences with fat suppression or T2-weighted gradient-echo images (fast-field echo) (19). Alternatively, helical CT scans may used to create a map of the injured physis (20,44). The technique of excision is well described by Peterson (60). A peripheral bridge can be approached directly. A central bridge is approached through a metaphyseal window. The area of union between the epiphysis and the metaphysis is carefully removed with a curet and power bur. The defect is filled with autogenous fat (42,43) or cranioplastic methacrylate.

Hemiepiphysiodesis may be considered in maturing adolescents with progressive varus or valgus angulation associated with a central bony bridge with some remaining growth medially or laterally. Enough growth may remain in the segment of physis between the bony bridge and the perimeter on the same side to correct the deformity. Either stapling (85) or percutaneous epiphysiodesis (65) can be done at the edge of the physis opposite the bony bridge, often with satisfactory results. Bowen et al. (10) devised a chart based on skeletal age that is useful in estimating the amount of correction of angular deformity that hemiepiphysiodesis will effect. Nevertheless, because of the physeal bar, this procedure has an element of unpredictability that counterbalances its simplicity. If hemiepiphysiodesis is used to correct angular deformity, timely epiphysiodesis of the opposite limb may be required to prevent significant limb-length discrepancy (Fig. 23-19).

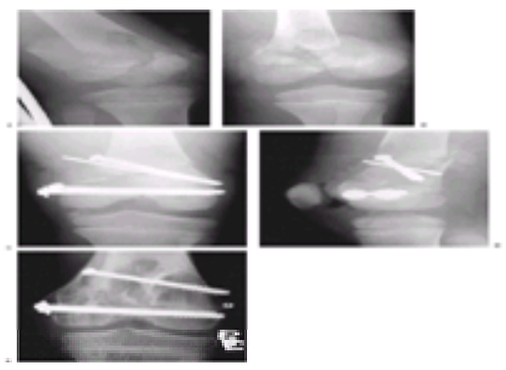

FIGURE 23-19. A and B: Comminuted, open, T-condylar fracture of the distal femoral metaphysis and epiphysis in a 10-year-old girl. **C and D:** After irrigation and debridement and cannulated screw fixation of the metaphyseal and epiphyseal fractures. **E:** One year after injury, the articular surface is restored but the distal femoral physis is closed.

If the patient is within 2 years of skeletal maturity, correction of significant angular deformity by epiphysiolysis with an external fixator may be considered (23,25,48,58,59). The pins can be held by one of the many types of adjustable lengthening fixators (24,25,37,55). Gradual distraction and realignment are done with careful attention to the possibility of neurologic compromise. These techniques are demanding and are best done by those with experience.

If the patient is approaching skeletal maturity, corrective osteotomy is the preferred treatment. For associated shortening, an opening-wedge osteotomy is preferable. The technique for correcting deformity has been described and illustrated by Abbott and Gill (1) and by Scheffer and Peterson (69). An osteotomy is made at the supracondylar level, parallel to the articular surface of the condyles. The hinge of the osteotomy should be in metaphyseal bone, which is better able to deform plastically than is cortical bone. Usually no more than 15 degrees of correction can be obtained without cracking the hinge. The distal fragment is then tilted to place the articular surface in horizontal alignment. A triangular fragment of autogenous iliac bone is inserted in the opening. If the hinge is strong and the patient is slender, immobilization in a cast may be all that is needed. Otherwise, fixation with crossed pins or plate and screws may be necessary.

An alternative method of fixation for an opening-wedge osteotomy or for lengthening and angular correction of the distal femur is external fixation. The DeBastiani device or an Ilizarov construct (33,55) is useful because the amount of lengthening or angulation can be adjusted postoperatively, and significant angulation and length deformities can be corrected.

Abbott and Gill (1) noted that a compensatory deformity may occur in the proximal tibia, and if angulation of the femur is corrected, subsequent osteotomy for correction of the tibial deformity may be indicated. Although no long-term data exist, any coexisting tibial deformity of more than 10 degrees probably should be corrected to maintain a horizontal knee joint.

Leg-Length Discrepancy

Progressive leg-length discrepancy may follow a separation of the distal femoral epiphysis if premature arrest of the physis occurs (22). If the patient is within 2 years of skeletal maturity at the time of injury, the shortening probably will be insignificant. If there are more than 2 years from the time of injury to skeletal maturity, the leg-length discrepancy may progress at a rate of 1 cm ($^3/_8$ in.) per year.

Sometimes the growth disturbance is not a discrete bar but a partial physeal slowing. The progression of leg-length discrepancy is best followed by serial

examinations. Every 6 months, a scanogram and bone age are obtained and the clinical discrepancy is measured. The leg lengths can be plotted on the Moseley straight-line graph (49). After three sequential scanograms over a period of 12 to 18 months, discrepancy at skeletal maturity can be estimated by extrapolation according to the rate of growth of each limb.

If the estimated discrepancy at skeletal maturity is less than 2.5 cm (1 in.), no definitive treatment is indicated. If the estimated discrepancy is 2.5 to 5 cm, surgical closure of the contralateral femoral or tibial physes in the opposite extremity at the appropriate time should be considered (47). In older patients close to skeletal maturity, shortening of the contralateral femur at the subtrochanteric or mid-diaphyseal level is an option.

If the estimated discrepancy at maturity exceeds 5 cm, lengthening of the short femur by corticotomy and slow distraction with an external fixator should be considered (Fig. 23-20). Large discrepancies after injury early in life can be equalized by repeated lengthenings, combined if needed with appropriate epiphysiodesis or shortening of the opposite limb. Epiphysiodesis should be timed by either the Moseley method (49) or Green-Anderson method (31).

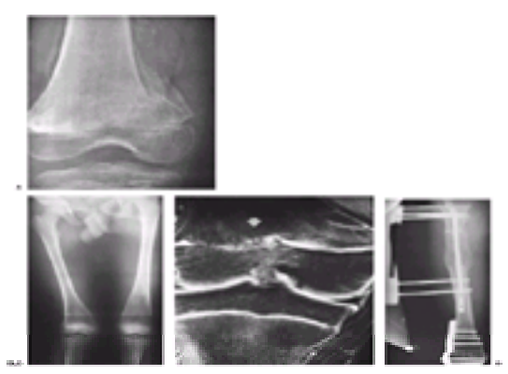

FIGURE 23-20. A: Salter-Harris type II fracture of the distal femur with medial metaphyseal fragment in an 8-year-old boy. **B:** After being lost to follow-up for 4 years, he presented with 6 cm of shortening and a mild varus deformity. **C:** Magnetic resonance image with gradient-echo sequence shows physeal bar formation involving approximately 40% of the physis. **D:** Distal femoral osteotomy and proximal femoral lengthening of 9 cm to match the existing and anticipated future discrepancy produced satisfactory results.

Stiffness

Limitation of knee motion after separation of the distal femoral epiphysis may be caused by intraarticular adhesions, capsular contracture, or muscular contracture. Regaining knee motion is difficult after immobilization in flexion for reduction of an anteriorly displaced epiphysis. As soon as possible, the knee should be gradually extended. Limitation of knee extension usually is caused by contracture of the posterior capsule and a weak, stretched-out quadriceps muscle. This should be treated with active and active-assistive range-of-motion exercises, with emphasis on quadriceps strengthening. Internal fixation with early motion may be considered. For patients with stiff knees in whom conservative treatment has failed, surgical release of contractures and adhesions, followed by continuous passive motion, may regain significant motion (21).

Intraarticular adhesions may form in the knee with hemarthrosis. An irregular articular surface from a Salter-Harris type III or IV injury may contribute to early degenerative changes. The incidence of permanent persistent stiffness is relatively low [23 of 140 patients (16%) (2,45,51,65,76); see Table 23-5].

FRACTURE OF THE PROXIMAL TIBIAL EPIPHYSIS

Historical Review

The physis of the proximal tibia is well protected, in contrast to the distal femoral physis. On the lateral aspect, the proximal tibial epiphysis is buttressed by the upper end of the fibula. Anteriorly, the tubercle projects down from the epiphysis to overhang the adjacent metaphysis. The superficial portion of the medial collateral ligament (MCL) extends beyond the physis to insert into the upper metaphysis. In the posteromedial corner, the insertion of the semimembranosus muscle spans the physis. Thus, there is nearly circumferential reinforcement to the perichondrium.

Because of this protection, separation of the proximal tibial epiphysis is relatively rare (see Table 23-1). Neer and Horwitz (52) reported an incidence of 0.8% in 2,500 consecutive physeal fractures. Mann and Rajmaira (46) reviewed 2,650 long bone fractures in children; 15 (0.6%) were physeal separations of the proximal tibia, mostly in adolescent boys.

The most serious complication of injury to the proximal tibia is vascular compromise. The popliteal artery is tethered by its major branches near the posterior surface of the proximal tibial epiphysis. The posterior tibial branch passes under the arching fibers of the soleus. The anterior tibial artery passes forward through an aperture above the proximal border of the interosseous membrane. A hyperextension injury that results in posterior displacement of the upper end of the metaphysis may stretch and tear the bound popliteal artery (Fig. 23-21).

FIGURE 23-21. Medial view of fracture—separation of the proximal tibial epiphysis resulting from hyperextension of the right knee. Posteriorly displaced proximal tibial metaphysis impinges on the adjacent popliteal artery.

Similar to separations of the distal femoral epiphysis, injuries to the proximal tibial epiphysis may cause shortening or angulation from subsequent growth inhibition. This inhibition can occur after Salter-Harris type I and II injuries (76,82,89). Presumably, a concurrent longitudinal compression force damages the deeper proliferative zone of the physis.

Some authors (87,93) include complete avulsions of the tibial tubercle in reviews of fracture–separations of the proximal tibial epiphysis. However, avulsion fractures of the tibial tubercle constitute a specific subgroup considered in a separate section of this chapter.

Poland (61) reported 24 children with fracture–separations of the proximal tibial epiphysis, most of them younger than 9 years of age. He stated that the usual mechanism of injury was a direct crushing force, such as a wagon wheel rolling over a child's leg. In Poland's day, such an injury was often open, and infection frequently led to amputation, if not death. Poland found that experimental separation of the upper tibial epiphysis could be produced most easily on cadavers between

the ages of 8 and 15 years, and most injuries to the proximal tibial epiphysis occur in this age group.

Nicholson (90) reported four separations of the proximal tibial epiphysis, all in children struck by automobiles. In three of the four patients, the displacement was posterior. Burkhart and Peterson's (87) clinical review of 28 fracture–separations included four avulsion fractures of the tibial tubercle and five open injuries to small children from rotary lawn mowers. Of the 19 remaining injuries, half occurred during athletics and half in motor vehicle accidents. Corrective surgery for subse-[ol0]quent growth disturbance was required in a third of the patients. Two patients presented late with associated arterial insufficiency.

Shelton and Canale (93) reported 39 injuries to the proximal tibial epiphysis. Posterior displacement of the shaft with disruption of the popliteal artery was found in two patients. Unsatisfactory results because of chronic vascular insufficiency, growth disturbance, or traumatic arthritis occurred in four patients.

In 1983, Bertin and Goble (7) reported a retrospective study of physeal fractures about the knee in which 8 of 13 patients with separations of the proximal tibial epiphysis had ligamentous laxity manifested by positive anterior drawer and Lachman tests. These authors described a subset of three patients with almost identical Salter-Harris type III fracture–separations with associated MCL tears.

In 1989, Poulsen et al. (91) reviewed 15 patients with proximal tibial epiphyseal fractures. Concomitant avulsion fractures of the tibial insertion of the ACL occurred in five patients. One patient had primary repair of the tibial collateral ligament. At follow-up, two patients had combined anterior and medial laxity, and another two patients had isolated anterior laxity.

In 1991, Wozasek et al. (96) reported 31 injuries of the proximal tibial epiphysis. Four patients had signs of distal ischemia before reduction that resolved after reduction. One patient had a delayed diagnosis of ischemia that required amputation, and one had peroneal palsy.

In 1998, Gautier et al. (89) performed a meta-analysis of the literature including their own cases, and found a 25% incidence of significant growth disturbance.

Surgical Anatomy

Bony Anatomy

The ossific nucleus of the proximal tibial epiphysis appears by 2 months of age. It lies in the center of the cartilaginous anlage, somewhat closer to the metaphysis than to the articular surface. Occasionally, the ossification center is double. The secondary center in the tubercle appears between the 9th and 14th years. By the 15th year, the upper epiphysis unites with the tubercle and is almost completely ossified.

The distal surface of the epiphysis is concave to match the convex upper surface of the metaphysis. There is a slight central notch in the surface of the metaphysis. The epiphysis is higher on the lateral surface than on the medial surface. The physis slopes down somewhat farther on the lateral side than on the medial side. In the posterolateral corner, the physeal surface is immediately inferior to the upper tibiofibular joint. From this point, the perimeter of the physis extends across the posterior aspect of the upper tibia proximal to the origin of the popliteus muscle. On the medial side, the physis is proximal to the insertion of the superficial MCL. On the anteromedial and anterolateral surfaces of the upper tibia, the physis creates a circumferential ridge between the vertical surface of the epiphysis and the sloping of the metaphysis. This ridge is palpable through the overlying skin and subcutaneous tissue. In the midline anteriorly, the physis dips down underneath the tibial tubercle.

The lateral edge of the physis is separated from the proximal tibiofibular joint by a thin layer of joint capsule. Hemorrhage from a separation may extend into the adjacent joint cavity and through it into the knee joint itself (92). The physis closes slightly earlier posteriorly than anteriorly (86).

Soft Tissue Anatomy

The synovium and the capsule of the knee joint insert into the proximal tibial epiphysis well above the physis. There is a defect in the capsule where the popliteus tendon runs over the posterolateral corner of the tibia. The arcuate ligament arches over the popliteus tendon from the proximal tibia to the posterior aspect of the epiphysis. The capsular ligament anchors the menisci to the tibial epiphysis medially and laterally. The lateral collateral ligament (LCL) of the knee inserts into the fibula (Fig. 23-22). The MCL inserts beyond the physis into the upper metaphysis of the tibia. The patellar ligament inserts, for the most part, into the secondary ossification center of the tubercle, although some fibers extend beyond the physis into the anterior aspect of the upper tibial diaphysis. The semimembranosus muscle inserts above and below the physis in the posteromedial corner. As this tendon approaches the proximal tibia, it divides into four insertions: the posterior capsule of the knee joint, the posterior surface of the tibial epiphysis, the medial surface of the tibial epiphysis, and the medial surface of the tibial metaphysis.

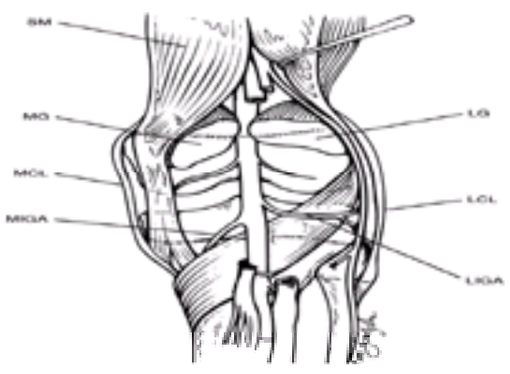

FIGURE 23-22. Posterior anatomy of the right popliteal region. Note that the popliteal vessels are protected from bone (especially the tibia) only by the popliteus muscle. The vessels are tethered by the geniculate branches and by the trifurcation. MG and LG, medial and lateral gastrocnemius heads; SM, semimembranosus; MCL, medial collateral ligament; LCL, lateral collateral ligament; MIGA, medial inferior geniculate artery; LIGA, lateral inferior geniculate artery; ATA, anterior tibial artery.

Vascular Anatomy

The distal portion of the popliteal artery lies close to the posterior aspect of the upper tibia. Firm connective tissue septa hold the vessel against the knee capsule. The popliteus muscle intervenes between the artery and bone. The lateral inferior geniculate artery runs across the surface of the popliteus muscle, anterior to the lateral head of the gastrocnemius, and turns forward underneath the LCL. The medial inferior geniculate artery passes along the proximal border of the popliteus muscle, anterior to the medial head of the gastrocnemius, and extends forward along the medial aspect of the upper tibia. Beneath the soleal arch, the popliteal artery divides into the anterior tibial and posterior tibial branches.

The proximal tibial epiphysis derives much of its blood supply from an anastomosis between the geniculate arteries posterior to the patellar ligament. Multiple small vessels pass backward and downward into the anterior aspect of the epiphysis. Other small vessels enter the epiphysis on the posterior surface, adjacent to the attachment of the posterior cruciate ligament (PCL). More vessels enter the medial and lateral surface of the epiphysis. The diffuse extraarticular blood supply to this epiphysis makes it less vulnerable to ischemia from injury.

Mechanism of Injury

Fracture–separation of the proximal tibial epiphysis can be caused by a direct or indirect force. A direct force may be imposed when a child's leg is run over by the wheels of a vehicle or when it is caught between bumpers of two automobiles (Fig. 23-23). More often, separation of the proximal tibial epiphysis is caused by an indirect mechanism. The lower leg is forced into abduction or hyperextension against the fixed knee. An apex of deformity on the medial side implies a partial tear of

the superficial portion of the MCL. Indirect injuries to adolescents occur during sports, motor vehicle accidents, or falls. Less frequently, flexion injuries of the proximal tibial physis have been described, all in boys 15 or 16 years of age as they started or landed from a jump (95). Many had closure of the physis posteriorly, resulting in genu recurvatum deformity. Vascular injury has not been reported with this injury (96). These fractures represent a transition between tibial tubercle fractures and tibial epiphyseal separations, in comparing the mechanism of injury and fracture anatomy.

FIGURE 23-23. A: Comminuted Salter-Harris type II fracture of the proximal tibial epiphysis in a 9-year-old boy. Additional injuries included peroneal nerve injury, popliteal artery laceration, and compartment syndrome of the tibia. **B:** At follow-up, note valgus deformity of the proximal tibia with delayed union of the proximal tibial metaphysis.

Injury to the proximal tibial epiphysis can occur from passive extension of the legs of a newborn at the time of a difficult breech delivery (74). Separations of this epiphysis have occurred during passive manipulation of the lower limbs in infants with arthrogryposis (26), and attempts at closed manipulation of valgus deformities have produced this lesion. Pathologic separations have been reported in association with osteomyelitis of the proximal tibia or meningomyelocele (27,84).

Classification

Most separations of the proximal tibial epiphysis are Salter-Harris type I and II injuries (Table 23-6 and Table 23-7). The frequency of Salter-Harris type III injuries may be skewed by the inclusion of displaced avulsion fractures of the tibial tubercle, and the incidence of Salter-Harris type IV injuries depends on whether open injuries to the knee (i.e., lawn mower) are included, as in the series by Burkhart and Peterson (87).

Classification	Implications
Mechanism of injury	
I. Hyperextension	Risk of vascular disturbance
II. Varus/valgus	Usually results from jumping; very near maturity
III. Flexion	Pes anserinus or periosteum may be entrapped
Salter-Harris pattern	
I	Fifty percent nondisplaced
II	Thirty percent nondisplaced
III	Associated collateral ligament injury possible
IV	Rare
V	Has been reported; diagnosis usually late

TABLE 23-6. CLASSIFICATIONS AND IMPLICATIONS OF PROXIMAL TIBIAL PHYSEAL FRACTURES

Salter-Harris Classification	Aitken[a]	Burkhart[b]	Shelton[c]	Total
I	—	3	9	12 (15%)
II	9	9	17	35 (43%)
III	2	6[d]	10[d]	18 (22%)
IV	3	8[e]	3	14 (17%)

[e] Includes five open injuries from rotary lawn mowers.

TABLE 23-7. FREQUENCY OF TYPES OF FRACTURE–SEPARATION OF THE PROXIMAL TIBIAL EPIPHYSIS

Fifty percent of Salter-Harris type I separations of the proximal tibia are nondisplaced. Stress radiographs may reveal widening on the medial or posterior aspect. If displaced, the metaphysis is medial or posterior relative to the epiphysis. Presumably, the overhanging tubercle prevents anterior displacement and the fibula prevents lateral displacement of the metaphysis. There may be an associated fracture of the proximal diaphysis of the fibula or a separation of the proximal fibular epiphysis.

Two thirds of Salter-Harris type II fracture–separations of the proximal tibial epiphysis are displaced. Displacement of the tibial metaphysis usually is medial (Fig. 23-24), and the associated metaphyseal fracture usually is lateral, resulting in valgus deformity. The proximal fibula also may be fractured.

FIGURE 23-24. A: Salter-Harris type II separation of the proximal tibial metaphysis, with medial displacement of the proximal tibial metaphysis and complete fracture of the upper third of the fibula with complex soft tissue injury. **B:** After reduction and percutaneous fixation with a 4.5-mm cannulated screw.

Salter-Harris type III separations have a vertical fracture line through the proximal epiphysis from the articular surface to the physis. Most commonly, the lateral epiphysis is fractured, and the MCL frequently is torn. This lateral fragment may require internal fixation, and the MCL may require surgical repair.

Salter-Harris type IV injuries can involve the medial or lateral tibial plateau. Salter-Harris type V injuries are rare but have been reported in the proximal tibia. Usually, the diagnosis is made in retrospect when progressive angulation or leg-length discrepancy is noted. A type V injury localized to the anterior portion of the physis may cause genu recurvatum. A triplane fracture–separation may rarely involve the proximal tibial epiphysis.

Proximal tibial fractures also can be classified by the direction of deformity (Fig. 23-25). The classic hyperextension type has an apex-posterior angulation and results from forced hyperextension. The flexion type results from internally generated forces of jumping or landing and has a anterior apex. Varus and valgus types result from abduction or adduction forces.

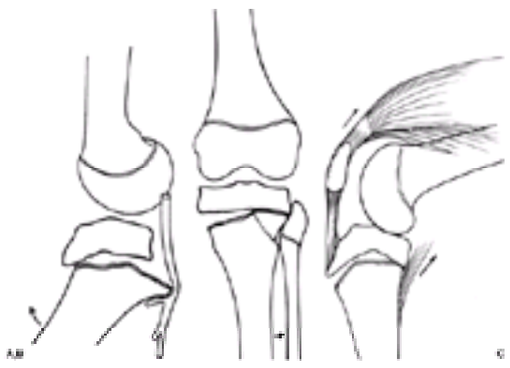

FIGURE 23-25. Classification of proximal tibial physeal fractures by direction of displacement. **A:** Type I: hyperextension type, usually caused by direct force. Risk of vascular damage exists. **B:** Type II: varus or valgus type. Less risk of vascular injury. Reduction may be inhibited by interposition of pes anserinus or periosteum. **C:** Type III: flexion type (rare), usually caused by internal forces as in jumping. Carries least risk of vascular injury; occurs near end of growth.

Signs and Symptoms

P>A patient with a separation of the proximal tibial epiphysis usually has a knee joint tense with hemarthrosis. Extension is limited because of hamstring spasm. Typically, tenderness is present over the proximal tibial physis 1 to 1.5 cm distal to the joint line.

If the proximal end of the metaphysis is displaced posteriorly, a concavity is seen and felt anteriorly at the level of the tibial tubercle. If the metaphysis is displaced medially, a valgus deformity is present. There may be tenderness or angulation of the proximal fibula as well. If the proximal end of the metaphysis protrudes under the subcutaneous tissues on the medial aspect of the knee, a tear of the distal end of the MCL should be suspected.

Vascular status must be carefully documented. Routine angiography is not mandatory because ischemia usually resolves with reduction, but motor function, pulses, warmth, and color should be checked frequently during the initial 48 to 72 hours. Welch and Wynne (94) described a nondisplaced separation of the proximal tibial epiphysis that was initially misdiagnosed as an isolated tear of the MCL because tenderness over the medial aspect of the proximal tibia was interpreted as evidence of an avulsed ligament. Operative exploration showed the distal attachment of the ligament was intact below the level of the physis. Stress radiographs revealed an epiphyseal separation.

Fracture–separations of the ipsilateral distal femoral and proximal tibial epiphyses may occur simultaneously (Fig. 23-26). This injury in children is analogous to the floating knee injury in adults. Internal derangement of the knee joint may occur with separation of the proximal tibial epiphysis. Concomitant avulsion of the tibial eminence also has been reported.

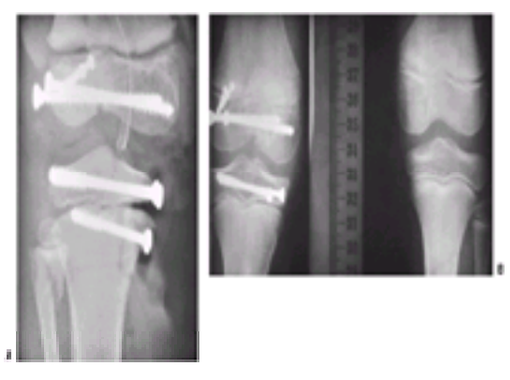

FIGURE 23-26. A: Salter-Harris type IV fracture of the proximal tibia and Salter-Harris type III fracture of the distal femur treated with open reduction and internal fixation.**B:** Four years later, growth is restored.

Radiographic Findings

Nondisplaced separations may not be visible radiographically. Swelling about the proximal tibia may obscure soft tissue shadows. An associated hemarthrosis is manifested by an increased space between the patella and distal femur. Stress radiographs in both coronal and sagittal planes should be obtained, but hyperextension of the knee should be avoided because of the possibility of injury to the popliteal vessels.

The radiographs are scanned for evidence of fracture lines extending proximally through the epiphysis or distally through the metaphysis. A small bony fragment at the periphery of the metaphysis may be the only clue to the diagnosis. Fracture lines may be visible only on oblique views.

Most patients with separations of the proximal tibial epiphysis are adolescents in whom the secondary ossification of the tibial tubercle has appeared. A smooth, horizontal radiolucent line through the base of the tubercle should not be confused with an epiphyseal fracture. It may represent an incomplete fusion of the two secondary ossification centers: the tubercle ossicle and the main portion of the proximal tibial epiphysis.

Computed tomographic scans may be helpful in determining the treatment of Salter-Harris type III and IV fracture–separations. MRI may identify soft tissue interposition in displaced proximal tibial epiphyses, which are difficult to reduce by closed methods. Wood et al. (95) reported a patient in whom the pes anserinus was folded into the fracture site.

Treatment

Nonoperative Treatment

Hyperextension fractures are reduced with a longitudinal force on the tibia combined with a gentle, anterior translating force on the proximal metaphysis. Countertraction on the femoral shaft is applied by an assistant.

Nicholson (90) reported reduction of posterior displacement of the metaphysis by pulling the proximal tibia forward and flexing the knee to 90 degrees with mild internal rotation of the tibia.

Böhler (9) advised placing a calcaneal pin. The leg is then flexed over the surgeon's forearm, which is placed in the popliteal fossa. Longitudinal traction is applied to the pin while the surgeon's arm lifts up. Upward traction on the proximal tibial metaphysis may be accomplished with a second pin inserted under the tibial tubercle. A long leg cast is applied after reduction is obtained.

An abduction fracture with valgus angulation usually can be reduced by adducting the leg on the extended knee. This should be a gentle manipulation to decrease the risk of injury to the peroneal nerve. After reduction, a long leg cast with varus molding is applied with the knee in slight flexion.

Indications for Operative Treatment

Separations of the proximal tibial epiphysis may be surprisingly unstable. Smooth pins can be inserted percutaneously, crossing distal to the physis to maintain reduction. The proximal ends should not protrude into the knee joint. An image intensifier makes percutaneous fixation easier.

Open reduction is indicated for displaced Salter-Harris type III injuries. An anterior incision is used to allow inspection of the articular surface. A pin is inserted in the displaced fragment and is used to guide it toward reduction. Other pins or screws are then inserted horizontally across the epiphysis. Small cannulated screws often are helpful in this type of fracture.

A similar technique is used for displaced Salter-Harris type IV injuries. Fixation can be obtained by placing screws across the larger metaphyseal, as well as the epiphyseal, fragments (Fig. 23-26). If there is a linear peripheral tear of the meniscus overlying the injured condyle, repair is performed. Primary repair of concomitant complete ligamentous injury also should be considered.

Operative fixation of a hyperextension injury may be indicated for stabilization if an associated popliteal artery injury is repaired. Immediate exploration is not indicated for symptoms of peroneal nerve injury. Peroneal neuropathy associated with a separation of the proximal tibial epiphysis usually recovers spontaneously with time.

AUTHOR'S PREFERRED METHOD OF TREATMENT

If a proximal tibial epiphysis is nondisplaced, we place the patient in a long leg cast with the knee flexed 30 degrees. The cast and underlying padding are initially bivalved from top to bottom. Anteroposterior and lateral radiographs are repeated 1 week after injury to confirm acceptable position. The cast is removed 6 to 8 weeks after injury. If subperiosteal new bone formation has appeared and if the leg is nontender, active range-of-motion and muscle-strengthening exercises are begun. We do not allow the patient to return to vigorous activities until the region is nontender and knee range of motion and quadriceps strength are near normal.

Before reducing a Salter-Harris type I hyperextension injury, we check for signs of neurologic or circulatory impairment. If the displacement is significant, we prefer to use general anesthesia for reduction. With the patient supine, the fracture is reduced by flexing the hip and knee to 45 degrees while applying longitudinal traction. The upper leg is grasped behind the calf. The distal tibia is stabilized, usually by holding it between the surgeon's knees or between his or her elbow and chest. The proximal metaphysis is pulled gently forward. At this point, flexion of the knee is increased to 90 degrees, the peripheral pulses are checked again, and a lateral radiograph is obtained. If reduction is satisfactory, a long leg cast with the knee flexed at 60 degrees is applied, and the cast is bivalved from top to bottom. Direct pressure over the proximal posterior tibia should be minimal. Radiographs are obtained the next day and 1 week later. The cast is changed to extend the knee to 30 degrees at 3 to 4 weeks. At 6 to 8 weeks after injury, the cast is converted to a posterior splint, and active range-of-motion exercises are begun.

For an abduction injury with valgus angulation, we sedate the patient, aspirate any significant knee effusion under sterile precautions, and test carefully for a concomitant tear of the MCL or cruciate ligament. Valgus angulation is corrected by putting manual longitudinal traction on the leg. The knee is held in almost full extension. With an assistant stabilizing the distal thigh and knee, the valgus angulation is corrected by guiding the leg into adduction. Traction is not released until reduction is accomplished. If the radiographs confirm reduction, the extremity is immobilized in a long leg cast, molded into varus, with the knee flexed 15 to 20 degrees. Neurovascular status is checked before and after reduction. The cast is removed in 6 to 8 weeks, and a knee immobilizer may be used for support for an additional 2 to 4 weeks.

For flexion injuries, reduction usually is obtained by applying longitudinal traction with the knee in full extension. An extension cast is worn for 4 to 6 weeks, after which muscle-strengthening and range-of-motion exercises are begun. If a Salter-Harris type I or II fracture is unstable after reduction, percutaneous crossed Kirschner wires should be used for fixation. These can be inserted from a distal-to-proximal direction to avoid passing through the joint capsule. Smooth $^{5}/_{64}$-or $^{3}/_{32}$-in. Kirschner wires can be used and removed 6 to 8 weeks after insertion.

For nondisplaced Salter-Harris type III separations, a long leg cast is worn for 6 to 8 weeks. If displacement exceeds 2 mm, we perform closed or open reduction and fixation with percutaneous pins or cannulated screws. After the patient has been anesthetized, a Steinmann pin is inserted into the fragment and used to guide the fragment into position with the help of an image intensifier. After reduction, one or two smooth pins or small cannulated screws are inserted transversely across the epiphysis, taking care not to cross the physis in a young child. After internal fixation has been obtained, the knee is again carefully stressed into valgus to see if the MCL is intact. Similarly, a lateral view with stress in the sagittal plane is obtained to rule out associated cruciate injury. If a tear of the MCL is detected, we may proceed with primary ligamentous repair, especially in an adolescent.

A similar technique is used for reduction and fixation of Salter-Harris type IV separations. If reduction is not anatomic, we perform an open reduction under direct vision. Fixation pins may be removed under brief general anesthesia when the cast is removed, 6 to 8 weeks after injury. If the fracture is open and the fragment is devitalized (i.e., lawn mower injury), the avascular piece is removed. Non-weight bearing is advised for 2 months after Salter-Harris type III and IV injuries, but active range-of-motion exercises should be started immediately after removal of the cast.

The patient is followed for 2 years to watch for signs of angular deformity or persistent instability.

Prognosis

The overall prognosis for separations of the proximal tibial epiphysis is fairly good. Shelton and Canale (93) found that 24 of 28 patients (86%) followed until after skeletal maturity had satisfactory results. If a small group of lawn mower injuries is separated from the series of Burkhart and Peterson (87), 76% of the remaining 21 patients did well after initial reduction. Most of the fractures in both series occurred in adolescents, and most injuries were closed.

Open injuries of the proximal tibia have a much worse prognosis. All the lawn mower injuries reported by Burkhart and Peterson (87) had adverse sequelae. Four patients had significant angulation (Fig. 23-27), two patients had major leg-length discrepancies, one contracted osteomyelitis, and one had a severed peroneal nerve. Direct crushing injuries to the knee with extensive bruising or laceration of overlying soft tissue also have a poor prognosis.

FIGURE 23-27. Despite anatomic reduction, growth disturbance *(solid arrow)* and valgus deformity occurred after metaphyseal fracture of the proximal tibia caused by a lawn mower accident. The fracture proved to be a Salter-Harris type IV injury because of fracture extension through the unossified epiphysis.

Bertin and Goble (7) warned that nearly half the patients with proximal tibial physeal fractures can be expected to have ligamentous instability 5 years after injury. They noted that persistent MCL insufficiency, genu valgum, and early degenerative changes in the knee could follow Salter-Harris type III injuries. Poulsen et al. (91) found that 6 of 11 patients complained of pain or discomfort at an average follow-up of 7 years. Four patients had persistent ligamentous laxity, and three patients had degenerative changes on radiographs.

The Salter-Harris classification is not always useful in predicting risk of growth disturbance after separation of the proximal tibial epiphysis. Complete or partial growth arrest can occur after Salter-Harris type I, II, and III injuries, as well as after type IV and V injuries. Burkhart and Peterson (87) reported two patients with significant leg-length discrepancies and angular deformities after Salter-Harris type I and II injuries. Shelton and Canale (93) reported that all seven patients in their series with growth disturbances had fractures classified as Salter-Harris type I or II. No significant growth disturbances were associated with 13 Salter-Harris type III or IV injuries. Subsequent osteoarthritic changes in the knee were related to fracture patterns with intraarticular extension.

The direction and degree of displacement are factors in the frequency of associated neurovascular or ligamentous injuries. Posterior displacement of the metaphysis relative to the epiphysis is more likely to cause neurovascular or ligamentous injury than is displacement in the medial or anterior direction. Hyperextension injuries often cause neurovascular deficits because of impingement and stretch on structures running through the popliteal fossa.

Complications

Complications of proximal tibial fractures may be early or late. Table 23-8 shows the incidences of the most common complications from major series.

Complication	Incidence
Vascular impairment	10%
Peroneal palsy	3%
Knee instability/degenerative joint disease	33%
Growth disturbance	10%–25%

Data from references 53, 87, 89, 90, 93, and 96.

TABLE 23-8. COMPLICATIONS OF PROXIMAL TIBIAL FRACTURES

Instability

Separations of the proximal tibial epiphysis are surprisingly unstable, regardless of the Salter-Harris type. This is because of loss of periosteal stability or ineffective splinting from surrounding soft tissues. The fact that the collateral ligaments do not attach to the proximal tibial epiphysis also may be a factor in instability. It is wise to obtain radiographs 1 week after injury to check reduction. At that point, it still is not too late to remanipulate the extremity if necessary. If reduction cannot be maintained initially, percutaneous pin fixation or open reduction with internal fixation may be indicated, especially with displaced fractures. In unstable fractures with vascular injury, reduction and pin fixation should precede exploration of the popliteal artery. If the knee is swollen, sufficient flexion to maintain reduction of an anteriorly displaced separation may compromise circulation of the lower leg. Internal fixation allows flexibility in positioning the knee in a cast after injury.

Vascular Injury

Nicholson's report (90) of a patient with associated arterial injury is notable. The patient was seen less than an hour after an injury sustained while playing football. The knee was tense with effusion and extremely tender. There was a deep depression in the area of the tibial tubercle, indicating posterior displacement of the metaphysis relative to the epiphysis. The foot was warm, but the patient could not move his toes actively. Both pulses in the foot were absent and did not return after reduction of the fracture. Exploration of the popliteal fossa revealed that both the popliteal artery and vein were completely severed. An attempt at anastomosis failed and amputation was performed.

Burkhart and Peterson (87) reported a patient with vascular occlusion. A 12-year-old hurdler sustained a closed Salter-Harris type III injury that was treated with closed reduction and a long leg cast. Increased pressure in both the anterior and posterior muscle compartments caused narrowing of the terminal branches of the popliteal artery, although arteriography showed that the popliteal artery itself remained patent. Fasciotomies and a sympathectomy failed to save the leg.

Arterial insufficiency may result from either a tear in the popliteal artery at the time of epiphyseal separation (Fig. 23-28) or from a compartment syndrome. Delay in recognition results in delay of treatment, which is potentially catastrophic. Arteriography is not mandatory for isolated injuries but may be helpful if the vascular supply is questionable. Fracture fixation should be followed by arterial exploration (posterior or posteromedial approach) and repair or vein grafting. Compartment syndrome is treated by fasciotomy and delayed wound closure or skin grafting.

FIGURE 23-28. Anteroposterior radiograph at the time of arteriogram shows a Salter-Harris type III fracture–separation of the proximal tibial epiphysis. The arterial flow through the popliteal vessels is blocked.

Premature Growth Arrest

Angulation from a localized area of growth inhibition may occur after any type of proximal tibial separation. The degree of progressive angulation depends on the proximity of the area of growth arrest to the periphery of the physis. The amount of angulation also depends on the years left for growth after injury.

If the area of growth arrest is localized to less than a third of the total area of the physis and at least 2 years of growth remain, resection of the bony bridge may be attempted. Alternatively, epiphysiodesis or stapling of the side of the physis opposite a peripheral bar may stop progression of the deformity (88). Existing deformity at the time of surgery may require proximal tibial osteotomy. If there is significant valgus deformity, an opening-wedge osteotomy to correct valgus deformity and gain length may injure the peroneal nerve. Slow correction after corticotomy, with guided lengthening using an external fixator by surgeons familiar with this technique, is an option in patients close to skeletal maturity who have severe angular deformity and a large leg-length discrepancy.

Leg-Length Discrepancy

The proximal tibial physis grows approximately ¼ in. per year. If complete growth arrest follows an epiphyseal separation at this level and the patient is within 3 years of the end of growth, an equalization procedure is unnecessary. If more years of growth remain, epiphysiodesis of the opposite extremity may be considered. If arrest occurs before age 6 to 8 years, leg lengthening at a later stage may be indicated. If the growth arrest is partial, it is helpful to measure with sequential scanograms the relative growth rates of the two extremities so that the discrepancy at skeletal maturity can be predicted. If the predicted discrepancy is less than 2.5 cm, no equalization procedure is planned. If the expected discrepancy is 2.5 to 5 cm, epiphysiodesis of the opposite lower extremity is appropriate. If the expected discrepancy exceeds 5 cm, limb lengthening should be considered.

AVULSION OF THE TIBIAL TUBERCLE

Considering the force with which the contracting quadriceps muscle pulls on its insertion, especially during jumping (concentrically) or landing (eccentrically), it is surprising that the tibial tubercle is not avulsed more frequently. The incidence relative to injuries of other apophyses remains ill defined for two reasons. First, the severe type of avulsion of the tibial tubercle that extends proximally through the upper epiphysis of the tibia into the knee joint is sometimes reported as a Salter-Harris type III separation of the proximal tibial epiphysis. Second, an acute localized avulsion fracture of the tibial tubercle is sometimes thought to be a variant of the Osgood-Schlatter (OS) lesion. For example, Shelton and Canale (93) and Burkhart and Peterson (87) included extraarticular tubercle avulsions in their reviews of proximal tibial physeal separations, whereas Ogden (53) included in his series of tibial tubercle avulsions some cases that overlap with OS lesion.

The incidence of avulsion fractures of the tibial tubercle, compared with all epiphyseal injuries, is probably between the 0.4% reported by Burkhart and Peterson (87) and the 2.7% reported by Ogden et al. (117). The difficulty in separating avulsion fractures of the tibial tubercle from OS lesions stems largely from the lack of precise definition of either entity. Some differences are listed in Table 23-9, but some clinical features are similar. Some patients with OS lesions have a history of specific trauma. Avulsion fractures of the tibial tubercle localized to the distal fragment of the tubercle (type I) occasionally cause little more than point tenderness.

Osgood-Schlatter Lesion	Acute Traumatic Avulsion of the Tibial Tubercle
Onset often insidious	Acute injury (often in athletics)
Intermittent mild symptoms	Immediate marked pain and swelling
Partial disability	Often unable to stand or walk
Symptomatic and supportive treatment	Often open reduction and internal fixation
Prognosis fairly good (occasionally long-term symptoms with ununited ossicle)	Rapid healing and return to full activities

TABLE 23-9. COMPARISON OF THE CLINICAL FEATURES OF OSGOOD-SCHLATTER LESION AND ACUTE TRAUMATIC AVULSION OF THE TIBIAL TUBERCLE

An OS lesion may precede an acute avulsion of the tibial tubercle. Deliyannis (106) reported a complete avulsion of the tibial tuberosity in a 16-year-old boy who had been seen previously for an OS lesion. Levi and Coleman (115) stated that 4 of 15 patients with fractures of the tibial tubercle had histories of OS lesions. Ogden et al. (117) reported that 9 of their 14 patients with fractures of the tibial tuberosity had preexisting OS lesions, 7 in the contralateral knee and 2 in the ipsilateral knee. Ogden (53) defined an OS lesion as an avulsion of the anterior surface of the apophysis. He stated that there is no separation between the ossific nucleus of the apophysis and the adjacent tibial metaphysis. If there is a separation through the physis deep to the ossific nucleus of the tubercle, an avulsion fracture of the tubercle has occurred. This distinction often is difficult to recognize on radiographs of an incompletely ossified tibial tubercle.

In an adolescent, the patellar ligament inserts not only into the developing tibial tubercle, but beyond into the adjacent perichondrium of the physis and the periosteum of the adjacent metaphysis (107,117). With an OS lesion, the central fibers of the patellar ligament avulse a localized fragment of surface cartilage and bone from the secondary ossification center. The displacement of this fragment is not severe because the remaining fibers of the patellar ligament that fan out medially and laterally remain intact. With a limited, minimally displaced avulsion fracture of the tibial tubercle, a cleavage plane is present through part of the physis between the secondary ossification center of the tubercle and the adjacent metaphysis of the proximal tibia. The perichondrium is torn adjacent to the separated portion of the physis. A severely displaced avulsion fracture of the tibial tubercle implies a more extensive tear of the fibrous expansion of the insertion of the patellar ligament.

In 1971, Hand et al. (109) reported seven avulsion fractures of the tibial tubercle, all in boys 14 to 16 years of age and all resulting from sports or play activities. Six of the seven patients were treated successfully by open reduction and internal fixation. These authors noted that a large periosteal flap could become folded into the gap underneath the avulsed tubercle.

Levi and Coleman (115) reported uniformly good results in 14 patients with avulsions of the tibial tubercle. All but one of the patients were boys, with an average age of 14 years, and all injuries were sustained during sports or play activities. All were treated by open reduction, with various forms of fixation. The authors warned that the size of the avulsed fragment often is underestimated because the tibial tubercle is incompletely ossified at the time of injury.

In an in-depth study of 14 fractures of the tibial tubercle by Ogden et al. (117), the sequence of events in the morphologic development of the tibial tuberosity was related to the narrow age range in which these fractures occur. An analogy was drawn to the fracture of Tillaux because both injuries occur at an age when physiologic epiphysiodesis has begun. Two pathologic fractures were included in this report.

In 1981, Christie and Dvonch (103) reported eight avulsion fractures of the tibial tubercle in seven patients. All the injuries occurred in boys 13 to 17 years of age who were playing basketball. The degree of displacement varied. The authors recommended an attempt at closed reduction, even in severely displaced fractures, before resorting to open reduction and internal fixation. They pointed out that the healing of this injury occurs by epiphysiodesis, but genu recurvatum rarely results because the patients are close to skeletal maturity.

Surgical Anatomy

Bony Anatomy

In its final adult form, the tibial tubercle is a bony prominence on the anterior aspect of the proximal tibia. It lies approximately one to two fingerbreadths distal to the proximal articular surface of the tibia and forward of the anterior rim of the proximal articular surface. The tubercle is at a point where the broad, flat anterior surface of the tibial condyles narrows sharply to become the anterior border of the diaphysis. Helfet (110) showed that the tibial tubercle is in line with the medial half of the patella when the knee is flexed and with the lateral half when the knee is extended. Thus, the position of the tibial tubercle in the coronal plane relative to the patella is a function of the position of the knee joint. This is because the proximal end of the tibia rotates relative to the distal end of the femur with flexion and extension movements of the knee.

Ehrenborg (107) divided the postnatal development of the tibial tubercle into four stages (Fig. 23-29). The cartilaginous stage occurs before the secondary ossification center appears and persists in girls until 9 years and in boys until 10 years of age. The apophyseal stage, in which the ossification center appears in the tongue of cartilage, occurs between 8 and 12 years in girls and between 9 and 14 years of age in boys. The epiphyseal stage, in which the secondary ossification centers coalesce to form a tongue of bone continuous with the proximal tibial epiphysis, occurs in girls between 10 and 15 years and in boys between 11 and 17 years of age. In the final bony stage, the epiphyseal line is closed between the fully ossified tuberosity and the tibial metaphysis.

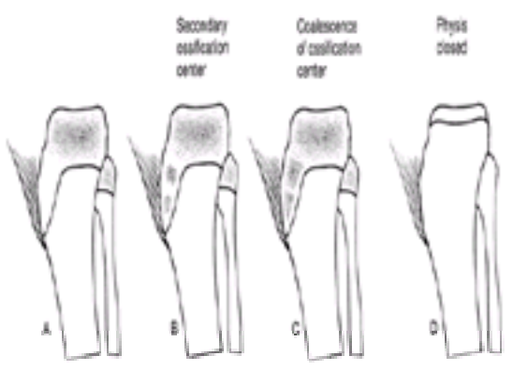

FIGURE 23-29. Development of the tibial tubercle. **A:** In the cartilaginous stage, there is no ossification center in the cartilaginous anlage of the tibial tubercle. **B:** In the apophyseal stage, the secondary ossification center or centers forms in the cartilaginous anlage of the tibial tubercle. **C:** In the epiphyseal stage, the primary and secondary ossification centers of the proximal tibial epiphysis have coalesced. **D:** In the bony stage, the proximal tibial physis has closed.

Soft Tissue Anatomy

The patellar ligament, which lies between the distal pole of the patella and the tibial tubercle, is the terminal portion of the inserting tendon of the powerful quadriceps muscle. During the apophyseal stage of development of the tubercle, the patellar ligament inserts into an area approximately 10 mm long, corresponding to the fibrous cartilage proximal and anterior to the secondary ossification center. The main attachment is in the proximal area of this insertion zone, at the level of the cartilage lying between the secondary ossification centers of the tubercle and the main portion of the proximal tibial epiphysis. The fibrocartilaginous tissue lying anterior to the secondary ossification center receives only the distal part of the insertion. During the epiphyseal stage, the patellar ligament inserts through fibrocartilage on the anterior aspect of the downward-projecting tongue of the proximal tibial epiphysis. The inserting fibers merge distally into deep fascia after spanning the physis. With traumatic avulsion of the tibial tubercle in this stage of development, a broad flap of adjacent periosteum is attached to the displaced fragment. In the final bony stage, the tendon fibers insert directly into bone. After physiologic epiphysiodesis has occurred, the tibial tubercle rarely is avulsed if the patient has normal bone.

Although the patellar ligament represents the main insertion of the quadriceps muscle onto the leg beyond the knee joint, it is reinforced by retinacular fibers radiating from the medial and lateral margins of the patella obliquely down to the respective tibial condyles. Also, longitudinally oriented retinacular fibers extend from the distal margin of the vastus lateralis down to the anterior aspect of the lateral tibial condyle, partly merging with the inserting fibers of the iliotibial band (120). Similarly, longitudinal fibers extend from the distal margin of the vastus medialis down to the anterior aspect of the medial tibial condyle. Frazer (100) showed that the insertion of the medial retinaculum extends beyond the proximal tibial physis into the metaphysis. After traumatic avulsion of the tibial tuberosity, a limited amount of active extension of the knee still is possible through the retinacular extensions of the extensor mechanism. However, patella alta and an extensor lag are present.

The anatomic position of the tibial tubercle is biomechanically important (102,105,114). It is one factor that determines the length of the moment arm from the patellar ligament to the center of rotation of the knee (113). This moment arm helps determine the amount of patellofemoral reaction force developed by extending the knee against resistance (116).

Vascular Anatomy

The tibial tubercle receives its main blood supply from an anastomosis behind the quadriceps tendon. In particular, a prominent leash of vessels bilaterally arises from the anterior tibial recurrent artery and may be torn with this fracture (118,122). Several small branches extend down into the secondary ossification center. A smaller part of the blood supply enters the superficial surface of the tubercle from adjacent periosteal vessels. Trueta (121) showed in injection studies that a few of the longitudinal vessels in the patellar ligament itself extend into the tubercle. Ogden et al. (117) showed blood vessels entering the medial and lateral aspects of the tubercle. They demonstrated cartilage canals in the physis carrying these branches of the metaphyseal vessels in children up to 10 to 12 years of age.

Mechanism of Injury

Acute traumatic avulsions of the tibial tubercle occur most often during sports or play activities (97,104,108,112,119). Böhler (9) stated that most avulsions originated from “a leap over a wooden horse” in physical training. Of the seven avulsions reported by Hand et al. (109), four occurred while playing football and three while jumping during play. Of the 15 injuries reported by Levi and Coleman (115), 5 occurred while playing basketball, 2 while diving from a springboard, 2 during competitive running, and 1 during a high jump. All eight injuries reported by Christie and Dvonch (103) occurred while playing basketball.

Avulsion of the tibial tubercle occurs when the patellar ligament traction exceeds the combined strength of the physis underlying the tubercle, the surrounding perichondrium, and the adjacent periosteum. This can occur in two ways. The first mechanism is violent contraction of the quadriceps muscle against a fixed tibia. This can happen when an athlete jumps or lands, as in basketball or track. The second mechanism is acute passive flexion of the knee against the contracted quadriceps. This can happen when a person makes a bad landing at the end of a jump or fall. In other words, avulsion of the tubercle can result from sudden acceleration or deceleration of the knee extensor mechanism.

Some predisposing factors to avulsion of the tibial tubercle have been identified. Patella infera, with a relatively short patellar ligament, can impose increased tension on the distal insertion of the quadriceps mechanism. Tight hamstrings can increase flexion torque, opposing active extension of the knee (Fig. 23-30). As mentioned earlier, the weak link in the extensor mechanism in adolescents is the changing physis beneath the tibial tubercle. Acute disruptions are more common in knees with preexisting OS disease, which indicates a mechanical vulnerability from either overdevelopment of the quadriceps mechanism, lack of flexibility of the knee flexors, or impaired coordination between opposing torques about the knee. In addition, Ogden et al. (117) reported two patients with what were probably pathologic fractures. One injury occurred in a child with myelomeningocele, and the other patient had metaphyseal dysplasia with preexisting varus deformity of the injured knee.

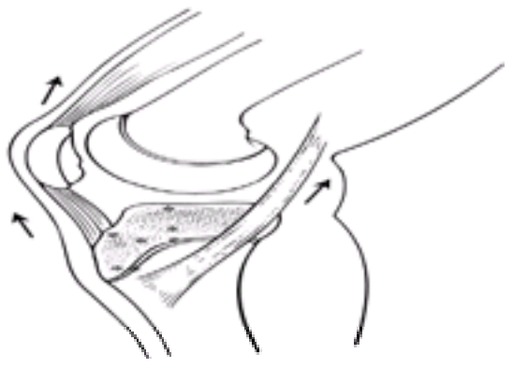

FIGURE 23-30. Contracting quadriceps mechanism exerts extension torque on the knee joint, whereas contracting hamstring muscles exert flexion torque on the knee joint. *Asterisks* indicate points of possible failure when the knee is jammed by opposing torques.

Classification

Watson-Jones (82) described three types of avulsion fractures of the tibial tubercle. In the first type, a small fragment, representing part of the tubercle, is avulsed and displaced upward. In the second type, the secondary center of ossification in the tubercle has already coalesced with the rest of the proximal tibial epiphysis, and the entire lip formed by the front of the upper tibial epiphysis is hinged upward. In the third type, the line of fracture passes proximally across the proximal physis of the tibia.

Ogden and associates (117) refined the classification and described three types, depending on the distance of the fracture from the distal tip of the tubercle (Fig. 23-31). Each type is divided into two subtypes, depending on the severity of displacement and comminution:

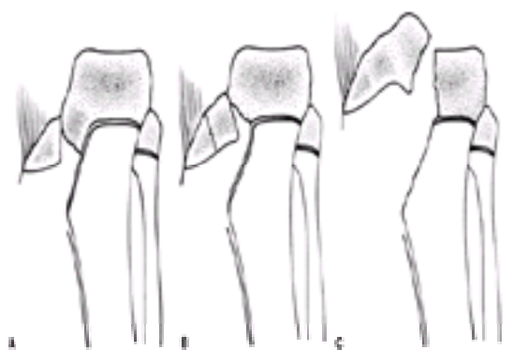

FIGURE 23-31. Classification of avulsion fractures of the tibial tubercle. **A:** Type I fracture across the secondary ossification center level with the posterior border of the inserting patellar ligament. **B:** Type II fracture at the junction of the primary and secondary ossification centers of the proximal tibial epiphysis. **C:** Type III fracture propagates upward across the primary ossification center of the proximal tibial epiphysis into the knee joint. This fracture is a variant of the Salter-Harris type III separation and is analogous to a Tillaux fracture of the ankle because the posterior portion of the proximal tibial physis is closing. (From Ogden JA, Tross RB, Murphy MJ. Fractures of the tibial tuberosity in adolescents. *J Bone Joint Surg Am* 1980;62:205–215; with permission.)

Type I—The separation through the distal portion of the physis under the tubercle breaks up proximally through the secondary ossification center of the tubercle.

Type II—The separation extends anteriorly through the area bridging the ossification centers of the tibial tubercle and the proximal tibial epiphysis.

Type III—The separation beneath the tubercle propagates through the proximally proximal tibial epiphysis into the knee joint under the anterior attachments of the menisci.

Ogden noted that the degree of displacement depends on the severity of injury to adjacent soft tissue attachments.

Signs and Symptoms

Swelling and tenderness are centered over the anterior aspect of the proximal tibia. Joint effusion and tense hemarthrosis may be present. A freely movable triangular fragment of bone may be palpated subcutaneously between the proximal tibia and the femoral condyles. This fragment may have rotated so that the distal end projects forward, tenting the overlying skin. If the avulsed fragment is held and moved passively, crepitus may be felt between the fragment and the proximal tibia. A palpable defect on the anterior aspect of the tibia at the upper end of the anterior border of the diaphysis represents the bed from which the fragment was avulsed. In a markedly displaced Watson-Jones type III avulsion, the palpable defect can be as much as 3 cm long.[nb

The injured knee is held in 20 to 40 degrees of flexion by hamstring spasm. The amount of patella alta is proportional to the severity of displacement of the tibial tubercle. The patella may be displaced proximally as much as 10 cm. With associated joint effusion, the patella may seem to float off the anterior aspect of the distal femur. With a type I avulsion, the patient usually can actively extend the knee, although not completely. With type II and III lesions, full extension is impossible.

Radiographic Findings

Because the tubercle lies just lateral to the midline of the tibia, the best profile can be obtained by a lateral projection, with the tibia rotated slightly internally. Soft tissue technique helps define the margins of the patellar ligament and smaller fragments of bone. In children and adolescents 9 to 17 years of age, the normal tubercle is ossified to varying degrees. One or more secondary ossification centers form at the distal end of the tubercle during the apophyseal stage of development. The presence of several centers does not represent an abnormality. Multiple ossification centers coalesce and join with the proximal tibial epiphysis during the epiphyseal stage of development. At this time, a horizontal radiolucent band becomes apparent on the anteroposterior radiograph at the distal end of the tubercle. The band represents a groove filled with cartilage between the tip of the tibial tubercle and the upper end of the anterior border of the diaphysis. During the epiphyseal stage of development, the borders of the tubercle are sharply defined.

After an avulsion of the tibial tubercle, the size and degree of displacement of the fragment are best seen on the lateral radiograph (Fig. 23-32). In a type I injury, the distal end of the tubercle is displaced upward and forward to varying degrees. The avulsed fragment corresponds to that part of the tubercle between the proximal border of the inserting patellar ligament and the distal end of the secondary ossification center. In the second type of avulsion of the tubercle, the fragment is larger, hinging or separating at the level of the horizontal portion of the proximal tibial physis. In type III, the fracture line extends proximally from beneath the tubercle through the proximal tibial epiphysis and exits the upper surface of the epiphysis (Fig. 23-33). The fracture line emerges anterior to the tibial spine. If this type of injury is comminuted, fragmentation occurs at the level of the horizontal component of the proximal tibial physis. In a type III lesion, the central portion of the physis beneath the proximal tibial epiphysis may have already closed. Bruijn et al. (101) reported a “sleeve” fracture of the tibial tubercle in a 14-year-old gymnast; his radiographs appeared normal, but 6 months later a 4-cm, ossified, proximally displaced sleeve representing the base of the patellar tendon was seen.

FIGURE 23-32. Three variations of avulsions of the tibial tubercle. **A:** Anterior injury with avulsion of the tubercle and anterior aspect of the epiphysis. **B:** Classic Salter-Harris type III fracture, beginning in the physis and extending into the articular surface of the epiphysis. **C:** Comminuted epiphyseal–metaphyseal fracture of the proximal tibia.

FIGURE 23-33. A: A 15-year-old boy with a comminuted, displaced tibial tuberosity avulsion sustained while jumping in a basketball game. **B:** After open reduction and internal fixation with multiple cancellous screws.

Closure of the gap between the avulsed fragment and its bed indicates satisfactory reduction. Persistence of even a small gap between the distal end of the tubercle and the adjacent metaphysis may indicate an interposed flap of periosteum.

Before reduction of an avulsed tibial tubercle, the degree of patella alta and, therefore, the severity of displacement can be determined by one of several radiographic methods (98,99,111). Because the tibial tubercle is displaced proximally to the same extent as the patella, the ratio between the overall length of the patella and the distance between the patella and tibial tubercle would not change. The best method for estimating patella alta after avulsion of the tibial tubercle is that described by Blackburne and Peel (98): the position of the patella is compared with a line extrapolated forward from a tangent across the upper surface of the tibia. Even this method gives varying degrees of patellar displacement, depending on contraction or spasm in the quadriceps muscle.

Treatment

Minimally displaced, small avulsion fragments have been treated successfully by closed methods. The leg is positioned with the knee extended and the hip slightly flexed. Reduction can be held by a long leg cast that is well molded above the proximal pole of the patella. Most authors advise open reduction and internal fixation of type II and III fractures. A midline vertical incision is recommended to facilitate any possible knee surgery in the future. The fracture bed is carefully cleared of debris. If a periosteal flap is folded under the avulsed fragment, it is extracted and held spread out while the fragment is reduced with the knee extended. Depending on the size of the avulsion fragment and the patient's age, fixation is obtained with transfixing pins or screws and is reinforced by repair of the torn periosteum.

Operative Treatment

We recommend open reduction and internal fixation of all but the smallest undisplaced fragments. Closed methods can be used in minimally displaced fractures if the knee can be actively extended to 0 degrees. For open reduction, we prefer a vertical incision centered over the tibial tubercle, along either its medial or lateral border. We are careful to clear the gap between the displaced fragment and its bed of any soft tissue interposition. With type III fractures, the menisci should be inspected for tears. If the reduced fragment is large enough, we prefer to use one or two cancellous screws, extending through the tubercle, parallel to the joint into the metaphysis. If the patient is more than 3 years from skeletal maturity, smooth pins are used (Fig. 23-34). If the fracture is comminuted, we prefer multiple screws or threaded Steinmann pins reinforced by periosteal sutures. A strong, tension-holding suture such as the Krackow (running locking) suture may add strength to the repair; sutures also may be used in the periosteum and lateral tendon expansion. After wound closure, a well-fitting long leg or cylinder cast is applied. The cast is carefully molded on either side of the reduced tibial tubercle and proximal to the patella so that the latter is held downward.

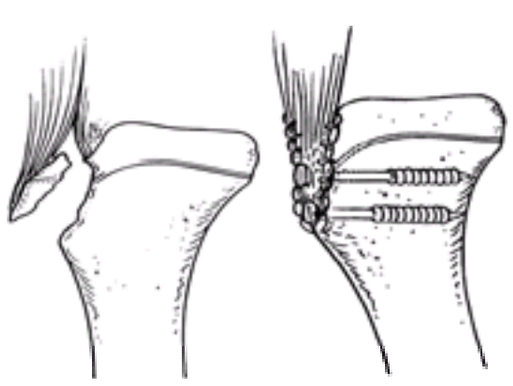

FIGURE 23-34. Open reduction and internal fixation of type II tibial tubercle fracture **(A).** After anatomic reduction **(B),** a large fragment is stabilized with two screws.

Postreduction Care

The cylinder or long leg cast applied after reduction of the avulsed tubercle is worn for 4 to 6 weeks and then is bivalved. For the next 2 weeks, the posterior half of the cylinder cast is worn as a splint between exercise periods. Gentle active range-of-motion and quadriceps-strengthening exercises are begun three times a day. At 6 weeks after injury, exercise of the quadriceps against some resistance can be started if there is no tenderness over the tibial tubercle. The patient is permitted to return to athletics and vigorous play only after the quadriceps strength equals that of the opposite side and range of motion has been regained.

Prognosis

The outcome of a well-reduced avulsion fracture of the tibial tubercle is consistently good. Most patients return to normal function, including sports. All 15 patients reported by Levi and Coleman (115) had returned to normal activity without deformity or restriction 1 to 18 years after injury. All but one of the patients reported by

Ogden et al. (117) were completely asymptomatic, with no disability. All seven patients reported by Christie and Dvonch (103) had returned to normal function at an average of 3 years after injury.

Complications

The early and late complications of avulsion of the tibial tubercle are listed in Table 23-10.

Early
Compartment syndrome
Meniscal tears
Infection
Late
Genu recurvatum
Loss of flexion
Refracture

TABLE 23-10. COMPLICATIONS OF TIBIAL TUBERCLE AVULSION

Blount (8) noted that genu recurvatum caused by premature closure of the anterior portion of the physis is likely to occur after avulsion of the tibial tubercle in skeletally immature children, usually those younger than 11 years of age. Genu recurvatum is rare after avulsion fracture of the tibial tubercle, despite the fact that healing actually occurs by epiphysiodesis. The explanation of this apparent paradox is that avulsions of the tubercle almost always occur in patients very close to skeletal maturity.

Compartment syndrome has been reported in seven patients with type III fractures, presumably because of tearing of anterior tibial recurrent vessels, which fan out at the tubercle but retract into the anterior compartment when torn (118,122) (Fig. 23-35). Close monitoring is necessary for patients treated nonoperatively and careful inspection, possibly with prophylactic anterior fasciotomy, is recommended for patients treated operatively (118,122).

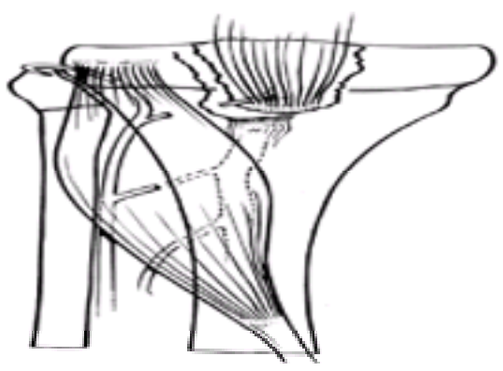

FIGURE 23-35. Probable mechanism of development of compartment syndrome after tibial tubercle avulsion. The anterior tibial recurrent artery is torn and retracts into the anterior compartment musculature.

Minor complications also have been reported. Christie and Dvonch (103) reported a patient with persistent loss of 25 degrees of knee flexion 19 months after a type III injury. Hand et al. (109) reported a patient with persistent quadriceps atrophy, and Levi and Coleman (115) reported a patient with a persistent prominence 7 years after open reduction and internal fixation. To this short list could be added the expected complication of patella alta if a displaced tibial tubercle is not reduced adequately.

OSGOOD-SCHLATTER LESION

Osgood-Schlatter (OS) lesions are considered separately from acute traumatic avulsions of the tibial tubercle because the pathophysiologic process, treatment, and outcome differ somewhat (121,129). Although acute avulsion of the tubercle is almost always related to a specific injury, the patient with an OS lesion often can give only a vague history about the onset of symptoms. Whereas an adolescent with a displaced acute avulsion of the tibial tubercle is immediately unable to stand or walk, an adolescent with OS disease often tries to continue sports and play activities despite discomfort. Treatment of acute avulsion of the tubercle depends on the size of the avulsed fragment and the degree of displacement, but usually open reduction and internal fixation are indicated. Treatment of OS lesions usually is symptomatic and supportive. The prognosis for a reduced and healed avulsed tubercle is excellent. The patient makes a rapid return to full activities within several months. On the other hand, it usually takes up to 2 years for resolution of the symptoms of an OS lesion, and occasionally disability persists into adulthood.

Despite these differences, there is convincing evidence that the OS lesion and acute traction of the tibial tubercle represent a spectrum of avulsion phenomena. The contrasting clinical picture probably is due to the fact that a limited amount of tissue is displaced to a limited degree in the OS lesion (see Table 23-9).

In 1891, Paget (62) described the clinical syndrome that later became known as OS disease. In 1903, Osgood (132) and Schlatter (136) published separate papers on the subject. Beginning with Osgood's article, three timely papers on the subject have in common the conviction that the etiology is trauma.

Osgood (132) reported 10 patients in whom he observed that function was not completely lost, although recurrent soreness and weakness caused some disability in athletic participation. In a dissected specimen, Osgood observed that after simulating the lesion with localized osteotomy of the tibial tubercle at the insertion of the central ligament, repeated traction on the quadriceps muscle produced upward displacement of the detached fragment of no more than ¼ in. The knee still could be extended with the tibial tubercle detached if the retinaculum was intact. Osgood concluded that the clinical lesion represented a localized rupture of the central insertion of the quadriceps mechanism.

In 1962, Ehrenborg (125) published a comprehensive study of OS disease that included 218 affected knees in 170 patients. No patient was older than 15 years of age at the time of initial examination, and the age of onset of the clinical syndrome coincided with the apophyseal stage of development of the tubercle. He explained the relatively painless onset of the clinical course by noting that the avulsed cartilaginous tissue contained very few pain fibers.

