I want to acknowledge my wife Mary and children Erin, Colleen, John, and Kelly for patience and understanding while I dedicated many hours to this project. They understand that Dad has homework too. Also, I would like to recognize the injured children, medical students, residents, and fellows who count on this textbook to be the trusted source of information for fracture care; their needs are the inspiration that drive us to create an excellent final product.

Jack Flynn

I want to most of all thank my wife Val for her never-ending support, and tolerance of when I am "too busy". Thanks to my children Clay, Jamie, and Kira for being good friends, helping me with work-life balance, and assisting me with the many children who come to our home with injuries. And thanks to my PA Alison and nurse Elaine who take such good care of my patients.

David L. Skaggs

I wish to thank my wife Janet, expanding family of James, Rebecca, Billy, and Izzy, They, along with our unique collection of friends, supported me doing the binge work of this book early in the morning, on our vacations and reported free time together before the real fun began. And of course, my partners and patients who constantly teach me about fracture care every day.

Peter M. Waters

Preface

The eighth edition of *Rockwood & Wilkins' Fractures in Children* has new editors with our promotion from associate editors of the seventh edition. We are grateful to Drs. Jim Beaty and Jim Kasser for trusting us with carrying on their tradition of excellence. Jim and Jim have been great mentors and we are indebted. All texts are dependent on the outstanding contributions of the authors. This edition is no exception. All of the chapters have up-to-date information on techniques, treatment options, clinical outcomes, and the basic science information that guides care.

This edition has further expanded our electronic and visual content. Both the print and improved electronic versions are available. We have added a video section of operative cases for quick reference and visual-based learning. We reorganized the chapters and added new ones to make the book more clinical and in depth. We updated the illustrations and added more color clinical and surgical photographs to ease your learning. Our goal is to keep pace with the rapid changes around us in how we all receive and process information.

We hope this edition continues the excellent work started by Drs. Rockwood, Wilkins, and King, carried on by Drs. Beaty and Kasser, and now under our stewardship. Our goal is to help you provide better and safer care for your patients with pediatric musculoskeletal injuries.

Acknowledgments

This book has immense value for practicing pediatric and general orthopedic surgeons because our authors are willing to share their expertise openly and honestly. Each chapter has a complete and fair review of the literature, well-illustrated cases, and technical tips on how to avoid and treat unintended complications. We are indebted to our authors for their hard work and timely completion of their chapters.

The staff at Lippincott Williams and Wilkins provided excellent support and guidance. As times have changed their industry, they have adapted and reorganized to bring to all of us another outstanding edition of this text. Specifically, we thank Brian Brown who took over for Bob Hurley and seamlessly led this project; Dave Murphy, who had added responsibility but still managed to get it done so well; and to Abhishan Sharma for his assistance in organization of a unified final product. Personnel at our respective institutions kept each of us on task. We recognize their outstanding assistance in the timely and professional completion of this book. Specifically, Jim Koepfler, Virginia Brunelle, Rebecca Baron, Daryl MaClaren, and Jenny Martinez.

SECTION ONE

Basic Principles

1 EPIDEMIOLOGY OF FRACTURES IN CHILDREN

Brian Brighton and Michael Vitale

Introduction

Epidemiology is defined as the study of the distribution and determinants of health and disease and the application of this science to the control of diseases and other health problems. As such, epidemiology is the cornerstone of an evidence-based approach to preventing disease, and to optimizing treatment strategies. The term "epidemiology" is derived from the Greek roots epi = upon, demos = people, logos = study, meaning "the study of what is upon the people." Although epidemiology was originally applied to communicable diseases, those who care for children will immediately understand that trauma is the disease that is "upon the people" under our care. Various epidemiologic methods including surveillance and descriptive studies can be used to investigate the distribution of frequency, pattern, and burden of disease whereas analytical methods can be used to study the determinants of disease. An understanding of the epidemiology of pediatric trauma is a prerequisite for the timely evolution of optimal care strategies, and for the development of effective prevention strategies.

Injuries in children and adolescents represent a major public health challenge facing pediatric patients, families, and health care providers worldwide. The incidence of pediatric trauma in the United States is among the highest in the developing world, reflecting the realities of urban violence, firearms, and the dangers of a highly mechanized society. Given the wide-reaching impact that pediatric musculoskeletal injury has on public health, an understanding of the epidemiology of pediatric fractures provides an opportunity to maximize efforts aimed at prevention and optimal treatment. Unintentional injuries are the leading cause of death for children in the United States. In 2009, the Centers for Disease Control and Prevention (CDC) reported 7,712 deaths of children between the ages of 0 and 18 years caused by unintentional injuries (http://webappa.cdc.gov/sasweb/ncipc/mortrate10_us.html). However, fatalities only represent a small portion of the impact unintentional injuries have on children. There were 8,612,481 nonfatal unintentional injuries to children of the same age group in 2010. (http://webappa.cdc.gov/sasweb/ncipc/nfirates2001.html) Pediatric trauma often results in temporary activity limitation,

hospitalization, and sometimes in permanent disability.[2,63] Injuries requiring medical attention, or resulting in restricted activity, affect more than 20 million children and adolescents and cost $17 billion annually for medical treatment.[33] As the leading cause of death and disability in children, pediatric trauma presents one of the largest challenges to the health of children, as well as an important opportunity for positive impact.

Incidence of Fractures in Children

"Classification Bias": Difficulties Defining Disease

Rigorous epidemiologic studies demand consistent information about how we define and classify a given disease state. This is a challenge in pediatric trauma, making it difficult to compare studies. Some studies extend the pediatric age group to only 16 years, for example, whereas others include patients up to 21 years of age. Moreover, it is particularly difficult to examine injuries that only sometimes result in admission. Many studies[18,81] are limited to injuries that require hospital admission, despite the fact that most injuries in children do not. Reports vary in the precision of their defined types of fracture patterns. In the older series, reports were only of the long bone involved, such as the radius. Series that are more recent have emphasized a more specific location, separating the radius, for example, into physeal, distal, shaft, and proximal fracture types. Recently, an international study group has developed and attempted early validation of a standardized classification system of pediatric fractures.[84,130–133] The authors of an agreement study found that with appropriate training, the AO comprehensive pediatric long bone fracture classification system could be used by experienced surgeons as a reliable classification system for pediatric fractures for future prospective studies.[130]

Thus, in trying to define the exact incidence of pediatric fractures, it is difficult to compare series because of cultural, environmental, and age differences. In the following synopsis, these differences were considered in grouping the results and producing average figures. These data are presented in an attempt to provide a reasonable and accurate reflection of the overall incidence of injuries and fractures in all children. It is estimated that the incidence of nonfatal injuries in children is 25% annually representing 56,000 injuries per day in the United States with an estimated 38 fatal injuries per 100,000 children.[33,119] Fractures account for 8.5% to 25% of those injuries.[71,128,147]

Early studies on the incidence of fractures in children formed a knowledge base about fracture healing in children. In 1941, Beekman and Sullivan[11] published an extensive review of the incidence of children's fractures. Their pioneering work—still quoted today—included a study of 2,094 long-bone fractures seen over a 10-year period at Bellevue Hospital in New York City. The major purpose of their study was to develop basic principles for treating children's fractures.

In 1954, two reports, one by Hanlon and Estes[49] and the other by Lichtenberg,[77] confirmed the findings of the previous studies with regard to the general incidence of children's long bone fractures and their ability to heal and readily remodel. These initial reviews were mainly statistical analyses and did not delve deeply into the true epidemiology of children's fractures. In 1965, Wong[155] explored the effect of cultural factors on the incidence of fractures by comparing Indian, Malay, and Swedish children. In the 1970s, two other studies, one by Iqbal[56] and another by Reed,[110] added more statistics regarding the incidence of the various long bone fractures.

Landin's 1983 report on 8,682 fractures remains a landmark study on the incidence of fractures in children.[70] He reviewed the data on all fractures in children that occurred in Malmo, Sweden, over 30 years and examined the factors affecting the incidence of children's fractures. By studying two populations, 30 years apart, he determined that fracture patterns were changing and suggested reasons for such changes. His initial goal was to establish data for preventive programs, so he focused on fractures that produced clean, concise, concrete data. In 1997, Landin[71] updated his work, reemphasizing the statistics from his previous publication. He suggested that the twofold increase in fracture rate during the 30 years from 1950 to 1979 in Malmo was caused mainly by an increased participation in sports. In 1999, in cooperation with Tiderius and Duppe, Landin studied the incidence in the same age group again in Malmo and found that the rate had actually declined by 9% in 1993 and 1994.[144] The only exception was an increase of distal forearm fractures in girls, which he attributed to their increased participation in sporting events. The authors attributed this to less physical activity on the part of modern-day children coupled with better protective sports equipment and increased traffic safety (e.g., stronger cars and use of auto restraint systems).

Cheng and Shen,[26] in their 1993 study from Hong Kong, also set out to define children's fractures by separating the incidences into age groups. They tried to gather epidemiologic data to build preventive programs. In 1999, this study was expanded to include almost 6,500 fractures in children 16 and younger over a 10-year period.[25] The fracture patterns changed little over those 10 years; however, there was an increased frequency of closed reduction and percutaneous pin fixation of fractures, with a corresponding decrease in open reductions along with a marked decrease in the hospital stay of their patients.

More recently, studies on the incidence of fractures in Edinburgh, Scotland in 2000, as reviewed by Rennie et al.,[111] was 20.2 per 1,000 children annually. A similar fracture incidence of 201/10,000 among children and adolescents was reported in northern Sweden between 1993 and 2007 with a 13% increase during the years between 1998 and 2007. The authors also reported the accumulated risk of sustaining a fracture before the age of 17 being 34%.[52] In Landin's series from Malmo, Sweden, the chance of a child sustaining a fracture during childhood (birth to age 16) was 42% for boys and 27% for girls.[70] When considered on an annual basis, 2.1% of all the children (2.6% for boys; 1.7% for girls) sustained at least one fracture each year. These figures were for all fracture types and included those treated on an inpatient basis and an outpatient basis. The overall chance of fracture per year was 1.6% for both girls and boys in a study from England of both outpatients and inpatients by Worlock and Stower.[157] The chance of a child sustaining a fracture severe enough to require inpatient treatment during

TABLE 1-1 Overall Frequency of Fractures

Percentage of children sustaining at least one fracture from 0—16 y of age: Boys, 42%; girls, 27%

Percentage of children sustaining a fracture in 1 y: 1.6—2.1%

Percentage of patients with injuries (all types) who have fractures: 17.8%

the first 16 years of life is 6.8%.[26] Thus, on an annual basis, 0.43% of the children in an average community will be admitted for a fracture-related problem during the year. The overall incidence of children's fractures is summarized in Table 1-1.

Early reports of children's fractures lumped the areas fractured together, and fractures were reported only as to the long bone involved (e.g., radius, humerus, femur).[11,49,56,77,81] More recent reports have split fractures into the more specific areas of the long bone involved (e.g., the distal radius, the radial neck, the supracondylar area of the humerus).[26,56,70,110,157]

In children, fractures in the upper extremity are much more common than those in the lower extremity.[49,56] Overall, the radius is the most commonly fractured long bone, followed by the humerus. In the lower extremity, the tibia is more commonly fractured than the femur (Table 1-2).

Given the fact that different reports classify fractures somewhat differently, it is somewhat of a challenge to distill detailed and accurate prevalence data for specific fractures; in trying to do so, we have identified areas common to a number of recent reports,[26,56,70,110,157] but have taken some liberties in doing so. For example, distal radial metaphyseal and physeal fractures were combined as the distal radial fractures. Likewise, the carpals, metacarpals, and phalanges were combined to form the region of the hand and wrist. All the fractures around the elbow, from those of the radial neck to supracondylar fractures, were grouped as elbow fractures. This grouping allows comparison of the regional incidence of specific fracture types in children (Table 1-3).

The individual reports agreed that the most common area fractured was the distal radius. The next most common area, however, varied from the hand in Landin's series to the elbow (mainly supracondylar fractures) in Cheng and Shen's data (Fig. 1-1).[26]

Physeal Fractures

The incidence of physeal injuries overall varied from 14.5%[30] to a high of 27.6%.[89] To obtain an overall incidence of physeal fractures, six reports totaling 6,479 fractures in children were combined.[13,30,89,94,110,157] In this group, 1,404 involved the physis, producing an average overall incidence of 21.7% for physeal fractures (Table 1-4).

Open Fractures

The overall incidence of open fractures in children is consistent. The data were combined from the four reports in which the incidence of open fractures was reported.[26,49,89,157] The incidence in these reports varied from 1.5% to 2.6%. Combined, these reports represented a total of 8,367 fractures with 246 open fractures, resulting in an average incidence of 2.9% (Table 1-5).

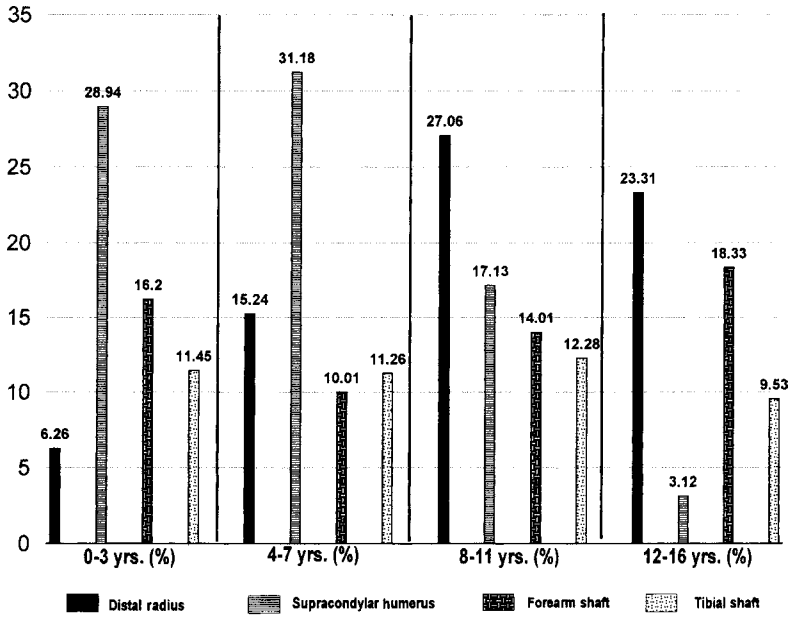

FIGURE 1-1 The frequency of occurrence of the most common fracture areas in children. The frequency of each fracture pattern differs with the various age groups. The figures express the percentage of total fractures for that age group and represent boys and girls combined. (Reprinted from Cheng JC, Shen WY. Limb fracture pattern in different pediatric age groups: A study of 3,350 children. *J Orthop Trauma.* 1993;7(1):15–22, with permission.)

Regional trauma centers often see patients exposed to more severe trauma, so there may be a higher incidence of open fractures in these patients. The incidence of open fractures was 9% in a report of patients admitted to the trauma center of the Children's National Medical Center, Washington, DC.[18]

Multiple Fractures

Multiple fractures in children are uncommon: The incidence ranges in the various series from 1.7% to as much as 9.7%. In four major reports totaling 5,262 patients, 192 patients had more than one fracture (Table 1-6).[26,49,56,157] The incidence in these multiple series was 3.6%.

Fractures in Weak Bone

Children with generalized bone dysplasias and metabolic diseases that produce osteopenia (such as osteogenesis imperfecta) are expected to have recurrent fractures. In these patients, the etiology is understandable and predictable. However, some children with normal osseous structures are prone to recurrent fractures for reasons that remain unclear. The incidence of recurrent fractures in children is about 1%.[36]

Decreasing incidence of fractures in children: An epidemiological analysis of 1,673 fractures in Malmo, Sweden, 1993-1994. *Acta Orthop Scand.* 1999;70(6):622–626.

Landin and Nilsson[69] found that children who sustained fractures with relatively little trauma had a lower mineral content in their forearms, but they could not correlate this finding with subsequent fractures. Thus, in children who seem to be structurally normal, there does not appear to be a physical reason for their recurrent fractures.

Repeat Fractures

Failure to find a physical cause for repeat fractures shifts the focus to a psychological or social cause. The one common factor in accident repeaters has been a high incidence of dysfunctional families.[58] In Sweden, researches found that children who were accident repeaters came from "socially handicapped" families (i.e., those on public assistance or those with a caregiver who was an alcoholic).[101] Thus, repeat fractures are probably more because of behavioral or social causes than physical causes. Landin,[71] in his follow-up article, followed children with repeat fractures (four or more) into adolescence and adulthood. He found these children had a significantly increased incidence of convictions for serious criminal offenses when compared with children with only one lifetime fracture.

Despite the importance of understanding the epidemiology of pediatric fractures, there are still significant gaps in our

knowledge base, and there is much work to be done. There are several challenges to gathering appropriate data in this area: risk factors for pediatric injury are diverse and heterogenous, practice patterns vary across countries and even within countries, and the available infrastructure to support data collection for pediatric trauma is far from ideal.

Patient Factors Influence Fracture Incidence and Fracture Patterns

Age

Fracture incidence in children increases with age. Age-specific fracture patterns and locations are influenced by many factors including age-dependent activities and changing intrinsic bone properties. Starting with birth and extending to age 12, all the major series that segregated patients by age have demonstrated a linear increase in the annual incidence of fractures with age (Fig. 1-2).[16,25,26,56,70,111,157]

Although there is a high incidence of injuries in children of ages 1 to 2, the incidence of fractures is low with most fractures being related to accidental or nonaccidental trauma from others.[67] The anatomic areas most often fractured seem to be the same in the major series, but these rates change with age. Rennie et al.[111] demonstrated in their 2000 study from Edinburgh that the incidence of fractures increased and fracture patterns changed as children aged. Fracture incidence curves for each of the most commonest fractures separated by gender were shown on six basic incidence curves similar to Landin's initial work (Fig. 1-3).[70] When Landin compared these variability patterns with the common etiologies, he found some correlation. For example, late-peak fractures (distal forearm, phalanges, proximal humerus) were closely correlated with sports and equipment etiologies. Bimodal pattern fractures (clavicle, femur, radioulnar, diaphyses) showed an early increase from lower energy trauma, then a late peak in incidence caused by injury from high- or moderate-energy trauma likely caused by motor vehicle accidents (MVAs), recreational activities, and contact sports in the adolescent population. Early peak fractures (supracondylar humeral fractures are a classic example) were mainly caused by falls from high levels.

Prematurity may also have some impact on the incidence of fractures in the very young child. Fractures not related to birth trauma reportedly occur in 1% to 2% of low–birth-weight or premature infants during their stay in a neonatal intensive care unit.[7] A combination of clinical history, radiographic appearance, and laboratory data has shown evidence of bone loss from inadequate calcium and phosphorus intake in these infants. Correcting the metabolic status of these low–birth-weight infants, with special emphasis on calcium and phosphorus intake, appears to decrease the incidence of repeat fractures and to improve the radiographic appearance of their bony tissues. Once the metabolic abnormalities are corrected, this temporary deficiency seems to have no long-term effects. When premature infants were followed into later years, there was no difference in their fracture rate compared with that of children of normal birth weight.[32]

Gender

Gender differences can be seen across the incidence of injures, location of injuries, and etiology of injuries across all age groups. For all age groups, the overall ratio of boys to girls who sustain a single fracture is 2.7:1.[26] In girls, fracture incidence peaks just before adolescence and then decreases during adolescence.[26,70,110] In the 10-year study from Hong Kong by Cheng et al.,[25] the male incidence in the 12- to 16-year age group was 83%. The incidence of fractures in girls steadily declined from their peak in the birth to 3-year age group.

In some areas, there is little difference in the incidence of fractures between boys and girls. For example, during the first 2 years of life, the overall incidence of injuries and fractures in both genders is nearly equal. During these first 2 years, the injury rates for foreign body ingestion, poisons, and burns have no significant gender differences. With activities in which there is a male difference in participation, such as with sports equipment and bicycles, there is a marked increase in the incidence of injuries in boys.[25,112] The injury incidence may not be caused by the rate of exposure alone; behavior may be a major

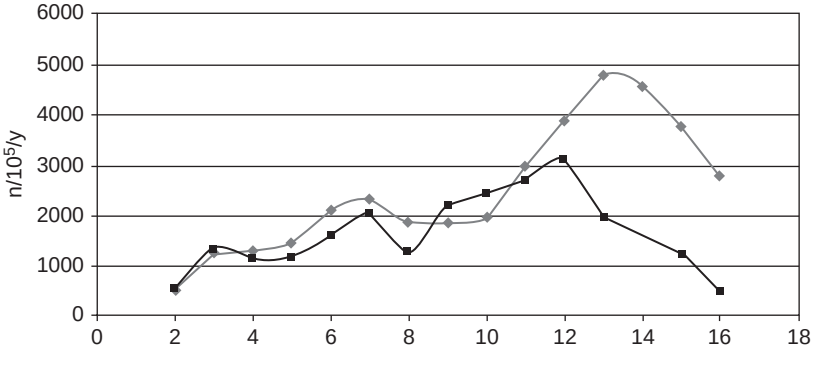

FIGURE 1-2 Incidence of fractures by age. Boys (◆) peak at 13 years whereas girls (■) peak earlier, at 12 years, and then decline. (Reprinted from Rennie L, Court-Brown CM, Mok JY, et al. The epidemiology of fractures in children. *Injury.* 2007;38(8):913–922, with permission.)

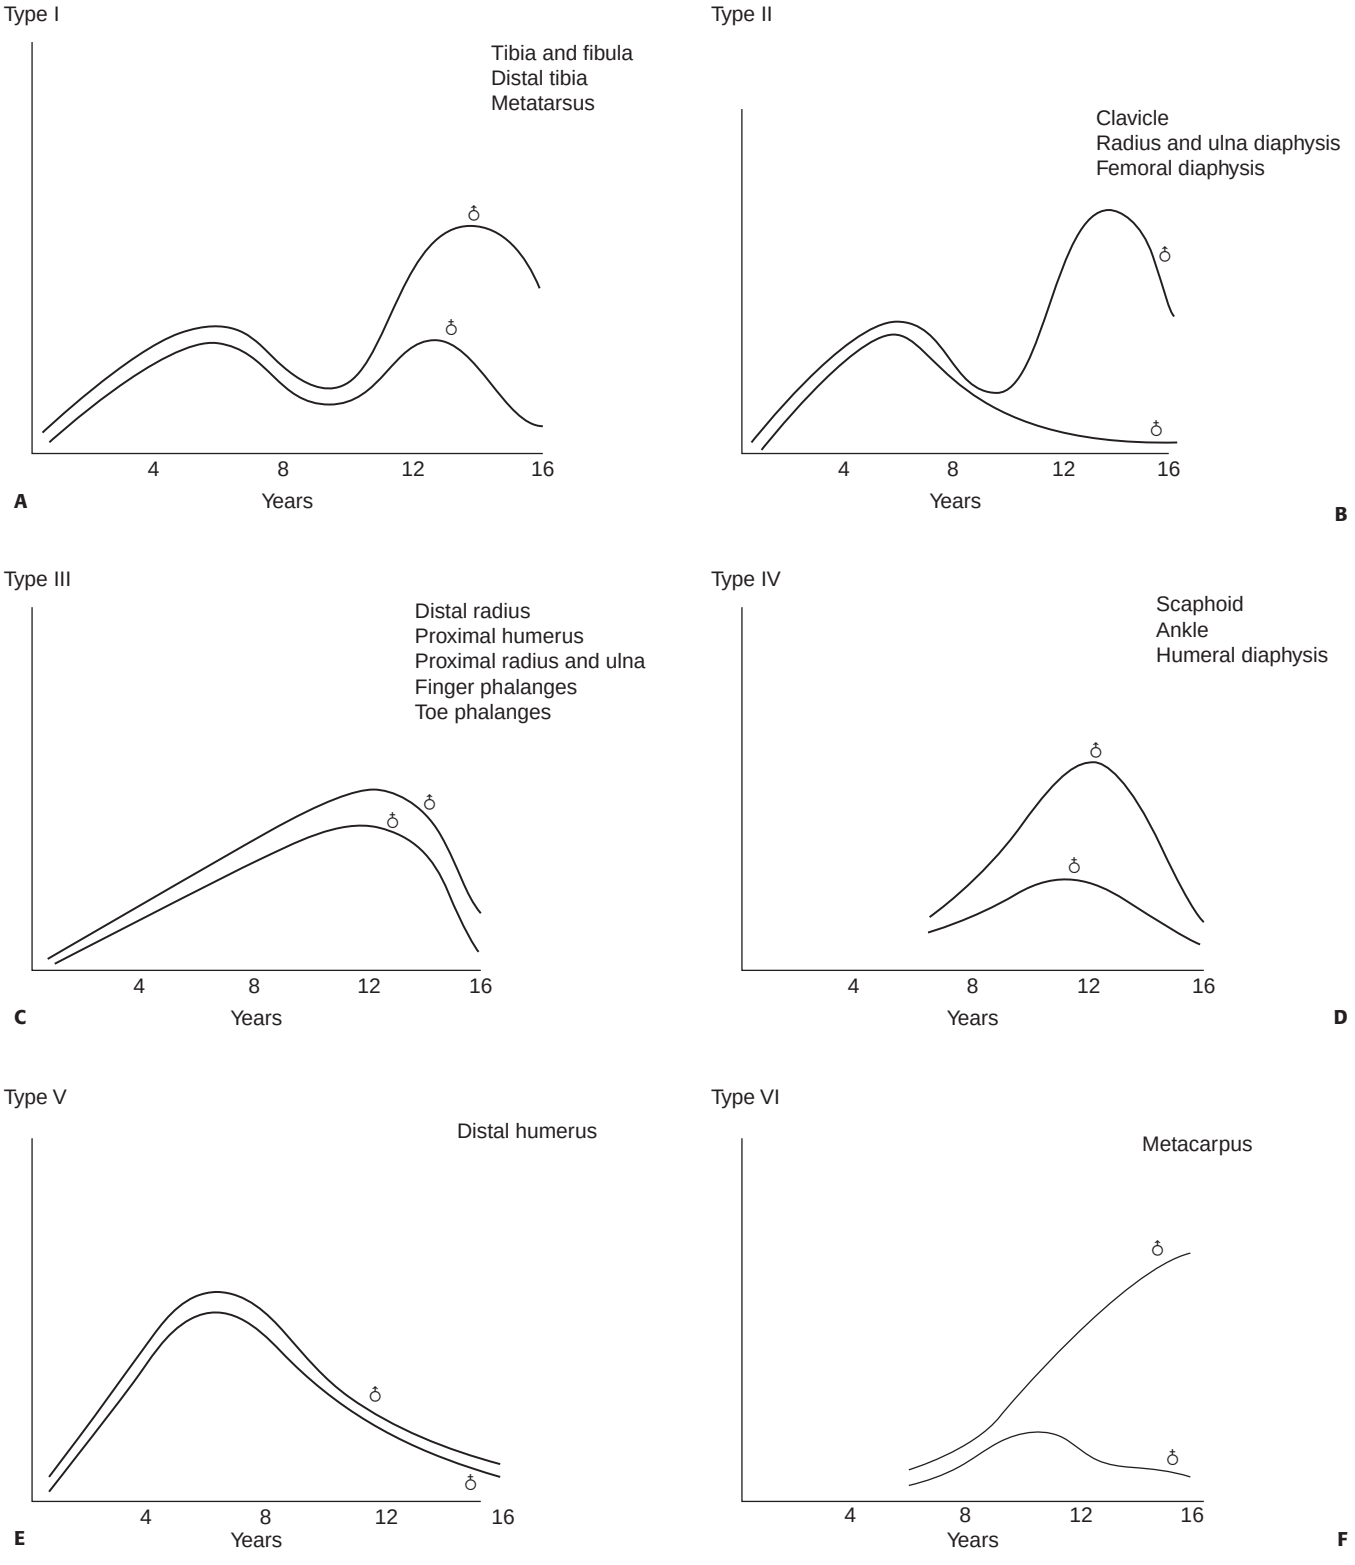

FIGURE 1-3 Patterns of fracture: Variations with age. The peak ages for the various fracture types occur in one of six patterns. (Reprinted from Rennie L, Court-Brown CM, Mok JY, et al. The epidemiology of fractures in children. *Injury*. 2007;38(8):913–922, with permission.)

factor.[146] For example, one study found that the incidence of auto/pedestrian childhood injuries peaks in both sexes at ages 5 to 8.[116] When the total number of street crossings per day was studied, both sexes did so equally. Despite this equal exposure, boys had a higher number of injuries. Thus, the difference in the rate between the sexes begins to develop a male predominance when behaviors change. The difference in the injury rate between the genders may change in the future as more girls participate in activities with increased physical risk.[25,112,144]

Hand Dominance

In most series, the left upper extremity demonstrates a slight but significant predominance.[14,31,32,35,40,45] The ratio of left to right overall averages 1.3:1. In some fractures, however, especially those of supracondylar bones, lateral condyles, and the distal radius, the incidence is far greater, increasing to as much as 2.3:1 for the lateral condyle. In the lower extremity, the incidence of injury on the right side is slightly increased.[49,70]

The reasons for the predominance of the left upper extremity have been studied, but no definite answers have been found. Rohl[114] speculated that the right upper extremity is often being used actively during the injury, so the left assumes the role of protection. In a study examining the left-sided predominance in the upper extremity, Mortensson and Thonell[96] questioned patients and their parents on arrival to the emergency department about which arm was used for protection and the position of the fractured extremity at the time of the accident. They found two trends: Regardless of handedness, the left arm was used more often to break the fall, and when exposed to trauma, the left arm was more likely to be fractured.

Socioeconomic and Cultural Differences

The incidence of pediatric fracture varies in different cultural settings. For instance, Cheng and Shen[26] studied children in Hong Kong who lived in confined high-rise apartments. Their risk of exposure to injury differed from the study by Reed[110] of children living in the rural environment of Winnipeg, Canada. Two separate reviews by Laffoy[67] and Westfelt[101] found that children in a poor social environment (as defined by a lower social class or by dependence on public assistance) had more frequent accidents than more affluent children. In England, children from single-parent families were found to have higher accident and infection rates than children from two-parent families.[42] In the United States, the increased rate of pediatric femur fractures was influenced by adverse socioeconomic and sociodemographic fractures.[55]

Two additional studies in the United Kingdom looked at the relationship of affluence to the incidence of fractures in children. Lyons et al.[85] found no difference in the fracture rates of children in affluent population groups compared to those of children in nonaffluent families. On the other hand, Stark et al.[138] in Scotland found that the fracture rates in children from nonaffluent social groups was significantly higher than those in affluent families.

Clinical Factors

In recent years there has been an attention to a number of clinically related factors in determining children's fractures, such as obesity, low bone mineral density, and low calcium and vitamin D intake. Obesity is an increasing health problem in children and adolescents representing a complex interaction of host factors, and is the most prevalent nutritional problem for children in the United States. In a retrospective chart review, Taylor et al.[142] noted that overweight children had a higher reported incidence of fractures and musculoskeletal complaints. Although Leonard et al.[75] found increased bone mineral density in obese adolescents, the lack of physical activity often seen in obesity may in fact lead to reduced muscle mass, strength and coordination resulted in impaired proprioception, balance and increased risk of falling and fracture. In a recent study, Valerio et al.[147] confirmed a greater prevalence of overweight/obesity in children and adolescents with a recent fracture when compared to age- and gender-matched fracture-free children, and found obesity rate was increased in girls with upper limb fractures and girls and boys with lower limb fractures.

Low bone mineral density and decreased bone mass are linked to increased fracture risk in the adult population; however, in children the relationship is less clear with a meta-analysis showing some association between fracture risk and low bone mineral density.[29] In 2006, Clark examined in a prospective fashion the association between bone mass and fracture risk in childhood. Over 6,000 children, at 9.9 years of age were followed for 2 years and the study showed an 89% increased risk of fracture per SD decrease in size-adjusted bone mineral density.[27] In a follow-up study of this same cohort the risk of fracture following slight or moderate-to-severe trauma was inversely related to bone size relative to body size perhaps reflecting the determinants of volumetric BMD such as cortical thickness on skeletal fragility.[28]

Nutritional factors may also play a role in the incidence of fractures in children. In a study in Spain, a significant difference in fracture rates was found when cities with a higher calcium content in their water were compared with those with a lower calcium content. With all other factors being equal (e.g., fluoride content, socioeconomic background), children who lived in the cities with a lower calcium content had a higher fracture rate.[148] An increase in the consumption of carbonated beverages has also been shown to produce an increased incidence of fractures in adolescents.[158]

Environmental Factors Impact on Fractures in Children

Seasonal and Climatic Differences

Fractures are more common during the summer, when children are out of school and exposed to more vigorous physical activities (Fig. 1-4). An analysis of seasonal variation in many studies shows an increase in fractures in the warmer months of the years.[25,26,52,70,111,114,151,157] The most consistent climatic factor appears to be the number of hours of sunshine. Masterson et al.,[90] in a study from Ireland, found a strong positive correlation between monthly sunshine hours and monthly fracture admissions. There was also a weak negative correlation with monthly rainfall. Overall, the average number of fractures in the summer was 2.5 times than that in the winter. In days with

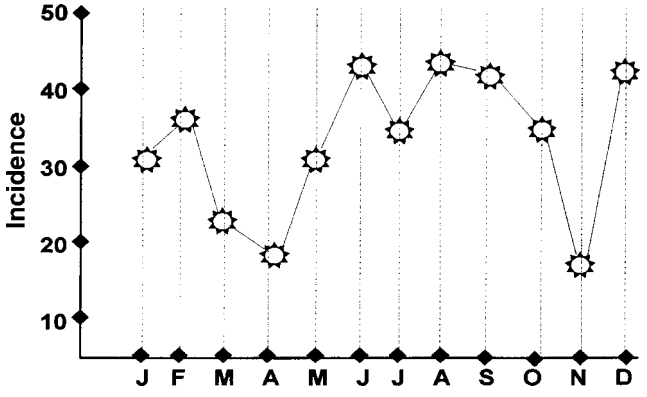

FIGURE 1-4 Distribution of children's fractures on a monthly basis. Note the general increase from May to October. (Reprinted from Reed MH. Fractures and dislocations of the extremities in children. *J Trauma.* 1977;17(5):351–354, with permission.)

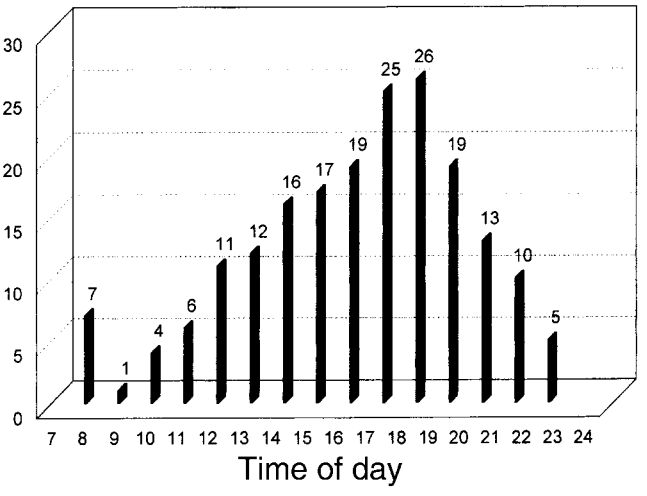

FIGURE 1-5 Incidence of children's fractures per time of day. There is an almost bell-shaped curve with a peak at around 6 PM. (Reprinted from Shank LP, Bagg RJ, Wagnon J. Etiology of pediatric fractures: The fatigue factors in children's fractures. Paper presented at: Proceedings of the 4th National Conference on Pediatric Trauma; September 24–26, 1992; Indianapolis, IN, with permission.)

more sunshine hours than average, the average fracture admission rate was 2.31 per day; on days with fewer sunshine hours than average, the admission rate was 1.07 per day.

In Sweden, the incidence of fractures in the summer had a bimodal pattern that seemed to be influenced by cultural traditions. In two large series of both accidents and fractures in Sweden by Westfelt[101] and Landin,[70] the researchers noticed increases in May and September and significant decreases in June, July, and August. Both writers attributed this to the fact that those children in their region left the cities to spend the summer in the countryside. Thus, the decrease in the overall fracture rate was probably because of a decrease in the number of children at risk remaining in the city.

Masterson et al.[90] speculated that because the rate of growth increases during the summer, the number of physeal fractures should also increase, as the physes would be weaker during this time. For example, the incidence of slipped capital femoral epiphysis, which is related to physeal weakness, increases during the summer.[8] However, Landin, in his study of more than 8,000 fractures of all types, found that the overall seasonal incidence of physeal injuries to be exactly the same as nonphyseal injuries.[70] Thus, it appears that climate, especially in areas where there are definite seasonal variations, influences the incidence of fractures in all children, especially in older children. However, in small children and infants, whose activities are not seasonally dependent, there appears to be no significant seasonal influence.