In 1976, Ogden and Southwick (131) reported 53 patients with OS lesions; 41 were in the apophyseal stage of tibial tubercle development at the onset of symptoms. They observed new bone formation anterior to the secondary ossification center and concluded that the weak link that failed under tension was the developing ossification center with overlying hyaline cartilage rather than the cartilage at the base of the tubercle apophysis (Fig. 23-36).

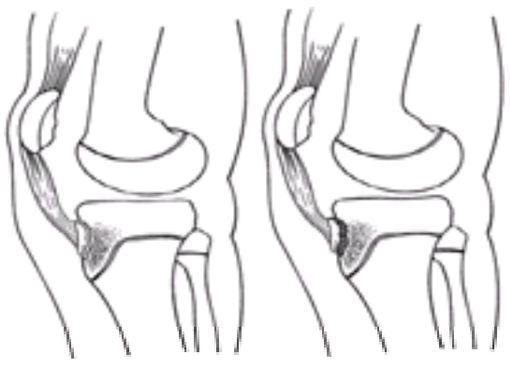

FIGURE 23-36. Development of Osgood-Schlatter lesion. **A:** Avulsion of osteochondral fragment that includes surface cartilage and a portion of the secondary ossification center of the tibial tubercle. **B:** New bone fills in the gap between the avulsed osteochondral fragment and the tibial tubercle.

Surgical Anatomy

The age range in which each of the two principal types of avulsion injuries occurs is related to the specific stage of development of the tuberosity at that time (110). The OS lesion occurs when the tibial tubercle is in the apophyseal stage and the secondary ossification center has appeared. The cartilage overlying the ossification center anteriorly and underlying it posteriorly is fibrocartilaginous and can resist tension forces better than the bone in the secondary ossification center itself, which may give way during contraction of the extensor mechanism. During the epiphyseal stage of tibial tubercle development, the ossification center has become stronger by enlargement and coalescence with the main ossification center of the proximal tibial epiphysis. During this stage of development, violent contraction of the quadriceps mechanism produces the acute fracture–separation through the tubercle physis that was discussed in the preceding section.

Mechanism of Injury

Usually no specific injury or event can be directly related to the onset of symptoms; however, repeated normal stresses or overuse can produce a limited or localized disruption (117,130,131). Bilateral lesions are found in approximately one fourth of patients.

Other anatomic variants may predispose to the development of OS lesions. Lancourt and Cristini (114) found patella infera in a small series of adolescents with OS lesions before physeal closure. The low-lying patella, with shortening of the patellar ligament, may explain the increased stress on the tibial tubercle. Jakob et al. (128) found patella alta in 185 knees in 125 patients with OS disease. In most, the lesion had healed. These findings also were reported by Aparicio (123). They believed that patella alta after OS disease had run its course implied a preexisting quadriceps contracture, especially of the rectus femoris. They repeatedly observed that children with OS disease had a well-developed, even hypertrophic quadriceps muscle with decreased elasticity. Willner (139) found genu valgum, pronated feet, and internal rotation of the knee in all of his 78 patients with OS lesions. Turner and Smillie (138) found that patients with the OS lesion had a substantial increase in lateral tibial torsion. Also, as in acute avulsion of the tibial tubercle, tight hamstrings may increase the resistance of the knee to extension by quadriceps action, thereby increasing the tension force on the patellar ligament. Patients with cerebral spastic diplegia, characterized by hamstring contracture, are vulnerable to OS lesions in the appropriate age group. Rosenthal and Levine (134) showed a relatively high incidence of the OS lesion in patients with cerebral palsy.

Signs and Symptoms

The patient with an OS lesion usually is between 11 and 15 years of age. Boys are more frequently affected than girls. Approximately half the patients give a history of precipitating trauma. The pain usually has been present intermittently over a period of several months before the patient is seen by the physician. The pain is aggravated by running, jumping, kneeling, squatting, and climbing or descending stairs. Rest or restriction of strenuous activities usually brings relief.

Physical findings are localized swelling and tenderness at the insertion of the patellar ligament. There is no effusion of the knee joint. Pain is reproduced by extension against forced resistance. There may be some quadriceps atrophy.

Radiographic Findings

Radiographs are not indicated in all patients with OS lesions. The diagnosis is clinical, but plain films may be helpful if other bony entities must be ruled out, if symptoms are prolonged, or if the patient is older. The OS lesion is best seen on a lateral projection taken with the knee in slight internal rotation. A film taken with soft tissue technique may confirm the diagnosis by showing that the edges of the patellar ligament are blurred. Small, flakelike fragments of the secondary ossification center of the tubercle may be displaced slightly anteriorly and superiorly, but these are difficult to distinguish from normal multicentric ossification of the tubercle. Later in the course of the disease, the ossicles may enlarge, presumably because of further ossification of the cartilaginous component of the avulsed fragment. Also, the gap between the avulsed fragments and the tibial tuberosity may fill in with bone. The displaced fragments sometimes fail to unite and remain as separate ossicles detached from the anterior border of the maturing tubercle (Fig. 23-37). An undue prominence of the tubercle itself may be present in the residual stages. Occasionally it is helpful to compare lateral radiographs of the affected knee with those of the normal side.

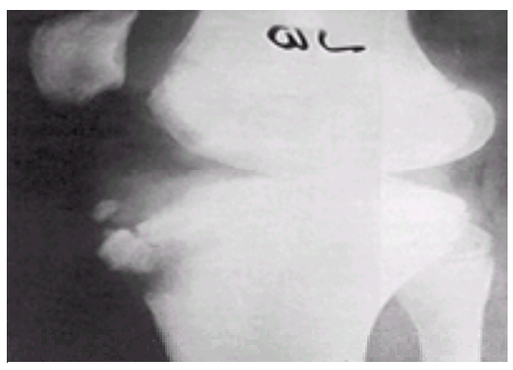

FIGURE 23-37. Extreme example of Osgood-Schlatter lesion. Lateral radiograph shows enlargement of the tibial tubercle, ununited ossicles, and patella alta.

A prospective study (133) of OS lesions done with serial MRI, CT, and bone scans showed that the most striking feature was soft tissue inflammation, not bony avulsion. Tendon thickening was seen in all patients and a distended deep infrapatellar bursa was present in two thirds. An ossicle was seen in only one third of the patients, with both early and late disease. Scintigraphic uptake rarely exceeded normal.

Treatment

The most important thing a physician can do is to explain the natural history of the disease to the family, because OS disease is related to activity and resolves with rest and maturation. Many are relieved to know that it is not related to any intraarticular derangement or risk of arthritis. Treatment measures most often recommended for OS lesions are symptomatic and supportive (79,124,125 and 126). The goal of such treatment is to ease pain and swelling. A temporary restriction of athletics or vigorous activities may be sufficient. In the acute stages of OS disease, activities should be restricted to mild forms of athletic participation, such as walking or swimming. As symptoms improve, moderate activities such as tennis, baseball, swimming, and roller skating can be allowed. Jakob et al. (128) proposed stretching exercises for the quadriceps to relieve tension on the tibial tubercle. Stretching exercises also are indicated for the hamstrings, which commonly are tight.

If severe symptoms interfere with normal activities, a knee immobilizer or a cylinder cast may be used for 6 weeks. Turner and Smillie (138) suggested multiple drilling in patients with enlargement and irregularity of the tubercle, and they advised excision of ununited fragments or ossicles after maturity.

Some investigators (135,139) recommend against treating OS lesions with local injections of steroids because this may impair healing and result in scarring of the overlying skin, with significant cosmetic deformity.

AUTHOR'S PREFERRED METHOD OF TREATMENT

When we see an adolescent early in the course of symptoms from an OS lesion, we discuss the natural history with the patient and parents. We tell them that symptoms may wax and wane with activities for several years, but this is not a sign of serious internal derangement of the joint. If symptoms are markedly severe, we advise a knee immobilizer or cylinder cast for weight-bearing activities. When there is no acute tenderness, quadriceps-strengthening exercises and hamstring-stretching exercises are begun. Restriction of athletic activities is advised according to the severity of symptoms. The patient often can tell which activities cause recurrent discomfort—usually those that involve jumping, such as basketball or hurdling, and those that require repetitive knee flexion and extension, such as bicycling. Nonsteroidal antiinflammatory medications and icing after sports may relieve symptoms.

Operative treatment is reserved for ununited ossicles with persistent symptoms after the physes have closed. Excision is performed through a short incision by longitudinally splitting the distal fibers of the patellar ligament. The ossicle can be shelled out without extensive dissection. Postoperative casting for 6 weeks may be necessary if more dissection is performed.

Prognosis

The overall prognosis for OS lesions is excellent. After the symptoms run their course, the patient usually returns to full activity, including participation in athletics. Some prominence of the tibial tubercle may persist, and rarely kneeling may be difficult (140).

Symptoms persisting beyond the normal course of the lesion usually are associated with an ununited ossicle (127,137). Mital et al. (130) found ununited ossicles in 14 of 118 patients with OS lesions. Painful ossicles in adults are successfully treated with simple excision.

An OS lesion occasionally predisposes to an avulsion fracture of the tibial tubercle. Patients and their parents should be informed about this if they choose to continue recreational or sports activities despite persistent discomfort.

FRACTURES OF THE PATELLA

Patellar fractures are much less common in children than in adults (143,152,153). Bostrom (145), in his discussion of the incidence of patellar fractures in children, cited three large series: Diebold (148), who reported that 16 of 1,200 patients were younger than 16 years of age; Schoenbauer (163), who reported 5 of 578 patients to be younger than 16 years of age; and Ray and Hendrix (159), who reported 12 of 185 patients younger than 16 years of age. In these three series, less than 2% of patellar fractures occurred in skeletally immature patients.

The low incidence of fractures of the patella in children may be due to the fact that the osseous portion of the patella is less subject to both impact and tensile forces in children than in adults. It is surrounded by a thick layer of cartilage that acts as a cushion against a direct blow (146). The relative magnitude of forces generated in the extensor mechanism of a child's knee is no doubt less than an adult's knee because of the smaller muscle mass and shorter moment arm in children. A child's patella also has greater mobility in the coronal plane.

Although the patella may escape fracture from direct injury in children, it is more vulnerable to osteochondral fracture or avulsion of the medial margin associated with lateral patellar dislocation (160).

Avulsion fractures of the patella are classified according to location. A superior avulsion involves the superior pole of the patella and appears to be the least common pattern. An inferior avulsion involves the lower pole of the patella and usually is caused by an acute injury (142), however, it should be distinguished from a Sinding-Larsen–Johansson lesion (164), an incomplete avulsion caused by repetitive cyclic stress. A medial avulsion involves most of the medial margin of the patella and accompanies acute lateral dislocation of the patella. Lateral avulsion fracture usually involves the superolateral margin of the patella and usually is described as a bipartite patella (149,150,161) or dorsal defect of the patella.

The greatest difficulty with fractures of the patella in children is diagnosis. Developmental anomalies may be confused with fractures (141,155,158), and the size of fracture fragments, especially in sleeve fractures, may be underestimated in a growing child because the patella is partly cartilaginous (153). Belman and Neviaser (143) pointed out that it is not uncommon for the diagnosis of patellar fracture in a child to be missed or substantially delayed.

Anatomy

Bony Anatomy

The anlage for the patella develops in the ninth embryonic week. It lies deep to the tendon, not embedded in it. At birth, the shape is well defined in cartilage form. Ossification of the cartilaginous anlage begins between 3 and 6 years of age. Often there is more than one central ossicle—there may be as many as six irregular centers. Gradually, the ossicles coalesce, and ossification proceeds peripherally until all but the articular surface is replaced by bone. Until ossification is complete, the edges of the enlarging ossific nucleus may appear irregular on a radiograph (18). The pattern of bony development is similar in this respect to the growing epiphysis of the distal femur (Fig. 23-38). Ossification of the patella usually is complete by the beginning of the second decade.

FIGURE 23-38. Normal knee in a 6-year-old child. Note irregular ossification of the patella and the distal femoral condyle.

Congenital absence (144) and congenital hypoplasia (163) of the patella are uncommon. Although these variations in development have been reported as isolated findings, they also occur as part of the hereditary symptom complex onychoosteodysplasia or nail-patella syndrome (144).

An unossified patella may be bipartite or multipartite. Partition of the patella into almost equal anterior and posterior portions has been reported, often in patients with multiple epiphyseal dysplasia (149). The overall incidence of bipartite patella in adolescents is reported to range from 0.2% to 6%. It is more common in boys than in

girls. Although Kohler and Zimmer (155) stated that unilateral bipartite patella is rare, Green (150) found that 57% of his patients had unilateral bipartite patella.

Vascular Anatomy

Scapinelli (162) studied the blood supply to the human patella in specimens ranging from birth to old age. Because neither he nor Crock (146) noted differences between immature and mature specimens, it is presumed that the pattern of blood supply in children is similar to that in adults. An anastomotic circle surrounds the patella. Contributions to the anastomosis derive from the paired superior and inferior geniculate arteries, as well as from the supreme geniculate artery above and the anterior tibial recurrent artery below. From the anastomotic ring, branches converge centripetally toward the anterior surface of the patella and enter through foramina in the middle third of this surface. Additional blood supply to the patella enters the distal pole behind the patellar ligament. Thus, virtually the entire blood supply to the patella comes from the anterior surface or distal pole, with essentially no penetration of vessels from the medial, proximal, or lateral margins of the patella. Scapinelli (162) noted that these findings correlate with the fact that marginal fractures of the patella rarely unite. Also, injury to blood vessels entering the anterior aspect of the patella may lead to osteonecrosis of the proximal pole.

Mechanism of Injury

As in adults, fractures of the patella in children result from a direct blow (most common), sudden contraction of the extensor mechanism, or a combination of both. Direct impact may cause a linear or comminuted fracture pattern.

Avulsion of the distal pole of the patella can occur from tensile loading. Houghton and Ackroyd (153) reported three displaced avulsion fractures sustained in this way. Two patients were jumping, and the third was propelling a skateboard. Each injury was witnessed by a parent or teacher, and in none was there direct trauma to the knee.

Preexisting abnormalities in the extensor mechanism may predispose to avulsion fractures (Fig. 23-39). Blount (8) reported a displaced transverse fracture of the patella in a 6-year-old boy who had sustained a previous laceration of the quadriceps mechanism that resulted in limited knee flexion. The acute patellar fracture was produced by sudden forceful flexion against the scarred quadriceps. Rosenthal and Levine (134) found fragmentation of the distal pole of the patella in seven patients with spastic cerebral palsy involving the lower extremities. They believed that the fragmentation represented stress fractures caused by excessive tension in the muscle associated with a flexed-knee gait. Three of the fragmented patellae healed after hamstring lengthening. Kaye and Freiberger (154) found either elongation or fragmentation of the patella in nearly a third of patients with cerebral palsy and fragmentation of the patella in a patient with arthrogryposis.

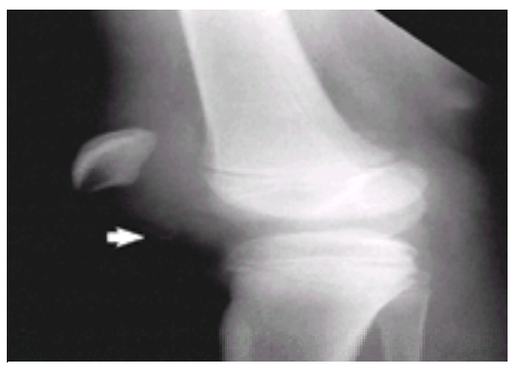

FIGURE 23-39. A 15-year-old male renal transplant recipient felt a “pop” in the knee after a fall down stairs. Lateral radiograph demonstrates avulsion of the patellar tendon from the interior pole of the patella with proximal migration of the patella and quadriceps muscle.

Classification

Fractures of the patella usually are classified according to location, pattern, and displacement of the fracture. To the anatomic classification should be added the sleeve fracture, which occurs in younger children (Fig. 23-40). A sleeve fracture is an avulsion of a small bony fragment from the distal pole of the patella, together with a sleeve of articular cartilage, periosteum, and retinaculum pulled off the remaining main body of the patella. The extent of injury is not appreciated on initial radiographs. If allowed to heal without reduction and fixation, this gap may fill in completely or partially with bone and fibrous tissue, with enlargement of the patella. This injury has been reported in children 8 to 12 years of age (153).

FIGURE 23-40. Sleeve fracture of the patella. **A:** A small segment of the distal pole of the patella is avulsed with a relatively large portion of the articular surface. **B:** On lateral view, the small osseous portion of the displaced fragment is visible, but the cartilaginous portion is not seen. **C:** Healed sleeve fracture after open reduction and internal fixation.

Signs and Symptoms

The injured knee is swollen and tender, often with tense hemarthrosis. Full knee extension is difficult, and weight bearing often is impossible. Palpation may reveal a high-riding patella or a palpable defect in the extensor mechanism. If the distal pole is avulsed, voluntary contraction of the quadriceps muscle draws the patella upward, but the patellar ligament remains lax.

With marginal fractures, there may be little more than tenderness and localized swelling over the lateral or medial margin of the patella, and straight-leg raising may be possible (147). An avulsion fragment adjacent to the medial margin of the patella may indicate that an acute lateral dislocation of the patella has occurred. The patella may have reduced spontaneously after the injury. If dislocation has occurred, the apprehension test is positive. The patient either resists passive manipulation by contracting the quadriceps or may even grasp the examiner's hand to prevent further passive displacement.

Radiographic Findings

Transverse fractures are best seen on lateral radiographs. The amount of displacement varies. In a child, the major fragments may tilt away from one another, with the maximal gap anteriorly and minimal gap posteriorly (143). This may signify that the articular cartilage remains intact, even with a complete fracture through the bony

portion of the patella (Fig. 23-41). The extent of displacement may not be fully appreciated unless the knee is flexed to 30 degrees when the radiograph is made.

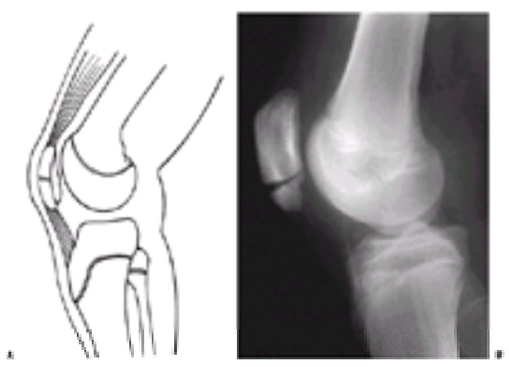

FIGURE 23-41. A: Incomplete transverse fracture of the patella. The articular cartilage of the patella remains intact, but the fracture gaps anteriorly. **B:** Lateral radiograph shows incomplete transverse fracture of the patella.

Longitudinally oriented marginal fractures are best seen on axial or skyline views. It is important to differentiate a medial marginal fracture that traverses the entire thickness of the bone from a medial tangential osteochondral fracture. The latter may be difficult to appreciate on an overpenetrated radiograph. An osteochondral fracture may include a substantial amount of cartilage not visible on plain radiographs. Lateral marginal fractures usually are vertically oriented and include the entire thickness of the patella. If a marginal fracture is old, the edges of the fragment are sclerotic. Lateral tilt, lateral subluxation, and lateral overhang of the patella relative to the femoral condyles also are best evaluated on the axial or skyline view.

Small flecks of bone adjacent to the distal pole may be noteworthy (142). If the fragment is scalelike and closely approximated to the anterior surface of the patella, it may represent an accessory ossification center. A symptomatic, small, visible radiodensity after specific injury or overuse may represent a Sinding-Larsen–Johansson lesion (164). Small and similarly benign-looking ossicles may signify a sleeve fracture if a good history of acute avulsion injury is given and associated clinical signs are present. Fragmentation or elongation of the distal pole associated with patella alta in a child with cerebral palsy indicates long-standing extensor mechanism stress.

A bipartite patella is best seen on the anteroposterior radiograph, which shows a crescent-shaped radiolucent line in the superolateral quadrant of the patella and rounded margins of the accessory ossicle. If symptoms are confusing, comparison radiographs of the opposite knee are helpful. A similar radiographic appearance of the contralateral patella supports the diagnosis of bipartite patella.

Treatment

Closed treatment is recommended for nondisplaced fractures. Aspiration of hemarthrosis relieves pain. A well-molded cylinder cast in extension is applied, and progressive weight bearing is permitted. Immobilization may be continued for 4 to 6 weeks.

Operative Treatment

Operative treatment is reserved for displaced fractures that exhibit 3 mm or more of articular displacement or fractures that disrupt the extensor mechanism. Reduction and internal fixation are preferable to patellectomy. Fixation techniques include a circumferential wire loop, nonabsorbable sutures through longitudinally drilled holes, the AO tension-band technique, or screws or threaded pins. Ogden (53) believes that to avoid growth disturbance, circumferential wiring through adjacent soft tissue around the patella is preferable to wiring through the patella. Blount (8) also advised a circular turn of wire about the patella. Others have pointed out that circular wire fixation may threaten the blood supply to the patella. However, Maguire and Canale reported no growth disturbance after the use of cerclage wires. Weber et al. (83) advised tension-band wiring through a transverse incision, and Rang (62) advised tension-band wiring for displaced transverse fractures in older children. An experimental study by Weber et al. (165) supported fixation by either modified tension-band wiring or by the Magnusson wiring method. The former consists of a wire loop passed beyond the tips of two longitudinal fixation wires and over the anterior surface of the patella (Fig. 23-42). The Magnusson technique consists of a wire loop passed through longitudinal drill holes in the two apposed fragments. All authors agree that meticulous repair of any adjacent retinacular tear is as important as accurate approximation and stable fixation of bony fragments (9,145,151).

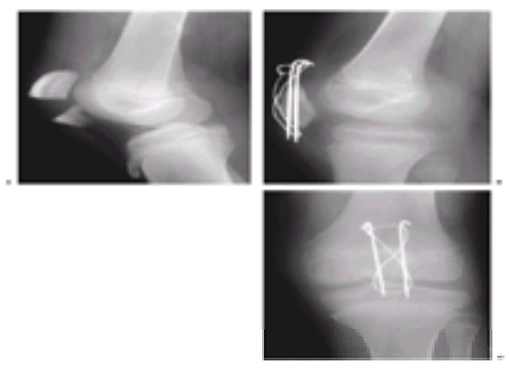

FIGURE 23-42. A: Displaced transverse fracture of the patella; note open distal femoral and proximal tibial physes. **B and C:** After reduction and internal fixation with tension-band technique using figure-of-eight wire over parallel longitudinal pins.

Sleeve fractures require careful approximation of the distal pole to prevent persistent deformity and extensor lag. Houghton and Ackroyd (153) and Wu et al. (166) advised careful reduction of the distal pole with the attached sleeve of cartilage to the main body of the patella. Modified tension-band wiring around two longitudinal Kirschner wires helps centralize fixation in the small fragment. The extensor retinaculum should be repaired.

For medial marginal fractures, Rorabeck and Bobechko (160) advised excising the osteochondral fragment and repairing the extensor apparatus in acute dislocation of the patella. Griswold (151) suggested that marginal fractures of the patella do best with surgery. He advised excision because fibrous union can cause persistent pain. Peterson and Stener (158) described treatment of concurrent avulsions of the medial and lateral margins of the patella in a 12-year-old boy; a good result was obtained with operative repair.

Operative Versus Conservative Treatment

Indications for open treatment of fractures of the patella in children are essentially the same as for fractures of the patella in adults. A diastasis of 3 mm or more on radiographs or a step-off on the articular surface of 3 mm or more is an indication for open reduction and internal fixation. It may be more difficult to estimate the amount of gap or the degree of step-off in a younger child because of the partial ossification of the patella. An inability voluntarily to extend the knee fully indicates an associated tear of the retinaculum that should be repaired. An open fracture requires appropriate debridement and irrigation, as well as internal fixation when indicated.

AUTHOR'S PREFERRED METHOD OF TREATMENT

We advise closed treatment if the fracture is not displaced. A well-molded cylinder or long leg cast is applied to hold the knee in extension. Partial weight bearing is allowed as soon as symptoms permit, usually within the first several days. Straight-leg raising should be possible by 1 week after injury.

For displaced transverse fractures, we perform open reduction with internal fixation using the modified tension-band technique with a wire loop over parallel Kirschner wires. A longitudinal midline incision is preferred to facilitate possible future surgery about the knee. The retinaculum on both the medial and lateral sides is repaired meticulously from outward in toward the margins of the patella.

We advise excising displaced marginal fractures, whether they are on the medial or lateral margin. The exception is a marginal fracture that includes a significant part of the articular surface. This lesion is more properly considered an osteochondral fracture, and a fragment larger than 1 cm should be replaced and fixed by Herbert screws.

Postoperative and Postfracture Care

Immobilization in a cylinder cast is continued for 4 to 6 weeks after either closed treatment or open reduction and internal fixation. Quadriceps-strengthening exercises are begun as soon as possible. The cast may have to be changed as swelling diminishes. After removal of the cast, quadriceps-strengthening exercises are continued and range-of-motion exercises are begun. It is helpful to begin flexion exercises with the patient prone. Return to vigorous activities or athletics is not permitted until muscle mass and range of motion are equal to those in the opposite extremity.

Prognosis

The prognosis is good for nondisplaced fractures in which accurate apposition of fragments, with healing, has been achieved. Comminuted, displaced patellar fractures are uncommon in growing children. Those treated without reduction may heal with elongation of the patella and diminution of function of the extensor mechanism. Comminuted fractures in adolescents approaching skeletal maturity are best treated by patellectomy. Symptoms that persist after marginal fractures usually can be treated by simple excision of the fragment.

Complications

Complications of unreduced displaced fractures include patella alta, extensor lag, and quadriceps atrophy. Houghton and Ackroyd (153) reported these findings at short-term follow-up of a displaced sleeve fracture in a 9-year-old girl treated by aspiration and immobilization alone. The fragments had remained separated and the bone had filled the defect. Two years later, moderate quadriceps atrophy and an extensor lag persisted, along with a subchondral defect in the central area of the articular surface. Failure to restore length after injury precludes return to optimal function (156,157).

PART II: INTRAARTICULAR AND LIGAMENTOUS INJURIES ABOUT THE KNEE

OSTEOCHONDRAL FRACTURES

Osteochondral fractures of the knee usually involve the medial or lateral femoral condyle or the patella. The diagnosis often is difficult because even a large osteochondral fragment may contain only a small ossified portion that is visible on plain radiographs. Differential diagnoses include meniscal injury and osteochondritis dissecans (169,174,176).

Coleman (173) reported five osteochondral fractures of the patella in children and recommended removal of loose bodies, repair of articular defects, and repair of the medial retinaculum to prevent recurrent patellar dislocation. Rosenberg (186) reported 15 osteochondral fractures of the lateral femoral condyle caused by flexion–rotation forces to the knee rather than by direct blows. He concluded that osteochondral fractures of the lateral femoral condyle are caused by direct force from the patella, although not all patients had patellar dislocations. He also recommended removal of the loose osteochondral fragments. Rorabeck and Bobechko (185) reported 18 children with acute patellar dislocations and osteochondral fractures of the patella or lateral femoral condyle. They recommended repair of the medial retinaculum in addition to removal of the osteochondral fragment.

Surgical Anatomy

The patella tracks in the intercondylar notch between the medial and lateral femoral condyles during flexion and extension of the knee (175,178). With increasing knee flexion, the contact area on the articular surface of the patella moves to the proximal patella. Between 90 and 135 degrees of flexion, the patella glides into the intercondylar notch between the femoral condyles. The two primary areas of contact are the medial patellar facet with the medial femoral condyle and the superolateral quadrant of the lateral patellar facet with the lateral femoral condyle. Soft tissue support for the patellofemoral joint includes the quadriceps muscle, the patellar ligament, and the vastus medialis and lateralis muscles.

Dislocation of the patella may tear the medial retinaculum, but the rest of the quadriceps muscle–patellar ligament complex continues to apply significant compression forces as the patella dislocates laterally. These forces are believed to cause fracture of the medial patellar facet, the lateral femoral condyle articular rim, or both (180,184,186) (Fig. 23-43). Osteochondral fractures are uncommon with chronic recurrent subluxation or dislocation of the patella because of laxity of the medial retinaculum and lesser compressive forces on the patella and the lateral femoral condyle. In adults, compressive or rotary forces at the knee are dissipated between calcified and uncalcified cartilage without involvement of the subchondral bone. In adolescents, osteochondral fracture extends into the subchondral bone.

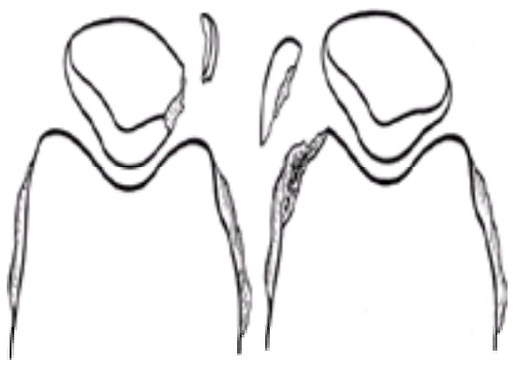

FIGURE 23-43. Osteochondral fractures associated with dislocation of the right patella. **A:** Medial facet. **B:** Lateral femoral condyle.

Mechanism of Injury

Kennedy (180) described the two mechanisms of osteochondral fractures: exogenous, a direct blow and a shearing force to either the medial or lateral condyle, and endogenous, a flexion–rotation injury of the knee in which contact between the tibia and femoral condyle causes the fracture. The endogenous mechanism is also the cause of osteochondral fracture with patellar dislocation secondary to the shearing force of the patella against the lateral femoral condyle (172,182). Ahstrom (168) reported 18 osteochondral fractures; 14 occurred during sports-related activities. Most patients give a history of a twisting injury consistent with acute patellar dislocation, but a few report a direct blow to the lateral or medial femoral condyle, accounting for a shear injury. Nietosvaara et al. (183) reported that of 69 acute

patellar dislocations in children and adolescents, 62 (90%) occurred in falls; 39% also had osteochondral fractures.

Classification

The classification of osteochondral fractures of the knee is based on the site, the type, and the mechanism of injury. The classification outlined in Table 23-11 is based on the descriptions of osteochondral fractures by Kennedy (180) and Smillie (188).

Site	Mechanism
Medial femoral condyle	Direct blow (fall) Compression and rotation (tibiofemoral)
Lateral condyle	Direct blow (kick) Compression and rotation (tibiofemoral) Acute patellar dislocation
Patella (medial margin)	Acute patellar dislocation

TABLE 23-11. MECHANISM OF OSTEOCHONDRAL FRACTURES

Signs and Symptoms

Most children and adolescents with osteochondral fractures of the knee give a history of a flexion–rotation injury consistent with patellar dislocation. Rarely, patients with multiple trauma have an osteochondral fracture from a severe direct blow or open injury of the knee. Severe pain, swelling, and difficulty in weight bearing are immediate after osteochondral fracture.

Physical findings may include knee effusion and tenderness over the medial or lateral femoral condyle or the medial patella. The knee usually is held in 15 to 20 degrees of flexion, and movement in any direction is resisted. Attempts at flexion or extension of the knee and manipulation of the patella elicit pain. Sterile aspiration of the knee using local anesthesia usually obtains a bloody aspirate, occasionally with fat globules suggestive of an intraarticular fracture. Late physical findings are identical to those of a loose body: intermittent locking and catching of the knee joint or a palpable fragment beneath the skin.

Radiographic Findings

Because the osteochondral fragment may be difficult to see on plain radiographs, anteroposterior and lateral views must be carefully assessed for even the smallest ossified fragment (Fig. 23-44). A tunnel view may help locate a fragment in the region of the intercondylar notch. Osteochondral fragments also may be located at the extreme periphery of the joint in the suprapatellar pouch or beneath the MCL or LCL (Fig. 23-45). The tibial tuberosity should not be confused with an osteochondral fragment, as noted by Ogden (184). Occasionally, a large osteochondral fragment with a small ossified portion can be seen more clearly with arthrography, CT arthrography, or MRI.

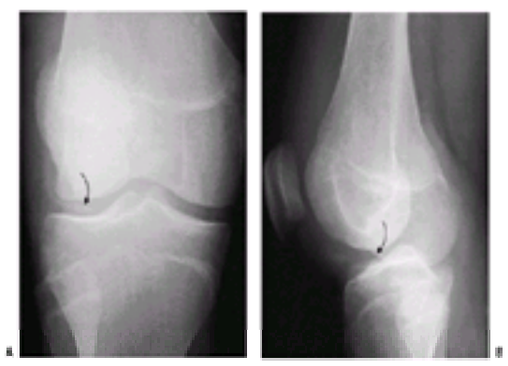

FIGURE 23-44. Osteochondral fracture of lateral femoral condyle after patellar dislocation. **A:** Fragment seen in lateral joint space. **B:** Lateral view.

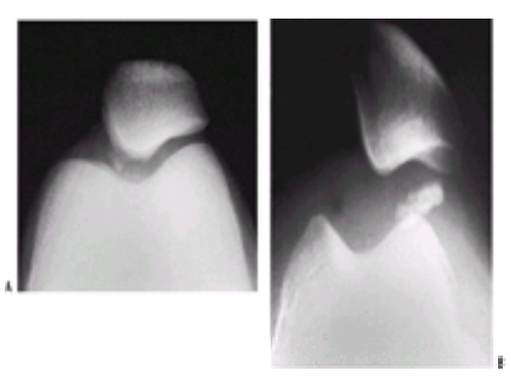

FIGURE 23-45. Osteochondral fractures associated with dislocation of the patella. **A:** Medial facet of patella. **B:** Lateral femoral condyle.

Methods of Treatment

Most authors recommend operative treatment of acute osteochondral fractures of the knee, either excision of the fragment or fixation to its anatomic location. Kennedy (180) and Smillie (188) recommend replacement in acute injuries if the fragment is large, easily accessible, and in a weight-bearing area of the knee. If arthrotomy is delayed for 10 days or more, fixation is contraindicated because the articular surface defect has already begun to fill in with fibrocartilage. Other authors recommend excision of small fragments from the medial or lateral condyle or the patella (167,177,179,187). Excision or fixation of the fragment may be done with arthroscopy or arthrotomy, and fixation devices vary from small, smooth or threaded Steinmann pins to countersunk screws (171,190). Lewis and Foster (181) reported good results in eight osteochondral fractures after fixation with Herbert bone screws. They cite as advantages of this technique:

1. Little cartilage damage is done during insertion.
2. Because the screw is entirely buried, it does not interfere with soft tissues.
3. Fixation is rigid enough to allow the use of continuous passive motion.
4. Reoperation for screw removal is unnecessary.

AUTHOR'S PREFERRED METHOD OF TREATMENT

Treatment of the osteochondral fragment depends on five factors: size, site, stability, surface, and subchondral status of the lesion (189,191). If the fragment is from a non–weight-bearing area, arthroscopic excision is recommended with debridement of the fragment's crater to stable edges and perforation of the underlying subchondral bone to encourage cell ingrowth. With unstable or loose lesions larger than 3 mm in weight-bearing contact areas, fragment salvage is attempted if the fragment can be reduced, its articular surface is pristine and not crenellated, and its subchondral segment is adequate for fixation, usually 3 mm in depth. Bioabsorbable fixation devices can be used but carry a risk of sterile synovitis with recurrent effusions. Most osteochondral fractures associated with patellar dislocation, either from the patella or lateral femoral condyle, can be removed arthroscopically. Rarely, after a severe direct blow, a large osteochondral fracture of the femoral condyle requires open reduction and internal fixation.

Operative Treatment

The first step in treatment is to obtain adequate radiographic studies to assess the size and origin of the fragment accurately. If the fragment is small (<2 cm) and from a non–weight-bearing area, we prefer arthroscopy for inspection of the joint and removal of the fragment. Arthroscopic examination also may be done if imaging studies do not clearly reveal the size and origin of the fragment. If the fragment is larger than 2 cm and from a weight-bearing surface, either medial or lateral arthrotomy may be necessary, as indicated by the location of the fragment, to return the fragment to its bed and fix it with small, threaded Steinmann pins placed in a retrograde or transverse direction through the femoral condyle into the subcutaneous tissue medially or laterally. The pins should not be left protruding into the joint, but should be buried beneath the articular cartilage and cut off in the subcutaneous tissue for easy removal after fracture healing. For very large fragments, especially in adolescents nearing skeletal maturity, we use countersunk minifragment screws or Herbert screws. These screws may require later removal even if buried beneath articular cartilage. Regardless of the fixation device chosen, care should be taken to avoid penetration of the distal femoral physis, especially in younger children.

Postoperative Care

After fixation of a large osteochondral fragment with pins or screws, a long leg, bent-knee cast is applied with the knee flexed to 30 degrees. Non–weight-bearing ambulation is allowed on crutches, and quadriceps muscle-strengthening exercises are begun. The cast is removed at 6 weeks after surgery, quadriceps exercises are continued, and weight bearing gradually progresses. Full weight bearing is allowed after swelling has subsided and radiographs show healing of the fracture fragment. Return to athletic activities is permitted when knee range of motion has recovered and quadriceps strength is equal to that of the uninvolved extremity.

After arthroscopic excision of a small fragment, a knee immobilizer splint is fitted, quadriceps-strengthening exercises are begun, and weight bearing is allowed as tolerated. The immobilizer is discontinued 2 weeks after arthroscopy.

Prognosis

Osteochondral fractures with small fragments not involving the weight-bearing portion of the joint usually have a good prognosis. The prognosis is more uncertain, however, if the fracture fragment involves a large portion of the weight-bearing surface. When acute patellar dislocation requires arthrotomy for fixation or removal of a large osteochondral fragment, Rorabeck and Bobechko (185) and Bassett (170) recommend operative repair of the medial retinaculum. Ahstrom (168) noted poor results after osteochondral fracture associated with recurrent patellar dislocation, but believed these were related more to the chronic dislocation or subluxation than to the articular injury. Even after surgical fixation, large osteochondral fractures with incongruous articular surfaces may cause loss of motion and late osteoarthritic changes (Fig. 23-46).

FIGURE 23-46. Comminuted osteochondral fracture of the patella after acute lateral dislocation of the patella at the time of a karate kick. (Courtesy of John Roberts, MD, Bangor, Maine.)

Complications

Complications of surgical treatment, especially with large fragments, include adhesions in the suprapatellar pouch, quadriceps insufficiency, and malalignment of the quadriceps–patellar ligament complex. Threaded Steinmann pins or countersunk screws that protrude into the joint may cause synovitis and loss of knee joint motion.

FRACTURE OF THE TIBIAL SPINE (INTERCONDYLAR EMINENCE)

Avulsion fracture of the tibial spine is a relatively rare injury in children: Skak et al. (219) reported that it occurred in 3 per 100,000 children each year. The most common causes of these fractures are bicycle accidents and athletic activities (210,211). A stable, painless knee can be obtained in many patients with closed treatment (190), but displaced fractures irreducible by closed means require open reduction.

Garcia and Neer (199) reported 42 fractures of the tibial spine in patients ranging in age from 7 to 60 years, 6 of whom had positive anterior drawer signs indicating associated collateral ligament injuries. They reported successful closed management in half their patients. Meyers and McKeever (209), however, recommended arthrotomy and open reduction for all displaced fractures, followed by cast immobilization with the knee in 20 degrees of flexion rather than hyperextension, believing that hyperextension aggravated the injury in one of their patients. Gronkvist et al. (201) reported late instability in 16 of 32 children with tibial spine fractures, and recommended surgery for all displaced tibial spine fractures, especially in children older than 10 years because “the older the patient the more the demand on the anterior cruciate ligament–tibial spine complex.” Because of elongation of the anterior cruciate ligament (ACL), which contributes to instability, they recommended countersinking the tibial spine–proximal tibial epiphyseal fragment during open reduction. Baxter and Wiley (193) noted mild to moderate knee laxity at follow-up in 45 patients, even after anatomic reduction of the tibial spine.

McLennan (208) reported 10 patients with type III intercondylar eminence fractures treated with closed reduction and with arthroscopic reduction with or without internal fixation. At second-look arthroscopy 6 years after the initial injury, those treated with closed reduction had more knee laxity than those treated arthroscopically. In a long-term (average 16 years) follow-up study of 61 children with anterior tibial spine fractures, Janarv et al. (203) found pathologic knee laxity from 3 to 9 mm in 18 (38%) of the 47 patients clinically tested.

Falstie-Jensen and Søndergard-Petersen (197) reported four patients with moderate or complete displacement of the fracture and incarceration of the medial meniscus beneath the tibial spine. They recommended arthroscopic release of the incarcerated meniscus and open reduction and fixation of the tibial spine fracture if necessary (206,207). Hayes and Masear (202) reported one patient with an anterior tibial spine fracture associated with injury of the MCL. For patients with a positive anterior drawer sign or other evidence of ligamentous instability, they recommended stress radiographs and, if necessary, examination under anesthesia, followed by repair of any injury to the ACL or collateral ligament. Robinson and Driscoll (217) reported one patient with avulsions of the femoral and tibial insertions of the ACL

and associated MCL injury.

The posterior intercondylar eminence is even more rarely injured in children than the anterior eminence (222) (Fig. 23-47). Roberts and Lovell (216) found the anterior tibial spine to be injured 10 times more frequently than the posterior tibial spine. Goodrich and Ballard (200) and Ross and Chesterman (218) reported isolated avulsion of the posterior tibial spine at the insertion of the PCL.

Christian, MD, Memphis, Tennessee.)

Surgical Anatomy

The ACL attaches distally to the anterior tibial spine and the anterior horn of the medial meniscus, with separate slips anterior and lateral as well. The ligament rests against the lateral roof of the intercondylar notch of the femur. The intercondylar eminence is that part of the proximal surface of the tibia lying between the anterior poles of the menisci forward to the anterior tibial spine. It is triangular, with its base at the anterior border of the proximal tibia. In the immature skeleton, the proximal surface of the eminence is covered entirely with cartilage. Matz et al. (266) found the medial meniscus to be trapped under the fragment in 8 of 10 type III lesions.

In a cadaver study by Roberts and Lovell (215,216), fracture of the anterior intercondylar eminence was simulated by oblique osteotomy beneath the eminence and traction on the ACL. In each specimen, the displaced fragment could be reduced into its bed by extension of the knee. In adults, the same stress might cause an isolated tear of the ACL, but in children the incompletely ossified tibial spine is weaker to tensile stress than the ligament, so failure occurs through the cancellous bone beneath the subchondral bone of the tibial spine.

Mechanism of Injury

A fall from a bicycle was the most common mechanism of injury in the series of Meyers and McKeever (210) and Roberts and Lovell (216), but anterior tibial spine fractures also have been reported in children participating in athletic activities or with multiple trauma (213,214). The injury probably occurs as the tibia is rotated relative to the femur and forced into hyperextension.

Classification

Meyers and McKeever (210) proposed a classification of tibial spine fractures based on the degree of displacement (Fig. 23-48):

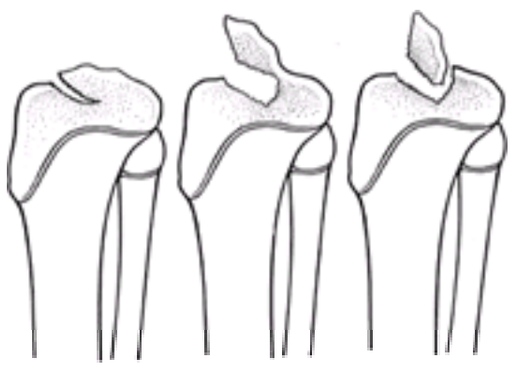

FIGURE 23-48. Classification of tibial spine fractures. **A:** Type I—minimal displacement. **B:** Type II—hinged posteriorly. **C:** Type III—complete separation. (Modified from Meyers MH, McKeever FM. Fracture of the intercondylar eminence of the tibia. *J Bone Joint Surg Am* 1959;41:209–222; with permission.)

1. Type I—minimal displacement of the fragment from the rest of the proximal tibial epiphysis
2. Type II—displacement of the anterior third to half of the avulsed fragment, which is lifted upward but remains hinged on its posterior border in contact with the proximal tibial epiphysis
3. Type III—complete separation of the avulsed fragment from the proximal tibial epiphysis, with upward displacement and rotation

Signs and Symptoms

Physical findings in acute injury include pain, effusion from associated hemarthrosis, and reluctance to bear weight. Extremes of motion are resisted because of increasing pain. Gentle stress testing should be performed to detect any tear of the MCL or LCL or physeal fracture of the distal femur or proximal tibia. Patients with late malunion of a displaced tibial spine fracture may lack full extension because of a mechanical bony block.

Radiographic Findings

Adequate anteroposterior and lateral radiographs are essential to evaluate the degree of displacement of the anterior tibial spine, although the fracture is best seen on the lateral view. Both views should be carefully scrutinized: the avulsed fragment may be mostly nonossified cartilage with only a small, thin ossified portion visible on the lateral view. Obtaining the anteroposterior radiograph more parallel to the normal posterior tilt of the proximal tibial articular surface may better reveal the fragment (Fig. 23-49).

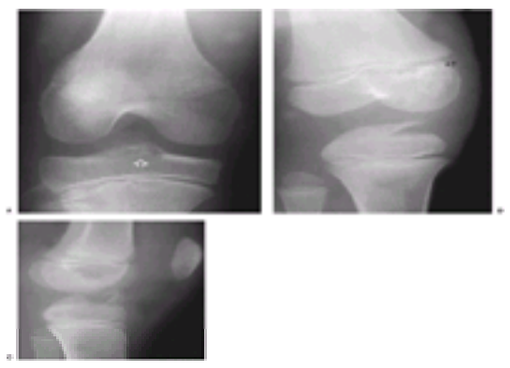

FIGURE 23-49. Stages of displacement of tibial spine fractures. **A:** Type I fracture, minimal displacement *(open arrow).* **B:** Type II fracture, posterior hinge intact. **C:** Type III fracture, complete displacement and proximal migration.

If the fragment appears narrow and confined to the central portion of the intercondylar eminence, closed reduction may be successful. If the fragment is wider and extends medially or laterally beneath the articular surface of the tibial epiphysis, the anterior horn of a meniscus may be interposed beneath the fracture fragment.

Stress views should be obtained if collateral ligament injury or physeal fracture is suggested by physical examination. These can be done with the patient sedated or, if necessary, under general anesthesia. Abnormal widening of the joint space confirms an associated tear of the collateral ligament or may indicate occult fracture of the distal femoral or proximal tibial physis.

A malunited displaced fragment appears on the lateral view as a large intraarticular extension into the intercondylar notch. A lateral view taken with the knee in hyperextension may reveal impingement of the proximal portion of the malunited fragment on the articular surface of the distal femur.

Methods of Treatment

For nondisplaced or minimally displaced (types I and II) fractures of the anterior tibial spine, most investigators recommend closed treatment. The position of immobilization, however, is controversial; some recommend hyperextension, others 10 to 20 degrees of flexion. For type III displaced fractures, most authorities recommend open reduction and internal fixation (194,209,222,223,226). Bakalim and Wilpulla (192) reported successful closed reduction in 10 patients, none of whom had evidence of laxity of the ACL at follow-up, although some complained of anteroposterior instability. Smillie (186) suggested that closed reduction by hyperextension can be accomplished only with a large fragment. Meyers and McKeever (209) recommended cast immobilization with the knee in 20 degrees of flexion for all type I and II fractures and open reduction or arthroscopic treatment of all type III fractures.

AUTHOR'S PREFERRED METHOD OF TREATMENT

We prefer closed treatment of most type I and II fractures. If hemarthrosis causes severe pain, aspiration can be done under sterile conditions, after which the child is placed in a long leg cast with the knee in a position of neutral to 10 degrees of flexion (Fig. 23-50). Anteroposterior and lateral radiographs are obtained to confirm satisfactory reduction of the tibial spine fragments and are repeated in 1 to 2 weeks to ensure that the fragment has not become displaced. The cast is removed in 6 weeks and physical therapy is continued to strengthen the quadriceps and hamstring muscles and to increase range of motion.

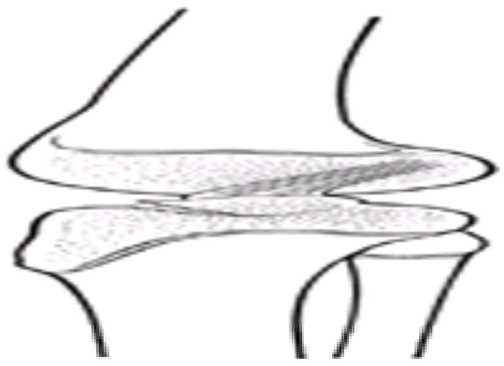

FIGURE 23-50. Reduction of type II tibial fracture with knee in 10 to 20 degrees of flexion.

Operative Treatment

Although closed reduction of type III fractures can be attempted by placing the knee in neutral to slight flexion, we usually have not found this successful. We prefer open reduction through an anteromedial arthrotomy or arthroscopic treatment. This approach allows inspection of the anterior horns of both menisci and distraction of the meniscus if its interposition beneath the anterior tibial spine fragment prevents anatomic reduction. The fragment is reduced with the knee in neutral or 10 to 20 degrees of flexion.

If open surgery is used, numerous fixation techniques are available (206,207 and 208) (Fig. 23-51). In a young child in whom the fragment often is large and mostly cartilaginous, the fragment can be reduced in the tibial epiphyseal crater and secured with peripheral absorbable sutures. In an adolescent with a small fragment, a nonabsorbable suture can be woven through the ACL and out the distal end of the tibial spine fragment. From an anteromedial starting point on the tibial metaphysis, drill holes are placed obliquely into the crater in the tibial epiphysis, carefully avoiding the remainder of the tibial physis. The fragment is then reduced in its bed, and sutures are brought out through the drill holes anteromedially and tied securely (Fig. 23-52). In skeletally mature patients, in whom the integrity of the tibial physis is not a concern, the anterior tibial spine can be fixed with a minifragment screw directed obliquely into the proximal tibial metaphysis (Fig. 23-53).

Open Reduction and Internal Fixation of Fractures of the Tibial Spine

The knee is exposed through the distal portion of an anteromedial parapatellar incision (196). The capsule is opened medially to expose the fracture fragments and the defect in the proximal tibia. After the medial meniscus is examined, retraction is used to allow examination of the anterior horn of the lateral meniscus to ensure the menisci are not impeding the reduction. The knee is placed in extension, and the fragment is reduced after any clots and cancellous bone have been removed from the defect. Two holes are drilled from distal to proximal through the tibial metaphysis and epiphysis, with care taken to drill the holes into the central area of the crater in the tibial epiphysis. A 1-0 nonabsorbable suture is passed through the distalmost portion of the ACL just proximal to the fracture fragment. With suture carriers, the ends of the suture are passed through the drill holes and tied on themselves after the reduction is satisfactory. The knee is flexed and extended to ensure the reduction is stable. The wound is irrigated and closed.

After reduction and fixation, a long leg cast is applied with the knee in neutral or slight (10 to 20 degrees) flexion. The cast is removed 6 weeks after surgery, and strengthening exercises of the quadriceps and hamstrings and active range-of-motion exercises are begun. Weight bearing progresses from touch-down to full weight bearing.

Arthroscopic Technique

After removal of any obstructions to reduction, the fracture is reduced by probe manipulation. Reduction is maintained by use of an ACL reconstruction guide. For fixation of noncomminuted fragments larger than 1 cm, a 20-mm cannulated screw is inserted through a proximal medial parapatellar portal (194,223). The screw should be placed so the proximal tibial physis is not violated. The screw head should be within the ACL substance to prevent impingement in extension. Countersinking the screw in an attempt to restore isometry is counterproductive because the ligament already is attenuated from the initial injury.

Prognosis and Complications

Prognosis of tibial spine injuries in children is good, with most patients regaining an excellent range of motion. Wiley and Baxter (224) found a measurable loss of extension in 45 patients with tibial spine fractures, 60% of whom had losses of more than 10 degrees; no patient, however, complained of any subjective feelings of knee instability. Willis et al. (225) found clinical signs of anterior instability in 64% of 50 patients at an average follow-up of 4 years and objective evidence of laxity in 74%, but again no patient complained of instability.

Poor results may occur after type III fractures of the tibial spine associated with unrecognized injuries of the collateral ligaments or complications from associated physeal fracture (211,220,221). Malunion of type III fractures may cause mechanical impingement of the knee during full extension (206,207 and 208) (Fig. 23-54). For symptomatic adolescents, this can be corrected by excision of the malunited fragment and anatomic reinsertion of the ACL. Lombardo (205) reported avulsion of a fibrous union of the tibial spine 3 years after original injury.

FIGURE 23-54. Lateral radiograph of a malunited displaced fracture of the intercondylar eminence of the tibia with an extension block.

Mylle et al. (212) reported anterior epiphysiodesis with hyperextension of the knee 2 years after transepiphyseal screw fixation of an ACL avulsion in an 11-year-old girl. They recommended early removal of transepiphyseal metalwork or the use of arthroscopically inserted intraepiphyseal fixation to avoid this complication. This technique probably should be reserved for skeletally mature patients or the screw should be angled to avoid the physis. Mah et al. (206,207) found that both of their

surgically treated type III patients had negative Lachman, anterior drawer, and pivot-shift tests at follow-up, with a mean anterior translation of 2.5 mm measured arthrometrically. They suggested that the anatomic reconstruction prevented laxity, findings not shown by other reports that acknowledged that the laxity after injury or surgery was due to the interstitial elongation of the ACL accompanying the avulsion fracture.

LIGAMENT INJURIES

The increasing number of reports of acute disruption of the knee ligaments in children and adolescents (218,229,234,241,242,257,262,263,266,268,277,278,280) refutes the long-held belief that complete disruption of knee ligaments can occur only after the physes have stopped growing (188). This increased frequency of knee ligament injuries in children probably is related to the more frequent participation of children in vigorous sports, the increasing incidence of multiple trauma, and a heightened awareness among physicians concerning the frequent association of ligamentous injury with fractures about the knee.

Fractures of the epiphyses or physes about the knee are more common than ligamentous injuries alone. Isolated knee ligament injury is rare in children younger than 14 years of age because the ligaments are stronger than the physes (237,243,261,267,288). The inherent ligamentous laxity in children also may offer some protection against ligament injury, but this decreases as the adolescent approaches skeletal maturity. Bertin and Goble (232), after reviewing 29 fractures, concluded that physeal fractures about the knee are associated with a higher incidence of ligamentous injury.

Before the 1990s, reports of ligamentous injuries in children were isolated case reports, and most recommendations were for conservative treatment. More recent reports have indicated an increased awareness of ligament injury in association with physeal fractures (238), as well as isolated ligament injuries, and a more aggressive approach, especially in adolescents approaching skeletal maturity (231,242,244,246,272,279,287).

Stanitski et al. (285) reported 70 children and adolescents with acute traumatic knee hemarthroses; arthroscopic examination revealed ACL injuries in 47% of those 7 to 12 years of age and in 65% of those 13 to 18 years of age. They determined that boys 16 to 18 years of age engaged in organized sports and girls 13 to 15 years of age engaged in unorganized sports had the highest risk for complete ACL tears; 60% of these patients had isolated ACL tears.

Surgical Anatomy

The MCL and LCL of the knee originate from the distal femoral epiphysis and insert into the proximal tibial and fibular epiphyses, except for the superficial portion of the MCL, which inserts into the proximal tibial metaphysis distal to the physis (Fig. 23-55). In children, these ligaments are stronger than the physes, and significant tensile stresses usually produce epiphyseal or physeal fractures rather than ligamentous injury. The ACL originates from the posterolateral intercondylar notch and inserts into the tibia slightly anterior to the intercondylar eminence. The PCL originates from the posteromedial aspect of the intercondylar notch and attaches on the posterior aspect of the proximal tibial epiphysis. The ACL in children has collagen fibers continuous with the perichondrium of the tibial epiphyseal cartilage; in adults, the ligament inserts directly into the proximal tibia by way of Sharpey's fibers. This anatomic difference probably accounts for the fact that fracture of the anterior tibial spine occurs more frequently in children than does ACL injury.

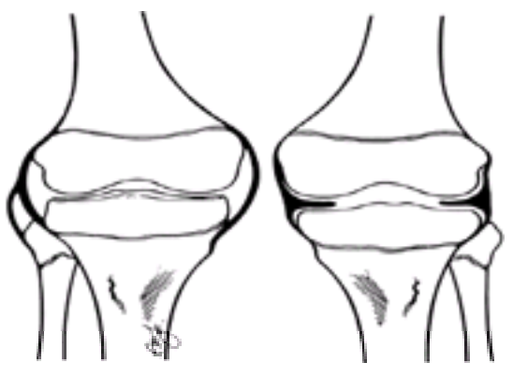

FIGURE 23-55. Anatomy of medial and collateral ligaments of the knee in the adolescent. **A:** Superficial origins and insertions. **B:** Capsular and meniscal attachments.

Mechanism of Injury

The mechanism of ligamentous injury varies with the child's age. In younger children, ligamentous injury typically is associated with significant polytrauma. Clanton et al. (237) reported that five of nine children with acute knee ligament injuries were struck by automobiles. In contrast, adolescents are more likely to sustain ligamentous injury during contact sports or sports that require “cutting” maneuvers while running (219,268). As exact a description as possible of the mechanism of injury should be obtained, including the position of the knee at the time of injury, the weight-supporting status of the injured knee, whether the force applied was direct or indirect (generated by the patient's own momentum), and the position of the extremity after injury. Older adolescents may describe the knee as buckling or “jumping out of place” and can usually relate the location and severity of their pain as well as the time between injury and onset of pain and swelling. Rapid intraarticular effusion within 2 hours of injury suggests hemarthrosis, usually from injury to the ACL.

Palmer (274) described four mechanisms capable of producing disruption of the ligamentous structures about the knee: abduction, flexion, and internal rotation of the femur on the tibia; adduction, flexion, and external rotation of the femur on the tibia; hyperextension; and anterior–posterior displacement. The most common mechanism in adolescents is abduction, flexion, and internal rotation of the femur on the tibia occurring during athletic competition when the weight-bearing extremity is struck from the lateral side. The classic abduction, flexion, and internal rotation injury in the adolescent may cause the “unhappy triad” of O'Donoghue: tears of the MCL and ACL and injury to the medial meniscus.

Isolated injury of the LCL is rare in children, but a direct blow to the medial aspect of the knee may tear the LCL, usually with avulsion from the fibula or a physeal injury through the distal femur (258). Isolated injuries of the ACL and PCL have been reported (256,267,278). Disruption of the ACL with minimal injury to other supporting structures may be caused by hyperextension, marked internal rotation of the tibia on the femur, and pure deceleration. In contrast, isolated injury of the PCL most often is caused by a direct blow to the front of the tibia with the knee in flexion.

Classification

Classification of knee ligament injuries is based on three considerations: the severity of the injury, the specific anatomic location of the injury, and the direction of the subsequent instability caused by an isolated ligament injury or combination of ligament injuries.

A first-degree ligament sprain is a tear of a minimal number of fibers of the ligament with localized tenderness but no instability. A second-degree sprain is disruption of more ligamentous fibers, causing loss of function and more joint reaction but no significant instability. A third-degree sprain is complete disruption of the ligament, resulting in instability. Although difficult to assess clinically, the degree of sprain also is determined during stress testing by the amount of separation of the joint surfaces: first-degree sprain, 5 mm or less; second-degree sprain, 5 to 10 mm; and third-degree sprain, more than 10 mm.

The anatomic classification of ligament injuries describes the exact location of the disruption (250):

A. MCL insufficiency (Fig. 23-56)

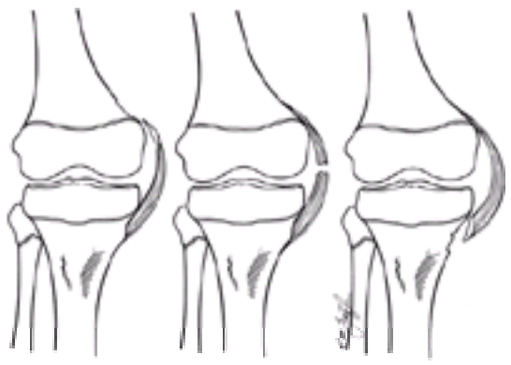

FIGURE 23-56. Medial collateral ligament injury. **A:** Femoral origin. **B:** Middle portion. **C:** Tibial insertion.

1. Superficial
    a. Femoral origin
    b. Middle portion
    c. Tibial insertion
2. Deep
    a. Meniscofemoral
    b. Middle portion
    c. Meniscotibial

B. ACL insufficiency
    1. Femoral origin
    2. Interstitial
    3. Tibial insertion
        a. Without avulsion of the intercondylar eminence
        b. With avulsion of the intercondylar eminence

C. LCL insufficiency (Fig. 23-57)

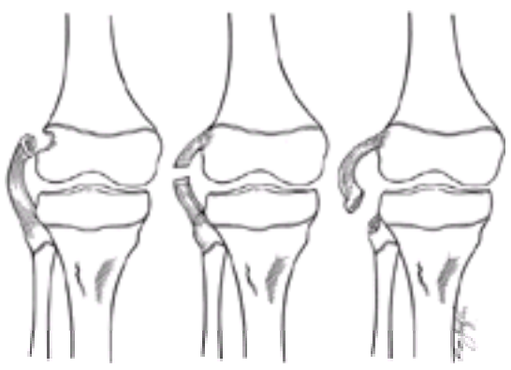

FIGURE 23-57. Lateral collateral ligament injury. **A:** Femoral origin. **B:** Middle portion. **C:** Fibular insertion.

    1. Femoral origin
    2. Middle portion
    3. Fibular insertion

D. PCL insufficiency
    1. Femoral origin
    2. Interstitial
    3. Tibial insertion
        a. Without avulsion of the intercondylar eminence
        b. With avulsion of the intercondylar eminence

Finally, the instability of the knee joint caused by the ligament disruption is classified as follows (255,281):

A. One-plane instability (simple or straight)
    1. One-plane medial
    2. One-plane lateral
    3. One-plane posterior
    4. One-plane anterior

B. Rotary instability
    1. Anteromedial
    2. Anterolateral
        a. In flexion
        b. Approaching extension
    3. Posterolateral
    4. Posteromedial
    5. Combined instability
        1. Anterolateral–posterolateral
        2. Anterolateral–anteromedial
        3. Anteromedial–posteromedial

Using this classification, one-plane medial instability, for example, means that the tibia moves abnormally away from the femur on the medial side. In anteromedial rotary instability, the tibia rotates anteriorly and externally and moves away from the femur on the medial side. The classification becomes more complex as more significant ligamentous injuries involving more anatomic locations are included, but determining the type of instability resulting from the injury is helpful in planning treatment.

Signs and Symptoms

Both lower extremities are examined for comparison. Large areas of ecchymosis and extensive effusion are easily identified, but smaller areas may require careful palpation. In general, acute hemarthrosis suggests rupture of a cruciate ligament, an osteochondral fracture, a peripheral tear in the vascular portion of a meniscus, or a tear in the deep portion of the joint capsule (239,240,245). The absence of hemarthrosis is not, however, an indication of a less severe ligament injury, because with complete disruption the blood in the knee joint may escape into the soft tissues rather than distend the joint. The range of motion of the injured knee, especially extension, is compared with that of the uninjured knee. If significant effusion prevents full extension, sterile aspiration can be performed. If complete knee extension is impossible after aspiration, the diagnosis of an entrapped meniscus should be considered.

Palpation of the collateral ligaments and their bony origins and insertions should locate tenderness at the site of the ligament injury. A defect in the ollateral ligaments often can be felt if the MCL is avulsed from its insertion on the tibia or if the LCL is avulsed from the fibular head. If the neurovascular status is normal, stability should

be evaluated by stress testing.

Stress testing for ligament injury in children (248,249), with or without concomitant fracture, is very subjective, and its usefulness depends on the knowledge and experience of the examiner. Stress testing may be done immediately after injury in cooperative adolescents who do not have other significant injuries, but sedation or general anesthesia may be required for accurate diagnosis. In nonemergent situations, beginning the examination by testing the uninjured knee often calms patients and makes them more cooperative; it also establishes a baseline for assessing the ligamentous stability of the injured knee. In the standard stress tests of specific collateral and cruciate ligaments of the knee described in the following sections, the uninjured knee should be examined first.

Valgus Stress Test of Medial Collateral Ligament

The valgus or abduction stress test is done with the child supine on the examining table and the knee to be examined on the side of the table closest to the examiner. The extremity is abducted off the side of the table and the knee is flexed approximately 20 degrees (Fig. 23-58). With one hand about the lateral aspect of the knee and the other supporting the ankle, the examiner applies gentle abduction or valgus stress to the knee while the hand at the ankle gently externally rotates the leg. Stability of the knee is noted at 20 degrees of flexion and again at neutral.

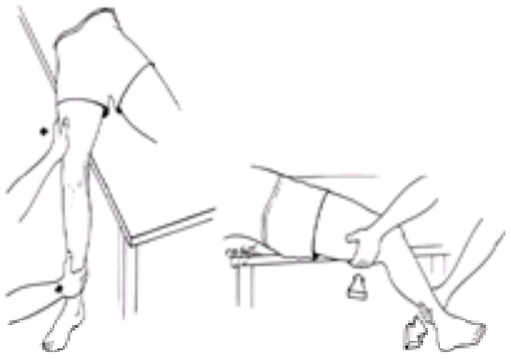

FIGURE 23-58. Valgus stress test of medial collateral ligament. Extremity is abducted off table, knee is flexed to 20 degrees, and valgus stress is applied. **A:** Frontal view. **B:** Lateral view.

Varus or Adduction Stress Test of Lateral Collateral Ligament

The varus or adduction stress test is done in a manner similar to the valgus stress test. It should be done with the knee in full extension and in 20 degrees of flexion. The LCL may be palpable as a taut structure on the lateral aspect of the knee.

The stability of the collateral ligaments may be different when tested in extension and in flexion. If a collateral ligament is torn but the cruciate ligaments and posterior capsule are intact, little instability can be detected with the knee extended. Flexion of the knee relaxes the capsule and more instability is evident with the same degree of ligamentous injury. Significant instability with varus or valgus stress testing with the knee in full extension usually indicates a cruciate as well as a collateral ligament disruption.

Stress Testing of Anterior Cruciate Ligament

The anterior drawer test, as described by Slocum, is the classic maneuver for testing the stability of the ACL (Fig. 23-59). The Lachman and pivot-shift tests, however, are considered more sensitive for evaluating ACL injury when the examination can be done in a relaxed, cooperative adolescent (Fig. 23-60). To perform the Lachman test, the examiner firmly stabilizes the femur with one hand while using the other hand to grip the proximal tibia, with the thumb placed on the anteromedial joint margin. An anteriorly directed lifting force applied by the palm and fingers causes anterior translation of the tibia in relation to the femur that can be palpated by the thumb; a soft or mushy end point indicates a positive test. When the ACL is disrupted, the normal patellar ligament slope is obliterated.

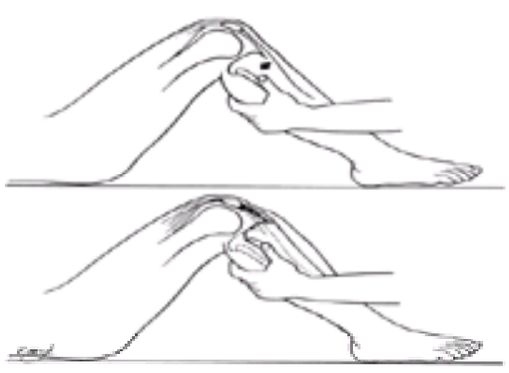

FIGURE 23-59. Anterior drawer test of anterior cruciate ligament. Foot is positioned in internal, external, and neutral rotation during examination. With anterior cruciate insufficiency, an anterior force **(A)** displaces the tibia forward **(B)**.

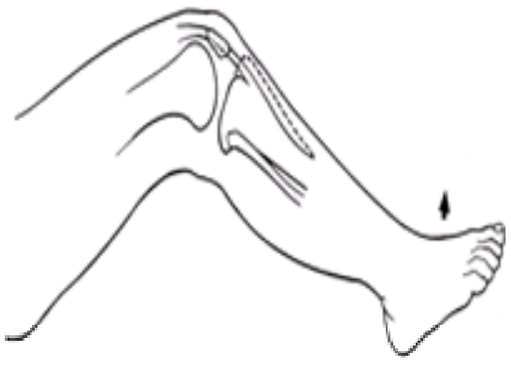

FIGURE 23-60. Lateral pivot-shift test of anterior cruciate ligament.

Stress Testing of Posterior Cruciate Ligament

The posterior drawer test for evaluation of the PCL is done with the patient supine. With the patient's foot secured to the table and the hip flexed 90 degrees, a posterior force is applied to the proximal tibia. Posterior movement of the tibia on the femur greater than in the uninjured extremity indicates posterior instability (Fig. 23-61).

FIGURE 23-61. Posterior cruciate ligament injury. Note posterior sagging of the tibia with posterior cruciate injury.

Active Quadriceps Contraction Test of Posterior Cruciate Ligament

With the patient supine, the relaxed limb is supported with the knee flexed to 90 degrees. It is important to support the thigh adequately so that the child's muscles are completely relaxed. The examiner's other hand stabilizes the foot and the patient gently slides the foot down the table to contract the quadriceps muscle. Tibial displacement resulting from the quadriceps contraction is noted (Fig. 23-62). When the PCL is ruptured, contraction of the quadriceps muscle results in an anterior shift of the tibia.

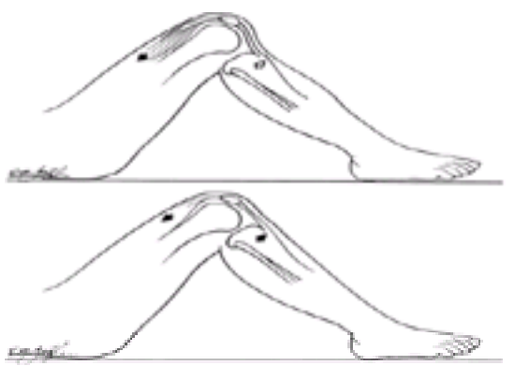

FIGURE 23-62. Active quadriceps contraction test of posterior cruciate ligament. **A:** Patient gently slides foot down the table to contract the quadriceps muscle. **B:** The tibia shifts anteriorly with quadriceps contraction when the posterior cruciate is torn.

Radiographic Findings

Anteroposterior and lateral radiographs are obtained when any ligament injury of the knee is suspected in children. The radiographs are carefully inspected for evidence of occult epiphyseal or physeal fractures or bony avulsions. The intercondylar notch, especially, is inspected to detect a tibial spine fracture, which is confirmed by anterior or posterior instability on physical examination. Occasionally, a small fragment of bone avulsed from the medial femur or proximal tibia indicates injury to the MCL. Similarly, avulsion of a small fragment of bone from the proximal fibular epiphysis or the lateral aspect of the distal femur may indicate LCL injury.

In children with open physes, stress radiographs are especially helpful to evaluate medial and lateral instability associated with physeal fractures (Fig. 23-63). Gentle stress views may be obtained with sedation, but general anesthesia may be required if the diagnosis is unclear. There are no accepted guidelines correlating joint space widening medially or laterally with knee joint instability in children, and stress views of the opposite knee may be required for comparison. If plain radiographs show a fracture of the distal femoral or proximal tibial physis, stress views may be obtained only to evaluate suspected ligamentous instability. Conversely, if the initial radiographs appear normal but there is significant effusion about the knee, stress views should be obtained to rule out a fracture of the physis of the distal femur or proximal tibia.

FIGURE 23-63. Stress radiographs of suspected ligamentous injury. **A:** Valgus stress radiograph of 14-year-old boy with medial collateral ligament injury and tibial spine fracture. **B:** Varus stress radiograph of 10-year-old boy with lateral collateral ligament injury. (**A** courtesy of John Roberts, MD, Bangor, Maine.)

Other radiographic findings include avulsion of the anterior or posterior tibial spine indicative of injury to the ACL or PCL, widening of the joint space, and posterior subluxation of the tibia on the femur. Clanton et al. (237) consider a joint space of 8 mm or wider to be a definitive indication of ligament injury. Sanders et al. (278) reported 1.8 cm of posterior subluxation of the tibia on the anteroposterior stress view in a 6-year-old child with complete PCL disruption. MRI should be used to evaluate ligamentous and meniscal lesions in confusing cases (284).

Methods of Treatment

Clanton et al. (237) and others have noted that the best treatment for knee ligament injuries in children has not been clearly defined. Poor results have been reported after conservative treatment and after primary repair (236,238,270). Most authorities recommend conservative treatment of acute ligament injuries in young children, but give no clear indications for surgery. The numerous reconstructive techniques devised for the ACL are basically either extraarticular (avoiding the physes) or intraarticular (228,254,260,265,286). The intraarticular procedures more accurately replace the ACL with an anatomic or biomechanical substitute that allows the isometric placement of the graft critical to prevent subsequent loosening.

McCarroll et al. (268) compared 16 adolescents with ACL injuries treated conservatively with a similar group of 24 adolescents who had arthroscopic examination and extraarticular or intraarticular reconstruction of the ACL. Of the 16 treated nonoperatively, 6 required later surgery for meniscal injury and only 7 returned to sports activities; all experienced recurring episodes of giving way, effusion, and pain. Of the 24 treated surgically, torn menisci were found arthroscopically in 18 and 22 had

satisfactory results.

Lipscomb and Anderson (263) reported treatment of 24 ACL injuries in adolescents (12 to 15 years of age) with intraarticular augmentation using the semitendinosus or gracilis tendon. They used holes drilled in the appropriate position through the tibial physis and an over-the-top technique for placement of the augmentation over the femoral condyle. One patient had significant growth disturbance. Wester et al. (289) developed graphs to help predict the amount of shortening and angular deformity to expect after ACL repair in skeletally immature patients. According to their calculations, when done within 1 year of maturity, reconstruction should result in a maximum of 5 degrees of valgus angulation and 1 cm of shortening.

DeLee and Curtis (242) and Engebretsen et al. (247) reported moderate to severe instability in adolescents with ACL ruptures after primary suture with intraarticular or extraarticular augmentation. Kannus and Järvinen (262) reported successful closed treatment of grade II (moderate) ligament injuries in adolescents, but unacceptable results in grade III (complete) ligamentous tears; they recommended surgical repair of all grade III ligament injuries in adolescents. Parker et al. (275) reported good results after ligament reconstruction using hamstring tendons in six children with open physes (10 to 14 years of age). They placed a groove over the front of the tibia and another over the top of the femur without violating the physes, although this is not an isometric position of the ACL.

AUTHOR'S PREFERRED METHOD OF TREATMENT

Before determining treatment, we analyze each knee ligament injury, considering the child's skeletal age, the family's athletic expectations for the child, the presence of associated fractures, whether the injury is to an isolated ligament or to multiple ligaments, and whether the resulting instability is single-plane or multiplane.

Medial Collateral Ligament

Isolated grade I or II sprains of the MCL are treated with crutches or a hinged knee brace for 1 to 3 weeks, depending on resolution of symptoms. Return to athletic activities is allowed when a full, painless range of motion is achieved and the patient can run and cut without pain. Isolated complete (grade III) disruption of the MCL can be treated with 6 weeks of immobilization in a hinged knee brace followed by rehabilitation of the quadriceps muscles and knee motion provided this is an isolated injury. The physician must ensure that there is no associated injury to the ACL before using nonoperative treatment for a grade III MCL injury.

Grade III disruptions of the MCL in adolescents often are associated with ACL injury or tibial spine fracture, as well as severe injury to the posteromedial knee capsule. If stress testing demonstrates gross instability, surgical repair is indicated. Midsubstance tears of the MCL and tears of the capsule can be sutured. An MCL avulsed from its distal insertion can be reattached with a staple if it can be placed well distal to the physis; if not, the ligament is repaired to the surrounding soft tissue.

Anterior Cruciate Ligament

A torn ACL does not constitute a surgical emergency, despite the image projected by celebrity athletes and their urgent care. A frank discussion must be held with the parents and the patient concerning future vocation, sport demands, treatment options, outcomes, and risks involved with return to current sport activity. The orthopaedic surgeon must assume the role of a “knee counselor,” particularly with patients with a history of chronic knee abuse. All treatment algorithms are based on an accurate and complete diagnosis, which is achieved by clinical, imaging, and, if necessary, arthroscopic means. The treatment goal is a functional knee without progressive intraarticular damage or predisposition to premature osteoarthrosis.

Nonsurgical treatment does not indicate nontreatment (229,252,271). The goal of this program is defined from the outset: it is a temporizing measure until the patient becomes mature enough for an adult-type ACL reconstruction, or it is the defini-[jytive choice for a patient willing to accept the functional limitations. We use a three-phase approach. Phase one begins shortly after injury and lasts 7 to 10 days. Brief immobilization (3 to 5 days) with a knee immobilizer for comfort is followed by daily out-of-brace exercises with active knee flexion and passive knee extension. Ambulation is with crutch-protected partial weight bearing. During this time, we reinforce patient education on the consequences of imprudent return to high-level sports. Phase two focuses on rehabilitation of the lower extremity and lasts approximately 6 weeks. Emphasis is placed on restoration of full knee motion, flexibility, strength, and endurance with particular attention to regaining the normal quadriceps/hamstring strength ratio. As the ratio is normalized, crutch use is decreased and then eliminated. The role of functional bracing has not been defined in children and issues of fit, size, and cost need to be considered. Phase three continues the rehabilitation, incorporates the use of a functional brace for sports, and allows return to low- and moderate-demand sports when quadriceps and hamstring strength and endurance are equal to those of the opposite, noninjured side as determined by isokinetic testing at functional speeds (>260 degrees/second). In the final part of this phase, sports readiness tasks are done at less than full speed. Monthly follow-up evaluates program compliance and rules out any further knee changes in function. Compliance with a nonoperative program designed to be a temporizing measure often is quite difficult for an emerging athlete who is surrounded by peer, coaching, and, often, parental pressures to return to high-demand sports.

Surgical management of ACL tears in skeletally immature patients is highly controversial. In patients with what we term an *ACL plus knee* (one with combined ACL and meniscal injuries), surgical reconstruction usually is recommended because of the poor prognosis of meniscal repair alone with compromised ACL function (227,229,233,252,264,269,272,275,282,283). However, physeal injury and restoration of ligamentous isometry are concerns in the maturing femur and tibia. The safe percentage of physeal invasion, even in the central portion, that will be tolerated, is unknown. Experimental work in rodents by Garces et al. (251), lapin models by Guzzanti et al. (253) and Janarv et al. (259), and in canines by Stadelmeyer et al. (282) suggests that central femoral physeal invasion by drilling that involves less than 7% to 9% of the total physeal area does not produce significant length or angular deformities in these experimental models. In animal studies that used tendon or fascial autografts, either free or in continuity, to fill the defects created in femoral and proximal tibial physes and epiphyses, Janarv et al. (259) found that thin bone cylinders developed around the tunnels filled with tendon grafts and questioned whether large tunnels would create enough cylinder bone to cause physeal bridges of consequential size, even when centrally placed. Whether the effects seen in these various quadruped models can be translated to the unique demands of human bipedal gait remains unanswered. Also in question are the effects of exposure time after physeal invasion because the animal models had short exposure times in contrast to the 2 to 4 years of growth remaining in adolescent humans, especially boys. An additional concern is the outcome of the grafted tissue that provides the biologic scaffold for neoligament formation in terms of the tissue's size, strength, isometry, and growth. None of the animal series used any type of transphyseal fixation.

No data specifically address the timing of ACL reconstruction in skeletally immature patients after acute injury. We wait 14 to 21 days to allow abatement of the initial inflammatory phase, in keeping with the data that suggest in adults a reduced frequency of fibroarthrotic complications if surgery is delayed. During this time, crutch-protected gait is used and restoration of full passive extension is sought. We also use this time to reemphasize the 6-month time frame expected for recovery before return to sports. Even with contemporary accelerated rehabilitation programs, return to sport is a function of biology and not arthroscopic technology. The rare patient who presents with a locked knee from a concomitant displaced meniscal tear requires more urgent surgery for both injured structures.

Reconstruction of the ACL requires consideration of the three “Ts”: tissues, tunnels, and technique. Autograft tissues include patellar and hamstring tendons, most commonly the semitendinosus alone or with gracilis augmentation. Allograft ACL substitution has been reported in eight children (227). Concerns of potential viral transmission and graft strength alterations secondary to sterilization effects remain (273). Synthetic ACL use as a backup to autograft or allograft causes concerns about longevity, foreign body synovitis from wear particles, and fixation techniques. Direct ACL repair is destined to failure unless a sufficient-sized bone fragment is avulsed to allow direct bone union.

Extraarticular ACL reconstruction using fascia lata slings in a variety of configurations has had limited success in adults, and similar outcomes are predicted in skeletally immature patients who wish to return to high-demand sports. An additional concern is the potential tethering effect on the lateral knee produced by this method with secondary femoral or tibial physeal asymmetric growth.

Tunnels for ACL reconstruction are technique dependent and include grooves in the proximal tibial epiphysis, over-the-top femoral placement, and more vertical proximal tibial physeal and epiphyseal tunnel orientation to provide improved graft isometry. When selecting tunnels, we consider three types: physeal sparing, partial transphyseal, and complete transphyseal (283). Physeal-sparing methods avoid any physeal invasion with intraarticular passage of the graft. Partial transphyseal techniques use a central transphyseal and epiphyseal proximal tibial tunnel with intraarticular passage of a hamstring or patellar tendon graft to an over-the-top femoral position with femoral metaphyseal fixation. Complete transphyseal procedures involve central, isometrically oriented tibial and femoral tunnels and intraarticular graft passage and femoral and tibial epiphyseal or metaphyseal graft fixation sites. Physeal-sparing techniques are used with quite skeletally immature, Tanner stage 0 to 1 patients, usually with an associated meniscal injury that requires treatment (Fig. 23-64). In patients who are somewhat more mature (Tanner

stage 2), partial transphyseal methods are suggested (Fig. 23-65). In patients who are Tanner stage 3 (boys with curly axillary hair and girls who are postmenarchal) and above, complete transphyseal, adult-type reconstructions are done because growth remaining at the distal femur and proximal tibia is limited (Fig. 23-66).

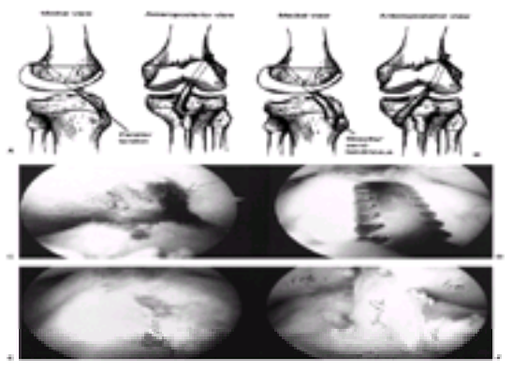

FIGURE 23-64. Physeal-sparing anterior cruciate ligament reconstruction technique **(A and B).** Intraoperative arthroscopic views of tibial tunnel preparation of the epiphysis **(C)** and notchplasty **(D).** Epiphyseal "tunnel" groove under the anterior transverse meniscal ligament **(E)** with semitendinosus graft in place **(F).** (Courtesy of Scott Cameron, MD, Marshfield, Wisconsin.)

FIGURE 23-65. A and B: Schematic views of a partial transphyseal anterior cruciate ligament (ACL) reconstruction with medial hamstring graft. **C, D, and E:** Radiographs of a 16-year-old girl 5 years after partial transphyseal ACL reconstruction done at Tanner stage 2. Note the notchplasty effect. There is no evidence of femoral or tibial deformity.

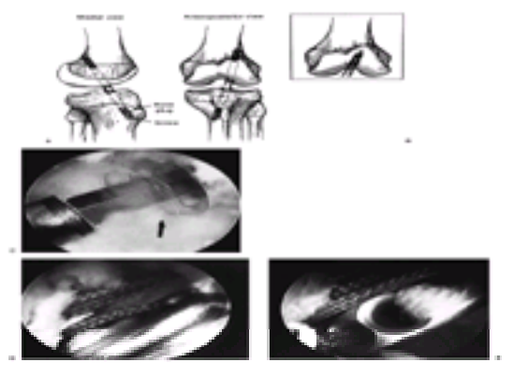

FIGURE 23-66. A and B: Schematic views of one type of complete transphyseal anterior cruciate ligament reconstruction using a patellar tendon–bone construct. *Inset* shows an alternative intraarticular fixation method. **C:** An arthroscopic view of such fixation using a bioabsorbable screw. **D and E:** An alternative fixation technique using a multistranded hamstring graft with "button" femoral fixation.

The major limitation of the physeal-sparing procedure described by Parker et al. (275) is the lack of anatomic isometry of the neoligament. Each of their six patients who were 10 to 14 years of age had an associated meniscal tear that required treatment. At 2-year follow-up, outcomes were favorable. Although not optimal, this technique provides a reasonable option in very young patients with symptomatic functional instability, usually due to noncompliance in a nonoperative program and often associated with a subsequent meniscal tear.

Partial transphyseal techniques use 6- to 8-mm patellar or hamstring autografts in continuity that are passed through 6- to 8-mm tibial proximal tunnels more vertically oriented in an attempt to improve graft isometry. The over- the-top graft is attached to the femoral metaphysis, with care taken to not violate the lateral femoral physis. Lo et al. (264) reported 29 truly skeletally immature patients who had reconstruction of their torn ACL using this method, the largest series to date. All patients had excellent functional outcomes and objective test results at an average follow-up of 3 years. No clinical or radiographic evidence of limb deformity was seen.

Complete transphyseal ACL reconstruction methods are the same as adult techniques and are done in patients who are Tanner stage 3 or higher.

Graft choice depends on the surgeon's preference and may be a multistrand hamstring configuration or a patellar bone–patellar tendon–tibial tubercle construct. Graft fixation may be intraarticular or extraarticular. McCarrol et al. (269) reported good results from such reconstructions in mature adolescents with arthroscopically documented ACL complete tears that commonly were associated with meniscal tears that required repair. Even with the excellent results achieved by this experienced group of knee surgeons, they advocated delaying reconstruction in skeletally immature patients until sufficient maturity is reached to allow a complete transphyseal procedure.

Postoperative rehabilitation is based on physiologic principles that reduce deleterious effects of immobilization, protect the healing tissues, avoid negative misuse effects, and encourage graft maturation by providing physiologically tolerable stresses to it. Advancement to the next rehabilitative phase is predicated on the patient achieving previously determined functional criteria. The program is divided into four phases: phase1, weight bearing and motion restoration; phase 2, muscle strength gains; phase 3, progressive improvement in speed, power, endurance, and agility; and phase 4, sport readiness and return to sport. Phase 1 begins immediately after surgery and continues for 6 weeks. The patient uses crutches for protected weight bearing and is encouraged to progress to full weight bearing without crutch support by 4 to 5 weeks. The postoperative knee immobilizer is replaced with a postoperative brace that limits extension to –30 degrees and flexion to 90 degrees. Active flexion is encouraged and passive full extension out of the brace is done a minimum of four times daily. At the end of this phase, full weight bearing and passive extension are expected, as is knee flexion to 110 degrees. Resistive closed-chain hip flexor, quadriceps, hamstring, and gastrocnemius and anterior tibial and peroneal exercises are done three times daily. If concomitant meniscal repair was done, protected weight bearing and knee flexion limitation to 90 degrees are continued for 8 weeks. Phase 2 encompasses the next 6 weeks, during which time closed-chain resistive exercises are continued with quadriceps strength expected to be two thirds of the opposite normal side by isokinetic testing at 120 degrees per second with the knee protected at –30 degrees of extension. Gait should be normal and passive knee motion full. Phase 3 lasts 6 weeks, with progressive emphasis on restoration of the quadriceps–hamstring strength ratio, which should be 75% to 80% of normal by isokinetic testing. A functional brace is fitted during this time and a running program is instituted. Phase 4 lasts for 6 weeks and involves normalization of lower extremity muscle strength, power, and endurance. Agility drills are advanced and sport-specific readiness tasks are done at progressively higher rates of speed. At the end of this phase, knee range of motion should be full and without pain, there should be no signs of functional instability, and the knee sagittal stability should be within 3 mm of the opposite normal side with normal muscle strength, power, and endurance. Functional brace use is continued for 3 to 6

months after return to sport, usually at the patient's request.

Prognosis and Complications. Limited data exist about postoperative complications after ACL reconstruction in skeletally immature patients, but the same type of complications seen in adults also might be expected in younger patients: loss of motion, donor and insertion site problems, and reflex sympathetic dystrophy. Although limited clinical and experimental data in skeletally immature models suggest that deformity and growth complications are uncommon after ACL reconstruction, these complications are possible, especially when judgmental or surgical technical errors occur.

Authors' Preferred Treatment. In immature patients with isolated ACL tears, we recommend nonoperative management with strong emphasis on patient counseling about the potential for additional intraarticular damage with return to high-demand sports. In patients with a concomitant meniscal injury that requires repair, the so-called “ACL plus” knee, we recommend ACL reconstruction, even in those who are relatively immature, because of the high potential for repeated intraarticular damage leading to premature degenerative arthrosis. Three types of ACL reconstruction are possible: physeal sparing, partial transphyseal, and complete transphyseal. The choice must be tailored to the patient's physiologic and anatomic assets and liabilities.

Grade III Sprains of Both Medial Collateral and Anterior Cruciate Ligaments

The combination of grade III injuries of both the MCL and ACL is, unfortunately, fairly common, especially in older adolescents. In addition to complete disruption of the ACL, the MCL is torn either from its femoral origin, in its midsubstance, or from its tibial insertion. This combination of injuries results in multiplane instability. Treatment is based on the child's age and the specific injuries. In children with more than 2 years of skeletal growth remaining who have an avulsion of the MCL from its femoral origin, we recommend 6 weeks of immobilization in a hinged knee brace, followed by vigorous rehabilitation. If the MCL is torn in its midsubstance or avulsed from its tibial insertion with gross laxity, we recommend surgical repair with sutures in the midsubstance tear or a staple in the proximal tibia distal to the physis with no repair of the ACL, thus converting the multiplane instability to single-plane instability. If anterior or anterolateral instability persists during growth in a very young child, an extraarticular tenodesis can be done to protect the menisci until skeletal maturity. If symptoms warrant, intraarticular reconstruction of the ACL can be done as the adolescent nears skeletal maturity. For an adolescent within 12 to 24 months of skeletal maturity with grade III injuries of the MCL and ACL resulting in multiplane instability, we recommend surgical treatment of both ligaments. Careful repair of the posteromedial knee joint capsule often is required.

Lateral Collateral Ligament

Grade III injuries of the LCL are rare in children. Occasionally, the lateral capsular sign is seen on radiographs obtained for evaluation of knee injury. Most often, the LCL is avulsed from the proximal fibular epiphysis; proximal and midsubstance tears are uncommon. This injury is treated in the same manner as injury to the MCL. For isolated grade III injuries, a 6-week period of immobilization in a hinged knee brace is recommended. If ACL injury is associated with LCL injury, treatment is as described for combined injuries of the MCL and ACL. In young children, the LCL is repaired and the ACL is left untreated. If instability persists as the adolescent nears skeletal maturity, intraarticular reconstruction can be done at that time. In adolescents near skeletal maturity at the time of injury, we prefer to repair both the ACL and LCL.

Posterior Cruciate Ligament

In general, PCL injuries in children are associated with a bony avulsion. If nondisplaced, they should be treated with immobilization; if displaced, they should be treated with open reduction and internal fixation.

Isolated grade III injury of the PCL in children and adolescents can be treated with 6 weeks of immobilization in a cast-brace or hinged knee brace. If significant functional symptoms persist in an adolescent, the PCL can be reconstructed at or near skeletal maturity. In a young child with grade III MCL or LCL injury in addition to PCL injury, the collateral ligament can be surgically repaired to convert the multiplane instability to a single-plane instability. PCL injury may be associated with ACL injury, primarily in knee dislocations, and surgical intervention usually is appropriate for this combination of injuries, especially in patients nearing skeletal maturity (235).

Postoperative Care and Rehabilitation

After cast-brace or hinged brace immobilization, aggressive rehabilitation is recommended, including strengthening of the quadriceps and hamstrings, progressive range-of-motion exercises, and progressive weight bearing. A vigorous physical therapy program is more difficult for younger children, but rehabilitation becomes progressively more important as the child becomes older, and it is critical in adolescents returning to high-demand competitive sports. Bracing is recommended during sports activities for adolescents with previous ACL injury.

Prognosis

Isolated injuries of the collateral ligaments, with or without physeal fractures, have a generally good prognosis. With grade III isolated injuries of the ACL, however, long-term results are extremely variable, depending on the amount of late instability and the demands placed on the knee during athletic activities during adolescence or young adulthood. The worst prognosis is for combined grade III injuries of the cruciate and collateral ligaments that are treated conservatively.

Complications

The three most serious potential complications of knee ligament injury are neurovascular complications, meniscal injuries, and late instability.

Careful assessment of the neurovascular status is mandatory at the initial examination. Any indication of neurovascular injury associated with severe knee ligament injury should prompt immediate investigation, including arteriography of the popliteal artery.

There is a high incidence of meniscal injury associated with ACL disruption, especially in adolescents. Even if surgical reconstruction of an isolated ACL rupture is not planned, arthroscopy may be done to identify any associated meniscal injury and to determine if primary repair or partial meniscectomy is appropriate.

Rarely, children with combined grade III injuries of the collateral and cruciate ligaments that have been treated conservatively acquire late instability. For young children with functional instability, reconstruction of the collateral ligament should be done to convert the multiplane instability to a single-plane instability. Then, as the child nears skeletal maturity, the cruciate ligament can be reconstructed if necessary. In an adolescent approaching skeletal maturity who has multiplane instability, both the cruciate and collateral ligaments should be reconstructed as in adults.

KNEE DISLOCATIONS

Acute dislocations of the knee are uncommon in children because the forces required to produce dislocation are more likely to fracture the distal femoral or proximal tibial epiphysis (300). Acute knee dislocation usually involves major injuries of associated soft tissues and ligaments and often neurovascular injuries.

Adequate follow-up studies of acute knee dislocations in children younger than 10 years of age are few (296), and most information has been obtained from reports of knee dislocations in adults. Kennedy (305), in a classic 1963 study, analyzed 22 dislocations in young adults and recommended early ligament repair if the knee was unstable after reduction. Sisk and King (313) reviewed 62 patients treated for acute knee dislocations and recommended surgical treatment for patients younger than 40 years of age.

Surgical Anatomy

Soft Tissue Anatomy

The pertinent surgical anatomy in acute dislocation of the knee involves the soft tissues and the vascular and ligamentous structures about the knee. Knee dislocation usually occurs with disruption of both cruciate ligaments. With direct anterior or posterior dislocation, the collateral ligaments and the soft tissues may be retained because the femoral condyles are stripped out of their capsular and collateral ligament attachments, and when reduced slip back inside them. Knee dislocations in

adolescents have been associated with tibial spine fractures, osteochondral fractures of the femur or tibia, meniscal injuries, and peroneal nerve injuries (295).

Vascular Injury

The anatomic structure of particular clinical significance is the popliteal artery. The collateral circulation about the knee is relatively poor, and if the popliteal artery is damaged, collateral circulation usually is insufficient to maintain viability of the extremity distal to the knee (295,302). The popliteal artery basically is fixed to the femur at the adductor hiatus and to the tibia by a fibrous arch. During anterior dislocation of the knee, the artery often is stretched enough to cause intimal disruption and possibly subsequent vascular occlusion.

Mechanism of Injury

Most knee dislocations in children occur with multiple trauma, especially in car, bicycle, or motorcycle accidents or pedestrian–vehicle accidents.

Classification

There is no specific classification of knee dislocations in children, but the dislocation may occur anteriorly, posteriorly, medially, or laterally. The most common single-plane dislocation is anterior.

Signs and Symptoms

Because of the potential for associated vascular injury, acute knee dislocations in children may be emergent situations. The dislocation causes obvious deformity about the knee. With anterior dislocation, the tibia is prominent in an abnormal anterior position. With posterior dislocation, the femoral condyles are abnormally prominent anteriorly.

After the dislocation is reduced, the stability of the knee should be evaluated with gentle stress testing. For isolated anterior or posterior dislocations, the integrity of the collateral ligaments should be carefully evaluated.

The neurovascular status of the extremity should be carefully evaluated both before and after reduction, especially the dorsalis pedis and posterior tibial pulses and peroneal nerve function. Any abnormal vascular findings, either before or after reduction, require arteriography and, if necessary, arterial exploration. Abnormalities in the sensory or motor function of the foot and distribution of the peroneal nerve function should be noted.

Radiographic Findings

Anteroposterior and lateral radiographs at the initial evaluation confirm the clinically suggested direction of the dislocation, most commonly anterior (Fig. 23-67). Radiographs in both views after reduction detect any occult fractures of the tibial spine, distal femoral physis, or proximal tibial physis. If collateral ligament injury is suspected, stress views also are obtained.

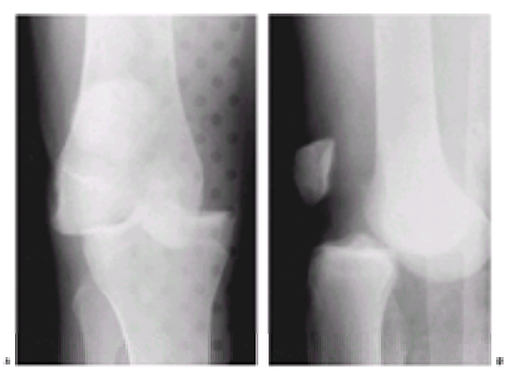

FIGURE 23-67. Dislocation of the knee. **A and B:** Anteromedial dislocation of the knee in a 14-year-old girl. **C:** Intimal tear and occlusion of popliteal artery after anterior knee dislocation in a male 19-year-old. (Courtesy of Richard E. King, MD, Atlanta, Georgia.)

Femoral arteriograms are obtained at the initial evaluation if dorsalis pedis or posterior tibial pulses are absent or diminished. The knee dislocation is reduced as quickly as possible and the vascular status reevaluated. Although distal pulses often are absent immediately after injury and return after reduction, an arteriogram can be done even after satisfactory pulses are restored to detect an intimal tear that may cause late thrombosis and occlusion. Arteriography is unnecessary when pulses are normal before and after reduction; however, the vascular status should be carefully monitored for 48 to 72 hours after reduction.

Methods of Treatment

When treating a knee dislocation in a child, the physician must consider not only the acute knee injury with associated soft tissue and ligament injury and underlying fractures, but the possibility of neurovascular injury. No large series are available for comparison of the methods of treatment. In reports of knee dislocations in adults, most surgeons recommend repair of ligamentous injuries, especially in young patients. Closed reduction and splinting followed by 6 weeks of immobilization in a long leg cast usually is appropriate for children with acute knee dislocations without arterial injury. In adolescents approaching skeletal maturity, grade III injuries of the cruciate or collateral ligaments may be surgically repaired.

AUTHOR'S PREFERRED METHOD OF TREATMENT

Our choice of treatment of knee dislocations in children is based on three factors: the child's age, associated ligamentous injury, and associated vascular injury.

In a child without vascular injury, the dislocation is reduced and the stability is tested by clinical examination and, if necessary, stress radiographs. Isolated cruciate ligament injury is treated nonoperatively, as described earlier.

Operative Treatment

Injuries to both the cruciate and collateral ligaments are treated as outlined earlier. In an adolescent approaching skeletal maturity with cruciate and collateral ligament injuries but no vascular injury, we recommend repair or reconstruction of the ligaments as previously described.

In any child with a suspected arterial injury, arteriography is mandatory. If pulses are absent before reduction, even if they are satisfactory after reduction, we frequently obtain an arteriogram to detect any intimal tears that we believe should be repaired surgically. Obviously, the absence of the pulses after reduction is an emergent situation. If vascular injury has occurred, surgical correction must be done within 6 to 8 hours of injury to prevent subsequent ischemia and possible limb loss. In this critical situation, we obtain the arteriogram in the operating room, if at all. Arteriography is not mandatory in an isolated injury but is necessary to pinpoint the site of vascular injury if ipsilateral proximal injuries are present.

If primary arterial repair or grafting of the popliteal artery is required, we recommend fasciotomy of all four compartments of the leg at the same time to prevent the development of a compartment syndrome. Repair or reconstruction of ligaments should not be attempted at this time because this is too extensive a procedure to be

undertaken during emergent arterial repair.

If there are no postoperative complications after vascular repair, children may be immobilized in a cast for an additional 4 to 6 weeks and then started on a rehabilitation program. For adolescents near skeletal maturity who require vascular repair, two options are available for treatment of the ligamentous injuries. The ligaments can be repaired approximately 2 weeks after vascular repair; under ideal circumstances, with good wound healing and no postoperative complications, an experienced surgeon can undertake delayed primary repair of the ligament injuries. The other option is to wait and perform late reconstruction if required for cruciate or collateral ligament instability.

Postoperative Care

For most knee dislocations treated with closed reduction, 3 to 6 weeks of cast immobilization is followed by quadriceps and hamstring strengthening, range-of-motion exercises, and progressive ambulation with crutches. If surgical repair is required, postoperative rehabilitation is the same as that described earlier for ligament injuries.

Prognosis

The prognosis for acute knee dislocations in children is identical to that for isolated or combined ligamentous injuries. The worst prognosis is in children in whom late vascular repair results in ischemic changes in the extremity and in adolescents who require late ligament reconstruction because of knee instability.

Complications

The most serious complications result from unrecognized and untreated vascular injury or a late intimal tear that causes thrombosis of the popliteal artery within 24 to 72 hours of injury. Careful evaluation and constant monitoring of the vascular status of the injured limb are mandatory, and aggressive use of arteriography is recommended, with immediate surgical exploration and repair or vein grafting when indicated.

PATELLAR DISLOCATIONS

Patellar dislocation is relatively common in children if all subluxations and dislocations from varying causes are considered, but acute traumatic patellar dislocation caused by a direct blow is rare in children. McManus et al. (309) reviewed 55 acute patellar dislocations in children and concluded that acute dislocation occurs only in children with underlying patellofemoral dysplasia. Most acute patellar dislocations occur in patients between 16 and 20 years of age and are more common in female than in male patients.

Surgical Anatomy

The patella is a sesamoid bone in the quadriceps mechanism. As the insertion site of all muscle components of the quadriceps complex, it serves biomechanically to provide an extension moment during range of motion of the knee joint. The trochlear shape of the distal femur stabilizes the patella as it tracks through a range of motion. The hyaline cartilage of the patella is the thickest in the body.

At 20 degrees of knee flexion, the inferior pole of the patella contacts a relatively small area of the femoral groove. With further flexion, the contact area moves superiorly and increases in size. The medial facet of the patella comes in contact with the femoral groove only when flexion reaches 90 to 130 degrees.

The average adult trochlear femoral groove height is 5.2 mm and lateral femoral condyle height is 3.4 mm. The patellar articular cartilage is 6 to 7 mm deep, the thickest articular cartilage in the body and a reflection of the joint's inherent incongruity. The usual normal lateral alignment of the patella is checked by the medial quadriceps expansion and focal thickening of the capsule in the areas of the medial patellofemoral and medial meniscopatellar ligaments (297). Dynamic stability depends on muscle forces, primarily the quadriceps and hamstrings acting through an elegant lower extremity articulated lever system that creates and modulates forces during gait. The quadriceps blends with the joint capsule to provide a combination of dynamic and static balance. Tightness or laxity of any of the factors involved with maintenance of the balance leads to varying levels of instability. Acute patellar dislocation almost always is in a lateral direction unless it is due to a medially oriented direct blow or follows overvigorous lateral retinacular release. Sallay et al. (312) demonstrated avulsions of the medial patellofemoral ligament from the femur in 94% (15 of 16) of patients during surgical exploration after acute patellar dislocation. Desio et al. (297), using a cadaveric serial cutting model, found that the medial patellofemoral ligament provided 60% of the resistance to lateral patellar translation at 20 degrees of knee flexion. The medial patellomeniscal ligament accounted for an additional 13% of the medial quadrant restraining force. If the deficit produced by attenuation of the medial vectors after acute dislocation is not eliminated, patellofemoral balance is lost, resulting in feelings of knee instability and recurrent dislocation.

The patella is under significant biomechanical compressive load during activity. It has been estimated that at 60 degrees of knee flexion, the forces across the patellofemoral articulation are three times the body weight and increase to over seven times the body weight during full knee flexion.

The quadriceps mechanism is aligned in a slightly valgus position in relation to the patellar tendon. This alignment can be approximated by a line drawn from the anterosuperior iliac spine to the center of the patella. The force of the patellar tendon is indicated by a line drawn from the center of the patella to the tibial tubercle. The angle formed by these two lines is called the *quadriceps angle* or *Q angle* (Fig. 23-68). As this angle increases, the pull of the extensor mechanism tends to subluxate the patella laterally. Recurrent patellar dislocation is most likely associated with some congenital or developmental deficiency of the extensor mechanism, such as patellofemoral dysplasia, deficiency of the vastus medialis obliquus, or an increased Q angle with malalignment of the quadriceps–patellar tendon complex.

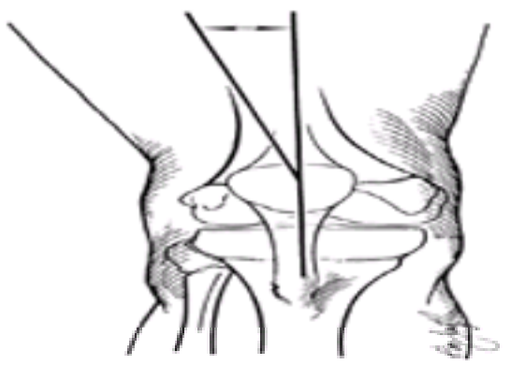

FIGURE 23-68. The Q angle. Normal valgus alignment of the quadriceps mechanism: line drawn from the anterosuperior iliac spine to center of the patella, line drawn from center of the patella to tibial spine.

Mechanism of Injury

Larsen and Lauridsen (306) found that a direct blow to the medial aspect of the patella accounted for only 10% of the acute knee dislocations in their series. Patellar dislocations are more likely to be caused by falls, gymnastics, dancing, cheerleading, and a wide variety of other activities. Acute patellar dislocation also should be considered in the evaluation of all athletic injuries in adolescents and young adults.

Classification

Although there is no specific classification of patellar dislocations in children, acute dislocation should be distinguished clinically from chronic patellar subluxation or dislocation. Approximately 15% of children with acute patellar dislocations experience recurrent dislocations. Cash and Hughston (293) reported a 60% incidence of

redislocation in patients 11 to 14 years of age, 30% in patients 19 to 28 years of age, and in only one patient older than 28 years of age. Intraarticular dislocation of the patella also should be recognized (292,298,299,301). This injury is uncommon in children but occurs frequently in adults with chronic soft tissue laxity or severe degeneration of the quadriceps tendon.

Signs and Symptoms

The orthopaedist rarely sees a child with an acute patellar dislocation in whom the patella remains in a dislocated position (Fig. 23-69). Usually, the patella has reduced spontaneously with active or passive extension of the knee. Symptoms include diffuse parapatellar tenderness and pain with any attempt passively to displace the patella. A defect may be palpable in the medial attachment of the vastus medialis obliquus to the patella if the medial retinaculum is completely avulsed. Tenderness on the lateral aspect of the knee usually is not as severe as on the medial side. Hemorrhage into the joint may cause hemarthrosis, and severe hemarthrosis should suggest the possibility of an osteochondral fracture (311). Nietosvaara et al. (183) reported that of 72 patients with acute patellar dislocations, 28 (39%) had associated osteochondral fractures. These fractures included 15 capsular avulsions of the medial patellar margin and 15 loose intraarticular fragments detached from the patella, the lateral femoral condyle, or both. All knee ligaments should be carefully evaluated because the mechanism of patellar dislocation may cause associated ligamentous injuries.

FIGURE 23-69. Acute dislocation of the left patella in a 6-year-old boy.

Radiographic Findings

Radiographs after acute dislocation are obtained primarily to detect any associated osteochondral fracture. Occasionally, an osteochondral fragment from the medial aspect of the patella or the lateral femoral condyle is visible on the anteroposterior or lateral view. The classic “sunrise” view is difficult to obtain in a child after acute dislocation because the required positioning of the knee causes pain. Rarely, stress radiographs may be obtained for evaluation of suspected physeal fracture or ligamentous injury. CT or MRI is valuable to check for an osteochondral fracture.

Methods of Treatment

Most acute patellar dislocations in children reduce spontaneously; if not, reduction usually can be easily obtained. After appropriate sedation, reduction is done by flexing the hip to relax the quadratus femoris, gradually extending the knee, and gently pushing the patella medially back into its normal position.

Surgery rarely is indicated for acute patellar dislocations in children (170,294,306). Surgical repair may be indicated if the vastus medialis obliquus is completely torn from the medial aspect of the patella, leaving a large, palpable soft tissue gap. If osteochondral fracture has occurred, arthroscopy may be indicated for removal or repair of an osteochondral loose body. Even more rarely, open reduction and fixation of a large fragment and repair of the medial retinaculum may be necessary.

Avulsion of the quadriceps tendon from the patella most often causes intraarticular dislocation. Closed treatment is unsuccessful, so open reduction is necessary to reduce the patella and repair the tear of the quadriceps tendon. Even more uncommon is the intraarticular dislocation, in which the patellar ligament is torn from the tibial tuberosity. Associated injury of the cruciate ligaments should be carefully evaluated at the time of surgery and surgically repaired as indicated.

AUTHOR'S PREFERRED METHOD OF TREATMENT

Most acute patellar dislocations in children are easily treated by closed methods with satisfactory results. A cylinder cast is used for 2 to 4 weeks or, in children with compliant parents, a knee immobilizer is worn for the same duration. Surgical intervention is appropriate in the circumstances outlined previously, most commonly for an intraarticular osteochondral fracture. We generally prefer arthroscopic examination and removal of the fragment if possible, and perform arthrotomy only if necessary for removal or fixation of a large osteochondral fracture. Acute surgical repair of the vastus medialis obliquus rarely is indicated.

Postoperative Care and Rehabilitation

After the 2- to 4-week immobilization period, a physical therapy program is begun for progressive strengthening of the quadriceps muscles and gentle range-of-motion knee exercises. After arthroscopic debridement and removal of an osteochondral fragment, immobilization is continued an additional 3 weeks, followed by the same rehabilitation program. Rarely, if surgical repair of the vastus medialis obliquus is required, cylinder cast immobilization is continued for 4 to 6 weeks during the postoperative period.

Prognosis

The prognosis of patellar dislocations in children is generally good. Approximately one in six children with acute patellar dislocations experiences recurrent dislocations. Cash and Hughston (293) noted 75% satisfactory results after nonoperative treatment in carefully selected patients.

Complications

Complications frequently occur because of an unrecognized osteochondral fracture, which is diagnosed later by the presence of a loose body. Radiographs obtained after injury should be carefully scrutinized for any osteochondral injury. Occasionally, complications occur because of associated ligamentous injury, particularly of the medial collateral or cruciate ligaments, and especially in adolescent male athletes.

Chronic Patellar Subluxation

Chronic patellar subluxation or dislocation is common in adolescents, especially girls. Several risk factors have been identified in children likely to have chronic subluxation or dislocation, including age younger than 16 years, radiographic evidence of dysplasia of the patella or lateral femoral condyle, significant atrophy of the vastus medialis obliquus, hypermobility of the patella, and multiple previous dislocations (Fig. 23-70).

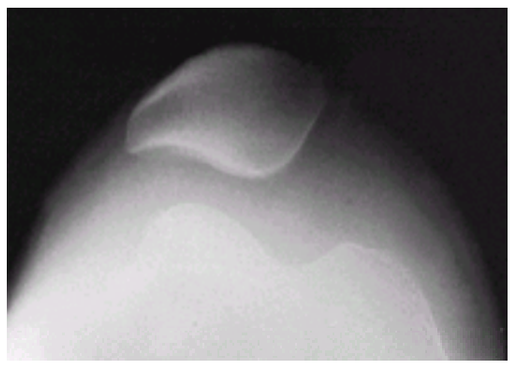

FIGURE 23-70. Chronic lateral patellar subluxation in 13-year-old girl.

Initial treatment of chronic patellar subluxation or dislocation in adolescents is immobilization followed by aggressive physical therapy for rehabilitation of the vastus medialis obliquus and quadriceps muscles. Surgical intervention is warranted in children with several risk factors who do not respond to this treatment regimen and continue to have subluxation or dislocation (291,304,307,308). Micheli and Stanitski (310) reviewed 33 skeletally immature patients with lateral retinacular releases and found that the procedure did not interfere with permanent alignment of the extensor mechanism. They recommended the technique for children who do not respond to an aggressive physical therapy program.

Operative Treatment

If subluxation or dislocation persists after adequate lateral release, correction of the medial deficiency is indicated, usually by advancement of the medial retinaculum and muscle and plication of the vastus medialis muscle (Fig. 23-71A). If deficiency of the vastus medialis obliquus is severe, this procedure can be done at the time of lateral retinacular release. Transfer of the semitendinosus through the inferior pole of the patella also has been[jyreported in skeletally immature patients (303) (Fig. 23-71B). This may be indicated in adolescents with continued instability after lateral release and medial realignment, or in children with associated connective tissue disorders. In skeletally mature patients with a significantly abnormal Q angle, the Elmslie-Trillat procedure reportedly achieves good results in approximately 80%. This technique displaces the anterior tibial tubercle medially to decrease the Q angle (Fig. 23-71C). The Elmslie-Trillat procedure is contraindicated in patients with open physes because of the possibility of growth disturbance of the anterior tibial tubercle, with resulting genu recurvatum.

MENISCAL INJURIES

Although less common in children than in adults, meniscal injuries are becoming more frequent in children and adolescents, especially those involved in competitive athletics (314,319,343,364,377). DeHaven and Lintner (330), in a study of 3,431 athletes, found internal derangement of the knee to be one of the two most common injuries in young athletes, particularly boys. Most meniscal injuries occur in adolescents older than 12 years of age, but they have been reported in very young children (290,339,363,374). King (348) reported 52 patients younger than 15 years of age who had undergone arthrotomy because of suspected meniscal injuries, and Fowler (334) reported 117 meniscectomies in patients 12 to 16 years of age.

Surgical Anatomy

The menisci develop early in fetal life from the intermediate zone of mesenchyme between the distal femur and the proximal tibia and assume their adult semilunar form by the 10th fetal week (325,347). During the remainder of growth, the menisci change in size but not in shape. Growth of the meniscus occurs in the peripheral part, where the avascular fibrocartilage becomes loose-textured vascular fibrous tissue. The peripheral edges of the menisci are convex, fixed, and attached to the inner surface of the knee joint capsule, except where the popliteus is interposed laterally, and are attached loosely to the borders of the tibial plateaus by the coronary ligaments. The inner edges are concave, thin, and unattached. The menisci are largely avascular, except near their peripheral attachment to the coronary ligaments.

Although the lateral meniscus shows more developmental variation, as demonstrated by Clark and Ogden (325), it is never discoid in shape during normal development. The predominant collagen is type I arranged circumferentially with oblique, vertical, and radial fibers present to diminish hoop stresses with weight bearing. The menisci show constant ratios of meniscal to articular tibial plateau surface areas during development and demonstrate intimate concordant maturation of the menisci with the tibia (325). In addition to lesser roles of synovial fluid distribution and contribution to knee stability, the major role of the menisci is to share weight-bearing loads by increasing articular contact area and reducing the load per unit area on articular cartilage, with 70% of the lateral compartment load borne by the lateral meniscus and 50% of the medial load by the medial meniscus. Recent *in vivo* MRI documentation of normal meniscal motion under load was reported by Vedi et al. (373). With weight bearing, the anterior medial meniscus moved an average of 7.1 mm and the posterior medial horn showed an average excursion of 3.9 mm along with 3.6 mm average mediolateral radial displacement. The lateral anterior meniscus and the lateral posterior horn moved an average of 9.5 and 5.6 mm, respectively, with a radial mediolateral average displacement of 3.7 mm. These findings of dramatic dynamic changes of meniscal position reaffirm the preliminary work reported by Thompson et al. (371).

Biomechanically, the menisci act as a joint filler to compensate for the incongruity between the articulating surfaces of the femur and tibia and prevent capsular and synovial impingement during flexion and extension of the knee. The menisci are pushed outward by the compression forces of the tibia and femur, but the strong anterior and posterior attachments of the menisci generate circumferential tension forces (hoop forces) that counteract this outward or radial force (366). The menisci transmit and distribute loads between the articular surfaces, serving as shock absorbers to spare the articular cartilage from compressive loads and to protect the joint from osteoarthritic changes.

The menisci also are believed to nourish the articular cartilage and lubricate the joint by the distribution of synovial fluid. They contribute to stability in all planes but are especially important rotary stabilizers and are essential for the smooth gliding or rotation motion as the knee moves from flexion into extension.

Mechanism of Injury

Meniscal tears are most commonly produced by rotation as the flexed knee moves toward extension. This rotational force with the knee partially flexed changes the relation of the femoral condyles to the menisci, and forces the menisci toward the center of the joint, where they are likely to be injured. These twisting mechanisms occur primarily in sports and may cause associated ligamentous injuries. Meniscal injuries also may be associated with degenerative changes, cystic formation, or

congenital anomalies (334).

Classification

The most commonly used classification is based on the type of meniscal tear found at surgery, either peripheral, bucket-handle, horizontal cleavage, transverse, or complex. Although previous studies reported that lateral lesions were more common in children, King (348) found more medial lesions in his patients, most commonly peripheral detachment of the posterior portion (Fig. 23-72). He also noted that the younger the patient, the more peripheral the tear; conversely, bucket-handle tears occurred most often in older children and adolescents.

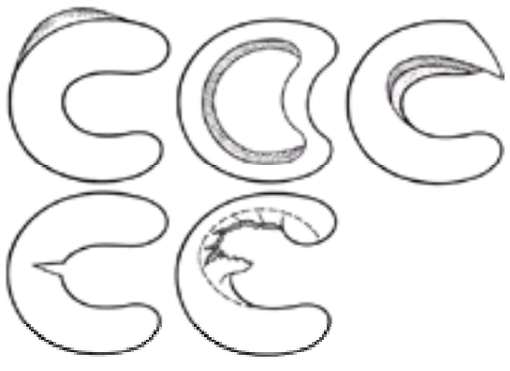

FIGURE 23-72. Meniscal tears in adolescents. **A:** Peripheral. **B:** Bucket-handle. **C:** Horizontal cleavage. **D:** Transverse. **E:** Complex.

Signs and Symptoms

The most difficult aspect of treatment may be making the correct diagnosis. Bergstrom et al. (231) and Juhl and Boe (345) reported diagnostic accuracy in approximately 20% of children believed to have meniscal injury. An accurate history may be difficult to obtain in a very young child. The older the patient, the more likely a history of specific injury. The patient usually relates feeling or hearing a “pop” at the time of injury, with frequent popping and giving way after injury. Pain is reported by approximately 85% of patients, with tenderness over the affected joint line. More than half report giving way and effusion of the knee joint. McMurray's and Apley's tests may be helpful in the diagnosis of a chronic lesion, but with acute injury the knee usually is too painful to allow these maneuvers (329).

In Vahvanen and Aalto's series of patients with documented meniscal tears (372), almost one third of the patients had no significant findings on physical examination. We find the classic McMurray test of little value in this age group whose tears are peripheral and not degenerative posterior horn lesions. The most accurate physical findings are joint line tenderness (especially middle to posterior) and exacerbation of the pain with varus (medial) and valgus (lateral) and rotation stress (internal, medial; external, lateral) at 30 to 40 degrees of knee flexion. These signs have value: 92.3% negative predictive value, 93.3% sensitivity, and 92.3% specificity (284).

Radiographic Findings

Routine radiographs are obtained primarily to eliminate other sources of knee pain. Arthrography (326) may help delineate meniscal tears, but has been used less frequently since the advent of arthroscopy and MRI (357,359). MRI's accuracy rates reportedly range from 45% to 90% in the diagnosis of meniscal tears (324,343,361,365), and it is the preferred imaging method for evaluating meniscal injuries in children. MRI should not be used as a screening procedure because of significant limitations of the technique in this age group (284,323,351,361,368). Takeda et al. (370) reviewed the MRI signal intensity and pattern in the menisci of 108 knees in 80 normal children 8 to 15 (average 12.2) years of age using the classification of Zobal et al. (379), which allows for equivocation for type III signals. Using tibial tubercle maturity as a definition of skeletal maturity, Takeda et al. (370) found signal intensity to be proportional to age, with high signal (grades III and III) evident in 80% of patients 10 years of age or younger, 65% by 13 years of age, and 33% at 15 years of age, similar to the false-positive rate of 29% reported in asymptomatic adults (336,351). Overall, two thirds of the patients had positive findings (grades II or III), often grade III-A, which is equivocal extension through the surface of the meniscus. Takeda et al. suggested that the decrease in signal intensity was proportional to diminution of peripheral vascularity, especially in the posterior horn of the meniscus. Schwartzberg et al. (368) used unilateral MRI to study 55 asymptomatic 9- to 15-year-olds with negative knee examinations and found that 51% had grade III and 27% grade II signal changes in their medial menisci. Grade III signals were found in 7% and grade II changes were seen in 7% of lateral menisci. All children with grade III changes in the lateral meniscus also had grade III signals in the medial side. These investigators cautioned against misinterpretation of pediatric knee MRIs and emphasized the necessity for correlation of the clinical findings with any imaging study results. In another series (284), poor correlation was seen between MRI reports and arthroscopic findings, with significant numbers of false-positive and false-negative findings reported on MRI interpretation by radiologists: 37.5% accuracy, 50% positive and 50% negative predictive indexes, 50% sensitivity, and 45% specificity. Current MRI techniques usually provide limited information about tear size and stability or predictability of healing after repair. As with any test, clinical correlation is mandatory before treatment decisions are made.

Methods of Treatment

The traditional treatment of a torn meniscus has been meniscectomy, but numerous reports (317,322,333,342,350,355,369,372) indicating the poor long-term results of meniscectomy in children have made this less common. Up to 60% to 75% of patients have degenerative changes after meniscectomy. Manzione et al. (352) reported 60% poor results in 20 children and adolescents after meniscectomy. In cadaver studies, Baratz et al. (320) showed that the contact stresses on the tibiofemoral articulation increase in proportion to the amount of the meniscus removed and the degree of disruption of the meniscal structure. Clearly, as much of the meniscus should be preserved as possible.

As King (348) pointed out, removal of a damaged meniscus to minimize irreversible damage to the joint is advisable, but every effort should be made to spare the meniscus. The exact meniscal injury and potential for repair can be determined arthroscopically to help formulate treatment plans. Zaman and Leonard (378) recommended observation of small peripheral tears, repair of larger peripheral tears, and, when necessary, partial meniscectomy, leaving as much of the meniscus as possible; they concluded that total meniscectomy is contraindicated in young patients (Fig. 23-73). In general, peripheral tears, which are most common in children, and longitudinal tears are good candidates for repair, with success rates of up to 90% reported (328,338,341,353,357). Sisk (366) recommended that repair be limited to the most peripheral 25% of the meniscus.

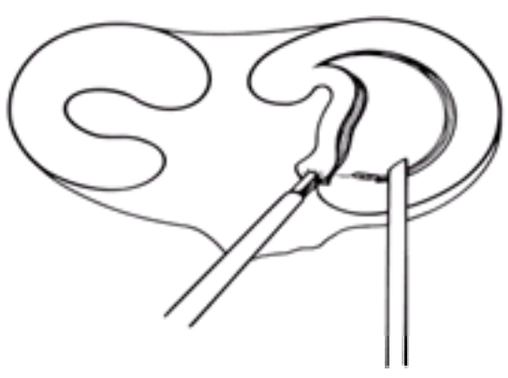

FIGURE 23-73. Arthroscopic partial medial meniscectomy for bucket-handle tear in an adolescent.

Open and arthroscopic techniques for meniscal repair share several important factors:

1. Anatomic reduction of the meniscus
2. Multiple, closely placed sutures that are not readily absorbable
3. Careful avoidance of neurovascular structures
4. Fixation of the meniscus directly on the knee capsule (Fig. 23-74)

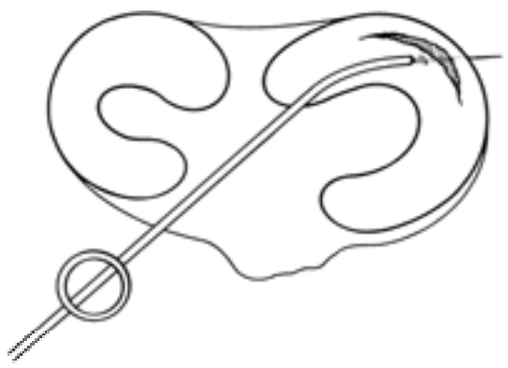

FIGURE 23-74. Arthroscopic repair of a peripheral tear of the posterior horn of the medial meniscus.

Although King (349) suggested over six decades ago that, based on experimental evidence in dogs, longitudinal meniscal tears could heal if communication with peripheral blood supply existed, it was not until the work of Arnoczky and Warren (318) in the 1980s that meniscal repairs were begun based on documentation of the meniscal blood supply. They believed that tears within 3 mm of the meniscosynovial junction were vascularized, and ones more than 5 mm away were avascular unless bleeding was seen at surgery. Tears in the 3- to 5-mm range had inconsistent vascularity. The zones of meniscal injury are 0 to 3: 0 represents the synovial–perimeniscal vascular plexus, 1 corresponds to the red–red junction of vascularity (0 to 3 mm), 2 is the red–white transitional area from vascular to avascular (3 to 5 mm), and 3 is the white–white avascular region (5 mm to the central border).

Some questions still remain about the ability of the repaired meniscus to transmit load because of the altered fiber arrangement.

AUTHOR'S PREFERRED METHOD OF TREATMENT

Treatment is based on a classification scheme we call *SAKS,* an acronym that represents size, site, shape and stability of the tear (S); acuity of the lesion (A); and knee stability (KS) or ACL and MCL integrity. In a stable knee with an acute, arthroscopically documented outer third peripheral tear that is less than 1 cm long and cannot be displaced more than 3 mm, we immobilize the knee in a cylinder cast for 3 weeks in the acute setting. For similar chronic injury (>3 months), we arthroscopically rasp the interface between the meniscal edges and immobilize the knee in a cylinder cast for 4 weeks. If the tear is in zones 1 or 2, and is longitudinal with a noncomminuted inner segment that can be reduced anatomically, repair is done (Fig. 23-75 and Fig. 23-76). If a chronic situation exists, rasping of the fragment edges and use of a fibrin clot are techniques that have been reported to enhance healing. Mintzer et al. (356) had a 100% success rate in meniscal repairs in 26 adolescent athletes (29 repairs) with an average follow-up of 5 years. Four patients had open physes at time of the meniscal repair. Most (78.5%) were zone 0 to 1 tears with an average length of 2.3 cm. Thirteen patients had associated ACL tears that were reconstructed. All but two of the patients returned to their preinjury sport level. If the central fragment is macerated with multiplanar tears or ones that cannot be reduced, repair is not done (Fig. 23-77). The fragment is excised to the stable remaining meniscal rim. Results of repairs of tears that are unstable and located in the central third (zone 2 to 3) have not been reported to any extent in skeletally immature patients. Rubman et al. (362) reported good results in adults with central zone meniscal repairs, with 80% being asymptomatic at an average follow-up of under 4 years. Most (72%) had associated ACL injuries that were reconstructed. These investigators suggested that the repairs would seem to be more indicated in patients in their second and third decades than in older patients. Unstable tears in the central third, white–white zone are excised, taking care to preserve as much stable meniscal rim as possible. The rare radial tear or horizontal tear is debrided, leaving as much intact meniscus as is stable. With horizontal tears, the smaller of the two leaves is resected.

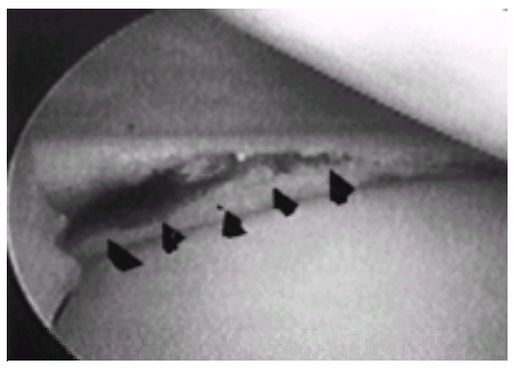

FIGURE 23-75. Arthroscopic view of a red–white junction tear in a 15-year-old girl. *Arrowheads* denote the vascular edge of the peripheral meniscus.

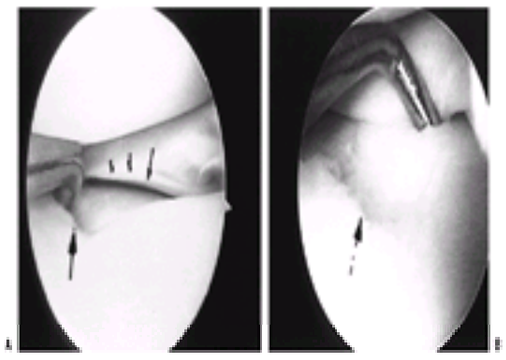

FIGURE 23-76. A: Arthroscopic view of a displaced fragment *(large arrow)* of a large peripheral longitudinal tear of the lateral meniscus. The *small arrows* indicate the stable peripheral meniscal margin. **B:** Full-thickness articular damage *(arrow)* of the lateral tibial compartment from the trauma that caused the meniscal injury.

FIGURE 23-77. Arthroscopic view of a comminuted, macerated white-zone free edge tear of the medial meniscus. This pattern of injury is best treated by tear debridement and not by repair.

In an adolescent patient with an unstable knee from an MCL injury and a peripheral meniscal tear, repair of the meniscus and ligament is indicated. If the meniscal tear is in a zone not amenable to repair, the fragment is debrided and the collateral ligament injury is managed nonoperatively.

Outcomes after meniscal repair in adults are negatively related to the length and chronicity of the meniscal injury. Failure rates of 10% to 15 % are seen in peripheral tears of less than 2 cm and in 60 % if the tears exceed 4 cm. In tears that have been present for less than 8 weeks, the results are good in approximately 85 %, compared with 65 % in more chronic tears (>8 weeks) (325). These data probably are applicable to patients older than 11 or 12 years of age because the perimeniscal blood supply pattern at that age is identical to the flow in adults.

In patients with what we call the “ACL plus” knee, one with concomitant meniscal and ACL tears, meniscal salvage, by repair if possible, and ACL reconstruction are indicated. To allow knee instability to persist invites repeat meniscal injury and additional articular compromise.

Multiple techniques exist for repair (309,316,323,325,356). Four main types of repair are used: outside-in, inside-out, all inside, and open, depending on the meniscal tear characteristics. Open repair usually is reserved for injuries associated with complete tears of the MCL or meniscal damage that cannot be approached arthroscopically. Inside-out repairs use various zone-specific cannulae that allow precise suture placement, usually a vertical mattress stitch, which has been shown to have suture strength twice that of a horizontal stitch. Outside-in repairs use spinal needles placed across the capsule and meniscus. A suture is passed through the needle and brought outside the knee, a knot is fashioned, the suture is reintroduced intraarticularly, and the knot is used to maintain meniscal reduction and fixation. The outsides of the sutures are then tied to the outer capsule. This technique is helpful in areas where more blind suture passage could cause neural and vascular compromise. The all-inside suture technique is technically demanding and currently an emerging method. A variety of bioabsorbable meniscal anchors are in use that obviate the need for capsular exposure and external sutures. These devices sometimes are too long or bulky to use in a child's knee.

Preparation of the edges of the meniscal tear is a matter of the tear's acuity and pattern. A meniscal rasp can be used to stimulate a vascular response at the perimeniscal vascular leash. Improved results in patients with chronic tears have been reported with use of a fibrin clot, which provides a collagen framework for vascular invasion and repair. The reader is referred to standard arthroscopic texts for details of meniscal repair (325).

Postoperative Care and Rehabilitation

Because meniscal healing is slow, careful rehabilitation after surgical repair is especially important. Knee motion should be restricted by a cast or brace for 4 to 6 weeks, with limited weight bearing. Full weight bearing is then allowed and a strengthening program is begun. Return to vigorous sports activities is not allowed for at least 6 months.

H4>Complications

Complications after either arthroscopic or open repair may include hemorrhage, infection, persistent effusion, stiffness, and neuropathy. Both the popliteal artery and inferior geniculate branches are close to the posterior capsule and are easily lacerated. Postoperative infection should be suspected if swelling or pain persists with an elevated temperature. Swelling is best treated with external compression dressings, and stiffness is best prevented by appropriate postoperative rehabilitation. Neuroma formation rarely causes significant symptoms, but occasionally persistent localized tenderness may warrant excision.

DISCOID MENISCUS

Discoid meniscus (327,331,332,344,358) is a common cause of knee symptoms in children and adolescents. As noted by Woods and Whelan (376), discoid meniscus probably is a congenital deviation that usually occurs laterally. According to Hayashi et al. (340), the thickness of a discoid meniscus, its poor vascularization, and a flimsy attachment of the posterior area to the capsule make it more susceptible to mechanical stress than a normal meniscus. In their study of 53 symptomatic discoid lateral menisci, most of the patients were between 10 and 15 years of age.

The most frequent symptom is pain during ordinary activities, followed by giving way, locking, and snapping of the knee joint (346). Knee extension usually is limited and the quadriceps muscles often are atrophied. Occasionally, effusion, hemarthrosis, and instability also are present. Radiographs often are negative, but they may show widening of the lateral compartment, squaring of the femoral condyle, hypoplasia of the lateral tibial spine, tilting of the tibial articular surface, and apparent elevation of the fibular head. Arthrography or MRI may be helpful in establishing the diagnosis (330,333,337), but a horizontal tear in the midsubstance or a transverse cleavage in the middle segment may not be visible. Even with arthroscopy, identification of tears in the midsubstance of the meniscus may be difficult. Hamada et al (337) reported that intrameniscal regions of high signal intensity and flattening on MRI correspond to intrasubstance tears or degeneration of lateral discoid menisci not detectable by arthroscopy. Based on their findings, MRI seems to be more sensitive than arthroscopy in the detection of intrasubstance lesions of lateral discoid menisci (Fig. 23-78).