The climate may be a strong factor as well. Children in colder climates, with ice and snow, are exposed to risks different from those of children living in warmer climates. The exposure time to outdoor activities may be greater for children who live in warmer climates. Pediatric trauma should be viewed as a disease where there are direct and predictable relationships between exposure and incidence.

Time of Day

The time of day in which children are most active seems to correlate with the peak time for fracture occurrence. In Sweden, the incidence peaked between 2 PM and 3 PM.[101] In a well-documented study from Texas by Shank et al.,[124] the hourly incidence of fractures formed a well-defined bell curve peaking at about 6 PM (Fig. 1-5).

Home Environment

Fractures sustained in the home environment are defined as those that occur in the house and surrounding vicinity. These generally occur in a fairly supervised environment and are mainly caused by falls from furniture, stairs, fences, and trees as well as from injuries sustained from recreational equipment (trampolines and home jungle gyms). Falls can vary in severity from a simple fall while running to a fall of great magnitude, such as from a third story window. In falling from heights, adults often land on their lower extremities, accounting for the high number of lower extremity fractures, especially the calcaneus. Children tend to fall head first, using the upper extremities to break the fall. This accounts for the larger number of skull and radial fractures in children. Femoral fractures also are common in children falling from great heights. In contrast to adults, spinal fractures are rare in children who fall from great heights.[10,91,129,136] In one study, children falling three stories or less all survived. Falls from the fifth or sixth floor resulted in a 50% mortality rate.[10]

Interestingly, a Swedish study[101] showed that an increased incidence of fractures in a home environment did not necessarily correlate with the physical attributes or poor safety precautions of the house. Rather, it appears that a disruption of the family structure and presence of social handicaps (alcoholism, welfare recipients, etc.) is an important risk factor for pediatric fracture.

School Environment

The supervised environments at school are generally safe, and the overall annual rate of injury (total percentage of children

injured in a single year) in the school environment ranges from 2.8% to 16.5%.[15,74,101,126] Most injuries occur as a result of use of playground or recreational equipment or participation in athletic activity. True rates may be higher because of inaccurate reporting, especially of mild injuries. In one series, the official rate was 5.6%, but when the parents were closely questioned, the incidence of unreported, trivial injuries was as much as 15%.[40] In 2001 to 2002, a review of the National Electronic Injury Surveillance System (NEISS) demonstrated that 16.5% of the nearly 15 million injuries resulting in ED visits in school-aged children occurred at school.[79] The annual fracture rate of school injuries is thought to be low. Of all injuries sustained by children at school in a year, only 5% to 10% involved fractures.[40,74,126] In Worlock and Stower's series of children's fractures from England,[157] only 20% occurred at school. Most injuries (53%) occurring in school are related to athletics and sporting events,[74] and injuries are highest in the middle school children with one study citing a 20% fracture rate in school-aged children of those injured during physical education class.[102] The peak time of day for injuries at school is in the morning, which differs from the injury patterns of children in general.[42,74]

Etiology of Fractures in Children

Three Broad Causes

Broadly, fractures have three main causes: (i) Accidental trauma, (ii) nonaccidental trauma (child abuse), and (iii) pathologic conditions. Accidental trauma forms the largest etiologic group and can occur in a variety of settings, some often overlapping others. Nonaccidental trauma and fractures resulting from pathologic conditions are discussed in later chapters of this book.

Sports-Related Activities

The last two decades have seen an increase in youth participation in organized athletic participation, especially among younger children. Injuries in this population can occur in team or individual, organized or nonorganized, and contact and noncontact sporting activities. Wood et al. studied at the annual incidence of sports-related fractures in children 10 to 19 years presenting to hospitals in Edinburgh. The overall incidence was 5.63/1,000/year with males accounting for 87% of fractures. Soccer, rugby, and skiing were responsible for nearly two-thirds of the fractures among the 30 sporting activities that adolescents participated in. Upper extremity fractures were by far the most common injury accounting for 84% of all fractures with most being low-energy injuries and few requiring operative intervention.[156] A retrospective study over a 16-year time period from an emergency department at a level 1 trauma center in the Netherlands examined risk factors for upper extremity injury in sports-related activities. Most injuries occurred while playing soccer and upper extremity injuries were most common. Risk factors for injury were young age and playing individual sports, no-contact sports, or no-ball sports. Women were at risk in speed skating, in-line skating, and basketball, whereas men mostly got injured during skiing and snowboarding.[141] In Canada, soccer accounted for a significant proportion of injuries presented to Canadian Hospitals Injury Reporting and Prevention Program emergency departments during 1994 to 2004 with over 30% of these injuries presenting as fractures or dislocations.[48] A study using data from the Dutch Injury Surveillance System revealed a substantial sports-related increase in the incidence rate of wrist fractures in boys and girls aged 5 to 9 and 10 to 14 years in the period from 1997 to 2009. The authors concluded that incidence rate of wrist fractures in childhood in this study population is increasing, mainly as a result of soccer and gymnastics at school and recommended that future sport injury research and surveillance data are necessary to develop new prevention programs based on identifying and addressing specific risk factors, especially in young athletes.[34]

In the United States, football- and basketball-related injuries are common complaints presenting to pediatric emergency departments, with fractures occurring more frequently in football.[95] In a 5-year survey of the NEISS-All Injury Program, injury rates ranged from 6.1 to 11 per 1,000 participants/year as age increased, with fractures and dislocations accounting for nearly 30% of all injuries receiving emergency room evaluation.[92]

Recreational Activities and Devices

In addition to increasing participation in sports, new activities and devices have emerged that expose children to increased fracture risk. Traditional activities such as skateboarding, roller skating, alpine sports, and bicycling have taken on a new look in the era of extreme sports where such activities now involve high speeds and stunts. In addition, several recreational devices have been the focus of public health interventions and legislation because of their association with injuries in children. Many of these activities have safety equipment available but that does not assure compliance. Organizations such as the American Academy of Pediatrics and the American Academy of Orthopaedic Surgeons (AAOS) have issued position statements regarding the proper use and supervision of such devices, but it remains within the duty of the physician to educate and reinforce to patients and families to promote safety around these activities.[82]

Playground Equipment

Play is an essential element of a child's life. It enhances physical development and fosters social interaction. Unfortunately, unsupervised or careless use of some play equipment can endanger life and limb. When Mott et al.[97] studied the incidence and pattern of injuries to children using public playgrounds, they found that approximately 1% of children using playgrounds sustained injuries. Swings, climbers, and slides are the pieces of playground equipment associated with 88% of the playground injuries.[86]

In a study of injuries resulting from playground equipment, Waltzman et al.[150] found that most injuries occurred in boys (56%) with a peak incidence in the summer months. Fractures accounted for 61% of these injuries, 90% of which involved the upper extremity and were sustained in falls from playground equipments such as monkey bars and climbing frames. Younger children (1 to 4 years old) were more likely to sustain fractures than older children.

Similar observations were made in a study by Lillis and Jaffe[78] in which upper extremity injuries, especially fractures, accounted for most of hospitalizations resulting from injuries on playground equipment. Older children sustained more injuries on climbing apparatus, whereas younger children sustained more injuries on slides.

Loder[80] utilized the NEISS dataset to explore the demographics of playground equipment injuries in children. Monkey bars were the most common cause of fractures. In another study looking specifically at injuries from monkey bars, the peak age group was the 5- to 12-year-old group, with supracondylar humeral fractures being the most common fracture sustained.[87]

The correlation of the hardness of the playground surface with the risk of injury has been confirmed in numerous studies.[68,80,98,99] Changing playground surfaces from concrete to more impact-absorbing surfaces such as bark reduced the incidence and severity of head injury but increased the tendency for long bone fractures (40%), bruises, and sprains. Chalmers et al.[23] determined that the height of the equipment was just as great a risk factor as the surface composition. Using a novel composite playground safety score, researchers from Hasbro Children's Hospital in Rhode Island found that the incidence of supracondylar humerus fractures was increased in their community with playgrounds with lower composite safety scores and suggested that improvements in playground infrastructure may potentially reduce the incidence of supracondylar humerus fractures, and other injuries in children.[105]

Public playgrounds appear to have a higher risk for injuries than private playgrounds because they usually have harder surfaces and higher pieces of equipment,[106] although playground injury was most likely to occur at school compared to home, public, and other locations.[107]

Bicycle Injuries

Bicycle injuries are a significant cause of mortality and morbidity for children.[109] Bicycle mishaps are the most common causes of serious head injury in children.[154] Boys in the 5- to 14-year age group are at greatest risk for bicycle injury (80%). Puranik et al.[109] studied the profile of pediatric bicycle injuries in a sample of 211 children who were treated for bicycle-related injury at their trauma center over a 4-year period. They found that bicycle injuries accounted for 18% of all pediatric trauma patients. Bicycle/motor vehicle collisions caused 86% of injuries. Sixty-seven percent had head injuries and 29% sustained fractures. More than half of the incidents occurred on the weekend. Sixteen percent were injured by ejection from a bicycle after losing control, hitting a pothole, or colliding with a fixed object or another bicycle. Fractures mainly involved the lower extremity, upper extremity, skull, ribs, and pelvis in decreasing order of incidence. Over the last decade, youth participation in mountain biking has seen an increase and with that so has the number of injuries related to mountain biking increased with many caused by unpredictable terrain and falls as one rides downhill.[3,4]

The study by Puranik et al.[109] pointed out an equally important issue related to bicycle safety as they detected that helmet use was disturbingly low (<2%). Other studies confirm the observation that fewer than 13% to 15% of children wear helmets while riding bicycles.[41,113] The Year 2000 Health Objectives called for helmet use by 50% of bicyclists.[21] Even as recently as 2003, the use of bicycle helmets was still below 20%.[50] Research has shown that legislation, combined with education and helmet subsidies, is the most effective strategy to increase use of safety helmets in child bicyclists.[19] As public awareness of both the severity and preventability of bicycle-related injuries grows, the goal of safer bicycling practices and lower injury rates can be achieved.[109]

Bicycle spokes and handlebars are also responsible for many fractures and soft tissue injuries in children. D'Souza et al.[39] and Segers et al.[123] found that bicycle spoke injuries are typically sustained when the child's foot is caught in the spokes of the rotating wheel. Of 130 children with bicycle spoke injuries, 29 children sustained fractures of the tibia, fibula, or foot bone. Several had lacerations and soft tissue defects. D'Souza et al.[39] suggested that a mesh cover to prevent the toes from entering between the spokes and a plastic shield to bridge the gap between the fork and horizontal upright could substantially decrease the incidence of these injuries.

Skateboarding

Skateboarding and in-line skating have experienced a renewed surge in popularity over the past three decades. With the increasing number of participants, high-tech equipment development, and vigorous advertising, skateboard and skating injuries are expected to increase. There was an initial increase in the early 1980s, with a decrease after 1993. Since 1998, there has been an increase in the number of skateboard injuries.[66] Because the nature of skateboarding encompasses both high speed and extreme maneuvers, high-energy fractures and other injuries can occur, as highlighted by several studies.[43,104,108] Studies have shown that skateboarding-related injuries are more severe and have more serious consequences than roller skating or in-line skating injuries.[104] In a study of skateboarding injuries, Fountain et al.[43] found that fractures of the upper or lower extremity accounted for 50% of all skateboarding injuries. Interestingly, more than one-third of those injured sustained injuries within the first week of skateboarding. Most injuries occurred in preadolescent boys (75%) from 10 to 16 years of age; 65% sustained injuries on public roads, footpaths, and parking lots. In a study over a 5-year period of time using data from the National Trauma Data Bank, skateboarding injuries were associated with a higher incidence of closed head injuries and long bone fractures with children under age 10 more likely to sustain a femur fracture.[83] Several reports[43,122] have recommended safety guidelines and precautions such as use of helmets, knee and elbow pads, and wrist guards, but such regulations seldom are enforced.

It was thought that formal skate parks could decrease the injury rate. However, a study by Sheehan et al.[125] demonstrated that dedicated skate parks led to an increase in pediatric fractures referred to the hospital. The authors suggested that there should be closer supervision and training of children and more emphasis on limb protective gear. Lustenberger et al.[83] did however find that helmet use and designated skateboarding areas decreased the incidence of serious head injury (Table 1-7).

TABLE 1-7 Skateboard Safety Measures

Children younger than 5 years of age should not ride a skateboard
Children between 6 and 10 years of age should only ride with adult supervision
Use a quality skateboard and keep it in good working order
Learn proper falling and rolling techniques
Do not ride in traffic

From: Lovejoy S, Weiss JM, Epps HR, et al. Preventable childhood injuries. *J Pediatr Orthop.* 2012;32(7):741–747, with permission.

Roller Skates and In-Line Skates

In a study of in-line skate and roller skate injuries in childhood, Jerosch et al.[57] found that in a group of 1,036 skaters, 60% had sustained injuries. Eight percent of these were fractures, mostly involving the elbow, forearm, wrist, and fingers (78%). Fewer than 20% used protective devices, and most lacked knowledge of the basic techniques of skating, braking, and falling. In a larger study of 60,730 skating injuries in children, Powell and Tanz[108] found that 68% of the children were preadolescent boys with a mean age of 11.8 years. Fractures were the most common injury (65%) and two-thirds of these involved the distal forearm. Two and a half percent required hospital admissions; 90% of these admissions were for a fracture. Similarly, Mitts and Hennrikus[93] found that 75% of in-line skating fractures in children occurred in the distal forearm as a result of falls on the outstretched hand. One in eight children sustained a fracture during the first attempt at the sport. The orthopedic community has an obligation to educate the public on the need for wearing wrist guards when using in-line skates or roller skates.

Over the last decade there has also been a new product known as skate shoes or "heelys" that has increased in popularity and with this a rise in injuries associated with the use of these devices.[1] Ruth et al. (Ruth, Shah, & Fales, 2009) examined data over a 5-year period from the NEISS database for injuries related to skate shoes in children of ages 5 to 14. Most injuries in younger patients were fractures with the most frequent sites of fracture being the forearm and the wrist.

In-Line Scooters

Since 2000, a substantial increase in injuries related to nonmotorized scooters (kickboards) has been observed among children. The wheels of the scooter getting caught by uneven ground caused most of the scooter-related accidents, whereas most skateboard accidents occurred during attempted trick maneuvers. Protective gear was seldom used.[24,88,119] Scooters seem to have a high incidence of collisions with motor vehicles.[88] The recent motorizing of the scooters will only increase the severity of the injuries sustained.

Trampolines

Trampolines enjoyed increasing popularity in the 1990s and are a significant cause of morbidity in children. Several studies have noted a dramatic increase in the number of pediatric trampoline injuries during the past 10 years, rightfully deeming it as a "national epidemic."[45,134]

Using the NEISS data, Smith[134] estimated that there are roughly 40,000 pediatric trampoline injuries per year. Furnival et al.,[45] in a retrospective study over a 7-year period, found that the annual number of pediatric trampoline injuries tripled between 1990 and 1997. In contrast to other recreational activities in which boys constitute the population at risk, patients with pediatric trampoline injuries were predominantly girls, with a median age of 7 years. Nearly a third of the injuries resulted from falling off the trampoline. Fractures of the upper and lower extremities occurred in 45% and were more frequently associated with falls off the trampoline. In another excellent study on pediatric trampoline injuries, Smith[134] found that there was virtually a 100% increase in injuries from 1990 to 1995, with an average of more than 60,000 injuries per year. Younger children had a higher incidence of upper extremity fractures and other injuries. In a later study, Smith and Shields[135] reported that fractures, especially involving the upper extremity, accounted for 35% of all injuries. Interestingly, more than 50% of the injuries occurred under direct adult supervision. More disturbingly, 73% of the parents were aware of the potential dangers of trampolines, and 96% of the injuries occurred in the home backyard. These researchers, along with others,[45] rightly concluded that use of warning labels, public education, and even direct adult supervision were inadequate in preventing these injuries and have called for a total ban on the recreational, school, and competitive use of trampolines by children.[17,134,135] (Table 1-8)

Skiing Injuries

In a study of major skiing injuries in children and adolescents, Shorter et al.[127] found that more than 90% of injured children were boys from 5 to 18 years of age. Sixty percent of the accidents occurred in collisions with stationary objects such as trees, poles, and stakes. Most injuries occurred in the afternoon, among beginners, and in the first week of skiing season. Fractures accounted for one-third of the total injuries sustained. The two main factors implicated in skiing injuries are excessive speed and loss of control; effective prevention efforts should target both of these factors.

TABLE 1-8 Trampoline and Moon Bouncer Safety Measures

Although use of a net or ground-level trampoline may decrease injuries sustained while falling off of a trampoline, it does not prevent injuries sustained from collisions and twisting events
Single child trampolining or moon bouncing is safest
If the children play together in small groups on these devices, they should be of the same age and size
An adult should directly supervise trampoline and moon bounce use at all times

From: Lovejoy S, Weiss JM, Epps HR, et al. Preventable childhood injuries. *J Pediatr Orthop.* 2012;32(7):741–747, with permission.

Snowboarding Injuries

Snowboarding runs a risk similar to skiing. Bladin et al.[14] found that approximately 60% of snowboarding injuries involved the lower limbs and occurred in novices. The most common injuries were sprains (53%) and fractures (26%). Compared to skiers, snowboarders had $2^1/_2$ times as many fractures, particularly to the upper limb, as well as more ankle injuries and higher rates of head injury. The absence of ski poles and the fixed position of the feet on the snowboard mean that the upper limbs absorb the full impact of any fall. Wrist braces can decrease the incidence of wrist injuries in snowboarding.[115] In addition, fractures of the lateral process of the talus can be seen in snowboarding ankle injuries.[72] Of some concern, a recent study has shown that rates of snowboard injuries seem to be rising, whereas rates of ski injuries have been flat.[51]

Motor Vehicle Accidents

This category includes injuries sustained by occupants of a motor vehicle and victims of vehicle–pedestrian accidents.

The injury patterns of children involved in MVAs differ from those of adults. In all types of MVAs for all ages, children constitute a little over 10% of the total number of patients injured.[70,119] Of all the persons injured as motor vehicle occupants, only about 17% to 18% are children. Of the victims of vehicle-versus-pedestrian accidents, about 29% are children. Of the total number of children involved in MVAs, 56.4% were vehicle–pedestrian accidents, and 19.6% were vehicle–bicycle accidents.[35]

The fracture rate of children in MVAs is less than that of adults. Of the total number of vehicle–pedestrian accidents, about 22% of the children sustained fractures; 40% of the adults sustained fractures in the same type of accident. This has been attributed to the fact that children are more likely to "bounce" when hit.[35]

Children are twice as likely as adults to sustain a femoral fracture when struck by an automobile; in adults, tibial and knee injuries are more common in the same type of accident. This seems to be related to where the car's bumper strikes the victim.[18,22] MVAs do produce a high proportion of spinal and pelvic injuries.[18]

All-Terrain Vehicles (ATVs)

Recreational all-terrain vehicles (ATVs) have emerged as a new cause of serious pediatric injury. In 1988, the United States Consumer Product Safety Council signed an agreement with the ATV industry banning ATV use in children under 16 years of age, discontinuing production of three-wheeled ATVs, and promoting educational and safety programs. The consent decrees expired in 1998. An ATV Action Plan remained in place that prohibited manufacturers to market or sell three-wheeled ATVs, not market or sell adult-size ATVs to or for use by children younger than 16, promote training, and conduct safety education campaigns.[5] Despite these efforts ATV accidents have increased over the last two decades.[53] According to the 2007 report of the Consumer Product Safety Commission, serious ATV injuries in children younger than 16 years requiring emergency room treatment rose from 146,000 in 2006 to 150,900 in 2007. Using the Kids' Inpatient Database (KID) dataset, Killingsworth et al.[61] showed that 5,292 children were admitted to a hospital in 1997 and 2000 (the 2 years for which KID data was available) resulting in 74 million dollars in hospital charges, with rates of hospitalization increasing 80% between these 2 years. In fact, using the Oregon State database, Mullins et al.[100] showed that the number of patients who sought tertiary care for severe injuries caused by off-road vehicles doubled over a period of 4 years. In contrast to other etiologies of injury, children who sustained ATV-related fractures had more severe injuries and a higher percentage of significant head trauma, with 1% of these injuries resulting in inhospital death. These statistics point to the failure of voluntary safety efforts to date and argue for much stronger regulatory control.

In their 11-year review of ATV injuries treated at a level 1 pediatric trauma center, Kute et al.[65] determined that ATV accident-related admissions increased almost five times and overall fracture number increased four times over the study period; 63% of the 238 patients sustained at least one fracture. In a review of 96 children who sustained injuries in ATV-related accidents during a 30-month period, Kellum et al.[59] noted age-related patterns of injury. Younger children (≤12 years) were more likely to sustain an isolated fracture and were more likely to sustain a lower extremity fracture, specifically a femoral fracture, than older children. Older children were more likely to sustain a pelvic fracture. Kirkpatrick et al.[62] expressed concern about the frequency and severity of fractures about the elbow in their 73 patients injured in ATV accidents between 2001 and 2007: All six open fractures involving the upper extremity involved the elbow. In a recent review of the 2006 KID, Sawyer et al.[118] found that despite the known risks associated with ATV use in children, their use and injury rate continue to increase. The injury rate for children from ATV accidents has increased 240% since 1997, whereas the spinal injury rate has increased 476% over the same time frame. The authors found that injuries to the spinal column occurred in 7.4% of patients with the most common level of fracture was thoracic (39%), followed by lumbar (29%) and cervical (16%). Pelvic fractures were the most common associated fractures, accounting for 44% of all musculoskeletal injuries, followed by forearm/wrist fractures (15%) and femoral fractures (9%). Despite educational and legislative efforts, children account for a disproportionate percentage of morbidity and mortality from ATV-related accidents. The sport of motocross has also been shown to have a high rate of musculoskeletal injuries requiring hospitalization in children.[73] (Table 1-9)

TABLE 1-9 Strategies to Improve All-Terrain Vehicle (ATV) Rider Safety in Children

State-sponsored safety courses should be required
Always use a helmet
Never ride on paved roads shared by automobile traffic
Restrict riders till 16 years of age
No passenger

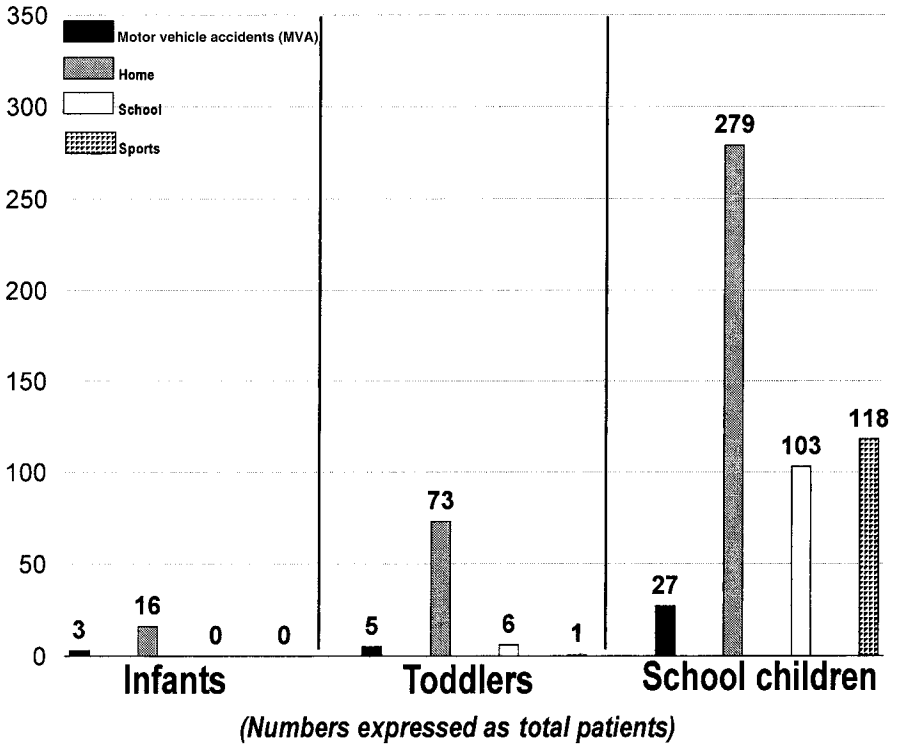

FIGURE 1-6 The incidence of fractures in children expressed as the four common etiologic categories. Most fractures occur at home. The numbers are expressed as total patients per each age category. (Reprinted from Worlock P, Stower M. Fracture patterns in Nottingham children. *J Pediatr Orthop.* 1986;6(6): 656–660, with permission.)

The etiologic aspects of children's fractures are summarized in Figure 1-6 and Table 1-10.

Gunshot and Firearm Injuries

Etiology. Gunshot or missile wounds arise from objects projected into space by an explosive device. Gunshot wounds have become increasingly common in children in the United States.[1] In a sad reflection of the changing times and the newly pervasive gun culture, firearms are determined to be second only to motor vehicles as the leading cause of death in youths. In considering the prevalence of firearms in the United States, it has been estimated that there are about 200 million privately owned guns in the United States and that approximately 40% of US households contain firearms of some type.[38]

In two reports from inner-city hospitals in the United States in the 1990s, most injuries resulted from random violence to innocent bystanders; the prime example was "drive-by shootings."[140,152] Few were self-inflicted, either voluntarily or accidentally. In a 1976 report on patients in a relatively rural setting in Canada, almost all the missile injuries were accidental, having been caused by the patient or a close friend or relative.[76]

In the urban setting, handguns and rifles are the most common weapons.[140,145,152] In the rural setting, the most common weapon is a shotgun.[76] The firepower of these weapons has changed over the years. In one urban hospital reporting gunshot wounds from 1973 to 1983, most of the injuries were from .32- or .38-caliber weapons; only 5% were high-caliber or high-velocity weapons.[103] In a later study of gunshot wounds from the same institution from 1991 to 1994, the incidence of injuries from high-caliber and high-velocity weapons (e.g., .357 Magnum, AK-47, and other assault rifles) had increased to 35%.[152]

In the urban setting, the victims' ages ranged from 1 to 17 years, and most of the injuries were in children aged 12 to 14.[103,140,145,152] In the rural setting, the patients were younger; the average age was 9 years.[76]

TABLE 1-10 Summary of Etiologic Factors in Children's Fractures

- Home environment
  - Injuries
    - 83% of all children's injuries
  - Fractures
    - 37% of all children's fractures
- School environment
  - Injuries
    - Overall rate, 2.8–9.2% annually
    - 53% related to athletic events
    - Peak age: Middle school group
  - Fractures
    - Occur in only 5–10% of all school-related injuries
    - About 20% of all children's fractures
- Motor vehicle accidents (MVAs)
  - Injuries
    - Children only 10% of all MVAs
    - Of children's MVAs, only 17–18% were occupants; remainder were vehicle/pedestrian or vehicle/bicycle
  - Fractures
    - High incidence of femur fractures in vehicle–pedestrian accidents in children
    - Children have a higher incidence of spinal and pelvic fractures with MVAs than with other mechanisms

Of 839 children sustaining gunshot wounds, 274 (32.6%) involved the extremities.[103,140,145,152] Of the gunshot wounds that involved the extremities, 51.3% produced significant fractures.[76,145,152] No single bone seemed to predominate, although most of the fractures were distal to the elbow.[103,140,145,152]

Complications from Gunshot Wounds. The two most common complications were growth arrest and infection. Other complications included delayed union and malunion. The treatment of fractures associated with gunshot wounds in children is never simple. Bone defects, associated peripheral nerve injuries, and involvement of the joint can negatively influence outcomes.[9] Considering the magnitude of many of these injuries, the infection rate for extremity wounds was low (about 7.3%). The type of missile did not seem to have any relation to the development of an infection.[152]

In Letts and Miller's 1976 series, one-sixth of the patients had some type of growth disturbance.[76] In a third of their patients, the missile was only in close proximity to the physis, but still appeared to cause a growth disturbance. In a 1995 report by Washington et al.,[152] the incidence of missiles' growth arrest was exactly the same; however, all were a result of a direct injury to the physis by the missile. None of their patients with growth arrest had proximity missile wounds. The higher incidence of growth abnormalities in the 1976 series was because of the larger number of shotgun and hunting rifle injuries, which dissipate more of their energy peripheral to the missile track.

In two of the studies in which patients were followed closely, all of the fractures ultimately healed.[76,152] On the other hand, DiScala and Sege[37] found in their review of children and adolescents who required hospitalization for gunshot wounds that almost half of them were discharged with disabilities.

Prevention. Firearm-related injury and safety have received much attention nationally and internationally in the wake of the events over the last decade. In a 1998 report, Freed et al.[44] analyzed the magnitude and implications of the increasing incidence of firearm-related injuries in children. They suggested a product-oriented approach, focusing on the gun, in an attempt to provide an efficient strategy of gun control and hence reduce the disturbing trend of firearm-related injuries and death among youths. Rather than modifying behavioral or environmental issues, which are more complex, they suggested focusing primarily on strategies that offset the accessibility and design of firearms. In brief, these strategies included reducing the number of guns in the environment through restrictive legislation, gun buy-back programs, gun taxes, physician counseling, and modifying the design of guns to make them more childproof and prevent unauthorized and unintended use.

Evolving Epidemiology of Fractures in Children

Preventive Programs

While studying the epidemiology of fractures, it is important to focus on the etiology of fractures and the settings in which they occur. Fractures do not occur in a vacuum, and well-researched studies that analyze the physical and social environment in which they occur are extremely valuable. Efforts can be made toward creating a safer environment for play and recreation. It is hoped that by targeting these areas, programs can be designed to decrease the risk factors.

National Campaigns

Several national organizations have developed safety programs. The foremost is the American Academy of Pediatrics, which has committees on injury and poison prevention and sports medicine and fitness that has produced guidelines for athletics,[153] playgrounds, trampolines,[17] ATVs,[5] and skateboards.[6] The AAOS has also produced a program designed to decrease the incidence of playground injuries. These programs offer background data and guidelines for various activities, but their effectiveness has not been fully studied. In addition, the AAOS, the Orthopaedic Trauma Association (OTA), and Pediatric Orthopaedic Society of North America (POSNA) have issued updated position statements regarding the safe use of ATVs, trampolines, skateboards, and in-line skating.

Local Community Participation

To be effective, accident prevention programs require local participation and cooperation. They must be broad based, and they require considerable effort by members of the local community. In the United States, one effective program is the New York Health Department's "Kids Can't Fly" campaign, developed in response to the large number of injuries and deaths from children falling out of apartment house windows in the 1970s.[137] This extensive program consisted of a good reporting system from hospital emergency rooms, with follow-up by public health personnel; a strong media campaign to educate the public; a door-to-door hazard identification program; and the distribution of low- or no-cost, easily installed window guards to families in high-rise apartments. The city required property owners to provide window guards in apartments where children of 10 years or younger lived. The success of this program was demonstrated by a 50% decrease in reported falls after 3 years and a 96% decrease after 7 years.[10,137]

Over the past 30 years, Sweden has developed broader-based, community-oriented programs to decrease the incidence of all types of childhood injuries.[12] The development of these pilot programs has been relatively easy in a country like Sweden because the population is homogeneous, the incidence of poverty is low, and the government is stable. The Swedish program had a three-pronged approach: Injury surveillance and prevention research; establishment of a safer environment for children through legislative regulation; and a broad-based safety education campaign. These programs have produced positive results. Schelp[121] demonstrated a 27% reduction in home accidents in the municipality of Falkoping only 3 years after the establishment of a community-wide campaign.

Effective prevention programs require local community participation and education. All the articles, lectures, and pamphlets in the world cannot help unless local communities make the necessary changes to decrease accident risks.

Modern Day Data Systems may Provide Expanded Opportunities to Examine the Epidemiology of Pediatric Trauma

Several sources of administrative, national, and regional data have recently become available providing significantly improved investigation into various areas within pediatric trauma. The Healthcare Cost and Utilization Project (HCUP) is a family of databases including the State Inpatient Databases (SID), the Nationwide Inpatient Sample (NIS), and the KID. Although administrative data may lack clinical detail for certain purposes, these datasets provide a comprehensive overview of health care utilization in the United States and are available without purchase (http://www.ahrq.gov/research/data/hcup/index.html).[139] The KID database has been increasingly used to examine the incidence of pediatric trauma as well as practice patterns in pediatric trauma. Data for KIDS are collected and published every 3 years, with data currently available for 1997, 2000, 2003, and 2006. KIDS is "nationally representative," meaning that the database contains a large but incomplete sample of the hospital discharge records (3.1 million in 2006), which are then statistically weighted upward to reflect the complete population of pediatric discharges (7.6 million in 2006). In the United States, using the HCUP KID dataset, Galano et al.[46] examined the face of pediatric inpatient trauma in 1997. They estimated that roughly 84,000 children were admitted for fracture care that resulted in about 1 billion dollars in hospital charges. Of some interest, more than 70% of children were treated at nonchildren's hospitals. In 2011 study, utilizing the 2006 HCUP KID dataset, Gao[47] reported on lower extremity fractures requiring hospitalization and found there were about 11,500 admission records for children aged 0 to 20 with lower extremity fractures. Urban hospitalizations accounted for 93% of cases and 66% of admissions were to teaching hospitals in Gao's study. There was an increased mortality risk among patients cared for in nonteaching hospitals and hospitals located in a rural region.

Several other databases including the United States Consumer Product Safety Commission's NEISS (http://www.cpsc.gov/library/neiss.html) have also been useful in providing information about the epidemiology of pediatric trauma. The NEISS provides a national sample from hospitals with patient information regarding emergency room visits related to an injury with associated consumer products. The information from the NEISS provides data necessary for surveillance efforts to identify problem areas, risk factors for injuries, and translation into prevention programs. Internationally, many countries have national health registries that can provide epidemiologic data on injury patterns. On a local level, many hospitals and hospital systems have created their own trauma and injury registries for clinical and academic use. One limitation to the currently available data sources is that they provide scant clinical detail, limiting broader utility as a source of health outcomes data in the field. Pilot efforts on an organizational level have also evaluated the feasibility of a national pediatric musculoskeletal trauma outcomes registry.[149]

Trauma registries are another source for injury data that document clinical and demographic information regarding acute care delivered to hospitalized patients with injuries at trauma centers. These databases are designed to provide information that can be used to study the effectiveness and quality of trauma care and identify areas for quality improvement. Although the amount of information available through regional and national databases allowed is immense, the creation and maintenance of these registries require a significant amount of time and financial resources. Several limitations of these databases include the focus on adult over pediatric injuries and the data that does not always reflect population-based samples. Constructed in an attempt to fill such a role, the National Pediatric Trauma Registry (NPTR) was a multi-institutional database designed to provide a snapshot of physiologic and clinical information regarding pediatric injuries. The NPTR was functional for about 15 years and provided a source of important data in the realm of pediatric trauma.[143] Attempts are being made to transform the NPTR into a more comprehensive database that will be called the National Trauma Registry for Children.[20] Currently the American College of Surgeons National Trauma Data Bank serves as the largest database which does produce annual reports on pediatric injury from trauma centers from the United States and Canada (http://www.ntdb.org). In the future, databases such as these may provide the infrastructure needed to study pediatric musculoskeletal trauma care.

ACKNOWLEDGMENT

With appreciation to Kaye Wilkins for previous work on this chapter.

2 THE IMMATURE SKELETON

Benjamin A. Alman

Roughly 20% of children will sustain a fracture, and the incidence of pediatric fractures associated with minor trauma is increasing over time.[24,36,53] Thus, childhood fractures are not only important from an orthopedic standpoint, but are also an important societal health issue. Children are not just small adults, and nowhere in the practice of orthopedics is this principle more important than in understanding the differences between how a growing child's and an adult's skeleton responds to trauma, and how injuries are best treated. Understanding these differences provides important insights into how to manage children's fractures. The age of a child can help to identify the most likely fracture type, based on which tissues are weakest in the growing skeleton. A child's bones heal quicker, are surrounded by thicker periosteum, and have a substantially greater remodeling potential than adults. These differences change the way fractures are treated. For instance, midshaft femur fractures that are treated by internal fixation in adults are successfully managed in a cast in a young child.[29]

In a growing child, injury can damage the growth plate, which can be the weakest region of bone.[53] Such injury can result in temporary or permanent growth arrest. Physeal fracture patterns vary with the extent of chondroosseous maturation. Salter and Harris classified growth plate injuries and found that type I and II injuries are common in younger children, whereas types III and IV become more common as the secondary ossification center enlarges and physeal undulations develop.[86] The growth plate can also remodel less than perfect reductions and there can be tremendous remodeling potential. As an example, the distal radius can correct deformities at a rate of one degree a month in line with the flexion and extension arc of motion of the wrist.[30,38,54]

Children can have underlying disorders that weaken bone or slow healing, such as osteogenesis imperfecta,[32,83] neurofibromatosis,[28] or a bone tumor.[41] The first presentation of such conditions may be a referral to an orthopedist for a fracture. Understanding how the bone normally behaves to an injury can help in the identification of a pathologic bone injury, which may be caused by such an underlying condition. For instance, an avulsion fracture, such as in the ulna, can be the first presentation for a preteen with osteogenesis imperfecta.[64] Identification of unusual fracture patterns can also help in the identification of nonaccidental trauma, and an orthopedist can save a child's life by the early identification of nonaccidental trauma childhood.[44] Childhood osteoporosis is increasing in frequency, and a fracture with an abnormal injury pattern may the first presentation of childhood osteoporosis. For these reasons it is critical to understand the normal response of a child's bone to trauma to know when there is something unusual in the presentation or course of healing, to make these diagnoses.