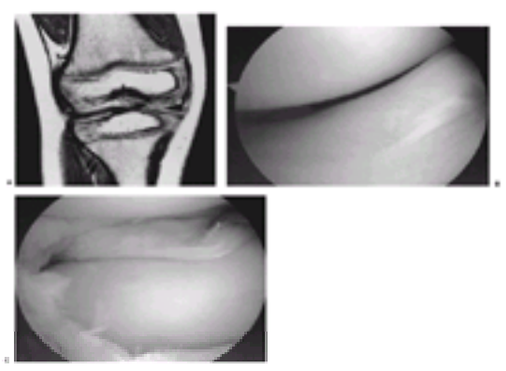

FIGURE 23-78. A: Magnetic resonance image of a 3-year-old girl who had symptoms of popping and catching in the knee demonstrates large discoid lateral meniscus. **B:** Arthroscopic view of discoid lateral meniscus. **C:** Arthroscopic subtotal meniscectomy. (Courtesy of Robert H. Miller III, MD, Memphis, Tennessee.)

Classification

Watanabe et al. (375) described three major types of discoid meniscus: type 1, completely disk-shaped semilunar type with a thinner center; type 2, incomplete semilunar type with a concave or convex free edge; and type 3, hypermobile or Wrisberg type without posterior tibial capsular attachment. The most common is the complete type. Neither Bellier et al. (321) nor Hayashi et al. (340) found any Wrisberg type 3 lesions in their combined total of 72 discoid menisci, and they believed it to be a rare lesion. The most common sites of meniscal tear are at the posterior segment and inside the middle segment.

Methods of Treatment

When chronic locking of the knee, joint effusion, or pain warrants surgical treatment, arthroscopic subtotal or partial meniscectomy is preferred whenever possible (335,354). Hayashi et al. (340) advised reducing the thickness of complete-type discoid menisci to prevent new tears; they recommended leaving a rim of 6 mm in complete and 8 mm in incomplete lesions. Because the arrangement of collagen fibers of the discoid meniscus differs from that in the normal meniscus, and because the tear is most commonly close to the least vascular and most mobile area, partial meniscectomy may not be helpful for many tears in discoid menisci.

In a study of 47 knees with symptomatic discoid lateral menisci, Pellacci et al. (360) found that the results of partial meniscectomy were better than those of total meniscectomy. Aichroth et al. (315), however, recommended arthroscopic partial meniscectomy only when the posterior attachment of the discoid meniscus is stable; total meniscectomy is recommended for Wrisberg-type (type 3) discoid menisci with posterior instability.

Sugawara et al. (367) evaluated 139 partial or complete arthroscopic meniscectomies and found that 9 knees (6.5%) required 2 or more operations. Of this group, seven knees had partial meniscectomies of lateral discoid menisci. Because of their findings, they suggested that the most appropriate initial treatment for lateral discoid menisci without tears is observation of the clinical course, with minimal treatment using diagnostic arthroscopy. If clinical symptoms are serious or if an apparent meniscal tear is identified, they recommended subtotal or total meniscectomy rather than partial meniscectomy.

The need for total meniscectomy usually is dictated by the thickness of the discoid meniscus, the location of the tear, and the duration of symptoms preoperatively. Despite the generally poor prognosis after total meniscectomy, several investigators (321,331,340) report excellent results in children after total meniscectomy of discoid lateral menisci.

AUTHOR'S PREFERRED METHOD OF TREATMENT

For types 1 and 2 discoid menisci, we recommend arthroscopic partial meniscectomy and shaving to a stable meniscus with an intact peripheral rim. For the rare type 3 discoid meniscus with no posterior capsular attachment, the options are total meniscectomy or posterior repair combined with partial meniscectomy.

TIBIOFIBULAR DISLOCATIONS

Dislocations of the proximal tibiofibular joint are infrequent in children and adolescents, but may be more common than appreciated; the injury is estimated to go unrecognized initially in approximately one third of patients (378,381,382,386,387,388,390,395). Most of these dislocations occur during athletic activities, especially with a severe twisting movement. The dislocation or subluxation may be associated with other skeletal injuries, especially proximal tibial fractures (392). Disruption of the proximal tibiofibular joint is classified as subluxation, anterolateral dislocation, posteromedial dislocation, or superior dislocation (Fig. 23-79). The most common type is anterolateral dislocation. Pain along the lateral side of the knee and leg is the most common symptom of subluxation. Isolated anterolateral dislocation may be identified by a palpable mass lateral to the tibia and usually is visible on radiographic examination.

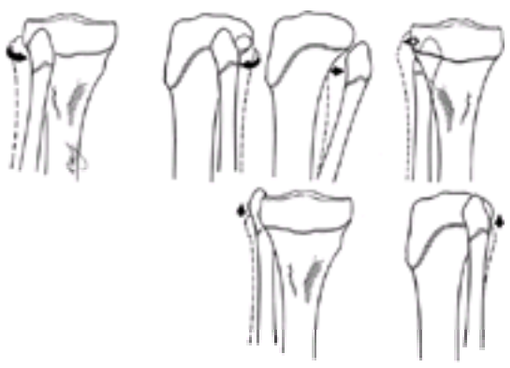

FIGURE 23-79. Tibiofibular subluxation–dislocation (Ogden). **A:** Anterolateral. **B:** Posteromedial. **C:** Superior.

Symptoms caused by subluxation usually subside with rest, but cylinder cast immobilization may be required. Most dislocations, especially acute dislocations, can be reduced closed by pushing the head of the fibula backward. Posteromedial dislocations often are associated with severe disruption of the joint capsule and rupture of the LCL, and these may require open reduction, capsulorrhaphy, and repair of the ligament. Superior dislocations are rare and usually are associated with fractures of the tibia, which may require open reduction and internal fixation. Recurrent subluxation or dislocation may cause progressive peroneal neuropathy and may require ligament reconstruction, resection of the proximal fibula, or arthrodesis of the tibiofibular joint (380,383,385,389,391,393,394).

AUTHOR'S PREFERRED METHOD OF TREATMENT

We prefer ligament reconstruction to arthrodesis or proximal fibular resection. Shapiro et al. (391) described a technique of reconstruction using an iliotibial band fascial graft. They cited as advantages of this procedure the maintenance of normal motion of the knee and normal mechanics of the ankle. Arthrodesis results in loss of rotational motion of the fibula, which can cause problems at the knee and ankle joints. Resection of the fibular head alters the normal contour of the knee and may cause peroneal nerve palsy, chronic ankle pain, and lateral knee instability. These procedures should be reserved for patients with failed ligament reconstruction or those who are not candidates for reconstruction.

24
FRACTURES OF THE SHAFT OF THE TIBIA AND FIBULA

STEPHEN D. HEINRICH

EPIDEMIOLOGY

Tibial and fibular fractures are the third most common pediatric long bone injuries (15%) after femoral and radial/ulnar fractures (11,12). The overall prevalence of tibial fractures in both boys and girls has increased since 1950 (Table 24-1) (7). The average age of occurrence is 8 years, and the frequency of occurrence does not change significantly with age (6). Seventy percent of pediatric tibial fractures are isolated injuries; ipsilateral fibular fractures occur with 30% (4,12,13). Fifty percent to 70% of tibial fractures occur in the distal third, and 19% to 39% in the middle third. The least commonly affected portion of the tibia is the proximal third, yet these may be most problematic. Thirty-five percent of pediatric tibial fractures are oblique, 32% comminuted, 20% transverse, and 13% spiral (11). Tibial fractures in children under 4 years of age usually are isolated spiral, sharply oblique fractures of the distal and middle thirds. Most tibial fractures in older children and adolescents are at the ankle. Rotational forces produce an oblique or a spiral fracture and are responsible for approximately 81% of all tibial fractures without fibular fractures (2,4,5,10,11). Bicycle spoke injuries are common among children 1 to 4 years of age, whereas most tibial fractures in children 4 to 14 years of age occur in sporting or traffic accidents (2,4,6,7,10,11). Over 50% of combined tibial and fibular fractures result from vehicular trauma. In contrast to the rotational etiology of most tibial fractures, most isolated fibular fractures result from a direct blow (6,11).

	Years	
	1950–1955	1980–1983
Female		
0–9 years old	6.6	7.2
10–19 years old	3.8	4.9
Male		
0–9 years old	10.1	14.3
10–19 years old	7.1	10.7

TABLE 24-1. CHANGE IN THE PREVALENCE OF PEDIATRIC TIBIAL FRACTURES[a]

The tibia is the second most commonly fractured bone in abused children. Approximately 26% of all abused children with a fracture have an injured tibia (9).

Approximately 9% of pediatric tibial fractures are open. Concomitant fractures of the ankle and foot are the most common injuries associated with fractures of the tibia and fibula, followed by humeral, femoral, and radial/ulnar fractures (3). The average index severity score of a child with a tibial fracture is 10 (range 0–45). The average hospital stay is 6½ days (range 1–50). The average hospital cost for a pediatric tibial fracture is $7,156.00 (range $488.00 to $88,706.00) (3). The cost variation depends on (a) associated injuries, (b) open fracture, and (c) need for surgical management.

Surgical Anatomy

Bony Structure

The tibia (“flute”) is the second largest bone in the body. At the proximal aspect of the tibia are two concave condyles: the medial condyle is larger, deeper, and narrower than the lateral condyle. An elevated process, the tibial tubercule, located between the two condyles is the site of attachment of the patellar tendon. The shaft of the tibia is prismoid, with a broad proximal extent that decreases in size until the distal third, where it gradually increases in size. The tibial crest is prominent medially from the tibial tubercle to the tibial plafond and is subcutaneous without any overlying muscles (5).

The tibia develops from three ossification centers: one in the shaft and one in each epiphysis. The tibial diaphysis ossifies at 7 weeks of gestation and expands both proximally and distally. The proximal epiphyseal center appears shortly after birth and unites with the shaft at approximately 16 years of age. The distal epiphyseal ossification center appears in the second year of life, and the distal tibial physis closes at approximately 15 years of age. Two other centers may occur occasionally: in the medial malleolus and in the tibial tubercle (5).

The tibia articulates with the condyles of the femur proximally, with the fibula at the knee and the ankle, and with the talus distally (5). Twelve muscles have either their origin or insertion on the tibia (Table 24-2).

Semimembranosus	Inserts on inner tuberosity of the proximal tibia
Tibialis anterior, extensor digitorum longus, biceps femoris	Attaches to the lateral condyle of the tibia
Sartorius, gracilis, semitendinosus	Inserts on the proximal medial surface of the tibial metaphysis
Tibialis anterior	Arises on the lateral surface of the tibial diaphysis
Popliteus, solice, flexor digitorum longus, tibialis posterior	Attach to the posterior diaphysis of the tibia
Patellar tendon	Inserts into the tibial tubercle
Secondary slip of fascia lata	Occasionally inserts into the tibial tubercle
Tensor fascia lata	Attaches to Gerdy's tubercle the lateral aspect of the proximal tibial metaphysis

Reprinted from Gray H. Anatomy: descriptive and surgical. In: Pick TP, Howden R, eds. *Anatomy: descriptive and surgical.* New York: Bounty Books, 1977:182; with permission.

TABLE 24-2. MUSCLE ORIGINS AND INSERTIONS ON THE TIBIA

The fibula articulates with the tibia and the talus. The fibular diaphysis ossifies at about 8 weeks of gestation. The distal epiphysis is visible at 2 years of age, and the proximal secondary ossification center at 4 years. The distal fibular physis closes at about 16 years; the proximal physis closes later, at age 16 to 18 years (5). Nine muscles have either their origin or insertion on the fibula (Table 24-3) (5).

Soleus, flexor hallucis longus	Arise from the posterior aspect of the diaphysis
Peroneus longus, peroneus brevis	Arise from the lateral aspect of the fibular diaphysis
Biceps femoris, soleus peroneus longus	Attach to the head of the fibula
Extensor digitorum longus, peroneus tertius extensor hallucis longus	Attach to the anterior surface of the fibular shaft
Tibialis posterior	Arises from the medial aspect of the fibular diaphysis

Reprinted from Buckley SL, Gotschall C, Robertson W, et al. The relationship of skeletal injuries with trauma score, injury severity score, length of hospital stay, hospital charges and mortality in children admitted to a regional pediatric trauma center. *J Pediatr Orthop* 1994;14:440; with permission.

TABLE 24-3. MUSCLE ORIGINS AND INSERTIONS ON THE FIBULA

Vascular Anatomy

The popliteal artery descends vertically between the condyles of the femur and passes between the two heads of the gastrocnemius muscle. It ends at the distal border of the popliteus muscle, where it divides into the anterior and posterior tibial arteries. The anterior tibial artery passes between the tibia and the fibula over the proximal aspect of the intraosseous membrane. The posterior tibial artery divides several centimeters distal to this point, leading to the peroneal artery (Fig. 24-1) (5).

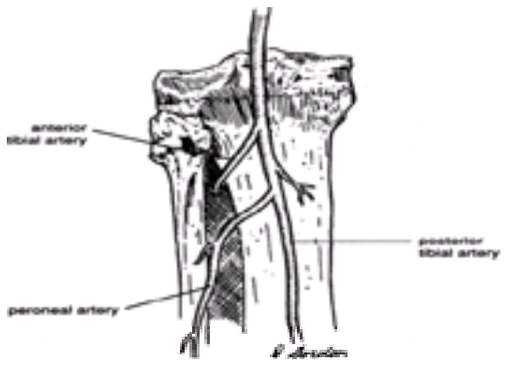

FIGURE 24-1. Vascular anatomy of the proximal tibia.

Nerves

The posterior tibial nerve runs adjacent and posterior to the popliteal artery through the popliteal fossa. The common peroneal nerve passes around the proximal neck of the fibula. It divides into the deep and superficial branches, passing into the anterior and the lateral compartments of the lower leg (5), respectively. Each branch inervates the muscles within its compartment. The deep peroneal nerve provides sensation to the first web space, whereas the superficial branch has a sensor representation across the dorsal surface of the foot.

Fascial Compartments

The lower leg has four fascial compartments (Fig. 24-2). The anterior compartment contains the extensor digitorum longus, the extensor hallucis longus, and the tibialis anterior muscles; the anterior tibial artery and deep peroneal nerve run in this compartment. The lateral compartment contains the peroneus longus and brevis muscles. The superficial peroneal nerve runs through this compartment. The superficial posterior compartment contains the soleus and gastrocnemius muscles. The deep posterior compartment contains the flexor digitorum longus, the flexor hallucis longus, and the tibialis posterior muscles. The posterior tibial artery, peroneal artery, and tibial nerve run in this compartment (5).

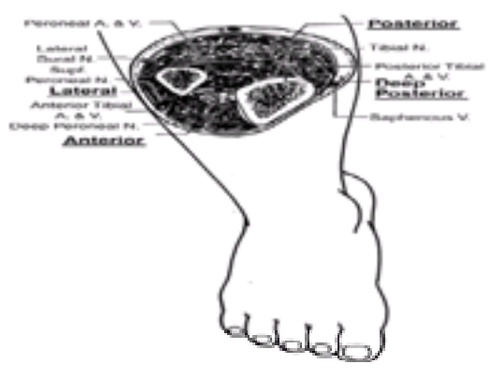

FIGURE 24-2. Fibroosseous compartments of the leg. (Reprinted from Sharps CH, Cardea JA. Fractures in the shaft of the tibia and fibula. In: MacEwen GD, Kasser JR, Heinrich SD, eds. *Pediatric fractures: a practical approach to assessment and treatment.* Baltimore: Williams & Wilkins, 1993:318; with permission.)

CLASSIFICATION

Nonphyseal injuries of the tibia and the fibula can be classified into three major categories based on the combination of bones fractured and the location of the injuries (Table 24-4).

TABLE 24-4. CLASSIFICATION: NONPHYSEAL FRACTURES OF THE PEDIATRIC TIBIA/FIBULA

Fractures of the Proximal Tibial Metaphysis

The peak incidence for proximal tibial metaphyseal fractures is between the ages of 3 and 6 years. The most common mechanism of injury is a force applied to the lateral aspect of the extended knee. The cortex of the medial tibial metaphysis fails in tension, often resulting in an incomplete fracture. The fibula ordinarily escapes injury, although plastic deformation may occur (14,15,16,17,21,22,23,24,27,32,33,34,35,36,37 and 38).

Children with proximal tibial metaphyseal fractures present with pain, swelling, and tenderness in the region of the fracture. Motion of the knee causes moderate pain, and the child will not walk. Crepitance is seldom identified on physical examination, especially if the fracture is incomplete (14,15,16,17,21,22,23,24,27,32,33,35,36,37 and 38).

Radiographs usually show a complete or incomplete fracture of the proximal tibial metaphysis. The medial aspect of the fracture often is open, producing a valgus deformity (14,15,16,17,21,22,23,32,33,35,36,37 and 38).

Valgus Deformity

The most common sequelae resulting of proximal tibial meta- physeal fractures is valgus deformity (Fig. 24-3). In 1953, Cozen (17) reported four patients with valgus deformities after fractures of the proximal tibial metaphysis. Since that time, many other investigators (12,15,16,21,22,23,24,25,27,35,36) have reported tibia valga after proximal tibial metaphyseal fractures.

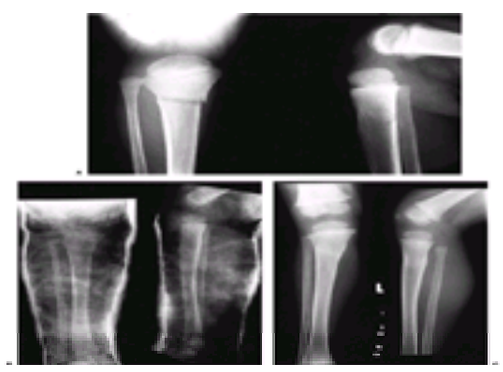

FIGURE 24-3. A: Anteroposterior and lateral radiographs of the proximal tibia metaphyseal fracture with an intact fibula in a 3-year-old child. **B:** Anteroposterior and lateral radiographs in the initial long leg cast demonstrate an acceptable alignment. **C:** Posttraumatic tibia valga is present 1 year after fracture union. (Reprinted from Sharps CH, Cardea JA. Fractures in the shaft of the tibia and fibula. In: MacEwen GD, Kasser JR, Heinrich SD, eds. *Pediatric fractures: a practical approach to assessment and treatment.* Baltimore: Williams & Wilkins, 1993:321; with permission.)

Many theories have been proposed to explain the development of a valgus deformity after a proximal metaphyseal fracture (Table 24-5). Proximal tibia valga can be caused by a poor reduction, particularly if the knee is immobilized in flexion, because the flexed position of the knee makes it difficult to determine the mechanical axis of the leg on radiographs (33,37). Lehner and Dabas suggested that an expanding medial callus produced a valgus deformity (25), whereas Goff (20) and Keret et al. (24) believed that the lateral aspect of the proximal tibial physis was injured (Salter Harris type V fracture), resulting in asymmetric growth of the proximal tibial physis. Taylor (23) believed that the valgus deformity was secondary to postfracture stimulation of the tibial physis without a corresponding stimulation of the fibular physis. Pellen (28) suggested that premature weight bearing produced an angular deformity of the fracture before union. Rooker and Salter (31) believed that the periosteum was trapped in the medial aspect of the fracture, producing an increase in medial physeal growth and a developmental valgus deformity.

Asymmetric activity of medial portion of proximal tibial physis (overgrowth) (14,21,23,25,27,30,35,37)
Tethering effect, fibula (8,22,35)
Inadequate reduction (29)
Interposed soft tissue (pes anserinus) (36); medial collateral ligament (16)
Loss of tethering effect of the pes anserinus (23)
Early weight bearing producing developmental valgus (28)
Physeal arrest of the lateral aspect of the proximal tibial physis

TABLE 24-5. PROPOSED ETIOLOGIES OF TRAUMA INDUCED TIBIA VALGUS

A recently suggested etiology for the valgus deformity that develops after a proximal tibial fracture in a child relates the deformity to a concomitant injury to the pes anserinus tendon plate. The pes anserinus tethers the medial aspect of the physis just as the fibula tethers the lateral aspect of the proximal tibial physis. The proximal tibial fracture disrupts the pes anserinus tendon plate, producing a loss of the tethering affect and leading to medial physeal overgrowth and a hemichondrodiastasis (15,18,19,36,38). Removal from the fracture and repair of the folded periosteum that forms the foundation of the plate has been suggested to decrease the risk of recurrence of the varus deformity.

Another theory postulates that the progressive valgus deformity occurs because vascular flow to the proximal tibial physis increases after fracture, producing an asymmetric physeal response that causes increased medial growth (23). Support for this theory includes quantitative bone scans performed months after proximal tibial metaphyseal fractures that have shown increased tracer uptake in the medial aspect of the physis compared with the lateral aspect (37). Developmental tibia valga has been reported to occur after simple excision of a bone graft from the proximal tibial metaphysis (35), tibial osteotomy (14,22), and osteomyelitis of the proximal tibial metaphysis (14,35). Ogden identified an increase in the collateral geniculate vascularity to the medial proximal tibia in a cadaver angiography study of a

5-year-old child. This also supports the theory that medial overgrowth occurs secondary to an increase in the blood flow supplying the medial aspect of the proximal tibia following injury (26). The overgrowth of the tibia that occurs in many children with tibial valgus deformity after fracture is further evidence of an abnormality in the response of the proximal tibial physis to fracture (22,35). Tibia valga deformity can occur after nondisplaced fracture and can recur after corrective tibial osteotomy (Fig. 24-4), further supporting the premise that asymmetric physeal growth is the cause of most posttraumatic tibia valga deformities (37). Robert et al. (30), in an analysis of 25 patients with proximal tibial fractures, identified three groups of patients. Twelve children with greenstick or complete fractures developed valgus deformities, which were progressive in 11. No child with a torus fracture developed a valgus deformity. In 3 children, altered growth at the distal tibial physis compensated for the compromised tibia valga; in 4 children, corrective osteotomies were performed. The valgus deformity recurred in 2 of these 4 children, and two had iatrogenic compartment syndromes. This study supports the recommendation that developmental tibia valga should not be corrected until the child reaches puberty. At that point, a proximal tibial medial epiphysiodesis can be performed to allow the tibia to correct slowly (2,27,30,34,35).

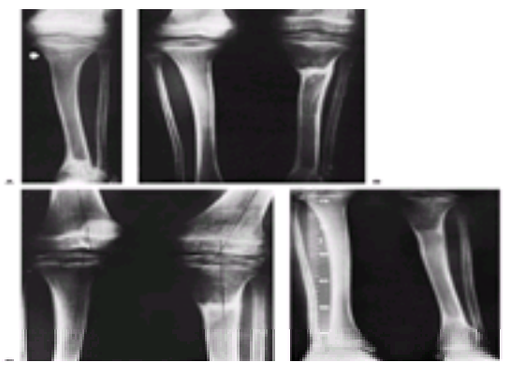

FIGURE 24-4. Developmental valgus after a proximal tibial metaphyseal fracture and a subsequent corrective osteotomy. **A:** Radiograph taken 6 months after a fracture of the proximal and distal tibia in a 5-year-old girl. The proximal tibial injury was nondisplaced. The scar from the initial proximal metaphyseal fracture is still seen (*arrow*). This child developed a moderate valgus deformity of the tibia within 6 months of fracture. **B:** A proximal tibial corrective osteotomy was performed. **C:** Two months postoperatively the osteotomy was healed and the deformity corrected. **D:** Five months later there was a recurrent valgus deformity of 13 degrees. (Courtesy of John J.J. Gugenheim, M.D.).

Support for a “wait and see” attitude also was provided by Zionts and MacEwen (38), who followed for an average of 39 months seven children with progressive valgus deformities of the tibia after metaphyseal fractures. Most of the deformity occurred during the first year after injury. The tibia continued to deform at a slower rate for up to 17 months after injury. Six of their seven patients had spontaneous clinical corrections. At follow-up, all children had less than a 10 degree deformity.

Treatment

Nondisplaced proximal tibial metaphyseal fractures are stabilized with a long leg cast with the knee in nearly full extension and a varus mold.

Displaced proximal tibial fractures require closed reduction with general anesthesia in the operating room, with fluoroscopy to verify an anatomic reduction. If closed reduction to an anatomic position or slight varus cannot be obtained, an open reduction is indicated. Interposed soft tissue is removed from the fracture (Fig. 24-5), and the pes anserinus plate is repaired if ruptured. The child is placed into a long leg, straight knee cast after reduction, and the fracture is checked once again. Frequent follow-up visits are required to verify maintenance of the reduction. The cast is removed approximately 6 weeks after injury. The child may return to normal activities after recovery of normal knee and ankle range of motion. Long-term follow up with a warning to the family of possible growth abnormality is mandatory.

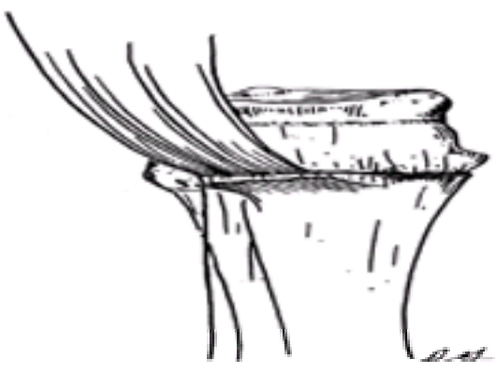

FIGURE 24-5. Proximal tibial metaphyseal fracture with interposition of both the pes anserinus fibers and the periosteum into the fracture medially.

A child with a posttraumatic valgus deformity is followed until spontaneous correction occurs or until the child is old enough for surgical intervention. Tibial osteotomies rarely are indicated and generally should be delayed until adolescence. A well-timed proximal tibial medial epiphysiodesis can provide comparable results without many of the risks of osteotomy (34). Orthotic devices do not alter the natural history of posttraumatic tibia valga and are not recommended. However, because the valgus deformity usually is associated with overgrowth, a contralateral shoe lift of appropriate size may make the deformity less apparent.

DIAPHYSEAL FRACTURES OF THE TIBIA AND FIBULA

Seventy percent of pediatric tibial fractures are isolated injuries (11,13,101). The fractures can be incomplete (torus, greenstick) or complete. Most tibial fractures in children under 11 years of age are caused by a torsional force and are located in the distal third of the tibia. These oblique or spiral fractures occur when the body rotates with the foot in a fixed position on the ground. The fracture line starts in the distal anteromedial aspect of the bone and propagates proximally in a posterolateral direction. Although the intact fibula prevents significant shortening of the tibia, varus angulation develops in approximately 60% of isolated tibial fractures within the first 2 weeks after injury (101) (Fig. 24-6) because the force of contraction of the long flexor muscles of the lower leg are converted into an angular moment by the intact fibula (Fig. 24-7). Isolated transverse and comminuted fractures of the tibia are caused by direct trauma. Transverse fractures of the tibia with an intact fibula seldom displace (8,46). Comminuted fractures drift into varus alignment like oblique and spiral fractures (8,46,101).

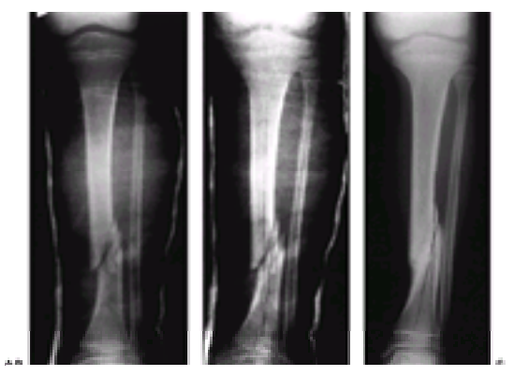

FIGURE 24-6. Anteroposterior radiograph of a distal one-third tibia fracture without a concomitant fibula fracture in a 10-year-old child. **A:** The alignment in the coronal plane is acceptable (note that the proximal and distal tibial growth plates are parallel). **B:** A varus angulation developed within the first 2 weeks after injury. **C:**

At radiographic union, a 10 degree varus angulation is present.

FIGURE 24-7. A: Fracture of the proximal third of the tibia without a concomitant fibular fracture. Note the valgus angulation of the tibia fracture. **B:** The valgus malalignment spontaneously corrected into neutral alignment. **C:** The fracture united with a mild posterior and medial translation without an angular deformity.

Approximately 30% of pediatric tibial diaphyseal fractures have associated fibular fractures (11,13,101). Plastic deformation of the fibula may produce valgus malalignment of the tibia. The fibular injury must be identified to prevent recurrence of the malalignment after reduction. An associated complete fracture of the fibula usually results n valgus malalignment because of the action of the muscles in the anterolateral aspect of the leg (Fig. 24-8).

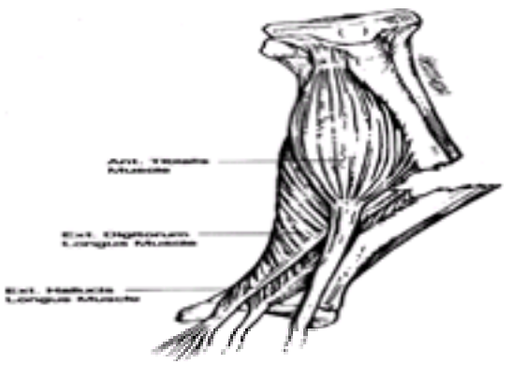

FIGURE 24-8. The muscles in the anterior and the lateral compartments of the lower leg produce a valgus deformity in complete ipsilateral tibia and fibula fractures.

An isolated fracture of the fibular shaft is rare in children and normally results from a direct blow to the lateral aspect of the leg (Fig. 24-9). Most isolated fractures of the fibular shaft are nondisplaced and heal quickly with symptomatic care. Compartment syndrome may accompany this injury, and observation for this associated problem is mandatory.

FIGURE 24-9. A: Plastic deformation of fibula secondary to a direct blow to the lateral aspect of the leg (*closed arrows*). Note medial nondisplaced fracture of the tibia. **B:** The tibia fracture displaced in the cast a week later from the force exerted by the plastically deformed fibula.

Signs and Symptoms

The signs and symptoms associated with tibial and fibular diaphyseal fractures vary with the severity of the injury and the mechanism by which it was produced. Pain is the most common symptom. An isolated fibular fracture normally produces mild pain, whereas tibial fractures produce more severe pain. Children with stress fractures of the tibia or fibula complain of pain on weight bearing, but no pain at rest.

Children with fractures of the tibia or fibula have edema at the fracture site, and the area is tender to palpation. Young children with nondisplaced fractures may refuse to walk. If there is significant injury to the periosteum, a bony defect may be present to palpation in patients with a complete fracture. Neurologic impairment secondary to the force that created the fracture is rare except with fibular neck fractures caused by direct trauma.

Although arterial disruption is uncommon in pediatric tibial and fibular diaphyseal fractures, both the dorsalis pedis and the posterior tibial pulses should be checked, and a Doppler examination should be performed if they are not palpable. Capillary filling, sensation, and pain response patterns also should be monitored.

Concomitant soft tissue injuries must be evaluated carefully. Open fractures must be treated aggressively to reduce the risk of late complications.

Radiographic Evaluation

Anteroposterior and lateral radiographs that include the knee and ankle joints (Fig. 24-10) should be taken whenever a tibial or fibular shaft fracture is suspected. Comparison views of the uninvolved leg normally are not necessary. Children with suspected fractures not apparent on the initial radiographs may need to be treated with supportive casting to control the symptoms associated with the injuries. Technetium radionuclide scans obtained at least 3 days after injury are useful to identify fractures that are unapparent radiographically.

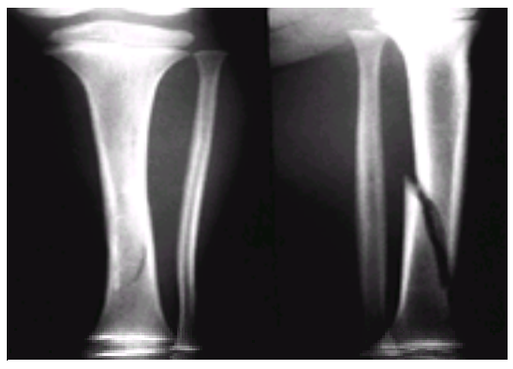

FIGURE 24-10. A: Spiral fracture of the distal tibia. The fracture is difficult to identify on the anteroposterior radiograph. **B:** The fracture is easily identified on the lateral radiograph.

Treatment

Cast Immobilization

Pediatric tibial and fibular shaft fractures usually are uncomplicated and can be treated by a simple manipulation and cast application (67). Isolated fractures of the tibial shaft often develop a varus malalignment. Valgus angulation and shortening can present a significant problem in children who have complete fractures of both the tibia and the fibula (Fig. 24-11). A recurvatum deformity also can develop.

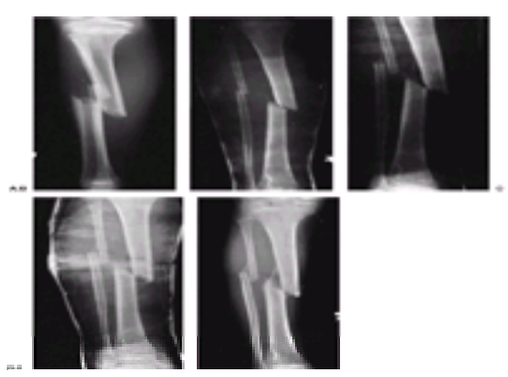

FIGURE 24-11. A: Complete fracture of the tibia and the fibula with a valgus deformity and shortening. **B:** The fracture was closed reduced. **C:** The valgus deformity increased after 2 weeks. **D:** The cast was wedged. **E:** Radiograph 6 weeks after injury shows a good alignment and callus formation.

Displaced fractures are reduced in the operating room to allow painless manipulation with muscle relaxation and the use of fluoroscopy to guide the reduction. The child's ankle initially may be left in some plantar flexion (20 degrees for fractures of the middle and distal thirds, 10 degrees for fractures of the proximal third) to prevent posterior angulation at the fracture.

The fracture is evaluated under fluoroscopy before cast application to determine the most appropriate way to manipulate the bone to achieve an acceptable reduction. A short leg cast is applied with the foot in appropriate position and with either a varus or valgus mold. The cast material is taken to the inferior aspect of the patella anteriorly and to a point 2 cm distal to the popliteal flexion crease posteriorly. Plaster is used for the initial cast because of its ability to mold to the contour of the leg and the ease with which it can be manipulated while setting. The alignment of the fracture is rechecked after the short leg cast has been applied. The cast is then extended to the mid-thigh with the knee flexed. Most children with complete unstable diaphyseal tibial fractures are placed into a bent knee (45 degrees) long leg cast to control rotation at the fracture site and assist in keeping the child non–weight bearing during the initial healing phase.

The alignment of the fracture must be checked closely during the first 3 weeks after the cast has been applied, when muscle atrophy and a reduction in tissue edema may lead to a loss of fracture alignment. Some children require a second cast application with remanipulation of the fracture under general anesthesia several weeks after injury. Acceptable position is somewhat controversial. Remodeling of angular deformity is limited. No absolute number can be given, but the following general principles may be beneficial in decision making.

1. Varus and valgus deformity in the upper and mid-shaft tibia remodel slowly if at all. Up to 5 degrees of deformity can be accepted, but not more than 10 degrees.
2. Translation of the entire shaft of the tibia in a young child is satisfactory, whereas in an adolescent, 50% apposition should be obtained.
3. Up to 10 degrees of posterior angulation may be tolerated, although remodeling is slow
4. No more than 1 cm is acceptable, because overgrowth is minimal.

Wedging of a Cast

Occasionally, loss of fracture reduction requires the cast to be “wedged.” The fracture alignment in the cast can be changed by creating a closing wedge, an opening wedge, or a combination of wedges. The location for the wedge manipulation is determined by evaluating the child's leg under fluoroscopy and marking the mid-point of the tibial fracture on the outside of the cast. If fluoroscopy is not available, a series of paper clips are placed at 2-cm intervals on the cast. Anteroposterior and lateral radiographs are then taken. The paper clips define the location of the fracture and the location of the cast manipulation.

Closing Wedge Technique

A wedge of cast material encompassing 90% of the circumference of the leg with its base over the apex of the fracture is removed. The cast is left intact opposite the apex of the fracture. The edges of the cast are brought together to correct the angulation at the fracture. This wedging technique produces mild fracture shortening and may pinch the skin at the location the wedge is removed. It also may increase compartment pressures because the volume of the cast is reduced.

Opening Wedge Technique

The side of the cast opposite the apex of the fracture is cut perpendicular to the long axis of the bone. A small segment of the cast is left intact directly over the apex of the malaligned tibia (approximately 25%). A cast spreader is used to “jack” the cast open. A plastic block (Fig. 24-12) of the appropriate size is placed into the open segment and the cast is wrapped with new casting material after the alignment has been checked radiographically. This wedging technique lengthens the tibia while correcting the malalignment (Fig. 24-13).

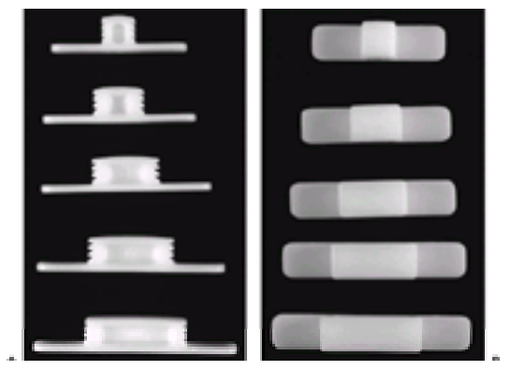

FIGURE 24-12. A and B: Blocks used to hold casts open after wedge corrections of malaligned fractures. The wings on the blocks prevent the blocks from migrating toward the skin.

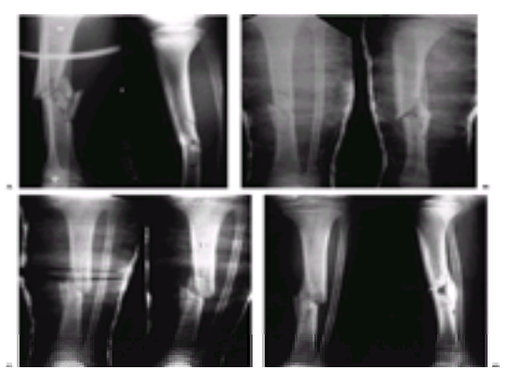

FIGURE 24-13. A: Anteroposterior and lateral tibial radiographs of an 11-year-old boy who was struck by an automobile sustaining a markedly comminuted tibia fracture without a concomitant fibula fracture. **B:** Despite the comminution, length and alignment were maintained in a cast. **C:** The patient's fracture shifted into a varus malalignment that measured 10 degrees **(right)**. The cast was wedged, resulting in the reestablishment of an acceptable coronal alignment **(left)**. **D:** The patient's fracture healed without malunion.

Combination Technique

Approximately 45% of the cast opposite the apex of the malaligned fracture is cut perpendicular to the shaft of the tibia. Two vertical cuts separated by approximately 0.5 cm are made 90 degrees from the first cut in both directions directly over the fracture. A wedge of casting material is removed from the apex side of the malaligned fracture, and the cast opposite the apex of the fracture is opened. This closes the defect in the cast over the apex of the fracture and produces a change in the angular alignment of the bone without a significant change in the length of the bone.

Operative Treatment

Unstable fractures of the tibia and fibula may require operative reduction and surgical stabilization. Common methods of fixation include percutaneous pins, bioabsorbable pins (42), external fixation, and plates with screws. Intramedullary nails are seldom indicated.

Operative treatment is rarely needed for tibial fractures in children. Weber et al. (13) reported that only 29 (4.5%) of 638 pediatric tibial fractures required surgical intervention. The indications for operative treatment include open fractures, fractures in children with spasticity (head injury or cerebral palsy), and fractures in which open treatment facilitates nursing care (floating knee, multiple long bone fractures, multiple system injuries) (40,44,52,54,57,60,64,70,72,77,80,81,87,92,100).

Children with stable fractures or minimally displaced fractures should be treated conservatively whenever possible. Comminuted tibial fractures, unreducible fractures, fractures that cannot be maintained in a reduced position, fractures associated with a compartment syndrome, grade II or III open injuries (Fig. 24-13), or fractures associated with multiple system injuries should be treated with operative stabilization (40,44,52,54,57,60,64,70,72,77,80,81,87,92,100).

Open Fractures

Open tibial fractures in children are treated in the same manner as comparable injuries in adults, and they are classified by the Gustillo and Anderson System (61) (Table 24-6 and Fig. 24-14). Most open fractures of the tibia result from high-velocity injuries.

Grade I
Low-energy wound, <1 cm long
Bone piercing skin from inside/out
Minimal muscle damage
Grade II
Wound >1 cm in length
Moderate soft tissue injury
Grade III
High-energy wound
Usually >10 cm
Extensive muscle devitalization
Bone widely displaced or comminuted
Special cases
Shotgun wound
High-velocity gunshot (>2,000 ft/s)
Segmental fracture
Segmental diaphyseal loss
Farmyard environment
Associated vascular injury

TABLE 24-6. CLASSIFICATION OF OPEN FRACTURES

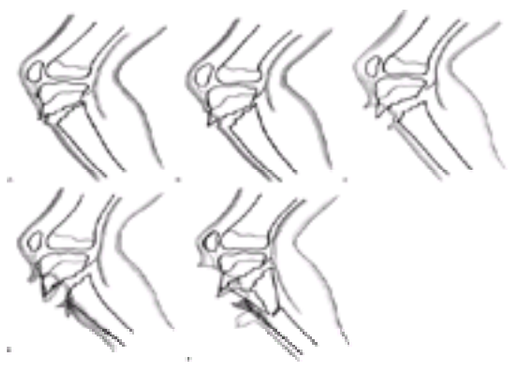

FIGURE 24-14. Gustillo and Anderson classification of open fractures. **A:** Grade I. The skin wound measures less than 1 cm long, usually from within, with little or no skin contusion. **B:** Grade II. The skin wound measures more than 1 cm long, with skin and soft tissue contusion but no loss of muscle or bone. **C:** Grade IIIA. There is

a large severe skin wound with extensive soft tissue contusion, muscle crushing or loss, and severe periosteal stripping. **D:** Grade IIIB. Like grade IIIA but with bone loss and nerve or tendon injury. **E:** Grade IIIC. Like grade IIIA or B with associated vascular injury. (Reprinted from Alonso JE. The initial management of the injured child: musculoskeletal injuries. In: MacEwen GD, Kasser J, Heinrich SD, eds. *Pediatric fractures:a practical approach to assessment and treatment.* Baltimore: Williams & Wilkins, 1993:32; with permission.)

Treatment Principles

Edwards outlined management principles for high-grade open fractures in 1983 (56):

- Rapid debridement, irrigation, and antibiotic therapy
- Fracture reduction followed by application a rigid fixation device
- Intraoperative angiography and compartment pressure studies when sufficiency of the vascular profusion is unclear or compartments tight
- Open wound treatment with loose gauze packing
- Postoperative suspension of the leg
- Staged debridement of necrotic soft tissue and bone in the operating room every 24 to 72 hours until a good granulation base develops
- Delayed closure or application of a split-thickness skin graft when necessary; delayed myocutaneous flap as needed
- Closed cancellous bone grafting for bone defects or delayed union
- Removal of external fixation device followed by application of a weight-bearing cast in compressible fractures after successful soft tissue coverage
- Continued external fixation and grafting for noncompressible fractures

The principles of treatment for open tibial fractures in adults have been modified by the unique characteristics of the pediatric skeleton. These differences include the following (40,52,60,95):

- Soft tissue injuries heal better in children than in adults.
- Devitalized uncontaminated bone that can be covered with soft tissue will incorporate into the fracture callus.
- External fixation can be maintained, when necessary, until fracture consolidation.
- Periosteum can reform bone even with segmental bone loss in younger children.
- Some uncontaminated grade I open wounds can be primarily closed.

Buckley et al. (47) reported on 41 children with 42 open fractures of the tibia (18 grade II, 6 grade IIIA, 4 grade IIIB, and 2 grade IIIC). Twenty-two (52%) of the fractures were comminuted. All wounds were irrigated and debrided, and antibiotics were administered for at least 48 hours. Twenty-two fractures were treated with reduction and cast application, and 20 with external fixation. Three children had early infections, and one of them developed late osteomyelitis. All infections had resolved at last follow-up. The average time to union was 5 months (range 2–21months). The time to union was directly proportional to the severity of the soft tissue injury. Fracture pattern also had an effect on time to union. Segmental bone loss, infection, and the use of an external fixation device were associated with delayed union. Four angular malunions of more than 10 degrees occurred, three of which spontaneously corrected. Four children had more than 1 cm of overgrowth (47).

In a series of 40 open lower extremity diaphyseal fractures in 35 children, Kramer et al. (76) reported 22 tibial fractures (1 grade I, 10 grade II, and 11 grade III). External fixation was used for 15 fractures, casting for 5, and internal fixation for 2. Two children required early amputation, 4 required soft tissue flaps, and 13 children had skin grafts. Two additional children required fasciotomy for compartment syndrome and were included in the group of open tibial fractures. Ten of the 24 injuries healed within 24 weeks. Five children required bone grafting before healing.

Hope and Cole (69) reported the results of open tibial fractures in 92 children (22 grade I, 51 grade II, and 19 grade III). Debridement and irrigation were performed on admission, antibiotics were given for 48 hours, and tetanus prophylaxis was administered as needed. Primary closure was performed in 51 children, and 41 fractures were left open. Eighteen soft tissue injuries healed secondarily, and 23 required either a split-thickness skin graft or a tissue flap. Sixty-five (71%) of the 92 fractures were stable and were reduced and immobilized in an above-the-knee plaster cast. External fixation was used for unstable fractures, injuries with significant soft tissue loss, and fractures in patients with multiple system injuries.Early complications of open tibial fractures in these children were comparable with those in adults (Table 24-7) (44,47,49,51,53,62,66,69,78,84,86,89). Primary closure did not increase the risk of infection if the wound was small and uncontaminated (40,52,69). At reevaluation 1.5 to 9.8 years after injury, Hope and Cole found that 50% of the patients complained of pain at the fracture site; 23% reported decreased abilities to participate in sports, joint stiffness, and cosmetic defects; and 64% had leg length inequalities (Table 24-8). Levy et al. (81) found comparable late sequelae after open tibial fractures in children, including a 25% prevalence of nightmares surrounding the events of the accident. Blasier and Barnes (43) and Song et al. (95) found that most late complications associated with pediatric open tibial fractures occurred in children over the age 12 and 11, respectively.

	Grade			
Complication	**I**	**II**	**III**	**Combined**
Delayed union	18%	12%	26%	16%
Nonunion	5%	6%	16%	7.5%

TABLE 24-8. LATE COMPLICATIONS ASSOCIATED WITH OPEN PEDIATRIC TIBIA FRACTURES

Soft-Tissue Closure

The timing of soft tissue closure after an open tibial fracture that cannot be primarily closed is important in decreasing the morbidity associated with this injury (73,83).

In a series of 168 open tibial fractures with late secondary wound closure, Small and Mollan (93) found increased complications with early fasciocutaneous flaps and late free flaps and no complications with fasciocutaneous flaps created more than 1 month after injury. Complications associated with free flaps were decreased if the procedure was performed within 7 days of injury.

Ostermann, Henry, and Seligson (85) reported 115 grade II and 239 grade III tibial fractures in a series of 1,085 open fractures. All patients were treated with early broad-spectrum antibiotics, serial debridements, and the application of an external fixation device. Tobramycin-impregnated polymethylmethacrylate was placed into the wounds, and dressings were changed every 48 to 72 hours until the wounds spontaneously closed, or had delayed primary closure or a flap. No infections occurred in grade I fractures; approximately 3% of grade II fractures and 8% of grade III fractures became infected. No infections occurred in patients who had the wound closed by 8 days after injury. On the basis of this and other analyses, it now is recommended that wounds associated with open tibial fractures be closed within 7 days of injury (7,48,49,50,75,85,88,98). A delayed primary closure can be performed if the wound is clean and does not involve significant muscle loss. Tension at the suture line must be avoided.

Vascular Injuries

Vascular injuries have been reported in approximately 5% of children with open tibial fractures. Arterial injuries associated with open tibial fractures include those to the popliteal artery, the posterior tibial artery, the anterior tibial artery, and the peroneal artery. Complications are common in patients with open tibial fractures and associated vascular injuries. Amputation rates as high as 21% have been reported with grade IIIB fractures and as high as 79% with grade IIIC fractures. Isolated anterior tibial and peroneal artery injuries have a good prognosis, whereas injuries of the posterior tibial and popliteal arteries have a poor prognosis (39,63,68). Patients with open tibial fractures and vascular disruption may benefit from an arterial and possibly venous shunt before the bony reconstruction is performed. This allows a meticulous repair of fracture and keeps the limb perfused until the primary vascular repair is performed (58).

Compartment Syndrome

The prevalence of compartment syndromes in adults with open tibial fractures ranges from 6% to 9% (44,53,78). Compartment syndromes occur in approximately 5% of children with open tibial fractures. Normal compartment tissue pressure in the lower leg is approximately 0 mm Hg. Compartment blood inflow is decreased at 20 mm Hg, and prolonged pressures of 30 to 40 mm Hg or within 30 mm Hg of diastolic blood pressure may cause severe nonreversible injury to the muscles within a fascial compartment.

Symptoms and signs associated with compartment syndrome include pain out of proportion to the injury, burning, throbbing, pain increased by passive stretch, and nerve dysfunction. The compartment is tense to palpation. Because tissue pressures can be elevated enough to produce an ischemic injury but not high enough to occlude arterial inflow, the pressure of peripheral pulses is an unreliable sign of elevated tissue pressures.

Compartment pressure measurements are mandatory in any patient suspected of having a compartment syndrome. This can be performed by needle manometry, saline infusion, or a wick catheter. A fasciotomy is indicated for any patient with a significant elevation of compartment pressures or, more importantly, symptoms suggestive of a compartment syndrome. When measuring compartment pressure in the leg after a tibial fracture, placement of the needle is a problem. Buchholz showed that there was a pressure gradient vertically through a compartment.

AUTHOR'S PREFERRED METHOD OF TREATMENT

Diaphyseal Fractures

Simple pediatric diaphyseal tibial fractures unite quickly, and cast immobilization can be used without affecting the long-term range of motion in the knee and the ankle. A bent knee, long leg cast provides maximal comfort to the patient and controls rotation of the fractured fragments. Children with nondisplaced fractures generally do not need to be admitted to the hospital. Children with more extensive injuries should be admitted for observation and teaching of wheelchair, crutch, or walker use.

Displaced fractures may significantly disrupt the surrounding soft tissues and produce a large hematoma in the fascial compartments of the lower leg. Circulation, sensation, and movement of the toes should be monitored carefully after injury. The child should be admitted to the hospital, and reduction should be performed with general anesthesia and fluoroscopy. Stable fractures are casted after reduction. The fracture must be checked within a week of manipulation to verify maintenance of the reduction. The cast can be wedged to correct minor alignment problems. Significant loss of reduction requires repeat reduction with general anesthesia (Table 24-9). The long leg cast is changed to a short leg cast at 4 to 6 weeks after injury. Children over 11 years of age are placed into a patellar tendon–bearing cast after removal of the long leg cast (89).

	Patient Age	
	<8 Years	≥8 Years
Valgus	5°	5°
Varus	10°	5°
Anterior angulation	10°	5°
Posterior angulation	5°	0°

TABLE 24-9. ACCEPTABLE ALIGNMENT OF A PEDIATRIC DIAPHYSEAL TIBIAL FRACTURE

Fractures in patients with spasticity, a floating knee, multiple long bone fractures, extensive soft tissue damage, or multiple system injuries are stabilized with an external fixation device, percutaneous Kirschner wires, or flexible intramedullary nails.

Open Fracture Treatment

Grade I open fractures can be pinned after irrigation and debridement of the wound (Fig. 24-15). A long leg splint is applied and is changed to a long leg cast after wound closure. External fixation generally is used for grade II or III open tibial fractures.

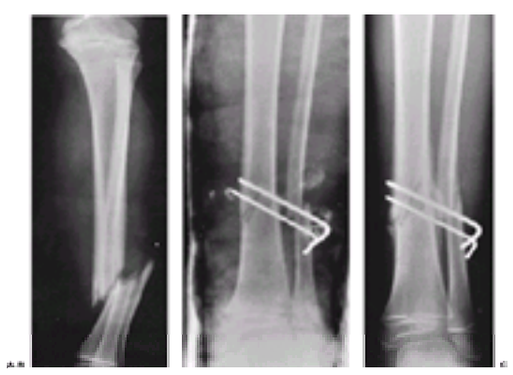

FIGURE 24-15. A: Anteroposterior radiograph of a grade I open distal one-third tibia fracture in a 7-year-old child. **B:** Two percutaneous pins were used to stabilized this fracture after irrigation and debridement. **C:** Good fracture callus was present and the pins were removed 4 weeks after injury.

Open tibial fractures of any grade should have thorough irrigation and debridement of the wound as soon as possible. The patient's tetanus status is determined, and prophylaxis is administered as needed. The soft tissue wounds can be extended to be certain that the area is cleansed and debrided of all foreign material. Devitalized bone can be left in place if it is clean. The operative wound extension can be closed with the open segment in clean grade I injuries. The wound is allowed to heal by secondary intention if it has moderate contamination at the time of the irrigation and debridement. Grade II and III wounds also are debrided of devitalized tissue and foreign material. Patients with uncomplicated grade I fractures can be placed in a cast. Smooth pin fixation will prevent displacement of unstable fractures. Most children with grade II and all children with grade III wounds require more rigid fracture stabilization, usually with external fixation.

The most versatile external fixation device for grade II or III open pediatric tibial fractures is a unilateral frame (Fig. 24-16). The unilateral frame is easy to apply and allows minor corrections in angular alignment and length. Secondary pins can be used for added support (Fig. 24-17). These are connected to the standard pins or the body of the external fixation device. This allows control of segmental fragments. Fracture reduction clamps can be applied to the pin clamps to assist in manipulating the fracture. A small-pin circular frame can be used for complicated fractures adjacent to the joint (Fig. 24-18).

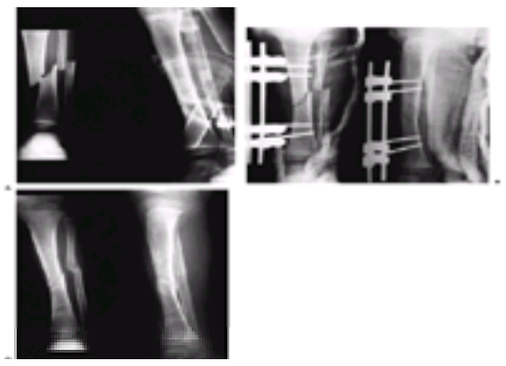

FIGURE 24-16. A and B: Type II open fracture of the tibia in a 5-year-old boy treated with debridement, unilateral external fixation, and split-thickness skin graft. **C:** Four months after removal of the external fixation.

FIGURE 24-17. A: Anteroposterior and lateral radiographs of a grade IIIB open fracture of the distal tibia and fibula. **B:** Anteroposterior and lateral radiographs after fracture reduction and stabilization with an Ilizarov circular fixation frame. (Reprinted from Sharps CH, Cardea JA. Fractures in the shaft of the tibia and fibula. In: MacEwen GD, Kasser J, Heinrich SD, eds. Pediatric fractures: a practical approach to assessment and treatment. Baltimore: William & Wilkins, 1993:325; with permission.)

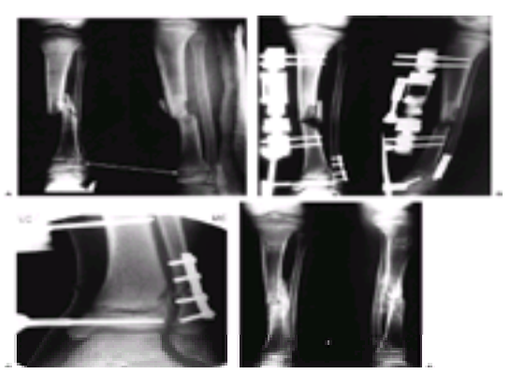

FIGURE 24-18. A: Anteroposterior and lateral radiograph of the tibia of a 12-year-old boy who was struck by a car. This child sustained a grade IIIB open middle one-third tibia fracture, a Salter-Harris type II fracture of the distal tibial physis with associated distal fibular fracture (*closed arrows*), and a tibial eminence fracture (*open arrow*). **B:** Irrigation and debridement, and application of an external fixation device, were performed. **C:** The fracture of the distal tibial physis was stabilized with a supplemental pin attached to the external fixation device. Open reduction and internal fixation of the fibula were performed to enhance the stability of the external fixator in the distal tibia. **D:** Anteroposterior and lateral radiographs of the tibia approximately 9 months after injury demonstrate healing of the tibial eminence fracture, the comminuted middle one-third tibia fracture, and the distal tibial physeal fracture. The distal tibial physis remains open at this time.

External fixation pins are applied no closer than 1 cm to the physis. The external fixation device is applied, and a reduction maneuver is performed. All of the connections in the external fixation device are tightened after reduction has been obtained. Secondary pins to improve fracture stability are placed at this time. Limited internal fixation of the fracture can be used to aid in controlling fracture alignment (Fig. 24-19). A posterior splint can be applied to prevent the foot from dropping into plantar flexion. This splint is easy to remove during subsequent pin care and dressing changes of the open injury.

FIGURE 24-19. Safe drilling zone. **A:** The area occupied by the growth plate is approximately 1 cm in height because of its undulations. **B:** The safe drilling zone is at least 1 cm from the physis. (Reprinted from Alonso JE. The initial management of the injured child: musculoskeletal injuries. In: MacEwen GD, Kasser J, Heinrich SDH, eds. *Pediatric fractures: a practical approach to assessment and treatment.* Baltimore: Williams & Wilkins, 1993:36; with permission.)

POSTFRACTURE IMMOBILIZATION

The length of immobilization varies with the child's age and the type of fracture. The duration of immobilization was 8 to 10 weeks in the Steinert and Bennek series (96). Hanson et al. (6) found that healing time ranged from 5 to 8 weeks for “fissures and infractions” and from 5 to 13 weeks for oblique, transverse, and comminuted fractures. Hoaglund and States (66) reported that in 43 closed fractures in children, the average time in a cast was 2.5 months (range 1.5–5.5 months), whereas the five children with open fractures were immobilized for 3 months.

Kreder and Armstrong (77) found an average time to union of 5.4 months (range 1.5–24.8 months) in a series of 56 open tibial fractures in 55 children. The factor with the most effect on union time was the age of the patient. Grimard et al. (60) reported that the age of the patient and the grade of the fracture were significantly associated with union time. Blasier and Barnes (43) found that children under 12 years of age required less aggressive surgical treatment and healed faster than older children. They also found that younger children were more resistant to infection and had fewer complications than older children.

POSTFRACTURE REHABILITATION

Most children with a tibial fracture do not require extensive rehabilitation. Children's normal walking and running activities serve as therapy. Most children limp with an out-toeing rotation gait on the involved extremity for several weeks after the cast is removed. This usually is due to muscle weakness rather than a malalignment of the fracture. As the muscle atrophy and weakness resolve, so does the limp.

Active physical therapy may be beneficial in treating children with a tibial fracture. In an older child progressing from a bent knee cast to weight bearing on a short leg cast, knee range of motion exercises and quadriceps strengthening are useful. Progressive weight bearing on a short leg cast requires the patient to wean off crutches or a walker. In some children, this requires supervision. After removal of the cast, toe rises for strength should be performed. The child may return to sports with a healed fracture and the ability to hop equal to the uninjured side.

FRACTURES OF THE DISTAL TIBIAL METAPHYSIS

Fractures of the distal tibial metaphysis often are greenstick injuries. The anterior cortex is impacted while the posterior cortex is displaced, with a tear of the overlying periosteum. A recurvatum deformity often occurs (Fig. 24-20). Reduction of these injuries should be performed with general anesthesia and maintained with a long leg cast. The foot should be in plantar flexion to prevent recurvatum at the fracture site. The foot is brought up after 3 to 4 weeks, and a short leg walking cast is applied. Unstable injuries can be treated with percutaneous pins (Fig. 24-21) or with open reduction and internal fixation (Fig. 24-22).

FIGURE 24-20. A: The lateral radiographs demonstrate a mild recurvatum deformity. **B:** The ankle was initially immobilized in an ankle neutral position, producing an increased recurvatum deformity. The cast was removed and the ankle remanipulated into plantar flexion to reduce the deformity. **C:** The ankle was then immobilized in plantar flexion, which is the proper position for this type of fracture.

FIGURE 24-21. A and B: Unstable distal metadiaphyseal fracture of the tibia and fibula in a 15-year-old girl. **C:** This fracture was stabilized with percutaneous pins because of marked swelling and fracture instability.

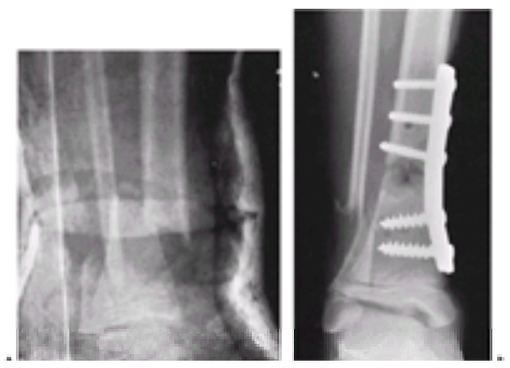

FIGURE 24-22. A: Anteroposterior radiograph of a distal one-third tibia/fibula fracture in a 9-year-old girl with a closed head injury and severe spasticity. The initial reduction in a cast could not be maintained. **B:** An open reduction and internal fixation with a medial buttress plate was performed to achieve and maintain the alignment.

COMPLICATIONS ASSOCIATED WITH DIAPHYSEAL TIBIA/FIBULA FRACTURES

Compartment Syndrome

The anterior compartment of the leg includes the extensor hallucis, the extensor digitorum longus, and the tibialis anterior muscles. It is surrounded by the tibia, the fibula, the interosseous membrane, and the anterior fascia. A compartment syndrome may occur after either a minor closed fracture or a severe injury in which the interosseus membrane is disrupted (79). Schrock (90) also described compartment syndromes after derotational osteotomies of the tibia in children.

Compartment syndromes also have been reported in the other three compartments of the lower leg after trauma. Hemorrhage and soft tissue edema produce an elevation in the pressure within the myofascial compartment that impairs venous outflow. The small arterioles leading into the compartment become less efficient in delivering blood as venous outflow becomes occluded. The arterioles and capillaries close when the pressure in the compartment exceeds the pressure in the vessels. Ischemia soon follows.

Patients with a compartment syndrome complain of pain out of proportion to the severity of the injury. The compartment is firm to palpation. The patient may have a sensory defect in the distribution of the nerves that run through the compartment. Weakness of the muscles within the involved compartment and pain on passive motion of the toes also are common. Paralysis of the muscles in the involved compartment is a late finding.

Patients with a compartment syndrome of the deep posterior compartment have severe pain that increases with passive extension of the toes, plantar hyperesthesias, weakness of toe flexion, and tenseness of the fascia between the tibia and the triceps area in the distal medial part of the leg (82). Late complications include clawed toes and limited subtalar motion secondary to a fibrous contracture of the muscles in the deep posterior compartment (71).

Diagnosis

Direct intracompartmental pressure measurements at the level of the fracture provide an accurate assessment of compartment conditions and allow early fasciotomy to reduce the pressure. Whitesides et al. (99) designed an inexpensive apparatus that permits accurate measurement of compartment tissue pressure (Fig. 24-23). Other commercial devices also are available to measure compartment pressures. Normal tissue pressures are about 0 mm Hg. Vascular flow ceases in the microcirculation of an extremity by the time tissue pressures within a closed compartment reach the diastolic pressure. Compartment release should be performed when the pressures are within 20 to 30 mm Hg of the diastolic pressure. This is especially critical in a hypotensive polytrauma patient.

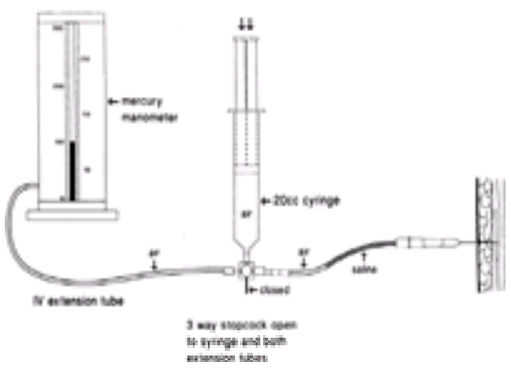

FIGURE 24-23. Whitesides' technique for measuring intercompartmental pressure. (Reprinted from Whitesides TE, Hanley TC, Morinotok K, et al. Tissue pressure measurement as a deterinant for the need of fasciotomy. *Clin Orthop* 1975;113:43; with permission.)

Treatment

First the cast should be bivalved and the padding divided. If after removal of circular wraps there is no relief, fasciotomy should be considered. Any child who has evidence of a compartment syndrome should undergo an emergent fasciotomy. The two-incision technique is preferred (Fig. 24-24). One incision is anterolateral and the second posteromedial. The fascia surrounding each of the four compartments should be opened from proximal to distal. If the wound can be closed primarily, it should be, but usually the wound is left open with retention sutures and a delayed closure is performed. Fibulectomy should not be performed for decompression of a compartment syndrome in a skeletally immature patient because subsequent fibular shortening can produce a valgus deformity at the ankle and may result in external tibial torsion and a severe gait impairment (17,55).

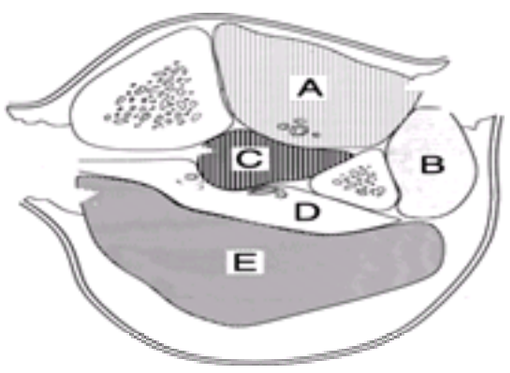

FIGURE 24-24. Preferred decompression technique for the lower leg, using medial and lateral incisions. **A:** Anterior compartment. **B:** Lateral compartment. **C:** Tibialis posterior. **D:** Posterior compartment. **E:** Superficial posterior compartment. (Reprinted from Alonso JE. The initial of evaluation of the injured child: musculoskeletal injuries. In: MacEwen G, Kasser J, Heinrich SD, eds. *Pediatric fracture: the practical approach to assessment and treatment.* Baltimore: Williams & Wilkins, 1993; with permission.)

Irreversible injury to muscles and nerves begins after approximately 5 hours of ischemia (91). Ninety percent of muscle fibers show evidence of injury after 8 hours of ischemia (65). Hyperesthesia, motor defects, and decreased pulses are late changes and denote significant tissue injury. They occur only after the ischemia has been well established and the injury is permanent (71,99).

Vascular Injuries

Vascular injuries associated with tibial fractures are uncommon in children; however, when they do occur, the sequelae can be devastating. In an evaluation of 14 patients with lower extremity fractures and concomitant vascular injuries, Allen et al. (39) noted that only 3 children returned to normal function. One factor leading to a poor outcome was a delay in diagnosis. Evaluation for vascular compromise is imperative (during the primary and secondary trauma surveys) in all children with tibial fractures.

The tibial fracture most frequently associated with vascular injury is in the proximal metaphysis. The anterior tibial artery is in close proximity to the proximal tibia as it passes over the interosseous membrane into the anterior compartment (63,68). Distal tibial fractures also are associated with injuries to the anterior tibial artery. The vessels are injured when the distal fragment is translated posteriorly. Posterior tibial artery injury is rare.

Angular Deformity

Spontaneous correction of axial malalignment after a diaphyseal fracture of a child's forearm or femur is common. Remodeling of a malaligned tibial fracture, however, often is incomplete (Fig. 24-25) (45).

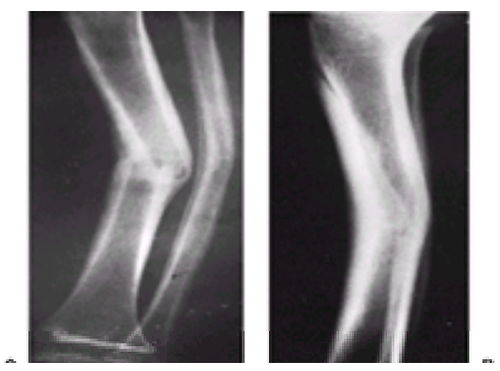

FIGURE 24-25. Four-year, two-month old child with a middle one-third transverse tibia fracture and a plastically deformed fibula fracture. **A:** Lateral view shows 20 degrees posterior angulation. **B:** The deformity is still 15 degrees 4 years after the injury.

Swaan and Oppers (97) evaluated 86 children treated for fractures of the tibia. The original angulation of the fracture was measured on radiographs in the sagittal and frontal projections. Girls 1 to 8 years of ge and boys 1 to 10 years of age demonstrated moderate spontaneous correction of residual angulation after union. In girls 9 to 12 years of age and boys 11 to 12 years of age, approximately 50% of the angulation was corrected. No more than 25% of the deformity was corrected in children over 13 years of age. Bennek and Steinert (41) found that a recurvatum malunion of more than 10 degrees did not completely correct. Twenty-six of 28 children with varus or valgus deformities at union had significant residual angular deformities at follow-up. Valgus deformities had a worse outcome because the tibiotalar joint was left in a deficient position.

Weber et al. (13) demonstrated that a fracture with varus malalignment of 5 to 13 degrees completely corrected at the level of the physis. Most children with valgus deformities of 5 to 7 degrees did not have a full correction.

Hanson et al. (6) reported 102 pediatric tibial fractures, 25 of which had malunions of 4 to 19 degrees. Angular malunions ranged from 3 to 19 degrees at follow-up, without a single patient having a complete correction. The spontaneous correction was approximately 13.5% of the total deformity. Shannak (11) reviewed the results of treatment of 117 children with tibial shaft fractures treated in above-the-knee casts. Deformities in two planes did not remodel as completely as those in one plane. The smallest correction occurred in posteriorly angulated fractures, followed by fractures with a valgus malalignment (Fig. 24-26). Spontaneous remodeling of malunited tibial fractures in children has been reported to stop 18 months after fracture (6).

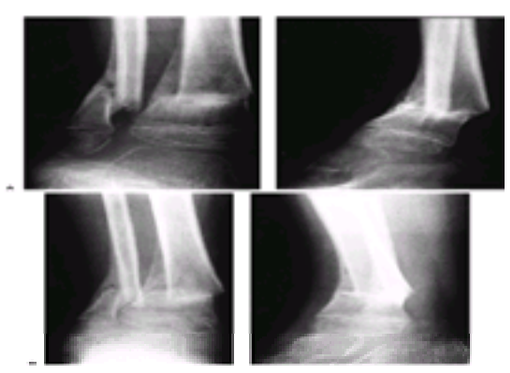

FIGURE 24-26. A: Anteroposterior and lateral radiographs 2 months after injury in a 6-year-old boy reveal a valgus and an anterior malunion at the fracture. **B:** One year later, the child still has a moderate valgus and anterior malalignment of the distal fractured segment. This malalignment produced painful hyperextension of the knee at heel strike during ambulation.

Malrotation

Because rotational malalignment of the tibia does not spontaneously correct with remodeling (6), all malrotation should be avoided. A rotational computerized tomographic evaluation can be performed if there is any question about the rotational alignment of the fracture.

Rotational malalignment of more than 10 degrees may produce significant functional impairment and necessitate a derotational osteotomy of the tibia. The derotational osteotomy should be performed in the supramalleolar aspect of the distal tibia. The tibia is osteotomized and internally fixed. The fibula is left intact.

Leg Length Discrepancy

Hyperemia associated with fracture repair stimulates the physes in the involved leg, producing growth acceleration. Tibial growth acceleration after fracture is less than that seen after femoral fractures in children of comparable ages. Shannak (10) showed that the average growth acceleration of a child's tibia after fracture is approximately 4.5 mm. Comminuted fractures have the greatest risk of accelerated growth and overgrowth.

Swaan and Oppers (97) reported that young children have a greater chance for overgrowth than older children. Accelerated growth after tibial fracture occurs in children under 10 years of age, whereas older children may have a mild growth inhibition associated with the fracture (6). The amount of fracture shortening also has an effect on growth stimulation. Fractures with significant shortening have more physeal growth than fractures without shortening at union (10). The presence of angulation at union does not affect the amount of overgrowth (59).

Upper Tibial Physeal Closure

Morton and Starr (83) reported closure of the upper tibial physis after fracture in two children. Both patients sustained a comminuted fracture of the tibial diaphysis without a concomitant injury of the knee. Both fractures were reduced and stabilized with Kirschner wires placed distal to the tibial tubercle. A genu recurvatum deformity developed after the anterior physis closed.

Smillie (94) reported one child who had an open tibial fracture complicated by a second fracture involving the supracondylar aspect of the femur. This patient also developed a recurvatum deformity secondary to closure of the anterior proximal tibial physis. At present, no universally acceptable explanation can be given for this phenomenon. Some patients have iatrogenic closure after placement of a proximal tibial traction pin, the application of pins and plaster, or the application of an external fixation device. Other children have an undiagnosed injury of the tibial physis at the time of the ipsilateral tibial diaphyseal fracture (74). Regardless of etiology, closure of the physis produces a progressive recurvatum deformity as the child grows.

Delayed Union and Nonunion

Delayed union and nonunion are uncommon after tibial fractures in children. The use of an external fixation device or infection after operative intervention may lengthen the time to union in some patients. Inadequate immobilization that allows patterned motion also can slow the rate of healing. A fibulectomy approximately 4 cm from a tibial nonunion allows compression at the nonunion site and induces healing (Fig. 24-27). A posterolateral bone graft also is an excellent technique to produce union in younger children (Fig. 24-28). Adolescents near skeletal maturity can be treated with a reamed intramedullary nail, with a concomitant fibular osteotomy and correction of angulation at the nonunion site performed as necessary (Fig. 24-29).

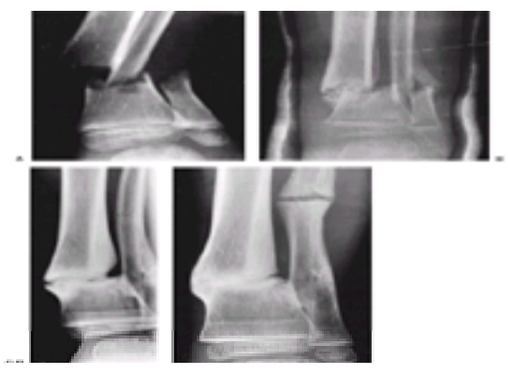

FIGURE 24-27. A: Anteroposterior radiograph of the distal tibia and fibula in a 5-year-old boy with an open fracture. **B:** Early callus formation is seen 1 month after injury. **C:** The tibia has failed to unite 10 months after injury. **D:** The patient underwent a fibulectomy 4 cm proximal to the tibial nonunion. The tibial fracture united 8 weeks after surgery.

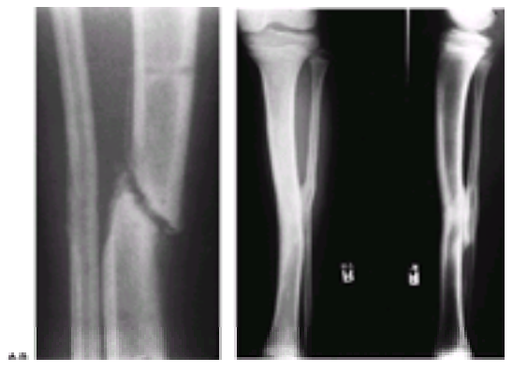

FIGURE 24-28. A and B: Posterolateral tibial bone graft for a nonunion of an open tibia fracture.

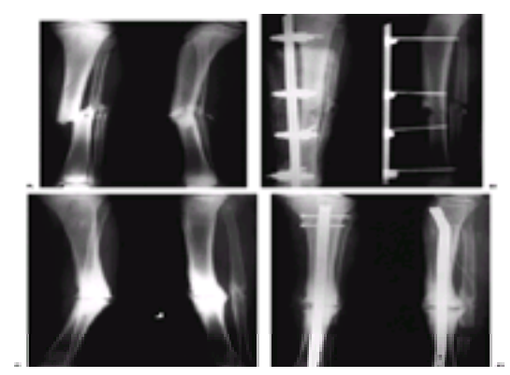

FIGURE 24-29. A: Anteroposterior and lateral radiographs of a 14-year-old adolescent who was struck by a car, sustaining a grade IIIB open fracture of the tibia. **B:** Anteroposterior and lateral radiographs of the tibia after irrigation and debridement, and application of an external fixation device. **C:** The patient developed a nonunion at the tibia, which progressively deformed into an unacceptable varus alignment. **D:** The nonunion was treated with a fibular osteotomy followed by a closed angular correction of the deformity and internal fixation with a reamed intramedullary nail.

SPECIAL FRACTURES

Toddler's Fractures

External rotation of the foot with the knee fixed in an infant or toddler can produce a spiral fracture of the tibia without a concomitant fibular fracture (Fig. 24-30). This fracture pattern was first reported by Dunbar et al. (108) in 1964. The traumatic episode often is unwitnessed by the adult caretaker. Most children with this injury are under 6 years of age. Sixty-three of 76 such fractures reported by Dunbar et al. were in children under 2½ years of age. Spiral tibial fractures occur in boys more often than in girls and in the right leg more often than in the left. The average age at injury in one study was 27 months. Most children report tripping or twisting their ankles. Occasionally, a child sustains a toddler's fracture in a fall from a height (104,140).

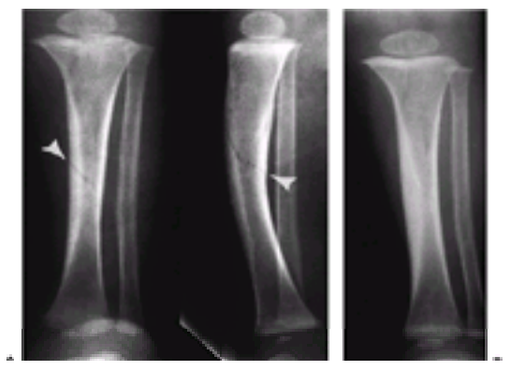

FIGURE 24-30. A: Anteroposterior and lateral radiographs of an 18-month-old child who presented with refusal to bear weight on her leg. Note the spiral middle one-third “toddler's” fracture (*arrows*). **B:** This fracture healed uneventfully after 4 weeks of immobilization in a cast.

Oujhane et al. (129) analyzed the radiographs of 500 acutely limping toddlers and identified 100 in whom a fracture was the etiology of the gait disturbance. The most common site of fracture was the distal metaphysis of the tibia. The fibula was fractured with the tibia in 12 of the 56 tibial fractures. Only one physeal injury was noted.

The examination of a child with an acute limp starts on the uninvolved side. This serves as a control for the symptomatic extremity. The examination begins at the hip and proceeds to the thigh, knee, lower leg, ankle, and foot. It is important to note the areas of point tenderness, an increase in local temperature, and any swelling or bruising of the leg (140).

Radiographs of the tibia and fibula should be obtained in both anteroposterior and lateral projections. An internal oblique view can be helpful in identifying a nondisplaced toddler's fracture. Fluoroscopy also may assist in the identification of subtle fractures. Occasionally, a fracture line cannot be identified, and the first evidence of fracture becomes apparent radiographically when periosteal new bone forms 1 week to 10 days after the injury (Fig. 24-31). Technetium radionuclide imaging can assist in the diagnosis of radiographically unapparent fractures. A patient with a spiral fracture of the tibia has diffuse increased uptake of tracer throughout the affected bone (black tibia). This can be differentiated from infection because infection tends to produce a local area of increased tracer uptake (108).

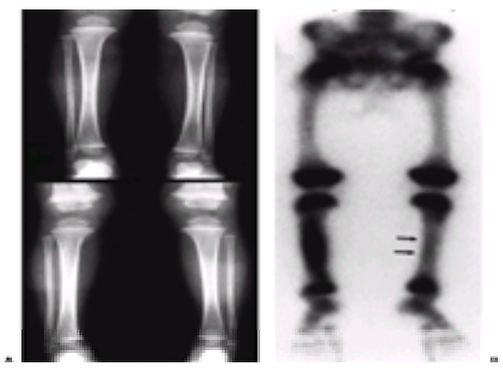

FIGURE 24-31. A: An anterior posterior radiograph of the tibia is in a 3-year-old child who refused to bear weight on the right leg 3 weeks before presentation. The history of obvious trauma was absent. His parents brought him into the hospital also when he refused to weight bear on his left leg. The radiographs revealed periosteal new bone formation in the mid-shaft of the right tibia. There was also tenderness to palpation in the mid-left tibia as well despite normal radiographs. **B:** A bone scan was obtained which showed increased uptake in both the left and right tibia. There was significantly less uptake on the left side, the more recent injury.

A child with a toddler's fracture should be immobilized in a bent knee, long leg cast for approximately 3 weeks. Most children require an additional 2 weeks of immobilization in a below-the-knee walking cast once the above-the-knee cast is removed.

Bicycle Spoke Injuries

Bicycle spoke injuries normally occur when a bicycle overturns and the child's foot is thrust forcibly between the spokes of the turning wheel (Fig. 24-32). This produces a severe compression or crushing injury to the soft tissues of the foot and ankle. An oblique or spiral fracture of the tibia also can occur (Fig. 24-33). The injury to the foot, ankle, and lower leg can be compounded when the child's foot is extracted forcibly from the spokes of the bicycle. This scenario occurs most commonly when two children are riding a bicycle designed for one, with the injured passenger riding on the handlebars or the rear fender (111,126).

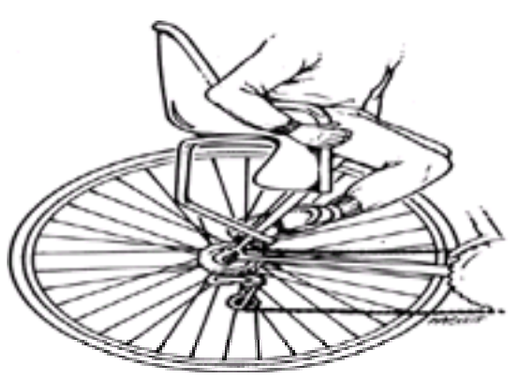

FIGURE 24-32. The mechanism of a bicycle spoke injury. The foot is impinged between the spokes of the wheel and the frame of the bike.

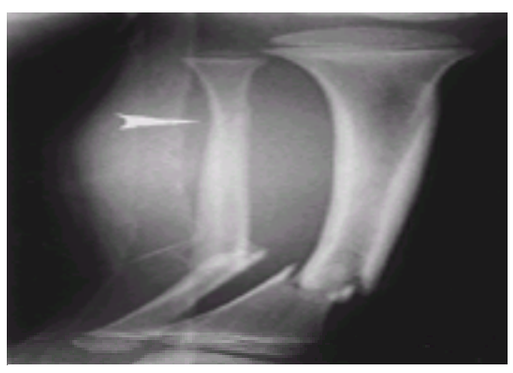

FIGURE 24-33. Oblique radiograph of a 4-year-old child who sustained an oblique fracture of the distal tibia and transverse fracture of the fibula when his foot was caught in the spokes of a bicycle. Note the proximal fibular fracture (*arrow*).

Izant et al. (120) reviewed 60 bicycle spoke injuries in children under 14 years of age. The most common age range of injury was 2 to 8 years.

The initial appearance of the extremity in a child with a bicycle spoke injury may be deceiving. The foot often appears normal or may show only minor skin abrasions. The patient often presents 24 to 48 hours after the accident complaining of a painful swollen foot and leg. This injury is similar to a “wringer” injury of the arm because the initial examination may not reveal the true extent of the injury. Izant et al. (120) identified three components to this trauma: (a) a laceration of the tissue from the knifelike action of the spoke, (b) a crushing from the impingement between the wheel and the frame of the bicycle, and (c) a shearing injury from the coefficient of these two forces. The laceration created by this injury often involves the malleoli, the Achilles tendon area of the heel, and the dorsum of the foot. A child with a bicycle spoke injury may require multiple debridements, and definitive treatment must await delineation of the necrotic area.

A child with a bicycle spoke injury should be admitted to the hospital because the extent of the damage may not be identified initially. Initial therapy consists of a mild compression dressing with a multilayered cotton bandage. The extremity is elevated and the child is kept at bedrest during the first 24 hours. A long leg splint is applied if a tibial fracture is present. The child may ambulate with crutches non–weight bearing after that. Frequent inspection of the extremity must be made during the subsequent 48 hours. Debridement of devitalized tissue is performed as necrosis becomes apparent. Large areas of hematoma formation are treated with aspiration to prevent further elevation of the overlying skin. Wound closure with a split-thickness skin graft is performed if full-thickness skin loss occurs. Occasionally, a free flap may be required, but this is rare. Most patients regain normal function of the foot and ankle. The average time for complete healing may be 5 to 6 weeks (111,120,126). A child with a concomitant tibial fracture is placed in an above-the-knee non–weight-bearing cast at the completion of care for the foot injury (111). The tibial fracture may need to be stabilized with an external fixation device if the soft tissue loss on the foot and ankle is severe.

Floating Knee

Significant trauma can cause fractures involving both the femur and the tibia. In the past, these injuries often were treated with traction and casting (Fig. 24-34). The extent of the injuries often left permanent functional deficits when not aggressively managed (45,80).

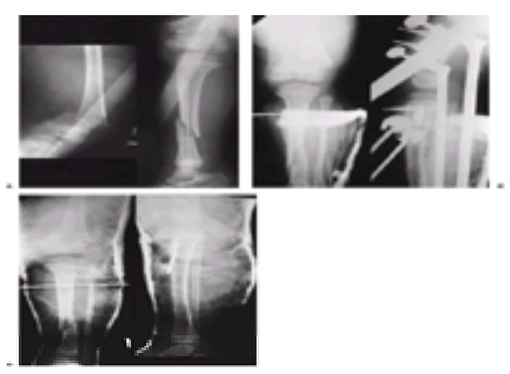

FIGURE 24-34. A: Ipsilateral fracture of the distal femur and tibia without an ipsilateral fibula fracture in a 5-year-old. **B:** The child was treated with tibial pin traction for the femoral injury (pin applied below the tibial tubercle) and a short leg splint for the tibia fracture initially. **C:** The child was placed into a spica cast after 2 weeks of traction. The tibial traction pin was used to help stabilize both fractures.

Most children over 2 years of age with ipsilateral femoral and tibial fractures are treated with operative stabilization of the femur and cast immobilization of the tibia after reduction. In children under 6 years of age, the femoral fracture can be stabilized with a unilateral external fixator or a plate with screws; in children 6 years of age and older, flexible intramedullary nails can be used. Open reduction and plate fixation are used for fractures in the subtrochanteric or supracondylar area of the femur in adolescents. The tibial fracture is reduced closed and stabilized with a long leg cast after the femoral fracture has been reduced and stabilized. Open tibial fractures and those in which a reduction cannot be maintained after casting are reduced (open if necessary) and stabilized with a unilateral external fixator (Fig. 24-35). If closed reduction is not possible, open reduction with pin fixation or external fixation is indicated.

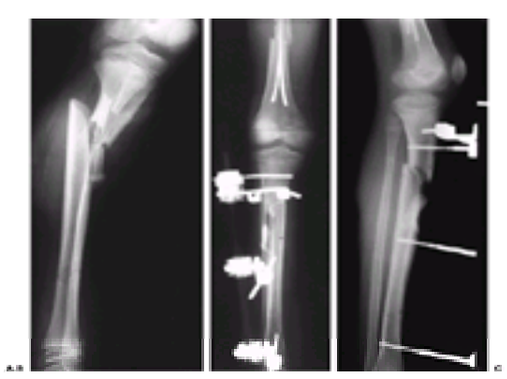

FIGURE 24-35. A: Anteroposterior radiograph of a grade IIIA segmental tibia fracture with an ipsilateral fibula and femur fracture in a 10-year-old boy with aplastic anemia. **B:** The tibia fracture was irrigated, debrided, reduced, and stabilized with an external fixation device. The femur fracture was stabilized with antegrade Ender nail fixation. **C:** Lateral radiograph of the tibia demonstrates the segmental nature of this fracture (*arrows*) and the excellent alignment achieved with the external fixation device.

Tibial Fracture in Paraplegic Children

Motor paralysis from poliomyelitis was once the most common cause of lower extremity weakness in children. Because these patients have sensation, fractures are identified early. Disease trends have changed, however. As late as 1958, 90% to 95% of children with myelomeningocele died in the first year of life, usually from a neurosurgical complication. Recent advances in neurosurgery and urology have significantly increased the life span of children with myelomeningocele. The mortality rate for these children is now 3% to 5%. Orthopaedic surgeons, therefore, are seeing an increasing number of paraplegic children who have sensory deficits (107,112,113).

Tibial fractures in children without sensation require special attention. Gillies and Hartung (113) are the first to report children with myelomeningocele who sustained pathologic fractures of the proximal tibia. These two children had tense hyperemic skin and radiographic evidence of exuberant new bone formation, suggesting a malignant tumor (Fig. 24-36). Both children had a biopsy because of this radiographic finding.

FIGURE 24-36. An undisplaced fracture of the proximal tibial metaphysis in a child with myelodysplasia. Note the exuberant new bone formation.

Fractures around the knee are common in children with paraplegia because of the length of the lower extremity and the association with joint contractures (116). These fractures are more common in children with flaccid paralysis than those with spastic paralysis (121,133).

Soutter (98) stressed that clinical findings such as swelling, warmth, and erythema are common in paraplegic children with a fracture. He stated that “fractures to the growth plate in paraplegic children often resemble osteomyelitis.”

James (121) reported 44 fractures in 22 children in a population of 122 children with myelomeningocele. The most common age range at fracture was 3 to 6 years. These fractures were more common in a flail limb. Only 6.6% of the patients with quadriceps activity had fractures, whereas 19% of those with no active muscle contraction (flail limb) had fractures. This incidence decreased to 12.5% in a group of children with spastic paralysis. The tibia and femur were the most common bones affected. The most common locations for tibial fractures were the distal diaphysis and distal metaphysis.

Parsch and Rossak (130) reported 31 fractures in 120 patients with myelomeningocele. They emphasized treatment with a wrap and splint until early fracture consolidation. To prevent “fracture disease,” they stressed early standing and walking to help reduce the degree of osteopenia these children develop.

Drummon and Freehafer (107) reported 58 fractures in 25 patients among 84 children with myelomeningocele. Ten fractures were in the tibia. Eleven of the 58 fractures occurred after the removal of a spica cast, suggesting that immobilization worsened osteopenia and increased the risk of subsequent fracture.

Complications in patients with paralysis and a tibial fracture are rare and usually are related to pressure sores produced by ill-padded casts. Early physeal arrest can occur, producing a leg length discrepancy, and physeal involvement is common in paralytic children with fractures (137). Golding (114) reported one physeal injury to the distal tibia in a child with myelomeningocele. Gyepes et al. (116) reported seven metaphyseal and physeal injuries in patients with myelomeningocele. Radiographs were characterized by an irregular, dense, widened physis and adjacent subperiosteal new bone formation. Stern et al. (138) reported bilateral distal tibial and fibular physeal injuries in a child with myelomeningocele.

Trauma probably is the primary factor producing the complex radiographic findings associated with a tibial fracture in a paralytic child (116). Repeated microtrauma can lead to a metaphyseal infraction, subperiosteal hemorrhage, and, perhaps, physeal hemorrhage. Subsequent healing produces endosteal and periosteal callus formation and some generalized osteopenia secondary to the immobilization (Fig. 24-36). The widening of the physis most likely is secondary to a disturbance of the normal reabsorption mechanism during bone development at the metaphysis. This results from frequent subclinical metaphyseal infractions. It also could be produced by hemorrhage into the physis itself.

Fracture of the tibia in a paralytic child can occur with minor trauma. Many fractures are nondisplaced, and nonoperative therapy is indicated. Displaced fractures are reduced closed and immobilized for 3 to 4 weeks in a bulky dressing or a posterior, molded, well-padded splint. The child should be fitted with an orthosis or placed back into a reciprocal gait orthosis (if the child already had one) after the immobilization is discontinued.

Lower extremity fractures are common after a child has been immobilized in a cast, especially after hip surgery. This finding has led to the term *fracture disease,* which describes multiple fractures secondary to osteopenia after immobilization. Because of this, a child predisposed to fractures after immobilization may benefit from a short course of in-hospital split Russell's traction with frequent general physical therapy for range of motion. The child should not be allowed to walk or crawl for approximately 7 days after the traction is discontinued. This allows the stiffness that accompanies the immobilization to improve.

Physeal injuries may require prolonged periods of immobilization. Healing is determined by the absence of local warmth and swelling and the reconstitution of the width of the physis radiographically (124).

Stress Fractures of the Tibia and Fibula

Roberts and Vogt (132) reported an “unusual type of lesion” in the tibia of 12 children in 1939. All of these were determined to be stress fractures involving the upper third of the tibial shaft. Since then, numerous reports of stress fractures involving the tibia and the fibula have been published (Fig. 24-34) (56,102,106,110,117,119,123,125,127,128,131,134,135,139).

The pattern of stress fractures in children differs from that in adults (105,106,136). In adults, the fibula is involved in stress fractures twice as often as the tibia; in children the tibia is affected more often than the fibula. The prevalence of stress fractures in boys and girls is equal.

A child with a stress fracture usually has an insidious onset of symptoms (105,106). There is evidence of local tenderness that worsens with activity. The child may have a painful limp. A toddler with a stress fracture will not bear weight on the involved extremity. The pain tends to be worse in the day and to improve at night and with rest. The knee and the ankle have full ranges of motion. Usually, there is no swelling at the fracture site (75,103,105,106,110,118).

Radiographs reveal changes consistent with a stress fracture approximately 2 weeks after the onset of symptoms (106). Radiographic evidence of fracture repair can manifest in one of three ways: localized periosteal new bone formation, endosteal thickening, or, rarely, a radiolucent cortical fracture line (Fig. 24-37) (75,105,106,117,135).

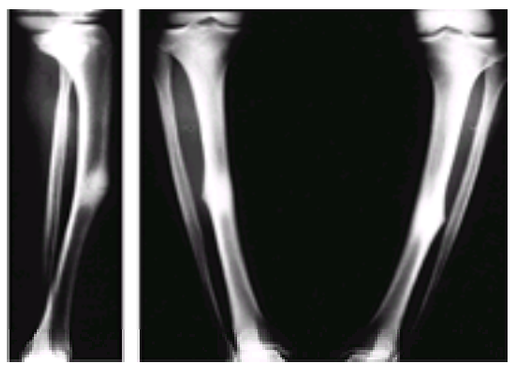

FIGURE 24-37. Bilateral mid-tibial stress fractures in an adolescent with genu varus.

Technetium radionuclide bone imaging reveals a local area of increased tracer uptake at the site of the fracture (Fig. 24-38). Computerized tomography rarely demonstrates the fracture line, but delineates increased marrow density and endosteal and periosteal new bone formation. It also may show soft tissue edema. Magnetic resonance imaging (75,118) shows a localized band of very low signal intensity continuous with the cortex. MR signaling can be diagnostic of stress fracture and differentiate it nicely from malignancy obviating the need for biopsy (Fig. 24-39).

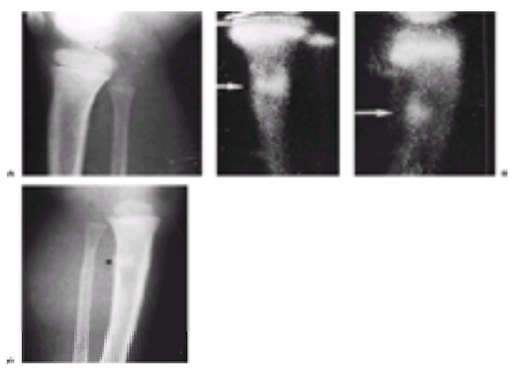

FIGURE 24-38. A: Lateral radiograph of the proximal tibia in a 9-year-old who complained of pain in the right leg. There was no history of trauma, and the radiographs were unremarkable. **B:** A bone scan 2 days after the onset of symptoms demonstrates increased tracer uptake in the proximal one third of the tibia in both the anteroposterior and the lateral projections (*arrows*). **C:** Increased bone density and subtle periosteal new bone formation was identified in the proximal tibia 3 weeks later (*arrows*). (Courtesy of James Conway, M.D.)

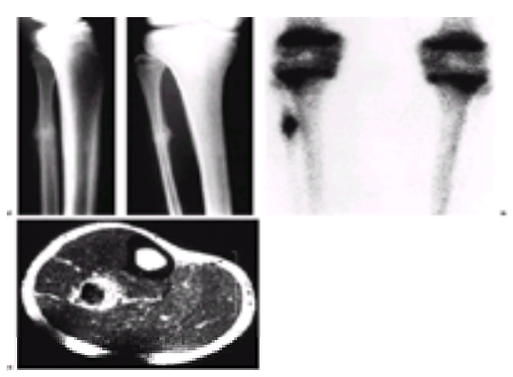

FIGURE 24-39. A: Stress fracture of the dyplasia of the fibula in a 14-year-old girl with mild genu varus. **B:** Bone scan of stress fracture showing marked increased tracer uptake. **C:** Magnetic resonance image demonstrates new central bone formation and an inflammatory zone around the fibular cortex. (Reprinted from Sharps CA, Cardea JA. Fractures of the shaft of the tibia and fibula. In: MacEwen GD, Kassar JR, Heinrich SD, eds. Pediatric fractures: a practical approach to assessment and treatment. 1993:324; with permission.)

Stress fractures occur when the force applied to a bone is exceeded by the bone's capacity to withstand it. Initially, osteoclastic tunnel formation increases. These tunnels normally fill with mature bone. With continued force, cortical reabsorption accelerates. New bone is produced to splint the weakened cortex. This bone is immature, however, and does not have the strength of the bone it replaces. A fracture occurs when bone reabsorption outstrips bone production. When the offending force is reduced or eliminated, bone production exceeds bone reabsorption. This produces cortical and endosteal widening with dense repair bone that later remodels to mature bone (109,122,129).

Tibia

The most common location for a tibial stress fracture is in the upper third. The child normally has a painful limp of gradual onset with no history of a specific injury. The peak incidence of tibial stress fractures in children is between 10 and 15 years of age. Pain is relieved with rest. The pain is described as dull, occurring in the calf near the upper end of the tibia on its medial aspect, and occasionally is bilateral. Physical findings include local tenderness on one or both sides of the tibial crest with a varying degree of swelling.

The treatment of a child with a stress fracture of the tibia (or fibula) begins with activity modification. An active child can rest in a long leg walking cast for 4 to 6 weeks followed by gradual increase in activity. Nonunions of stress fractures of the tibia have been described. Green (114) reported six nonunions, three of which were in children. Two required excision of the nonunion site with iliac crest bone grafting. The third was treated by electromagnetic stimulation. In all three, the stress fractures occurred in the middle third of the tibia.

Fibula

Pediatric fibular stress fractures normally occur between the ages of 2 and 8 years (115). The fractures are normally localized to the distal third of the fibula.

The child presents with a limp and may complain of pain. Tenderness is localized to the distal half of the fibular shaft. Swelling normally is not present. The obvious bony mass commonly seen in a stress fracture of the fibula in an adult is normally not seen in a comparable fracture in a child.

No radiographic abnormalities are identified in the first 10 days to 2 weeks after the symptoms begin. The earliest sign of a stress fracture of the fibula is the presence of “eggshell” callus along the shaft of the fibula (Fig. 24-37) (103). Fracture itself cannot always be seen because the periosteal callus may obscure the changes in the narrow canal. Radionuclide bone imaging can help to identify stress fractures before the presence of radiographic changes.

The differential diagnosis includes sarcoma of bone, osteomyelitis, and a soft tissue injury without accompanying bony injury. Treatment consists of rest or, in a very active child, a short leg walking cast for 4 to 6 weeks.

DISTAL TIBIAL AND FIBULAR FRACTURES

R. JAY CUMMINGS

Injuries to the distal tibial and fibular physes are generally reported to account for 25% to 38% of all physeal fractures (57), second in frequency only to distal radial physeal fractures (93); however, Peterson et al. (94) reported that phalangeal physeal fractures were most common, followed by physeal injuries of the radius and ankle. In skeletally immature individuals, physeal ankle fractures are slightly more common than fractures of the tibial or fibular diaphysis (80). Up to 58% of physeal ankle fractures occur during sports activities (45,127) and account for 10% to 40% of all injuries to skeletally immature athletes (87,91,115). Physeal ankle fractures are more common in males than in females (112). Tibial physeal fractures most commonly occur between the ages of 8 and 15 years, and fibular fractures between the ages of 8 and 14 years (112).

Although Foucher (39) reported the first pathologic study of these injuries in 1863, Poland's 1898 monograph (97) is generally recognized as the most extensive early study of physeal fractures. He pointed out that in children ligaments are stronger than physeal cartilage; forces that result in ligament damage in adults cause fractures of the physes in children. In 1922, Ashhurst and Bromer (4) published a thorough review of the literature and the results of their own extensive investigations and described a classification of ankle injuries based on the mechanism of injury. This classification did not differentiate between ankle injuries in adults and those in children. Bishop (8) in 1932 classified 300 ankle fractures according to Ashhurst and Bromer's system; 33 fractures were physeal injuries, and the grouping of these injuries according to mechanism of injury represents one of the first attempts to classify physeal ankle injuries.

Aitken's (2) study of 21 physeal ankle injuries in 1936 is one of the first to attempt to determine the results of treatment of these injuries; he also outlined an anatomic classification. Only one of his patients (5%) had a deformity after fracture, in contrast to McFarland (82), who in 1932 reported deformities in 40% of a larger series of patients. In 1955, Caruthers and Crenshaw (21) reported 54 physeal ankle fractures, which were classified according to their modification of Ashhurst and Bromer's system. They confirmed that growth-related deformities were frequent after adduction (Salter-Harris type III and IV injuries) fractures and infrequent after fractures caused by external rotation, abduction, and plantarflexion (Salter-Harris type II injuries). Spiegel and colleagues (112), in a 1978 review of 237 physeal ankle fractures, reported a high incidence of growth abnormalities after Salter-Harris type III and IV injuries but also found complications in 11 (16.7%) of 66 patients with Salter-Harris type II fractures. Most of these patients had only mild shortening, but 6 had angular deformities that did not correct with growth. Based on the results of 65 physeal ankle fractures, Kling and co-workers (69) concluded that the frequency of growth-related deformities could be reduced by open reduction and internal fixation of Salter-Harris III and IV fractures.

A separate group of fractures, occurring in adolescents and known as transitional fractures, has been identified. Such fractures, which include juvenile Tillaux and triplane fractures with two to four fracture fragments, have been described by Kleiger and Mankin (67), Marmor (81), Cooperman and co-workers (27), Karrholm (61), and Denton and Fischer (31).

DIAGNOSIS

Patients with significantly displaced fractures have severe pain and obvious deformity. The position of the foot relative to the leg may provide important information about the mechanism of injury (Fig. 25-1) and should be considered in planning reduction. The status of the skin, pulses, and sensory and motor function should be determined and recorded. Tenderness, swelling, and deformity in the ipsilateral leg and foot should be noted. In patients with tibial shaft fractures, the ankle should be carefully evaluated clinically and radiographically.

FIGURE 25-1. Severe clinical deformity in a 14-year-old boy with an ankle fracture. It is obvious without radiographs that internal rotation will be needed to reduce this fracture.

Patients with nondisplaced or minimally displaced ankle fractures often have no deformity, minimal swelling, and moderate pain. Because of their benign clinical appearance, such fractures may be easily missed if radiographs are not obtained. The fact that all physicians have an obligation to try to minimize unnecessary radiographs, both to avoid unnecessary irradiation of patients and for cost containment, creates a dilemma for physicians evaluating pediatric ankle injuries. Guidelines known as the Ottawa Ankle Rules have been established for adults to try to determine which injuries require radiographs (114). The indications for radiography according to the guidelines are complaints of pain near a malleolus with either inability to bear weight or tenderness to palpation at the malleolus. Chande prospectively studied 71 children with acute ankle injuries to determine if these guidelines could be applied to pediatric patients with ankle injuries (25). It was determined that if radiographs were obtained only in children who had tenderness over the malleoli and an inability to bear weight, a 25% reduction in radiographic

examinations could be achieved without missing any fractures. Therefore, a systematic search for localized tenderness, keeping in mind the physeal anatomy of the ankle, is helpful in determining when to order radiographs as well as how to interpret them.

For patients with obvious deformities, anteroposterior and lateral radiographs centered over the ankle may provide sufficient information to plan treatment. Although obtaining views of the joint above and below is recommended for most fractures, obtaining a film centered over the mid-tibia to include the knee and ankle joints on the radiograph significantly decreases the quality of ankle views and is not recommended.

For patients without obvious deformities, a high-quality mortise view of the ankle is essential in addition to anteroposterior and lateral views. On a standard anteroposterior view, the lateral portion of the distal tibial physis is usually partially obscured by the distal fibula. The vertical component of a triplane or Tillaux fracture can be hidden behind the overlying fibular cortical shadow (73). A study by Vangsness and co-workers (121) found that diagnostic accuracy was essentially equal when using anteroposterior, lateral, and mortise views compared with using only mortise and lateral views. Therefore, if only two views are to be obtained, the anteroposterior view may be omitted and lateral and mortise views obtained.

Haraguchi et al. described two special views designed to detect avulsion fractures from the lateral malleolus that are not visible on routine views and to distinguish whether they represent avulsions of the anterior tibiofibular ligament or the calcaneofibular ligament attachments (49). The anterior tibiofibular ligament view is made by positioning the foot in 45 degrees of plantar flexion and elevating the medial border of the foot 15 degrees. The calcaneofibular ligament view is obtained by rotating the leg 45 degrees inward.

Stress views may occasionally be needed to rule out ligamentous instability (Fig. 25-2), although ligamentous injury at the ankle is infrequent in skeletally immature patients. Stress views may be considered to document a Salter-Harris type I fracture, but a patient with clinical signs of this fracture should be treated appropriately, regardless of stress view findings. Stress views may help document lack of motion at the fracture in an apparent nonunion (Fig. 25-3).

FIGURE 25-2. A: Stress radiograph showing abnormal varus tilt in a 5-year-old who had sustained a left ankle injury. Note the small avulsion fracture from the talus (*arrow*) and soft tissue swelling laterally. **B:** Comparative stress radiograph of the right ankle.

FIGURE 25-3. A: Anteroposterior radiograph of a 10-year-girl after 12 weeks of immobilization for an initially nondisplaced Salter-Harris type III fracture of the distal tibia. **B:** Stress view showing no motion at the fracture site.

Bozic et al. studied the age at which the radiographic appearance of the incisura fibularis, tibiofibular clear space, and tibiofibular overlap develop in children (15). The purpose of their study was to facilitate the diagnosis of distal tibiofibular syndesmotic injury in children. They found that the incisura became detectable at a mean age of 8.2 for girls and 11.2 years for boys. The mean age at which tibiofibular overlap appeared on the anteroposterior view was 5 years for both sexes; on the mortise view, it was 10 years for girls and 16 years for boys. The range of clear space measurements in normal children was 2 to 8 mm, with 23% of children having a clear space of greater than 6 mm, a distance considered abnormal in adults.

Computed tomography (CT) is useful in the evaluation of intraarticular fractures, especially juvenile Tillaux and triplane fractures (Fig. 25-4) (54). In the past, some physicians preferred plain tomograms (126). A lower cost appears to be their only advantage over CT scans. CT evaluations involve less radiation to the patient and in many institutions are now easier to obtain than are plain tomograms. Cuts are generally made in the transverse plane. With thin cuts localized to the joint, it is possible to generate high-quality reconstructions that allow evaluation in the coronal and sagittal planes without repositioning the ankle. With plain tomography the transverse anatomy can only be deduced from the anteroposterior and lateral tomograms. Three-dimensional CT reconstructions rarely add further useful information. Other indications for CT scanning are discussed in the section on Treatment.

FIGURE 25-4. A: Anteroposterior view of a 13-year-old boy with a tibial fracture extending into the ankle joint. It is unclear on this view whether the metaphyseal fracture is a separate injury or part of the intraarticular fracture. **B:** Transverse CT scan a few millimeters above the ankle joint confirmed the triplane nature of this injury. **C:** Anteroposterior reconstruction from the CT scan shows 3 mm of displacement at the fracture site in the tibial epiphysis.

Magnetic resonance imaging (MRI) has been reported to be occasionally helpful in the identification of osteochondral injuries to the joint surfaces in children with ankle fractures (66). Smith and associates (111) found that of four patients with acute (3–10 days) physeal injuries, MRI showed that three had more severe fractures

than indicated on plain films (Fig. 25-5). Early MRI studies (3–17 weeks after injury) not only added information about the pattern of physeal disruption but also supplied early information about the possibility of growth abnormality.

FIGURE 25-5. A: Follow-up radiograph of a 7-year-old boy 1 week after an initially nondisplaced Salter-Harris type III fracture from a supination–inversion injury of the distal tibia. **B:** Because of the incomplete ossification of this area and concern that the fracture might have displaced, magnetic resonance imaging was performed. Note that the distance between the medial malleolus and the talus is greater than the distance between the talus and the distal tibia or lateral malleolus, confirming displacement of the fracture.

Carey et al. obtained MRI studies on 14 patients with known or suspected growth plate injury (20). The MRI detected five radiographically occult fractures in the 14 patients, changed the Salter-Harris classification in 2 patients, and resulted in a change in treatment plan in 5 of the 14 patients studied. These studies would seem to contradict an earlier study by Petit et al. that showed only 1 patient in a series of 29 patients in whom MRI revealed a diagnosis different from that made on plain films (96). Later (>6 months after injury) scans have been reported useful for mapping physeal bars (42,52).

MECHANISM OF INJURY AND CLASSIFICATION

Classifications of ankle fractures are of two broad types: anatomic (2,89,95,106,112) and mechanism-of-injury (4,8,71). Anatomic classifications divide fractures into groups based on the parts of the epiphyses or metaphyses that make up the fracture fragments. Mechanism-of-injury classifications are based on the nature of the force that creates the fractures and often include the position of the foot at the time the force is applied. Most mechanism-of-injury classifications include the anatomic type of injury produced by a particular mechanism.

Anatomic classifications (Fig. 25-6) are effective for rapid communication because most have few groups without multiword titles that require visualization of movements that sometimes seem incompatible with the position of the foot on the ground. Because they are applicable to all physes, anatomic classifications are used more frequently and are easier to recall than mechanism-of-injury classifications. Mechanism-of-injury classifications are considered by some to be more precise because they reflect not only the anatomic fracture pattern but also the position of the fragments in relation to each other. This increased precision, however, may result in less rapid and possibly more confusing communication.

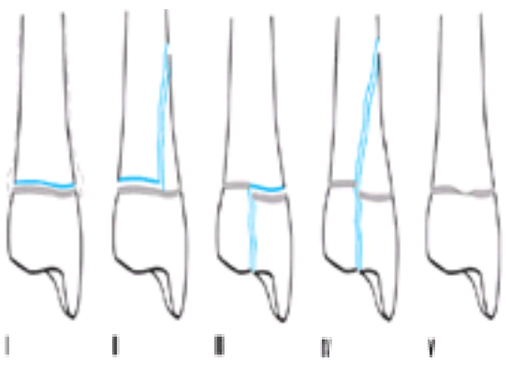

FIGURE 25-6. Salter-Harris anatomic classification as applied to injuries of the distal tibial epiphysis.

Both anatomic and mechanism-of-injury classifications can provide useful information for determining appropriate treatment. The prognoses for growth and deformity have been predicted on the basis of both types of classification (62,63,112). A theoretical advantage of mechanism-of-injury classifications is that identification of the force producing the injury might give even more information about the possible development of growth arrest than anatomic classifications. For example, a Salter-Harris type III or IV fracture of the tibia produced by a shearing or crushing force might be more likely to result in growth arrest than is a similar injury produced by an avulsion force (Fig. 25-7). However, it is difficult to establish that one type of classification is superior to the other in this regard because of the relatively small numbers of patients reported, the varying ages of patients in most series, and questions about the reproducibility of various classifications.

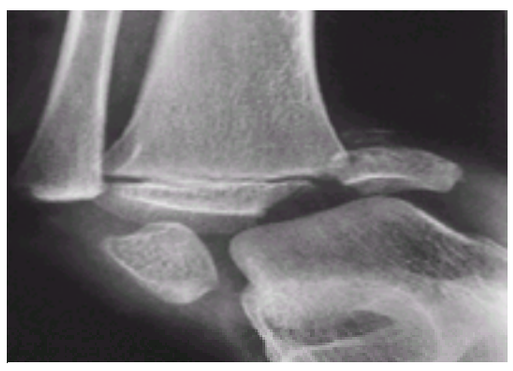

FIGURE 25-7. Comminuted Salter-Harris type IV fracture of the distal tibia and displaced Salter-Harris type I fracture of the distal fibula produced by an inversion (shearing) mechanism in a 10-year-old girl.

An important benefit of mechanism-of-injury classifications (Table 25-1) is that they provide clues that may be helpful in planning closed reduction: the mechanism of injury is simply reversed to reduce the fracture. Surgeons who rely on anatomic classifications usually attempt to obtain reduction by returning the displaced fragments directly to their proper anatomic locations. In reality, surgeons who use either classification probably reduce most fractures in similar manners.

	Applied Force							
Ashhurst-Bromer (adult)								
External rotation	Abduction	Abduction	–	Compression	–			
Carothers-Crenshaw (child)

Lauge-Hansen pronation: external rotation of foot, abduction of hindfoot, and eversion of forefoot. Lauge-Hansen supination: external rotation of foot, abduction of hindfoot, and inversion of forefoot.

TABLE 25-1. REPRESENTATIVE MECHANISM OF INJURY CLASSIFICATIONS

Any classification system that cannot be easily remembered and reproducibly applied will ultimately prove to be less than useful. Thomsen and co-workers (118) studied the reproducibility of the Lauge-Hansen (mechanism-of-injury) and Weber (anatomic) classifications in a series of adult ankle fractures. After all investigators in the study had received a tutorial on both systems and their application, they were asked to classify 94 fractures. On the first attempt, only the Weber classification produced an acceptable level of interobserver agreement. On a second attempt, the Weber classification and most of the Lauge-Hansen classification achieved an acceptable level of interobserver agreement. These investigators concluded that all fracture classification systems should have demonstrably acceptable interobserver agreement rates before they are adopted, an argument made even more forcefully in an editorial by Burstein (18). Vahvanen and Aalto (119) compared their ability to classify 310 ankle fractures in children with the Weber, Lauge-Hansen, and Salter-Harris classifications. They found that they were “largely unsuccessful” using the Weber and Lauge-Hansen classifications but could easily classify the fractures using the Salter-Harris system.

The most widely accepted mechanism-of-injury classification of ankle fractures in children is that described by Dias and Tachdjian (34) (Fig. 25-8), who modified the Lauge-Hansen classification based on their review of 71 fractures. Their original classification (1978) consisted of four types in which the first word refers to the position of the foot at the time of injury and the second word refers to the force that produces the injury. Four other types were subsequently added (116) (in 1985). Although these are designated differently, the first three have identifiable mechanisms of injury. *Axial compression injury* describes the mechanism of injury but not the position of the foot. *Juvenile Tillaux and triplane fractures* are believed to be caused by external rotation. The final category, *other physeal injuries,* includes diverse injuries, many of which have no specific mechanism of injury.

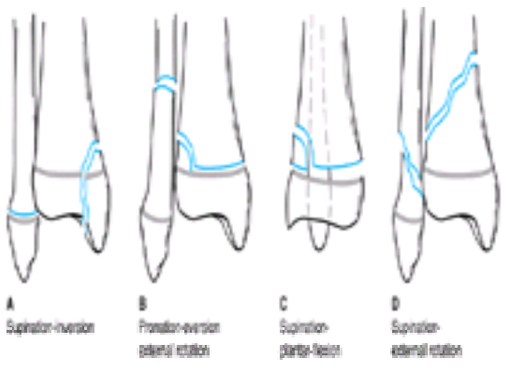

FIGURE 25-8. Dias-Tachdjian classification of physeal injuries of the distal tibia and fibula.

Classification of Ankle Fracture in Children (Dias-Tachdjian)

Supination–Inversion

Grade I: The adduction or inversion force avulses the distal fibular epiphysis (Salter-Harris type I or II fracture). Occasionally, the fracture is transepiphyseal; rarely, the lateral ligaments fail.

Grade II (Fig. 25-9): Further inversion produces a tibial fracture, usually a Salter-Harris type III or IV and rarely a Salter-Harris type I or II injury, or the fracture passes through the medial malleolus below the physis (Fig. 25-10).

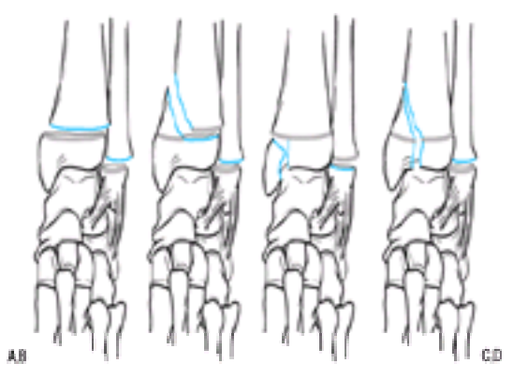

FIGURE 25-9. Variants of grade II supination–inversion injuries (Dias-Tachdjian classification). **A:** Salter-Harris I fracture of the distal tibia and fibula. **B:** Salter-Harris I fibula, Salter-Harris II tibia fractures. **C:** Salter-Harris I fibula, Salter-Harris III tibia fractures. **D:** Salter-Harris I fibula, Salter-Harris IV tibia fractures.

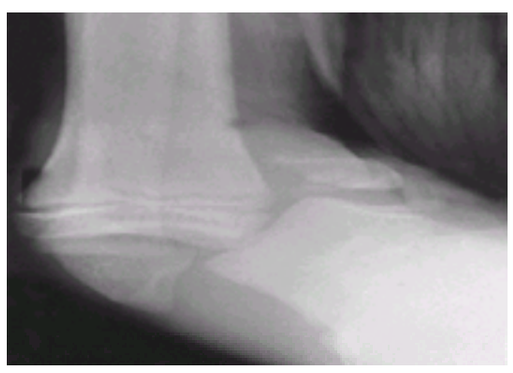

FIGURE 25-10. Severe supination–inversion injury with displaced fracture of the medial malleolus distal to the physis of the tibia.

Supination–Plantarflexion

The plantarflexion force displaces the epiphysis directly posteriorly, resulting in a Salter-Harris type I or II fracture. Fibular fractures were not reported with this mechanism. The tibial fracture usually is difficult to see on anteroposterior radiographs.

Supination–External Rotation

Grade I: The external rotation force results in a Salter-Harris type II fracture of the distal tibia (Fig. 25-11). The distal fragment is displaced posteriorly, as in a supination–plantarflexion injury, but the Thurston-Holland fragment is visible on the anteroposterior radiograph, with the fracture line extending proximally and medially. Occasionally, the distal tibial epiphysis is rotated but not displaced.

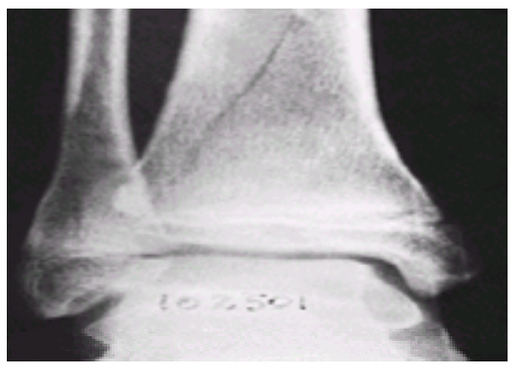

FIGURE 25-11. Stage I supination–external rotation injury in a 10-year-old child; the Salter-Harris type II fracture begins laterally.

Grade II: With further external rotation, a spiral fracture of the fibula is produced, running from anteroinferior to posterosuperior (Fig. 25-12).

FIGURE 25-12. Stage II supination–external rotation injury. **A:** Oblique fibular fracture is also visible on anteroposterior view. **B:** Lateral view shows the posterior metaphyseal fragment and posterior displacement.

Pronation–Eversion–External Rotation

A Salter-Harris type I or II fracture of the distal tibia occurs simultaneously with a transverse fibular fracture. The distal tibial fragment is displaced laterally and the Thurston-Holland fragment, when present, is lateral or posterolateral (Fig. 25-13). Less frequently, a transepiphyseal fracture occurs through the medial malleolus (Salter-Harris type II). Such injuries may be associated with diastasis of the ankle joint, which is uncommon in children.

FIGURE 25-13. A: According to the Dias-Tachdjian classification, this injury in a 12-year-old boy would be considered a pronation–eversion–external rotation injury resulting in a Salter-Harris type II fracture of the distal tibia and a transverse fibular fracture. **B:** The anterior displacement of the epiphysis, visible on the lateral view, however, makes external rotation an unlikely component of the mechanism of injury; the mechanism is more likely pronation–dorsiflexion.

Axial Compression

This is a Salter-Harris type V injury of the distal tibial physis. Initial radiographs usually show no abnormality, and the diagnosis is established when growth arrest is demonstrated on follow-up radiographs.

Juvenile Tillaux Fracture

This is a Salter-Harris type III fracture involving the anterolateral distal tibia. The portion of the physis not involved in the fracture is closed (Fig. 25-14).

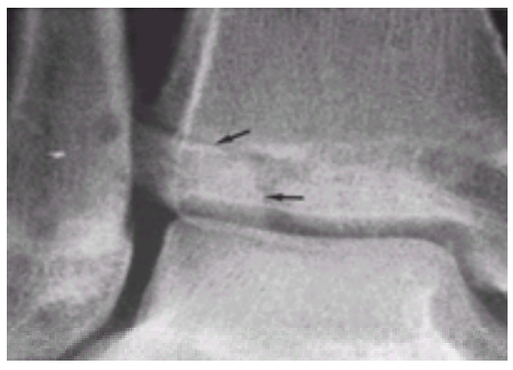

FIGURE 25-14. Salter-Harris type III fracture (juvenile Tillaux) (*arrows*) of the anterolateral portion of the distal tibial epiphysis in a 13-year-old girl.

Triplane Fracture

This group of fractures have the appearance of a Salter-Harris type III fracture on the anteroposterior radiograph and of a Salter-Harris type II fracture on the lateral radiograph.

Other Physeal Injuries

These are the fractures that do not fit into any of the other seven types (such as injuries to the perichondral ring and stress fractures) (Fig. 25-15).

FIGURE 25-15. Stress fracture of the distal tibia in normal 13-year-old child who complained of pain in his ankle after running. **A:** Initial radiographs were interpreted as being normal, although abnormal widening of the tibial physis was present. The ankle was immobilized for 10 days. **B:** Six weeks later, pain persisted and radiographs showed further widening and irregularity of the physis, with a faint periosteal new bone formation (*arrows*) around the distal tibial metaphysis.

Unusual Fracture Patterns

A number of accessory ossification centers and normal anatomic variations may cause confusion in the interpretation of plain films of the ankle (Fig. 25-16). In a group of 100 children between the ages of 6 and 12 years, Powell (99) found accessory ossification centers on the medial side (os subtibiale) in 20% and on the lateral side (os subfibulare) in 1%. If they are asymptomatic on clinical examination, these ossification centers are of little concern, but tenderness localized to them may indicate an injury. Stress views to determine motion of the fragments or bone scanning may occasionally be considered if an injury to an accessory ossification center is suspected.

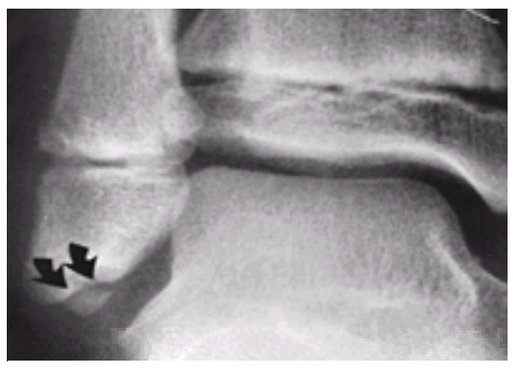

FIGURE 25-16. Secondary ossification center in the lateral malleolus (*arrows*) of a 10-year-old girl. Note the smooth border of the fibula and the ossification center. She also has a secondary ossification center in the medial malleolus.

Clefts in the lateral side of the tibial epiphysis may simulate juvenile Tillaux fractures, and clefts in the medial side may simulate Salter-Harris type III fractures (65). The presence of these clefts on a radiograph of a child with an ankle injury may result in overtreatment if they are misdiagnosed as a fracture. Conversely, attributing a painful irregularity in these areas to anatomic variation may lead to undertreatment (Fig. 25-17). Other anatomic variations include a bump on the distal fibula that simulates a torus fracture and an apparent offset of the distal fibular epiphysis that simulates a fracture.

FIGURE 25-17. A: Mortise view of the ankle of a 10-year-old girl who had slight swelling and tenderness at the medial malleolus after an “ankle sprain.” The ossicle at the tip of the medial malleolus was correctly identified as an os subtibiale. A subtle line extending from the medial physis to just distal to the medial tibial plafond (*arrow*) was believed to also be an anatomic variant. **B:** Four weeks after injury, soreness persisted and radiography clearly demonstrated a Salter-Harris type III

fracture.

ANATOMY

The ankle is the joint that most closely approximates a hinge joint. It is the articulation between the talus and the ankle mortise, which is a syndesmosis consisting of the distal tibial articular surface, the medial malleolus, and the distal fibula or lateral malleolus.

Ligamentous structures bind the distal tibia and fibula into the ankle mortise (Fig. 25-18). The anterior and posterior inferior tibiofibular ligaments course inferiorly from the anterior and posterior surfaces of the distal lateral tibia to the anterior and posterior surfaces of the lateral malleolus. The anterior ligament is important in the pathomechanics of transitional ankle fractures. Just anterior to the posteroinferior tibiofibular ligament is the broad, thick inferior transverse ligament, which extends down from the lateral malleolus along the posterior border of the articular surface of the tibia, almost to the medial malleolus. This ligament serves as a part of the articular surface for the talus. Between the anterior and posterior inferior tibiofibular ligaments, the tibia and fibula are bound by the interosseous ligament, which is continuous with the interosseous membrane above. This ligament may be important in the pathomechanics of what we have termed incisural fractures.

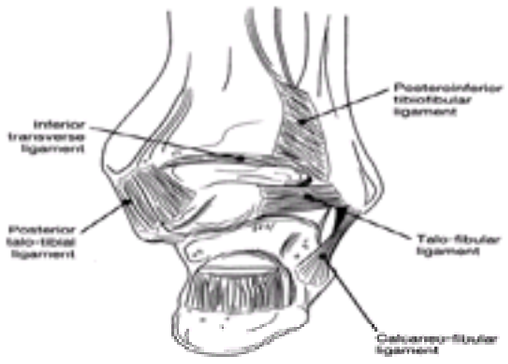

FIGURE 25-18. Posterior view of the distal tibia and fibula and the ligaments making up the ankle mortise.

On the medial side of the ankle, the talus is bound to the ankle mortise by the deltoid ligament (Fig. 25-19). This ligament arises from the medial malleolus and divides into superficial and deep layers. Three parts of the superficial layer are identified by their attachments: tibionavicular, calcaneotibial, and posterior talotibial ligaments. The deep layer is known as the anterior talotibial ligament, again reflecting its insertion and origin. On the lateral side, the anterior and posterior talofibular ligament, with the calcaneofibular ligaments, make up the lateral collateral ligament (Fig. 25-20).

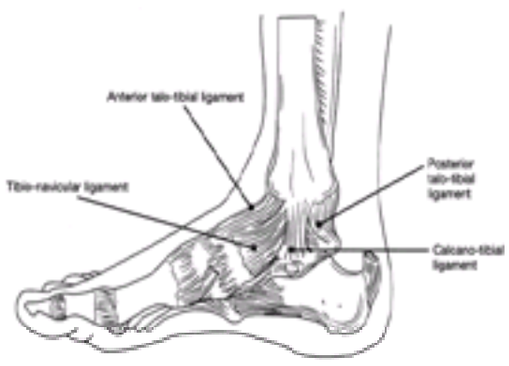

FIGURE 25-19. Medial view of the ankle demonstrating the components of the deltoid ligament.

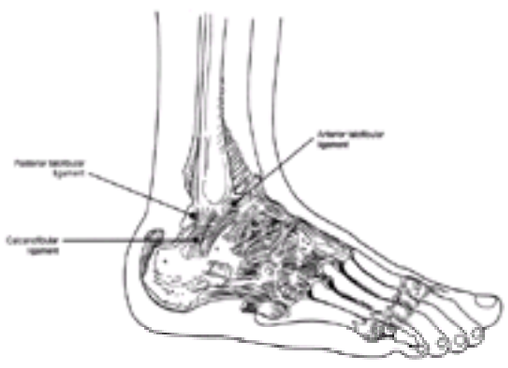

FIGURE 25-20. Lateral view of the ankle demonstrating the anterior and posterior talofibular ligaments and the calcaneofibular ligament.

In children, all of the ligamentous structures that bind the medial and lateral malleoli to the talus and the distal tibial epiphysis to the distal fibular epiphysis are attached to the malleoli distal to the physes. Because the ligaments are stronger than the physes, physeal fractures are more common than ligamentous injuries in children. When they accompany distal tibial physeal injuries, displaced diaphyseal fibular fractures are usually associated with injuries to and displacement of the entire distal tibial epiphysis rather than with injuries to the ligaments, making diastasis of the ankle uncommon in children (Fig. 25-21).

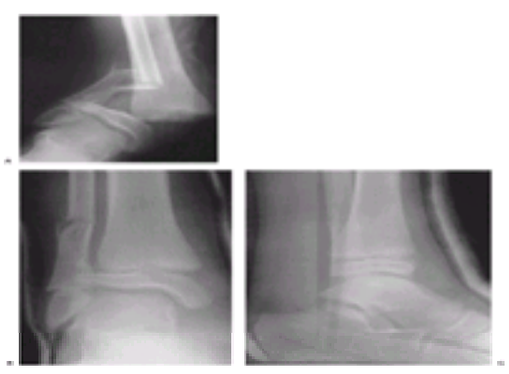

FIGURE 25-21. A: Pronation–external rotation injury resulting in a Salter-Harris type I fracture of the distal tibial physis. **B and C:** Anteroposterior and lateral

radiographs demonstrate satisfactory closed reduction.

The distal tibial ossification center generally appears at 6 to 24 months of age. Its malleolar extension begins to form around the age of 7 years and is mature or complete at the age of 10 years. The physis usually closes around the age of 15 years in girls and 17 years in boys. This process takes approximately 18 months and occurs first in the central part of the physis, extending next to the medial side, and finally ending laterally. This asymmetric closure sequence is an important anatomic feature of the growing ankle and is responsible for certain fracture patterns in adolescents (Fig. 25-22).

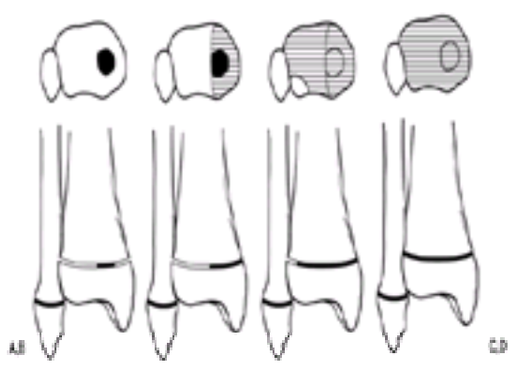

FIGURE 25-22. Closure of the distal tibial physis begins centrally **(A)**, and extends medially **(B)** and then laterally **(C)** before final closure **(D)**.

The distal fibular ossification center appears around the age of 9 to 24 months. Its physis is located at the level of the ankle joint. Closure of this physis generally follows closure of the distal tibial physis by 12 to 24 months.

TREATMENT

Appropriate treatment of ankle fractures in children depends on the location of the fracture, the degree of displacement, and the age of the child. Nondisplaced fractures may be simply immobilized. Closed reduction and cast immobilization may be appropriate for displaced fractures; if the closed reduction cannot be maintained with casting, skeletal fixation is necessary. If closed reduction is not possible, open reduction is indicated, provided there is significant physeal or articular displacement, followed by internal fixation or cast immobilization.

The anatomic type of the fracture (usually defined by the Salter-Harris classification), the mechanism of injury, and the amount of displacement of the fragments are important considerations. When the articular surface is disrupted, the amount of articular step-off or separation must be measured. The neurovascular status of the limb or the status of the skin may require emergency treatment of the fracture and associated problems. The general health of the patient and the time since injury also must be considered.

Other considerations in treatment decision making include the following:

Is a below-knee or above-knee cast appropriate?

How long should immobilization be continued?

When can weight bearing be allowed?

How important is immediate reduction of the ankle fracture, especially if other injuries or logistical problems exist?

Is a general anesthetic required or can some form of local anesthesia or sedation be as effective and safer for closed reduction?

If closed reduction is incomplete, how much residual displacement in each plane is acceptable?

If open reduction is necessary, what surgical approach is appropriate?

How can the most anatomic reduction be ensured at the time of surgery?

What type of internal fixation device is most appropriate?

Distal Tibial Physeal Fractures

Salter-Harris Type I Fractures

According to Dias and Tachdjian (34,116), Salter-Harris type I fractures of the distal tibia can be caused by any of four mechanisms: supination–inversion, supination–plantarflexion, supination–external rotation, or pronation–eversion–external rotation. Spiegel and associates (112) reported that these fractures accounted for 15.2% of 237 ankle injuries in their series and occurred in children significantly younger (average age, 10.5 years) than those with other Salter-Harris types of fractures.