Bone Growth

During embryonic and postnatal development, cells proliferate, differentiate, and even die off to ultimately form a normally patterned adult. In the limb, progenitor cells proliferate and compact to form the limb bud. Cells on the outside of the limb

bud, the ectoderm, provide information to pattern the limb, whereas cells on the inside, the mesoderm, form the limb structures. As the mesoderm cells proliferate, regions within the limb bud that undergo greater cell condensation will form the future long bones. At the sites where the joints eventually form, the cells develop a fibroblast like phenotype and some undergo programmed cell death, or apoptosis, forming the interzone, the first overt sign of joint formation.[52,90]

The cells between the interzone form the long bones through a process of enchondral ossification. These cells differentiate to chondrocytes, which are distinguished by their expression of type II collagen. Chondrocytes at the ends of the bone (or epiphysis) become articular chondrocytes (located at joint surfaces) or growth plate chondrocytes (responsible for longitudinal bone growth), which are located closer to the middle of the bone. Vascular cells enter the center of the cartilaginous template of the bone, and osteoblasts replace the cartilage to form the primary center of ossification. Later in development a similar process occurs at the ends of the bones to form a secondary center of ossification, and this separates the articular from the growth plate chondrocytes. Articular chondrocytes remain relatively quiescent throughout life, regulating the turnover of extracellular matrix components for normal joint function. In contrast, growth plate chondrocytes undergo a coordinated process of cell differentiation, ultimately undergoing hypertrophy, and then apoptosis, providing the scaffolding on which new bone is formed.[4,22,71] Adjacent to the region where chondrocytes undergo terminal differentiation, blood vessels play an important role both in the removal of cartilage and in osteoblast recruitment to lengthen the bone. Osteoblasts derive from mesenchymal progenitor cells, termed mesenchymal stem or stromal cells (MSCs). MSCs come from a number of sources. They exist in bone in the bone marrow as stromal cells, in the periosteum surrounding the bone, and around blood vessels as pericytes.[23] Recent data suggest that the pericytes are an important source of new osteoblasts.[58] However, many types of mesenchymal cells, even chondrocytes, can change their phenotype to a cell that makes bone. As such there is probably not a single cell type responsible for becoming an osteoblast, but instead multiple cell types can contribute to make new bone.[76] This makes sense from the standpoint of developing a system to maintain the skeleton after trauma, as if repair could only happen from a single cell type, we would be limited in our capacity to heal a fracture. Bone formation and growth plate function are intimately linked, as cell signaling pathways that regulate growth plate chondrocyte differentiation also regulate osteoblast differentiation. These factors may also be responsible in part for the differences between how bone heals between growing children and adults (Fig. 2-1).

When bone is initially formed, it is immature woven bone, which is remodeled to more mature, and stronger, lamellar bone. During bone growth at the metaphysis, the trabeculae of bone-covered calcified cartilage (called primary spongiosa) are resorbed by osteoclasts and the cartilage template is replaced by lamellar bone, which is remodeled into more mature bone trabeculae (secondary spongiosa). The deposited secondary bone trabeculae at the metaphyseal–diaphyseal junction is further remodeled and incorporated into the diaphysis, in a process in which osteoclasts remove bone from the periphery of the metaphysis and new bone is formed at the endosteal surfaces. The cortical bone is remodeled into a complex structure of osteons that together form the cortical bone.[31] Osteons are tubular structures that consist of layers of ordered lamellar bone around a central canal. The central canal contains blood vessels, lymphatics, and in some cases, nerves.[45]

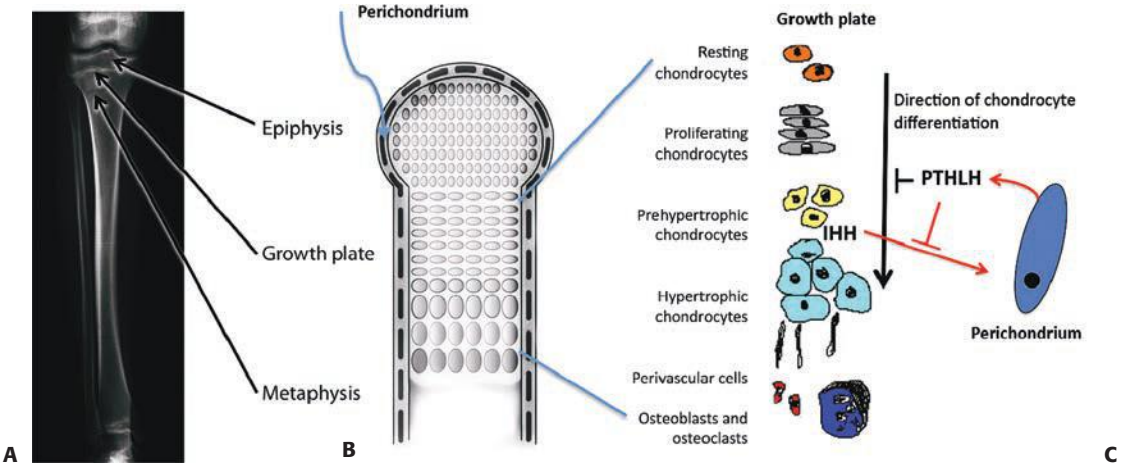

FIGURE 2-1 Bone development. During embryonic development, undifferentiated cells proliferate and compact to form the limb bud. As these cells proliferate, regions within the limb bud that undergo greater condensation will form future long bones. **A:** Radiograph of a tibia showing the anatomic portions of the long bones. **B:** The ends of long bones consist of the epiphysis and metaphysis, with the growth plate between the two. **C:** Growth plate chondrocytes undergo a programmed differentiation pathway causing the longitudinal growth of the bones, ending in hypertrophy and programmed cell death. Indian hedgehog (IHH) and parathyroid hormone-like hormone (PTHLH) act in a negative feedback loop regulating this differentiation process. Vascular cells enter the center of the cartilaginous template of the bone, and osteoblasts replace the cartilage to form the primary center of ossification.

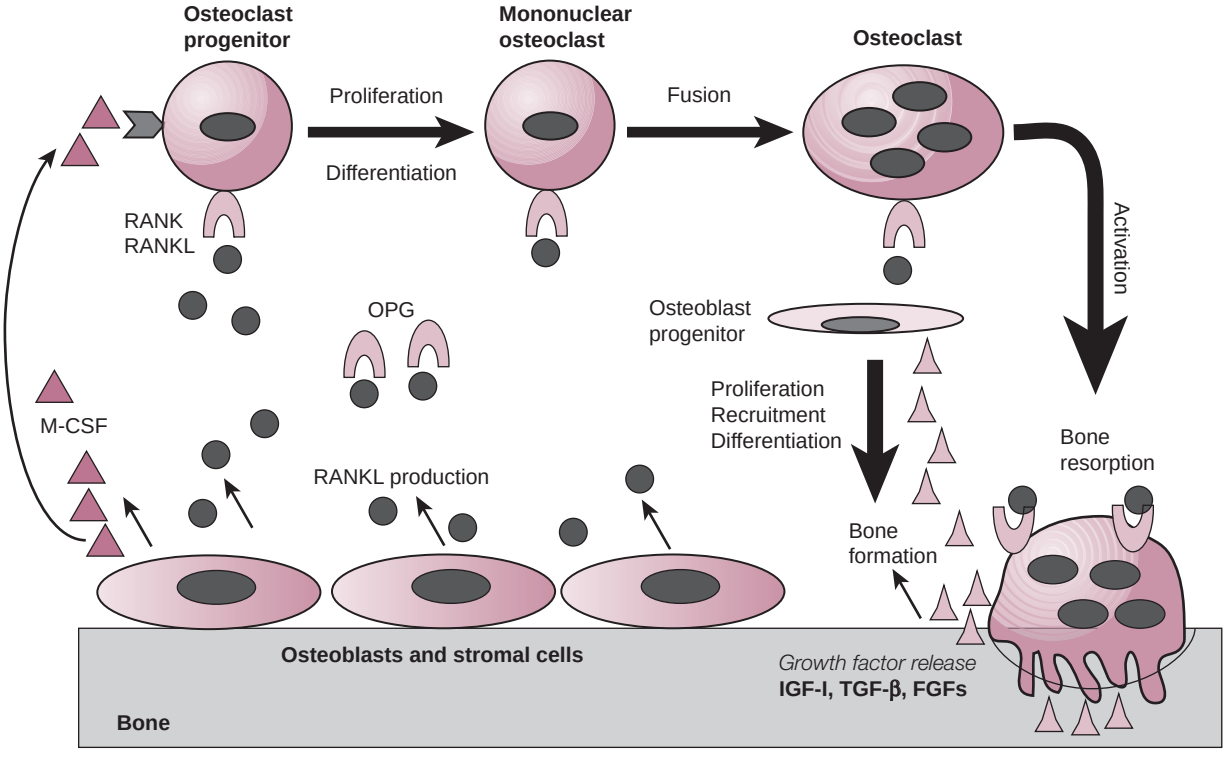

FIGURE 2-2 The linked activities of osteoclast bone resorption and osteoblast bone formation during bone remodeling. Bone-lining cells, osteoblasts, or some marrow stromal cells express RANKL, which activates receptor RANK on osteoclast progenitors of the monocyte–macrophage lineage and stimulates the osteoclast differentiation and activation. M-CSF is another essential factor for osteoclast differentiation. However, decoy receptor osteoprotegerin (OPG) binds RANKL and antagonizes RANK function and thus inhibits osteoclast formation. Activated osteoclasts secrete acid and proteases and erode bone on the surface. During the resorption process, sequestered growth factors, such as IGF-I, TGF-β, and FGFs, are released from the bone matrix and activated, which results in the recruitment, differentiation, and activation of the osteoprogenitors to become osteoblasts to initiate bone matrix synthesis and bone formation.

Bone is constantly remodeled by osteoclasts and osteoblasts. Osteoblasts produce new bone, and start as bone-lining cells with slender cellular processes that make contact with the more mature osteocytes within the mineralized bone. Osteocytes are thought to arise from osteoblasts that have become entrapped during bone formation. Besides the cellular processes that connect osteocytes to one another and to the bone-lining cells, these cells also can sense their mechanical environment. When mechanical stress is higher, they will deposit more bone matrix, whereas if a lack of stress, bone resorption occurs. Osteoclasts are bone-degrading cells that are produced from hematopoietic progenitors. Upon activation, they bind to the surface of the bone and secrete enzymes into the space beneath. The space is acidic and contains proteolytic and bone-degrading enzymes.[34,59,69]

Osteoblast and osteoclast activities are linked during the bone remodeling. Osteoclastic activity releases growth factors, such as insulin growth factor and bone morphogenetic protein (BMP), from the matrix stimulating osteoblastic differentiation. Osteoblast lineage cells produce a protein called receptor activator of NF-κB ligand (or RANKL), which binds its receptor, RANK, on osteoclast precursors, to cause osteoclast activation. Osteoprotegerin (OPG), is a decoy receptor for RANKL, which blocks the binding of RANKL, and thus, inhibits the development of osteoclasts. Modulation of this system has been developed into a pharmacologic agent (Denosumab), which blocks RANK activation and osteoclast-mediated bone resorption[50,93] (Fig. 2-2).

Anatomic Regions of the Child's Bone

Long bones can be divided into epiphysis, physis, metaphysis, and diaphysis.

Epiphysis

The epiphysis is the region of a long bone between the end of the bone and the growth plate (or physis). At birth, the end of the bones is completely cartilaginous (except for the distal femur), and termed a chondroepiphysis. A secondary center of ossification forms at a specific time for each chondroepiphysis, which gradually enlarges until the cartilaginous area has been almost completely replaced by bone at skeletal maturity. The appearance of the ossification centers differs between different bones, and this needs to be taken into account when diagnosing fractures of these regions.[10,57] As the ossification center matures, there is

increased rigidity at the end of the bone, and this increase in rigidity is responsible for changes in the fracture pattern with age. Indeed, injuries that might not result in a fracture in this region in the very young may do so as the skeleton becomes more rigid.

The external surface of the epiphysis is composed of articular cartilage or perichondrium. Muscle fibers, tendons, and ligaments attach to the perichondrium, which also contributes to the centrifugal enlargement of the epiphysis. The perichondrium blends into the periosteum. This perichondrial/periosteal tissue continuity contributes to the biomechanical strength of the epiphyseal/metaphyseal junction at a region that is called the zone of Ranvier.[14,88] Hyaline cartilage below the articular cartilage contributes to the growth of the epiphysis. As skeletal maturity is reached, a tidemark develops at the demarcation between the articular and calcified epiphyseal hyaline cartilage. Articular and hyaline chondrocytes cannot perform each other's functions, and this was demonstrated by studies[61] showing that when a contiguous core of articular and hyaline cartilage is removed, turned 180°, and reinserted, the transposed hyaline cartilage eventually will form bone at the joint surface, whereas the transposed articular cartilage remains cartilaginous and becomes surrounded by the enlarging secondary ossification center. Such a situation in a child will lead to a nonunion.

Physis

The physis, or growth plate, is located between the cartilaginous epiphysis and the newly generated bone in the metaphysis, is responsible for longitudinal bone growth. The perichondrium is a layer of dense connective tissue which surrounds the growth plate. Within the growth plate, chondrocytes undergo differentiation progressing through the resting, proliferation, prehypertrophic, and hypertrophic stages, eventually undergoing programmed cell death. The hypertrophic chondrocytes form columns parallel to the long axis of the bone, and produce type X collagen, which may act as a template for the new bone formation. Adjacent to the region where chondrocytes undergo apoptosis, blood vessels invade the cartilage matrix, presumably bringing in osteoblasts that produce endochondral bone.[14,88,94] Because the epiphyseal cartilage remains radiolucent throughout the early stages of growth, its location is inferred from the metaphyseal contour, which follows the physeal contour.

The blood supply to the growth plate comes from the epiphyseal side. If a segment of the epiphyseal vasculature is compromised, the cartilaginous growth associated with the particular vessels slow. Unaffected regions of the physis continue normal growth; however, growth rates of the cells directly adjacent to the affected area are more compromised than cellular areas farther away. The differential growth results in an angular or longitudinal growth deformity, or both. In contrast, interruption of the metaphyseal circulation has no effect on chondrogenesis, but the transformation of cartilage to bone is blocked, causing widening of the growth plate. Once the disrupted metaphyseal circulation is reestablished, this widened region of the physis is ossified, returning the physis to its normal width (Fig. 2-3).

In the past decade there has been a substantial increase in research into the control of growth plate chondrocyte function. Such work is the first step in developing approaches to modulate

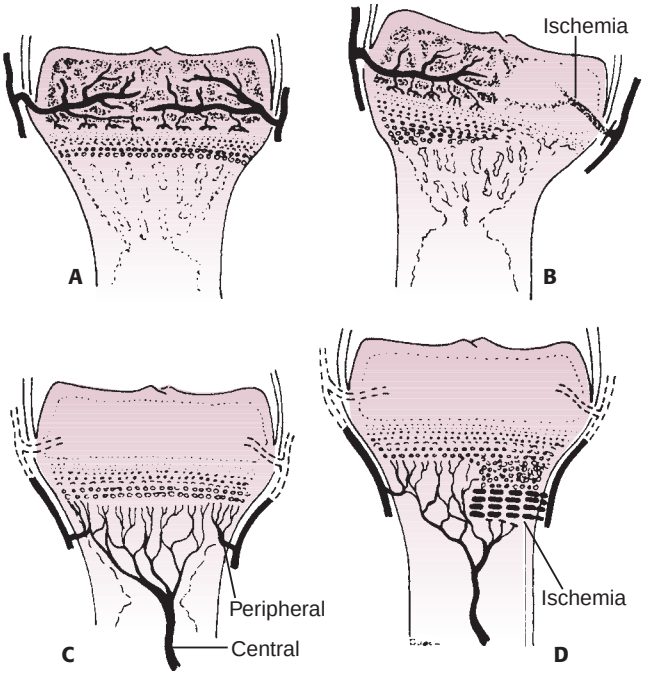

FIGURE 2-3 Patterns of response to ischemia of the growth plate. Response to ischemia of the epiphyseal **(A, B)** versus metaphyseal **(C, D)** circulatory systems. Metaphyseal ischemia is usually transient; epiphyseal ischemia is usually severe and permanent.

growth plate function, such as using a drug, a cell, or a biologic approach. Such treatments could someday be used to treat a partial growth arrest following an injury. Research using genetically modified mice is one approach that has been particularly useful in improving our knowledge about growth plate regulation. This is because mice can be genetically engineered to have particular genes deleted from just chondrocytes, thus providing a robust method to determine the function of a particular gene. Chondrocytes develop from an undifferentiated mesenchymal precursor cell, sometimes called MSCs, which differentiate into a common osteochondroprogenitor cell. The Wnt/β-catenin signaling pathway plays a key role in determining if these cells become osteoblasts or chondrocytes, as in the absence of β-catenin they develop into chondrocytes. Several drugs are available that modulate β-catenin, and these could someday be used to modulate growth plate activity.[37,39,51] Once cells become committed to become growth plate chondrocytes, they undergo a coordinated process of differentiation, with expression of various genes (*SOX9, IHH, PTHrP, RUNX2,* and then *type X Collagen*)[1,40,96] marking the states of differentiation. Resting cells proliferate, then hypertrophy, before undergoing terminal differentiation, where they express *type X Collagen* and become replaced by bone. The resting cells maintain the growth plate cells, and as such these cells located nearest to the epiphysis are critical to normal bone growth, and damage to these cells will permanently disrupt growth.

The hedgehog (Hh) signaling pathway is crucial in the regulation of chondrocyte fate in the growth plate. Prehypertrophic chondrocytes in the growth plate express the Hh ligand Indian Hh (IHH).[11,56,73] IHH serves as a key regulator of endochondral

ossification, acting in a negative feedback look with parathyroid hormone-like hormone (PTHLH), also called parathyroid hormone-related protein (PTHrP). IHH regulates the onset of hypertrophic differentiation by signaling the periarticular chondrocytes to upregulate PTHLH which inhibits the differentiation of proliferating chondrocytes. IHH also regulates chondrocyte differentiation and induces ossification of the perichondrium in a PTHLH-independent manner.[52] The regulation of PTHLH by IHH involves mediators such as BMPs which also play a role initiating the chondrocyte differentiation cascade.[62] In this way IHH and PTHrP act in a feedback loop controlling the pace of growth plate chondrocyte differentiation (Fig. 2-1).

Metaphysis

The metaphysis is the flared portion of the bone at each end of the diaphysis. It has a decreased cortical thickness and increased volume of trabecular bone in the secondary spongiosa. During growth, endochondral modeling centrally and peripherally initially forms the primary spongiosa, which then is remodeled into the more mature secondary spongiosa by osteoclasts and osteoblasts. For this reason, there is considerable bone turnover in the metaphysis compared to other regions of the bone. The metaphyseal cortex is thinner and is more porous than the diaphysis, and there are cortical fenestrations, which contain fibrovascular soft tissue elements that connect the metaphyseal marrow spaces with the subperiosteal region. The metaphyseal region does not develop extensive secondary and tertiary Haversian systems until the late stages of skeletal maturation. These microscopic and anatomic changes correlate with changing fracture patterns, and the ability of bone to deform without breaking in this region is why buckle (or torus) fractures are more likely to occur than complete metaphyseal or epiphyseal/physeal fractures.[46,75,95]

Although the periosteum is attached relatively loosely to the diaphysis, it is firmly fixed to the metaphysis because of the increasingly complex continuity of fibrous tissue through the metaphyseal fenestrations. The periosteum subsequently attaches densely into the peripheral physis, blending into the zone of Ranvier as well as the epiphyseal perichondrium. The zone of Ranvier is a specialized region between bone and cartilage formation, and cells in this zone contribute to growth plate remodeling over time.[14,88] The fenestrated metaphyseal cortex extends to the physis as the thin osseous ring of Lacroix. There are no significant direct muscle attachments to the metaphyseal bone; instead, muscle fibers primarily blend into the periosteum. The medial distal femoral attachment of the adductor muscles is a significant exception. Because of extensive remodeling and insertion of muscle and tendon in this area, the bone often appears irregular and may be misinterpreted as showing chronic trauma.

Growth Lines of Park and Harris

Many bones exhibit transversely oriented, dense trabecular linear bone patterns within the metaphysis. These lines duplicate the contiguous physeal contour, and appear after processes which transiently slow growth or increase mineralization. As such, they are seen after generalized illnesses, treatment with bisphosphonate drugs (which inhibit osteoclasts, and therefore increase mineralization), or after localized processes within the bone, such as infection or growth plate trauma. The lines are called Harris or Park growth slowdown or arrest lines. Once the normal longitudinal growth rate resumes, longitudinal trabecular[2] orientation is restored. The thickened, transversely oriented osseous plate is left behind, and will be gradually remodeled, and with time will disappear[89] (Fig. 2-4).

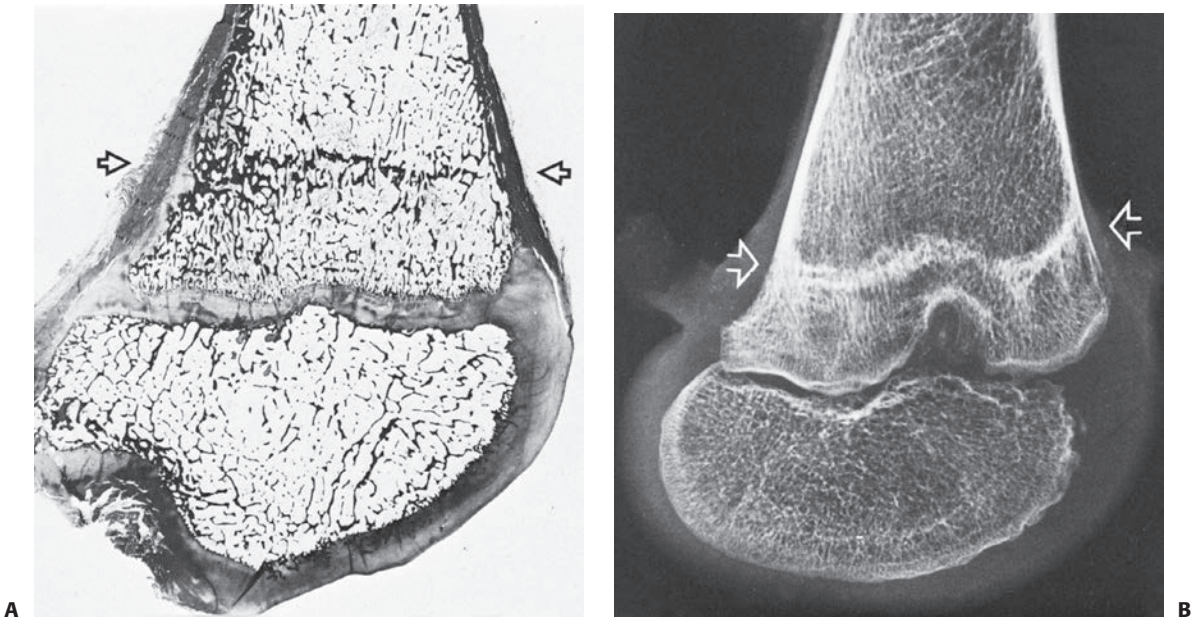

FIGURE 2-4 Growth lines. Histologic section **(A)** and x-ray study **(B)** of a distal femur showing a typical Harris line (*arrows*). This is formed during an acute illness and chemotherapy for leukemia. The child then resumed a more normal pattern of growth until her death from leukemia about 14 months later.

In a systemic problem slowing bone growth, the lines are distributed relatively symmetrically throughout the skeleton, and are thickest in metaphyses from bones that grow most rapidly. In response to administration of bisphosphonate in children (e.g., in the treatment of osteogenesis imperfecta) there are distinct metaphyseal bands in the growing skeleton, whose spacing is determined by the frequency of treatment, age of the patient, and rate of growth. These are sometimes called zebra lines.[2] The lines are important in analyzing the effects of a fracture on growth. They can be measured and the sides compared to corroborate femoral overgrowth after diaphyseal fracture and eccentric overgrowth medially after proximal tibial metaphyseal fracture. A line that converges toward a physis suggests localized growth damage that may result in an osseous bridge and the risk of angular deformity (Fig. 2-5). This radiographic finding is best evaluated roughly 6 months after the injury, and requires an x-ray centered over the physis.[55,72] If a line parallel to, but separate from the growth plate is seen at this time point, the risk of future growth disturbance is very low.

Diaphysis

The diaphysis constitutes the major portion of each long bone, and is formed from bone remodeled from the metaphysis. Mature, lamellar bone is the dominant feature of the diaphyseal bone, and the developing diaphyseal bone is extremely vascular. When analyzed in cross section, the center is much less dense than the maturing bone of older children, adolescents, and adults. Subsequent growth leads to increased complexity of the Haversian (osteonal) systems and the formation of increasing amounts of extracellular matrix, causing a relative decrease in cross-sectional porosity and an increase in hardness. Some bones, such as the tibia, exhibit a decrease in vascularity as the bone matures; this factor affects the rate of healing and risk of nonunion.[13,74] The vascularity of bone is important not only because it bring nutrients to the bone, but also because pericyte cells surrounding blood vessels contribute to new osteoblasts.[7] In addition, hematopoietic progenitor cells exist in the vascular centre of the bone, where bone cells are required to maintain the stem cell population maintaining blood cells.[79]

Periosteum

A child's periosteum is thicker, is more readily elevated from the bone than in adults. It also has a much greater osteogenic potential than that of an adult. Indeed, in young children, one can remove the entire diaphysis of a bone, but leave the periosteum, and the bone will regrow. The thicker and stronger periosteum affects fracture displacement, ease of closed reduction, and the capacity to form new bone. The periosteum is an important internal restraint in closed reductions, where it helps to both obtain and maintain acceptable fracture alignment. The periosteum usually remains intact on the concave (compression) side of an injury. This intact periosteal hinge or sleeve may lessen the extent of displacement of the fracture fragments, and it also can be used to assist in the reduction, because the intact portion contributes to the intrinsic stability. Thus, accentuating the deformity, unlocks the periosteum, helping with the reduction. Because the periosteum allows tissue continuity across the fracture, the subperiosteal new bone that forms quickly bridges the fracture gap and leads to more rapid long-term stability.[3,8]

The periosteum comprises two tissue layers. An outer fibroblast layer provides fibrous attachment to subcutaneous connective tissue, muscles, tendons, and ligaments, whereas the inner cambium layer contains a pool of cells that support bone formation and repair. The periosteum, rather than the bone itself, serves as the origin for muscle fibers along the metaphysis and diaphysis. This mechanism allows coordinated growth of bone and muscle units; something that would be impossible if all the muscle tissues attached directly to the developing bone or cartilage. Exceptions include the attachment of muscle fibers near the linea aspera and into the medial distal femoral metaphysis. The latter pattern of direct metaphyseal osseous attachment may be associated with significant irregularity of cortical and trabecular bones. Radiographs of this area often are misinterpreted as showing a neoplastic, osteomyelitic, or traumatic response, even though this is actually a variation of skeletal development. The periosteum in the growing child also plays a critical role in remodeling, as the tissues in tension over the concave side of a deformity will produce new bone. The bone on the tension, or convex, side of a deformity will be resorbed over time, ultimately resulting in a straight diaphysis.[3,8,42]

Apophysis

An apophysis is composed of fibrocartilage instead of columnar cartilage and grows primarily in response to tensile forces. They are generally attached to muscular structures. With growth secondary ossification centers can form in the apophysis. Because of the differing histologic composition of these structures, they fail differently than other parts of the bone, and excessive tensile stress may avulse the apophysis, especially during the late stages of closure. Such injuries can generate large amounts of new bone, and may be mistaken for tumors, especially around the pelvis. Healing of a displaced fragment to the underlying undisplaced secondary center creates the symptomatic reactive overgrowth, and in the tibial tuberosity apophysis, this is known as an Osgood–Schlatter lesion.[25,60,81]

Composition of Cartilage and Bone

The cartilage matrix is synthesized by chondrocytes, and the main constituents of the cartilaginous matrix are collagens (mainly type II) and proteoglycans. Although collagen provides structural strength, the proteoglycans contribute the ability to respond to resist deformation, and also has regulatory effects on cells. Except for a small percentage of molecules from the circulation and pre-existent matrices that may become entrapped, the bone matrix is almost entirely synthesized by osteoblasts. Bone matrix is a composite material composed of an inorganic (mineral) portion and an organic portion. The composition of living bone is 60% to 70% inorganic components, 5% to 8% water, and the remainder 22% to 35% is organic. The inorganic portion is mainly hydroxyapatite, with some carbonate and acid phosphate groups. It has also been suggested that bone crystals do not contain hydroxyl groups and should be termed apatite rather than hydroxyapatite. The organic portion is composed of collagen type I (90%) and noncollagenous proteins. The noncollagenous protein portion includes a number of proteins and proteoglycans that perform structural and regulatory functions. The composite structure provides physical strength and resilience to fracture. Bone with deficient inorganic mineral content is pliable, and bone with deficient organic content is brittle.[5,43,63]

Proteoglycans are critical components of cartilage and bone, and are present in large amounts within all connective tissues. They have either one or a number of polysaccharide chains linked to a protein core. The polysaccharide's glycosaminoglycan side chains are heparin, heparin sulfate, chondroitin sulfate, dermatan sulfate, or keratan sulfate. The glycosaminoglycans differ in the composition of their constituent disaccharide structures. They can combine with other molecules within the matrix to form macromolecular structures. The proteoglycans present in the physis include large proteoglycans like aggrecan as well as smaller proteoglycans, such as decorin and biglycan. Decorin and biglycan have side chains of dermatan sulfate, and betaglycan has chondroitin and heparin sulfate chains. Fibromodulin has side chains of keratan sulfate. Proteoglycans have not only a structural role but also interaction with growth factors.[82]

Fracture Repair Mechanisms

Fracture healing is a complex regenerative process initiated in response to injury, in which bone can heal by primary or secondary mechanisms. In primary healing, new bone is laid down without any intermediate. This type of healing is rare in a complete bone fracture, except when the fracture is rigidly fixed through certain types of surgery. In the more common secondary healing, immature and disorganized bone forms between the fragments, which is termed the callus.[15,26,61,77] During the fracture repair process, cells progress through stages of differentiation reminiscent of those that cells progress through during normal fetal bone development. In normal development of long bone, undifferentiated mesenchymal cells initially form a template of the bone, which differentiate to chondrocytes. This cartilaginous template is termed the bone's anlage. Following this phase, blood vessels enter the cartilaginous template, and osteoblasts, which differentiate from perivascular and other cells surrounding the bone form bone.

There are, however, several important differences between bone repair, and development. One is that repair does not need to progress through a cartilaginous template. Another is that the liberation of growth factors in the extracellular environment and inflammatory mediators initiates fracture repair, and the activation of these factors does not occur during development. Indeed, this inflammatory initiation of repair processes may be the fundamental difference between development and regeneration. This is one reason that agents that modulate inflammation can affect bone formation. Although some inflammatory pathways can have both positive and negative effects on bone repair, an inhibition of prostaglandin activity inhibits bone formation, and indeed this has been used clinically to prevent bone formation.[12,65,80]

Osseous repair progresses through closely integrated phases. In the *initial* phase of fracture repair, bleeding from the damaged tissues causes a hematoma at the fracture site, stopping blood loss and liberating growth factors and cytokines. Endothelial cells respond by increasing their vascular permeability, allowing leukocytes, monocytes, macrophages, and multipotential mesenchymal cells to reach the fracture site.[70] The blood supply is temporarily disrupted for a few millimeters on either side of the fracture site, producing local necrosis and hypoxia. It is likely that necrosis also results in the release of sequestered growth factors (e.g., BMPs), which promotes differentiation of the surrounding mesenchymal cells into bone-forming cells.[16,20,49,68,87] In the *proliferative* phase, undifferentiated mesenchymal cells aggregate at the site of injury, proliferate, and differentiate presumably in response to growth factors produced by the injured tissues.[15] This process involves both intramembranous and endochondral ossification. Intramembranous ossification involves the formation of bone directly from committed osteoprogenitor cells and undifferentiated mesenchymal cells that reside in the periosteum, resulting in hard callus formation.[84] During endochondral ossification, mesenchymal cells differentiate into chondrocytes, producing cartilaginous matrix, which then undergoes calcification and eventually is replaced by bone. The formation of primary bone is followed by extensive *remodeling* until the damaged skeletal element regains its original shape and size[26,61,84] (Fig. 2-6).

The strength of bone is a function of the intrinsic mechanical properties of the ossified tissue as well as the way the tissue is organized. The moment of inertia is a measure of how the shape of a material changes, how it resists deformation, and is a function of how far the material is placed from the center of the deforming force. If the material is placed further from the center, it will resist deformation as a unit better. An example of this is a plastic ruler, which is shaped like a long thin rectangle. If you try to bend the ruler in its thin axis, it is easy to bend, but if you try to bend it along its thicker axis, it is much harder to bend, even though one bends the same amount of material. It is the shape and how far the material is from the center that make it stronger. When a child's fracture heals, the weaker callous has a larger diameter than the intact bone, but because the weaker material is farther from the center, the moment of

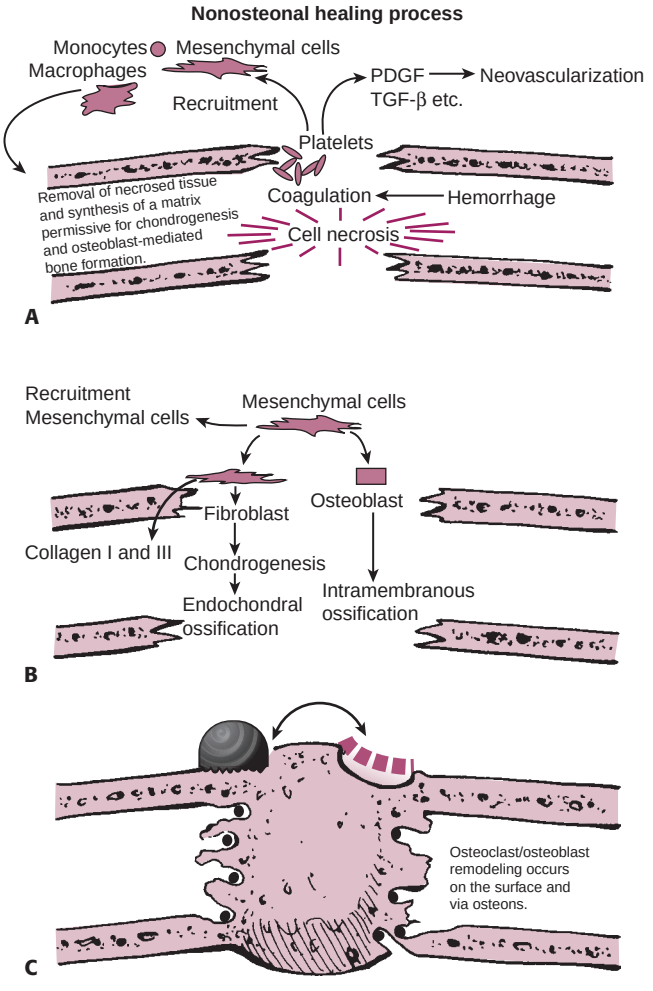

FIGURE 2-6 Phases of fracture repair. The figure demonstrates the three phases of fracture repair **(A)** inflammatory phase, **(B)** reparative phase, and **(C)** remodeling phase. The inflammatory cells remove the debris from the fracture site and, together with the fibroblastic cells, develop the site into a matrix that will support the cells that enable new bone to be formed. The mesenchymal cells are recruited by the release of growth factors in the fracture site. The mesenchymal cells may differentiate into osteoblasts that produce bone in a membranous fashion. Alternately the mesenchymal cell may become chondrogenic and produce bone by the endochondral pathway. Remodeling begins with resorption of mechanically unnecessary, inefficient portions of the callus and the subsequent orientation of trabecular bone along the lines of stress.

inertia is increased, and as a whole unit the bone can be just as strong as if it had not fractured. Children form a larger diameter callous than adults, in part because the stronger periosteum comes off the bone easier and forms a wider barrier to the callous. In addition, during the proliferative phase of fracture repair, children form new bone faster than adults. These factors combine to make children's bone regain its strength much quicker following a fracture than an adult. Furthermore, these factors are responsible for the observation that the younger the child the quicker a fractured bone will regain its strength.

Several cell signaling pathways are normally activated during fracture repair, and many of these are the same ones that are activated during bone development. In the case of one of these signaling pathways, BMP signaling, such studies have already led to improved clinical management. Certain BMPs are liberated early in the repair process, and they stimulate undifferentiated mesenchymal cells to achieve an osteoblastic phenotype. Tibial fractures are a high-risk injury for developing a nonunion and clinical studies show that treatment with select BMPs will improve the rate of healing in this situation.[33] Another pathway that plays an important role in bone repair is β-catenin. There is upregulation of β-catenin during the healing process,[9,17,18] and healing is repressed in mice lacking β-catenin. However, β-catenin functions differently at different stages of fracture repair. In early stages, precise regulation of β-catenin is required for mesenchymal cells to differentiate to either osteoblasts or chondrocytes. Once these cells have become committed to the osteoblast lineage, β-catenin positively regulates osteogenesis.[17] Because drugs are in development that modulate β-catenin, this is an area in which novel therapies may be able to be used to improve delayed repair.[17,19,91]

The various signaling pathways which play a role in bone repair also interact with each other during the repair process. For instance, the inflammatory process activates prostaglandin synthesis, which regulates BMP expression in mesenchymal progenitors.[6] In a similar manner, prostaglandin activity also regulates β-catenin activity.[48] Furthermore, BMP stimulation requires β-catenin to produce bone.[18] Thus, the various signaling pathways involved in bone repair and regeneration do not act alone but in a coordinated manner to allow for bone regeneration.

Physeal Healing

Fractures through the physis heal faster than through the bone, usually within 2 to 4 weeks. This rate of healing is important as manipulation after healing can lead to growth arrest. The physis also has a limited ability to repair, and injury does not always lead to a restoration of normal function. The growth plate heals by increased endochondral bone and cartilage formation, and gradual reinvasion by the disrupted metaphyseal vessels. Depending on the level of injury within the physis, different types of chondroosseous healing may occur. When the fracture occurs through the hypertrophic chondrocytes healing occurs primarily by continued, relatively rapid increases in the number of cells within the columns of hypertrophic chondrocytes, causing moderate widening of the physis. Small epiphyseal vessels, which act to resorb damaged tissues and produce a hyperemic response, will also increase the cellular proliferation rate. This causes an increased rate of bone replacement of the hypertrophic cartilage.[21,95]

The most common level for a physeal fracture is through the transition of hypertrophic cells to primary spongiosa. When this occurs, there is a separation of the tissue and the gap is filled by hemorrhagic and fibroblastic tissues. This region will progressively form disorganized cartilaginous tissue, similar to in the initial phases of repair of fracture through bone. The growth plate continues to proliferate and differentiate on the

epiphyseal side of the callus, leading to widening of the physis. Vascular invasion of the remnants of hypertrophic, calcified cartilage also rapidly occurs on the metaphyseal side of the fracture. However, once metaphyseal vessel invasion reaches the disorganized cartilaginous callus, vascular-mediated bone replacement is temporarily slowed, because there is no pattern of cell columns to invade in an organized fashion. The callus is replaced at different rates, and the invading metaphyseal vessels reach the normal cell columns, which have been maturing in a normal sequence but without osseous replacement. This widened physis is rapidly invaded by the vessels and replaced by primary spongiosa, and normal physeal width is progressively restored.[27,35,66,78]

When the injury extends across all cell layers of the physis, fibrous tissue fills the gap between separated physeal components, whereas typical callus formation occurs in the contiguous metaphyseal spongiosa or epiphyseal ossification center. The reparative response shows irregular healing of the epiphyseal and physeal cartilages, with loss of normal cellular architecture. The gap remains fibrous, but with the potential to ossify. For the fibrous tissue to become replaced with cartilage the germinal and hypertrophic cell regions needs to expand by cell division, maturation, and matrix expansion. The intervening fibrous tissue may disappear through growth, but only if the gap is narrow. Because blood supply is minimal in this region, the fibrous tissue is not well vascularized, and significant cell modulation, especially to osteoblastic tissue, is less likely in the short term. However, the larger the gap filled with fibrous tissue and the longer the time from fracture to skeletal maturity, the greater the likelihood of developing sufficient vascularity to commence an osteoblastic response and to form an osseous bridge. The time for vascularization explains the delayed appearance of the osseous bridge. If accurate anatomic reduction is performed, a thin gap should be present that should fill in with minimal fibrous tissue, allowing progressive replacement of the tissue by the growth of the physis.[27,35,66,78]

Physeal injury can be classified by how the fracture anatomically crosses the growth plate. The Salter–Harris classification is used most frequently. In type I fractures, the fracture line goes through the growth plate; type II fractures go through the metaphysis and the growth plate; type III through the epiphysis and the growth plate; type IV across the growth plate from the metaphysis to the epiphysis; and a type V fracture is a crush of the growth plate. Failure to correct anatomic displacement, especially in Salter–Harris type IV growth mechanism injuries, increases the possibility of apposition of the epiphyseal ossification center and metaphyseal bone, and thereby enhances the risk of forming an osseous bridge between the two regions. When the defect was large enough and the fracture involved the whole width of the physis extending from the metaphysis to the epiphysis, the injured physis will have structural disorganization, formation of vertical septa, and finally formation of a bone bridge. When the bone bridge is large enough, particularly in Salter–Harris types III and IV injuries, the defect will result in a growth arrest. Although growth arrest at the peripheral portions of the physis results in angular deformities, centrally located lesions may cause longitudinal shortening[38,86] (Fig. 2-7).

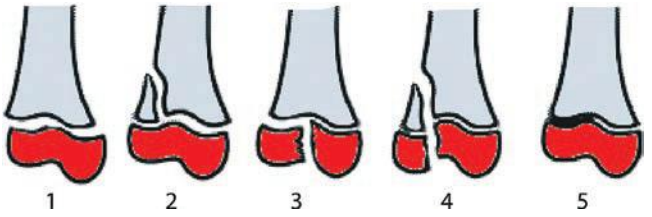

FIGURE 2-7 Salter–Harris classification of physeal fractures. The anatomic region of the fracture through the growth plate is shown, in each type. A higher number is associated with a higher risk of growth arrest.

The risk of growth arrest is a function of the anatomy of the growth plate, the anatomic type of injury (higher Salter–Harris types have an increased rate of growth arrest), and the force of the injury. A large and irregularly shaped growth plate, like the distal femur, takes more energy to fracture than a smaller growth plate, with less irregularity, like the distal radius. Severe damage to the cartilage or an injury that leaves the growth plate unreduced, such as a displaced type II or IV injury, more likely will cause partial or complete arrest. Type IV injures are hardest to keep aligned, as both the epiphyseal and metaphyseal sides of the growth plate are unstable, and thus have a higher chance of partial growth arrest.[47,67]

Remodeling of Bones after a Fracture in Children

In a growing child, the normal process of bone growth and remodeling may realign initially malunited fragments, making anatomic reduction less important than in an adult. Bone and cartilage generally remodel in response to normal stresses of body weight, muscle action, and joint reaction forces, as well as intrinsic control mechanisms such as the periosteum. The potential for spontaneous, complete correction is greater if the child is younger, the fracture site is closer to the physis, and there is relative alignment of the angulation in the normal plane of motion of the joint.[92] This is particularly evident in fractures involving hinge joints such as the knee, ankle, elbow, or wrist, in which corrections are relatively rapid if the angulation is in the normal plane of motion. As an example, the distal radius can correct deformities at a rate of one degree a month.[30,38,54] However, spontaneous correction of angular deformities is unlikely in other directions, such as a cubitus varus deformity following a supracondylar fracture of the humerus. Similarly, rotational deformities usually do not correct spontaneously[75,85] (Fig. 2-8).

Growth Stimulation

Fractures may stimulate longitudinal growth by increasing the blood supply to the metaphysis, physis, and epiphysis, and at least on an experimental basis, by disrupting the periosteum and its physiologic restraint on the rates of longitudinal growth of the physes. Such increased growth may make the bone longer than it would have been without an injury. Eccentric overgrowth may also occur; this is particularly evident in tibia

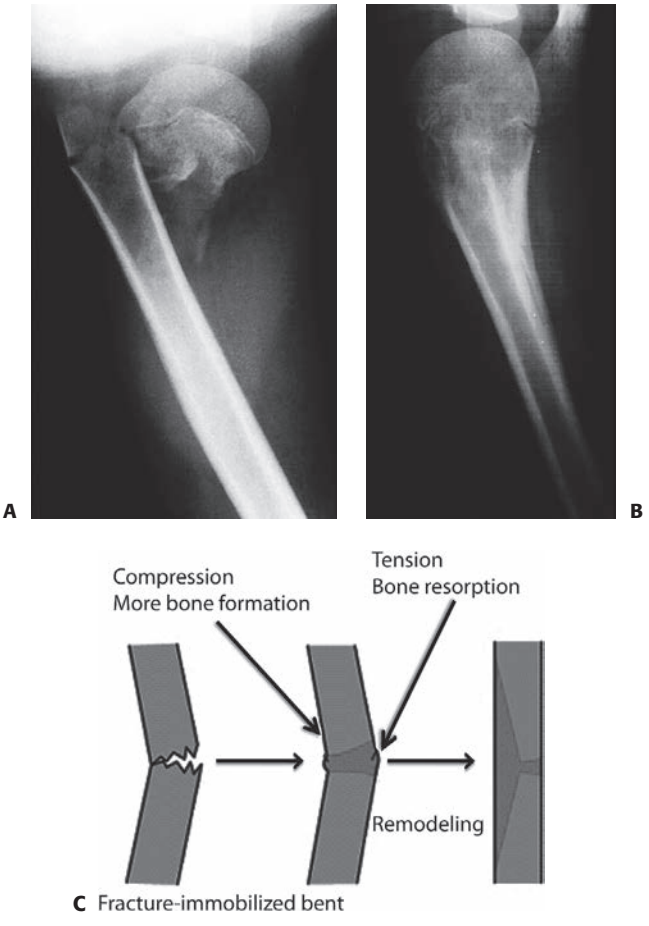

FIGURE 2-8 Remodeling of a fracture. A and **B** show the initial and follow-up radiographs of a proximal humeral fracture, illustrating an impressive degree of remodeling. **C** shows how bone deposition and resorption results in straightening of the deformity over time. Efficient remodeling requires an open growth plate, and as such is a unique feature of childhood injury.

valgum following an incomplete fracture of the proximal tibial metaphysis.[92]

Conclusion

Understanding differences in how bones grow, are anatomically organized, and heal following an injury between children and adults, provides important insights into how to best treat childhood injuries. Knowledge from this chapter provides the basic principles that one can build on to safely treat childhood bone injuries involving any anatomic site in the body.

3 PAIN MANAGEMENT AND PROCEDURAL SEDATION FOR THE INJURED CHILD

Lois K. Lee and Travis H. Matheney

Introduction

Pain management in the pediatric patient presenting with a musculoskeletal injury spans a continuum beginning with the initial presentation, continuing through the fracture treatment, and finally during the postmanagement phase of care. It includes a multimodal approach that can involve both pharmacologic and nonpharmacologic interventions. As the practice has evolved we have seen the inclusion of not just opioid analgesics, but also an increase in the appropriate use of nonsteroidal anti-inflammatories and local and regional anesthetics as well as other nonpharmacologic modalities, such as including the child life specialists as adjuncts to patient care.[71,84,89,106] Working with the patient and family to improve their understanding of the process can improve their expectations and outcomes as well. The objectives of this chapter are to discuss the acute pain management, use of procedural sedation, types of local/regional anesthesia, and postoperative care for children and adolescents with fractures. We will discuss current strategies to assess and treat pain in the pediatric patient presenting to the emergency department (ED) with a fracture. In addition, we will elaborate on the "how to" portion of pain management techniques from initial presentation to the posttreatment period. As always, proper indications for the use of any of these modalities require a thorough understanding of the risks and benefits of each treatment by the orthopedist, emergency medicine specialist, anesthesiologist, and nurses caring for the patient.

Emergency Department Management of Orthopedic Injuries

For children and adolescents, orthopedic fractures are among one of the most painful presenting conditions, and in the ED fracture reduction is one of the most painful procedures performed.[5,63,85] Effective and safe analgesia and sedation are essential for the management of fractures in the ED, as it decreases the child's pain and anxiety and improves patient, parent, and provider satisfaction. Initial analgesia can be provided by oral, intranasal (IN), intramuscular (IM), or intravenous (IV) medications.[5,104] Depending on the type of fracture reduction required, local or regional anesthesia can be applied or procedural sedation can be used.[63,85] Procedural sedation provides anxiolysis, analgesia, and sedation along a continuum while the patient maintains cardiorespiratory function, which enables painful procedures such as fracture reduction to be performed safely and effectively in the ED.

Emergency Department Management of Pain and Anxiety

The assessment and treatment of pain is a Joint Commission mandated priority for children presenting to the ED with potential fractures or other painful musculoskeletal injuries.[110] Several validated pain measurement tools have been developed for children, and they should be used for the initial assessment as well as ongoing evaluation of pain before, during, and after treatment. Pediatric pain scales include the faces pain scales (e.g., Wong–Baker Faces Pain Rating Scales, Faces Pain Scale-Revised) for children 3 to 18 years old,[45,57,112] the visual analog scale (VAS) for children greater than 5 years old,[16,93,114] and the color analog scale for children 6 to 15 years old.[81]

Awareness of the need for initial and ongoing pain assessment and management are important as children with fractures, including angulated fractures or children reporting severe pain, are not routinely treated with pain medications.[19,26,36] Early immobilization, in triage or during the initial assessment, with a splint and/or sling as well as elevation and ice packs are important in the initial pain management.[2] During the physical examination or during radiographic evaluation, manipulation of the injured area can result in movement of the fracture, causing increased pain; therefore, early administration of pain medications is essential for the ongoing management of fracture-related pain.[48] For nondisplaced fractures, oral pain medications may be sufficient (Table 3-11).[48] One strategy is to administer ibuprofen (10 mg/kg) and/or acetaminophen (15 mg/kg), as long as the child has no allergies to these medications, and has not received them in the past 4 to 6 hours.[2,27] If the child continues to have complaints of pain or elevated pain scores after acetaminophen and ibuprofen, oral oxycodone may be administered.[2,5,23] Codeine is a less optimal analgesic as pharmacogenomic data demonstrates up to 50% of individuals may be poor metabolizers who are not able to metabolize codeine to an active analgesic, resulting in suboptimal pain control for these children.[5] Other children may be ultrarapid metabolizers of codeine and are at risk for the side effects of opioid intoxication, including death.[78] Several studies have demonstrated ibuprofen is either equally effective as or more effective than codeine for analgesia, and with fewer side effects.[5,27,37,44]

For displaced fractures or for children reporting higher pain scores, IV, IM, or IN pain medications may be necessary. Fentanyl

TABLE 3-1 ASA Physical Status Classification System

ASA Physical Status 1—A normal healthy patient
ASA Physical Status 2—A patient with mild systemic disease
ASA Physical Status 3—A patient with severe systemic disease
ASA Physical Status 4—A patient with severe systemic disease that is a constant threat to life
ASA Physical Status 5—A moribund patient who is not expected to survive without the operation
ASA Physical Status 6—A declared brain-dead patient whose organs are being removed for donor purposes

may be preferable as the initial narcotic as it is a fast-acting drug with a shorter duration of action compared to morphine, which is slower in onset but has a longer duration.[104] IN fentanyl provides safe and effective analgesia to children with pain when an IV is not available.[105] In addition, subdissociative doses of ketamine at 0.25 to 0.5 mg/kg IV can be administered for analgesia.[104]

Author's Preferred Method of Treatment

In our ED, pain management guidelines begin in triage with immobilization and application of ice packs to the injured extremity. The Wong–Baker Faces Pain Rating Scale is used for children 3 years and older. For a moderate pain score of 4 or higher, both ibuprofen (10 mg/kg) and acetaminophen (15 mg/kg) are given orally. For higher pain scores, IN fentanyl is offered for rapid pain relief and can be given prior to x-ray evaluation. Given the short duration of IN fentanyl, additional pain medications (e.g., ibuprofen, acetaminophen, oxycodone, or IV fentanyl) should be considered, depending on the child's pain level and type of fracture.

Pain Management After Discharge

After ED discharge, children report the highest levels of pain in the first 48 hours after injury and use pain medications for analgesia for up to 3 days after injury.[38] Children with both nondisplaced and displaced fractures requiring ED reduction report clinically meaningful pain after discharge.[111] Caregiver's instructions for pain management after ED discharge should include the use of oral analgesics (e.g., ibuprofen for moderate pain and oxycodone for higher levels of pain) (Table 3-11).[5,23,37,38] Given the risks associated with codeine,[78] our institution has removed this medication from the formulary with a recommendation to use oxycodone instead.

Procedural Sedation for Emergency Department Fracture Reduction

Procedural sedation is defined as the method of administering sedatives or dissociative medications, with or without analgesics, to induce an altered state of consciousness, which allows the patient to tolerate unpleasant procedures while maintaining cardiorespiratory function.[8] Fracture reduction and casting for the majority of displaced and angulated fractures can be safely and successfully achieved in the ED with procedural sedation for analgesia, anxiolysis, amnesia, and sedation.[87] Sedation occurs along a continuum as the drug dose increases and drug levels in the central nervous system (CNS) increase, consciousness decreases, and the risk of cardiorespiratory depression increases. Minimal sedation, or anxiolysis, is a drug-induced state where the patient can still respond normally to verbal commands, but may have cognitive or coordination impairment while maintaining normal cardiorespiratory function. With moderate sedation (previously conscious sedation) patients may respond purposefully to verbal commands, either alone or with tactile stimulation, while maintaining cardiorespiratory function. The next level of sedation is dissociative sedation, which results in profound analgesia and amnesia while the patient is able to retain protective airway reflexes and maintain cardiopulmonary function. With deep sedation patients are not easily aroused, but may respond purposefully with repeated or painful stimulation. This level of sedation may result in impairment of spontaneous ventilation while cardiovascular function is maintained. Finally, with general anesthesia the patient has loss of consciousness with impairment of ventilatory and sometimes cardiovascular function.[69,87]

Personnel

Providers administering procedural sedation must be trained to rapidly identify and treat the most common cardiorespiratory complications of sedation agents (respiratory depression, central and obstructive apnea). They must also be able to perform maneuvers to maintain airway patency and provide assisted ventilation, if necessary. At least two providers are required: one to administer medications and provide airway support and another for monitoring and documentation.[70,87]

Presedation Assessment

To evaluate children for the potential risks of sedation, a presedation assessment should be performed. This assessment should include a directed history (including allergies and history of any prior adverse reactions to sedatives or anesthetics) and a physical examination, with emphasis on the child's airway and cardiopulmonary status.[87] The American Society of Anesthesiologists' (ASA) physical status classification for preoperative risk stratification can be used to stratify risk, with most children undergoing ED procedural sedation being ASA class 1 or 2 (Table 3-1).[69]

Preprocedure Fasting

Concern for pulmonary aspiration of gastric contents is the primary reason for assessment of preprocedure fasting status. Overall, the relative risk of aspiration during ED procedural sedation is rare and is likely much lower than during general anesthesia.[92] A prospective study of 905 children undergoing ED procedural sedation found that 56% were not fasted in accordance with established guidelines, and there was no association between preprocedural fasting and adverse events.[3] For children in the ED, a prolonged fasting period

TABLE 3-2 Normal Values for Heart Rate by Age

Age	Range (beats/min)
Newborn	110–150
1–11 mos	80–150
2 y	85–125
4 y	75–115
6 y	65–110
8 y	60–110

From: Rasch DK, Webster DE. *Clinical Manual of Pediatric Anesthesia.* New York, NY: McGraw-Hill; 1994:16, with permission.

would not allow for a timely fracture reduction to be performed. However, this must be balanced with consideration of a patient's individual risk of aspiration, including recent oral intake, for ensuring safe and effective, as well as timely, procedural sedation.

A consensus-based clinical practice advisory for ED preprocedural fasting outlined the stratification of aspiration risk by assessment of: (1) Potential airway/respiratory complications and systemic disease; (2) timing and nature of recent oral intake; (3) urgency of the procedure; and (4) targeted depth and length of sedation.[53] For a standard risk patient (normal airway, ASA < 3) with no oral intake or only clear liquids in the 3 hours prior to the procedure, all levels of sedation could be performed for fracture reduction. For a standard risk patient with a light snack 3 hours prior to the procedure, dissociative sedation with ketamine, >20 minutes of moderate sedation or <10 minutes deep sedation would be acceptable. If the standard risk patient had a heavier snack or meal in the 3 hours prior to sedation, dissociative sedation or >20-minute moderate sedation would be acceptable.[53]

Monitoring

Continuous close observation and monitoring of the child is crucial throughout the sedation. The child's face, mouth, and chest wall must be observed for respiratory effort. Noninvasive monitoring with continuous pulse oximetry, capnography, and cardiorespiratory monitoring must be maintained during the procedure. Capnography noninvasively measures the concentration of carbon dioxide in exhaled breath, providing continuous monitoring of ventilatory status, including respiratory rate, and provides the earliest indication of respiratory compromise.[52] In young children who can rapidly develop oxygen desaturation because of their smaller functional residual capacity and higher oxygen consumption,[90] early detection of respiratory compromise is critical in preventing more serious complications related to prolonged hypoxia.[69] Vital signs should be recorded before, during, and after the sedation at predetermined intervals, depending on the level of sedation.

Supplemental oxygen (e.g., high-flow oxygen by mask) administered during procedural sedation is recommended to reduce the risk of sedation-associated hypoxia.[7,9,33] Suction, reversal agents, and medications and equipment for advanced airway management must be readily available.[87] The highest risk for complications occurs 5 to 10 minutes after IV drug administration and immediately following the completion of the procedure, when the painful stimuli have concluded.[70] After the procedure is completed, the child should be monitored until he/she has returned to baseline with normal vital signs (Tables 3-2, 3-3, and 3-4) and age-appropriate level of consciousness, and can talk and sit as appropriate for their age (Table 3-5).[69]

TABLE 3-3 Normal Values for Blood Pressure by Age

	Blood Pressure (mm Hg)	
Age	**Systolic**	**Diastolic**
Full-term infant	60 (45)	35
3–10 days	70–75 (50)	40
6 mos	95 (55)	45
4 y	98	57
6 y	110	60
8 y	112	60
12 y	115	65
16 y	120	65

The numbers in parentheses refer to mean arterial blood pressure.

Pharmacologic Agents Used in Pediatric Procedural Sedation and Analgesia

Nitrous Oxide (N_2O)

Nitrous oxide (N_2O) is an odorless gas that provides anxiolysis and mild analgesia while the patient remains awake and is able to follow commands. It can be used for mild to moderately painful procedures as a sole agent or can be used for more painful procedures supplemented with local or regional anesthesia (e.g., hematoma or nerve blocks). Nitrous oxide is dispensed at concentrations between 30% and 70% in combination with oxygen.[104] Because of its rapid diffusion into air-filled cavities, N_2O is contraindicated in a patient with pneumothorax, bowel obstruction, head injury, or pregnancy. Other contraindications for the use of nitrous oxide include cardiac or pulmonary disease. Emesis is the most common adverse effect, reported in up to 10% of patients (Table 3-6).[104]

There is a rapid onset of action (5 minutes to peak effect) and offset (5 minutes) because of its low blood–gas solubility coefficient allowing it to rapidly reach equilibrium in the brain.[104] As a result, fracture reduction can proceed after 5 minutes of N_2O administration. Nitrous oxide and a hematoma block provide anxiolysis, amnesia, and analgesia for fracture reduction, while allowing the older child to be awake and responsive.[56] After the fracture reduction, supplemental oxygen at 100% is administered by face mask for 5 minutes to wash out the nitrous oxide and palliate any diffusional hypoxia.[56,104] A randomized ED comparison of N_2O with a hematoma block to ketamine plus midazolam in 102 children with fracture reduction, after initial oxycodone administration, found similar increases in distress during the reduction in both groups. However, the N_2O/hematoma block group had a significantly shorter recovery time and reported fewer adverse

TABLE 3-4 Calculation of Normal Blood Pressure by Age

80 + (2 × age in years) = normal systolic blood pressure for age

70 + (2 × age in years) = lower limit of normal systolic blood pressure for age

TABLE 3-5 Recommended Discharge Criteria After Sedation

1. Cardiovascular function and airway patency are satisfactory and within normal limits.
2. The patient is easily arousable, and protective reflexes are intact.
3. The patient can talk (if age-appropriate).
4. The patient can sit up unaided (if age-appropriate).
5. For a very young or disabled child incapable of the usually expected responses, the presedation level of responsiveness or a level as close as possible to the normal level for that child should be achieved.
6. The state of hydration is adequate.[a]

[a]Adequate hydration may be achieved with IV fluids. There is no specific requirement that children be able to tolerate oral fluids before discharge from a treatment facility. Children who are nauseated or actively vomiting should be treated and observed until this problem resolves.

From: American Academy of Pediatrics Committee on Drugs. Guidelines for monitoring and management of pediatric patients during and after sedation for diagnostic and therapeutic procedures. *Pediatrics.* 1992;89:110–115, with permission.

effects.[76] Randomized controlled trials of N_2O compared to other sedation regimens for ED fracture reduction are limited;[85] therefore, the specific use of N_2O, with or without a hematoma block, should be based on the skill and training of the treating providers as well as the individual patient and fracture type.

Author's Preferred Method of Treatment

When nitrous oxide is used by the authors it is most commonly used with a hematoma block. The authors use this regimen in patients with mild to moderately displaced fractures requiring reduction provided the patient can cooperate with self-administration of N_2O by face mask.

Benzodiazepines and Opioids

When used in combination, benzodiazepines and opioids are another option for fracture reduction, with midazolam and fentanyl being used the most commonly for moderate and deep sedation. When used together these two drugs have a synergistic effect with a higher risk of hypoxia and apnea compared to they

TABLE 3-6 Medications for Analgesia and Procedural Sedation[a]

Medication	Dose	Contraindications	Advantages	Disadvantages
Nitrous Oxide (N_2O)	30–50% N_2O with oxygen by mask	• Pneumothorax • Bowel obstruction • Pregnancy	• Rapid onset • Rapid offset	• Emesis
Midazolam	PO: 0.25–0.5 mg/kg (max dose: 20 mg) IN: 0.2–0.3 mg/kg (max dose: 0.5 mg/kg or 10 mg) IM: 0.05–0.15 (max dose: 10 mg) IV: 0.05–0.1 mg/kg (max dose: 10 mg)	• History of adverse reaction to benzodiazepines	• Reversible with flumazenil (10 µg/kg IV) if necessary • Rapid onset	• No analgesia • Respiratory depression, especially when combined with opioids
Fentanyl	IV: 0.001 mg/kg, may give in increments to a maximum of 0.003 mg/kg IN: 0.0015 mg/kg	• History of adverse reaction to opioids	• Rapid onset • Reversible with nalbuphine (0.1 mg/kg IM or IV) if necessary	• No amnesia • Risk of respiratory depression, especially when combined with benzodiazepines
Ketamine	IM: 4 mg/kg IV: 1–2 mg/kg	• <3 months old • History of psychosis	• Provides sedation, amnesia, analgesia • Rapid onset	• Laryngospasm • Recovery agitation—may be managed with midazolam • Emesis—may be managed with ondansetron • May have prolonged recovery
Propofol[b]	IV: 2 mg/kg (loading dose in infants/young children, followed by bolus of 1 mg/kg) 1 mg/kg (loading dose in older children/teenagers followed by bolus of 0.5 mg/kg)	• Allergies to soy or eggs	• Rapid onset • Rapid offset	• Respiratory depression and apnea common • Pain on injection—pretreat vein with l–2% lidocaine in IV with tourniquet in place • Hypotension

are when used alone. Therefore, careful IV titration with close monitoring for respiratory depression must be exercised when using these agents.[69,77,104]

Midazolam

Midazolam is a short-acting benzodiazepine with anxiolytic, amnestic, sedative, hypnotic, muscle relaxant, and anticonvulsant properties; however, it does not provide analgesia.[69,104] With IV administration, peak effect occurs within 2 to 3 minutes and lasts 45 to 60 minutes. In addition, midazolam can be administered intranasally or buccally in an aerosolized form, without need for IV access.[67,104] Midazolam can also be administered orally, but may result in unreliable clinical effects due to first-pass hepatic metabolism.[104]

Adverse effects of midazolam include mild cardiovascular depression, nausea, vomiting, and paradoxical reactions – which may be manifest by inconsolable crying, combativeness, disorientation, agitation, and restlessness.[63,69] Flumazenil is the benzodiazepine antagonist used to reverse severe respiratory depression and oversedation.[63] The duration of action of flumazenil is shorter (20 to 30 minutes) than that of midazolam, so multiple doses may be required to maintain reversal of benzodiazepine effects.[104]

Fentanyl

IV fentanyl is a rapidly-acting, extremely potent opioid with peak effect at 2 to 3 minutes and a duration of 20 to 60 minutes. It is preferred to morphine for procedural sedation because of its faster onset, shorter recovery time, and lack of histamine release. In infants and young children, more frequent dosing may be required as they have a higher clearance of the drug.[104] As it provides no sedation or anxiolysis at low doses (1 to 2 mcg/kg), fentanyl should be used in combination with a benzodiazepine (e.g., midazolam) for sedation of painful procedures.[69] Adverse effects of fentanyl include nasal pruritus and respiratory depression. Naloxone is an opioid antagonist that reverses opioid effects within 1 to 2 minutes of administration and lasts 20 to 40 minutes.[104]

Ketamine

Ketamine is a rapidly acting dissociative agent, which provides sedation, analgesia, and amnesia, while preserving cardiovascular stability and airway reflexes. This drug is classified as a dissociative as it chemically disconnects the thalamocortical and limbic systems resulting in a dissociation of the CNS to external stimuli, causing a trancelike cataleptic state.[48,63] It has a rapid onset of action (IV: 30 to 60 seconds; intramuscular [IM]: 3 to 5 minutes), with sedative effects lasting 10 to 15 minutes with a single dose and 20 to 30 minutes with multiple doses. Given its rapid onset, ketamine should not be administered until the orthopedist is ready to begin the procedure. The initial dose of IV ketamine should be administered over 30 seconds, as rapid administration can result in transient central apnea.[48] Recovery time is generally 50 to 110 minutes for IV administration and 60 to 140 minutes for IM.[64,80,100,104] Although it may be given IM, the IV route is generally preferred, as recovery is faster and emesis less common. It is associated with nystagmus, diplopia, pupillary dilatation, increased muscle tone, and transient hypertension.[104] Ketamine is contraindicated in children <3 months old because of the increased risk for airway adverse events, and in patients with a history of psychosis. Relative contraindications include: History of airway problems (e.g., tracheal surgery), active pulmonary infection or asthma, cardiovascular disease, any concern for increased intracranial pressure, or a thyroid disorder.[48]

Ketamine does not exhibit a typical dose–response relationship like other sedative and analgesic agents. At lower doses (0.25 to 0.5 mg/kg IV) it causes analgesia and disorientation, but does not result in a dissociative effect. These subdissociative doses can be used for analgesia prior to a procedure or in combination with propofol for painful procedures.[104] To reach a dissociative state, a dosing threshold for ketamine of approximately 1 to 2 mg/kg IV or 4 to 5 mg/kg IM needs to be administered. Additional or higher doses do not deepen the dissociative state and do not affect airway integrity; therefore, additional doses are only needed to maintain the dissociative state over time.[48,69]

Adverse events associated with ketamine are primarily respiratory compromise, emesis, or recovery reactions. A meta-analysis of airway and respiratory events associated with ketamine analyzed 8,282 pediatric ketamine sedations and found that the overall prevalence of airway or respiratory adverse events was 3.9%, including 0.3% with laryngospasm and 0.8% with apnea.[50] A secondary case-control analysis from this larger meta-analysis did not demonstrate any clinical, dosing, or age-related factors associated with an increased risk of laryngospasm.[49] Although laryngospasm may be a rare event, the clinician administering ketamine must be prepared to rapidly identify and manage respiratory complications including performing bag-valve-mask ventilation or tracheal intubation.[48] Another meta-analysis of the same cohort of 8,282 children found the overall prevalence of emesis was 8.4%, any recovery agitation (e.g., agitation, crying hallucinations, and nightmares) 7.6%, and recovery agitation described as severe and/or requiring treatment 1.4%. Early adolescence and IM administration was associated with more ketamine-associated emesis. There was no age relationship or change in risk with coadministered medications and recovery agitation.[51] A clinical practice guideline for ED ketamine sedation supports its use in healthy adults without cardiac disease and recommends treatment of recovery reactions with benzodiazepines.[48] In a study of post-ED discharge outcomes after procedural sedation, 18% of children had emesis, but there was a low prevalence of adverse behavioral events.[82]

The coadministration of prophylactic anticholinergics to decrease hypersalivation and the risk of airway complications is no longer recommended. Similarly, the prophylactic use of benzodiazepines to prevent recovery reactions is also no longer recommended, although they should be available to treat any unpleasant recovery reactions that may occur. In contrast, ondansetron may either be given prophylactically for vomiting (number needed to treat 13),[72] or may be given as needed after nausea/emesis has occurred.[48,104] When considering narcotic pretreatment for pain, one retrospective study of 858 children given ketamine for procedural sedation examined the use of

morphine pretreatment and found no increase in the number of adverse events compared to those children without morphine pretreatment.[118] Pretreatment with morphine before ketamine sedation, however, is associated with a longer recovery time compared to having no narcotic pretreatment.[75]

At dissociative doses ketamine is a very effective agent for ED fracture reduction because of its dissociative effects while preserving airway and cardiopulmonary status.[77] One study of 260 children randomized them to either a combination of fentanyl and midazolam or ketamine and midazolam for ED fracture reduction. The children receiving ketamine and midazolam had lower distress scores and parental ratings of pain and anxiety than children in the fentanyl group, and had fewer respiratory complications. Vomiting was more frequent in those receiving ketamine, and they also had a longer recovery.[64] Another study of 114 children given ketamine either IV or IM for fracture reduction reported that children had minimal or no pain during the reduction, as measured by the orthopedic surgeons using the Children's Hospital of Eastern Ontario Pain Scale (CHEOPS) with high parent satisfaction.[80] When adverse effects between ketamine and fentanyl/midazolam are compared, ketamine is associated with fewer respiratory adverse events, but more vomiting.[91,99]

Propofol/Ketofol

Propofol is an extremely rapidly acting (15 to 30 seconds) sedative with a narrow therapeutic range, and as a result has a higher risk of airway obstruction and central apnea.[63,104] It also has a very short recovery time (5 to 15 minutes) and inherent antiemetic properties.[69] With no analgesic properties, it must be combined with either ketamine (ketofol) or a narcotic for painful procedures. Several studies have reported the safety and efficacy of propofol for painful ED procedures including fracture reduction.[12,47,107] More recently studies have examined the use of ketamine/propofol (ketofol) for fracture reduction and reported effective sedation and analgesia. The most commonly reported adverse effects were respiratory complications, inadequate sedation, or recovery agitation.[10,121] Given the risks of apnea and respiratory depression associated with both of these drugs, providers must be skilled in the administration of the drugs and management of potential adverse reactions when ketamine and/or propofol are used for fracture reduction.

Author's Preferred Method of Treatment

For angulated and displaced fractures requiring manipulation for reduction and casting, the authors prefer the use of IV ketamine, without premedication, as it provides the most effective sedation and analgesia with the least risk of respiratory adverse events.[85] Ketamine sedation must be administered by a clinician who is knowledgeable about the effects and risk of this medication. The provider must also be skilled in the rapid recognition of respiratory complications as well as the capability of advanced airway management including bag-valve-mask ventilation and tracheal intubation, which may be indicated for laryngospasm. Although fentanyl and midazolam may be used for fracture reduction, when compared to the use of ketamine and midazolam for fracture reduction, fentanyl plus midazolam is more likely to be associated with respiratory complications and less effective sedation.[64,85] The use of propofol for procedural sedation is expanding in our ED, but at this time is not routinely being used for fracture reduction.

Perioperative Pain Management

Regional Anesthesia in Children for a Musculoskeletal Injury

The purpose of regional anesthesia is to provide site-specific analgesia, and it can be divided into three categories: Neuraxial, peripheral, and field blocks. Regional anesthetics are often preferred when possible over general anesthetics because of their decreased systemic side effects. Neuraxial blockade is injection of anesthetic agents into the epidural or intrathecal space. As this procedure is typically performed by an anesthesiologist, this chapter will focus on the latter two forms of blockade. As always, any of the described techniques should be performed within the strict comfort level of the treating physician and are not recommended for use without a clear understanding of the relevant anatomy. We will focus on specific techniques to perform procedural regional anesthesia with a "how to" organization. A basic review of local anesthetics will also be included.