The mechanism of injury is deduced primarily by the direction of displacement of the distal tibial epiphysis; for example, straight posterior displacement indicates a supination–plantarflexion mechanism. The type of associated fibular fracture is also indicative of the mechanism of injury; for example, a high, oblique, or transverse fibular fracture indicates a pronation–eversion–external injury, whereas a lower spiral fibular fracture indicates a supination–external rotation injury. Lovell (77), Broock and Greer (16), and Nevelos and Colton (86) reported unusual Salter-Harris type I fractures in which the distal tibial epiphysis was externally rotated 90 degrees without fracture of the fibula or displacement of the tibial epiphysis in any direction in the transverse plane.

Cast immobilization is generally sufficient treatment for nondisplaced Salter-Harris type I fractures of the distal tibia. Recommended treatment ranges from a below-knee cast worn for 4 weeks to a non–weight-bearing long cast worn for 3 weeks, followed by 3 weeks of immobilization in a short leg walking cast. Most displaced fractures can be treated with closed reduction and cast immobilization. An above-knee non–weight-bearing cast is preferable initially but can be changed to a short leg walking cast at 3 to 4 weeks.

Salter-Harris Type II Fractures

Salter-Harris type II fractures also can be caused by any of the four mechanisms of injury described by Dias and Tachdjian (34). In the series of Spiegel and associates (112), Salter-Harris type II fractures were the most common injuries (44.8%). In addition to the direction of displacement of the distal tibial epiphysis and the nature of any associated fibular fracture, the location of the Thurston-Holland fragment is helpful in determining the mechanism of injury; for example, a lateral fragment indicates a pronation–eversion–external rotation injury; a posteromedial fragment, a supination–external rotation injury; and a posterior fragment, a

supination–plantarflexion injury (Fig. 25-23).

FIGURE 25-23. A: Severe plantarflexion injury with severe swelling of the ankle and foot; the reduction obtained was unstable. **B:** The reduction was stabilized by two transmetaphyseal screws placed percutaneously. **C:** Anteroposterior view confirms an anatomic reduction.

Nondisplaced fractures can be treated with cast immobilization usually with an above-knee cast for 3 to 4 weeks, followed by a below-knee walking cast for another 3 to 4 weeks.

Although most researchers agree that closed reduction of significantly displaced Salter-Harris type II ankle fracture should be attempted, opinions differ as to what degree of residual displacement or angulation is unacceptable and requires open reduction. Based on follow-up of 33 Salter-Harris type II ankle fractures, Caruthers and Crenshaw (21) concluded that “accurate reposition of the displaced epiphysis at the expense of forced or repeated manipulation or operative intervention is not indicated since spontaneous realignment of the ankle occurs even late in the growing period.” They found no residual angulation at follow-up in patients who had up to 12 degrees of tilt after reduction, even in patients as old as 13 years at the time of injury. Spiegel and associates (112), however, reported complications at follow-up in 11 of 16 patients with Salter-Harris type II ankle fractures. Because 6 of these 11 patients had angular deformities that were attributed to lack of adequate reduction of the fracture, Spiegel and associates recommended “precise anatomic reduction.” Incomplete reduction is usually caused by interposition of soft tissue between the fracture fragments. Grace (46) reported three patients in whom the interposed soft tissue included the neurovascular bundle, resulting in circulatory embarrassment when closed reduction was attempted. In this situation, open reduction and extraction of the soft tissue obviously is required. A less definitive indication for open reduction is interposition of the periosteum, which causes physeal widening with no angulation or with minimal angulation. Good results have been reported after open reduction and extraction of the periosteal flap (Fig. 25-24) (69). It is not clear that failure to extract the periosteum in such cases results in problems sufficient to warrant operative treatment.

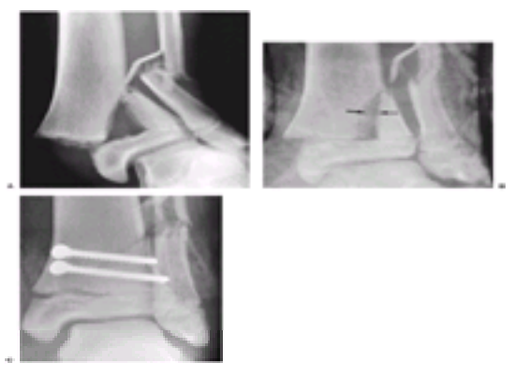

FIGURE 25-24. A: Severely displaced pronation–eversion –external rotation injury. **B:** Closed reduction was unsuccessful and a valgus tilt of the ankle mortise was noted. At surgery, soft tissue was interposed laterally (*arrows*). **C:** Reduction completed and stabilized with two cancellous screws placed above the physis.

Because of fears of iatrogenic damage to the distal tibial physis during closed reduction, many researchers recommend the use of general anesthesia with adequate muscle relaxation for all patients with Salter-Harris type II distal tibial fractures. However, no study has compared the frequency of growth abnormalities in patients with these fractures reduced under sedation and local analgesia to those with fractures reduced with the use of general anesthesia. I compared nine patients who underwent closed reduction in the emergency department with the use of sedation and hematoma block to nine patients who had closed reduction in the operating room with the use of general anesthesia. All fractures were reduced with a single manipulation, except for one in the emergency department group that required repeat manipulation. One patient in each group had a growth alteration.

When closed reductions are not performed under general anesthesia, they are usually performed under intravenous sedation. Furia et al. demonstrated significantly improved pain relief with hematoma block for ankle fractures in a study comparing patients treated with intravenous sedation to patients receiving hematoma block (41). Intravenous regional anesthesia or Bier block also has been reported to be effective for pain relief in lower extremity injuries (72).

Salter-Harris Type III and IV Fractures

Salter-Harris type III and IV fractures are discussed together because their mechanism of injury is the same (supination–inversion) and their treatment and prognosis are similar. Juvenile Tillaux and triplane fractures are considered separately. In the series of Spiegel and associates (112), 24.1% of the fractures were Salter-Harris type III injuries and 1.4% were type IV. These injuries are usually produced by the medial corner of the talus being driven into the junction of the distal tibial articular surface and the medial malleolus. As the talus shears off the medial malleolus, the physis also may be damaged (Fig. 25-25).

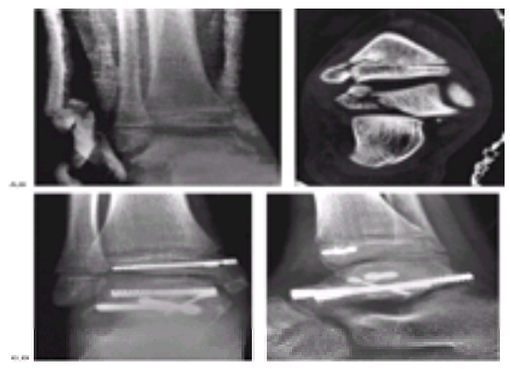

FIGURE 25-25. A: Severe ankle injury sustained by an 8-year-old involved in a car accident. The anteroposterior view in the splint does not clearly show the Salter-Harris type IV fracture of the tibia. The dome of the talus appears abnormal. **B:** Computed tomography scan shows the displaced Salter-Harris type IV fracture of the medial malleolus and a severe displaced intraarticular fracture of the body of the talus. **C and D:** Open reduction of both fractures was performed and Herbert screws were used for internal fixation. (Courtesy of Armen Kelikian, M.D.)

Nondisplaced Salter-Harris type III and IV fractures can be treated with above-knee cast immobilization, but care must be taken to be sure no displacement is present, which may require CT evaluation, and that no displacement occurs after casting, which requires weekly radiographic evaluation for the first 2 weeks after casting.

Displaced fractures require as anatomic a reduction as possible. Failure to obtain anatomic reduction frequently results in articular incongruity and posttraumatic arthritis, which often becomes symptomatic 5 to 8 years after skeletal maturity (Fig. 25-26) (23). The risk of growth arrest also has been linked to the accuracy of reduction (70). Closed reduction may be attempted but is likely to succeed only in minimally displaced fractures. If closed reduction is obtained, it can be maintained with a cast or with percutaneous pins or screws supplemented by a cast.

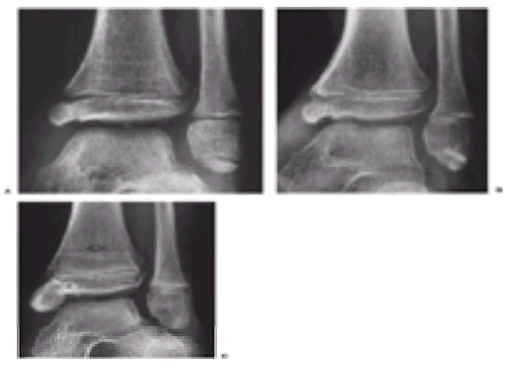

FIGURE 25-26. A: Displaced Salter-Harris type III supination–inversion fracture in an 8-year-old girl who presented for treatment 2 weeks after injury. **B:** After cast removal 6 weeks after injury. **C:** Two years after injury. Although the injury does not seem to have interfered with growth, as evidenced by the Park-Harris growth arrest line parallel to the physis (*black arrow*), her articular incongruity (*white arrow*) is associated with occasional mild ankle pain.

If anatomic reduction cannot be obtained by closed methods, open reduction and internal fixation should be performed. Lintecum and Blasier described a technique of open reduction achieved through a limited exposure of the fracture with the incision centered over the fracture site combined with percutaneous cannulated screw fixation (74). This technique was performed on 13 patients: 8 Salter-Harris IV fractures, 4 Salter-Harris III fractures, and 1 triplane fracture. The investigators reported one growth arrest at follow-up averaging 12 months. Beaty and Linton (6) reported a Salter-Harris type III fracture with an intraarticular fragment (Fig. 25-27); these fractures require open reduction for inspection of the joint to ensure that no osteochondral fragments are impeding reduction. Internal fixation devices should be inserted within the epiphysis, parallel to the physis, and should avoid the physis and ankle joint if possible (Fig. 25-28).

FIGURE 25-27. A: Salter-Harris type III fracture of the medial malleolus and Salter-Harris type I fracture of the fibula in a 9-year-old girl. An intraarticular fragment was visible only on a mortise view radiograph. **B:** Computed tomography scan outlined the Salter-Harris type III fracture of the medial malleolus and the fragment of bone. **C:** Two years after excision of the osteochondral fragment, open reduction of the malleolar fracture, and internal fixation. (**A and B** reprinted from Beaty JH, Linton RC. Medial malleolar fracture in a child: a case report. *J Bone Joint Surg [Am]* 1988;70:1254–1255; with permission.)

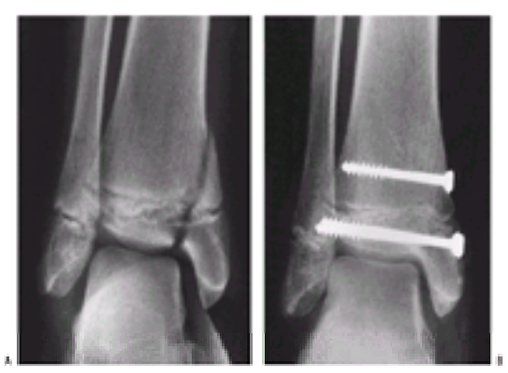

FIGURE 25-28. A: Grade II supination–inversion injury in a 12-year-old girl, resulting in a displaced Salter-Harris type IV fracture of the distal tibia and a nondisplaced Salter-Harris type I fracture of the distal fibula. **B:** After anatomic open reduction and stable internal fixation.

Options for internal fixation include smooth Kirschner wires, small fragment cortical and cancellous screws, and 4-mm cannulated screws (Fig. 25-29). Several reports (7,11,17) have advocated the use of absorbable pins for internal fixation of ankle fractures. Benz and colleagues (7) reported no complications or growth abnormalities after the use of absorbable pins with metal screw supplementation for fixation of five ankle fractures in patients between the ages of 5 and 13 years. In reports of the use of absorbable pins without supplemental metal fixation in adults (9,10,40,55), complications have included displacement (14.5%), sterile fluid accumulation requiring incision and drainage (8.1%), pseudarthrosis (8%), distal tibiofibular synostosis (3.8%), and infection (1.6%). Bucholz and co-workers (17) reported few complications in a series of fractures in adults fixed with absorbable screws made of polylactide and suggested that complications in earlier series might be related to the fact that those pins were made of polyglycolide. A report in 1993 by Bostman and associates (11), however, included few complications in a series of fractures in children fixed with polyglycolide pins. A follow-up report by Rokkanen et al. in 1996 reported a 3.6% rate of infection and a 3.7% rate of failure of fixation (103).

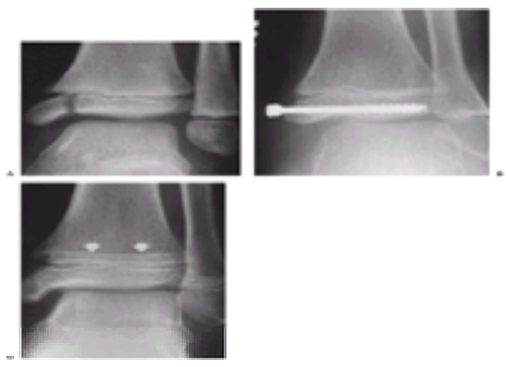

FIGURE 25-29. A: Supination–inversion injury with a Salter-Harris type III fracture of the medial malleolus. **B:** Six months after open reduction and internal fixation with two transepiphyseal cannulated screws. **C:** Eighteen months after injury, the fracture has healed with no evidence of growth arrest or angular deformity. Arrows note normal, symmetrical Park-Harris growth arrest line.

The main advantage of absorbable pins and screws is that hardware removal is avoided. Bostman compared the cost effectiveness of absorbable implants in 994 patients treated with absorbable implants to 1,173 patients treated with metallic implants. To be cost effective, the hardware removal rates required were calculated to range from 19% for metacarpal fractures to 54% for trimalleolar fractures (12). At this time, the use of absorbable pins remains investigational.

Salter-Harris Type V Fractures

Salter-Harris type V fractures of the ankle are believed to be caused by severe axial compression and crushing of the physis (Fig. 25-30). As originally described, these injuries are not associated with displacement of the epiphysis relative to the metaphysis, which make diagnosis of acute injury impossible from plain radiographs; the diagnosis can only be made on follow-up radiographs when premature physeal closure is evident. Spiegel and associates (112) have designated comminuted fractures that are otherwise unclassifiable as Salter-Harris type V injuries.

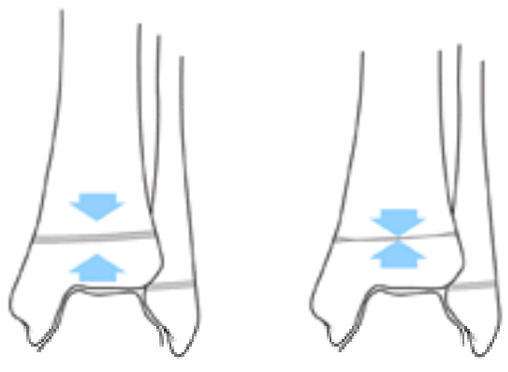

FIGURE 25-30. Compression-type injury of the tibial physis. Early physeal arrest can cause leg length discrepancy.

The incidence of Salter-Harris type V ankle fractures is difficult to establish because of the difficulty of diagnosing acute injuries. Spiegel and associates (112) included two type V fractures in their series, but both were comminuted fractures rather than the classic crush injury.

Because of the uncertain nature of this injury, no specific treatment recommendations have been formulated. Treatment is usually directed primarily toward the sequelae of growth arrest that invariably follows Salter-Harris type V fractures. Perhaps more sophisticated scanning techniques will eventually allow identification and localization of areas of physeal injury so that irreparable damaged cells can be removed and replaced with interposition materials to prevent growth problems, but at present this diagnosis is made only several months after injury.

Other Fractures of the Distal Tibia

Accessory ossification centers of the distal tibia (os subtibiale) and distal fibula (os fibulare) are common and may be injured. Treatment usually consists of cast immobilization for 3 to 4 weeks. Ogden and Lee (90) reported good results after cast immobilization in 26 of 27 patients with injuries involving the medial side of the tibia; only 1 patient required surgery. In contrast, 5 to 11 patients with injuries involving the lateral side had persistent symptoms that required excision.

Injuries to the perichondral ring of the distal tibial and fibular physes, with physeal disruption, have been described. Most of these injuries are caused by skiving of the bone by machinery such as lawn mowers. They may result in growth arrest or retardation and in angular deformities (see section on Open Fractures and Lawn Mower Injuries).

AUTHOR'S PREFERRED METHOD OF TREATMENT

Salter-Harris Type I and II Fractures of the Distal Tibia

I prefer to treat nondisplaced Salter-Harris type I and II fractures initially with above-knee cast immobilization. Non–weight bearing is continued until 3 to 4 weeks postinjury, when the cast is changed to a below-knee walking cast that is worn for an additional 3 to 4 weeks. Follow-up radiographs are obtained every 6 months for 2 years or until a Park-Harris growth arrest line parallel to the physis is visible and there is no evidence of physeal deformity.

For displaced fractures in children with at least 2 years of growth remaining, my objective is to obtain no more than 15 degrees of plantar tilt for posteriorly displaced fractures, 10 degrees of valgus for laterally displaced fractures, and 0 degrees of varus for medially displaced fractures (Fig. 25-31). For children with 2 years or less of growth remaining, the amount of acceptable angulation is reduced to less than 5 degrees. I prefer to attempt reduction of markedly displaced fractures with the use of general anesthesia with good muscle relaxation and image intensifier control. In children with mildly displaced fractures, especially if anesthesia is not going to be available for many hours, I occasionally make one attempt at gentle closed reduction under a hematoma block supplemented as needed by well-monitored intravenous sedation. Once adequately reduced, the fractures are usually stable and a long-leg cast can be used for immobilization. Rarely, for markedly unstable fractures or severe soft tissue injuries that require multiple debridements, percutaneous screws are used when the Thurston-Holland fragment is large enough to accept screw fixation. When the fragment is too small, smooth wire fixation across the physis is the only alternative. Repeated attempts at closed manipulation of these fractures may increase the risk of growth abnormality and should be avoided. In patients with fractures that are not seen until 7 to 10 days after injury, residual displacement is probably best accepted. If growth does not sufficiently correct malunion, corrective osteotomy can be performed later.

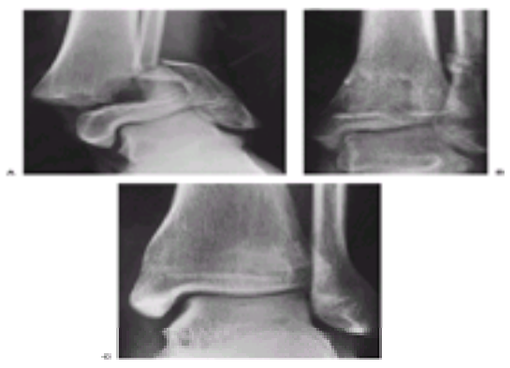

FIGURE 25-31. A: Displaced pronation–eversion–external rotation fracture of the distal tibia in a 12-year-old boy was treated with closed reduction and cast immobilization. **B:** After cast removal a 10 degree valgus tilt was present. **C:** At maturity, the deformity has completely resolved.

I have found that open reduction of these fractures is rarely indicated. The exception usually has been pronation–eversion–external rotation fractures with interposed soft tissue. For fractures with lateral and posterior displacement, an anteromedial incision is made and any interposed soft tissues, such as periosteum or tendons, are extracted before the fracture is reduced. Even though reduction is usually stable, I generally use internal fixation through the metaphyseal fragment, avoiding fixation across the physis if possible.

Salter-Harris Types III and IV Fractures of the Distal Tibia

Treatment of nondisplaced Salter-Harris type III and IV fractures is the same as for nondisplaced type I and II fractures with three modifications. First, after cast application I confirm the reduction of the fracture fragments with CT scanning. Second, these patients are examined more frequently (once a week) for the first 3 weeks after cast application to ensure that the fragments do not become displaced. Third, these patients are examined every 6 to 12 months after cast removal for a minimum of 24 to 36 months to detect any growth abnormality.

Generally, only truly nondisplaced Salter-Harris types III and IV fractures, or those with 1 mm or less of displacement, can be treated closed. Fractures with 2 mm or more of displacement require open reduction and internal fixation with anatomic alignment of the physis and fracture fragments.

For fractures with 2 mm or less of displacement, closed reduction is attempted in the operating room with the use of general anesthesia. After the extremity is prepared and draped, gentle longitudinal traction is applied to the foot, followed by eversion of the foot and direct digital pressure over the medial malleolus. If image intensification confirms anatomic reduction, the fracture may be fixed with two percutaneous smooth wires placed in the epiphysis parallel to the physis. Reduction is confirmed by a short, continuous fluoroscopic examination. Cannulated screws can be inserted if the epiphysis is large enough. For fractures that are seen more than 7 days after injury, I accept up to 2 mm of displacement without attempting closed or open reduction (Fig. 25-32). Reliable patients whose fractures are fixed with screws can be immobilized in below-knee casts. Above-knee casts are used for all other patients.

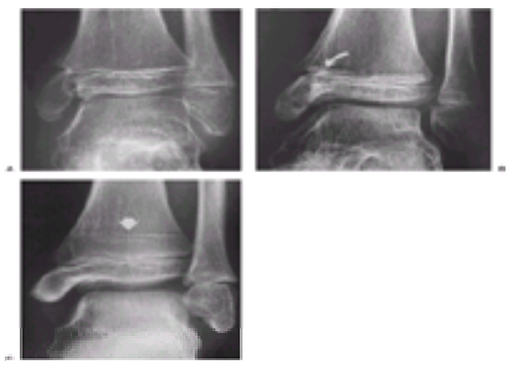

FIGURE 25-32. A: Salter-Harris type III fracture after supination–inversion injury of the distal tibia in a 10-year-old girl demonstrates 2 mm of displacement 4 weeks after injury. **B:** After 8 weeks of cast immobilization, healing is apparent but there is a suggestion of early physeal bar formation. **C:** Nine months later, growth is normal, as evidenced by the Park-Harris growth arrest line parallel to the physis.

Fractures with more than 2 mm of displacement should be reduced, regardless of whether the fracture is acute or not. Closed reduction can be attempted, but these fractures usually require open reduction. Occasionally, primary debridement of callus and soft tissue back to normal-appearing physis and fat grafting have been successful for fractures that are more than 7 days old (Fig. 25-33).

FIGURE 25-33. A: Eight-year-old girl who presented 10 days after a displaced Salter-Harris type IV fracture of the distal tibia. **B:** At open reduction, comminution of the physis was noted. The physis was debrided and a fat graft was inserted before reduction and internal fixation of the fracture. **C:** Three years after injury there is no evidence of physeal bar formation or growth abnormality.

OPERATIVE TREATMENT

Open Reduction and Internal Fixation of Salter-Harris Type III or IV Fracture of the Distal Tibia

The patient is placed supine on an operating table that is radiolucent at the lower extremity. After exsanguination of the extremity and inflation of the tourniquet, a hockey stick incision is made, extending from approximately 4 cm above the ankle joint to 1 cm posterior to the tip of the medial malleolus (Fig. 25-34). Alternatively, if more anterior exposure is required, a 4- to 6-cm transverse incision is made from the posterior aspect of the medial malleolus to the anterior aspect of the ankle. The saphenous vein is identified, dissected free, and retracted. The fracture site is identified, and an anteromedial capsulotomy of the ankle joint is performed. The arthrotomy is continuous with the fracture line and the traumatic disruption of periosteum and perichondral ring. The fracture surfaces are exposed and gently cleaned

with irrigation and forceps (curettage is not used).

FIGURE 25-34. Anteromedial surgical approach for reduction of a Salter-Harris type IV fracture of the medial malleolus.

For Salter-Harris type IV fractures, the periosteum may be elevated several millimeters from the metaphyseal fracture edges. I prefer not to excise the metaphyseal portion of a Salter-Harris type IV fragment. The epiphyseal edges and joint surfaces are examined through the arthrotomy. The perichondral ring should not be elevated from the physis. For Salter-Harris type III fractures, the reduction is evaluated by checking the joint surface and epiphyseal fracture edges through the arthrotomy. The epiphyseal fragment is grasped with a small towel clip or reduction forceps, and the fracture is reduced (Fig. 25-35). Internal fixation is performed under direct vision and fluoroscopic control. It is important to view both the lateral and anteroposterior projections because of the curved shape of the distal tibial articular surface. If the fragment is large enough, 4-mm cannulated lag screws are inserted through the epiphyseal fragment (Fig. 25-28); if the fragment is too small for screws, smooth Kirschner wires are used. The reduction and the position of the internal fixation are checked through the arthrotomy. In fractures with a significant Thurston-Holland fragment, a metaphyseal screw may be used if a gap exists after the epiphyseal screws are inserted. After reduction of the tibial fracture, the associated Salter-Harris type I or II fibular fracture usually reduces and is stable. If it is not, closed reduction and fixation with percutaneous oblique smooth Kirschner wires are performed. The wound is closed using a subcuticular suture for the skin. A well-padded above-knee cast is applied.

FIGURE 25-35. Technique for reduction of a Salter-Harris type IV fracture of the distal tibia.

The patient is kept non–weight bearing for 3 weeks, and then the cast is changed to a below-knee walking cast, which is worn for an additional 3 weeks. Frequent follow-up evaluations (every 3 months for the first year and yearly thereafter) are necessary to detect growth abnormalities until skeletal maturity.

Fractures Involving the Distal Fibula

Fractures involving the fibular physis are most commonly Salter-Harris type I or II fractures that are caused by a supination–inversion injury. Isolated fibular fractures are usually minimally displaced and can be treated with immobilization in a below-knee cast for 4 to 6 weeks. Significantly displaced fibular fractures accompany Salter-Harris types III and IV tibial fractures and usually reduce when the tibial fracture is reduced. Internal fixation of the tibial fracture generally results in stability of the fibular fracture such that cast immobilization is sufficient. If the fibular fracture is unstable after reduction and fixation of the tibial fracture, fixation with a smooth intramedullary or obliquely inserted Kirschner wire is recommended. In older adolescents in whom growth is not a consideration, an intramedullary rod or plate-and-screw device may be used as in adults (Fig. 25-36).

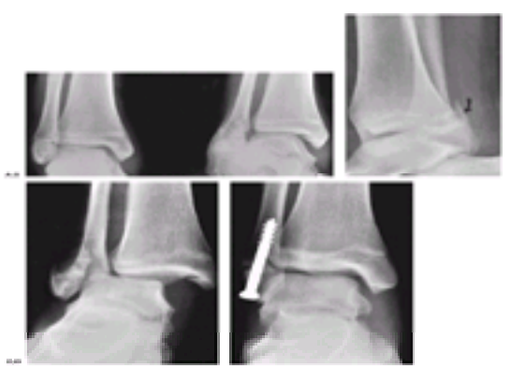

FIGURE 25-36. A: Salter-Harris type II fracture of the distal fibula in a 15-year-old. **B:** Lateral view shows the fibular metaphyseal fragment (*arrow*). Considerable soft tissue swelling was noted in the medial aspect of the ankle. **C:** Stress films showed complete disruption of the deltoid ligament. **D:** The fibular fracture was fixed with a cannulated screw; the deltoid ligament was not repaired.

Avulsion fractures from the lateral malleolus are seen in children with inversion sprain-type injuries to the ankle. These may fail to unite with cast immobilization. Patients with such nonunions may have pain without associated instability. In such patients simple excision of the ununited fragment usually relieves their pain (30,50). When the nonunions are associated with instability, reconstruction of one or more of the lateral ankle ligaments is required (see section on Lateral Ankle Sprains).

AUTHOR'S PREFERRED METHOD OF TREATMENT

I usually treat nondisplaced fibular physeal fractures with immobilization in a below-knee walking cast for 3 to 4 weeks. I have attempted closed reduction of displaced Salter-Harris types I and II fibular fractures, but when reduction was unsuccessful, I have accepted up to 50% displacement without problems at long-term follow-up (Fig. 25-37). Dias (32), however, reported a patient with a symptomatic spike that required excision after inadequate reduction. I have not found open reduction of isolated physeal fibular fractures necessary but would not hesitate to perform open reduction of a displaced Salter-Harris type III or IV fracture if necessary.

FIGURE 25-37. A: Lateral radiograph of a 13-year-old girl who was seen 7 days after an inversion sprain of the ankle; the Salter-Harris type I fracture of the distal fibula is displaced 50%. Closed reduction was unsuccessful. **B:** Six months after injury, remodeling is complete at the fracture site and the patient is asymptomatic.

Juvenile Tillaux and Triplane Fractures

Because the distal tibial physis closes in an asymmetric pattern over a period of about 18 months, injuries sustained during this period can produce fracture patterns that are not seen in younger children with completely open physes (78). This group of fractures has been labeled transitional fractures because they occur during the transition from a skeletally immature ankle to a skeletally mature ankle.

Classification of these fractures is even more confusing than that of other distal tibial fractures. Advocates of mechanism-of-injury systems agree that most juvenile Tillaux and triplane fractures are caused by external rotation, but they disagree as to the position of the foot at the time of the injury (32,33,98). Some researchers (33) classify juvenile Tillaux fractures as stage I injuries, with further external rotation causing triplane fractures, and still further external rotation causing stage II injuries with fibular fracture. Others emphasize the extent of physeal closure as the only determinant of fracture pattern (26).

Advocates of anatomic classifications are handicapped by the different anatomic configurations triplane fractures may exhibit on different radiographic projections, making tomography, CT scanning, or examination at open reduction necessary to determine fracture anatomy and number of fragments. Because these fractures occur near the end of growth, growth disturbance is rarely significant. Therefore, anatomic classification is more useful for descriptive purposes than for prognosis.

Juvenile Tillaux Fractures

This fracture is the adolescent counterpart of the fracture described in adults by the French surgeon Tillaux. It occurs when with external rotation of the foot, the anteroinferior tibiofibular ligament through its attachments to the anterolateral tibia avulses a fragment of bone corresponding to the portion of the distal tibial physis that is still open (Fig. 25-38). In the series of Spiegel and associates (112), these fractures occurred in 2.9% of patients.

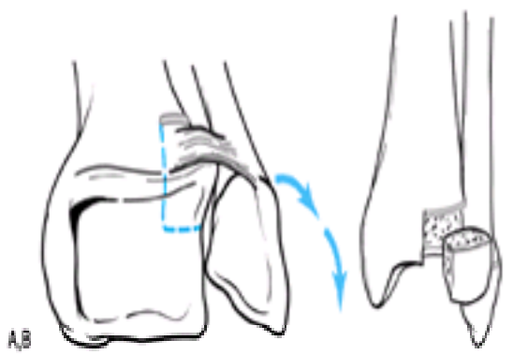

FIGURE 25-38. Juvenile Tillaux fracture. Mechanism of injury, the anteroinferior tibiofibular ligament avulses a fragment of the lateral epiphysis **(A)** corresponding to the portion of the physis that is still open **(B)**.

Tillaux fractures may be isolated injuries or may be associated with ipsilateral tibial shaft fractures (28). The fibula usually prevents marked displacement of the fracture, and clinical deformity is generally absent. Swelling is usually slight, and local tenderness is at the anterior lateral joint line, in contrast to ankle sprains, where the tenderness tends to be below the level of the ankle joint.

A mortise view is essential to obtain a view of the distal tibial epiphysis that is unobstructed by the fibula (Fig. 25-39). Steinlauf et al. reported a patient in whom the Tillaux fragment became entrapped between the distal tibia and fibula, producing apparent diastasis of the ankle joint (113). To allow measurement of displacement from plain films, the x-ray beam would have to be directly in line with the fracture site, which makes CT confirmation of reduction mandatory after all closed reductions of these fractures.

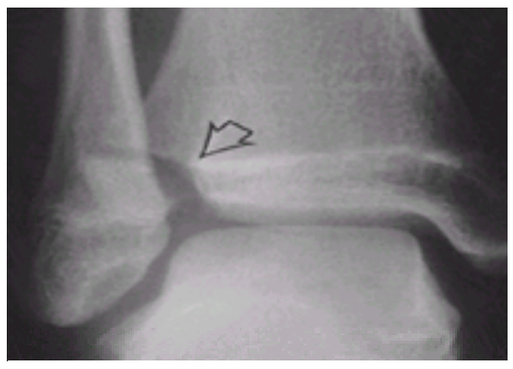

FIGURE 25-39. Anteroposterior mortise view of a 14-year-old who sustained a juvenile Tillaux fracture.

Treatment

Both below-knee and above-knee casts have been used for immobilization of nondisplaced juvenile Tillaux and triplane fractures. Fractures with more than 2 mm of displacement require closed or open reduction. Closed reduction is attempted by internally rotating the foot and applying direct pressure over the anterolateral tibia. If necessary, percutaneous pins can be used for stabilization of the reduction. If closed reduction is not successful, open reduction is required. Occasionally, percutaneously inserted pins can be used to manipulate the displaced fragment into anatomic position and then advanced to fix the fragment in place (108).

AUTHOR'S PREFERRED METHOD OF TREATMENT

For nondisplaced fractures and fractures displaced less than 2 mm, I prefer immobilization in an above-knee cast with the knee flexed 30 degrees and the foot internally rotated. If the position appears acceptable on plain films, CT scanning in the transverse plane with coronal and sagittal reconstructions is used to confirm acceptable reduction. For fractures with more than 2 mm of initial displacement, manipulation may be attempted by internal rotation of the foot and application of direct pressure over the anterolateral joint line. If reduction is not obtained with this maneuver, reduction can be attempted by dorsiflexing the pronated foot and then internally rotating the foot (79). Again, if the reduction appears adequate on plain radiographs, CT scanning is used for confirmation. I prefer to immobilize patients with these injuries in a long-leg cast with the knee flexed and the foot internally rotated.

OPERATIVE TREATMENT

Fixation of Juvenile Tillaux Fracture

If radiographs or CT scan after casting show an unacceptable reduction, the patient is taken to the operating room, where closed reduction is again attempted. If reduction is confirmed by C-arm fluoroscopy in all projections, a percutaneous cannulated screw is inserted for fixation. Because preservation of growth is not a concern, the screw does not have to be intraepiphyseal. If closed reduction is unsuccessful but residual displacement is not severe, I occasionally insert one or two smooth pins into the Tillaux fragment under fluoroscopic control (Fig. 25-40) and use them to attempt to guide the fragment into proper position (Fig. 25-41). Cannulated screw guide pins may not be stiff enough for this purpose, and a larger pin may be required. If successful, the pins are advanced and one or two screws are inserted (Fig. 25-42). If reduction is not successful, open reduction is performed through an anterolateral approach and a cannulated or cancellous screw is inserted for fixation (Fig. 25-43). In the anterolateral approach, be sure to identify the superficial perineal nerve to prevent injury. A short leg, non–weight-bearing cast is worn for 3 weeks, followed by a weight-bearing cast for another 3 weeks.

Fractures of the Incisura

At my institution we have seen two patients with what we have termed incisural fractures. On anteroposterior and mortise views, these patients appeared to have Tillaux fractures with the fractured piece appearing smaller than usual and essentially nondisplaced (Fig. 25-44). CT scans revealed that the fracture line did not extend through the anterior cortex, as is seen in a typical Tillaux fracture (Fig. 25-45). It would therefore appear that the fragment could not have been avulsed by the anterior tibiofibular ligament, the accepted mechanism of injury for a Tillaux fracture. It is my hypothesis that the fragment is avulsed by the intraosseous ligament and represents the pediatric equivalent of an adult diastasis injury.

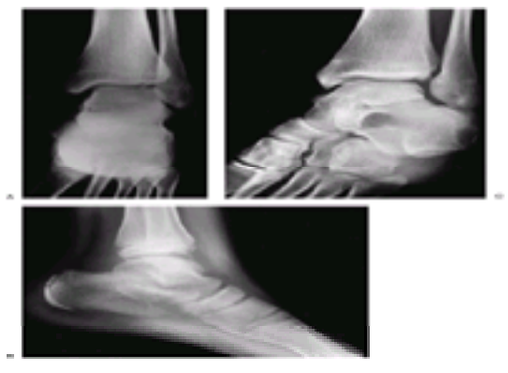

FIGURE 25-44. Anteroposterior **(A)**, lateral **(B)**, and oblique **(C)** views of the ankle demonstrating an apparent small juvenile Tillaux fracture in a 14-year-old girl.

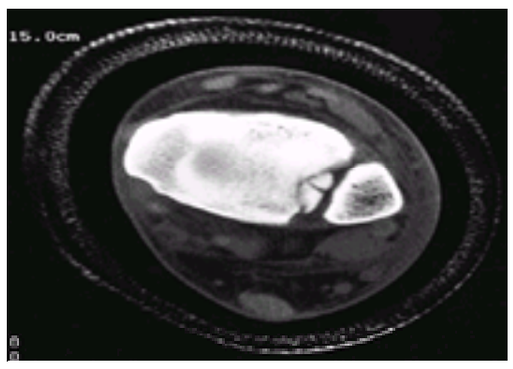

FIGURE 25-45. Computed tomography scan at the level of the tibiotalar joint demonstrates that the fracture fragment does not include the attachment of the anterior inferior tibiofibular ligament.

Both of these patients were treated elsewhere with cast immobilization initially. Casting was continued for 12 weeks. At that time, the patients demonstrated no bony healing. Cast immobilization was discontinued and rehabilitation begun. The patients were symptom free 2 years postinjury despite lack of bony union. It is therefore my feeling at this time that nonoperative treatment of this injury is indicated if the mortise is not widened.

Triplane Fractures

Karrholm attributes the original description of this injury to Bartl (5), in 1954, and notes that Gerner-Smidt (44), in 1963, described triplane and Tillaux fractures as different stages of the same injury. In 1957, Johnson and Fahl (58) described a triplane fracture in their report of 27 physeal ankle injuries and reported that they had seen 10 such fractures. Despite these earlier reports, the nature of triplane fractures was not appreciated until Marmor's (81) report in 1970 of an irreducible ankle fracture that at surgery was found to consist of three parts (Fig. 25-46). Two years after Marmor's report, Lynn (78) reported two additional such fractures and coined the term *triplane fracture.* He described the fracture as consisting of three major fragments: (a) the anterolateral quadrant of the distal tibial epiphysis, (b) the medial and posterior portions of the epiphysis in addition to a posterior metaphyseal spike, and (c) the tibial metaphysis. However, in their 1978 report of 15 such fractures, Cooperman and associates (27) concluded that, based on tomographic studies, most were two-part fractures produced by external rotation (Fig. 25-47). Variations in fracture patterns were attributed to the extent of physeal closure at the time of injury. Karrholm and colleagues reported that CT evaluation of four adolescents with triplane fractures confirmed the existence of two-part and three-part fractures and also revealed four-part fractures (62) (Fig. 25-48). Denton and Fischer (31) described a two-part medial triplane fracture that they believed was caused by adduction and axial loading, and Peiro and associates (92) reported a three-part medial triplane fracture. In the series of Spiegel and associates, 7.3% were triplane fractures (112).

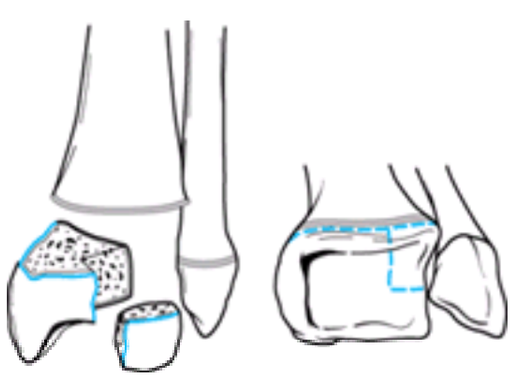

FIGURE 25-46. Anatomy of a three-part lateral triplane fracture (left ankle). Note the large epiphyseal fragment with its metaphyseal component and the smaller anterolateral epiphyseal fragment.

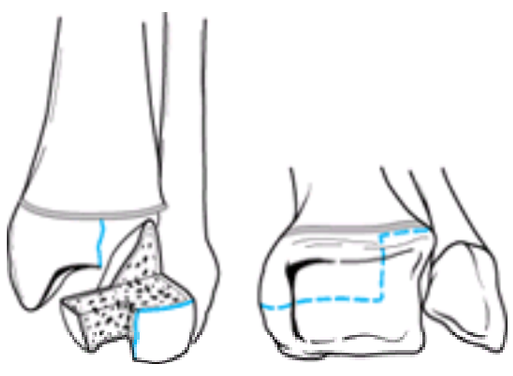

FIGURE 25-47. Anatomy of a two-part lateral triplane fracture (left ankle). Note the large posterolateral epiphyseal fragment with its posterior metaphyseal fragment.

The anterior portion of the medial malleolus remains intact.

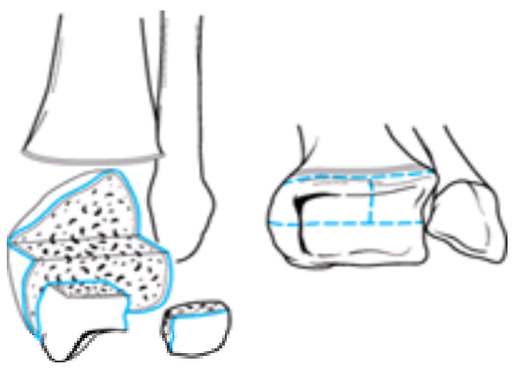

FIGURE 25-48. Anatomy of a four-part lateral triplane fracture (left ankle). The anterior epiphysis has split into two fragments and the posterior epiphysis is the larger fragment with its metaphyseal component.

Von Laer (122) described a subgroup of two-part and three-part triplane fractures in which the fracture line on the anteroposterior radiograph did not extend into the ankle joint but into the medial malleolus instead (Fig. 25-49). Feldman and co-workers also reported a case of an extraarticular triplane fracture in a skeletally immature patient (38). Shin et al. reported five patients with intramalleolar triplane variants (109). They divided these into three types: type I, an intramalleolar intraarticular fracture: type II, an intramalleolar, intraarticular fracture outside the weight-bearing surface; and type III, an intramalleolar, extraarticular fracture (Fig. 25-50). These researchers found that CT scans with three-dimensional reconstruction were helpful in determining displacement and deciding if surgery is indicated.

(Adapted from Shin A, Moran ME, Wenger DR. Intramalleolar triplane fractures. *J Pediatr Orthop* 1997;17:352–355; with permission.)

Karrholm reviewed 209 triplane fracture patients and found that the mean age at the time of injury was 14.8 years for boys and 12.8 years for girls (60). This type of injury did not occur in children under 10 or over 16.7 years. Patients with triplane fractures may have completely open physes. Swelling is usually more severe than with Tillaux fractures, and deformity may be more severe, especially if the fibula is also fractured. Radiographic views should include anteroposterior, lateral, and mortise views. Rapariz et al. found that 48% of triplane fractures were associated with fibular fracture and 8.5% were associated with ipsilateral tibial shaft fracture (101). Healy et al. reported a triplane fracture associated with a proximal fibula fracture and syndesmotic injury (Masionneuve equivalent) (53). Failure to detect such injury may lead to chronic instability. Therefore, tenderness proximal to the ankle should be sought; if found, it is certainly an indication for radiography of the proximal leg. CT has largely replaced plain tomography for evaluation of the articular surface and the fracture anatomy and should be routinely performed (Fig. 25-51).

Computed tomography scanning of a three-part triplane fracture. **A:** Coronal cut shows lateral epiphyseal fragment. **B:** Sagittal cut shows posterior displacement of the epiphyseal–metaphyseal fragment. **C:** Horizontal cut through the epiphysis shows displacement of the lateral epiphyseal fragment (*arrows*). **D:** Horizontal cut through the metaphysis shows the fibular fracture and the displaced metaphyseal fragment (*arrows*).

Treatment

Nondisplaced triplane fractures (those with <2 mm of displacement) as well as extraarticular fractures can be treated with long leg cast immobilization with the foot in internal rotation for lateral fractures and in eversion for medial fractures. Fractures with more than 2 mm of displacement (65% of the injuries in Karrholm's series) require reduction; this may be attempted in the emergency department or in the operating room with the use of general anesthesia. Closed reduction of lateral triplane fractures is attempted by internally rotating the foot. Based on the mechanism of injury, the most logical maneuver for reduction of medial triplane fractures is abduction. If closed reduction is shown to be adequate by image intensification as is the case about half the time, a long leg cast is applied or percutaneous screws are inserted for fixation if necessary. If closed reduction is unsuccessful, open reduction is required. This can be accomplished through an anterolateral approach for lateral triplane fractures or through an anteromedial approach for medial triplane fractures. Additional incisions are frequently necessary for adequate exposure.

Whipple and associates (124) described arthroscopic reduction of two-part triplane fractures in two patients. With the arthroscope in an anterolateral portal and an anteromedial portal used for inflow, two pins were inserted laterally into the epiphyseal fragment and used to maneuver it into proper position under direct arthroscopic vision. The pins were then advanced for fixation of the fragment.

AUTHOR'S PREFERRED METHOD OF TREATMENT

For nondisplaced or minimally displaced (less than 2 mm) fractures, I prefer immobilization in a long-leg cast with the knee flexed 30 to 40 degrees. The position of the foot is determined by whether the fracture is lateral (internal rotation) or medial (eversion). A CT scan is obtained immediately after casting to document adequate reduction. Plain films or CT scans are obtained approximately 7 days after cast application to verify that displacement has not recurred. At 3 to 4 weeks, the cast is changed to a below-knee walking cast, which is worn another 3 to 4 weeks.

For fractures with more than 2 mm of displacement, I usually attempt closed reduction with sedation in the emergency department. An above-knee cast is applied. If plain radiographs show satisfactory reduction, a CT scan is obtained. If reduction is acceptable, treatment is the same as for nondisplaced fractures. If the reduction is unacceptable, closed reduction is attempted in the operating room with the use of general anesthesia. If fluoroscopy shows an acceptable reduction, percutaneous screws are inserted, avoiding the physis, and a short leg cast is applied. If closed reduction is unacceptable, open reduction is performed. Preoperative CT scanning may be helpful for evaluating the position of the fracture fragments in the anteroposterior and lateral planes and for determining the appropriate skin incisions.

OPERATIVE TREATMENT

Open Reduction of Triplane Fracture

The patient is placed supine on a radiolucent operating table with padded elevation behind the hip on the affected side. The surgical approach depends on the fracture anatomy as determined by the preoperative CT scan. I prefer to approach a two-part medial triplane fracture through a hockey stick anteromedial incision. The fracture fragments are irrigated to remove debris, and any interposed periosteum is removed. The fracture is reduced, and reduction is confirmed by direct observation through an anteromedial arthrotomy and by image intensification. Two 4-mm cancellous screws are inserted from medial to lateral or from anterior to posterior or both, depending on the fracture pattern (Fig. 25-52). Anterior-to-posterior screw placement may require an additional anterolateral incision, or the screws may be inserted percutaneously.

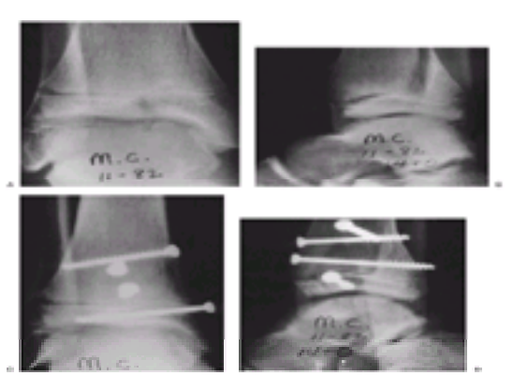

FIGURE 25-52. A and B: Irreducible three-part triplane fracture in a 13-year-old girl. **C and D:** After open reduction and internal fixation. Note anterior-to-posterior and medial-to-lateral screw placement that avoids the physis.

For two-part lateral triplane fractures, I prefer a hockey stick anterolateral approach. The fracture is reduced and stabilized with two screws placed from lateral to medial or from anterior to posterior or both, and reduction is confirmed through direct observation and by image intensification.

Fractures with three or more parts may occasionally require more exposure for reduction and internal fixation. If the fibula is fractured, posterior exposure of the tibial fracture can be readily obtained by detaching the anterior and posterior inferior tibiofibular ligaments and turning down the distal fibula on the lateral collateral ligament (Fig. 25-53). If the fibula is not fractured, a fibular osteotomy may be performed. Careful dissection is necessary to avoid iatrogenic fractures through the physis of the fibula. Medial exposure is obtained through an anteromedial or posteromedial incision. Reduction and internal fixation are performed in a stepwise fashion. For typical three-part fractures, I prefer to reduce the Salter-Harris type II fracture first and provisionally fix it to the distal tibia through the metaphyseal fragment. Usually, the Salter-Harris type III fragment can then be reduced and provisionally fixed to the stabilized type II fragment (Fig. 25-54). Occasionally, the order of reduction and fixation should be reversed. Fractures with four or more fragments require additional steps, but I have found it easier to fix the Salter-Harris type II or IV fragment through the metaphysis to the distal tibia before attaching the Salter-Harris type III fragment or fragments (Fig. 25-55). After reduction, reliable patients may be treated with immobilization in a short-leg cast for 6 to 8 weeks, with weight bearing allowed at 3 to 4 weeks.

Open Fractures and Lawn Mower Injuries

Severe open ankle fractures are often produced by high-velocity motor vehicular accidents or lawn mower injuries (Fig. 25-56) (37,47). Approximately 25,000 lawn mower injuries occur each year, 20% of which are in children. Riding lawn mowers are associated with the most severe injuries, requiring more surgical procedures and resulting in more functional limitations (1,3,35,39,105,123). Loder et al. reviewed 144 children injured by lawn mowers (75). The average age at the time of injury was 7 years. The child was a bystander in 84 cases. Sixty-seven children required amputation. Soft-tissue infection occurred in 8 of 118 and osteomyelitis in 6 of 117.

FIGURE 25-56. A: Severe lawn mower injury in a 5-year-old boy. **B:** One year after initial treatment with debridement, free flap, and skin graft coverage.

Principles of treatment are the same as in adults: copious irrigation and debridement, tetanus toxoid, and intravenous antibiotics. Gaglani et al. reported the bacteriologic findings in three children with infections secondary to lawn mower injuries (43). They found that organisms infecting the wounds were frequently different from those found on initial debridement. Gram-negative organisms were common, and all three patients were infected with fungi as well. In children with lawn mower injuries, grass, dirt, and debris are blown into the wound under pressure, and removal of these embedded foreign objects requires meticulous mechanical debridement.

In most patients, the articular surface and physis should be aligned and fixed with smooth pins that do not cross the physis at the time of initial treatment. Exposed physeal surfaces should be covered with local fat to help prevent union of the metaphysis to the epiphysis. An external fixator may be used if necessary, but small pins should be used through the metaphysis and epiphysis, avoiding the physis (56,59,76,102,104). Wound closure may be a problem in cases with significant soft tissue injury and exposed bone. Skin coverage with local tissue is ideal, but if local coverage is not possible, split-thickness skin grafting is generally the next choice. Free vascular flaps and rotational flaps may be required for adequate coverage. Klein et al. reported on two patients who had associated vascular injury precluding such flaps. The injury was covered successfully with local advancement flaps made possible by multiple relaxing incisions (68) Mooney et al. reported the use of cross-extremity flaps for such cases (85). They found external fixation for linkage of the lower extremities during the procedure to be valuable. After fixation removal, range of motion returned.

Vosburgh and associates (123) reported 33 patients with lawn mower injuries to the foot and ankle. They found that the most severe injuries were to the posterior–plantar aspect of the foot and ankle. Of their patients, five required split-thickness skin grafts and one required a vascularized flap for soft tissue coverage. Two ultimately required Syme amputation. Four of the patients had complete disruption of the Achilles tendon. Three had no repair or reconstruction of the triceps surae tendon, and one had delayed reconstruction 3 months after injury. Vosburgh and associates (123) speculated that dense scarring in the posterior ankle results in a “physiologic tendon” and that extensive reconstructive surgery is not always necessary for satisfactory function. Boyer et al. reported on a patient with deltoid ligament loss due to a severe grinding injury that required a free plantaris tendon graft to reconstruct the ligament (14). Soft tissue coverage was achieved using a free muscle transfer.

Lateral Ankle Sprains

In 1984, Vahvanen published a prospective study of 559 children who presented with severe supination injuries or sprains of the ankle (120). Forty patients, 28 boys and 12 girls, with an average age of 12 years (range 5–14) were surgically explored. The indications for surgery included swelling, pain over the anterior talofibular ligament, limp, clinical instability, and, when visible, a displaced avulsion fracture. Such fractures were visible radiographically in only 8 patients but were found at surgery in 19. Thirty-six ankles were found to have injury of the anterior talofibular ligament at surgery. Only 16 of these had either a positive lateral or anterior drawer stress test. At follow-up all patients were pain free and none complained of instability. Based on the incidence of residual disability after such injuries in adults reported in the literature (21%–58%), these researchers suggested primary surgical repair.

Busconi and Pappas reported 60 skeletally immature children with chronic ankle pain and instability (19). Fifty of these children responded to rehabilitation, but 10

had persistent symptoms. Although 3 of these patients' initial radiographs were within normal limits, all patients with persistent symptoms eventually were found to have ununited osteochondral fractures of the fibular epiphysis. All 10 patients with persistent symptoms were treated with excision of the ununited osteochondral fracture and a Brostrom reconstruction of the lateral collateral ligament. All were able to return to activities, and none reported further pain or instability.

It is my opinion that the diagnosis of an acute ankle sprain in a child with an open fibular physis is reasonable when the child has tenderness well localized to the tip of the fibula or over the anterior talofibular ligament with little or no tenderness over the open fibular physis. The presence on the otherwise normal radiograph of an avulsion fracture of either the tip of the fibula or the lateral aspect of the talus is also consistent with this diagnosis. When routine views fail to demonstrate such avulsion fractures, the views described by Haraguchi et al. may be helpful (49).

Because chronic pain and instability do not always complicate such injuries, I treat these injuries nonoperatively when they are seen acutely. Patients who have persistent complaints after adequate rehabilitation following such treatment are treated with excision of any ununited fragments and Brostrom reconstruction as necessary.

Ankle Dislocations

Nusem et al. reported on a 12-year-old girl who was seen with a posterior dislocation of the ankle without associated fracture (88). This was a closed injury and resulted from forced inversion of a maximally plantar flexed foot. The dislocation was reduced under intravenous sedation and the ankle immobilized in a short leg cast for 5 weeks. The patient was asymptomatic at follow-up 4 years postinjury. The inversion stress views at that time revealed only a 3 degree increase in laxity compared with the uninjured side. The anterior drawer sign was negative. There was no evidence of avascular necrosis of the talus on follow-up radiographs.

REHABILITATION

For patients treated with cast immobilization, quadriceps, hamstring, and abductor exercises are begun as soon as pain and swelling allow. Usually a below-knee cast is worn during the last 2 to 3 weeks of immobilization, and weight bearing to tolerance is allowed during this time. After immobilization is discontinued, ankle range-of-motion exercises and strengthening exercises are begun. Protective splinting or bracing is usually not required after cast removal. Running is restricted until the patient demonstrates an essentially full, painless range of ankle and foot motion and can walk without a limp. Running progresses from jogging to more strenuous running and jumping as soreness and endurance dictate. For athletes, unrestricted running and jumping ability should be achieved before return to sports. Patients should be able to hop on the injured side equal to the noninjured side. Protective measures such as taping or bracing are recommended initially for return to most sports.

Most patients with physeal ankle fractures recover quickly and require little or no formal physical therapy. For this reason, and because of compliance considerations, fractures treated with internal fixation are usually protected with below-knee casting instead of starting an early range-of-motion program in a removable splint.

Reflex sympathetic dystrophy occasionally develops after these injuries and is treated initially with an intensive formal physical therapy regimen that encourages range of motion and weight bearing (125). For patients who do not respond quickly to such a program, I have had good uccess with a brief hospital admission for physical therapy in association with continuous epidural analgesia.

PROGNOSIS AND COMPLICATIONS

Delayed Union and Nonunion

Delayed union and nonunion are rare after distal tibial physeal fractures (Fig. 25-57). Dias (32) reported on one patient with a delayed union and one patient with a previous physeal bar excision who had a nonunion that healed after open reduction, internal fixation, and bone grafting. Siffert (110) reported nonunion in a patient with avascular necrosis of the distal tibial epiphysis. I have seen two younger patients with Salter-Harris type III fractures that appeared to be progressing to nonunion. Because neither patient had any complaints of pain or any evidence of progressive displacement of the fracture and stress views showed no instability, no treatment was undertaken. Both fractures eventually united (Fig. 25-58). I have seen one patient with a nonunion after open reduction and internal fixation in whom pin fixation and cast immobilization were discontinued prematurely. The fracture healed after repeat open reduction and internal fixation.

FIGURE 25-57. Complex nonunion of a Salter-Harris type III fracture of the medial malleolus in an 8-year-old boy. Note that the distal tibial epiphysis is in valgus, whereas the talus is in varus. (Courtesy of Brent Broztman, M.D.)

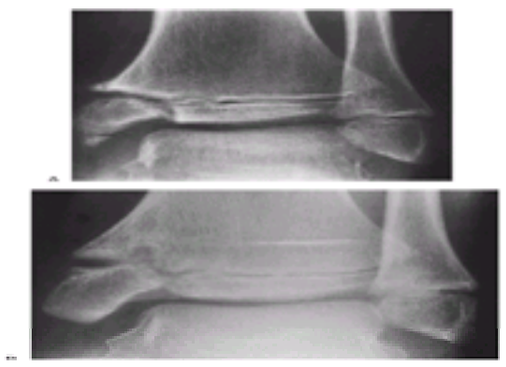

FIGURE 25-58. Nonunion and delayed union. **A:** Ten-year-old girl with incomplete healing of a supination–inversion Salter-Harris type III fracture of the distal tibia after 12 weeks of cast immobilization. **B:** Sixteen months after injury, the fracture united without further immobilization; no physeal bar formation or growth abnormality has occurred.

Deformity Secondary to Malunion

Rotational malunion usually occurs after triplane fractures that are either incompletely reduced or are initially immobilized in below-knee casts. It also has been reported after Salter-Harris type I and II injuries. Derotational osteotomy may be performed for extraarticular fractures if discomfort and stiffness occur. Guille et al. reported a rotational malunion of lateral malleolar fracture that led to a stress fracture of the distal fibula that went on to delayed union (48). Their patient required

correction of the malrotated distal fibula and bone grafting of the delayed union site.

Anterior angulation or plantarflexion deformity usually occurs after supination–plantarflexion Salter-Harris type II fractures. Theoretically, an equinus deformity might occur if the angulation exceeds the range of ankle dorsiflexion before fracture, but this is rare, probably because the deformity is in the plane of joint motion and tends to remodel with growth.

Valgus deformity is most common after external rotation Salter-Harris type II fractures. The degree to which the deformity may spontaneously resolve or remodel with growth is controversial. Caruthers and Crenshaw (21) reported resolution of a 12 degree valgus deformity in a 13½-year-old boy, but Spiegel and associates (112) reported persistent residual deformity in a significant number of their patients (Fig. 25-59). Varus deformity most often results from growth abnormality and infrequently is the result of simple malunion.

FIGURE 25-59. Radiograph of a 14-year-old boy, 4 months after pronation–eversion–external rotation injury, reveals 16 degrees of valgus angulation.

If significant angular deformity persists at the completion of growth, supramalleolar osteotomy should be performed. Moon et al. followed nine children with posttraumatic varus deformities of the ankle secondary to supination inversion injuries (84). These patients went on to develop medial subluxation of their ankles with associated internal rotational deformity. Takakura et al. described successful open wedge osteotomy for varus deformity in nine patients (117). Scheffer and Peterson recommend opening wedge osteotomy when the angular deformity is 25 degrees or less and the limb length discrepancy is or will be 25 mm or less at maturity (107). Preoperative planning should include templating the various types of osteotomies to determine which technique will maintain the proper mechanical alignment of the tibia and ankle joint and will not make the malleoli unduly prominent. Osteotomy is not recommended for malunion of intraarticular fractures because it cannot correct the joint incongruity that results from malunion (Fig. 25-60).

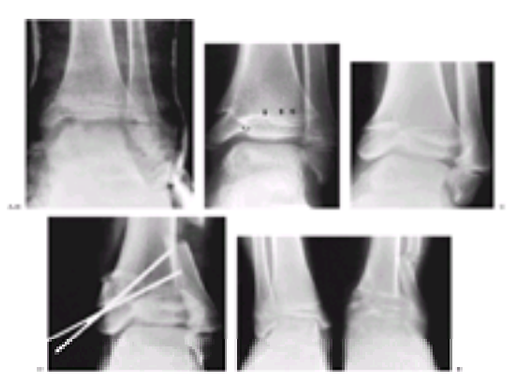

FIGURE 25-60. A: This apparently nondisplaced medial malleolus fracture in an 11-year-old boy was treated with immobilization in a long leg cast. **B:** Fourteen months after injury, there is a clear medial osseous bridge and asymmetric growth of the Park-Harris growth arrest lines (*black arrows*). Note the early inhibition of growth on the subchondral surface of the fracture (*open arrow*). **C:** Five years after injury, the varus deformity has increased significantly and fibular overgrowth is apparent. **D:** The deformity was treated with a medial opening-wedge osteotomy of the tibia, an osteotomy of the fibula, and epiphysiodesis of the most lateral portion of the tibial physis and fibula. **E:** Three months after surgery, the osteotomies are healed and the varus deformity is corrected; the joint surface remains irregular. (Courtesy of Earl A. Stanley, Jr., M.D.)

Growth Arrest

Deformity caused by growth arrest usually occurs after Salter-Harris types III and IV fractures in which a physeal bar develops at the fracture site, leading to varus deformity that progresses with continued growth. Spiegel and associates (112) reported growth problems in 9 of 66 patients with Salter-Harris type II fractures.

Earlier reports (21,29) attributed the development of physeal bars to crushing of the physis at the time of injury, but more recent reports (58,70) discount this explanation and claim that with anatomic reduction (open reduction and internal fixation if needed), the incidence of physeal bar formation can be decreased. The validity of this claim is difficult to determine from published reports. One problem is the small numbers of patients in all series and the even smaller numbers within each group in each series. Another problem is the age of the patients in operative and nonoperative groups in the various series; for example, many children reported to do well with a particular treatment method have so little growth remaining that treatment may have had little or no effect on growth.

Kling and co-workers (70) reported physeal bars in two of five patients treated nonoperatively and in none of three patients treated operatively in children 10 years of age and younger. However, in my experience with eight patients, two of five treated operatively developed physeal bars, whereas none of the three patients treated nonoperatively had physeal bars. This supports the conclusion of Cass and Peterson (22), Ogden (89), and others that growth problems after these injuries may not always be prevented by open reduction and internal fixation. Open reduction of displaced Salter-Harris type III and IV ankle fractures would seem advisable to restore joint congruity, regardless of whether growth potential can be preserved.

Harris growth lines have been reported to be reliable predictors of growth abnormality (57), but I have found that although lines parallel to the physis are reliable, lines that appear to diverge from the physis may be misleading (Fig. 25-61). Harcke and colleagues reported early detection of growth arrest with bone scanning techniques (51).

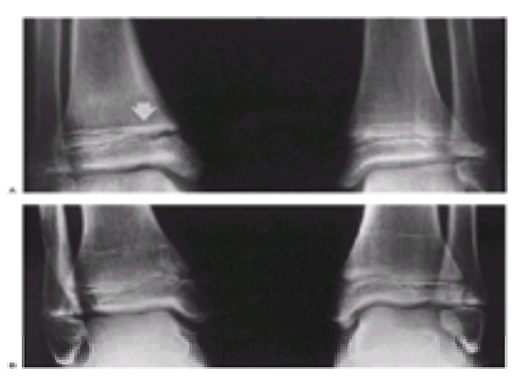

FIGURE 25-61. A: Six months after cast immobilization of a nondisplaced supination–inversion Salter-Harris type III fracture of the right distal tibia in an 8-year-old boy. The Park-Harris growth arrest line (*arrow*) appears to end in the physis medially and diverge from the physis laterally. **B:** Two years later, no physeal bar is present and growth is normal.

Spontaneous resolution of physeal bars has been reported (13,24), but is rare. Most patients require excision of small bony bars and may require correction of significant angular deformity with osteotomy (Fig. 25-62). Epiphisiodesis may be required as well in the margin at large physeal bridges. The evaluation and treatment of physeal bars, angular deformity, and leg-length discrepancy are discussed in Chapter 5.

FIGURE 25-62. A: One year after open reduction and internal fixation of a Salter-Harris type III fracture of the distal tibia in a 7-year-old boy, varus deformity has been caused by a physeal bar. **B:** Two years after excision of the physeal bar and insertion of cranioplast, satisfactory growth has resumed and the deformity has resolved.

Karrholm and co-workers (64) reported progressive ankle deformity caused by complete growth arrest of the fibula with normal growth of the tibia (Fig. 25-63). They found that continued fibular growth with complete arrest of tibial growth was usually compensated by proximal migration of the fibula so that varus deformity did not occur.

FIGURE 25-63. Valgus deformity of the ankle, lateral displacement of the talus with widening of the joint medially, and severe shortening of the fibula after early physeal arrest in a child who sustained an ankle injury at 6 years of age. (Courtesy of James Roach, M.D.)

Because the amount of growth remaining in the distal tibial physis is small (~l0.25 inch per year) in most older patients with these injuries, the amount of leg length discrepancy resulting from complete growth arrest tends to be relatively small. Treatment may be required if the anticipated discrepancy is projected to be clinically significant (Fig. 25-64).

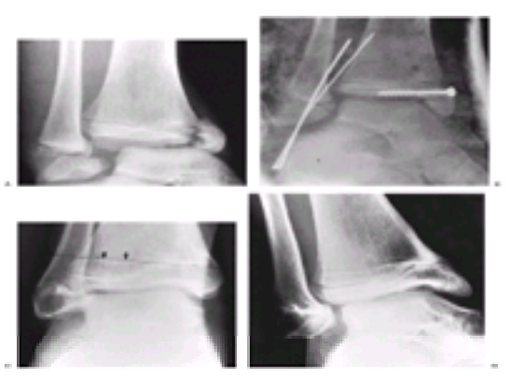

FIGURE 25-64. A: Stage II supination–inversion injury in an 11-year-old child. Salter-Harris III fracture of the medial malleolus and a Salter-Harris I fracture of the fibula. **B:** After open reduction and internal fixation. **C:** At 14 months postinjury, the distal fibular physis is completely closed. The Park-Harris growth arrest lines (*arrows*) in the tibia are asymmetric, indicating a possible arrest of the medial physis. **D:** Three years later, the lateral malleolus is short, mild varus deformity is present, and the medial physis is partially closed. The child had a leg length discrepancy of 2.4 cm. (Courtesy of Douglas Hyde, M.D.)