Regional and Local Anesthetic Agents

Several effective techniques for local and regional anesthesia have been described in the pediatric population including hematoma, IV regional, and regional nerve blocks. As always, use of these medications requires a thorough understanding of the pharmacokinetics and appropriate dosing of these drugs as well as proficiency in the techniques of administering them safely. Local and regional anesthetic drugs work by blocking the conduction of nerve impulses. At the cellular level they depress sodium ion flux across the nerve cell membrane. This results in the inhibition of the initiation and propagation of action potentials.[108,122] After injection, local anesthetics diffuse toward their intended site of action and also toward nearby vasculature where uptake is determined by the number of capillaries, the local blood flow, and the affinity of the drug for the tissues. Vasoconstrictors such as epinephrine are mixed with local anesthetics to decrease the vascular uptake and prolong the anesthetic effect.

Duration of action for the various local anesthetic medications is also determined in part by the type of regional block performed. For example, single-dose brachial plexus blocks tend to have a far longer duration than single-dose epidural or subarachnoid blocks.[30] Adverse effects in the tissue surrounding injection sites have been described and include erythema, swelling, and rarely, ischemia when injected into tissues supplied by terminal arteries. Adverse systemic effects are caused by high blood levels of local anesthetics and include tinnitus, drowsiness, visual disturbances, muscle twitching, seizures,

respiratory depression, and cardiac arrest. Bupivacaine can be particularly dangerous because it binds with high affinity to myocardial contractile proteins and can cause cardiac arrest.

Equipment

Before placing any anesthetic block it is important to consider ahead of time the equipment and medication that will be required for the procedure. Simple blocks may only require a weight-based dose of the preferred anesthetic agent, needle(s), syringe(s), and a sterile cleaning solution. For blocks that are placed in deeper planes such as the axillary and femoral nerve blocks and IV (Bier) blocks, additional equipment considerations include appropriate electrocardiographic monitoring, airway management equipment, and a double-cuffed tourniquet (Bier block). In addition, medications that should be readily available include IV diazepam to manage seizures and IV lipid to prevent potential cardiovascular collapse induced by accidental intravascular injection of the anesthetic (especially with bupivacaine). Again, a thorough understanding of the appropriate dosing and resuscitation procedures in the event of local anesthetic toxicity is necessary before performing these procedures. The use of nerve stimulators with insulated needles has gained in popularity. Their use as well as the use of ultrasound have dramatically improved efficacy of many regional blocks.

Local Anesthesia Toxicity

At least three types of adverse reactions can occur from local anesthetic agents. Clinically, the most important is systemic toxicity of the CNS and cardiovascular system from a relative overdose into the circulation (Table 3-7). This type of reaction is not a medication allergy, but is a function of having too much medication into the bloodstream. In the presence of a major artery, even a low dose of a local anesthetic can lead to seizure activity. In most cases, however, the severity of systemic toxicity is directly related to the concentration of local anesthetic in the bloodstream.[30] Seizures and cardiac arrest may be the initial manifestations of systemic toxicity in patients who rapidly attain a high serum level of medication.[39,86,94] Agents with greater intrinsic potency, such as bupivacaine and etidocaine, require lower levels for the production of symptoms.[30] Dysrhythmias and cardiovascular toxicity may be especially severe with bupivacaine, and resuscitation of these patients may be prolonged and difficult.[4,30] The prevention and treatment of acute local anesthetic systemic toxicity are outlined in Table 3-8. Although the potential for CNS toxicity may be diminished with barbiturates or benzodiazepines, given either as premedications or during the treatment of convulsions, these measures do not alter the cardiotoxic threshold of local anesthetic agents. With rapid and appropriate treatment, the fatality rate from local anesthetic-related seizures can be greatly decreased.[30] It is essential to stay within accepted dose limits when using any local anesthetic (Table 3-9). To aid in dose calculations, a simple formula for converting percent concentration to milligrams per milliliter is provided in Table 3-10. Local nerve damage and reversible skeletal muscle changes have also been reported from the use of local anesthetics.[30]

TABLE 3-7 Manifestations of Local Anesthetic Toxicity[a]

1. Numbness of the lips and tongue, metallic taste in the mouth
2. Light-headedness
3. Visual and auditory disturbances (double vision and tinnitus)
4. Shivering, muscle twitching, tremors (initial tremors may involve the muscles of the face and distal parts of the extremities)
5. Unconsciousness
6. Convulsions
7. Coma
8. Respiratory arrest
9. Cardiovascular depression and collapse

[a]With gradual increases in plasma concentration, these signs and symptoms may occur in order as listed. With the sudden development of high plasma concentrations of a local anesthetic agent, the first manifestation of toxicity may be a convulsion, respiratory arrest, or cardiovascular collapse. In young children, or in children who are heavily sedated, subjective evidence of impending local anesthetic toxicity (manifestations 1, 2, 3) may be difficult to elicit.

TABLE 3-8 Prevention and Treatment of Acute Local Anesthetic Systemic Toxicity

Preventive Measures

1. Ensure availability of oxygen administration equipment, airway equipment, suction equipment, and medications for treatment of seizures (diazepam or midazolam, thiopental, succinylcholine).
2. Ensure constant verbal contact with patient (for symptoms of toxicity) and monitor cardiovascular signs and oxygen saturation.
3. Personally prepare the dose of local anesthetic and ensure it is within the accepted dosage range.
4. Give the anesthetic slowly, and fractionate the dose.

Treatment

1. Establish a clear airway; suction if required.
2. Give oxygen by face mask. Begin artificial ventilation if necessary.
3. Give diazepam 0.1–0.3 mg/kg IV in incremental doses until convulsions cease. Lorazepam (0.05–0.1 mg/kg) may be used instead, also in increments until convulsions cease.
4. Succinylcholine (1 mg/kg IV) may be used if there is inadequate control of ventilation with the other medications. Artificial ventilation and possibly endotracheal intubation are required after using succinylcholine.
5. Use advanced cardiac life-support measures as necessary to support the cardiovascular system (more likely with local anesthetics of increased potency, such as bupivacaine).

Intravenous Regional Anesthesia

Bier Block

Bier block anesthesia was originally described in 1908 by August Bier who used IV cocaine to obtain analgesia.[15,17,60]

TABLE 3-9 Maximal Recommended Doses of Commonly Used Local Anesthetics in Children

Agent	Injection Dose (mg/kg)	
	Plain	With Epinephrine[a]
Lidocaine[b] (Xylocaine)	5	7
Bupivacaine[c] (Marcaine, Sensorcaine)	2.5	3
Mepivacaine (Carbocaine)	4	7
Prilocaine[d]	5.5	8.5

[a]The addition of epinephrine (vasoconstrictor) reduces the rate of local anesthetic absorption into the bloodstream, permitting use of a higher dose.

[b]For IV regional anesthesia (Bier blocks), the maximal lidocaine dose is 3 mg/kg. Preservative-free lidocaine without epinephrine should be used for either Bier blocks or hematoma blocks.

[c]Owing to its cardiotoxicity, bupivacaine should never be used for IV regional anesthesia or for hematoma blocks.

[d]Of the amide local anesthetics, prilocaine is the least likely to produce CNS and cardiovascular toxicity. However, a by-product of prilocaine metabolism may lead to severe methemoglobinemia in young children. Prilocaine is, therefore, contraindicated in children younger than 6 mos old.

TABLE 3-10 Conversion Formula from Percent Concentration to Milligrams/Milliliter

Percentage concentration × 10 × Number of mg/mL

Examples: 0.25% bupivacaine has 2.5-mg bupivacaine/mL; 2% lidocaine has 20-mg lidocaine/mL

Decreasing the percent concentration of anesthetic (as is done in the mini-dose Bier block technique) permits the infusion of a larger volume (mL) of drug with lower risk of systemic toxicity because the total amount (mg) of lidocaine is lower.

Although it declined in popularity as brachial plexus blocks were developed, it was revived in 1963, when its safe and successful use for the reduction of forearm fractures in adults was reported.[58] Subsequently, a number of studies have described the effective use of this technique of anesthesia for the treatment of upper extremity fractures in children in an ambulatory setting.[11,15,17,21,74] The block has also been described for use in lower extremity fractures, but is less commonly utilized for this indication.[74]

The technique for administering the Bier block in the upper extremity involves placement of a deflated pneumatic cuff above the elbow of the injured extremity. Holmes[58] introduced the concept of two cuffs in an effort to minimize tourniquet discomfort with prolonged inflation, but the practice has not proven to be necessary for the limited amount of time it takes for fracture reduction in a child.[11,17,29] The tourniquet should be secured with tape to prevent Velcro failure.[88] IV access is established in a vein on the dorsum of the hand of the injured extremity with a 22- or 23-gauge butterfly needle. The arm is exsanguinated by elevating it for 1 to 2 minutes (Fig. 3-1A).

FIGURE 3-1 A–C: Exsanguination with Esmarch bandage **(A),** application of the double-cuff tourniquet **(B),** and intravenous injection of local anesthetic into injured limb **(C).** (From: Military Advanced Regional Anesthesia Handbook, with permission. www.arapmi.org/maraa-book-project.html)

Although exsanguination with a circumferential elastic bandage is described classically, this method can be more painful and difficult to perform in an injured extremity and is no more efficacious than the gravity method.[17,29,54,60] The blood pressure cuff is then rapidly inflated to either 100 mm Hg above systolic blood pressure or between 200 and 250 mm Hg (Fig. 3-1B).[17,29,54,60] The arm is lowered after cuff inflation. Next, lidocaine is administered, the IV catheter removed, and reduction of the fracture performed (Fig. 3-1C). In the traditional technique, the lidocaine dose is 3 to 5 mg/kg[11,29,88] and, in the "mini-dose" technique, 1 to 1.5 mg/kg.[17,54,60]

The tourniquet is kept inflated until the fracture is immobilized and radiographs are obtained, in case repeat manipulation is necessary. In any event, the tourniquet should remain inflated for at least 20 minutes to permit the lidocaine to diffuse and become adequately fixed to the tissues, thus minimizing the risk of systemic toxicity.[88,115] The blood pressure cuff may be deflated in either a single stage or graduated fashion, although single stage release has proven to be clinically safe and technically easier.[42,60,88] During the entire procedure, basic respiratory monitoring is required, and cardiac monitoring is also suggested because of the potential cardiac toxicity. Routine IV access in the uninjured extremity is highly recommended because of the potential for cardiac effects, but is not required.[11,54] Patients should be observed for at least 30 minutes following cuff deflation for any adverse systemic reactions. Motor and sensory function typically returns during this period, allowing assessment of neurovascular status of the injured extremity prior to discharge.[115]

The literature within the past decade certainly speaks to the effectiveness of the traditional Bier block, utilizing a lidocaine dose of 3 to 5 mg/kg, in managing forearm fractures in children. Four large series with a total of 895 patients undergoing this technique demonstrated satisfactory anesthesia and successful fracture reduction in over 90% of cases.[11,29,88,113] The most common adverse effect of the procedure in these studies was tourniquet pain in about 6% of patients.[29,113] One patient experienced transient dizziness and circumoral paresthesias.[113] One patient developed persistent myoclonic twitching following tourniquet deflation and was hospitalized for observation.[88]

Despite the efficacy and relatively low number of complications with the "traditional" Bier block (lidocaine, 3 to 5 mg/kg), concerns and anecdotal reports of systemic lidocaine toxicity (i.e., seizures, hypotension, tachycardia, arrhythmias) have prompted the development of a "mini-dose" (lidocaine, 1 to 1.5 mg/kg) technique of Bier block anesthesia.[17,42,60] Reports by Farrell et al.[42] and Bolte et al.[17] utilizing a lidocaine dose of 1.5 mg/kg and by Juliano et al.[60] using a dose of 1 mg/kg in a total of 218 patients have shown the mini-dose Bier block to be effective in achieving adequate anesthesia in 94% of children studied. Although the exact mechanism of action is uncertain, the primary site of action of the Bier block is thought to be the small peripheral nerve branches. At this anatomic level, blockade is better achieved with a larger volume of anesthetic that can be distributed more completely to the peripheral nerve receptors. It appears to be the quantity (i.e., volume) and not the dose of anesthetic that predicates success of the block. For any given dose of lidocaine, diluting the concentration permits the administration of a larger volume of fluid (Table 3-4). This mechanism explains the success of the mini-dose technique. In the series by Juliano et al.[60] forearm fracture reduction was pain free in 43 of 44 patients (98%) following Bier block performed with a very dilute lidocaine solution (0.125%) and a relatively small total dose (1 mg/kg).

Bier block anesthesia, using either the traditional or mini-dose technique has several advantages. First, the technique is fairly easy to administer. Also the onset of action of the block is relatively fast (<10 minutes), but also of relatively short duration, which allows for the assessment of neurovascular function in the extremity after fracture reduction and immobilization. However, rapid recovery may also be considered a disadvantage as the analgesic effect of the local anesthetic is lost once the tourniquet is deflated. A recent report in adults examined the addition of the nonsteroidal anti-inflammatory drug (NSAID) ketorolac to the local anesthetic solution and found that patients did obtain prolonged analgesia after the tourniquet was released.[97] An empty stomach is not required. However, no pediatric studies have been performed on this technique.

Tourniquet discomfort is the most common adverse side effect. Inadvertent cuff deflation with loss of analgesia or systemic toxicity is a potentially significant problem. Compartment syndrome has also been reported. Technically, placing the tourniquet and obtaining IV access in the injured extremity can be a challenge in the uncooperative child, and application of the splint or cast can be cumbersome with the tourniquet in place. IV regional anesthesia is unsuitable for lesions above the elbow.[58] This technique is contraindicated in patients with underlying heart block, known hypersensitivity to local anesthetic agents, and seizure disorders. Although not completely contraindicated, caution is urged when using this technique in patients with underlying hemoglobinopathies such as sickle cell disease.

Author's Preferred Treatment

The basic steps involved in performing an Bier block are as follows:

1. Confirm the immediate availability of a functioning positive-pressure oxygen delivery system, as well as appropriate airway management equipment. Also, confirm the immediate availability of medications for the treatment of anesthetic-induced convulsions (Table 3-8). Personnel familiar with administration of rescue medications and emergency airway management should also be available.
2. Place an IV in the contralateral, uninjured, arm. A patent IV line is of paramount importance in treating the complications of this block. Obtain a baseline set of vital signs, including heart rate, respiratory rate, oxygen saturation, and blood pressure. Pulse oximetry as well as cardiorespiratory status should be monitored continuously.
3. Select an appropriate tourniquet. An orthopedic tourniquet that can be fastened securely should be used. Because Velcro may become less adhesive with time, check the tenacity of the tourniquet before use. As an added safety

measure, the tourniquet may be covered with strong adhesive tape or an elastic bandage after application. The tourniquet should fully encircle the arm and overlap back on itself by at least 6 cm. The arm may be minimally padded with cast padding underneath the tourniquet.[17] If a pneumatic tourniquet is used, the provider must be familiar with the location of the tourniquet pressure gauge and valves, because these features vary in location from model to model.[29] Narrow-cuffed double tourniquets may not effectively occlude arterial flow, and their use has been discouraged.[58] Tourniquet discomfort should not be a problem during short procedures, but if this develops, a second tourniquet can be applied distally over the anesthetized area of the arm.

4. Palpate the radial pulse of the injured limb.
5. Place and secure a short 22-gauge cannula or 23-gauge butterfly needle in a vein on the dorsum of the hand of the fractured limb. IV catheters can be secured more readily. If a distal vein is unavailable, a proximal vein or even an antecubital vein can be used, but may result in a less effective block.[58]
6. With the tourniquet deflated, exsanguinate the limb by vertically elevating it above the level of the heart for 60 seconds.
7. Rapidly inflate the tourniquet to a pressure of 225 to 250 mm Hg or 150 mm Hg above the patient's systolic blood pressure.[43] Check for disappearance of the radial pulse. Cross-clamping the tubing of the cuff after inflation is discouraged because it might prevent detection of a small leak.[58] Constant observation of the cuff pressure gauge is recommended.
8. Lower the extremity and slowly inject the local anesthetic. This injection should be done over a period of 60 seconds. A concentration of 0.125% to 0.5% plain lidocaine (1.25 to 5 mg/mL) is used. Bupivacaine is contraindicated for this block because of its cardiotoxicity. To prevent thrombophlebitis, the local anesthetic solution must be free of any additives or preservatives.[31] In different studies, the recommended dose of lidocaine has varied from 1.5 to 3 mg/kg.[11,17,29,42,88,113] A dose of 1.5 mg/kg appears to be safe and effective and may be associated with a decreased rate of complications.[17] One study has recommended a maximal lidocaine dose of 100 mg for this block.[42] The skin of the extremity becomes mottled as the drug is injected. The patient, unless he or she is very sedated, and the parents, if they are watching, should be warned that the extremity will look and feel strange. Analgesia and muscle relaxation develop within 5 minutes of injection.[58] For fractures at the wrist, placement of a regular Penrose drain tourniquet around the distal forearm may improve distribution of the local anesthetic solution at the fracture site.
9. To improve analgesia for fracture reduction, the last 2 mL of local anesthetic solution may be injected directly into the fracture hematoma. The technique of local infiltration anesthesia, or hematoma block, is discussed later in this chapter.
10. Reduce the fracture and apply the cast or splint.
11. Leave the cuff inflated for at least 15 minutes, even if the surgical procedure takes less time to prevent significant entry of local anesthetic into the general circulation.[58]
12. Monitor the patient closely for at least 15 minutes for any complications related to the block. The treatment of local anesthetic-induced systemic toxicity has been discussed (Table 3-8).
13. Depending on whatever sedation has been administered, the patient should be monitored until discharge criteria are met (Table 3-5). An assistant must be present to watch the patient, the tourniquet, and the monitors at all times.

Regional Nerve Blockade of the Upper Extremity

Regional nerve blockade can be administered at several levels of the upper extremity from the axilla to individual digits. In the following section, various nerve blocks will be described based upon anatomic level.

Axillary Block

The axillary block is the most common method to anesthetize the majority of the brachial plexus. This can be used for procedures at, or below the elbow. The only sensory nerve not reliably anesthetized with an axillary nerve block is the musculocutaneous nerve, from which the anterolateral cutaneous nerve of the forearm arises. Therefore, achieving a complete block of the forearm may require an additional, separate injection to anesthetize this nerve (see *musculocutaneous nerve block* below). A single infraclavicular injection could be utilized to obtain the same result, but usually requires ultrasound guidance. As there are easily palpable landmarks for an axillary block, this block can be performed without ultrasound.

Potential complications of an axillary nerve block include systemic lidocaine toxicity, hematoma formation, and persistent neurologic symptoms. During injection for an axillary nerve block, the provider should not continue to inject if they feel any resistance, as this may be a sign that the needle is within the nerve substance. Horner syndrome has also been reported. In actuality, complications of axillary block anesthesia are rare.[120] None were encountered in the series reported by Cramer et al.[31] of 111 children with displaced forearm fractures treated in an ED setting. Contraindications to axillary block anesthesia are the presence of a coagulopathy of any type, a pre-existing neurologic or vascular abnormality of the extremity, axillary lymphadenitis, or an uncooperative or combative patient.

Author's Preferred Treatment

The basic steps involved in performing an axillary block are as follows:

1. The axillary artery is the primary landmark for this block. The child is positioned supine with the injured arm abducted and externally rotated 90 degrees. Procedural

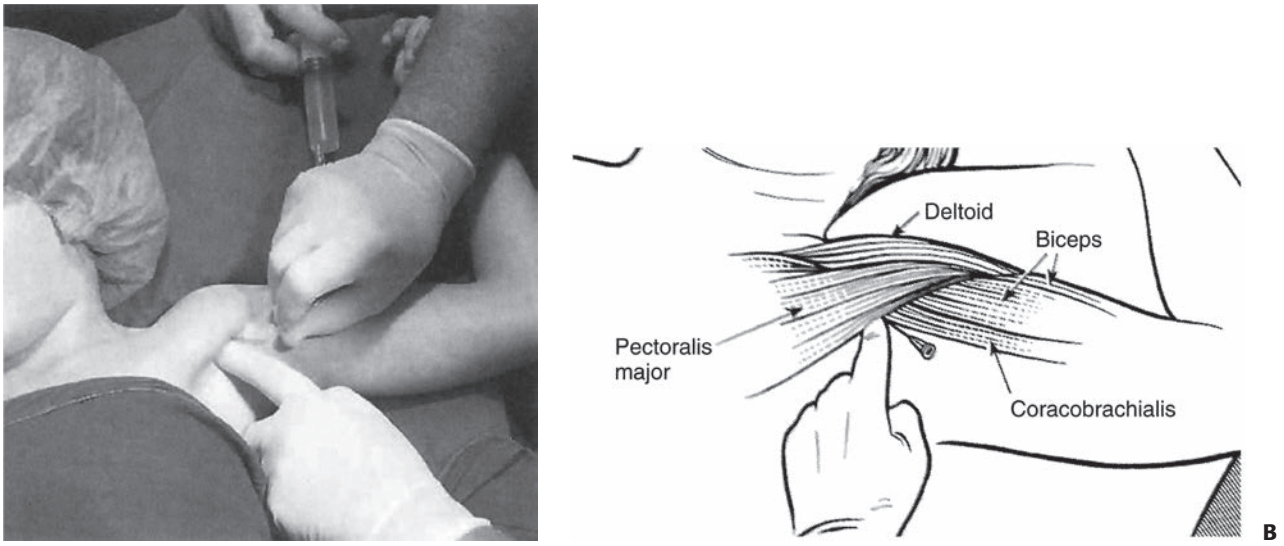

FIGURE 3-2 Technique of needle insertion for axillary block. The axillary artery is palpated and the needle is inserted at the lateral edge of the pectoralis major and parallel to the coracobrachialis. This is illustrated here by the clinical photograph **(A)** and drawing **(B)** of the left axilla. The patient's arm is abducted and externally rotated. The needle is seen inserted just lateral to the index finger of the person performing the block. (Adapted from: McCarty EC, Mencio GA. Anesthesia and analgesia for the ambulatory management of children's fractures. In: Green NE, Swiontkowski MF, eds. *Skeletal Trauma in Children*. 3rd ed. Philadelphia, PA: Saunders; 2003.)

sedation may be required for block placement in children.

2. The axilla is prepped with a bactericidal solution and draped with sterile towels.
3. The axillary artery is palpated in the axillary fossa and trapped between the index and long fingers against the humerus. If difficult to find, asking the patient to gently adduct the arm against resistance highlights the groove between the coracobrachialis and the pectoralis muscle where the artery can be located (Fig. 3-2).
4. A 1% lidocaine solution at a dose of 3 to 5 mg/kg is used for injection. The target for delivery of the anesthetic agent is the axillary sheath, which contains the axillary artery and vein surrounded by the radial nerve (posterior), median nerve (anterolateral), and ulnar nerve (medial). The musculocutaneous nerve courses outside of this sheath through the coracobrachialis muscle on its way to run between the biceps and the brachialis, and therefore, may escape blockade. Proper placement of the needle can be confirmed by several methods. If available, *ultrasound and/or nerve stimulator can be very helpful in placement.* If a nerve stimulator is available, it is attached to a 22-to 25-gauge insulated needle, set to 1 mA current, and the needle is inserted in line with the artery at a 45-degree angle until one of the three things happen: Blood returns, paresthesias are noted by patient, or distal muscle twitches are elicited. If local muscles are stimulated you need to back out and redirect as you have penetrated nearby muscles and will miss the desired nerves. Following this, the stimulator is switched off, and a weight-based dose of anesthetic is injected, stopping every 5 mL to aspirate to check for intravascular needle migration.
5. Alternatively, the *transarterial method* of axillary block has also been shown to be efficacious in a pediatric population.[31] It has the benefit of not requiring a nerve stimulator or ultrasound to localize the nerves.
6. Similar to the above description, the axillary artery is palpated in the axillary fossa between the index and long fingers in line with the upper arm.
7. A 25-gauge butterfly needle attached to tubing and a syringe with the desired amount of injectable anesthetic preloaded is inserted perpendicularly to the skin and artery.
8. The needle is advanced while being continuously aspirated until a flash of arterial blood is seen, and then it is advanced through the artery. In an effort to maximize the spread of anesthetic into all areas around the artery, approximately two-thirds of the lidocaine is injected into the sheath deep to the artery, checking by aspiration after every 5 cc to ensure extravascular positioning.
9. The needle is then withdrawn to the superficial side of the artery and the remaining lidocaine is injected.
10. Pressure is held over the puncture site for 5 minutes to reduce the chance of hematoma formation.
11. Onset time, duration, and completeness of anesthesia will depend on type of anesthetic and how close the injection was to the radial, median, ulnar, and musculocutaneous nerves.
12. If there is incomplete anesthesia of the volar lateral forearm a supplemental injection can be performed at the elbow as described below.

In most children, the axillary sheath is superficial because of the dearth of subcutaneous fat, which makes this a technically easier procedure in a child than in an adult. Of course, this advantage can be offset if the child is obese or uncooperative. For this reason IV midazolam may assist in administration of this block in a child by providing better tolerance of the procedure.

Nerve Blocks About the Elbow

Blockade at either the elbow or wrist anesthetizes the peripheral branches of the brachial plexus supplying the hand. Although a more proximal blockade (e.g., the axillary block) can serve the same purpose, the more peripheral alternatives are available if infection impedes access to the brachial plexus, the patient suffers from coagulation abnormalities, bilateral surgery is indicated, the patient has a difficult anatomy, or if blockade of the brachial plexus requires further supplementation.

Ultrasound imaging has diminished emphasis on other means of approximating the location of nerves (e.g., surface anatomy, nerve stimulation, and elicitation of paresthesias). The description to follow, however, is intended to guide the user in performing elbow and wrist blocks in the event that ultrasound imaging is unavailable.

Author's Preferred Treatment

The basic steps involved in performing blockade of the median, radial, musculocutaneous, and ulnar nerves *at the elbow* are as follows and a drawing of the basic nerve location about the elbow are shown in Figure 3-3.

Median Nerve

1. A line is drawn connecting the two humeral epicondyles. Medial to the point of intersection of this line and the biceps tendon is the brachial artery. Medial still is the median nerve (Fig. 3-4).
2. A 22- to 25-gauge needle and preloaded syringe with weight-based allowance of anesthetic are inserted in the region of the median nerve.
3. After eliciting nerve stimulation or paresthesias, aspirate first, flush any blood encountered back out, and redirect 2 to 3 mm more medially.
4. Injection of 3 to 5 mL of anesthetic is usually sufficient to obtain complete blockade.

Radial Nerve

1. A line is drawn connecting the two humeral epicondyles (Fig. 3-4).
2. The radial nerve courses over the lateral epicondyle and it can be anesthetized by inserting a needle approximately 2 cm lateral to the intersection between the intercondylar line and biceps tendon.
3. Advance a 22- to 25-gauge needle and preloaded syringe with a weight-based allowance of anesthetic until bone is encountered.
4. A fan-shaped injection of 3 to 5 mL of local anesthetic solution effectively blocks the radial nerve.

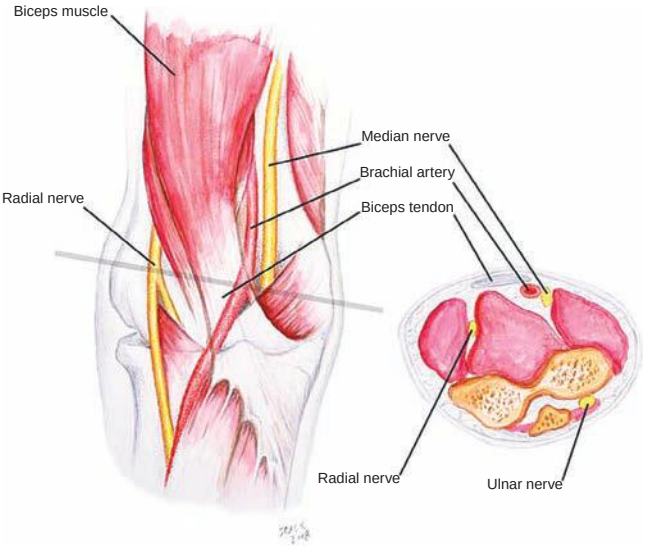

FIGURE 3-3 Illustration of frontal view of right antecubital fossa and cross-sectional view showing the relative location of median, radial, and ulnar nerves. (From: Military Advanced Regional Anesthesia Handbook, with permission. www.arapmi.org/maraa-book-project.html)

Musculocutaneous Nerve

1. A line is drawn connecting the two humeral epicondyles.
2. To anesthetize the musculocutaneous nerve (perhaps as a supplement to the axillary block), the needle should be positioned 1 cm lateral and 1 cm proximal to the intersection between the intercondylar line and biceps tendon.
3. Advance a 22- to 25-gauge needle and preloaded syringe with a weight-based allowance of anesthetic into the subcutaneous tissue.
4. A fan-shaped injection of 3 to 5 mL of local anesthetic solution effectively blocks the musculocutaneous nerve.

The needle and "x" on the median nerve injection site. (From: Military Advanced Regional Anesthesia Handbook, with permission. www.arapmi.org/maraa-book-project.html)

Ulnar Nerve

1. The ulnar nerve traverses the medial epicondyle on the posterior aspect of the elbow. Injection at this location, perhaps as a consequence of insulation by fibrous tissue, carries a higher risk of nerve injury (Fig. 3-5).
2. An alternative injection site is at a point 1 to 2 cm proximal to a line connecting the medial epicondyle and the olecranon.
3. Advance a 22- to 25-gauge needle and preloaded syringe with a weight-based allowance of anesthetic in the superficial subcutaneous tissue only. No paresthesia should be evoked using this approach.
4. A fan-shaped injection of 3 to 5 mL of lidocaine is employed in a fan-like manner.

Nerve Blocks About the Wrist

Radial, median, and ulnar nerve blocks as well as hematoma blocks can also be achieved for hand- and wrist-based anesthetic needs. Based on the location of the planned procedure, the clinician may opt for a nerve block at the wrist.

Author's Preferred Treatment

The basic steps involved in performing blockade of the median, radial, and ulnar nerves *at the wrist* are as follows:

Median Nerve

1. The forearm is supinated and a 22- to 25-gauge needle is inserted roughly 2 cm proximal to the wrist crease, between the flexor carpi radialis and palmaris longus tendons. In patients lacking a palmaris longus tendon, the median nerve is approximately 1 cm ulnar to the flexor carpi radialis tendon (Fig. 3-6).
2. The needle should be inserted vertically and advanced to a depth of roughly 1 cm, until the flexor retinaculum is pierced (indicated by a slight "pop").
3. At this point, 3 to 5 mL of anesthetic may be injected. Begin injecting while the needle is deeply inserted and continue while withdrawing the needle to the surface. Doing the opposite may result in deposition of solution above the retinaculum.

Radial Nerve

1. Because of the branching fibers of the radial nerve, blocking its various projections requires a field block (Fig. 3-7).
2. A 22- to 25-gauge needle is inserted at the base of the first metacarpal, superficial to the extensor pollicis longus tendon and 2 mL of local anesthetic is injected.
3. A similar amount is injected superficial to the extensor pollicis brevis tendon, on the opposite side of the anatomic snuffbox.
4. Smaller injections of 1 mL should be administered over the dorsum of the wrist until the dorsal midline of the wrist is reached.

Ulnar Nerve

1. At the level of the wrist, the ulnar nerve is medial to the ulnar artery and both are radial to the flexor carpi ulnaris (FCU) tendon (Fig. 3-8).
2. A 22- to 25-gauge needle is advanced perpendicular to the long axis of the forearm roughly 6 cm proximal to the wrist crease (this will ensure anesthetization of the nerve before the palmar cutaneous and dorsal radiations branch off) to a depth of approximately 1.5 cm, your goal is to insert the needle tip just deep to the FCU sheath.
3. This approach may elicit paresthesias or a motor/sensory response to nerve stimulation.
4. Aspirate to confirm extravascular placement.
5. When one of these end points is encountered, 4 to 8 mL of local anesthetic solution can be deposited.

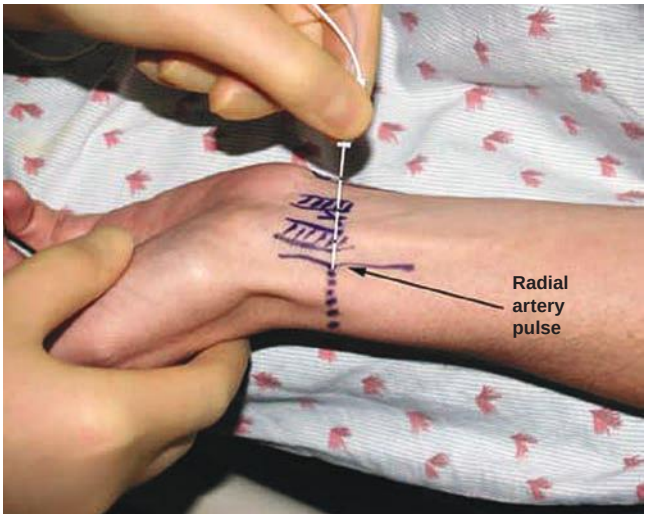

FIGURE 3-7 Picture of the radial aspect of the left wrist. *Solid line* indicates the location of the radial artery. The vertical *dashed line* indicates the area to inject for the field block that will block the sensory branches of the radial nerve. Local Infiltration Anesthesia: Hematoma Block

The hematoma block has been a popular method of anesthesia for the reduction of fractures, particularly in the distal radius, but also for the ankle.[1,6,22,35,59] In this technique, a local anesthetic agent is injected directly into the hematoma surrounding the fracture, the location of which is confirmed by aspirating blood into the syringe. This block is quick and relatively simple to administer. The anesthetic inhibits the generation and conduction of painful impulses primarily in small nonmyelinated nerve fibers in the periosteum and local tissues.[95] Although the medication is rapidly absorbed into the circulation, the resulting systemic blood levels of local anesthetic have been shown to be well below those required for CNS toxicity.[83] Although direct injection of the hematoma theoretically converts a closed fracture into an open one, there have been no reports of infection with this technique.[22] Reported complications with hematoma blocks in the upper extremity include compartment syndrome, temporary paralysis of the anterior interosseous nerve, and acute carpal tunnel syndrome.[68,123] Because of its greater cardiovascular risk profile with intravascular injection, bupivacaine is not recommended for this type of block.

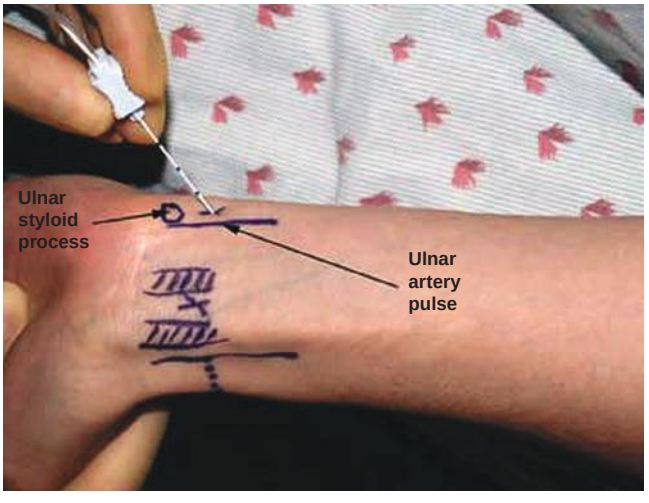

FIGURE 3-8 Picture of the volar aspect of the left wrist. Circle drawn on the skin signifies the ulnar styloid and nearby solid line the ulnar artery. The needle is over the injection site for an ulnar nerve block at the wrist. (From: Military Advanced Regional Anesthesia Handbook, with permission. www.arapmi.org/maraa-book-project.html)

Author's Preferred Treatment

The basic steps involved in performing a hematoma block are as follows:

1. The skin overlying the fracture site is prepped in a sterile manner.
2. A more concentrated solution of plain lidocaine (1 to 3 mg/kg) is recommended to increase efficacy and prevent the need to inject more than 10 mL of solution. This avoids soft tissue and compartment pressures.
3. A 20- or 22-gauge needle with attached syringe preloaded with plain lidocaine is inserted aspirating as it is advanced until fracture hematoma is encountered.
4. Once identified, plain lidocaine is injected to a maximum volume of 10 mL as previously mentioned (Fig. 3-9).

Digital Nerve Blocks

Although brachial plexus anesthesia may be efficacious for any fracture of the upper extremity below the elbow, more distal upper extremity blocks at the wrist or of the digital nerves in the hand may be useful for treatment of fractures or minor surgical procedures of the hand. Anesthesia to the digits can be achieved by block of the common digital nerves near the point of bifurcation at the level of the metacarpal heads or by block of the radial and ulnar digital nerves at the base of each finger. This technique is most useful for treatment of phalangeal fracture(s) of a single digit and soft tissue injuries to the fingertip and nail bed.

The anatomy of the hand consists of four nerves supplying each finger. Two of these run on the volar aspect of each finger and supply the volar surface of that digit; and two are dorsal in location and sensory distribution. The notable exception to this generalization is that the two volar nerves of the middle three fingers also provide sensation to the nail beds of these fingers. Nail beds of the thumb and fifth digit, however, are supplied by the two nerves running on the dorsal surface. This difference in sensory distribution is important when procedures involve the fingertip. In case of the middle three fingers, medicating the two volar nerves will suffice; whereas, in case of the thumb and fifth digit, anesthetizing all four nerves is necessary. The two blocks discussed here are the ring block and the transthecal block. The ring block is performed from a dorsal approach through a single needle stick on both sides of the digit raising

FIGURE 3-9 Picture of a fractured wrist with dorsally displaced distal radius (hand at top of picture). The needle is placed into the fracture site and aspiration performed to confirm injection into the fracture.

a wheal of subcutaneous anesthetic on radial and ulnar aspects of the base of the digit. The transthecal block is performed via single needle stick on the volar aspect of the hand at the level of the metacarpal head.[24] The goal is to inject local anesthetic into the flexor tendon sheath to obtain anesthesia of the entire digit. Anesthetic solutions should not contain epinephrine to avoid causing digital ischemia.

Author's Preferred Treatment

The basic steps involved in performing a digital block are as follows:

Ring Block

1. The ring block begins with the hand in pronation and the skin is prepped in a sterile manner.
2. A 25-gauge needle is positioned from a dorsal approach into the proximal region of the web space, as close as possible to the phalanx in question.
3. Going off to one side of the finger, the nearby dorsal nerve can be anesthetized by raising a small skin wheal using 1 mL of local anesthetic.
4. The needle is then advanced toward the palm until the skin on the palmar surface begins to tent, then the needle is retracted slightly.
5. The palmar branch nearby can be blocked using 1 to 2 mL of solution.
6. The same protocol is repeated to block the corresponding two nerves on the opposite side of the finger.

Transthecal Block

1. The hand is placed in supination and the skin is prepped in a sterile manner.
2. A 25-gauge needle is inserted perpendicular to the skin, directly over the metacarpal head and advanced until bone is encountered.
3. After making contact with bone, the needle is withdrawn slightly, your nondominant index finger is used to apply pressure proximal to the area of injection (to prevent flow into the proximal tendon sheath) and injection begun until the anesthetic flows easily into the flexor tendon sheath.

Regional Nerve Blockade of the Lower Extremity

Regional nerve blockade can be administered at several levels of the lower extremity from the inguinal ligament to individual digits. In the following section, various nerve blocks will be described based upon anatomic level.

Neural supply to the lower extremities is derived from the lumbar plexus, comprising the anterior rami of the L1–L4 spinal nerves, and the sacral plexus, comprising the anterior rami of the S1–S4 spinal nerves. The L2–L4 branches of the lumbar plexus supply the thigh and can be divided into the anterior and posterior branches. The anterior portions of L2–L4 include the obturator nerve, which innervates the medial aspects of the thigh. The posterior branches give rise to the femoral nerve (L2–L4) and the lateral femoral cutaneous nerves (L2–L3), which supply the anterior and lateral parts of the thigh, respectively. Once the femoral nerve passes under the inguinal ligament, it enters the thigh and immediately divides into several branches. Those descending anteriorly provide sensation to the anterior thigh from the inguinal ligament to the knee, whereas branches lying more posterior provide motor function to the extensors of the leg. The saphenous nerve descends into the leg along the medial aspect of the knee with the femoral artery and vein, branching off above the knee to run between the sartorius and gracilis muscles at the medial knee. At this point, the saphenous nerve becomes subcutaneous and forms branches that innervate the medial aspect of the leg and foot.

Both the lumbar and the sacral plexuses contribute to the formation of the sciatic nerve (L4–S3). The ventral branches of L4–S3 comprise that aspect of the sciatic nerve that will become the tibial nerve and dorsal branches form that part that will become the common peroneal nerve. Immediately after originating from the rami mentioned above, the sciatic nerve traverses the greater sciatic foramen (along with the posterior cutaneous nerves, S1–S3), and continues under the piriformis muscle, between the greater trochanter and the ischial tuberosity. At the lower edge of the gluteus maximus muscle, the nerve is at its most superficial point before descending to the popliteal fossa, where it divides into the tibial and common peroneal nerves. The tibial nerve is medial and anterior, whereas the common peroneal lies more posterior and lateral. Along its course, the sciatic nerve innervates the posterior

thigh, as well as all areas below the knee (with the exception of the medial aspect of the foot, which is the domain of the saphenous nerve).

Femoral Nerve Block

Femoral nerve blockade can be used in the treatment of femoral fractures.[14,25,34,98,119] Although the majority of children with femoral fractures are not managed on an outpatient basis, femoral nerve blockade can provide excellent anesthesia and analgesia for the initial management of this injury including manipulation of the fracture, application of an immediate spica cast, or placement of a traction pin. It is a good option for children unable to undergo general anesthesia or procedural sedation. This technique is most effective for fractures of the middle third of the femur. In one randomized control study, regional blockade of the femoral nerve was shown to provide clinically superior pain relief compared with IV morphine sulfate throughout the initial 6 hours of management in children aged 16 months to 15 years with isolated femoral shaft fractures.[119] In the reports of this technique, there have been few inadvertent arterial punctures with no long-term sequelae and no neurologic complications.[34,55,102] Other potential complications include systemic toxicity from intravascular injection, infection, and injury to the nerve. As with the axillary block, this method may be difficult in obese children as well as the young and/or uncooperative child. Contraindications include any pre-existing neurologic abnormality of the injured lower extremity and the inability to manage complications of systemic toxicity.

Author's Preferred Treatment

The basic steps involved in performing a femoral nerve block are as follows:

1. Prepare and drape the inguinal area and palpate the femoral artery.
2. A 22- or 23-gauge needle on a syringe containing an appropriately dosed local anesthetic agent (typically either 1% to 1.5% lidocaine with 1:200,000 epinephrine, dosed up to 7 mg/kg[14] or 0.5% bupivacaine, dosed at 1 to 1.5 mg/kg[102]) is inserted one fingerbreadth lateral to the artery and 1 to 2 cm below the inguinal ligament (Fig. 3-10).
3. The needle is advanced at a 30- to 45-degree angle to the skin and the syringe aspirated as the needle passes through the deep fascia into the femoral triangle. There is occasionally a palpable "pop" when passing this fascial plane (Fig. 3-11).
4. If no blood is aspirated, the anesthetic agent is injected around the femoral nerve.
5. Alternatively, the nerve can be blocked more proximally within the fascia iliaca compartment by entering just above the inguinal ligament with the advantage of accessing all branches of the nerve before it starts to arborize. As with axillary block, the volume of the anesthetic is the key to achieving anesthesia with this technique. The onset of analgesia occurs within 10 minutes and, with the use of long-acting agents such as bupivacaine, may last up to 8 hours.[34]

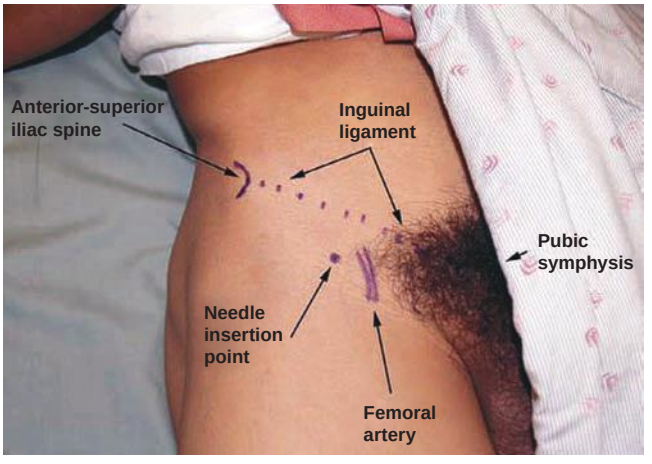

FIGURE 3-10 Picture of the anterior right hip and groin. The *dotted line* signifies the inguinal ligament, large blue dot the injection site for femoral nerve block, and adjacent lines the location of the femoral artery. (From: Military Advanced Regional Anesthesia Handbook, with permission. www.arapmi.org/maraa-book-project.html)

Saphenous Nerve

Blockade of this terminal branch of the femoral nerve is usually combined with a sciatic nerve block for procedures of the leg (distal to the knee) or a popliteal block for procedures involving the foot and ankle.[18,116] It becomes superficial at the level of the knee, runs with the greater saphenous vein, and has many smaller branches as it descends the medial aspect of the lower leg as it heads toward the ankle and foot (Fig. 3-12). For this reason the block should be made as distal as possible while still remaining proximal to the region of interest to maximize block effect.

FIGURE 3-11 Picture of the lateral right hip illustrating the correct angle of needle placement for a femoral nerve block distal to the inguinal ligament. (From: Military Advanced Regional Anesthesia Handbook, with permission. www.arapmi.org/maraa-book-project.html)

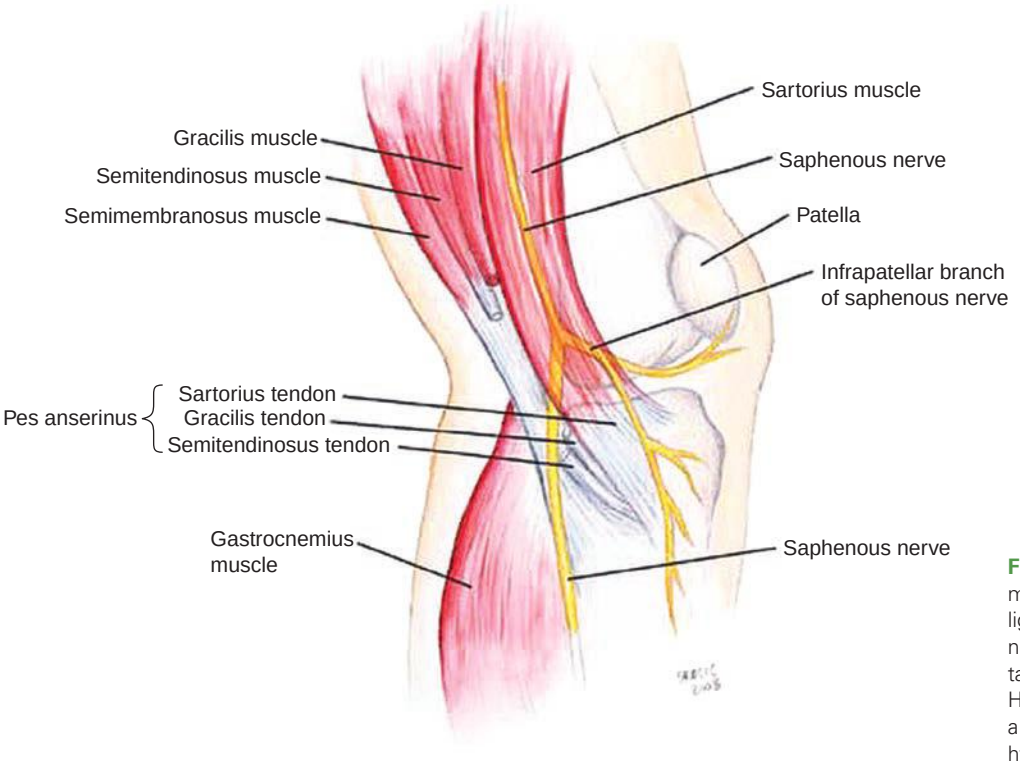

FIGURE 3-12 Illustration of the medial aspect of the knee. Highlighted is the course of the saphenous nerve about the knee. (From: Military Advanced Regional Anesthesia Handbook, with permission. www.arapmi.org/maraa-book-project.html)

Author's Preferred Treatment

The basic steps involved in performing a saphenous nerve block are as follows[18]:

1. The patient is placed supine and the knee may be flexed 45 degrees.
2. The primary landmark is the tibial tuberosity.
3. A 22- to 23-gauge, 1.5-in needle is inserted subcutaneously at 2 cm medial to the superior aspect of the tibial tuberosity in a line parallel to the tibial plateau.
4. Five to 10 mL of 1% lidocaine or 0.25% bupivacaine (for longer duration) with 1:200,000 epinephrine is used to raise a wheal from the starting point to the medial aspect of the knee.

Popliteal Block

The goal of the popliteal block is to localize the sciatic nerve prior to its division into the common peroneal and tibial nerves. This block is indicated in foot and ankle surgery, and is preferred over an ankle block in cases employing a calf tourniquet.[18,74,116] If surgery involves the medial aspect of the foot or if a calf tourniquet is employed, blocking the saphenous nerve is also essential (see above).

The muscular borders of the popliteal fossa are the medial and lateral heads of the gastrocnemius muscles (inferiorly) and the semimembranosus and semitendinosus muscles and biceps femoris muscles (superiorly). In the proximal portion of the fossa, the sciatic nerve is flanked on its medial aspect by the popliteal vein, and anteriorly by the popliteal artery (Fig. 3-13). Within the popliteal fossa the sciatic nerve branches into the common peroneal nerve (lateral) and the tibial nerve (which proceeds through the fossa). Utilization of a nerve stimulator with insulated needle and/or ultrasound can be helpful in locating the best placement of anesthetic. When not available, anatomic landmarks can be utilized. Potential complications include nerve injury from direct injection and intravascular injection.

Author's Preferred Treatment

The basic steps involved in performing a popliteal block are as follows[116]:

1. The popliteal block is commonly performed using a posterior approach.
2. Flexing the knee slightly and placing a rolled towel bolster under the ankle makes the borders of the fossa more evident and frees the foot to allow visible response.
3. The borders of a triangle are drawn with the knee crease as the base, the tendons of the semitendinosus and gracilis as the medial border, and the biceps femoris as the lateral border (Fig. 3-14).
4. A line is drawn from the apex of the triangle and ending perpendicular to the base.
5. Needle placement is approximately 1 cm lateral to the midline, and 7 to 9 cm superior to the base.

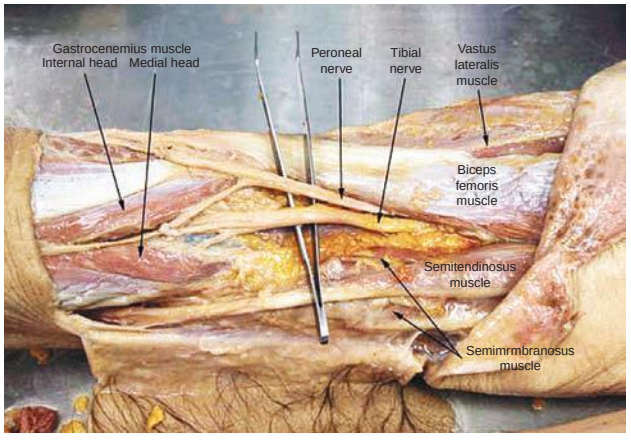

FIGURE 3-13 Cadaveric dissection of the popliteal fossa. The pick-ups are underneath the tibial and peroneal branches of the sciatic nerve after they have separated. (From: Military Advanced Regional Anesthesia Handbook, with permission. www.arapmi.org/maraa-book-project.html)

6. The needle is inserted at a 45-degree angle and advanced anterosuperiorly until paresthesias or nerve stimulator response (foot inversion) is evoked using 0.5 mA.
7. The syringe is aspirated to confirm extravascular placement, and 30 mL of anesthetic is injected. As always, if significant resistance is encountered do not inject as this may be a sign the needle is within the nerve.
8. Ultrasound imaging provides direct visualization of the sciatic nerve bifurcation, eliminating the need for surface landmarks.

Nerve Blocks About the Ankle

There are five peripheral nerves that innervate the foot. A drawing of the ankle in cross section is seen in Figure 3-15 illustrating their general relationships to adjacent structures. The saphenous nerve originates from the femoral nerve and the

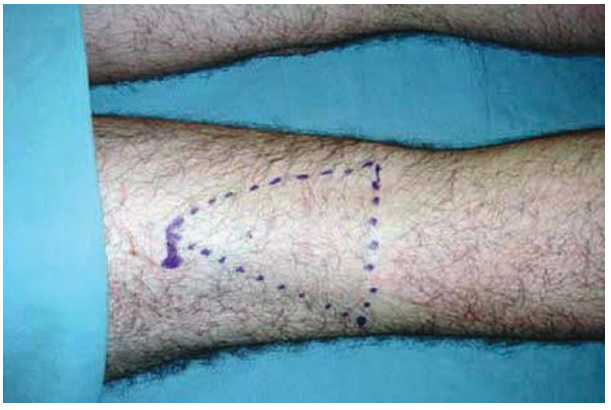

FIGURE 3-14 Photograph of the posterior aspect of the knee (patient's foot is to the left of the photo). The popliteal triangle is illustrated with a *dotted line*. The medial and lateral hamstrings make up the medial and lateral borders. (From: Military Advanced Regional Anesthesia Handbook, with permission. www.arapmi.org/maraa-book-project.html)

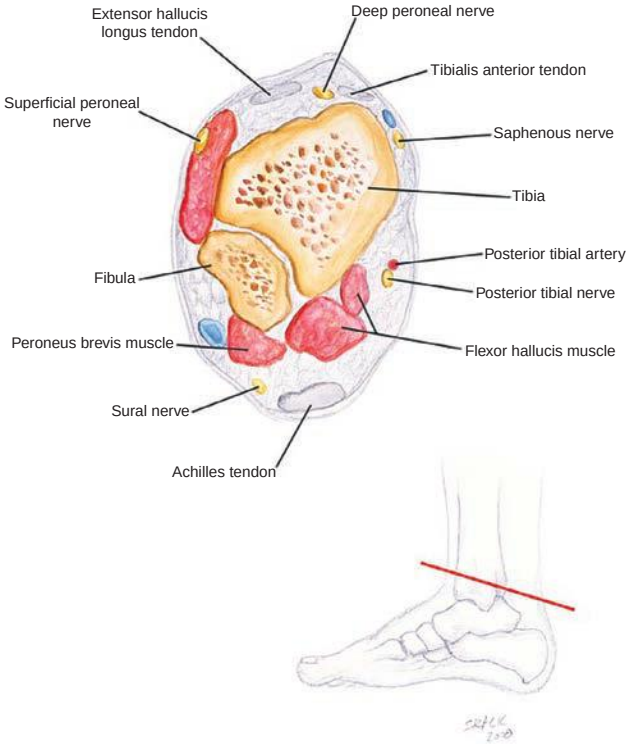

FIGURE 3-15 Illustration depicting the cross-sectional anatomy of the lower leg at the level of the malleoli. (From: Military Advanced Regional Anesthesia Handbook, with permission. www.arapmi.org/maraa-book-project.html)

remainder originates from the sciatic. At or slightly below the head of the fibula, the common peroneal nerve gives rise to its superficial and deep branches that eventually descend to the foot. The tibial nerve produces two of its own branches, the posterior tibial and sural nerves, at or slightly below the tibial midshaft. The two branches traverse the ankle on either side of the Achilles tendon: The sural nerve lies laterally, whereas the posterior tibial is medial. The last of the five nerves, the saphenous nerve, is a terminal branch of the femoral nerve and it supplies the proximal, medial aspect of the foot.[18,73]

The indications for an ankle block include any procedure involving the distal foot. A complete block typically requires at least three injections. It is contraindicated in the presence of infection. The regions of the foot by nerve are the following.

1. Sural: Achilles and posterior heel, plantar heel to midfoot, and midportion of the lateral third of the foot between lateral malleolus and fifth metatarsal head
2. Posterior tibial (medial and lateral plantar branches): Medial and lateral plantar foot distal half of the sole and plantar aspects of toes
3. Saphenous: Medial malleolus and (mixed with superficial peroneal) medial foot and arch
4. Deep peroneal: Dorsal and plantar aspects of first web space and short toe extensors
5. Superficial peroneal: Medial malleolus, dorsum of foot and toes, and (mixed with saphenous) medial arch and foot

Author's Preferred Treatment

The basic steps involved in performing an ankle block are as follows:

Posterior Tibial Nerve

1. With the patient prone, the posterior tibial artery can be palpated (immediately posterior to the medial malleolus) and used as a landmark (Fig. 3-16).
2. The skin is prepped with cleaning solution.
3. Slightly posterior to this artery, at the level of the medial malleolus, a 25-gauge needle may be inserted and advanced toward the medial malleolus.
4. At a depth of 0.5 to 1 cm, paresthesias should be sought by moving the needle from side to side.
5. If paresthesias are successfully evoked, aspiration should be performed to assess for intravascular placement, followed by injection of 3 to 5 mL of anesthetic. If resistance is met then withdraw 1 mm, aspirate, then try injecting once again as your needle tip may be lodged in nerve or tendon.
6. If no paresthesias are elicited, the needle is advanced until it encounters bone, and then withdrawn slightly before depositing 7 to 10 mL of solution.

Sural Nerve

1. The nerve courses between the lateral malleolus and the Achilles tendon, a relative safe zone free from superficial vascular structures.
2. With the patient prone, the skin between the lateral malleolus and Achilles tendon from the level of the malleolus to 2 cm proximal is prepped with cleaning solution (Fig. 3-17).
3. A 25-gauge needle is inserted lateral to the tendon (approximately 1 cm above the lateral malleolus) and advanced toward the malleolus while injecting 5 to 7 mL of anesthetic subcutaneously.

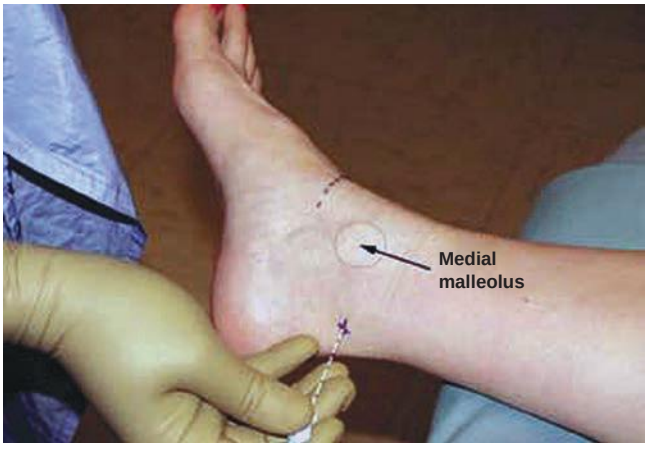

FIGURE 3-16 Photograph of the medial aspect of the ankle. The needle in the inferior portion of the picture depicts the insertion site for block of the posterior tibial nerve. (From: Military Advanced Regional Anesthesia Handbook, with permission. www.arapmi.org/maraa-book-project.html)

FIGURE 3-17 Photograph of the lateral aspect of the ankle. The needle in the inferior portion of the picture depicts the insertion site for block of the posterior sural nerve. (From: Military Advanced Regional Anesthesia Handbook, with permission. www.arapmi.org/maraa-book-project.html)

Peroneal and Saphenous Nerves

1. To block the two peroneal nerves, as well as the saphenous nerve through the same needle-entry point, a line should first be drawn connecting the two malleoli on the dorsal aspect of the foot.
2. The skin along this anterior ankle line is prepped with cleaning solution between malleoli.
3. Next, the anterior tibial artery is identified by palpating the area between the extensor hallucis longus tendon (which is evident on dorsiflexion of the first toe) and extensor digitorum longus muscle.
4. After prepping the skin with cleaning solution, raise a skin wheal immediately lateral to the artery.
5. A long (3.75 cm, or 1.5 in) 25-gauge needle can be inserted perpendicular to the skin.
6. To anesthetize the *deep peroneal* nerve, the needle is advanced under the extensor hallucis longus tendon until it encounters the tibia (usually at a depth of 1 cm, Fig. 3-18).
7. At this point, aspirate to confirm extravascular placement and inject 3 to 5 mL of anesthetic.
8. To anesthetize the *saphenous nerve,* the needle is withdrawn to a subcutaneous position without removing it completely.
9. The needle is then maneuvered medially, remaining subcutaneous until the midportion of the medial malleolus is reached, and another 3 to 5 mL of solution deposited (Fig. 3-19).
   a. Alternatively, as the saphenous nerve may bifurcate as many as 3 cm proximal to the medial malleolus, a second subcutaneous injection may be more efficacious.
10. Having just anesthetized the deep peroneal and saphenous nerves, the needle is withdrawn from areas medial to the tibia, and maneuvered laterally (through the same skin insertion point) toward the superficial peroneal nerve (located midway between the extensor hallucis longus tendon and the lateral malleolus) (Fig 3-20).
11. After aspirating, 5 to 7 mL of anesthetic is injected subcutaneously.

FIGURE 3-18 Photograph of the anterior aspect of the ankle. The needle in the central portion of the picture depicts the insertion site for block of the deep peroneal nerve. (From: Military Advanced Regional Anesthesia Handbook, with permission. www.arapmi.org/maraa-book-project.html)

Digital Nerve Blocks

The neural anatomy of the toes is similar to that of the fingers with four nerves supplying each digit. As with the thumb, the technique used to block the hallux varies slightly from that used for the lateral four toes. Because of its circumference, it is often necessary to utilize two injection sites. Like the hand, dorsal needle insertion sites are preferable, especially in the awake patient and epinephrine is strictly avoided in anesthetic solutions because of its vasoconstrictive effects.

Author's Preferred Treatment

The basic steps involved in performing a digital block of the foot are as follows:

1. For the great toe, the skin over the dorsal aspect of the first metatarsal–phalangeal joint is cleaned with alcohol or similar prep solution.

FIGURE 3-19 Photograph of the anteromedial aspect of the ankle. The needle in the superior portion of the picture depicts the insertion site for block of the saphenous nerve. The *dotted line* is the region where a wheel of anesthetic should be raised to hit all branches. (From: Military Advanced Regional Anesthesia Handbook, with permission. www.arapmi.org/maraa-book-project.html)

FIGURE 3-20 Photograph of the anterolateral aspect of the ankle. The needle in the superior portion of the picture depicts the insertion site for block of the superficial peroneal nerve. The *dotted line* is the region where a wheel of anesthetic should be raised to maximize the chance to anesthetize it. (From: Military Advanced Regional Anesthesia Handbook, with permission. www.arapmi.org/maraa-book-project.html)

2. A 25-gauge (or smaller) needle is positioned perpendicularly to the skin, dorsolateral to the proximal phalanx and advanced in the subcutaneous tissue to the plantar surface of the toe until skin tenting is noted.
3. Inject 1% lidocaine (0.25% bupivacaine or 50:50 mix of bupivacaine: Lidocaine can also be utilized) as the needle is withdrawn, raising a wheal from the plantar to dorsal aspect of toe to ensure the two nerves on the lateral aspect of this toe are anesthetized.
4. The needle is then withdrawn completely and reinserted on the contralateral side of the great toe, with this protocol repeated.
5. For the lesser toes the same procedure may be followed. Alternatively, because of the relatively smaller circumference of the smaller toes it may be possible to administer anesthetic to both sides of the metatarsal–phalangeal joint through the same needle stick.

Postoperative Analgesia

Postprocedural analgesia can include both operative and nonoperative treatments. Pain management should begin before the procedural portion begins with a plan for preprocedure, procedural, and postprocedural pain control. Therefore, the treating team should briefly discuss a plan for proper management so that pain management is optimized.

Nonpharmacologic Treatment

Introduction of nonpharmacologic interventions such as relaxation, distraction, and education may assist the patient and family by decreasing anxiety and perceived interpretation of

pain.[89,106] Child life specialists are frequently involved in pediatric as well as nonpediatric centers, and when available they can lend significant benefits as far as distracting the child and thereby reducing intensity and amount of perceived pain.[89] Though common practice in many institutions, addition modalities that bear mentioning include the use of elevation and ice for injured extremities both before and after fracture treatment. Use of transcutaneous electrical stimulation (TENS) may also affect activation of inhibitory nerve fibers. Currently there is no definitive evidence on its efficacy in the pediatric population.[71,89,106]

Nonsteroidal Anti-Inflammatory Drugs

This class of medications includes analgesics, antipyretics, and anti-inflammatories that work by the inhibition of cyclooxygenase leading to a decreased production of prostaglandins.[116] Although the potential side effects are many including sodium retention and edema, gastritis, and increased bleeding time, when combined with opioids postoperatively they can dramatically enhance pain relief while significantly decreasing opioid requirements.[84,89,109] The use of NSAIDs has been controversial with concern raised over the potential effect on bone healing. However, increasing literature suggests these concerns may be exaggerated in the pediatric population and further support is building for their use in pain control following bony procedures. Several studies in both animals and humans point to the fact that attaining normal bone strength may be slightly delayed in the initial period; however, there does not appear to be a significant difference in overall healing while decreasing duration and amount of opioid use.[20,46,61,62,66,103] In addition, a meta-analysis of studies assessing the efficacy of NSAIDs following surgery in pediatric populations showed that their use significantly decreased postoperative side effects of narcotic pain medication such as nausea and vomiting.[84] A listing of common NSAIDs and their dosing is presented in Table 3-11.

Local and Regional Anesthetics

Utilization of both local and regional anesthetic can provide an excellent addition to intraoperative and postoperative pain relief.[79] Local anesthetic nerve blockade and the methods used to perform these were previously covered. Central blocks for pediatric orthopedic patients include epidural catheters and peripheral nerve blocks, the latter can include a plexus or isolated peripheral nerve. Benefits include less intraoperative narcotic and anesthetic needs, so the patient is more alert and has fewer anesthetic side effects.[32] Moreover, there is evidence in the pediatric surgical literature that preoperative infiltration of the intended surgical site is more effective at providing pain relief than postoperative injections for hernia repair.[40]

Contraindications to regional blocks include systemic or local infection near the injection site, coagulopathies, and anatomic abnormalities that prevent adequate block placement. Lidocaine and bupivacaine are commonly used local anesthetics. Dosing limits for common local anesthetics are listed in Table 3-9. Risks of peripheral blocks include inability to recognize nerve damage and/or compartment syndrome masked by a dense sensory block.[106]

Postoperative Analgesia with Opioids

Opioids act as analgesics by raising the pain threshold in the spinal cord and peripheral nerves and by altering the brain's perception of pain.[116] There are three major groups of opioids. Natural derivatives of the opium poppy include codeine and morphine.[101] Semisynthetic opioids are hydrocodone and oxycodone. Synthetic opioids are fentanyl, meperidine, and sufentanil.[101] Morphine is more effective when given intravenously than orally because of the faster onset, better maintenance of blood concentration, and avoidance of significant first-pass metabolism in the liver.[106] IM administration should be avoided secondary to unpredictable absorption, discomfort, and patient fear of injections.[41,65,106,116] Using patient-controlled analgesia (PCA) pumps decreases fear of an injection. PCA is highly effective with fewer side effects of over- or underdosing for children of ages 6 years and older with normal cognitive function.[41,65] Oral morphine dosing is 0.2 to 0.4 mg/kg every 3 to 4 hours. Duration of action is 4 to 6 hours, with peak effects occurring after 15 to 30 minutes.[101] Parenteral morphine dosing is a 0.1-mg/kg bolus every 3 to 4 hours, 0.015 mg/kg every 8 minutes via PCA, or 0.02 to 0.04 mg/kg per hour for a continuous infusion.[65] Sutters et al.[109] studied pediatric orthopedic patients in a randomized prospective study comparing morphine via PCA with and without ketorolac. Patients in the two groups were comparable with respect to demographics and surgical procedures. Patients given ketorolac had better analgesia, reduced morphine use, and fewer opioid side effects.

Meperidine (Demerol, Sanofi Synthelab Inc., New York, NY) is a synthetic opioid given intravenously at 1 to 1.5 mg/kg every 3 to 4 hours with a maximum of 7.5 mg/kg per day.[101,116] Peak effects occur in 30 to 60 minutes.[117] It may be used in a PCA, but has one-tenth the potency of morphine.[101] Meperidine also has a greater euphoric side effect, giving it a higher risk of psychological dependence with prolonged repeated doses.[101,116] Fentanyl is a short-acting synthetic opioid that lasts 20 to 60 minutes, with an onset of less than 30 seconds.[101,116] Given intravenously, it has similar characteristics to natural opioids. Its fast onset and ease of titration make it an excellent choice for immediate postoperative pain management and for use during outpatient surgeries.[96] However, Claxton et al.[28] found pediatric patients given fentanyl in the recovery room after ambulatory surgery had higher pain levels compared with patients given morphine. This may be due to the need for frequent dosing to maintain adequate relief. Unique side effects of fentanyl include chest wall rigidity, laryngospasm, and nasal pruritus.[116] Unlike other opioids, fentanyl does not cause histamine release.[116]

Oral narcotics can be used when a patient tolerates oral intake. Codeine is no longer routinely recommended because of its inconsistent metabolism in children, which can result in either therapeutic failure with suboptimal pain control in poor metabolizers or severe opioid intoxication in the ultrarapid

TABLE 3-11 Dosing Formulations and Schedules for Oral Analgesic Medications for Children and Adolescents[a]

Medication	Formulation[b]	Dose
Acetaminophen[c]	Children's suspension: 160 mg/5 mL Chewable tablet: 80 mg Oral disintegrating tablet: 80 mg, 160 mg Tablet: 325 mg, 500 mg Rectal suppository: 80 mg, 120 mg	10–15 mg/kg/dose q4–6h, maximum dose 975 mg/dose
Hydrocodone with acetaminophen (Lortab, Anexsia, Co-Gesic, DuoCet, Hy-Phen, Vicodin)	2.5-mg hydrocodone/5-mL acetaminophen 120 mg/5 mL (Lortab Liquid)	Adult dose: Hydrocodone 5–10 mg q4–6h Children (only antitussive dose is published): 0.6 mg/kg/day divided in three to four doses/day. <2 y: Do not exceed 1.25 mg/dose. 2–12 y: Do not exceed 5 mg/single dose. >12 y: Do not exceed 10 mg/single dose.
Hydromorphone (Dilaudid, Hydromorphone HCl)	5-mg hydromorphone/5-mL solution	Optimal pediatric dosage for analgesia not established. Antitussive dose is: 6–12 y: 0.5 mg q3–4h >12 y: 1 mg q3–4h
Ibuprofen	Infant's suspension: 50 mg/1.25 mL Children's suspension: 100 mg/5 mL Chewable tablet: 100 mg Tablet: 200 mg	10 mg/kg/dose q6–8h, maximum dose 800 mg/dose
Morphine (morphine sulfate, Roxanol)	10 mg/5 mL and 20 mg/5 mL solution	0.2–0.4 mg/kg q4h (adult dose is 10–30-mg solution q4h). Absorption from the gastrointestinal tract is variable.
Naproxen (oral)	125-mg/5-mL suspension Tablets: 250, 375, 500 mg	5–7.5 mg/kg q12h, maximum dose 600 mg/day
Oxycodone	Oral solution: 5 mg/5 mL Capsule: 5 mg Tablet: 5 mg, 10 mg, 15 mg, 20 mg, 30 mg	0.1–0.2 mg/kg/dose q6–8h, maximum dose 10–20 mg/dose
Oxycodone + acetaminophen	Oral solution: 5-mg oxycodone + 325-mg acetaminophen/5 mL Capsule: 5-mg oxycodone + 500-mg acetaminophen Tablet: 2.5-mg oxycodone + 325-mg acetaminophen 5-mg oxycodone + 325-mg acetaminophen 7.5-mg oxycodone + 325-mg acetaminophen 7.5-mg oxycodone + 500-mg acetaminophen 10-mg oxycodone + 325-mg acetaminophen 10-mg oxycodone + 650-mg acetaminophen	Based on oxycodone content: 0.1–0.2 mg/kg/dose q6–8h, maximum dose 5 mg/dose

metabolizers.[78] Oxycodone, which is slightly more potent than hydrocodone, is now recommended instead of codeine.[106,116] It is commonly formulated with other pharmaceuticals, including acetaminophen. Hydrocodone is present in Lortab (UCB Pharma Inc, Atlanta, GA), Lorcet (Forest Pharmaceuticals, New York, NY), and Vicodin (Abbott Laboratories, Abbott Park, IL) and given at 0.2 mg/kg every 3 to 4 hours.[106] Oxycodone is found in Roxicodone (Elan Pharmaceuticals Inc, San Diego, CA), OxyContin (Purdue Frederick Co., Norwalk, CT), Percocet (Endo Pharmaceuticals Inc, Chadds Ford, PA), and Tylox (Ortho McNeil Corp., Raritan, NJ). It is given at 0.2 mg/kg every 3 to 4 hours.[106] A listing of common parenteral and oral opioid medications and their dosing schedules is presented in Tables 3-11, 3-12 and 3-13.