Arthritis

Epiphyseal ankle fractures that do not extend into the joint have a low risk of posttraumatic arthritis, but injuries that extend into the joint may produce this complication. Caterini and co-workers (23) found that 8 of 68 (12%) patients had pain and stiffness that began 5 to 8 years after skeletal maturity. Ertl and associates found that 18 to 36 months after injury 20 patients with triplane fractures were asymptomatic, but at 36 months to 13 years after injury only 8 of 15 patients evaluated were asymptomatic (36).

Ramsey and Hamilton (100) demonstrated in a cadaver study that 1 mm of lateral talar displacement decreases tibiotalar contact area by 42%, which greatly increases the stress on this weight-bearing joint. More recently, Michelson and colleagues (83) reported that a cadaver study using unconstrained specimens suggested that some lateral talar displacement occurs with normal weight bearing. Because of their findings, they questioned the current criterion of 2 mm of displacement for unstable ankle fractures. However, the results of Ramsey and Hamilton's study correlate well with other studies that have shown increased symptoms in patients in whom more than 2 mm of displacement was accepted (23,36).

Avascular Necrosis of the Distal Tibial Epiphysis

Siffert and Arkin (110), in 1950, were the first to call attention to this complication of distal tibial fractures. In their patient, the combination of nonunion of a medial malleolar fracture and avascular necrosis caused pain that required an arthrodesis 14 months after injury. Dias (32) reported a patient with this complication who did not require arthrodesis but who had a significant leg length discrepancy that required epiphysiodesis of the contralateral tibia. I have seen one patient with this complication. The patient had significant joint stiffness and developed a valgus deformity secondary to collapse. After revascularization of the epiphysis, the ankle was realigned with a supramalleolar osteotomy, and 5 years later the patient had satisfactory function without pain (Fig. 25-65).

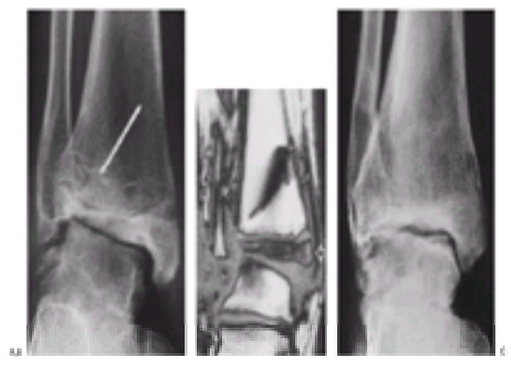

FIGURE 25-65. A: A 12-year-old girl with ankle pain 6 months after open reduction of severe open comminuted fractures of the distal tibia and fibula. Note the sclerosis and collapse of the distal lateral tibial epiphysis. **B:** Magnetic resonance imaging demonstrates lack of marrow signal from the tibial epiphysis. **C:** Five years after osteotomy for correction of the valgus deformity the patient's pain was relieved but joint motion remains limited.

FRACTURES AND DISLOCATIONS OF THE FOOT

THOMAS P. SAN GIOVANNI
RICHARD H. GROSS

Fractures of the foot in children are relatively unusual injuries that have generated little interest because they usually present little difficulty. As Rang (132) stated in *Fractures in Children,* “Injuries to children's feet, despite all the little bones and joints, are remarkably uninteresting. Very few fractures will be encountered that display any subtleties or tricks; few are even displaced” (26). Occasionally, a severe injury challenges the orthopaedist's ingenuity when deciding whether to attempt to salvage a functional foot or proceed to amputation. On the other end of the clinical spectrum, it is sometimes difficult to differentiate between relatively minor injuries and the multitude of sesamoids and minor growth variants in the growing foot.

At present there are more reports of children's foot injuries, but they are still rare when compared with forearm or femoral fractures. Because they are infrequent, guidance from the experience of others is helpful, but perplexing fractures, such as a badly displaced calcaneal fracture in a young child, must still be managed without a firm data base.

Computed tomography (CT) and magnetic resonance imaging (MRI) allow us a much greater understanding of the nature of injuries to the foot. The development of sophisticated techniques such as Ilizarov fixation and ankle arthroscopy allows more options for treatment, but expertise in all relevant techniques is difficult for any of us to attain.

ANATOMY

As in any injury, knowledge of the regional anatomy is essential in evaluating the injury and formulating an intelligent treatment plan. Although the foot lacks the intricacies of fine motor control evident in the hand, it is a remarkable structure in its own right. During the walking cycle, it is both flexible and rigid—flexible on foot strike and rigid at lift-off (102, 187). Any structural aberration that deprives the foot of its flexibility (such as talar arthrodesis) alters the normal distribution of forces through the foot during stance phase. A combination of normal muscular action and the architecture of the foot provides rigidity at toe-off, a situation obviously affected by injuries involving muscle–tendon units in the hindfoot (104).

The anatomic factors pertinent to the management of foot injuries in children are reviewed briefly, because an exhaustive knowledge of the ligaments of the mid-foot, for instance, is not often clinically applicable. Standard anatomy references can supplement the material in this chapter if further details are needed (74, 146).

Ossification

The calcaneus is the first major bone to ossify, usually in the fifth month of gestation; the talus may ossify as early as the eighth month or as late as after birth. The timing of the appearance and fusion of ossification centers in the foot has been well documented (Fig. 26-1). However, wide individual variations occur, for instance, in the appearance of the ossific nucleus for the tarsal navicular bone. Accessory bones in the foot have been noted in the fetus as early as the fourth postovulatory month.

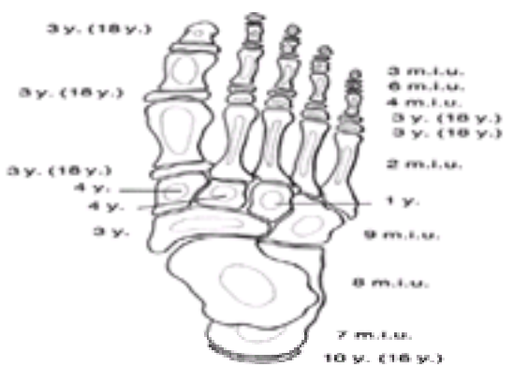

FIGURE 26-1. Time of appearance and fusion of ossification centers of the foot. Figures in parentheses indicate the time of fusion of primary and secondary ossification centers (*y.,* years; *m.i.u.,* months *in utero*). (Redrawn from Aitken JT, Joseph J, Causey G, et al. *A manual of human anatomy,* 2nd ed. Vol. IV. London: E & S Livingstone, 1966:80; with permission.)

Ogden (123) and others have emphasized that the shape of the ossific nuclei of the bones does not resemble the shape of the adult structure, or even the shape of the chondro-osseous bones. Talar ossification begins in the head and neck in the infant, extending in a retrograde direction into the body with growth. The calcaneal ossification center in the young child has a protective cartilaginous covering that alters fracture patterns.

Soft Tissue Structures

The skin on the plantar surface of the foot is the body's interface with the ground, and it is especially suited for that task. The superficial fascia is heavy and continuous with that of the leg. On the plantar surface, at the distal metatarsal level, it blends with the deeper tissue, surrounding the plantar metatarsal and common digital nerves. The fascial layer on the dorsum of the foot is thin and filmy. The deep fascia is analogous to the deep palmar fascia of the hand, with a strong central aponeurosis and thinner medial and lateral parts covering the intrinsic muscles of the big and little toes. Serrafian (153) described the plantar fascia as acting as a tie-rod; the bony columns and the plantar aponeurosis form a truss, a triangular structure with two struts or beams connected at the base by a tie-rod. When the foot is loaded, tensile stresses are taken up by the plantar aponeurosis, thus sparing the bony structures from tension.

Septae from the plantar aponeurosis descend to attach to the first and fifth metatarsals, dividing the plantar surface of the foot into three compartments, in addition to the four dorsal interosseous compartments. Shereff (154) and Myerson (117) noted that the three muscles of the central compartment—the abductor hallucis, the quadratus plantae, and the flexor digitorum brevis—all have separate compartments; thus, there are nine fascial compartments in the foot (the four interosseous, the three central, one lateral, and one medial; Fig. 26-2). Therefore, when a fasciotomy is performed for ischemia of the intrinsic muscles, all compartments must be released to avoid subsequent contracture.

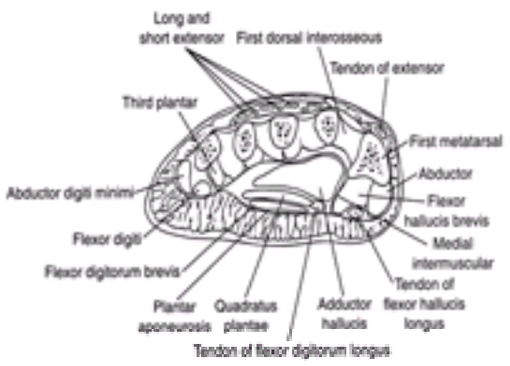

FIGURE 26-2. Cross section of the foot at the level of the proximal metatarsals to demonstrate the fascial compartments. (Modified from Hollinshead WH. *Anatomy for surgeons,* 2nd ed. Vol. 3. New York: Hoeber-Harper, 1969:857; with permission.)

Vascular Anatomy

The blood supply to the foot is almost exclusively derived from the terminal branches of the anterior and posterior tibial arteries. Occasionally, the perforating branch of the peroneal artery supplies much of the dorsum, but ordinarily the contribution of the peroneal artery is several lateral calcaneal branches and an anastomotic branch of the perforating peroneal artery with the lateral malleolar branch of the anterior tibial artery.

The dorsalis pedis artery, beginning at the ankle joint, is the continuation of the anterior tibial artery on the dorsum of the foot. It usually extends over the superior talus, navicular bone, and second cuneiform bone to branch at the second metatarsal into the deep plantar artery and the arcuate artery. The dorsal metatarsal arteries are branches of the arcuate artery. Medial and lateral tarsal arteries supply the dorsum of the mid-foot.

The posterior tibial artery divides into medial and lateral plantar arteries under cover of the flexor retinaculum. The medial artery is much smaller, passing under the abductor hallucis with the medial plantar nerve, and proceeding distally along the medial side of the flexor hallucis longus tendon to terminate at the great toe, accepting an anastomosis from the deep plantar artery. The larger lateral branch proceeds laterally and distally with its accompanying nerve between the flexor digitorum brevis and quadratus plantae. It is protected by the plantar aponeurosis as well. Between the flexor digitorum brevis and the abductor digiti minimi, it turns deeply and medially to lie on the plantar surface of the interossei, and forms the plantar arch. The plantar metatarsal arteries arise from the arch to form the common digital arteries and anastomose with smaller branches from the dorsal metatarsal arteries to supply the toes.

Injury to the posterior tibial artery at the ankle can severely compromise the blood supply to the heel pad. Injuries of the forefoot generally are less serious because of the more generous anastomosis in this area of the blood supply to the soft tissues.

The anatomic arrangements described here are not invariably present, and variants can be present.

Neurologic Anatomy

The nerve supply to the important plantar aspect of the foot is from the posterior tibial nerve. The medial and lateral plantar nerves supply all the musculature of the sole of the foot. In contrast to the medial plantar artery, though, the medial plantar nerve supplies most of the terminal sensory branches, including the proper digital

nerves to the great toe and the common digital nerves to the next three interspaces. The three and a half toes supplied by the medial plantar nerve are analogous to the median nerve innervation in the hand. The lateral one and a half toes are supplied by superficial branches of the lateral plantar nerve. This nerve also supplies all the interossei and the adductor hallucis, analogous to the distribution of the ulnar nerve in the hand.

Bony Anatomy

The bony architecture of the foot is well adapted for weight bearing, providing stability with sufficient flexibility to accommodate the complex rotational factors essential for a smooth gait. By convention, the talus and calcaneus are known as the hindfoot, the navicular cuboid and cuneiform bones as the mid-foot, and the metatarsals and phalanges as the forefoot.

The talus is the intermediary between the foot and leg, with the ankle joint above and the subtalar joint below. Its blood supply is rather precarious, because so much of its surface is covered with articular cartilage, leaving only the constricted neck to accept most of its nutrient vessels. Because a basic knowledge of the blood supply to the talus is helpful in determining the prognosis for an injury to the talus, it is discussed with the description of that fracture. The body of the talus is quadrilateral when viewed superiorly, being slightly wider anteriorly (Fig. 26-3). The tendon of the flexor hallucis longus passes between the tubercles; the lateral tubercle is sometimes separate and known as the os trigonum (62). The lateral process projects between the two articular surfaces, and to it attaches the talocalcaneal ligament. The inferior surface of the talus contains the articular surfaces of the subtalar joint. The anterior and middle facets often are joined and separated from the large posterior facet by the sulcus. The anastomotic ring passes through the sulcus, and the strong interosseous talocalcaneal ligament also attaches here.

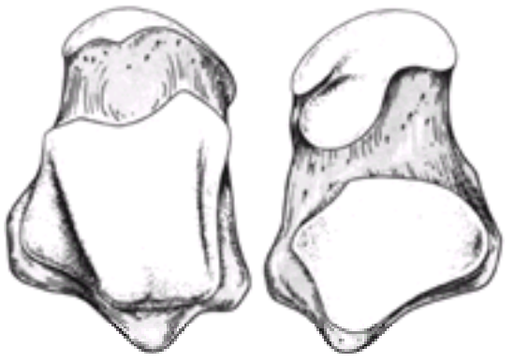

FIGURE 26-3. The superior **(left)** and inferior **(right)** surfaces of the talus. The divergence of the medial and lateral articular facets is evident on the superior view. The constricted neck is the major recipient of the vascular supply to the head and body; both are covered with articular cartilage. The confluence of the anterior and middle articular facets on the inferior surface is common. (Reprinted from Weber BG, Brunner C, Freuler F. *Treatment of fractures in children and adolescents.* New York: Springer-Verlag, 1980:373; with permission.)

The superior surface of the calcaneus is adapted to conform to the inferior talus. In addition, the prominent sustentaculum tali projects medially and articulates with the medial facet of the talus. The tendon of the flexor hallucis longus passes beneath the sustentaculum, and the strong calcaneonavicular “spring” ligament arises from it. The tuberosity is the posterior extremity of the calcaneus and is represented by an apophysis in childhood. The tuberosity has medial and lateral processes, with the medial tuber giving origin to the abductor hallucis and flexor digitorum brevis, the lateral to the plantar aponeurosis. The Achilles tendon inserts into the inferior half of the tuberosity; the superior half of the tuberosity is separated from the tendon by a bursa.

The navicular bone is interposed between the talus and the three cuneiform bones and articulates laterally with the cuboid. The medial tuberosity affords an insertion for the posterior tibial tendon and often remains as an “accessory” navicular bone, sometimes confused with a fracture.

The three cuneiform bones and cuboid form the distal row of tarsals. The first or medial cuneiform bone is the largest, the second the smallest. When viewed in cross section, the bones are wedge shaped, being blunt dorsally, to accommodate the arch of the foot. The relationship of the middle cuneiform bone with the second metatarsal (the longest metatarsal) is of particular clinical importance. The base of the second metatarsal is recessed between the medial and lateral cuneiform bones and is enclosed by strong ligaments to all three cuneiform bones. Thus, a tarsometatarsal dislocation must fracture the base of the second metatarsal to dislocate the remaining four joints. There is extensive ligamentous support of the mid-foot, and the ligaments are much more substantial on the plantar surface than the dorsal surface.

The metatarsals taper from their bases to their necks, then enlarge to form the heads. The secondary ossification center of the first metatarsal is proximal; those of the other four metatarsals are distal. The bases of the first and fifth metatarsals bear tuberosities for the insertion of the peroneus longus on the first and the peroneus brevis on the fifth. The tuberosity of the fifth often forms a separate ossification center that can remain ununited and is known as os vesalianum.

The proximal phalanges of the toes are much longer than the middle and distal phalanges. The middle phalanges can have little form and, except for the big toe, the distal phalanges can be tiny.

Knowledge of surface anatomy often is helpful in assessing a clinical injury. Landmarks in the small child are more difficult to delineate, but localized tenderness is always helpful in evaluating a clinical injury and can often point one to areas of the x-ray deserving special attention.

FRACTURES OF THE TALUS

Fractures of the talus are rare in children and appear to differ from those in adults. For some time it was thought that these fractures did not occur in children with any regularity. Canale and Kelly (23), in a study of 71 fractures of the neck of the talus, included 12 children who were 16 years of age or younger. Six were 15 or 16 at the time of injury, and four were less than 10 years old. Letts and Gibeault (95) reported 12 fractures of the neck of the talus in children, four of whom were under 3 years of age.

Forced dorsiflexion appears to be the common mechanism of injury in all series (Fig. 26-4) (31,108). However, the reported association of talar fractures with fractures of the medial malleolus implicates a supination component to at least some injuries; the disability reported seemed more attributable to the ankle fracture than the talar fracture (74). A supination mechanism has been associated with more severe injuries. With excessive forced supination, the talar neck impinges against the medial malleolus, which has been postulated as the cause of medial neck comminution and subluxation of the subtalar joint commonly associated with these fractures (37).

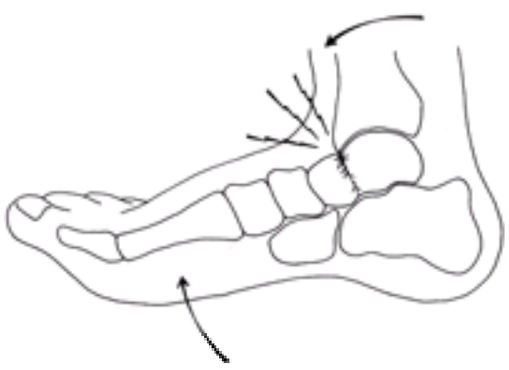

FIGURE 26-4. The mechanism of fracture of the neck of the talus by forced dorsiflexion of the foot. The talar neck is impinged on the anterior lip of the tibia.

Most talar fractures reported in children involve the talar neck. Fractures of the neck of the talus do not involve the articular surface of the ankle. The inferior portion of the neck is in the region of the interosseous ligament, so talar neck fractures are extraarticular. Although extraarticular, the inferior aspect of the talus articulates with the three facets of the calcaneus. Significant malalignment of talar neck fractures may alter the biomechanical relationships of the talocalcaneal articulations and could lead to early degenerative changes. Sangeorzan et al. emphasized the importance of avoiding varus malalignment at the time of fracture reduction (144).

Isolated fractures of the talar dome, or body, have been described. In adults, fractures of the body account for fewer than 20% of talar fractures; the incidence may be even less in children (159). Fractures of the body of the talus in adults have a worse prognosis than neck fractures. From an anatomic standpoint, the same principle should apply in children, but there is no published series to substantiate this opinion.

Anatomy

The talus generally is divided into three parts—the body, neck, and head. The body articulates with the ankle and calcaneus and its surface is almost entirely cartilaginous. The more constricted neck is perforated about its entire circumference to receive nutrient vessels, with the body then dependent on interosseous vessels from the neck. The head again flares and is cartilaginous for its articulation with the navicular bone. Inferiorly, the posterior facet articulates with the calcaneus. The interosseous ligament and sulcus lie under the neck, and the anterior and variable middle facet lie under the head.

A general knowledge of the vascular supply to the talus is basic to understanding the risk of avascular necrosis. Mulfinger and Trueta (116) described the vascular anatomy well, acknowledging the previous contributions by Wildenauer and Haliburton and associates (64,180).

The tarsal canal, formed by the sulcus of the talus and the sulcus of the calcaneus, is funnel-shaped from a posteromedial to anterolateral direction. The artery of the tarsal canal, arising from the posterior tibial artery about 1 cm proximal to the origin of the medial and lateral plantar arteries, passes posterolaterally through the canal, much closer to the talus than the calcaneus. It gives off a deltoid branch soon after its origin that anastomoses with branches from the dorsalis pedis over the neck of the talus.

The other main arterial source supplying the talus is the artery of the tarsal sinus, usually starting from an anastomotic loop between the perforating peroneal and the lateral tarsal branches of the dorsalis pedis artery. It usually is a little larger than the artery of the tarsal canal, with which it forms an anastomosis in the canal. This anastomotic artery supplies most of the talar body; the deltoid branches nourish the medial quarter.

Signs and Symptoms

Severe fractures with obvious local signs of injury present little problem in diagnosis, but nondisplaced fractures can be elusive. Swelling and pain in the region of the talus, especially with a history of a fall or forced dorsiflexion, should alert the examiner to the possibility of a talar fracture. Localized tenderness accompanies all fractures. Even nondisplaced talar fractures are characterized by tenderness just distal to the anterior ankle joint and pain with dorsiflexion. In their series of talar fractures in children, Letts and Gibeault (95) noted that occasionally the fracture was not suspected initially from the physical examination. This should not be interpreted as indicating that there were no physical findings; physical findings are noted only when the examiner has an index of suspicion for a particular injury. With nondisplaced fractures, minimal swelling may be present, but localized tenderness is always present. The presence or absence of tenderness posteriorly helps differentiate a talar fracture from an os trigonum.

Radiographic Findings

Anterior, posterior, lateral, and oblique radiographs should be made with the beam centered on the hindfoot. The technique described by Canale and Kelly (23) of pronating the foot 15 degrees with the tube angled at 75 degrees to the tabletop produces an excellent shadow of the talus and is recommended for evaluating the talus in the anteroposterior view (Fig. 26-5). Hawkins, in 1971, detailed his experience with 57 talar neck fractures in adults, and his classification of such fractures has become widely accepted (76,177): type I, nondisplaced; type II, displaced with a subtalar dislocation or subluxation; and type III, subluxation or dislocation of both subtalar and ankle joints.

FIGURE 26-5. The technique of Canale and Kelly to determine the position of fracture of the talar neck in the anteroposterior plane. This view is obtained with the ankle plantarflexed, 15 degrees internal rotation of the foot, and the x-ray beam directed 75 degrees cephalad from the table. (Reprinted from Canale ST, Kelly EB Jr. Fractures of the neck of the talus. Long-term evaluation of 71 cases. *J Bone Joint Surg [Am]* 1978;60A:151; with permission.)

AUTHOR'S PREFERRED METHOD OF TREATMENT OF TALAR NECK FRACTURES

Treatment of fractures of the neck of the talus in children is comparable with that in adults. Nondisplaced fractures are treated with simple immobilization in a long leg cast with the knee flexed to prevent weight bearing. When the fracture is united, usually in 6 to 8 weeks, weight bearing is allowed; the application of a weight-bearing short leg cast for 2 to 3 weeks smooths the transition from non–weight-bearing to weight-bearing status.

The amount of displacement that can be safely accepted in children is not definitely established. Canale and Kelly (23) considered a reduction of less than 5 mm displacement and less than 5 degrees of malalignment on the anteroposterior view to be adequate. If this position cannot be attained, open reduction is indicated. Adelaar recommended open reduction when closed reduction fails to achieve anatomic reduction and when there is 3 mm or more of dorsal displacement and 5 degrees of varus rotation (1).

OPERATIVE TREATMENT OF TALAR NECK FRACTURE

Patients with displaced fractures should be taken to the operating room for immediate reduction. Minimally displaced fractures of the talar neck (type II) often can be successfully treated with closed reduction by plantarflexion of the foot (Fig. 26-6). The hindfoot may be inverted or everted, depending on the direction of the subtalar instability. If the reduction is stable, the foot can be dorsiflexed for immobilization. If not, immobilization in plantarflexion for 6 to 8 weeks is indicated, carefully monitoring the fracture position when dorsiflexion is attempted. If reduction cannot be maintained by simple positioning, internal fixation is indicated. Fluoroscopy is of great help and often obviates the need for open reduction. Type III injuries usually require open reduction. Indirect reduction with the use of the calcaneal traction pin

connected to a small traction bow may aid in the reduction maneuver to reduce the dislocated or subluxed talar body back into the subtalar joint (Fig. 26-7). If satisfactory reduction of the talar neck fracture cannot be obtained, a limited anterior exposure can be made through either an anteromedial or anterolateral approach to allow reduction under direct vision. Through this exposure the fracture can be provisionally stabilized with Kirschner wires from anterior to posterior. A posterolateral approach is then made and two cannulated screws are placed from posterior to anterior for superior biomechanical fixation (Fig. 26-8). The provisional wires are then removed.

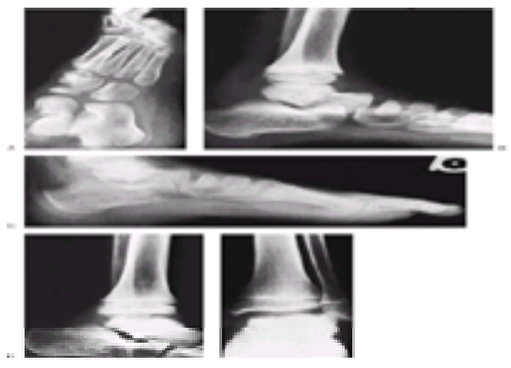

FIGURE 26-6. A: Displaced fracture of the talar neck in a 7. 2-year-old boy. **B:** Position after closed reduction by plantarflexion of the foot. **C:** Avascular necrosis is evident 10 weeks after injury. The fracture is healed and the boy is fully weight bearing despite instructions. **D:** Thirty months after injury, secondary changes are evident. The boy is asymptomatic and has not restricted activities. He returned for follow-up only as a result of a newly fractured forearm.

FIGURE 26-7. A calcaneal traction pin may at times aid in the reduction of the dislocated talar body within the subtalar joint in a Hawkins type III injury. The pin is attached to a small traction bow, then with combined traction plantarflexion and rotation of the foot the reduction is achieved. (Reprinted from Adelaar RS. Complex fractures of the talus. *Instr Course Lect* 1997;46:330; with permission.)

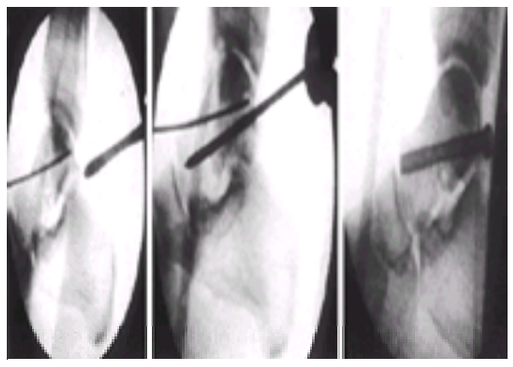

FIGURE 26-8. Anatomic reduction may need to be performed under direct visualization through an open anterior approach. Once reduced, the fracture is provisionally stabilized anteriorly with pin fixation. Posterior-to-anterior–directed screws are then placed for improved biomechanical stability, and the provisional Kirschner wire is then removed. (Reprinted from Adelaar RS. Complex fractures of the talus. *Instr Course Lect* 1997;46:329; with permission.)

Since the publication of the previous edition of this chapter, evidence for the mechanical superiority of screw fixation from posterior to anterior has been documented (163). The posterolateral approach allows extraarticular introduction of cannulated or noncannulated screws, which is not feasible through the talar head or neck (Fig. 26-9). Lemaire and Bustin (94), crediting Trillat and colleagues (169) for the idea, first recommended the posterior approach in 1980 for displaced fractures of the talus. If the ankle joint is intact, closed manipulation is performed; if the ankle joint is also disrupted by displacement of the talar body, open reduction is necessary. The posterior approach is simple anatomically: through a direct approach just lateral to the Achilles tendon. The posterior capsule is divided and the posterior talus exposed. Either two 4.0-mm or 4.5-mm cannulated screws or a single larger screw can be used with similar mechanical properties if the talus is large enough. The present assortment of cannulated screws allows greater application of this technique. Titanium screws have been used because their nonmagnetic properties allow better MRI scans should the presence of osteonecrosis later be suspected (1,166).

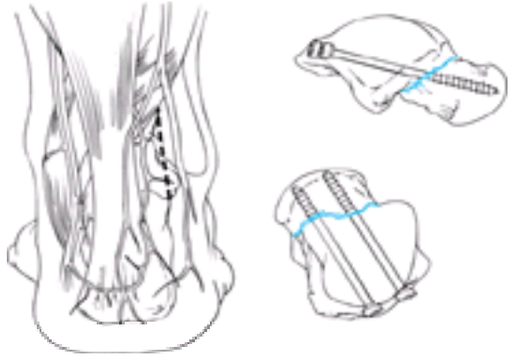

FIGURE 26-9. Left: Posterior lateral approach. Posterior-to-anterior screws may be placed percutaneously or through a formal posterior lateral approach. The incision is made lateral to the Achilles tendon, and the flexor hallucis longus is reflected medially, with the starting point of the guide pin at the posterior lateral tubercle. **Right:** The screws are directed slightly plantar medial in line with the long axis of the talar neck. Careful attention is focused on staying as extraarticular as possible with the starting point of the guide pin. The screw's threads should end beyond the fracture line of the talar neck for optimal compression at the fracture site. In general, two parallel screws are placed; however, a larger screw and a pin may be placed as an alternative. (Modified from Adelaar RS. Complex fractures of the talus. *Instr Course Lect* 1997;46:328; with permission.)

This approach is most useful if a manipulative reduction of the fracture can be attained, then held with posteriorly inserted fixation (Fig. 26-10). In this way, no surgical dissection around the vascularly vulnerable neck of the talus is necessary. Adelaar (1) noted that he does not hesitate to add a minimal anterior exposure if necessary to obtain a satisfactory reduction.

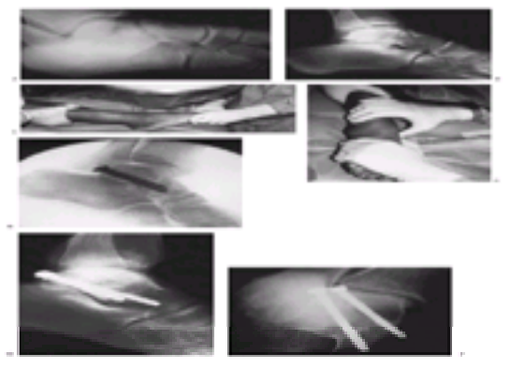

FIGURE 26-10. Anteroposterior **(A)** and lateral views **(B)** of a displaced talar neck fracture in a 15-year-old girl. Closed reduction was accomplished with longitudinal traction **(C)** and valgus movement **(D)** applied to the talus. This position was held while two guide pins were placed for 4.5-mm cannulated screw fixation. Intraoperative images **(E)**. Solid union 5 months postoperatively **(F and G)**.

Traditionally, open reduction of the talus has been performed through a dorsomedial approach, keeping the incision to the medial side of the extensor hallucis longus to avoid further damage to the anterior tibial vessels. Obviously, dissection in this region should be kept to the minimum necessary for reduction. Kirschner wire fixation is used, generally through the navicular and the head of the talus, or the head of the talus only if possible.

Monthly follow-up is indicated for the first 6 months after injury to monitor healing and the vascular status of the talus. Virtually all reported cases of avascular necrosis of the talus in children have been noted earlier than 6 months after injury. In the absence of complications, a nondisplaced fracture should be followed for 1 to 2 years after injury. Fractures healing with residual displacement require longer follow-up.

Complications

Avascular Necrosis

The most significant complication of fractures of the talus in children is avascular necrosis. The prognosis of any particular fracture depends on the location of the fracture line and the degree of displacement. The illustration of Marti (106) indicates the prognosis of any particular fracture of the talus in childhood. Nondisplaced fractures appear to have a better prognosis. However, Letts and Gibeault (95) noted the development of avascular necrosis in 3 of 12 nondisplaced talar fractures in children, a disconcerting proportion. On the other hand, Jensen et al. (78) reported no avascular necrosis in their 11 patients with nondisplaced talar fractures. They quoted a report in German by Linhart and Höllwarth (96) that noted a 27% incidence of avascular necrosis after nondisplaced fractures.

Hawkins (69,179) reported that no avascular necrosis resulted from nondisplaced fractures (type I) in his series of 57 talar neck fractures in adults. All type II fractures united, but the rate of avascular necrosis was 42%. Type III fractures, with subluxation or dislocation of both the subtalar and ankle joints, had a 91% rate of avascular necrosis following these severe injuries.

Mazel et al. (109) also noted a worse outcome in their younger patients with talar fractures associated with severe multiple trauma, such as falls from a considerable height. The severe fractures resulting from lawn mower injuries also have a worse prognosis.

The subchondral lucency in the dome of the talus, the so-called Hawkins sign, is an excellent indicator of viability of the talar body after fracture. Canale and Kelly (23) found that some patients, mostly those with nondisplaced fractures and relatively short periods of immobilization, did not develop this sign, presumably from the lack of disuse hyperemia. Thus, absence of this radiographic finding of subchondral lucency in a child does not necessarily indicate avascular necrosis, although it should raise suspicion that it may be developing.

Ogden (123) pointed out that the subchondral area in younger children is cartilaginous, which obviously interferes with the ability to see this area radiographically. MRI is now regarded as the noninvasive method of choice for the diagnosis of osteonecrosis; it may demonstrate findings on technetium scanning to be misleading (Fig. 26-11). MRI is clearly the optimal study at this time for the early diagnosis of avascular necrosis, and is useful for evaluating the extent or percentage of talar body involvement and potential for segmental collapse (166). Segmental collapse occurs in approximately one third of patients with total talar body involvement; however it is uncommon in patients with only partial avascular necrosis (40).

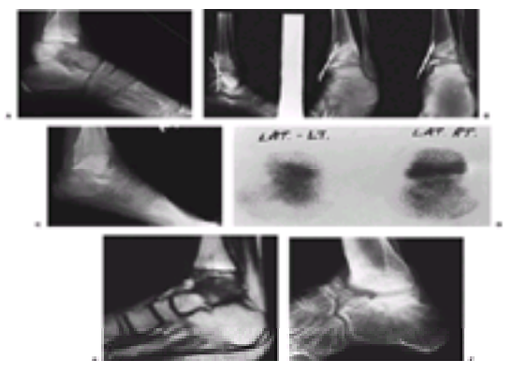

FIGURE 26-11. A: Injury film of a boy 11 years and 11 months of age who had a crush injury of the foot, along with other severe injuries (including head injury), sustained as a passenger in a motor vehicle accident. The talar neck is displaced and the tibiotalar joint subluxed. An open reduction was performed with the medial malleolar fracture fixed with Kirschner wires. The talus was not fixed. **B:** One month later, avascular necrosis of the talus is evident. A split-thickness skin graft was applied after further wound debridement, and coverage was obtained. Weight relief was afforded with a patellar tendon-bearing ankle-foot orthosis. **C:** Six months after injury, spontaneous drainage was noted from the posterior part of the wound. Film demonstrates avascular necrosis of the body. **D:** Technetium bone scan showed uptake in the body of the talus. **E:** Magnetic resonance imaging scan definitively demonstrated avascular necrosis and collapse of the talar body, despite the increased uptake on bone scan. **F:** Talectomy was performed, and the subsequent functional result has been gratifying. (Courtesy of J. Banta, M.D.)

The necessity of non–weight bearing in the management of avascular necrosis after fracture of the talus has not been determined. Hawkins recommended restricting weight bearing only until union was established, even in the presence of avascular necrosis (69,70). He stated that collapse of the talus was well tolerated by most patients, and that non–weight bearing did not necessarily protect against collapse. Furthermore, a period of several years may be required before radiographic evidence of revascularization is complete, and this period of non–weight bearing is difficult to impose. However, in the series reported by Letts and Gibeault (95), two of three children with avascular necrosis developed flattening of the talus and stiff ankles. Both of these children were allowed to bear weight, because the fracture was not recognized in one and the developing avascular necrosis was not recognized in the other. In another child who was not allowed to bear weight, the talus revascularized in 6 months with no residual deformity.

Canale and Kelly (23) recommended non–weight bearing for avascular necrosis, noting that the results in patients treated with non–weight bearing were superior to those allowed to bear weight. None of their 22 patients with avascular necrosis had undergone surgical treatment after an average of 15 years' follow-up. Stephens' (162) patients, both with displaced fractures, apparently developed satisfactory final results with early weight bearing, but radiographic deformity was present.

Avascular necrosis can run a protracted course (Fig. 26-12), and protected weight bearing until reossification is complete can be a test of patience for the child, family, and physician. In circumstances such as these, the conservative approach generally is recommended. Either approach, allowing weight bearing or prolonged protection from weight bearing, has undesirable side effects, and these decisions should be made with the family. Whether weight bearing can be sufficiently limited in children by a patellar tendon-bearing (PTB) orthosis is problematic; my impression is that a long leg cast or orthosis with a flexed knee is the only way to ensure non–weight bearing early, with conversion to a PTB orthosis until reossification is complete. Parents should be made aware that late segmental collapse may occur despite this treatment and may be more related to the natural history of avascular necrosis than to the choice of treatment or weight-bearing status.

FIGURE 26-12. A: Nondisplaced fracture of the talar neck in a 5-year-old boy at injury. **B:** Three months after injury. **C:** Eighteen months after injury, irregularities of the subchondral bone are evident. **D:** Nine years after injury. Clinically he is asymptomatic, and radiographically the subchondral radiolucencies have reossified. (Courtesy of S. Terrance Canale, M.D.)

Varus Malalignment

Varus malalignment is the most common posttraumatic deformity. Its presence leads to a varus hindfoot combined with a supinated forefoot as a result of medial column shortening (38,83,98). In a biomechanical study, 17 degrees of varus malalignment restricted 30% of subtalar motion (38). The varus malalignment should be corrected when possible, although its long-term significance in a child is undetermined. The potential for remodeling of a child's talus is illustrated with a 10-year follow-up of a 1-year-old boy with extensive open injury to the talus after his foot was crushed by an automobile (Fig. 26-13). He regenerated a peculiar-appearing but functional talus and can carry out all activities of early teenage years without difficulty. Figure 26-13 depicts the foot position of a talar neck fracture that healed or remodeled into varus. This example suggests the merits of a conservative approach before recommending talectomy for the residual effects of a fractured talus, unless infection is present or function is severely impaired.

FIGURE 26-13. An open crushing injury to the talus and distal tibia in a 2. 3-year-old boy whose foot was run over by an automobile. **A:** At the time of injury. **B:** Avascular changes are present 6 months after injury. **C:** Eleven years after injury, he is clinically asymptomatic and has 10 degrees dorsiflexion and 30 degrees plantarflexion of the involved ankle. **D:** Clinical appearance of the feet.

Other Fractures of the Talus

Fractures of the body (dome) of the talus appear to be unusual in children. Spak (160) reported two compression fractures of the talus in children; both were treated conservatively and showed radiographic deformity at 1 year of follow-up. Clinically, no deformity or loss of function was noted, but a 1-year follow-up for such an injury is very short. Marti (106) has recommended anatomic reduction of displaced fractures of the talar body (Fig. 26-14). Because the ankle joint does not tolerate derangement of articular surfaces well, it would seem prudent to attempt accurate reduction of any intraarticular fracture, regardless of the patient's age. The relationship between residual displacement and subsequent osteoarthritis has been documented in adults. Complications related to displacement can be controlled by the treating surgeon, but the frequent disruption of vascularity is a result of the injury. Whether early accurate reduction affects the rate of vascular complications is conjectural.

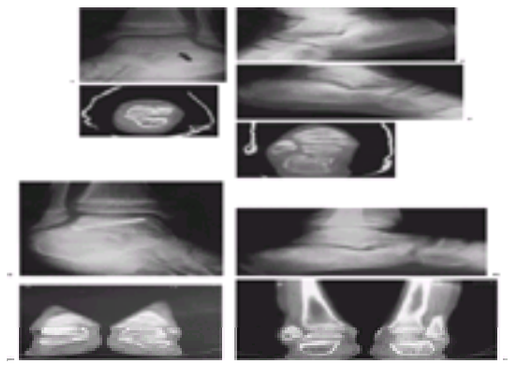

FIGURE 26-14. A 10-year-old boy sustained injuries to both feet from a fall. **A and B:** Displaced fracture of the right talar body. The arrow on the lateral view points to the talar fracture; the calcaneus is normal on this side. **C:** CT scan documents actual displacement of fracture. An open reduction was performed. **D:** Lateral view of left foot, demonstrating flattening of Böhler's angle secondary to an intraarticular fracture of the calcaneus. **E:** Widening and depression of calcaneal joint surface secondary to fracture. The fracture was manipulated in an effort to decrease hindfoot widening and was treated nonoperatively. **F:** Right talus 6 months after injury. The talus is viable, and the joint surface is congruous. **G:** Left calcaneus 6 months after injury. The joint surface is well maintained; the lateral process of the talus has hypertrophied, but Böhler's angle is still flattened. **H:** Computed tomography scan of talus 6 months after injury. The ankle joint surface is well maintained. **I:** Computed tomography scan of calcaneus 6 months after injury. The joint surface of the calcaneus has remodeled. Hindfoot posture is symmetric, with residual increased width of the calcaneus. The patient is asymptomatic. (Courtesy of Keith Merrill, M.D.)

The lesser fractures of the talus involving the lateral or posterior process appear to be rare. However, with the increasing popularity of snowboarding as a recreational activity for the younger population, fractures of the lateral talar process are being recognized with increasing frequency. Winter sports data have indicated that 80% of children who participate in snow sports have ridden snowboards by age 12 (111). Kirkpatrick et al. (89) reported that lateral talar process fractures represented 34% of fractures sustained about the ankle in snowboarders. The fracture is often missed on initial presentation and presents late as a “persistently painful sprained ankle.” The mechanism of injury is believed to be dorsiflexion of the ankle combined with inversion of the hindfoot (69). Internal rotation views of 20 to 25 degrees better demonstrate this fracture than traditional anteroposterior, lateral, and mortise views (115). CT scanning has been recommended for better delineation of the fracture (Fig. 26-15). Treatment is based on the size and displacement of the fracture fragment. For fragments larger than 1 cm and with more than 2 mm of displacement, open reduction and internal fixation has been recommended (83,106). Nondisplaced or minimally displaced fractures (<2 mm) can be treated in a short leg non–weight-bearing cast. For small displaced fragments or those with significant comminution, simple exclusion of the fragment can be performed if painful symptoms persist after conservative treatment.

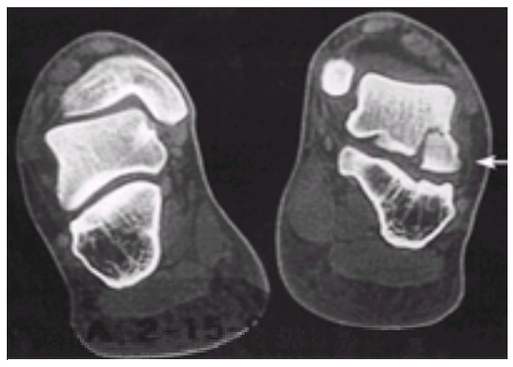

FIGURE 26-15. Coronal images of a computed tomography scan best demonstrate this rather large displaced fracture of the lateral talar process (*arrow*). The contralateral foot displays normal anatomy. (Reprinted from Kirkpatrick DP, Hunter RE, Janes PC, et al. The snowboarder's foot and ankle. *Am J Sports Med* 1998;26:275; with permission.)

A bipartite talus simulating a fracture has been reported (180) but appears to be so rare that treatment must be individualized. The os trigonum, a normal variant, can sometimes be confused on the radiographs with a fracture of the posterior process of the talus. This accessory center of ossification generally appears at 8 to 10 years of age in girls and 11 to 13 years of age in boys (62). It usually fuses to the body about a year after it appears radiographically, but it can remain separate and be a source of confusion. Careful inspection of the os trigonum reveals that it has smooth, rounded edges, not the sharp, jagged edges of a fracture.

OSTEOCHONDRAL FRACTURES OF THE TALUS

Several terms are commonly used to describe this entity, which previously could be diagnosed only by radiography or tomography (3,8,12,22,61,109,128,157). The use of modern imaging and arthroscopic surgical techniques has challenged some of our traditional tenets regarding this condition. In the literature, it may be called “osteochondral defect or lesion,” “osteochondritis dissecans,” “transchondral fracture,” or “osteochondral fracture.” Newer imaging techniques have demonstrated that some lesions may not involve the cartilage and may not in fact be “transchondral” (6).

Although this entity is most common in early adult life, it does occur in teenagers. Most of the patients in the series reported by Canale and Belding (22) were in the second decade of life at the onset of symptoms.

Mechanism of Injury

Berndt and Harty (12) coined the term *torsional impaction,* which is useful in understanding the mechanism of injury of these lesions. They experimentally reproduced the posteromedial lesion by inversion and plantarflexion of the foot combined with external rotation of the tibia (Fig. 26-16). Inversion and dorsiflexion produced the anterolateral lesion that could be accompanied by rupture of the fibular collateral ligaments. The posteromedial lesion was slightly more common, but in Canale and Belding's series (22) the lateral lesion predominated. Unless the fractured fragment is nondisplaced, healing is unlikely. If displacement is present, or if immobilization is incomplete, ingrowing capillaries from the body of the talus cannot invade the fractured fragment, and a layer of dense fibrous connective tissue becomes interposed between the fragment and the body. The articular cartilage (106), dependent only on the available synovial fluid, continues to thrive. The fracture fragment becomes avascular, “a dead prisoner in a sterile cell.”

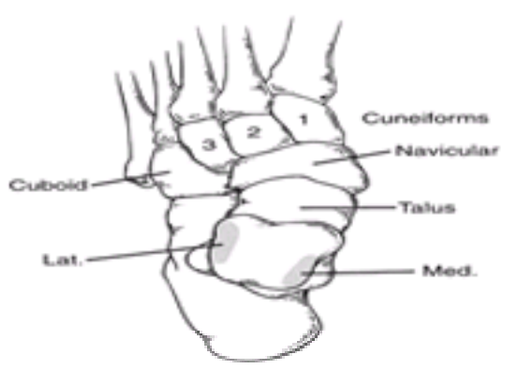

FIGURE 26-16. The usual sites of transchondral fractures of the talus in 201 cases reported by Berndt and Harty. The medial side was involved in 56%, the lateral in 44%. (Reprinted from Berndt AL, Harty M. Transchondral fractures (osteochondritis dissecans) of the talus. *J Bone Joint Surg [Am]* 1959;41:997; with permission.)

Canale and Belding (22) modified the concepts of Berndt and Harty (12) in that they could not elicit a history of injury as reliably for medial injuries as for lateral ones. They speculated that not all medial lesions were traumatic in origin. They also noted that the medial lesions were more often cup shaped, the lateral lesion wafer shaped (Fig. 26-17).

FIGURE 26-17. The medial lesion is deeper and cup shaped; the lateral lesion is thin and wafer shaped. (Reprinted from Canale ST, Belding RH. Osteochondral lesions of the talus. *J Bone Joint Surg [Am]* 1980;62:100; with permission.)

Anderson et al. (6) described a modified staging system for the classification of osteochondral fractures based on their examinations with CT and MRI (Fig. 26-18). Stage I, recognizable only with MRI scanning, consists of a subchondral fracture without collapse. Stage II denotes incomplete separation of the fragment, with the subcategory of IIA including a subchondral cyst. Stage III describes an unattached, undisplaced fragment, and stage IV an unattached, displaced fragment.

FIGURE 26-18. Modified staging system of Berndt and Harty proposed by Anderson and co-workers. Stage I is confined to subchondral trabecular compression, only identifiable by magnetic resonance imaging. Stage II denotes incomplete separation of an osteochondral fragment; if a subchondral cyst is present, the lesion is classified as IIA. Stage III designates the fragment as unattached but undisplaced. A displaced fragment would be classified as stage IV. (Reprinted from Alexander IF, Chrichton KI, Grattan-Smith Y, et al. Osteochondral fractures of the dome of the talus. *J Bone Joint Surg [Am]* 1989;71:1143; with permission.)

Signs and Symptoms

Osteochondral fractures have characteristically been diagnosed after a sprained ankle that does not resolve symptomatically.

Radiographic Findings

Smith and co-workers (157) recommended anteroposterior, lateral, and oblique radiographs for any persistently painful ankle sprain. Anderson and co-workers (6) incorporated newer imaging techniques for a diagnostic approach after study of 30 patients undergoing examination for persistent posttraumatic instability of the ankle.

The earliest stage of osteochondral fracture, microfracture of the subchondral bone, is not evident on conventional radiography. Small nondisplaced fractures also may not be visible unless the foot is positioned in such a way as to demonstrate the fracture. If symptoms persist after an ankle sprain, the previously recommended approach was to obtain bone scintigraphy (6). This approach is falling out of favor, with MRI as the alternative. Even when radiographs are negative, MRI can detect an early osteochondral defect as well as other soft tissue pathology without exposing the child to the radiation involved with bone scanning. MRI is superior for assessing the cancellous bone, especially with early lesions, but CT scanning is generally more helpful for staging and preoperative planning to locate the exact position of the fracture. Therefore, MRI is unnecessary for patients with lesions evident on conventional radiographs, but is helpful in those with positive bone scans and apparently normal radiographs. CT scanning is helpful for surgical planning.

AUTHOR'S PREFERRED METHOD OF TREATMENT OF OSTEOCHONDRAL FRACTURES

Treatment principles for osteochondral fractures of the talus are becoming fairly well established. For stage I and II lesions, a trial of 6 weeks of non–weight-bearing immobilization is warranted—the theory is that eliminating shear forces will allow reestablishment of vascular continuity. For persistently symptomatic lesions, surgical treatment is warranted. Arthroscopic treatment has become the preferred approach, because it is accompanied by less postoperative morbidity and can eliminate the need for malleolar osteotomy when treating posteromedial lesions. Arthroscopic techniques for moderate-sized lesions have focused on penetration of the subchondral bone surface (10,16,20,51,61,81,97,124,128,171). These techniques include subchondral drilling, abrasion arthroplasty, and the microfracture technique. The goal of these procedures is recruitment of stem cells brought via formation of a fibrin clot with subsequent differentiation into fibrocartilaginous repair tissue (21). Recent technological advances in the repair of cartilaginous lesions has led to alternative techniques with the goal of providing hyaline cartilage repair tissue. These include osteochondral autografts (mosaicplasty), periochondral and periosteal grafting, and allograft and autogenous chondrocyte implantation. The follow-up studies of these techniques have been short term and primarily in adults. Longer follow-up will determine whether these results offer improved results compared with previous methods. A medial malleolar osteotomy usually is required for open treatment of medial lesions (8,18,101). This technique should be restricted to older adolescents whose physis had closed.

Postoperative management of arthroscopically treated defects varies with the stage of the lesion and the procedure performed. If, for instance, a stage II lesion is drilled, cast immobilization is indicated in a young patient in an attempt to gain healing. Conversely, if an unattached fragment is debrided and a crater created, early motion is mandatory to create a favorably shaped fibrocartilaginous repair. The point at which weight bearing can be safely resumed is conjectural, but obviously depends in some degree on the site and extent of the lesion.

An intriguing alternative to arthroscopic management of medial osteochondral fractures in children was described by Greenspoon and Rosman (61). They bone grafted the defect after curettage and improved their percentage of favorable results when compared with curettage alone. However, an osteotomy of the medial malleolus is required.

SUBTALAR DISLOCATION

Subtalar dislocations are extremely rare in young children. Dimentberg and Rosman (44) reported five subtalar dislocations in children, two of which had delayed diagnosis due to the presence of other injuries. Zimmer and Johnson (190) reported this injury in a 15-year-old girl, but she was skeletally mature. Miller and Lehman (112) reported a 17-year-old patient who fractured a calcaneonavicular coalition accompanying a subtalar dislocation. Subtalar dislocations usually are caused by a plantarflexion mechanism (40,41,63), but, as in adults, complex injury patterns can cause associated injuries that complicate the subtalar dislocation and worsen the prognosis (28,110). Treatment of subtalar dislocation is closed reduction, with pin stabilization if the reduction is unstable.

CALCANEUS

Before 1982, fractures of the calcaneus in children were rarely reported (26,107,165). Of the 241 fractures of the calcaneus reported by Essex-Lopresti (49), only 12 were in the youngest age group, 9 to 20 years. Thomas (165) reported on five boys with fractures of the calcaneus in 1969, the largest reported series of that era. He found comminution and joint depression to be common. Marti's clinic in Amsterdam (106) treated three fractures of the calcaneus in children over a 10-year period; the youngest was 12 years old. Matteri and Frymoyer (103) described three calcaneal fractures in young children.

Schmidt and Weiner (150) reported that they had discovered 59 fractures of the calcaneus in patients under 20 years of age, of which 46 were in skeletally immature children. This was by far the largest series reported to date (1982). One third of the children had associated injuries, including three lumbar vertebral fractures. In 16

patients, the fracture was initially unrecognized. Soon thereafter, Wiley and Profitt (184) reported an additional 34 fractures of the calcaneus in children, and in 1986 Rasmussen and Schantz (133) reviewed 143 calcaneal fractures in patients under the age of 19.

The increased frequency of reports of calcaneal fractures in children since the early 1980s appears to be a result of improved diagnosis of nondisplaced or minimally displaced fractures. Children have fewer intraarticular fractures than adults, presumably because of less exposure to trauma, and have less severe injuries when fractures do occur (147). All studies reporting large numbers of calcaneal fractures in children mention difficulty in diagnosis, delay in diagnosis, and the benign nature of calcaneal fractures in children.

Younger children generally have fewer displaced fractures or fractures of the tuberosity or apophysis; fractures of the anterior process and inferolateral process are more common in older children. Displaced intraarticular fractures are much more common in older children.

None of the children studied by Wiley and Profitt (184) underwent surgery, but 3 of 20 patients examined at short-term follow-up did have mild symptoms. De Beer et al. (34) reported the outcome of nine children with calcaneal fractures, six of which were intraarticular. None were treated operatively, and all the patients were pain free at short-term follow-up. Schmidt and Weiner (150) did not report follow-up, nor did Rasmussen and Schantz (133), but both suggested that a good result usually can be expected (excepting obvious complicating factors such as lawn mower injuries).

Although operative treatment of intraarticular calcaneal fractures in adults has become standard, younger children may not require the same approach. Sandermann et al. (142) reported two patients treated nonoperatively, both with good results. Rasmussen and Schantz (133) studied 15 children with displaced intraarticular fractures an average of 12 years after injury and reported only “slight inconvenience” (148). When treated conservatively these fractures may heal, often with minimal symptoms, but they can result in significant restriction of subtalar motion and lead to problems with shoe wear. In adolescents, as the fracture patterns begin to resemble those of adults and less remodeling is anticipated, operative management should be considered if significant joint involvement or displacement occurs. Stress fractures of the calcaneus also have been reported in children (Fig. 26-19).

Anatomy

The calcaneus is the largest bone of the foot and the earliest to ossify. The posterior projection is called the tuberosity and has two plantar processes, which serve as sites of origin of the plantar fascia and the short muscles of the foot. The bone generally is rectangular when viewed laterally, with the posterior facet inclining superiorly to become the highest point of the calcaneus at the posterior margin of its articular surface (68). Flattening of this facet is of considerable clinical importance. The superior articular surfaces of the calcaneus are complex and adapted for articulation with the talus. The sustentaculum projects medially, supporting the end of the talus, and the anterior surface articulates with the cuboid.

The calcaneal apophysis covers the calcaneal physis, essentially occupies the tuberosity during the growing years, and demonstrates many irregularities in ossification (175). The heel cord inserts into the inferior portion of the tuberosity.

The differences in fracture patterns in children and adults are to some degree results of the anatomic differences between the immature and mature talus and calcaneus. The lateral process, the wedge that impacts on the calcaneus in joint depression injuries, is tiny in the immature talus, and the posterior facet is parallel to the ground rather than inclined. Add the cartilaginous covering of the bony nucleus, and it is easy to see how injuring forces from the lateral process in an adult are dissipated over a wider area in a child, with less severe injuries as a result.

Classification of Calcaneal Fractures

Most series have used a classification based on the original work of Essex-Lopresti (49,133,150,184). Generally, involvement of the subtalar joint is first determined, with subpatterns for each large group. The classification (Fig. 26-20) is difficult to memorize, but it may be helpful in analyzing data.

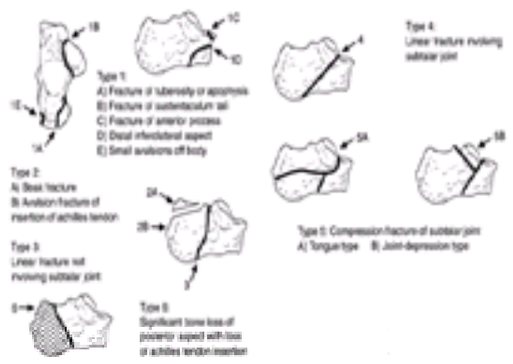

FIGURE 26-20. Classification used to evaluate calcaneal fracture pattern in children. **A:** Extraarticular fractures. **B:** Intraarticular fractures. **C:** Type VI injury with significant bone loss, soft tissue injury, and loss of insertion of Achilles tendon. (From Schmidt TL, Weiner DS. Calcaneus fractures in children: an evaluation of the nature of injury in 56 children. *Clin Orthop* 1982;171:150; with permission.)

The classification of calcaneal fractures is outlined as follows:

Type 1

A. Fracture of the tuberosity or apophysis
B. Fracture of the sustentaculum
C. Fracture of anterior process
D. Fracture of anterior inferolateral process

E. Avulsion fracture of body

Type 2. Fracture of posterior and/or superior parts of tuberosity

Type 3. Fracture of body not involving subtalar joint

Type 4. Fracture through the subtalar joint without displacement

Type 5. Displaced fracture through subtalar joint

A. Tongue type
B. Joint depression type

Type 6. Either unclassified (Rasmussen and Schantz) or serious soft tissue injury, bone loss, and loss of the insertions of the Achilles tendon

Intraarticular fractures are more accurately analyzed by CT scanning, with treatment individualized to age and degree of displacement in addition to fracture classification (57,126). Intraarticular fractures in adolescents may resemble adult fracture patterns. The Sanders CT classification scheme is commonly used to describe these patterns when the posterior facet is involved (Fig. 26-21).

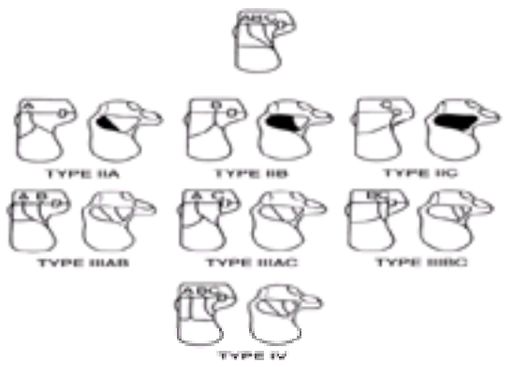

FIGURE 26-21. Sanders computed tomography classification of intraarticular calcaneal fractures. (Reprinted from Sanders R. Intra-articular fractures of the calcaneus: present state of the art. *J Orthop Trauma* 1992;6:254; with permission.)

Mechanism of Injury

Closed fractures of the calcaneus in children almost always occur as the result of a fall; however, the height of the fall appears to be less in children, possibly accounting for the lesser severity of injury in children's calcaneal fractures (148). Open fractures resulting from lawn mowers also are relatively common and are discussed later in the chapter.

Signs and Symptoms

Pain, localized swelling, tenderness, a history of a fall, and inability to walk as a result of this injury are clear indications of diagnosis. Many minimal fractures of the calcaneus are unrecognized, and careful palpation of this region in a child refusing to walk may provide the key to diagnosis. Localized tenderness in the region of the calcaneus in a toddler should raise suspicion of a calcaneal fracture, although the diagnosis may be difficult to establish without extensive imaging. Whether it is necessary to use such extensive technical assistance is subject to clinical judgment.

Radiographic Findings

Traditionally, three views (dorsoplantar, lateral, and axial) have been recommended for the diagnosis of calcaneal fractures, but many nondisplaced or minimally displaced fractures are not recognized at the time of injury. Rasmussen and Schantz (133) added the lateral oblique view, taken with the knee tilted medially with the foot on the cassette. They believed that all four projections should be routinely obtained. A lateral view of the spine should be made in the presence of more obvious fractures, because Schmidt and Weiner (150) reported that compression fractures of the spine can relate to fractures of the calcaneus in children as well as in adults. The lateral view, often not helpful in diagnosing minimally displaced fractures, is quite helpful in assessing joint depression. The tuber–joint angle (Böhler's angle, salient angle) is formed by a line parallel to the articular surfaces of the calcaneus, with a line drawn from the posterior lip of the posterior facet to the superior margin of the calcaneal tuberosity (Fig. 26-22) (100). An angle less than the uninjured side indicates depression of the joint surface. The tuber–joint angle is normally smaller in young children than the 25 degrees to 40 degrees that is normal in adults.

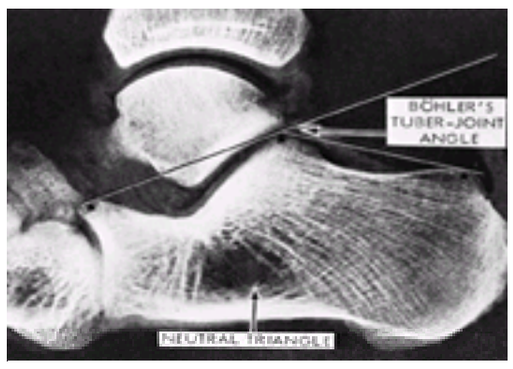

FIGURE 26-22. The landmarks for measuring Böhler's angle are the anterior and posterior facets of the calcaneus and the superior border of the tuberosity. The neutral triangle, largely occupied by blood vessels, offers few supporting trabeculae directly beneath the lateral process of the talus. (Reprinted from Harty MJ. Anatomic considerations in injuries of the calcaneus. *Orthop Clin North Am* 1973;4:180; with permission.)

Bone Scan

Starshak, Simons, and Sty (161) evaluated 10 children between the ages of 19 and 41 months with the so-called toddler's fracture to determine the role of scintigraphy in the diagnosis of unrecognized calcaneal fractures. Only 4 of the 10 patients with positive scans had radiographically demonstrable fractures. In 2 others, a fracture was evident on follow-up films 12 days later. The others had no follow-up films because symptoms had subsided. A similar series more recently reported by Laliotis and co-workers (90) also recommended bone scintigraphy. Schindler et al. (149) reported five occult fractures of the calcaneus in children under 36 months of age. Initial radiographs were normal, and treatment in a long leg cast was elected based on clinical examination results. Radiographs at 2- and 4-week intervals confirmed the diagnosis with notable sclerosis. They found no need for bone scanning in these individuals. I often apply a short leg walking cast for 2 weeks when confronted with a toddler who refuses to walk and has foot tenderness and normal radiographs. If after 2 weeks the child still cannot walk, further imaging can

be undertaken. If the child can walk, treatment is finished at considerably less cost than if scintigraphy were used (Fig. 26-23).

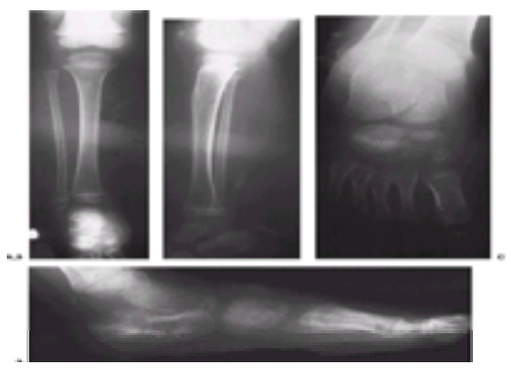

FIGURE 26-23. A and B: Radiographs of the leg and foot of a 2-year-old girl who refused to bear weight on the foot. No fracture was identified. A careful physical examination could have guided the treating physician toward a more localized radiographic examination. **C:** Two weeks later, tenderness of the calcaneus elicited on follow-up examination. Repeat radiography revealed a nondisplaced fracture of the lateral calcaneus. **D:** Obvious callus formation in the calcaneus 4 weeks after injury. (Courtesy of Paul Griffin, M.D.)

Computed Tomographic Scanning

Several reports of the value of CT scanning have been documented since the last edition of this book was published, and the role of CT scanning in the evaluation of calcaneal fractures is now well established (4,32,48,143). CT scanning has probably been the primary factor in the reassessment of treatment modalities for adults with calcaneal fractures, and anatomic reconstruction is emphasized much more than before the advent of CT scanning. For intraarticular fractures, CT scanning more reliably demonstrates the degree of anatomic alteration of the subtalar joint; for process fractures, CT scanning may be the only way to demonstrate a small fracture. The role of CT scanning for children's calcaneal fractures has been studied less extensively, but CT is warranted in fractures with significant comminution and in older adolescents.

Pablot et al (126) reported that CT scanning in adolescents with calcaneal fractures revealed fracture patterns similar to those in adults. Although this severity of injury in younger children is rare, Abel and Wenger reported open reduction of a calcaneal fracture in a 3-year-old on the basis of CT findings (Fig. 26-24).

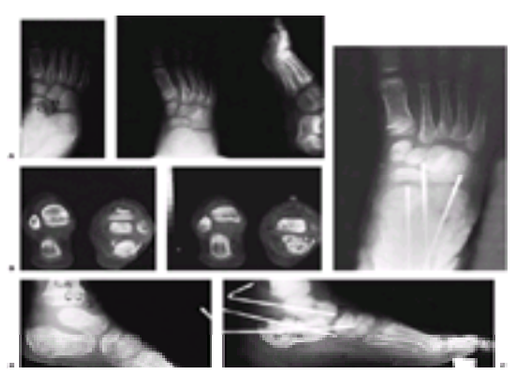

FIGURE 26-24. A boy 3 years and 9 months of age was struck by a car and sustained fractures of the talus and calcaneus. **A:** X-rays on the day of the injury demonstrate joint depression fracture of the calcaneus and minimally displaced fracture of the talar neck. **B:** Computed tomography scans demonstrate comminution and lateral spread of the calcaneus. **C:** Both fractures underwent open reduction and Kirschner wire fixation. **D:** Fractures healed in good position 8 weeks after injury. AUTHOR'S PREFERRED METHOD OF TREATMENT OF CALCANEUS FRACTURES

Most calcaneal fractures in very young children heal uneventfully, even when not promptly diagnosed. Treatment is relatively simple in this age group and consists of immobilization until healing is present in a few weeks. Restriction of weight bearing is not necessary for a nondisplaced fracture in a young child. In older children or in any displaced intraarticular fracture for which nonoperative treatment is selected, non–weight bearing is mandatory to prevent further displacement.

Thomas (165) gave a complete anatomic description of the five fractures in his series. One child sustained a tongue-type fracture; the other four demonstrated a similar fracture line commencing immediately behind the articular margin of the posterior facet to a delta-shaped comminuted fracture on the anterior or lateral cortex. There also was a second fracture, much less distinct, running from about the mid-portion of the first fracture toward the anterior margin of the posterior facet. This fragment appeared to involve the entire facet, because the axial view did not demonstrate the lateral compression usually seen in adults. All children were initially treated by immobilization with soft dressing and elevation. Active and passive motion of the foot was permitted. Weight bearing was forbidden for 6 weeks, after which all the patients regained a full range of painless motion and walked without a limp within 1 week. Follow-up examinations were performed 9 to 22 months after injury, and the results were satisfactory in all patients. Two patients had “trivial” limitation of motion in the subtalar joint, but range of motion was full in the other three. The clinical appearance was identical to that of the noninjured foot.