Opioids have many potential adverse effects. Severe respiratory depression, depressed cough reflex, and triggering of nausea and emesis can all contribute to significant risk for the patient if improperly administered and/or moni-

TABLE 3-12 Patient-Controlled Analgesia in Children

Loading dose: Morphine, 0.025–0.05 mg/kg
Maintenance dose: Morphine, 0.01–0.02 mg/kg
Lockout interval: 6–10 min
4-hr maximum: Morphine, 0.4 mg/kg/4 hr

Treatment of Side Effects

Pruritus: Diphenhydramine (0.5 mg/kg IV) OR low-dose naloxone (0.5–1 µg/h)
Nausea/vomiting: Metoclopramide (0.1 mg/kg IV) OR droperidol (10–30 µg/kg IV or IM) OR ondansetron (0.15 mg/kg IV over 15 min) OR low-dose naloxone as for pruritus
Urinary retention (<1 mL/kg/h in the face of adequate fluid intake): Low-dose naloxone infusion as above
Respiratory depression: Specify vital sign parameters that require treatment and method for contracting responsible physician. Stop PCA pump. Give 100% oxygen and maintain the airway. Give naloxone (1–5 µg/kg IV bolus); repeat as needed. Consider naloxone infusion (3–5 µg/kg/h).

From: Rogers J, Moro M. Acute postoperative and chronic pain in children. In: Rasch DR, Webster DE, eds. *Clinical Manual of Pediatric Anesthesia.* New York, NY: McGraw-Hill; 1994:298, with permission.

tored.[106,116] Other side effects include urinary retention due to an increase in antidiuretic hormone, postoperative ileus, and constipation. In addition, histamine release from mast cells can result in urticaria, diaphoresis, vasodilatation, and bronchoconstriction.[57,116]

Author's Preferred Method of Treatment

We prefer that postoperative analgesia incorporates a multimodal approach whenever possible. This should include at a minimum acetaminophen, nonsteroidal, and narcotic medication. In addition, we advocate the liberal use of regional blockade to not only improve pain management *during* procedures but also in the short- to midterm post injury and/or procedural period. The use of child life specialists are also frequently employed when available.

TABLE 3-13 Parenteral Opioid Dosing Schedule for Analgesia in Children[a]

IM[b]: Morphine, 0.1–0.15 mg/kg q3–4h; Meperidine, 1–1.5 mg/kg q3–4h
IV: Morphine, 0.05–0.1 mg/kg q2h; Meperidine, 0.5–1 mg/kg q2h

[a]Infants less than 3 mos old should be dosed in increments of one-third to one-half because of increased risk of respiratory depression.
[b]IM dosing should rarely be used.

4 CAST AND SPLINT IMMOBILIZATION, REMODELING AND SPECIAL ISSUES OF CHILDREN'S FRACTURES

Matthew Halanski, Blaise A. Nemeth, and Kenneth J. Noonan

INTRODUCTION

The last several decades have seen amazing enhancements in the management of adult orthopedic trauma; one of the most significant is the ability to operatively reduce fractures and to stabilize them safely with internal implants. These methods have resulted in less reliance on fracture manipulation and stabilization with external devices such as traction, splint and cast immobilization. Gone are the days of extended skeletal traction and spica cast application for adult femur fractures; tibia shaft fractures in adults are rarely treated with time-honored methods of reduction in the emergency ward, long leg cast application followed by months of patellar tendon bearing and short leg cast and splint application. Although still used with some frequency in adult trauma, upper extremity cast and splint application is often considered temporary until definitive internal fixation.

Parallel to changes in fracture management, medicine has seen similar changes in medical education as well as who delivers certain health care. For instance, as a result of specialization, many adult orthopedists manage less trauma, rarely place casts and even more rarely will they educate residents in the safe and effective use of these methods. As reimbursement for health care changes, orthopedic surgeons are called to do those things that only they can do . . . operate; many other aspects of patients' care are assumed by advanced practitioners such as NPs or PAs or other allied health specialists. In many emergency rooms and in most outpatient clinics, the patient who requires definitive cast immobilization will usually have these applied by cast technicians or nurses. As a result, large fracture clinics where orthopedic residents learn from senior residents or faculty to manage fractures with casting are replaced by cast technicians while residents learn who needs operations and how.

To a lesser degree and similar to adults, decades of advances in imaging and development of appropriate operative methods and implants have also benefited pediatric patients with orthopedic trauma. Despite wide changes in adult trauma, cast and splint methodology is used with great frequency in the management of pediatric trauma. In children, requisite attention to perfect reduction and extensive immobilization is not needed because of the rapidity of fracture healing and the remodeling potential seen in children. Greater than 90% of adult forearm fractures are treated with surgery; in children, 90% of forearm fractures are treated with reduction and cast immobilization.

In this textbook, organization of information is largely based upon anatomic location of trauma and fractures. Within each of these areas, attention is directed toward both operative and nonoperative methods of treatment. The purpose of this chapter is to review in detail the methods and pitfalls of nonoperative treatment that are common to all areas of pediatric trauma. In addition, we will review unique characteristics of children that are also of importance in all fracture locations and trauma. It is desired that this chapter, its figures and video clips will serve as a primer of pediatric orthopedic trauma. As such we have included 15 fractures that can be underappreciated and at risk for management error; extensive illumination of these fractures will be found in other chapters.

General

Because of the growth and remodeling potential of pediatric bones, acceptable alignment rather than exact anatomic reduction is sufficient for many fractures, allowing the majority of pediatric fractures to be managed in a cast. Similarly, joint stiffness is not typically a long-term problem in children treated in a cast.[7] The goals of pediatric cast treatment are to protect and provide stability to the broken bone, maintain alignment, and protect from further injury until sufficient healing has occurred. In general the alignment maintained in the cast should allow the child to eventually remodel to anatomic "normal" by the cessation of growth. The younger the child, the more malalignment may be acceptable. Likewise, deformity closer to the growth plate and in the plane of motion will typically remodel more than those elsewhere.

The duration of cast treatment is both age and site specific. Very young children, infants, and newborns will generally heal fractures quicker than adolescents. In general, fractures of the hands and feet require 4 weeks of immobilization; elbow fractures 3 to 6 weeks; tibial shaft fractures may take 12 to 16 weeks, whereas most other fractures require 6 weeks. Before discontinuing cast immobilization, fracture healing should be documented on radiographs and the child nontender at the fracture site.

In general, casts are utilized to *maintain* alignment. If a fracture is nondisplaced or has an acceptable alignment, the cast's purpose is to maintain that alignment until the bone has healed. If a fracture has an unacceptable alignment, it should be reduced to an acceptable alignment and the cast placed to maintain that alignment. Fractures that should be treated operatively include injuries in which adequate alignment or length cannot be easily obtained or maintained, displaced intraarticular fractures, and many fractures involving the physis. Postoperatively the limb may be protected with a splint or a cast if necessary. Problems may arise when a cast is used to *obtain* acceptable alignment. Pressure sores and soft tissue injuries have been documented when casts are used in this manner and should be done so with caution.[59,72,97]

To minimize motion at the fracture site, casts are placed to span the joint proximal, distal, or both. In general, the more proximal a fracture, the more likely joints at each end of the bone will be spanned. Increasing the length of the cast increases the resistance to rotation.[57] To maintain correct alignment, limbs may be casted in different positions to counteract specific displacing forces on the proximal or distal fragment of a given fracture. For example, in a subtrochanteric femur fracture, the proximal fragment is pulled into flexion, abduction, and external rotation by attached muscles, so the distal fragment must be positioned with this in mind.

Fractures treated in casts should be followed with radiographs. Some controversy may exist in the necessity of obtaining repeat radiographs of nondisplaced wrist fractures; however, scheduled follow-up of displaced fractures should be performed. It is prudent to follow fractures that required reduction weekly for 2 to 3 weeks to recognize if displacement occurs in time for re-reduction to be performed before healing is too far along. Some fractures such as lateral condyle fractures of the humerus or tenuous reductions of the forearm may require weekly radiographic evaluation for 3 weeks or more until early callus is observed. Late radiographic follow-up between 6 and 12 months should be considered for any fracture involving the growth plate with risk for growth arrest or in fractures in which overgrowth is a concern.

Cast Complications

Although casting is often viewed as "conservative" treatment, the treating physician and family should recognize that this does not imply that this treatment is without complications. Although the true incidence of cast complications is unknown, a litigation history of a large multispecialty multilocation pediatric group showed that casts were the number one cause of litigation. Over 25% of children treated in a hip spica cast have been shown to have skin complications.[27] Over a 5-year period at one institution, 168 unplanned visits to the emergency room were because of cast issues. Twenty-nine percent of these visits were for a wet cast, 23% for a tight cast, and 13% for a loose cast.[86] Over a 10-year period, Physicians Insurers Association of America (PIAA) reported 1,023 claims on problems of immobilization and traction for which 16% of all claims had an associated issue including failure of consent. This implies that many physicians and patients may expect cast immobilization to be without risk. Thus, it is important to inform patients and their caregivers of the risks associated with cast treatment. When the risks of treatment are given, it is beneficial that these risks be written and delivered to the patient and their family.[51]

The Wet and Soiled Cast

Wet casts that are not made with synthetic material and waterproof liners (and thus can dry quickly) should be changed. Failure to do so may result in skin irritation, breakdown, and possible infection. Light moisture or spotting may be dried with a hair drier on cool or low heat, with instructions to check the temperature of the dryer with their hand to ensure that it is not too warm. A frankly wet cast or cast padding that cannot be dried as described above usually requires inspection of the skin and cast change[68] (Fig. 4-1). Although the majority of limbs in these casts will only demonstrate skin maceration,[27] serious life-threatening complications such as toxic shock syndrome and necrotizing fasciitis have been reported.[25,73] Hip spica casts are often applied in the operating room and their removal and exchange at times require a

A

general anesthetic. Parents should be well instructed on positioning to avoid soiling, frequent diaper changes, and inspecting the children for skin irritation. Anesthetic risks must be weighed with the perceived soft tissue and skin risk.

Thermal Injury

Plaster and fiberglass, the two most common casting materials, harden through exothermic chemical reactions. Plaster has a much higher setting temperature than fiberglass and therefore a higher risk for thermal injury when a cast is placed. Two factors strongly associated with thermal injuries are dip water temperature and the thickness of cast material. Several studies have shown that risk of thermal injury is significant if the dip water temperature is too hot (>50°C) or if the casts are too thick (>24 ply).[39,46,61] Each plaster manufacturer has recommended dip water temperatures that should not be exceeded. Using warmer temperatures to "speed up" the setting time beyond those recommended should be avoided. Casts in excess of 24 ply are rarely encountered; however, increased amounts of casting material are often placed in the concavities of extremities (antecubital fossa and dorsum of the ankle) because of material overlap.[46] Incorporating splints on the convexity thus decreasing overlap in the concavity can minimize this. Similarly, clinicians placing plaster splints of 10 to 15 ply on an extremity may breech safe thicknesses when the splint is too long and the edges are folded over thus creating a focal area of 20 to 30 ply, a thickness at which temperatures do become a risk.[46] Studies have shown that temperatures high enough to cause significant thermal injuries can also be reached when the clinician places a curing cast on a pillow.[39,46] The practice of reinforcing a curing plaster cast with fiberglass may place the limb at significant risk because the synthetic overlap prevents heat from effectively dissipating, as well as an increased risk of case burns at removal in our experience. The plaster must be allowed to cure before setting the casted limb on a support or applying fiberglass reinforcement. Failure to wait may place the insulated portion of the limb at significant risk.[46] Case reports demonstrating this potential complication do exist.[9] Those patients undergoing regional or general anesthesia may be at increased risk as they will not report thermal injury.

Areas of Focal Pressure—Impending Pressure Sores

A key to preventing loss of fracture reduction is in the application of a well-molded cast. "Well molded" means casts should closely mimic the limb they are immobilizing. Cast padding should be applied between 3 and 5 layers thick over the limb being casted.[71,88] Bony prominences and cast edges should be additionally padded to prevent irritation yet allow a cast to be molded to fit snugly without undue pressure. The heel, malleoli, patella, ASIS, and olecranon, are areas that may require additional padding. The use of foam padding in such areas may help decrease the incidence of pressure sores.[35]

If areas of increased pressure are formed, they may lead to foci of decreased perfusion and result in pressure sores. Similarly, great care should be taken in preventing a change in limb position between application of the cast padding and the casting material. A common example is a short leg cast applied in less than 90 degrees of ankle flexion; if the ankle is flexed to 90 degrees during the application or curing of the cast, the material will bunch up and will impinge on the dorsum of the ankle.

Families and patients should be instructed to refrain from placing anything between a cast and the patients' skin. Often this is done to alleviate pruritus but should be avoided as inadvertent excoriation may occur. Despite these warnings, food, toys, writing utensils, money, and other items have been found down casts, and we have seen them erode through patients' skin. Numerous case studies report problems from foreign bodies placed down casts.[12,94] Any patient with a suspected foreign body down their cast should have the cast removed and skin inspected (Fig. 4-2).

A loose cast may result in a loss of reduction or skin sores as a result of shear forces repeatedly applied to the limb. One may rationalize that the best way to avoid pressure sores is to increase the amount of padding under the cast. Injudicious application of excessive padding can lead to a cast that is too loose and paradoxically increase the risk of skin irritation from sheer stress at the skin/padding interface. Loose-fitting casts can be further associated with fracture malunion because of loss of reduction.[48] In such cases, the distal fingers or toes are often noted to "migrate" proximally when this occurs and should alert the parent and the clinician that there is a problem. This has been termed the "disappearing toes/fingers sign."[99] It is during this migration that pressure sores may occur as the limb migrates proximally in a fixed cast. This causes a mismatch in the shape of the cast and

(*Property of UW Pediatric Orthopaedics.*)

the shape of the limb. In a lower extremity cast, which migrates distally, the dorsum of the foot receives pressure from the anterior ankle crease of the cast, while the heel is pulled up and rests along the posterior calf portion of the cast. Prolonged positioning in such a manner may result in pressure sores.

Detecting Cast Complications

That "there are no hypochondriacs in casts" is an important aphorism to remember and every effort should be taken to resolve the source of complaint in an immobilized patient. Any reports of casts getting wet, soiled, or questionable foreign bodies being lost down casts should be taken seriously and the patient evaluated in a timely manner. A complication of casting should be considered whenever an immobilized patient has an unexplained increase in pain, irritability, or unexplained fevers.[25]

Some cast complications such as soiling and wetness can be detected on physical examination, whereas others may be more difficult to diagnose. A foul-smelling cast may be a sign of wound infection and the cast should be removed or windowed to be inspected the source of the smell. Pressure sores may be diagnosed if the patient can localize an area of discomfort away from the fracture or operative site. Complaints of pain in high-risk areas such as the heel, dorsum of the foot, popliteal fossa, patella, olecranon, must alert the clinician of an impending problem. However with pediatric patients, localization may not be possible. One must correlate history, the clinical examination findings, such as the "disappearing toes sign" with radiographs. These images can be used to critically evaluate not only the alignment of the fractured bone, but also the outline and contour of the cast padding and material, especially in the antecubital, the popliteal

fossae, and over the dorsum of the foot. If there is a suspicion of a problem, the cast should be windowed or removed and the area inspected.

Certain pediatric patients may be at a higher risk for cast complications. These include patients with an inability to effectively communicate. The very young, developmentally delayed, or patients under anesthesia or sedation may have difficulty responding to noxious stimuli such as heat or pressure during the cast application. Discerning problems in this group may be quite difficult and cast sores can occur despite appropriate and careful application.

Similarly, patients with impaired sensation are at increased risk for injuries related to excessive heat and pressure. In this group are those with spinal cord injuries,[80,89] myelomeningocele,[66] and systemic disorders such as diabetes mellitus.[43] Furthermore, prolonged immobilization in many of these marginally ambulatory patients will potentiate existing osteopenia, thus, increasing the risk of fractures and need for further immobilization.

Patients with spasticity are also at increased risk for complications. Often these patients have multiple risk factors including communication difficulties and poor nutrition in addition to their spasticity. These factors place them at particular risk for developing pressure sores.[63,91]

Treating Cast Complications

Dermatitis

The majority of dermatitis under casts has to do with maceration of the skin and continued contact with wetness including fluids such as urine or feces. Often removal of the cast, cleansing of the skin, and allowing the skin to "dry out" is all that is required. Some recommend applying over-the-counter skin moisturizers.[27] If fungal infection is suspected, half-strength nystatin cream and 1% hydrocortisone cream may be applied followed by miconazole powder dusting twice daily.[27] If unstable, the fracture may be managed by a newly applied dry split cast or splint allowing time for the skin to recover. In rare cases internal or external fixation may be chosen to manage the fracture and to allow treatment of the skin issues. Often the skin will improve dramatically after a few days and a new cast may be applied. If significant concern for cellulitis exists, such as induration or fevers, laboratory tests should be ordered and empiric oral antibiotics prescribed.

Pressure Sores

Pressure sores are the result of a focal area of pressure, which exceeds perfusion pressure. Although there may be initial pain associated with this pressure, this can be difficult to separate from the pain of the fracture or surgery. Any pain away from the injured area should be suspected to have a problem with focal pressure. The heel is the most common site. These sores may vary from areas of erythema, to black eschars, to full thickness soft tissue loss and exposed bone (Fig. 4-3). In the benign cases removal of the cast over the heel and either cessation or careful reapplication is all that is necessary. Typically black eschars imply partial to full thickness injuries. If they are intact, nonfluctuant, nondraining, and mobile from the underlying bone they may be treated as a biologic dressing with weekly wound checks. If any concern exists, a "Wound Team" and/or Plastic Surgery consult should be sought earlier rather than later. Often dressing changes utilizing topical enzymatic ointments and antibiotic ointments can be used to treat these wounds

FIGURE 4-3 Examples of heel pressure sores. **A:** Mild erythema and superficial skin damage, **(B)** intact eschar, **(C)** partial/full thickness injury with exposed bone and fascia. (*Property of UW Pediatric Orthopaedics.*)

FIGURE 4-4 Picture of heel ulcer at clinical follow-up after operative debridement **(A).** After roughly 2 months of topical enzymatic and antibiotic treatment with dressing changes **(B).** (*Property of UW Pediatric Orthopaedics.*)

(Fig. 4-4). Whenever exposed bone is present, osteomyelitis is a concern requiring aggressive intervention and possible intravenous antibiotic therapy. In these severe cases vacuum-assisted closure (VAC) therapy, skin grafting, or flap coverage may be necessary.[62]

Joint Stiffness and Muscle Contractures

Determination of cast immobilization duration is often multifactorial; however, the clinician must recognize that unwanted physiologic changes occur. Although these changes are less pronounced in children than adults, excessive length of immobilization may lead to problems such as stiffness,[33] muscle atrophy, cartilage degradation, ligament weakening, and osteoporosis.[7,14,16,38,44,52,92] This must be weighed against the bony healing gained in prolonged immobilizations. Alternatives such as Pavlik harness bracing for infants with femur fractures,[75] patellar tendon bearing casts versus long leg casts for tibial fractures, short-arm casts for distal forearm fractures, and other functional braces may minimize some of the risks of cast immobilization or at least decrease the duration of cast treatment.

The ankle, elbow, and fingers are often locations prone to stiffness. The duration of immobilization should be minimized if at all possible. In minimally displaced medial epicondyle and radial neck fractures, the limb should only be immobilized for 7 to 10 days until the patient is comfortable, but protected from further injury during activities such as contact sports for at least 3 to 6 weeks after the fracture. Similarly, once clearly established healing has occurred in supracondylar humerus fractures, the limb should be allowed motion after 3 to 4 weeks of casting. The position of immobilization is also important in the nearly skeletally mature. Placing the foot in plantar flexion, or failing to splint fingers in the safety position (70 degrees MCP flexion/IP extension) may result in joint contractures that persist long after fracture healing, though this is uncommon in young children.

Compartment Syndrome

Most limbs with fresh fractures are more comfortable after immobilization. Therefore, increasing pain or neurovascular change should be fully evaluated to detect above complications and possibly compartment syndrome. Fractures and surgery can result in progressive soft tissue swelling that might not have been present at the time of cast application and may lead to compartment syndrome. In this scenario,[86] the first intervention should be relieving the circumferential pressure by splitting the cast and all underlying padding, as leaving the padding intact has been shown to not relieve compartment pressure. Should splitting the cast fail to alleviate symptoms, cast removal should be considered. Fractures of the tibia,[34,42] forearm,[42] and elbow have increased risk of compartment syndrome. High-energy fractures resulting from motor vehicle accidents,[34] crush injuries,[2] or two-level injuries such as a floating elbow, should raise the treating physician's awareness to the possibility of an impending compartment syndrome. Any child unable to detect pain associated with compartment syndrome (a nerve injury or regional anesthesia)[78] must be followed closely for the development of compartment syndrome.

Children do not usually exhibit the classical four Ps (pallor, paresthesias, pulseless, pain with passive stretch) associated with compartment syndrome until myonecrosis has occurred. Instead the three As of increased agitation, anxiety, and analgesic requirements have been documented as the earliest signs of compartment syndrome in children. Any child

exhibiting these symptoms that are not relieved with cast splitting should have the cast removed and limb inspected with a high suspicion of compartment syndrome. One should be ready to take the child to the operating room for formal compartment evaluation and decompression if needed.

Fractures with associated neurovascular injuries are at significant risk of developing a compartment syndrome and require frequent neurovascular checks. These limbs may be stabilized with a splint as opposed to circumferential cast application; which could worsen the risk of compartment syndrome. These limbs are most often treated with operative stabilization using internal or external fixation and/or splint immobilization. This allows continued neurovascular assessment, palpation of compartments, and inspection of the limb. For instance, the child with a floating elbow fracture and associated nerve palsy (at high risk for compartment syndrome) is usually best treated with internal fixation of the fractures, and either a splint, bivalved cast that is easily opened, or cast with thick foam to allow for swelling, with the volar forearm exposed to assess the compartments as well as the pulses.

Disuse Osteopenia and Pathologic Fractures Adjacent to Cast

Patients with paralytic conditions or cerebral palsy patients and those taking anticonvulsants may experience further disuse osteopenia with immobilization.[80,89] These patients are at significantly higher risk of pathologic fracture while casted or upon cast removal.[3,63] Strategies to prevent this includes minimizing immobilization (<4 weeks), weight-bearing casts, and the use of less rigid immobilization such as Soft Cast (3M Healthcare Ltd, Loughborough, England) and splints and braces.

Delayed Diagnosis of Wound Infections

Many children are placed in postsurgical casts. The vast majority does well without incident. However, casts over wounds or pins may cause a delay in the diagnosis of a wound infection (Fig. 4-5). For instance, an estimated 1% to 4% of all pediatric supracondylar humerus fractures treated with pinning the elbow, will develop a postoperative pin tract inflammation or infection.[5,33] Therefore, unexplained fever beyond the perioperative period, increase in pain at pin sites, foul smell, or discharge from a cast should be evaluated by a member of the orthopedic team. The wound should be examined either with cast windowing or cast removal. Laboratory tests including CBC, ESR, CRP are advisable. In cases of early pin site infection where the fracture is not yet healed, oral antibiotics may control the infection long enough to allow fracture healing. Infections of pins used for certain fractures may have a high chance of joint penetration (lateral condyle, distal femoral physeal, proximal humerus) and can lead to a septic joint. This is much more serious than simple pin site infections, and most often must be treated with surgical irrigation and debridement and pin removal should be considered.

Types of Casting Materials

Before placing a cast, the limb must be inspected. Any dirt, operative skin prep, jewelry should be removed before the cast

FIGURE 4-5 After getting a postoperative cast wet, dermatitis and possible cellulitis were found at the incision following a gastrocnemius recession. (*Property of UW Pediatric Orthopaedics.*)

is applied. Often appropriate size stockinette or liner is applied against the skin, under the cast and cast padding. Although not essential, these liners minimize skin irritation; allow nice well padded and polished edges to the cast to be applied. They also minimize the tendency of some children to "pick out" their cast padding. These liners are made of cotton, water-friendly synthetic materials such as polyester, sliver-impregnated cotton (to minimize bacterial growth), and Gore-Tex (W.L. Gore & Associates; Newark, Delaware). Some in the care of children who require spica cast application favors water-permeable liners such as Gore-Tex. In addition to being more convenient for patients, these newer materials have been shown to minimize skin irritation.[47,58,101]

Cast Padding

Different materials are used to pad the extremity between the cast material and the patient's skin. A thin layer (3 to 5 layers) of padding is applied to the portion of the extremity that is not prone to pressure sores and it is applied without wrinkles.[71,88] Additional layers may be placed over bony prominences to minimize pressure in these areas. Cotton is the cheapest and is historically most commonly used. But casts with cotton padding cannot be made waterproof as the cotton padding retains water. Newer synthetic materials have variable water resistance and when paired with fiberglass can allow patients to bathe and

swim. However, these materials are considerably more expensive than their cotton counterparts. In addition, some synthetic padding is less resistant to a cast saw. If one applies Gore-Tex (W.L. Gore & Associates; Newark, Delaware) padding, the blue DE FLEX safety strip (W.L. Gore & Associates; Newark, Delaware) can be placed along the path that the cast saw will take to remove the cast.

Cast edges are often a source of skin irritation and abrasion. This is especially true for fiberglass casts. When making a cast, applying the stockinette and cast padding at least 1 cm beyond the edge of the fiberglass, and folding the stockinette and padding back over the first layer of fiberglass, will make a cast with well-padded edges. Closed cell adhesive foam may also be applied to the edges of a cast and to pad bony prominences. It is important to recognize that some foam padding will accumulate moisture and will not be effectively wicked away from the liner and skin. Should difficulty be found in folding back the underlying stockinette or liner, the cast edges may be petaled with tape or moleskin adhesive. This involves placing a 1 to 2 in piece of tape on the inside of the liner and folding the taped liner over the opening of cast. Most commonly petaling is performed on hip spica casts, but may be performed on any cast.

Plaster of Paris

Plaster-impregnated cloth is the time-tested form of immobilization. It was first described in 1852 and has been the gold standard for cast immobilization for many years. This material is generally less expensive and is more moldable in comparison to the synthetic counterparts. The major advantages of plaster over synthetic materials in the prevention of cast sores and limb compression are its increase in pliability and its effective spreading after univalving. Inconveniences associated with plaster include its poor resistance to water and its lower strength-to-weight ratio resulting in heavier (thicker) casts.

Plaster of Paris combines with water in the following reaction:

$$\underbrace{2Ca(SO_4)\cdot H_2O}_{\text{Plaster of Paris}} + 3H_2O \rightarrow \underbrace{2[CaSO_4\cdot 2H_2O]}_{\text{Gypsum}}$$

In the process of setting up, the conversion to gypsum is an exothermic reaction with thermal energy as a by-product. In general the amount of heat produced is variable between each of the manufactured plasters. However, within each product line, faster "setting" plasters can be expected to produce more heat. As the speed of the reaction, amount of reactants, or temperature of the system (dip water and/or ambient temperature) increase; the amount of heat given off can cause significant thermal injury.[39,46,61] The low strength-to-weight ratio may also increase risk of thermal injury as those unfamiliar with the amount (ply) of plaster to use may inadvertently use too much, resulting in a burn.

Fiberglass

More recently, synthetic fiberglass materials have been introduced. These materials have the benefit of being lightweight and strong. In addition these materials can be combined with waterproof liners to allow patients to bathe and swim in their casts. These materials are often more radiolucent allowing better imaging within the cast.

Risk of thermal injury is much lower and is a major advantage over plaster.[46,76] However, because of the increased stiffness, some feel these casts are more difficult to mold, whereas others prefer fiberglass as the strength of the molded portion is greater. To prevent increased areas of pressure and constriction of the limb, special precautions are recommended when applying fiberglass rolls (see below).[23] In addition, fiberglass is more expensive than plaster (2–2.5×). Finally, there may be a small long-term risk to those applying and removing these materials. Studies have disputed the carcinogenic risks in the manufacturing and use of fiberglass materials.[37,93]

Other Casting Materials

In addition to the standard rigid casting materials of plaster and fiberglass, a less rigid class of nonfiberglass synthetic casting material is available. Although less rigid than standard casting materials, this Soft Cast (3M Healthcare Ltd, Loughborough, England) has several potential advantages. Experimental studies have shown that this material is more accommodating to increases in pressure than the other casting materials.[26] As this material is less rigid, it may be an ideal material to immobilize patients with severe osteopenia. Finally, this material can be removed without using a cast saw, which eliminates the risk of cast saw injury.[10]

Combination of Materials

Some combine plaster and fiberglass casting materials in hopes of obtaining the best features of both. One may reinforce a thin well-molded plaster cast by overwrapping it with fiberglass to increase its durability and minimize its weight. With this technique one must ensure that the plaster has set before overwrapping with the fiberglass. Failure to do so may result in a thermal injury.[46] Shortcomings of this technique include the fact that the two layers of material may obscure fine radiographic detail. Finally, great care must be taken when removing such casts as it may be difficult to "feel" the depth of the cast saw blade and blade temperatures may be more elevated than usual. As a result of the increased risks of burns, it is especially important to use plastic protection strips under the cast when using a standard vibrating cast saw for cast removal. Yet despite these shortcomings, fiberglass has become the most popular casting material in most centers; this is because of the increased strength, decreased weight, improved radiographic quality, and ability to make water-friendly casts.

General Cast Application Principles

Optimal cast application in children requires cooperation, or at least compliance, an issue in younger children, or those with cognitive or behavioral issues, such as autistic-spectrum disorder, who often do not understand the rationale for cast application. Anxiety is further compounded by the presence of strangers, a chaotic environment, and, if applicable, pain. Controlling all of these factors increases the chances of an appropriately fitted cast.

While pain control and sedation are often required, other techniques are helpful for calming and distracting a child during

cast application. Creating a calm environment begins with the first encounter with the child: Speak with a soft voice, sitting and placing oneself at a level at or below that of the child to present a less intimidating stature. Initial examination techniques should be soft and distant from the site of concern, progressing slowly to the area of concern. A less aggravated child prior to cast application more likely remains calm during cast application. Preparing casting materials outside of the room or out of direct visualization of the child during onset of sedation or distraction helps maintain a calm environment.

During cast application itself, a number of approaches may prove helpful, depending on the child. While some children are "attenders," coping better when given more information and being talked through a procedure, others are "distractors" who do better with guided imagery and distraction techniques[19,83]; both types of children benefit from relaxation exercises. Talking to the child and his parents helps identify the best approach for an individual child, and use of child life specialists proves extremely helpful in implementing the preferred approach.[17,84] Use of television/videos, games or interactive applications on a handheld device or tablet proves useful for most any age. For infants and toddlers, soft music, toys (especially those with lights or moving parts), and some interactive applications on handheld devices help with distraction and relaxation.[65] When using a cast saw for cutting the cast or cast removal, ear protection helps decrease anxiety.[13] For children with cognitive, behavioral, or autistic-spectrum disorders, discussion of possible approaches with the parents reaps rewards as they have the best sense of what will be calming, as well as stimulatory, for their child. Cast saws are now available that cut with a scissor-like mechanism that make very little noise and do not become hot. Use of these saws may reduce children's anxiety.

In general, cast or splint application consists of several critical steps. (1) Understanding the injury and development of an appropriate treatment strategy. (2) Collection of all of the needed materials. (3) Assembling the team that is required to execute the process. (4) Education and preparation of the family and the patient. (5) Performing the reduction (if needed) and immobilization (cast or splint).

Once the treatment plan is identified; the key to successful cast application begins well before a cast or splint is applied. It is important to have ready and in easy access the needed padding (cast lining and stockinette); water (at appropriate temperature) cast material (plaster and fiberglass in rolls and reinforcing slabs) as well as needed instruments (C-arm imaging, scissors, cast saws, spreaders etc.). It is important that these are ready as cast application is a timely undertaking with materials that cure and harden in a short period and the application may depend on a short window of time available for comfort or sedation of the child. It is further recognized that all needed personnel need to be ready and this will ideally include sedation team and child life specialists in addition to the one to three people needed to apply a splint or cast.

Several important concepts need to be kept in mind when handling plaster of Paris. This material depends on excellent handling techniques to maximize the benefits of mold ability and fit and also to maximize strength. Each practitioner will have biases on how the art of cast application proceeds in their hands. Some like the plaster to be wet to mold better, others will like a drier roll to ease application (less slippery) and speed the curing process. Within these two extremes will be a consistency that is appropriate as the plaster roll is unrolled onto the limb. It is optimal to keep the plaster roll in contact to the limb to avoid wrapping the material too tight (Fig. 4-6). The plaster should be unrolled with overlaps of ½ to ⅓ the width of the roll and tucks are taken to avoid the tendency of pulling and stretching the material (thus increasing tightness) to get a good distribution and fit of the plaster around the difficult concave areas of the ankle, knee, elbow, and thumb. The optimal cast technique requires frequent rubbing and incorporation (termed: Initial molding) of the plaster rolls as the cast is being applied. Constantly rubbing the plaster as the cast is applied will improve the fit but will also flatten the tucks and incorporate the mineral portion of the plaster into the fiber mesh for optimal strength. Plaster splints should be dipped and vigorously molded together before applying to the convexity of the limb (back of elbow or ankle) or where additional strength is needed (anterior knee [long-leg cast] or posterior thigh [spica cast]).

FIGURE 4-6 Plaster roll is not lifted off of the cast but kept in contact during application as it is "rolled" up the extremity with an overlap of 30% to 50%. (*Property of UW Pediatric Orthopaedics.*)

Once the plaster cast is applied and the initial molding has been accomplished, the cast must be held in a manner that maximizes reduction and prevents possibility of pressure sores. For instance it is critical that a cast is supported by broad surfaces such as the palm of a hand; the thorax of the surgeon is

FIGURE 4-7 The foot is supported on the surgeon's thorax and this holds the foot at 90 degrees while the rest of the cast is molded. (*Property of UW Pediatric Orthopaedics.*)

an excellent broad surface to hold the plantar foot in neutral flexion and extension (Fig. 4-7). Holding a cast with the tips of fingers will leave indentations that can lead to pressure sores. If fingers are needed for molding, pressure should be applied and then withdrawn as the plaster reaches the final curing at which point "terminal" molding of the cast can be done. Terminal molding is that point at which the plaster is fairly firm and warm; yet can be gently deformed without cracking the plaster of Paris. This is the appropriate time to do the final mold and hold of fracture fragments. As the cast goes through the final curing process it can be supported on pillows, provided the cast is not too hot (the pillow prevents heat loss and will increase the temperature at the skin surface). A leg cast should be supported under the calf and allowing the heel to hang free (Fig. 4-8) and thus prevent a gradual deformation of the heel into a point of internal skin pressure.

FIGURE 4-8 While the cooled cast is supported on the pillow, the heel is allowed to hang free and thus be at less risk for deformation and a heel sore. The cast is univalved with a cast saw that is supported by the surgeon's index finger. (*Property of UW Pediatric Orthopaedics.*)

Fiberglass material is applied and molded in a slightly different manner than plaster of Paris. Although synthetic cast material has superior strength in comparison to plaster, some believe its material properties make it harder to apply and mold in comparison to plaster of Paris. Fiberglass material should be removed from its package and dipped in water just prior to application as it will cure and harden in the air. Fiberglass is often tacky in nature and therefore increased tension is needed to unroll the fiberglass, this tension can be inadvertently applied to the limb and result in a cast that is circumferentially too tight. To avoid this, fiberglass should be applied in a stretch relaxation manner[23]; the fiberglass roll is lifted off of the limb (in contradistinction to plaster which stays in contact); unrolled first then wrapped around the limb (Fig. 4-9). Difficulty exists when wrapping a wide roll into a concavity (anterior elbow or ankle) as the fiberglass can only lay flat if pulled too tight. Small relaxing cuts in the fiberglass may be needed, as fiberglass does not tuck as easily as plaster of Paris. Fiberglass is not as exothermic as plaster of Paris and risk of burns is lower, yet the other principles of holding the cast as the fiberglass cures is the same as in plaster of Paris.

Cast Splitting

Casts are cut and split to decrease the pressure the limb experiences after trauma or surgery. In general, the more trauma (either from the trauma or the surgery performed) a limb experiences, the more edema that will ensue. Thus, minimally displaced fractures can often be managed without splitting a cast, while those requiring a closed or open reduction may initially need to be managed in a split cast or one padded with thick foam. Although splitting may be done prophylactically or as symptoms develop, the experienced clinician will often choose the former to avoid having to split the cast at a later time. Prophylactic cast splitting is often performed while the child is anesthetized or sedated and while this allows for a cooperative patient, great care should be taken when doing so. One must ensure that the plaster or fiberglass has set, that is hardened and cool, and that the blade temperature remains cool throughout the splitting process.