In four of the patients reported by Thomas, the Bohler's tuber-joint angle was 6 to 12 degrees less on the injured side, indicating some degree of joint depression. However, the inferior articular facet of the talus appeared to overgrow to such a degree as to accommodate the joint depression of the calcaneus precisely. The same researcher described a “talar facet” angle, measuring the overgrowth of the inferior articular facet of the talus; the sum of this angle, and the tuber–joint angle equaled the sum of the two angles on the normal side. He concluded that this remodeling potential of the talus minimized the effect of the depression of the calcaneal facet, and that a satisfactory clinical result was thus obtained. I have observed the same phenomenon.

Marti (106), however, stated, “A fracture of the calcaneus that has led to compression or simple discontinuity of the joint requires perfect reduction and reconstitution of the articular surface.” He treated calcaneal fractures in three boys, ages 12 to 15, in a 10-year period. All fractures were intraarticular, although one was very minimally displaced. All were managed surgically with lag screw fixation. Operative treatment of adults with intraarticular calcaneal fractures has become standard, and in older adolescents with minimal growth remaining the same approach is appropriate. In a report by Biert et al. (15), the researchers advocated the use of combined indirect reduction technique via ligamentotaxis through distraction, percutaneous reduction, and internal screw fixation as an alternative to conservative treatment of depressed intraarticular calcaneus fractures. They described a case of a 10-year-old with bilateral calcaneus fractures treated in this manner. An article on adults revisited the use of a percutaneous reduction technique originally described by Essex-Lopresti (167). This technique offered an alternative to either conservative treatment or open reduction and internal fixation for certain displaced calcaneus fractures. In particular, this technique may have merit in selected displaced pediatric fractures with more of a tongue-type pattern (Fig. 26-25). Other researchers advocate that displaced intraarticular fractures with significant joint incongruity in children ought to be treated with open reduction and internal fixation using similar methods described in adults (Fig. 26-26). The largest series of operative fixation of intraarticular fractures of the os calcis in children was recently presented (164). Thirty-four fractures with significant intraarticular involvement underwent open reduction and internal fixation. The researchers reported excellent results in 95% of their patients regaining near full subtalar range of motion and function at average 4.2 year follow-up (164). The only complication noted was subsequent claw toe deformity in 4 of the 31 patients.

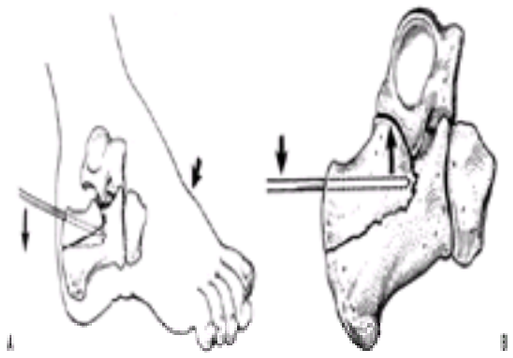

FIGURE 26-25. Essex-Lopresti reduction technique. **A:** Pin is placed into the tongue fragment. The fragment is then disengaged using the pin as a joystick. A downward force is placed on both the pin and the mid-foot as depicted. **B:** The thumbs are used as a fulcrum to elevate and reduce the posterior facet, then the pin is driven across the fracture site to stabilize the fracture. Pins or screws may be placed for definitive fixation. (Reprinted from Tornetta P III. The Essex-Lopresti reduction for calcaneal fractures revisited. *J Orthop Trauma* 1998;12:471; with permission.)

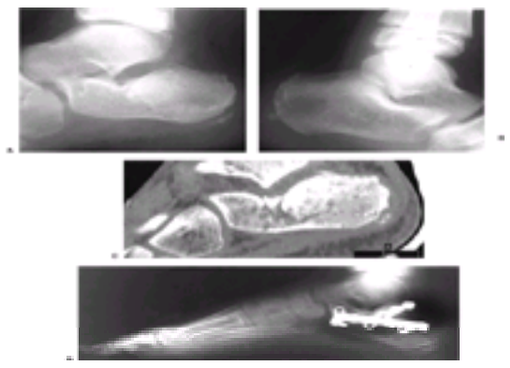

FIGURE 26-26. A 10-year-old boy sustained a calcaneus fracture following a trampoline injury. **A:** Radiographs displayed a severely depressed intraarticular fracture involving the posterior facet. Bohler's angle measured 15 degrees. **B:** Comparison lateral of the noninvolved side demonstrates significant difference in Bohler's angle measuring 40 degrees. **C:** Computed tomography scan further delineates amount of depression as the posterior facet has been driven down within the cancellous bone of the calcaneus. **D:** Open reduction internal fixation was performed through a lateral approach using an L-shaped incision. Anatomic reduction was achieved and maintained with a lateral calcaneal plate. No bone graft was used.

With the remodeling potential of the talus and calcaneus in a growing child, and the reported good results after conservative treatment, most intraarticular fractures in younger children can be managed nonoperatively. Certainly, with falls from unusual heights, severe joint depression is possible, and operative treatment may be best in individual instances. My approach for most children with intraarticular fractures would be non–weight-bearing immobilization for 6 weeks, because mild amounts of joint incongruity remodel very well (Fig. 26-22). In adolescents with significant joint involvement or displacement, operative management is considered. To date, there are no reports of impairment resulting from failure to surgically reduce a child's calcaneal fracture.

Extraarticular fractures seem to do well regardless of treatment, with the possible exception of fractures of the anterior process. The anterior process is not seen radiographically until about age 10 and varies greatly in shape. The mechanism of injury is most commonly plantarflexion and inversion, with the bifurcate ligament responsible for avulsing the anterior process via its calcaneal attachment (40). The distal portion of the fracture fragment is intraarticular and involves the calcaneocuboid joint (Fig. 26-27).

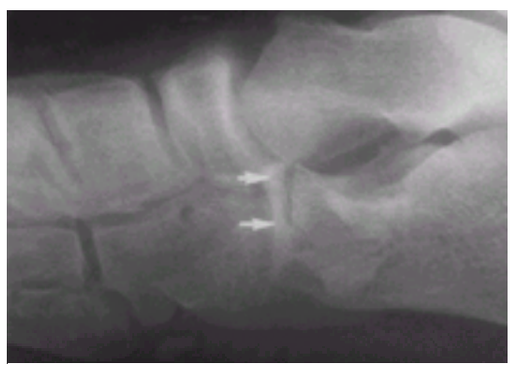

FIGURE 26-27. Fracture of anterior process of calcaneus in an 11-year-old girl. The fracture was evident only on the oblique view. (Courtesy of Kaye Wilkins, M.D.)

Degan et al. (39) reported 25 patients with fractures of the anterior process of the calcaneus. Eighteen healed with nonoperative management and became asymptomatic. Seven patients had excision of the fracture fragment because of nonunion and pain, and three of these seven were 13 to 17 years of age. Drvaric and Schmitt (47) reported an irreducible fracture of the calcaneus in a 4-year-old boy that resulted from displacement of the peroneal tendons into the fracture site. Degan et al. (35) thought this injury was often missed because the injuring force is usually that of an ankle sprain. However, the point of maximal tenderness indicated the diagnosis if pertinent radiographs were made. In addition to conventional views, an oblique radiograph made with the beam directed 10 to 15 degrees superior and posterior to the middle of the foot, as recommended by Bachman and Johnson (9), was considered helpful. A protracted period of disability was common with this injury, which often was not initially diagnosed.

There is some controversy about the need for open reduction of larger displaced anterior calcaneal fractures (40). With the problems reported by Degan et al. (39), a good case can be made for open reduction if severe articular displacement and joint depression are obvious.

Cole et al. (29) reported four patients with avulsion fractures of the tuberosity of the calcaneus, three of whom had taut overlying skin secondary to fracture displacement. Excellent results were obtained with open reduction of the three displaced fractures.

FRACTURES OF THE LESSER TARSAL BONES

Isolated fractures of the mid-foot are extremely unusual, although direct trauma, such as an object falling from a height, can produce such fractures. More often, they are accompanied by other injuries, and usually indicate a severe injury to the foot. Irregularities of ossification of the navicular bone can be confused with fracture, but lack of localized tenderness or the rounded bony margin should be adequate to differentiate between ossification irregularities and fracture. Treatment of these injuries is generally uncomplicated but may be determined by the nature of associated injuries. Open reduction and internal fixation is indicated for displaced intraarticular injuries.

TARSOMETATARSAL INJURIES

Tarsometatarsal injuries, although well documented in adults (185), have been described rarely in children. In fact, Trillat et al. (170), in a review of 81 fracture–dislocations of the tarsometatarsal joint, stated that “the lesion is not seen in children.” Wiley (181), however, reported on a series of 18 injuries to this region in children under age 16, and Cehner (24) described the management of an open fracture–dislocation of the tarsometatarsal joint in a 10-year-old.

Anatomy

Wiley (182) concisely described the anatomy and mechanism of tarsometatarsal injuries. The metatarsal bases are joined to each other and the tarsals by tough ligaments, with one exception: the ligamentous connection between the base of the first and second metatarsals is rather flimsy in comparison (74). In fact, Serrafian's (153) text noted that “there is no ligament between the first and second metatarsal on the dorsal or plantar aspect. The interosseous connection is through poorly individualized weak fibers.” Its presence is therefore not acknowledged on illustrations that are simplified to demonstrate the functional anatomy (Fig. 26-28). These ligamentous connections, much tougher on the plantar surface than dorsally, tether the base of the second metatarsal to all the cuneiform bones. The other metatarsal joints are all in the same plane, distal to the recessed second metatarsal base. The second metatarsal base, therefore, serves to lock the entire complex into place (2).

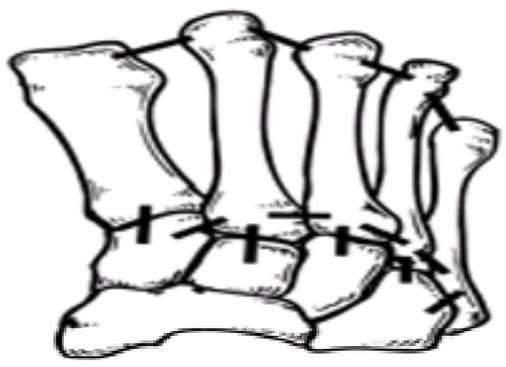

FIGURE 26-28. The ligamentous attachments at the tarsometatarsal joints. There is only a flimsy connection between the bases of the first and second metatarsals (not illustrated). The second metatarsal is recessed and firmly anchored. (Reprinted from Wiley JJ. The mechanism of tarsometatarsal joint injuries. *J Bone Joint Surg [Br]* 1971;53:474; with permission.)

Mechanism of Injury

The tarsometatarsal joints can be injured directly or indirectly; the indirect method is by far the more common. The direct injury, sustained by a falling object, results in no specific pattern and obviously depends on the character of the object and the distance of the fall. The metatarsals generally are displaced in a plantar direction, rupturing the tough plantar ligaments. The amount of force imposed on the foot to produce this injury is considerable, and extensive soft-tissue injury can be expected.

Forces producing an indirect injury are violent abduction or forced plantarflexion of the forefoot, either alone or in combination. With violent abduction, the metatarsals are impacted laterally, fracturing the recessed base of the second and crushing the cuboid. This combination of injuries is pathognomonic of a tarsometatarsal dislocation by this maneuver. The first and fifth metatarsals rarely are fractured.

The other mechanism of tarsometatarsal dislocation is violent plantarflexion of the forefoot. Occasionally, this is a result of an object falling on the heel with the patient in a kneeling position, but is much more commonly produced when the foot is forcibly loaded in the “tip-toe” position with the ankle in marked plantarflexion (Fig. 26-29). The metatarsals are then in line with the tibia, and the weak point in the link is the feeble dorsal ligamentous support at the tarsometatarsal joint. This can occur when the patient is a passenger in a car or uses the foot to break a fall from a bicycle, motorcycle, or toboggan. Fractures of the metatarsal shaft or neck often accompany this injury, and the metatarsal joint dislocation can be unrecognized if only minimally displaced. In Wiley's (180) series of 18 tarsometatarsal injuries in children, only four were a result of direct injuries; the rest were the result of indirect injuries. Ten of these occurred after jumping in the “tip-toe” position, and two were a result of a toboggan accident.

FIGURE 26-29. Vertical loading in the “tip-toe” position progresses to tarso/metatarsal dislocation as shown. (Reprinted from Wiley JJ. The mechanism of tarsometatarsal joint injuries. *J Bone Joint Surg [Br]* 1971;53:479; with permission.)

Classification of Tarsometatarsal Injuries

Hardcastle et al. (65) proposed an anatomic classification of tarsometatarsal injuries modified from a 1909 publication by Quénu and Küss (131). The merits of this classification are its simplicity and practicality. Type A is incongruity of the entire joint; type B denotes partial instability (either medial or lateral); and type C, which is quite rare, indicates divergent partial or total instability.

Signs and Symptoms

Typically swelling is present on the dorsum of the foot overlying the tarsometatarsal joints. There may not be an obvious deformity, however, because spontaneous reduction of the injury to a near-anatomic position very often occurs. Marked local pain and tenderness, accompanied by an inability to bear any weight on the foot, should increase suspicion that injury has occurred in this region. With subtle injuries, swelling may be absent, but localized tenderness persists (134). Faciszewski et al. (50) found the weight-bearing lateral radiograph view to be valuable in the evaluation of subtle injuries, demonstrating plantar displacement of the medial cuneiform bone in relation to the fifth metatarsal. Two or three millimeters of diastasis between the first and second metatarsal bases were found in every patient with a subtle tarsometatarsal injury. A diagnostic clue to the injury is ecchymosis of the plantar aspect of the mid-foot. Its presence has been named the plantar ecchymosis sign (137) (Fig. 26-30).

FIGURE 26-30. Plantar ecchymosis sign. Ecchymosis along the plantar aspect of the mid-foot is an important clinical finding in subtle Lisfranc tarsometatarsal injuries. (Reprinted from Ross G, Cronin R, Hauzenblas J, et al. Plantar ecchymosis sign: a clinical aid to diagnosis of occult lisfranc tarsometatarsal injuries. *J Orthop Trauma* 1996;10:120; with permission.)

Radiographic Findings

Anteroposterior, lateral, and oblique radiographs of the foot are essential (80). A fracture of the base of the second metatarsal should alert the examiner to the likelihood of a tarsometatarsal dislocation, because often a dislocation can spontaneously reduce (Fig. 26-31). As discussed above, the combination of a fracture of the cuboid with a fracture of the base of the second metatarsal indicates the presence of a tarsometatarsal dislocation. Many researchers advocate weight-bearing radiographs or pronation/abduction stress views if a Lisfranc joint injury is suspected yet routine radiographs are normal. Stress views, however, are almost impossible to obtain in an unanesthetized pediatric patient; an ankle block or general anesthesia usually is required, limiting the usefulness of these views.

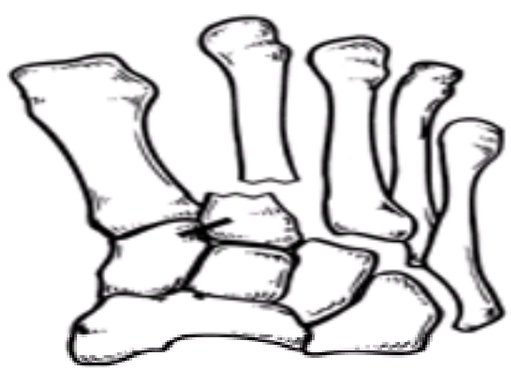

FIGURE 26-31. Fracture of the second metatarsal base and impaction of the cuboid are pathognomonic of disruption of the tarsometatarsal joints. (Reprinted from Wiley JJ. The mechanism of tarsometatarsal joint injuries. *J Bone Joint Surg [Br]* 1971;53:476; with permission.)

Treatment

Treatment is relatively straightforward. The occasional minimally displaced tarsometatarsal dislocation (less than 2 or 3 mm) can be treated with elevation and a compression dressing initially (with care not to wrap the compression dressing too tightly) and application of a short leg cast when swelling has decreased. Casting is continued for 2 to 4 weeks.

For any injury with more than minimal displacement, reduction is required. Closed reduction often is successful, but supplemental Kirschner wire fixation is essential if the reduction is unstable. If closed reduction is unsuccessful, open reduction and internal fixation are indicated. The key to reduction is stabilizing the fracture of the second metatarsal base. The first and the fifth metatarsal bases may be pinned to enhance stability (Fig. 26-32) (135).

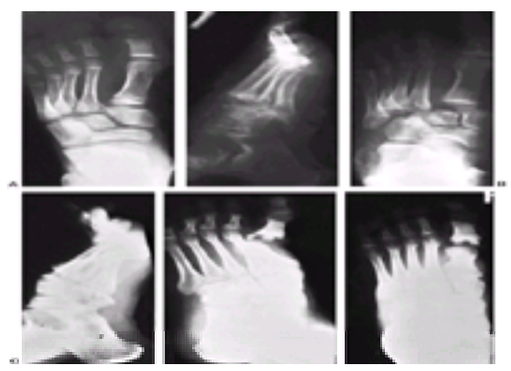

FIGURE 26-32. A: Avulsion fracture of the base of the second metatarsal in a 7.9-year-old girl. Although this injury resulted from direct trauma, this pattern of fracture of the base of the second metatarsal should alert the observer to the possibility of a tarsometatarsal disruption. **B:** A 13-year-old boy was injured when a hay wagon rolled over his foot and produced violent plantarflexion of the forefoot. With the suitable injury force, metatarsal dislocations are produced in skeletally immature patients. This injury was treated with closed reduction with pin fixation. Two years after the injury, he had minor discomfort with strenuous running or climbing in the region of the tarsometatarsal joints. **C:** A 14-year-old boy who fell 18 feet to the ground, landing in a tip-toe position, sustained a tarsometatarsal and metatarsal phalangeal dislocation of the first ray. Note that there is an impaction fracture of the cuboid, indicating an injury to the tarsometatarsal joint. Reduction was easily accomplished with closed manipulation under anesthesia. Casting was continued for 4 weeks; he was asymptomatic at follow-up. (Courtesy of James J. Wiley, M.D.)

With the patient prone, Chinese finger traps on the toes with about a 10-lb weight for traction can be used to accomplish reduction. A short leg cast, well molded over the dorsum of the foot, maintains reduction. The cast is removed at 4 weeks.

AUTHOR'S PREFERRED METHOD OF TREATMENT

I prefer to apply finger traps with the patient supine, confirming the reduction fluoroscopically. Percutaneous pinning then is performed to stabilize the base of the first, second, or fifth metatarsals. Conventional radiographs are taken before completion of the procedure, because fluoroscopy is occasionally misleading. Hardcastle et al. (65) noted that redisplacement was most likely when the first metatarsal was inadequately fixed. Type A injuries require at least medial and lateral pins; laterally displaced type B injuries require a lateral pin; medially displaced type B injuries require one or two medial pins.

In Wiley's series (181), seven fractures required operative reduction, which can be accomplished through a dorsal incision; four were internally fixed. After reduction, I prefer to leave Kirschner wires protruding through the skin and to bend the wires at a right angle to prevent migration. A bulky dressing is applied, with padding

between the pins and the skin to prevent erosion of the skin by the pins. At 4 weeks, the Kirschner wires and cast can be removed.

Results and Complications

The only series confined to pediatric tarsometatarsal injuries is that reported by Wiley (181). Fourteen of 18 patients were asymptomatic at follow-up. Of the four with symptoms, two had residual angular deformity. One patient developed Freiberg's infarction 4 months after this injury, but no definite connection between these two conditions has been established. This injury appears to be more benign in children than in adults: in a series of adults reported by Wiss et al. (186), no patient had a normal gait after a displaced Lisfranc fracture–dislocation. More recent reports have confirmed that in adults and in young adult athletes, delay in diagnosis and failure to attain an anatomic reduction have an ominous effect on the prognosis (33). Due to the recognition of poor functional outcome in adult patients when more than 2 mm of displacement was accepted, there is a trend toward a more aggressive treatment of adult transmetatarsal injuries (119). Rigid internal fixation with screws along the medial column combined with pin fixation of the lateral column has been advocated in adults.

METATARSALS

Fractures of the metatarsals are relatively common in children. They may be a result of direct trauma from a falling object or may occur indirectly from the mechanism of injury described for injuries of the tarsometatarsal joints or from torsional forces (Fig. 26-33). A particular type of injury to the first metatarsal, “bunk-bed fracture,” was described by Johnson (80). These injuries were caused by a fall on the foot, often from a bunk bed. The proximal first metatarsal, the lateral cuneiform bone, and less often the medial cuneiform bone were impacted. In short-term follow-up, healing was uneventful and uncomplicated.

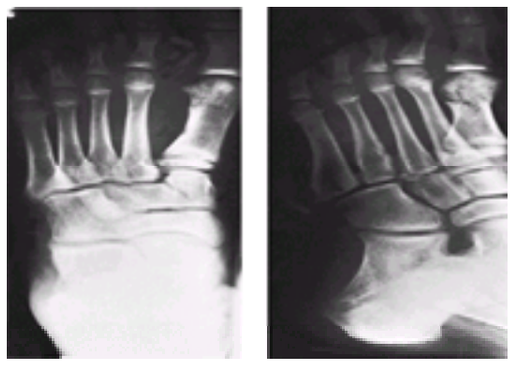

FIGURE 26-33. Minimally displaced fracture of the first metatarsal shaft sustained as a result of a brick falling on the foot of a 13-year-old boy. Treatment was uncomplicated, and a short-leg walking cast was used for 4 weeks.

Fractures of the Metatarsal Shafts and Necks

Because of their relatively small diameter, the metatarsal necks fail first when torque is applied to the forefoot, accounting for the frequency of fractures at this site. Fractures of the shafts usually result from a direct crushing blow. Only one study was found that focused on metatarsal fractures in children (125): a report of 62 such fractures. Age was found to be a factor in the distribution of injury. Overall, fifth metatarsal fractures were the most common, followed by first metatarsal fractures. However, there was a noticeably higher proportion of first metatarsal fractures in children under 5 years of age (73%). The most common mechanism of injury for first metatarsal fractures was a fall; for fifth metatarsal fractures the usual mechanism was inversion; and fractures of the second, third, and fourth metatarsals were crush injuries. No fractures in this study were treated operatively.

Signs and Symptoms

Severe metatarsal injuries produce obvious swelling, pain, and ecchymosis, but minimal swelling can occur with only slightly displaced fractures. The presence of localized tenderness, as usual, is an indispensable sign of such fractures.

Radiographic Findings

As is true for all injuries of the foot (with the exception of the phalanges), radiographic evaluation in three planes is essential to determine the site of the fracture and the amount of displacement. The anteroposterior and oblique views generally are more revealing, but the lateral view is necessary to assess displacement toward the plantar surface of the foot. Anderson et al. (6) noted that when radiographs of the foot are made, the exposure generally is set to provide penetration of the larger tarsal bones. This results in overexposure of the smaller metatarsal and phalanges. Therefore, when injuries to the forefoot are suspected, the technician should be requested to provide optimal exposure to this area of the foot rather than to the hindfoot.

Treatment of Metatarsal Fractures

Initial management depends on the severity of injury. Admission to the hospital is indicated in the presence of marked swelling and soft-tissue injury. The interossei and short plantar muscles are contained in closed fascial compartments, so fasciotomy is indicated if swelling is severe—just as in the hand. The clinical indications for fasciotomy are marked pain and swelling with the skin stretched and taut, sometimes accompanied by venous congestion in the toes. In patients with multiple injuries, this can easily be overlooked. The long-term results of failure to perform fasciotomy of the interossei when increased tissue pressure is present are fibrosis of the interossei and an intrinsic minus foot with claw toes. All nine compartments should be released (Fig. 26-2).

Treatment of most fractures of the metatarsals in children is simple and requires only immobilization in a short leg walking cast for comfort until healing is complete. This occurs rapidly, especially in young children, usually taking no longer than 3 to 6 weeks; the shorter time is for a minimally displaced fracture in a younger child.

Despite the relative ease of management of most of these injuries, there are pitfalls, many related to plaster technique. Application of a circular cast should never be the initial measure for anything but a nondisplaced fracture with minimal or no soft tissue swelling. A circular cast should not be applied in the presence of swelling; instead, a bulky dressing (which does immobilize) with the foot in equinus position should be used for a few days. When the swelling has diminished, the cast can be safely applied. No unacceptable contractures in children will result from a few days of immobilizing the foot in equinus.

If a cast is applied and the child is sent home with the parents, written instructions should explain cast care and the danger signals of impending circulatory embarrassment.

For fractures requiring reduction, the method described by Giannestras (56) and Sammarco (141), using Chinese finger traps, is recommended (69,70). It consists simply of placing the respective toes of the injured metatarsals in finger traps with counterpressure on the ankle, a manipulative reduction, and application of a well-molded cast. When molding the cast, it is relatively safe to mold dorsally and plantarly over the metatarsals, flattening the cast, but care should be taken not to extend the mold proximal to the ankle joint. If the reduction is unstable, percutaneous Kirschner wire fixation can be helpful for the first and fifth metatarsals. Rarely is open reduction indicated. A considerable degree of lateral displacement can be accepted, and moderate amounts of dorsal angulation of the metatarsal necks that would be unacceptable in an adult will remodel in a child (Fig. 26-34).

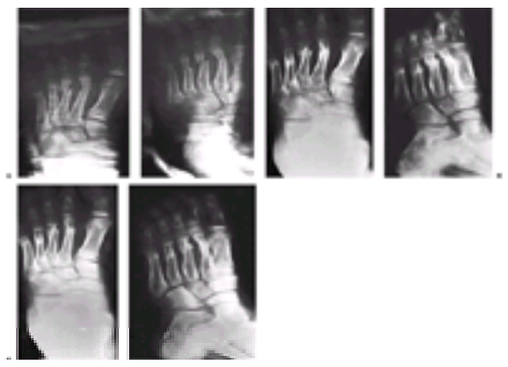

FIGURE 26-34. A: Closed fractures of the distal shafts of the second through fifth metatarsals in a 10-year-old boy. Fracture of the third metatarsal was very unstable and motion could be felt at that fracture site 4 weeks after injury. **B:** Seven weeks after injury, the fractures are solidly healed and remodeling. **C:** Ten weeks after injury, the boy has returned to full activity. Open reduction of this type of fracture in a child is not necessary.

OPERATIVE TREATMENT

When open reduction is required, the standard technique of dorsal exposure, Kirschner wire placement in the distal fragment exiting through the plantar skin, reduction of the fracture, and retrograde intramedullary fixation of the fracture can be used. Postoperatively, a non–weight-bearing cast (to protect the protruding pins from the plantar skin) is applied after the initial swelling has subsided. The pins are removed at about 3 weeks, and a weight-bearing cast is applied (Fig. 26-35).

FIGURE 26-35. Open fractures of the necks of the second through fifth metatarsals sustained when a circular saw fell on this boy's foot. **A:** At injury. **B:** Five weeks after open reduction. Extensor tendons were lacerated, but not repaired; 0.045-inch Kirschner wires were used. No extensor lag has resulted.

Complications

Albanese reported a 7-year-old girl with malunion of the metatarsals that interfered with ambulation. The foot injuries were not reduced initially because of a concomitant head injury. Function was improved after osteotomy (Fig. 26-36). The necessity of managing fractures expectantly in children with head injuries is underscored by this experience. The metatarsals' capability for remodeling is extensive but not infinite, and reasonable alignment must be obtained.

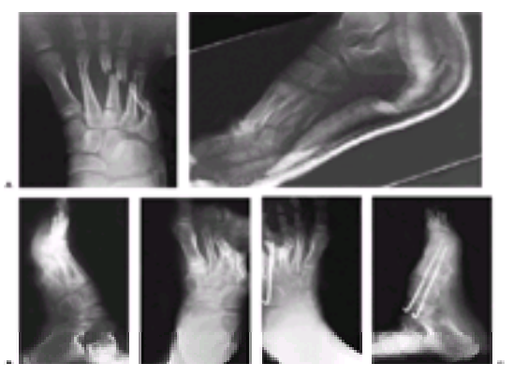

FIGURE 26-36. Malunion of metatarsal shaft fractures in a 7-year-old girl with multiple severe injuries, including head injury. **A:** Films on the day of the injury. **B:** After healing. Function was impaired by irregular weight-bearing surface of foot. **C:** After corrective osteotomy. (Courtesy of S.A. Albanese, M.D.)

FRACTURES OF THE BASE OF THE FIFTH METATARSAL

Avulsion fractures of the base of the fifth metatarsal are fairly common in children. Differentiating such a fracture from an apophyseal growth center or os vesalianum, a sesamoid proximal to the insertion of the peroneus brevis, is the primary diagnostic difficulty. The apophysis can be recognized because its long axis is parallel with the shaft (Fig. 26-37) (14). The apophysis is not present before age 8 and usually is united to the shaft by age 12 in girls and age 15 in boys (35).

FIGURE 26-37. The apophysis at the base of the fifth metatarsal is parallel to the shaft, and is a normal variant. The fracture of the distal metatarsal shaft is not.

Historically, the mechanism of injury has been thought to be an avulsion of the metatarsal base by the action of the peroneus brevis at its insertion, but this has been

questioned. A biomechanical study implicated the tough lateral cord of the plantar aponeurosis inserting into the fifth metatarsal base (136) This would explain the minimal displacement and the direction of the fracture line, which is perpendicular to the longitudinal axis of the shaft (Fig. 26-38). Dameron (35) dissected this muscle in 21 feet and found an insertion on the base of the fifth metatarsal in 18.

FIGURE 26-38. “Avulsion” fracture of the base of the fifth metatarsal. The fracture line appears to extend through the os vesalianum. The fibrous band of the abductor digiti minimi quinti, inserting into the base of the fifth metatarsal, probably tethers this portion of the bone as the foot is inverted and adducted. The peroneus brevis inserts into the dorsum of the fifth metatarsal, distal to the fracture line (illustrated here), and is not a likely culprit in the mechanism of injury. (Courtesy of Teresa M. Stacy, M.D.)

Treatment

A short leg weight-bearing cast worn for 3 to 6 weeks, depending on the child's age, generally is sufficient (Fig. 26-39). The swelling and local reaction to injury are much less than with metatarsal shaft fractures, so an initial period of elevation generally is unnecessary. Radiographic evidence of union may be hard to determine. I discontinue the external immobilization when swelling and tenderness have subsided and there is no pain with range of motion of the foot. Dameron (35) found that many of these fractures were asymptomatic after 3 weeks, and none had prolonged disability. Although the healing potential for this fracture is excellent, nonunion can occur. Nevertheless, these are rarely symptomatic, with many likely representing a fibrous union. Small, symptomatic nonunions can be excised. For larger symptomatic nonunions, fixation with a small lag screw may be considered. Operative fixation of acute tuberosity avulsion fractures is rarely indicated, but may be considered for significant displacement (>3 mm) in a young active patient with an unusually long tuberosity (36).

FIGURE 26-39. A: Nondisplaced incomplete fracture of the base of the fifth metatarsal in a boy 12 years and 10 months of age. **B:** Five weeks later, there is further resorption of the fracture line, but the fracture site is nontender and immobilization was discontinued. Radiographic union may be delayed for weeks to months.

Fractures of the base of the fifth metatarsal have been the subject of much more attention in the past two decades. Several classification systems have been presented to assist in differentiating between acute fractures and stress fractures, in addition to localizing the fracture to the metaphysis, diaphysis, or metaphyseal–diaphyseal junction (92). The literature concerning fractures of the base of the fifth metatarsal can be confusing, and much of it relates only to adult patients.

The main area of contention is the so-called Jones fracture: as with many eponyms, this term has been applied differently by different researchers. To summarize recent reports, a fracture of the diaphyseal–metaphyseal junction should arouse suspicion that a stress reaction may have predated the fracture (92,141,157,158). If such is the case, healing will be retarded, especially in athletes, and bone grafting or internal fixation usually is indicated.

Kavanaugh, Brower, and Mann (85) emphasized that the Jones fracture is not an avulsion fracture; rather, it appears to result from vertical or mediolateral ground forces on the weight-bearing foot. Because the foot was weight bearing, inversion was impossible, and these researchers concluded that inversion was not at fault. The strong ligamentous and capsular attachments firmly bind the base of the fifth metatarsal to the adjacent cuboid and fourth metatarsal, subjecting the proximal shaft to excess strain when loaded as described above. This injury is most common in patients 15 to 21 years of age and is most often seen in athletes. Conservative treatment with a non–weight-bearing cast was described as ineffective by Kavanaugh et al. (85), but effective by Torg et al. (167) and Josefsson et al. (82), who speculated that some of the injuries treated by Kavanaugh et al. might not have been acute, and nonacute injuries are less likely to heal with immobilization. With non–weight-bearing immobilization, 14 of the 15 acute fractures treated by Torg et al. (167) healed. DeLee, Evans, and Julian (42) reported on 10 young adult athletes they treated with immediate intramedullary screw fixation, with healing in all patients. Mindrebo et al. (113) and Portland et al. (130) demonstrated that the time to union was shorter after operative treatment, with earlier return to weight bearing and full activities. The average time to healing was 6 to 7 weeks compared with 2 to 3 months in series with nonoperative treatment. Acute surgical management can be considered as a treatment option, particularly in high-level athletes who desire to return promptly to their sporting activities (Fig. 26-40).

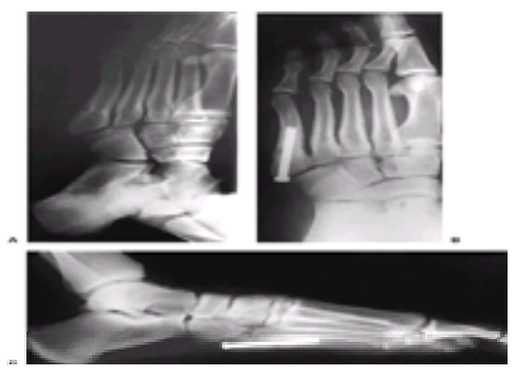

FIGURE 26-40. A 15-year-old high-level high school basketball player sustained a proximal fifth metatarsal fracture at the metaphyseal–diaphyseal junction. The patient opted for intramedullary screw fixation with desire to return to sport as promptly as possible, lessen his time in immobilization, and lessen the risk of the possibility of delayed versus nonunion. **A:** Injury film. **B and C:** Following intramedullary screw fixation. (Courtesy of Keith S. Hechtman, M.D.)

A Jones fracture must be differentiated from a fracture of the tuberosity, because the two differ considerably in prognosis and management. Smith et al. (157,158) found that the blood supply of the proximal diaphysis is much sparser than that of the tuberosity, which probably is a factor in the slower healing evident in proximal diaphyseal fractures.

The results obtained by Torg et al. (167) with non–weight-bearing immobilization of acute fractures support this method of treatment for Jones fractures. They emphasized that to be classified as an acute injury, there must be no previous history of pain or trauma, there must be a sharp, well-differentiated fracture line, and most importantly, there must be no intramedullary sclerosis. With repetitive symptoms or intramedullary sclerosis, the prognosis for healing with immobilization is dismal.

OPERATIVE TREATMENT

Guidelines for operative treatment of Jones fractures are not well established. Most of these injuries occur in athletes, and in this group, regardless of age, there is a trend toward immediate intramedullary screw fixation of acute fractures, as well as for delayed unions and nonunions (without bone grafting). An inlay bone grafting technique has been described by Torg et al. (167) with the proximal tibia as the donor site. This area is unsuitable as a donor site in skeletally immature children; if bone grafting is elected, the iliac crest is preferable. Intramedullary fixation avoids this problem, although there are technical traps. The surgical technique described by Lehman et al. (93) is recommended when this method is selected.

STRESS FRACTURES

Stress fractures have been reported in children in most of the bones of the foot. Yngve (189) reviewed reports of stress fractures in children and found 94 fractures in which the involved bone was identified. However, if the number of reported cases indicates the actual incidence, these injuries are fewer in children than in adults. The metatarsals were involved in 14% of stress fractures in adults, the tarsals in 13%; in children, metatarsals and tarsals were each involved in only 2%. This could be a result of underreporting in children (Fig. 26-41).

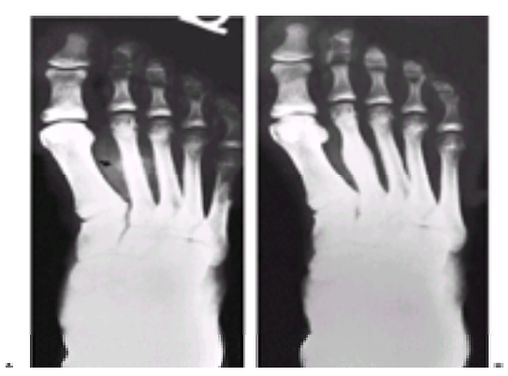

FIGURE 26-41. Painful second metatarsal of about 2 weeks' duration in a 16-year-old boy. **A:** A subtle fracture line can be seen underlying a callus beginning to ossify. **B:** Residual of callus 3 months later. (Courtesy of Teresa M. Stacy, M.D.)

The most common sites of stress fractures in children are the tibia and fibula, but 4 of the 35 stress fractures in children reported by Devas (43) occurred in the metatarsals. Childress (30) reported a typical stress fracture of the metatarsal in a 7-year-old. Symptoms are pain on weight bearing, but with much less discomfort at rest than with a fracture resulting from trauma. Swelling is minimal or nonexistent, but localized tenderness is marked. With most stress fractures, awareness of the possibility and an index of suspicion aid greatly in diagnosis. Bone scans can be fallible in excluding the diagnosis (Fig. 26-19). Stress fractures seem to be particularly common in adults and children who undertake a sudden increase in physical activity. The pediatric population at risk are skeletally maturing adolescents starting to participate in intensive training for sports.

Mechanism of Injury

The mechanism of injury appears to be reabsorption and demineralization at the site of stress, followed by a reparative process evidenced by periosteal layering of new bone. The relationship of stress fractures to sudden increases in activity is well documented and is supported experimentally. Rubin and Lanyon (139) used rooster ulnae to demonstrate that bone mineral does not increase until after the second week of increased loading. This correlates with the appearance of symptoms resulting from stress fractures at this time during a training regimen (151). In a study of Israeli army recruits, modifying the activity level during the third week resulted in a decrease in the stress fracture rate from 4.8% to 1.6% (140).

A short first metatarsal (Morton's toe) is cited in many publications as a factor in the production of stress fractures in runners commonly located in the second and third metatarsals. However, Drez et al. (46) could not document any difference in the relative lengths of the first and second metatarsals between patients with stress fractures and a control population. The factors responsible for the development of a stress fracture have not been precisely elucidated, but it does not appear that a short first metatarsal is one of them. Hormonal factors may play a role. An increased incidence of stress fractures was reported in ballet dancers 18 to 36 years of age, who were also older than average at the time of menarche (176).

Radiographic Findings

If the patient presents early, radiographs are normal. Anteroposterior, lateral, and oblique radiographs should be taken, but the lateral view usually is the least helpful, because the metatarsals are stacked one upon the other. Periosteal callus formation about 2 weeks after the process commences establishes the diagnosis (Fig. 26-41). Bone scanning has been advocated for making the diagnosis if conventional radiographs demonstrate no abnormality (144), but I prefer a 2-week trial of immobilization in a short-leg walking cast if the history, symptoms, and signs indicate a stress fracture. When the cast is removed, radiographs usually reveal periosteal callus. Scanning might be useful at this point if the diagnosis is still in question, but this would be quite unusual.

AUTHOR'S PREFERRED METHOD OF TREATMENT

Patients with stress fractures differ from patients with traumatic injuries in that there is a definite temporal starting point with an acute fracture, and the period required for immobilization can be calculated from that point. There is no comparable starting point for stress fractures, although the onset of symptoms is helpful. The patient may be nearly healed the first time he or she presents for evaluation; in this case, immobilization is unnecessary. I try to adapt the treatment to the symptoms. If the foot is painful only during sports, restricting such activities until pain allows is all I recommend. If walking is painful, a 2-week period of immobilization in a short-leg cast is recommended, after which time it is discontinued if the tenderness has subsided and walking is painless. Bernstein and Stone (14) reported that pain associated with stress fractures of the metatarsals was relieved by eliminating metatarsophalangeal motion, and this could be accomplished by the use of a metatarsal bar countersunk into the sole of the shoe. Especially with the casual shoes worn by today's youth, I prefer to apply a cast if the symptoms warrant immobilization. If there is only a clinical suspicion with negative radiographs, the same approach is used. Repeat radiographs in 2 weeks usually reveal an area of stress reaction, combined with less tenderness on clinical examination.

FRACTURES OF THE PHALANGES

Fractures of the phalanges of the foot in children are uncommon and usually are caused by direct trauma from a falling object or kicking a structure less yielding than the toe. Radiographs can reveal the fracture site, but management is based entirely on clinical assessment. Reduction usually is unnecessary, although more care would be taken with the proximal phalanx of the great toe as the child matures. Rarely in an older child, reduction of a fracture of the proximal phalanx of the great toe

may be difficult to maintain with external immobilization, and percutaneous Kirschner wire fixation or open reduction is then indicated.

In most patients, however, the adjacent noninjured toes serve as splints and are simply taped to the injured toe, with gauze placed between the toes to prevent maceration (Fig. 26-42). Care should be taken to prevent rotational malunion; the nail bed of the injured toe should be in the same plane as the others. Healing usually is complete in 3 weeks, and immobilization generally is discontinued at this time if the fracture site is not tender. If the child is engaged in a running or kicking sport, an additional 2 to 3 weeks of prophylactic immobilization probably is worthwhile. Open reduction and internal fixation is indicated for fractures with displacement of more than 2 to 3 mm.

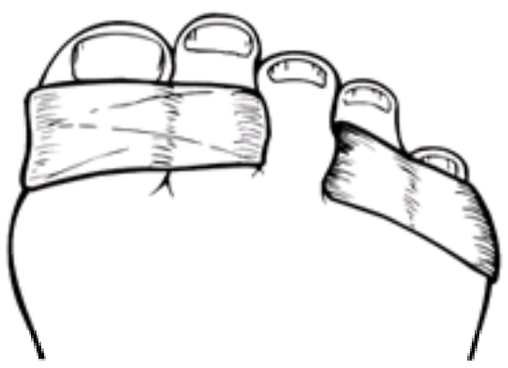

FIGURE 26-42. Method of taping to adjacent toe(s) for fractures or dislocations of the phalanges. Gauze is placed between the toes to prevent maceration. The nail beds are exposed to ascertain that malrotation of the injured toe is not present. (Reprinted from Weber BG, Brunner C, Freuler F. *Treatment of fractures in children and adolescents.* New York: Springer-Verlag, 1980:392; with permission.)

Dislocations of the Metatarsophalangeal or Interphalangeal Joint

Dislocations of the metatarsophalangeal or interphalangeal joint also are unusual in children, and again usually result from kicking. The toe is forced into hyperextension, the collateral ligaments rupture, and the proximal or middle phalanx comes to rest on the dorsal surface of the metatarsal head (or proximal phalanx; Fig. 26-43). In general, traction and manipulative reduction are effective. The toe is taped to the adjacent toes for 3 weeks to allow capsular healing, after which time full activity is resumed.

FIGURE 26-43. Dislocation of the proximal interphalangeal joint of the fourth toe in a 13-year-old boy. Reduction was easily accomplished with traction and manipulation of the dorsally displaced middle phalanx.

OPEN FRACTURES OF THE FOOT

The management of open fractures of the foot is no different from that of any other anatomic site. Parenteral antibiotics are instituted before the patient is taken to the operating room for debridement. A broad-spectrum antibiotic is chosen, depending on the patient's allergies and the surgeon's experience. I prefer a cephalosporin for 48 hours, repeated with further surgical treatment. Tetanus booster is given if 5 years has elapsed since the initial series of immunizations or the last booster.

However, the choice of antibiotic or the method of immobilization is less important than the quality of the initial debridement. All contaminated tissue is meticulously removed; optical magnification can be helpful. Wound cultures are obtained. Despite the functional importance of a particular structure (tendon, bone, physis, or articular cartilage), if it is contaminated or devitalized, it must be debrided. If it is allowed to remain, bacteria or spores may be harbored in devitalized tissue, which by definition is not accessible to parenteral antibiotics. Debriding such tissue is the first step toward avoiding chronic osteomyelitis: the time and energy devoted to avoiding such a situation pays long-term dividends to the child.

The wound is dressed open, and the patient is returned to the operating room 2 to 5 days after the injury for inspection of the wound. If it is clean, delayed primary closure or another form of wound coverage can be performed at this time. If tissue of questionable viability remains, further serial debridements are performed until a clean wound is attained.

There is considerable latitude as to the optimal time for the application of internal fixation (when necessary). If the foot is so unstable that the neurovascular bundles are in jeopardy of twisting, kinking, or traction, internal fixation is indicated at the time of initial debridement after a thorough examination for any questionable nonviable tissue. Fractures crossing the physis can be most accurately approximated at the time of initial debridement, so this is a relative indication for primary internal fixation. However, unless I can be satisfied that the bone involved is clean, I still prefer to wait until the time of delayed closure. I would prefer to have the problem of malunion or even possible early physeal closure rather than chronic osteomyelitis involving this region, which would not only destroy bone but would also undoubtedly require a more destructive procedure at a later date to eradicate the infection.

LAWN MOWER INJURIES AND OTHER CRUSH INJURIES

The most destructive injuries to the child's foot in northern latitudes result from being crushed by an automobile tire, a power lawn mower, or a snowmobile (129). These injuries require considerable judgment on the part of the surgeon, because the extent of tissue damage may be difficult to assess at the time of injury. Although more rigid manufacturing standards have resulted in more safeguards against injury, foot injuries sustained from power mowers are common during the spring and summer: over 10,000 injuries due to lawn mower accidents are reported annually. According to statistics from the Consumer Product Safety Commission, children under 14 years of age (along with older adults) are most susceptible to injury, and children under 6 have the greatest risk of death (122). Of the 18 children reported by Ross et al. (138), 11 were riding with a parent on the mower at the time of injury. Love, Grogan, and Ogden (99) reported 27 children injured by power lawn mowers, with acute amputations necessary in 19. Thirteen of these 19 amputations were through the mid-foot or toes. Fifteen of the 18 children reported by Ross et al. (138) had residual deformities. Older children are more often injured when using rotary lawn mowers, with the foot being the anatomic part most vulnerable to injury. In either case, the spinning blades carry tremendous destructive forces, cutting through soft tissue and bone alike (127). The kinetic energy generated from the blade at a typical speed of 3,000 rpm has been reported as 2,100 ft/lb. This amount of energy has been stated as the comparable to “dropping a 211 pound object from a height of 100 feet or three times the power of a .357 magnum gun” (5). Graham et al. (58) found that most rotary injuries involved the toes or foot, with avulsion or degloving of the injured part.

Fragments of dirt, debris, and grass are blown into the wound under pressure, and debridement of this type of wound requires especially meticulous and thorough

cleansing. The force with which the contaminants are blown into the tissue renders jet water lavage ineffective in removing debris, and it must be removed mechanically, bit by bit. Wound cultures from these injuries usually are polymicrobial. A mean of three organisms per intraoperative culture were identified when anaerobic and anaerobic cultures were performed (7).

Treatment

Considerable judgment is required to determine whether to amputate or save a questionable part. My approach is to perform a thorough debridement at the time of injury, preserving all tissue of questionable viability and leaving the wound open. The ability of children to maintain viability in injured fingertips is well recognized, and a very conservative approach at the time of the initial debridement is justified. The wound is examined with the child under anesthesia at intervals of 2 to 3 days until it is clean and ready for definitive coverage. Plastic surgery consultation is advisable at the time of initial injury to allow optimal preparation for a definitive procedure to provide adequate skin coverage (144).

Experience with the management of lawn mower injuries unfortunately is being compiled at a steady rate. Alonso and Sanchez emphasized the severity of these injuries secondary to the massive forces incurred and the need for triple antibiotic coverage (cephalosporin, aminoglycosides, penicillin), because they are in the same class as farm injuries (5). Formulas for determining the feasibility of salvaging the foot in adults are less meaningful for children because of the effects of subsequent growth. Split-thickness skin grafts can function surprisingly well on weight-bearing surfaces in children (45,173). Dormans et al. (45) found shredding types of injury tend to do poorly even if the limb is salvaged; paucilaceration types of injuries have a much better outlook. Amputation rates of about 70% are common in series of children with lawn mower injuries (173).

It is important for the surgeon to appraise the degree of injury to the foot realistically and not pursue limb salvage at any cost. There seldom is any need for an immediate decision, and the degree of tissue damage noted at the time of subsequent debridements often makes the best decision obvious. With the advent of stump-lengthening procedures, better function is possible with a short amputation than in the past. Available tendons can be transplanted to produce a functional mid-foot amputation, which has often been regarded as an unattractive option.

Soft Tissue Treatment

Probably the most dramatic recent changes have been in the choice and timing of skin coverage. In the past, split-thickness skin grafts often were used, because the alternative of a pedicle flap was associated with considerable morbidity. However, in the past decade, several innovative free flaps have made the cumbersome cross-leg pedicle flap largely obsolete (11,25,66,67,192). The choices for coverage are numerous. Muscle flaps can be used for an improved biologic environment when the wound is not optimal (144). Cutaneous, fasciocutaneous, or composite flaps may be useful (Fig. 26-44). Local flaps are ideal when feasible but often are not large enough. Free flaps are described from various sites, including the forearm, scapula, upper arm, and scalp. The choice depends on the site and size of the wound, coupled with the expertise and experience of the consulting plastic surgeon. Advances in bone transport with ring or other external fixators allow more potential for reconstructing a severely injured child's foot.

FIGURE 26-44. A boy 7 years and 6 months of age whose foot was run over by a car. **A:** Wound on dorsum of the foot on the day of injury. **B:** Appearance of the foot following primary thigh fasciocutaneous flap applied on the day of injury. Although the foot did not sustain bony injury, the child subsequently developed premature growth arrest of the distal fibular physis. (Courtesy of W. Gould, M.D., and C. Crawford, M.D.)

The closure of large wounds by secondary intention, although often considered an outdated concept, may still be an attractive option for the treatment of wounds that do not involve weight-bearing surfaces (Fig. 26-45).

FIGURE 26-45. A boy 9 years and 8 months of age, whose foot was run over by a car. He sustained necrosis of the dorsal skin, which healed by secondary intention under a weight-bearing cast. **A:** After necrosis of dorsal skin. **B:** Three weeks later. **C:** Four months later.

Modern microvascular techniques make it possible to salvage some partial foot amputations (27), although the prevalence of untidy and avulsive wounds involving the foot make successful reimplantation unlikely. If there is any question about such a possibility, the amputated portion should be thoroughly cleansed, placed in a sterile plastic bag, and immersed in ice. The proximal stump should be cleansed and the patient should be referred to a reimplantation team as quickly as possible.

Compartment Syndrome

Crush injuries bring with them several difficult decisions for the attending orthopaedist. Compartment syndromes have been described in the foot (19,71,72,105,114,117,154,155,178). Ziv et al. (191) found elevated compartment pressures in the foot accompanying open fractures. Closed crush injuries, already mentioned in the section on metatarsal fractures, can demand rapid action. The number of publications on compartment syndromes of the foot since the last edition of this volume continues to expand, although the patients studied are mostly adults. Silas et al. (155) reported seven children treated for compartment syndrome of the foot. All but one had crush injuries, all had swelling and pain with passive motion, but none had any neurovascular deficit. Two had no bony injury, and in none of the others was the bony injury dramatic. Compartment pressures were measured under general anesthesia. A dorsal or a medial approach to the compartments is satisfactory for decompression; if a hindfoot injury is present, a medial approach is recommended to allow decompression of the tarsal tunnel (Fig. 26-46).

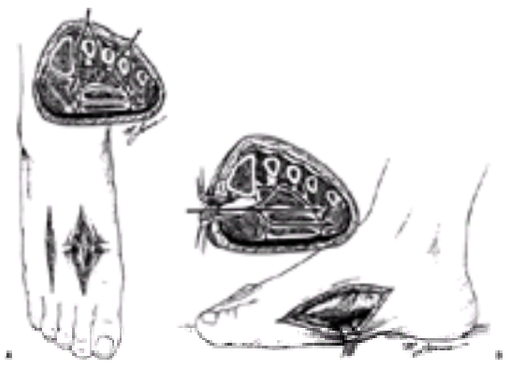

FIGURE 26-46. Surgical approaches for fasciotomy of the foot. **A:** The dorsal approach is via two incisions over the second and fourth metatarsal shafts and is more suitable for injuries of the forefoot or mid-foot. **B:** The medial approach is more suitable for injuries of the hindfoot, with the incision extending from the base of the first metatarsal to the medial malleolus. A tarsal tunnel release may be performed through this incision. (Reprinted from Myerson MS. Experimental decompression of the fascial compartments of the foot—the basis for fasciotomy in acute compartment syndromes. *Foot Ankle* 1988;8:308–314; with permission.)

Compartment syndrome should be suspected with crush injuries. Although uncommon in children, if the diagnosis of compartment syndrome is missed, the late sequelae can lead to significant disability in a young patient. Problems associated with missed compartment syndrome of the foot include claw toe deformities, paresthesias, cavus deformity, stiffness, and residual pain.

Often the diagnosis is indicated clinically by severe pain in association with tense swelling of the soft tissues or intense pain on passive stretching of the toes. The diagnosis can be made objectively with the measurement of compartment pressures (Fig. 26-47). There is no consensus in the literature regarding the threshold pressure level that mandates fasciotomy. In general, pressure readings of more than 40 mm Hg require surgical release of the compartments (118). Pressure readings of 30 to 40 mm Hg should prompt either fasciotomy or close monitoring. Less than 30 mm Hg can be observed clinically with strict ice and elevation. New devices such as foot pumps aimed at decreasing compartment pressures by actively eliminating edema have recently been advocated (118).

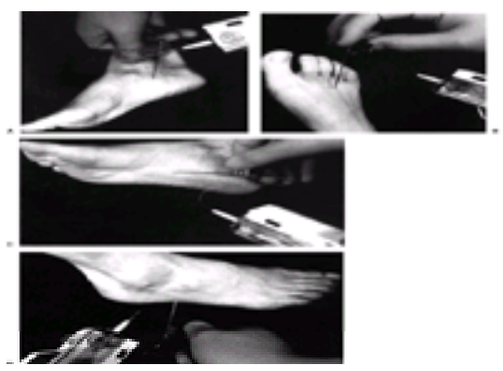

FIGURE 26-47. Compartment pressure measurement technique. **A:** The medial and calcaneal compartments are measured with the needle introduced within the medial hindfoot several centimeters below the medial malleolus. **B:** Forefoot pressures measured with the needle in the first or second interspace measuring the respective interosseous space pressure, advancement of the needle deeper measures the adductor compartment pressure. **C:** Superficial compartment is measured in the central plantar surface of the foot. **D:** Lateral compartment measurement is just below the base of the fifth metatarsal. (Reprinted from Manoli A II, Fakhouri AJ, Weber TG. Compartmental catheterization and fasciotomy of the foot. *Operative Techniques Orthop* 1992;2:205; with permission.)

LACERATIONS OF THE FOOT

The common problem of managing lacerations of the foot has received little attention in the literature. In 1977, Yancey (188) sent a questionnaire to the members of the American Orthopaedic Foot Society and the Association of Bone and Joint Surgeons, asking for methods of dealing with deep lacerations on the plantar aspect of the foot. He also asked for any reference in this area of which the respondent might be aware. None was cited. There was no uniformity of opinion about the management of lacerated tendons and nerves, although most surgeons would attempt repair.

Wicks et al. (183), in a report on tendon injuries about the foot and ankle in children, found that injuries to the heel cord or the anterior tibial or posterior tibial tendons resulted in severe foot deformity when not promptly recognized and repaired. They did not advocate repair of the extensor hallucis longus tendon, because no impairment was noted when this tendon was left unrepaired. Conversely, two patients had stiffness of the metatarsophalangeal joint after attempted repair. They thought that walking would passively maintain extension, and that there was no indication for repair of the long flexors or extensors to the toes. I would modify this recommendation slightly: I have seen a cock-up deformity of the second toe in a child who had an unrepaired laceration of the flexor tendon. If the tendons are not repaired, immobilization of the foot and toes by taping to the adjacent toes should be imposed for 3 weeks to allow restoration of continuity of the lacerated tendon. Lacerations to the nerves in the distal part of the foot in children appear to do very well, even when not repaired.

PUNCTURE WOUNDS

Since the 1960s, several reports (17,52,53,58,59,77,79,91,120) have documented the development of locally destructive osteomyelitis of the foot, usually near the metatarsophalangeal joints, after puncture wounds of the foot. Systemic symptoms, findings, and abnormal laboratory values do not accompany this entity.

Ninety-eight percent of all puncture wounds result from stepping on a nail (172) The incidence of cellulitis after initially treated puncture wounds of the foot is estimated at 8% to 15%; osteomyelitis develops in 0.6% to 1.8% (172). The prevalence of *Pseudomonas* as the offending organism in osteomyelitis appears to be due at least in part to the incidence of this organism in the soles of tennis shoes (52). However, the organism also has been found in work boots, and it appears that a warm, moist environment is the key factor; most footwear can provide that (58). The penetrating nail apparently acquires this organism as a rider on its passage into the sole of the foot.

No scientific basis for the initial management of puncture wounds is available, but the recommendations of Verdile, Freed, and Gerard seem reasonable (172). They use high-pressure wound irrigation with a 19-gauge needle, avoid hexachlorophene soaps, and perform debridement with a posterior tibial nerve block for especially dirty or deep wounds. Tetanus immunization is given when appropriate. They thought there was no basis for the use of routine prophylactic antibiotics, and that routine administration might even enhance the chances of subsequently developing gram-negative infection. Cellulitis generally is secondary to *Staphylococcus aureus* and is managed with wound culture, debridement, and appropriate antibiotic therapy.

The orthopaedist usually is consulted when there is a question of osteomyelitis. This entity is now well known among primary-care physicians and pediatricians, and delays in referral are less common (76). The instigating factor is a contaminating puncture wound, usually involving the cartilaginous metatarsal head or the proximal phalanx. Initially, the wound shows little evidence of infection because of the paucity of the inflammatory reaction (due to the relative avascularity of cartilage). Typically, after 5 to 10 days, the local reaction becomes more apparent. According to Green and Bruno (60), residual deformity depends on delay in diagnosis and treatment. Wounds managed by early surgical debridement and decompression of the joint, if involved, healed with minimal complications. If there was a 10- to 14-day delay in treatment, there sometimes was residual deformity. A 3-week delay in treatment essentially ensured residual deformity.

Treatment

The symptoms and pain involved with a puncture wound of the foot should subside in 2 or 3 days. If pain persists after this time, surgical exploration is indicated. Bone scintigraphy or MRI has been used for evaluation of possible osteochondritis secondary to puncture wounds and may be helpful, but if the physical findings are obvious for a deep inflammatory process, there is no need to delay surgery to obtain bone scintigraphy. If there is delay until the need for exploration is obvious, permanent deformity may be inevitable.

The choice of antibiotic and the necessary duration of therapy have not been established. One of the first patients with this problem, reported by Johanson (79) was treated with only surgical debridement. The aminoglycosides, the previous antibiotics of choice, are now recommended only for life-threatening *Pseudomonas* infections (121). Many of the newer beta-lactam antibiotics have variable degrees of activity against *Pseudomonas*; of these, ceftazidime appears to be the most effective, both *in vitro* and *in vivo.* A course of 10 to 14 days of antibiotic therapy after debridement has been recommended, although the authors of this recommendation acknowledge that shorter periods may suffice (76). Jacobs et al. (76) recommended aggressive surgical debridement and a 7-day course of intravenous antibiotics; even shorter durations are sufficient if debridement is complete. I administer parenteral antibiotics for 5 to 7 days after debridement if a good clinical response is attained, but like others I have no scientific basis for recommending this duration.

Two retrospective reviews of children with documented culture-positive *Pseudomonas* infections of the foot secondary to puncture wounds (77,120) emphasized the relative paucity of clinical signs of infection. Mild erythema and moderate tenderness at the puncture site were universal findings; however, relatively minimal inflammation and warmth were noted. In these patients, laboratory studies were often not suggestive of infection, and a high clinical suspicion was imperative. Adequate surgical debridement combined with anti-pseudomonal antibiotic coverage was stressed if rapid clinical improvement was not seen. In both of these studies the mean duration of intravenous antibiotic treatment approached 3 weeks.

LESIONS THAT MAY RESEMBLE FRACTURE

More confusing anatomic variants exist in the foot than anywhere else in the body. The more common variants are described, but it is impractical to attempt to be all inclusive and even more impractical for the clinician to try to learn all the variants.

Köhler's Disease

Waugh (177) studied the ossification and vascularization of the tarsal navicular bone and its relationship to Köhler's disease. He obtained radiographs of the feet of 52 boys and 52 girls at 6-month intervals from 2 to 5 years of age. Of these, 16 boys and 10 girls displayed abnormal ossification. Karp (84) found an even greater sex difference, with boys predominating by a ratio of 6.5 to 1. All the children in Waugh's series eventually developed a normal navicular bone due to the radial penetration of the arterial supply from the periphery of the ossifying bony nucleus. There was also no anatomic barrier (such as the physis in Legg-Perthes syndrome) to the ingrowing vascular supply, so revascularization was rapid and complete. Fragmentation of the ossification center of the navicular bone is a normal variant; irregularities and ossification at this site have no consistent relationship to symptoms (Fig. 26-48).

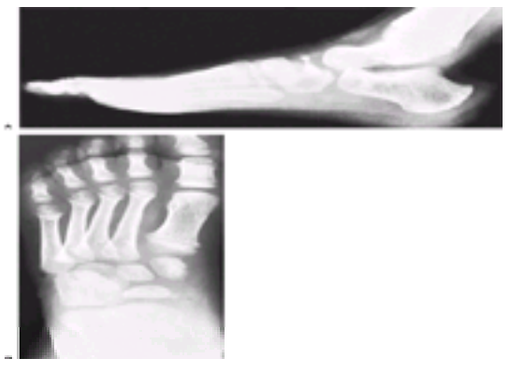

FIGURE 26-48. Köhler's disease in a 7-year-old boy. **A:** Collapse and condensation. **B:** Another boy with irregularity of ossification of medial portions of the navicular and medial cuneiform bones, a normal variant. Close inspection will reveal a fracture of the talar neck, shown in more detail in Fig. 26-6.

Freiberg's Infraction

Freiberg's infraction, an osteochondrosis of the second metatarsal head, can be confused with fracture—in fact, of Freiberg's (43) six original cases, three had a history of trauma, and subsequent reports by Smillie and Braddock (17,156) supported a traumatic etiology. Braddock (17) experimentally reproduced a comminuted fracture of the second metatarsal physis in anatomic specimens by loading the plantarflexed foot in skeletally maturing bone. A similar injury force produced fractures of the phalanges in younger children or adults, and he postulated that the physis was especially vulnerable at a certain stage of physeal maturation. This correlates with the age distribution of Freiberg's infarction, which is most common in the second decade of life. The second metatarsal also is the one most often injured, as it is the most rigidly fixed metatarsal. Wiley (184) discovered that one of his patients being followed after a tarsometatarsal dislocation developed Freiberg's infarction.

Pain and localized tenderness at the second metatarsal head are characteristic of Freiberg's infarction. On radiographs, there is a dense sequestrum in the metatarsal head when the process is active, with collapse and shortening of the residual effects (Fig. 26-49).

FIGURE 26-49. A: Freiberg's infarction of the second metatarsal head (*arrow*) in a 15.2-year-old girl. The metatarsal head is flattened and shortened. **B:** After curettage and bone grafting, with the base of the second metatarsal serving as a donor site. Symptoms were completely relieved.

Smillie (156) recommended immobilization as early treatment, with elevation of the depressed metatarsal head and bone grafting for a deforming head. He reported good results unless the fragment had completely separated. Wiley also had a favorable experience with this approach (J.J. Wiley, personal communication; Fig. 26-49), and my limited experience has also been favorable. Of course, many other procedures also have been recommended (73,88).

Other Variants

It usually is not difficult to differentiate a fracture from an anatomic variant with physical examination after trauma and the determination of localized tenderness; usually, the questionable radiographic finding is elsewhere. If not, the gentle, rounded edges of anatomic variants generally pronounce their long-standing presence,

in contrast to the sharp, jagged edges of a recent fracture (Fig. 26-50).

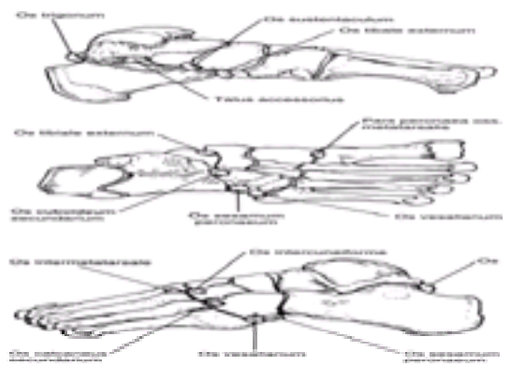

FIGURE 26-50. The supernumerary tarsal bones. **Top:** Medial view. **Center:** Plantar view. **Bottom:** Lateral view. (Redrawn from Schaeffer JP. *Morris' human anatomy,* 11th ed. New York: Blakiston Division, McGraw-Hill, 1953:279–280.)

The multiple accessory bones of the foot can be a source of confusion. Many ossification centers in the foot normally assume a peculiar configuration—for instance, the ossification center of the proximal phalanx of the first toe is often bipartite. Keats (86) has beautifully illustrated all the common and many of the uncommon potentially confusing radiographic variants that may be encountered in the foot.

The normal calcaneal apophysis can assume various shapes and densities; some of them in the past were designated as Sever's disease. The existence of such an entity is questionable (Fig. 26-51). A stress reaction at the physis, not distinguishable on routine radiographs, could be the source of pain. This would be analogous to Osgood-Schlatter disease at the tibial tubercle, where considerable force is generated by the quadriceps insertion on a relatively small maturing apophysis (recognizing that the radiographic picture of Osgood-Schlatter disease usually is unrelated to the clinical status). “Sever's disease” may be a comparable situation at the site of insertion of the Achilles tendon. Symptoms would then be present accompanying a variety of radiographic configurations of the calcaneal apophysis.

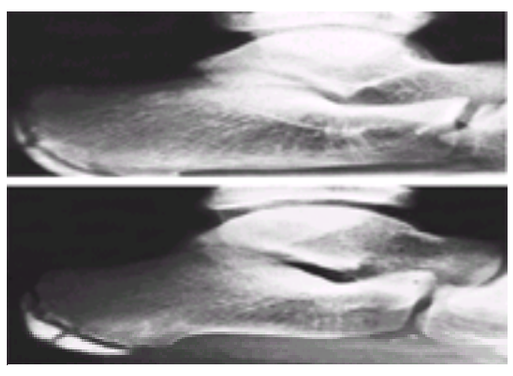

FIGURE 26-51. Two normal variants in configuration of the calcaneal apophysis. (Courtesy of Teresa M. Stacy, M.D.)

The clinician must attempt to correlate the symptoms, physical findings, and radiographic findings with his or her knowledge of anatomy and potential patterns of pathophysiology in the affected area. Solving a clinical puzzle often involves a higher level of analysis than merely trying to decide whether radiographic shadows are pathologic or normal.