Decreased pressure in a limb can be obtained by cutting and spreading casts and after releasing the underlying padding. The effect of cast splitting depends on the material used, how it was applied, and whether or not the associated padding was split. Plaster cast cutting and spreading (univalve) can be expected to decrease 40% to 60% of the pressure and release of padding may increase this by 10% to 20%.[8,23,40,69] Fiberglass casts applied without stretch relaxation are known to be two times tighter than those applied with plaster[23] and in these cases bivalving the fiberglass cast would be needed to see similar decreases in pressure. Casts that are applied with the stretch relaxation method are among the least constrictive of fiberglass casts and therefore univalving may be sufficient as long as the cast can be spread and held open. However, many of these synthetic casts often spring back to their original position after simply cutting one side. Thus, it may be wise to use commercially available plastic cast wedges to help hold these split casts open.

FIGURE 4-9 The fiberglass is applied with stretch relaxation method. The fiberglass is unrolled first then placed over the body. (*Property of UW Pediatric Orthopaedics.*)

Although splitting casts is the traditional means of relieving cast tightness and allowing for swelling, use of thick foam is gaining acceptance at many centers (Fig. 4-10A, B). One of the editors uses ½-in sterile foam on most postoperative casts when concern for swelling is present. In this technique the foam is placed directly on skin, to make sure circumferential pressure is not caused by cast padding. Stockinette and cast padding are then applied, followed by fiberglass. This type of cast is not used to hold a closed reduction with cast molding, but works well for casts with internal fixation. Advantages of this cast include the strength of a circumferential cast, while allowing for swelling similar to a split cast.

Cast Removal

Typically casts are removed using an oscillating cast saw. These saws are designed to cut the hard cast material and not soft

A **B**

FIGURE 4-10 **A** and **B:** Foam padding is placed on skin, followed by cast padding, then fiberglass casting material. This allows for welling and provides strength, but does not hold fracture reduction. Ideally stockinette at the ends of the cast would make for better edges. (*Image property of Children's Hospital of Los Angeles.*)

FIGURE 4-11 Examples of cast saw burns. Initial injury photo **(A)** and after healing **(B). C:** A separate injury. Both of these injuries occurred when clubfoot casts were removed. (*Property of UW Pediatric Orthopaedics.*)

material such as padding or skin. In one report the incidence of cast saw burns occurring with the removal of casting material was found to be 0.72%[4] (Fig. 4-11). Cast removal may lead to significant morbidity and several precautions are needed. If a waterproof cast was applied using the Gore-Tex padding one must not forget to cut over the incorporated safety strips prior to removal of the fiberglass cast (Fig. 4-12A, B). These can assist in preventing injury from the saw as this type of padding is less heat resistant than the cotton padding.

Studies have shown that increased cast thickness, decreased padding, and increased blade use result in higher blade temperatures.[56] Thus, blades should be inspected and changed frequently as dull blades can increase the heat generated and potential for morbidity. Most importantly the technician who removes the cast must be well trained in the use of the saws. One common pitfall is to slide the oscillating saw along the cast thus increasing the chance of a cut or burn. Proper technique dictates that the blade be used by alternating firm pressure with relaxation into the material and then withdrawn before replacing it at a different location.[88] Furthermore, the technician should intermittently feel the blade and pause during the removal process when necessary to allow the blade to cool. This is essential when cutting long casts (i.e., long leg plaster).

Cast removal may lead to significant morbidity and several precautions are needed. Various safety shields are available; which, at the time of cast removal may be slid between the skin and the padding to prevent saw injury. To protect the skin, the cast saw must cut directly over the shield. Often times, the safety shield cannot be slid up the entirety of the cast, so extreme care must be taken in these areas where the skin is not

FIGURE 4-12 A: A cutaway picture showing the DE FLEX (W.L. Gore & Associates; Newark, Delaware) strip under the fiberglass casting tape. **B:** This strip will protect the skin from cast saw that has a propensity to cut easily through synthetic cast padding. (*Property of UW Pediatric Orthopaedics.*)

protected. Alternatively, safety strips may be incorporated into the cast at the time of cast application. If a waterproof cast was applied using the Gore-Tex padding one must not forget to cut over the incorporated safety strips prior to removal of the fiberglass cast (Fig. 4-12). These can assist in preventing injury from the saw, as this type of padding is less resistant than the cotton padding. Finally, new advances in differing types of saws may improve the safety of cast removal. For instance, some saws with a scissor-like do not become as hot. These saws are quieter and may reduce children's anxiety.

Cast Wedging

In a fresh fracture (usually less than 2 weeks old and prior to significant callus formation) in which initial reduction was obtained and subsequently is found to have an unacceptable loss of reduction, cast wedging of a well-fitting cast may be attempted. Many techniques for cast wedging have been described; however, the most recent description by Bebbington[6] appears to be easy to apply for simple angular deformities. The radiograph of the malaligned limb is used to trace the long axis of the bone onto a sheet of paper. The paper is then cut along this line. The cut edge of the paper is traced onto the cast, matching the position of the apex of the paper with the apex of the deformity. The cast is then cut, nearly circumferentially at this level, leaving a bridge of intact plaster only at the apex. Corks or cast wedges are applied opposite this bridge, until the line transferred on the cast is straight.

If this fails, the cast may need to be removed and the fracture either remanipulated or treated in some other fashion. Great care should be taken when performing cast wedging, especially in the tibia. The clinician needs to ensure that no excessive focal pressure is exerted at the bridge causing a pressure ulcer or nerve compression. Performing a "closing wedge" of a cast allows the bridge to be placed on the opposite side of the limb, which may be advantageous in certain circumstances, such as correcting a procurvatum or valgus deformity of the tibia. A disadvantage of a "closing wedge" is that it may pinch soft tissue. After performing a cast wedging, it is wise to observe the patient in the clinic long enough to reasonably ensure that any pain associated with the correction has abated and no pain because of focal pressure exists. If any concern exists, a new cast should be applied or a different treatment course taken.

Casting Over Surgical Wounds and Implants

Often casts are applied over surgical wounds. While the majority of these heal uneventfully, special attention should be given to casts applied over traumatic or surgical wounds. When applying a stockinette over a surgical wound, care should be taken to ensure the dressing is not "bunched up" under the liner. It is vitally important that wounds should not be dressed with circumferential cotton gauze as they may become constrictive with dried blood over time and act as a tourniquet. We prefer to use sterile cast padding, which is able to stretch with swelling and limit the gauze directly over the wound itself. Applying nonstick dressings directly to the wound aid in decreasing the anxiety of wound inspection during the cast removal process. Should unexplained pain, fevers, foul odors, drainage, or worsening pain occur; wounds should be inspected; however without these, routine inspection is not often necessary.

Bending the exposed ends of pins under a cast prevents excessive migration and allows for easy removal; however, migration of the bent end of the pin can occur. Sterile felt or antibiotic dressing may be placed at the pin site to help provide mechanical protection of soft tissue from migrating pins. Be aware that pin caps may become displaced and cause pressure sores. Cast padding should be placed over the pins to prevent them from sticking to the casting material as it hardens.

Although the technique of pins and plaster has largely disappeared from adult orthopedics, it can be used occasionally in pediatric orthopedics. In this technique, a fracture is reduced using pins that are placed percutaneously and incorporated into a cast to act essentially as an external fixator. The pin sites should be managed as any other exposed pin with an antibiotic dressing and/or sterile felt at the pin/skin interface. This technique allows the pins to be removed when callus formation is observed without removing the entire cast.

To inspect any area of concern under a cast, the cast can be removed, split, or windowed. The process of windowing involves localizing the area of concern and removing the overlying cast in this area without disrupting the alignment of the underlying bone. One may consider removing this window as a circular or oval piece to avoid creating any stress risers in the cast that may alter its structural integrity. However, attempting to cut "curves" with an oscillating saw places torque on the blade, increases blade temperature. These factors should be remembered when windowing a cast. Once the cast and padding materials are removed, the wound can be inspected. Once satisfied, equal depth of padding should be replaced over the wound and the window replaced. It may be taped in place if serial examinations are required or it may be overwrapped with casting tape. Failure to replace the window can lead to swelling through the window aperture.

Medical Comorbidities That Affect Cast Care

Even with application of a "perfect" cast, numerous medical issues may complicate tolerance of casting or lead to complications.[45] Children with myelomeningocele are susceptible to a number of casting complications. Pressure sores commonly occur in insensate children who do not experience or exhibit discomfort when irritation arises under the cast. Caution should be taken to avoid areas of increased pressure or overmolding when casting. In addition, the many fractures in children with myelomeningocele result from casting used for immobilization following elective surgery.[66] Iatrogenic fracture risk can be minimized by utilizing casting for as short a time frame as possible and/or use of a soft fiberglass casting material or a soft, bulky dressing that creates less of a stress riser on the bone.[66] Children with cerebral palsy are also at increased risk for pressure sores.[91] The contractures that likely contributed to the fracture may make casting or splinting difficult.[77] Similar approaches may be considered in children with malnutrition, renal osteodystrophy or other bone fragility disorders. An additional consideration in cases of malnutrition and diminished bone health includes

increased duration of fracture healing that may require longer periods of protection to prevent refracture.[29]

Children with obesity present their own complications. Although there are no studies documenting the outcomes of casting in obese children, studies on surgical treatment have demonstrated complications of refracture, wound infection, and failure of surgical fixation,[64,98] issues that likely have nonoperative correlates. Loss of alignment when adequate molding cannot occur because of increased soft tissues can occur. When casting an obese child, inclusion of an extra joint above and/or below the fracture may be required to maintain cast position. Diligent monitoring of alignment allows intervention with recasting, wedging, or transition to surgical intervention. Obese patients are more likely to undergo surgical treatment, as opposed to closed reduction, although it is unclear whether this is related to fracture severity or concerns regarding fracture stabilization.[81]

Alterations in casting materials or approaches may also be necessary in children with behavioral issues. Children with autistic-spectrum disorder present additional complexity during cast application (see discussion on distraction techniques), but even prior to cast application considering their behavior guides decision making regarding the most appropriate immobilization. Children with violent tendencies pose even more risk once a cast is applied, not only to others but also themselves. Administration of behavioral medications may improve tolerance of casting.[18] Soft splinting may be preferable, accepting some risk of malunion over likely secondary injury. Discussion and shared decision making with the parents result in the best management for an individual child and her family.

Children with dermatologic conditions require other considerations when deciding on best methods of immobilization. Children with atopic dermatitis may react to synthetic padding, so cotton may be more preferable. Splinting allows for better skin management, but when casting is required, minimizing duration or performing frequent cast changes allows for monitoring of skin conditions or early transition to splinting. Soft casting material contains diisocyanate which has been suspected, but not proven, as a skin irritant in isolated cases[60]; avoiding such material in children with significant skin sensitivity or disorders seems prudent. Windowing the cast over an area of skin breakdown or infection allows for monitoring of the area. Varicella presents an even more complex issue as widespread skin breakdown occurs predisposing to superinfection. Casting helps prevent skin breakdown by covering itchy lesions, but monitoring lesions is not possible. Again, splinting may be preferable to allow for monitoring if it does not compromise maintenance of fracture reduction; otherwise, windowing, or frequent cast changes may allow for skin monitoring. There should be a low threshold for removal of the cast if the child complains of pain to assess for not only compartment syndrome or infection, but also necrotizing fasciitis.[20,25]

Location-Specific Immobilization

Sugar-Tong Splint Immobilization

Sugar-tong splints provide effective temporary support to the wrist and forearm until definitive reduction and casting or internal fixation, while allowing for swelling. Sugar-tong splints can be used for definitive treatment provided the splint is comfortable and is retightened after 3 to 5 days to accommodate the decrease in swelling. At that point reapplication of an elastic bandage or overwrapping with fiberglass is appropriate.

FIGURE 4-13 The plaster roll for the sugar-tong splint is measured and is chosen to be wider than the arm without allowing for overlapping once the plaster slab is dipped and applied. (*Property of UW Pediatric Orthopaedics.*)

Before treating, the contralateral uninjured limb may be used as a template to measure and prepare an appropriate slab of casting material which should be wide enough to fully support the volar and dorsal surfaces of the arm (without radial and ulnar overlap) and long enough to span the arm from the volar MP flexion crease in the hand, around the elbow (flexed at 90 degrees), and dorsally to the metacarpal heads (Fig. 4-13). It is important that plaster splints are no more than 10 layers thick and of appropriate length so that edges do not have to be folded over (increasing thickness and the heat from curing). The slab is further customized to cut out material around the thumb base and tuck cuts are made at the elbow to prevent bunching of the material during the application.

The injured arm is reduced and positioned as described above, it is wrapped with three to four layers of cotton padding from the hand and around the elbow (similar thickness as that used for long-arm casting). The slab is dipped in cool water, excess water is removed and the material is rubbed and the layers incorporated for strength. The ends of the slab have two to three layers of padding applied which will fold back and make the edges soft (Fig. 4-14). The splint is applied and held

FIGURE 4-14 After dipped and applied, the slab is held on by one layer of cotton while tucks are cut in the plaster at the elbow to allow for overlap and minimal bunching. (*Property of UW Pediatric Orthopaedics.*)

FIGURE 4-16 The elastic bandage has been removed and replaced with a self-adherent elastic tape that has been loosely applied. (*Property of UW Pediatric Orthopaedics.*)

with one roll of cotton and then an elastic bandage is tightly applied until the material is hardened (Fig. 4-15) and then the bandage is replaced with a new elastic bandage applied without significant tension (Fig. 4-16). This method ensures an optimal fit without having the splint be too tight.

In the method described above, the arm is circumferentially wrapped with cotton and then a slab of plaster with padded ends is applied over it. This method is advantageous in ensuring a smooth interface of cotton without bunching under the plaster slab. If the clinician fears a lot of circumferential cotton padding could worsen swelling; an alternative method exists. In this instance, a long strip of padding is made by layering three to five layers of cotton and then the plaster slab is laid on top of it. The cotton is long and wide enough to ensure that there are no rough edges. The padded slab is then applied and wrapped as described above.

FIGURE 4-15 An elastic bandage is wrapped tightly to assist with terminal molding of the splint.

Long Arm 90-Degree Cast Immobilization

Case study 1: A 7-year-old girl with a both bone forearm fracture undergoes attempted closed reduction and long-arm cast application. She presents to clinic the following day where radiographs reveal angulation of 18 degrees in the AP plane and 5 in the lateral plane (Fig. 4-17A–D). Critical review of this case demonstrates a cast applied with too much padding and thus a poor fit, is too short in the long-arm portion, has too much plaster applied throughout the cast and especially in the antecubital fossa (increased risk for burn), and has a curved ulnar border that allows the arm to settle into the angulation. She is indicated for cast removal and re-reduction.

Fracture reduction and long-arm cast application is best done in a setting where the child is adequately sedated and where enough qualified personnel can apply the cast under fluoroscopic guidance, although this may not be possible in many locations. Fracture reduction technique may consist of: (1) Longitudinal

A

B

C, D

FIGURE 4-17 A 6-year-old girl with a both bone forearm fracture. Clinical pictures demonstrate a huge cast that does not adequately immobilize the elbow **(A, B)**. AP **(C)** and lateral **(D)** radiographs demonstrate a poorly fitting cast with ulna bow, excessive padding, too much plaster in the elbow flexion crease, and a resultant poor reduction. (*Property of UW Pediatric Orthopaedics.*)

traction; (2) manipulation recreating the deformity (Fig. 4-18); (3) reducing the fracture and placing the intact periosteum on tension; (4) three-point molding can be used in completely displaced fractures at the same level in the forearm; hand rotation is the final position to account for based on angulation. In both bone forearm fractures where the fractures are at differing levels, apex volar greenstick angulation is reduced with pronation and apex dorsal angulation is reduced with supination. It may be helpful to remember the "rule of thumb"—rotate the thumb toward the apex of the deformity aids in reduction. Thus an apex volar greenstick is reduced with pronation, and apex dorsal with supination. Optimal hand and wrist rotations can be ensured with the use of the fluoroscope prior to cast application.

In this instance longitudinal traction is used with an assistant while a thin layer of cotton padding is applied (Fig. 4-19). Alternatively, the fingers could be placed in finger traps with the elbow flexed just short of 90 degrees and with weights from the distal humerus. Individual strips of cotton are placed

FIGURE 4-18 The deformity is accentuated and hyperflexion followed by reduction can allow the displaced ends to become opposed. (*Property of UW Pediatric Orthopaedics.*)

and torn with tension to fit intimately on the posterior elbow thus avoiding too much anterior padding (Fig. 4-20). Cotton is rolled high in the axilla to ensure enough padding for the proximal trimline (Fig. 4-21). After padding is applied to the entire arm a small splint of five layers of plaster of Paris is fashioned to fit into the first web space (Fig. 4-22) and then incorporated with sequential layers of plaster (Fig. 4-23); we find that this method allows for a better fit in the hand. Plaster is pushed and

FIGURE 4-19 While the limb is held reduced with longitudinal traction applied by the assistant, cotton padding is applied and overlapped by 50%. (*Property of UW Pediatric Orthopaedics.*)

FIGURE 4-20 To pad the convexity of the elbow without excessively padding the concavity, cotton strips are placed and torn over the elbow to prevent cotton from bunching up in the antecubital fossa. (*Property of UW Pediatric Orthopaedics.*)

FIGURE 4-21 In this instance, stockinette was not used. Cotton is placed high in the axilla to have a soft edge at the proximal trimline of the plaster which will be applied more distal in the arm. (*Property of UW Pediatric Orthopaedics.*)

FIGURE 4-22 A small plaster splint fits nicely into the web space and will be incorporated in the plaster of the forearm portion. (*Property of UW Pediatric Orthopaedics.*)

unrolled up the arm to the elbow (Fig. 4-6) without lifting the plaster roll off the arm unless tucks are needed in the concavity. We prefer to apply plaster of Paris or fiberglass to a limb in stages by focusing and immobilizing one joint at a time; for long-arm casts we apply and mold the wrist and forearm and we extend the cast up over the elbow after the material has hardened. Once enough plaster is applied, the initial mold to incorporate the layers is started by rubbing the arm circumferentially (Fig. 4-24). As the plaster begins to harden, terminal molding of the arm is performed under fluoroscopy by flattening the plaster over the apex of the deformity (Fig. 4-25), molding the ulnar border with the flat of the hand (Fig. 4-26), and finally with some interosseus molding (Fig. 4-27) that will make the cast flatter and less cylindrical in cross section. Fluoroscopy images are obtained as the short-arm portion hardens before extending the cast up the humerus. If acceptable reduction is apparent, the antecubital fossa is inspected closely to detect and trim back cast material which may be too high and which could lead to neurovascular compromise. Decreased pressure in a limb can be obtained by using foam underneath the cast material or by cutting and spreading casts and after releasing the underlying padding. This method of applying the cast in two stages has the potential downside of edges of the short-arm cast digging into soft tissue proximally, so this must

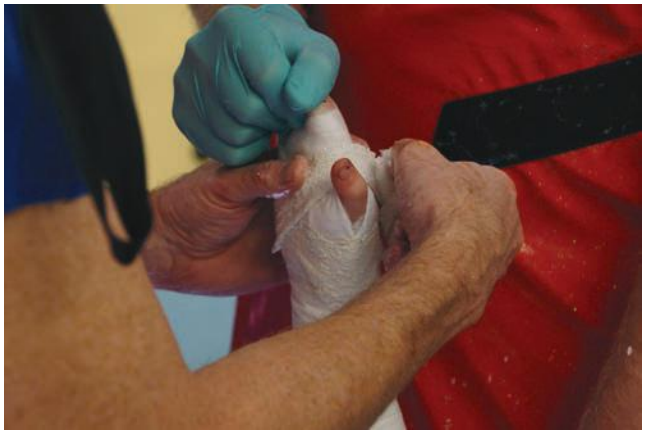

FIGURE 4-23 This splint is incorporated with rolls of plaster moving proximally. (*Property of UW Pediatric Orthopaedics.*)

FIGURE 4-24 The cast is initially molded to incorporate the fiber and plaster to make it stronger and to improve the fit. (*Property of UW Pediatric Orthopaedics.*)

FIGURE 4-25 Initial molding is performed to flatten the cast with a flat surface applied over the apex of the deformity. (*Property of UW Pediatric Orthopaedics.*)

FIGURE 4-26 Initial and terminal molding of the ulnar border will allow the cast to be straight and will resist ulnar sag of fracture fragments when the swelling goes down. (*Property of UW Pediatric Orthopaedics.*)

FIGURE 4-27 Gentle terminal interosseus mold keeps pressure on the apex, keeps the radius and ulna apart, and flattens the cast maintaining optimal cast index. (*Property of UW Pediatric Orthopaedics.*)

be avoided. As the cast is extended up the humerus, a small posterior splint can be applied to elbow convexity to decrease the tendency to fill the concavity of the elbow with thick exothermic plaster. The humerus portion is molded terminally by flattening the posterior humerus and molding along the supracondylar ridges. Plain radiographs are then obtained while the child is still sedated and if alignment is good the forearm cast is univalved and spread. In general the cast should be univalved and spread on the side of the arm which is opposite the direction of initial displacement; a fracture with a propensity for dorsal displacement should be split volarly and a fracture with a propensity for volar displacement should be split and spread along the dorsal surface. After 2 weeks, the plain radiographs demonstrate improved reduction and a more improved fitting cast (Fig. 4-28A, B).

Short-Arm Cast Immobilization

It should be noted that the above description of a long-arm cast application utilizing plaster, staged casting, splints, and univalving is the traditional method of casting preferred in many centers for displaced both bone diaphyseal fractures. Alternative methods include the use of fiberglass with the stretch relax technique, which generally does not require splints or univalving. As there are now good quality, randomized prospective studies showing that distal third both bone fractures are treated equally well in short or long-arm casts, short-arm cast immobilization is

FIGURE 4-28 **A:** AP and **(B)** lateral radiographs 2 weeks after the operative procedure demonstrate excellent maintenance of reduction and early healing. (*Property of UW Pediatric Orthopaedics.*)

FIGURE 4-29 Radiographs of a 7-year-old boy with a proximal both bone forearm fracture treated in a long-arm cast. The radius fracture is proximal to the ulna and this pattern is prone to loss reduction in a long-arm flexed cast as seen in this case with unacceptable alignment. (*Property of UW Pediatric Orthopaedics.*)

appropriate for most distal radius and ulna fractures. The technique of application is similar to that presented above; however, it is important that the distal cast be oval in cross section (Fig. 4-27) and the cast index (ratio of the AP cast width to lateral cast depth) to be near 0.7.

Long Arm–Thumb Spica Extension Cast Immobilization

Case study 2: A 6-year-old boy suffers a displaced both bone forearm fracture that is treated with long-arm cast application. Proximal and middle third both bone forearm fractures are harder to manage as there is less remodeling potential; further, when the radius is fractured proximal to the ulna one can often see more difficulty in holding the fractures reduced when the elbow is flexed. At 1 week, radiographs demonstrate loss in reduction with 30 degrees of angulation at the radius and the need for re-reduction (Fig. 4-29A, B).

In this instance we plan to reduce the arm with a combination of traction, pronation, and apex pressure with fluoroscopic guidance (Fig. 4-30). Once reduced, the arm is held with longitudinal traction, proximal and distal stockinet and cotton padding is applied for a long arm–thumb spica cast in extension (Fig. 4-31). Including the thumb in this cast will fully control forearm rotation while additionally maintaining the fracture out-to-length, which is obtained during the casting under traction. To prevent pressure sores over the thumb, extra padding is placed over the radial aspect of the anatomic snuff-box and

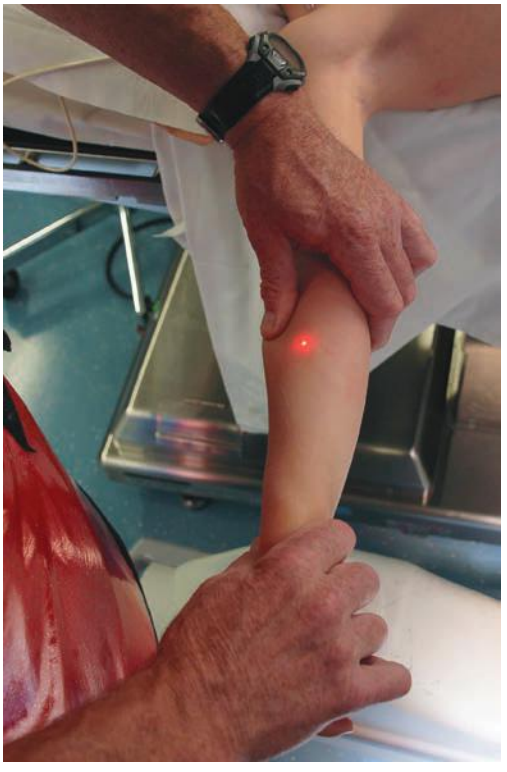

FIGURE 4-30 The arm is rotated under fluoroscopy to identify the rotation of the hand that best reduces the fracture. (*Property of UW Pediatric Orthopaedics.*)

FIGURE 4-31 The thumb spica cotton padding is applied. A moderate amount of padding is applied at the dorsal radial aspect of the thumb base. (*Property of UW Pediatric Orthopaedics.*)

FIGURE 4-33 Initial molding of the fiberglass is performed over the apex of the deformity. (*Property of UW Pediatric Orthopaedics.*)

thumb. The thumb spica portion of fiberglass is placed carefully out to the tip of the thumb whilst holding the thumb in neutral abduction and opposition (Fig. 4-32). The fiberglass is applied with 50% overlap and using the stretch relaxation technique; fluoroscopy is again utilized while terminal molding of the short-arm portion is performed in slight pronation and with broad pressure over the apex of the deformity (Fig. 4-33). The upper arm portion is next applied once the forearm portion is hardened and with the reduction confirmed under fluoroscopic imaging. As the upper fiberglass hardens, a supracondylar mold is applied with the arm in gentle traction as the butt of the surgeon's hand and thenar eminence terminally molds the fiberglass (Fig. 4-34); this mold in concert with the thumb spica mold should help to maintain rotation and length of the reduction. Final trimming and finishing the edges with the previously placed stockinette is done in the hand and the palmar trimline is cut back to allow MP finger flexion (Fig. 4-35). Finally the dorsum of the cast is univalved with a cast saw to allow for swelling; with fiberglass the cut edges of the cast need to be held open with commercially available spacers (Fig. 4-36) or other such material to keep the cast from springing closed; this is in contradistinction to plaster which can remain open once a terminally molded cast is spread. Plain radiographs after 3 weeks of immobilization confirm reduction of the fracture (Fig. 4-37).

FIGURE 4-32 Fiberglass is applied with the stretch relaxation method. (*Property of UW Pediatric Orthopaedics.*)

Thumb Spica Cast Immobilization

Usual incorporation of the thumb is needed for the extension cast described above as well as carpal injuries. Some surgeons include the thumb in all short-arm casts too. Regardless it's important to ensure the thumb is well padded and casted in

FIGURE 4-34 Supracondylar mold is applied above the elbow; this will prevent the cast from slipping down. (*Property of UW Pediatric Orthopaedics.*)

FIGURE 4-35 The hand portion is trimmed back to allow finger MP flexion and the spica portion of the cast is out to the tip of the thumb, which is neutrally placed. (*Property of UW Pediatric Orthopaedics.*)

FIGURE 4-36 The fiberglass cast is held open with a plastic spacer, univalved fiberglass casts tend to spring back while plaster casts tend to stay open. (*Property of UW Pediatric Orthopaedics.*)

a neutral position thumb abduction and opposition with well-padded distal trimline.

Shoulder Immobilization

Immobilization about the shoulder and the clavicle is somewhat limited when compared with other areas of the skeleton. Because of anatomic constraints about the shoulder it is often very challenging to gain a reduction of a bone (proximal humerus, clavicle); and it is not practical to expect that the fracture fragment to be firmly held in a reduced position. One historical exception may be the use of the shoulder spica cast for displaced proximal humerus fractures. Practically speaking this cast was challenging to apply and for the patient to wear and pediatric orthopedic trauma surgeons today would use internal fixation to maintain fracture reduction.

Despite the difficulty encountered when attempting reduction and firmly maintaining reduction with closed means, immobilization about the shoulder is used to provide comfort in the

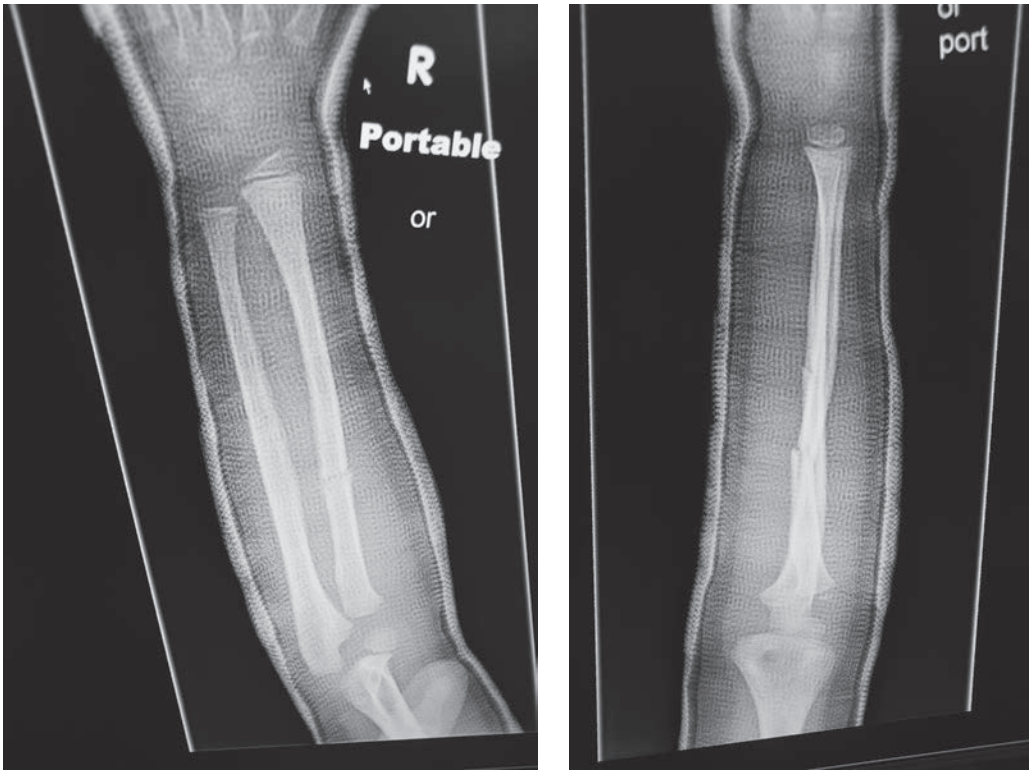

FIGURE 4-37 Radiographs obtained in the OR demonstrate excellent reduction and a well-fitting cast. (*Property of UW Pediatric Orthopaedics.*)

injured child. For clavicle fractures, a figure-of-8 collar or a shoulder sling can support the shoulder. Although the figure-of-8 collar was designed to retract the shoulder posteriorly and thus potentially reduce a shortened clavicle; practically the effect is minimal and the force needed to hold the shoulder back is often a challenge to the patient. Most patients find a personal preference between figure-of-8 collar and shoulder sling which is acceptable given equal clinical results between the two.

A proximal humerus fracture (whether treated nonoperatively or operatively) may be protected with immobilization with a sugar-tong splint. This splint is applied in stages. A slab of fiberglass or plaster is cut to a length that spans the proximal medial humerus (not too high in the axilla) and extends over the elbow and up the lateral aspect of the humerus up over the shoulder (Fig. 4-38). After dipping in water the slab is placed on appropriate padding and then applied to the arm. We find it helpful to wrap sugar-tong splints very tightly with an elastic bandage as this improves the mold and fit. The elastic bandage is removed when the splint material is hard and is replaced loosely with a new one. The common pitfalls with this type of immobilization include the medial splint edge in the axilla that is too thick or too high. In addition, when the lateral splint edge is too low and ends close to a fracture level, it does not immobilize and actually increases the lever arm forces at the fracture. This is due to the fact that the adjacent joints which are immobilized and that could normally move and decrease the length of the lever arm, cannot function as such.

Hanging arm casts can be used in proximal humerus and humeral shaft fractures. These synthetic long-arm casts are applied with the concept that gravity will act upon the humerus fracture and can be effective in gradually improving alignment in children with fractures that are minimally angulated or bayonet opposed. The children will have to sleep in an upright position for several weeks until the fracture is healed enough to be converted to splint immobilization. These casts are simple long-arm casts that do not require intimate molding; the weight of the cast will provide gradual distraction that aligns the fracture. Common pitfalls include a patient who cannot sleep upright and placing the neck collar attachment on the forearm too close to the elbow which could increase anterior angulation or placing the attachment too close to the wrist; which could lead to posterior angulation.

FIGURE 4-38 The plaster of a sugar-tong upper arm splint is folded over the shoulder and above the fractured proximal humerus fracture. (*Property of UW Pediatric Orthopaedics.*)

FIGURE 4-39 A 5 thickness posterior slab has been dipped and applied to the posterior foot and leg at the beginning of a short leg cast. Cuts have been made at the ankle to allow good overlap without bunching. This posterior splint brings thickness and strength to the posterior part and prevents anterior bunching of plaster over the ankle. (*Property of UW Pediatric Orthopaedics.*)

Short Leg Cast Application

Short leg casts are applied with goals of fully immobilizing the lower leg and keeping the ankle at 90 degrees while avoiding complications such as pressure sores. After applying proximal and distal stockinet the limb is wrapped with cotton padding and the ankle is held at 90 degrees. A potential pitfall is as the casting material is placed the ankle drifts into equinus, then as ankle flexion is restored to 90 degrees, casting material bunches up at the anterior ankle which can cause soft tissue damage over time as well as neurovascular constriction. To avoid excessive plaster of Paris cast material over the anterior ankle, a posterior splint of 5 layers thick is measured, and applied (Fig. 4-39) and then overwrapped with plaster rolls (Fig. 4-40).

FIGURE 4-40 Plaster is overlapped by half and rolled up the leg over the splint. (*Property of UW Pediatric Orthopaedics.*)

The ankle can be held at 90 degrees by the surgeon's torso and the plaster is carefully molded around the malleoli and the pretibial crest (Fig. 4-7). The cast should be hard and well cured; bivalving a wet cast will weaken it and the foot can drift into equinus. The cooled cast can be supported on a pillow with the ankle hanging free (Fig. 4-8). Once hardened the cast can be univalved and spread anteriorly if needed to accommodate swelling; if significant swelling is expected then the cast can be bivalved and spread with release of the cotton padding. Using fiberglass for short leg casts generally results in a lighter and stronger cast, but if fiberglass is improperly applied too tightly it can cause compartment syndrome.

Long Leg Cast Application

Long leg cast application incorporates all of the techniques above; once the short-leg portion has hardened the upper thigh is wrapped with padding and the knee (held in the chosen degree of flexion) and thigh is overwrapped with cast material. Care is needed to make sure the posterior trimline of the short-leg cast is not too high and which could be compressing in the popliteal fossa. The anterior knee portion can be reinforced with a splint and thus further decreasing the cast load in the popliteal fossa. Finally a medial and lateral supracondylar mold (similar to that in long-arm cast) can be used to support the weight of the cast and prevent distal migration. Plaster long leg casts can be heavy, as such we will use an all fiberglass cast or consider a composite cast whereby the short-leg portion is molded with plaster of Paris and then when hardened the proximal portion is placed with fiberglass.

Short Leg Splint Application

Posterior short leg splints are commonly used to immobilize the foot and ankle prior to definitive operative or nonoperative treatment and additionally to support the limb in the immediate postoperative period. These splints can accommodate significant swelling following trauma or surgery. Supplemental stirrup application may be needed in larger patients whose foot position cannot be controlled with a single posterior slab. In these cases, similar application methods and principles are used as seen in the upper extremity sugar-tong splint application.

Fundamental application includes holding the foot and ankle in 90 degrees of flexion while the limb is wrapped with four to six layers of cotton padding from the toes to the knee. A posterior slab of plaster is selected and should be wide enough to provide a medial and lateral trimline of an inch. It should be 10 layers thick; and measured similarly to that seen in short leg cast application described above. If needed a U-stirrup of plaster five layers thick is measured and is usually 1 to 2 inches narrower than the posterior plaster slab; this allows overlap of the two pieces of plaster without completely covering the anterior foot, ankle, and leg. Both the stirrup and the posterior slab are dipped in water and the proximal and distal trimlines are padded with three to four more layers of cast padding. The slab is applied posteriorly; any redundant material at the level of the heel can be cut away before the U-stirrup is applied with some overlap of the stirrup and the slab. The plaster is held in place with one layer of cast padding. An elastic bandage is applied tightly until the plaster is hard, and then removed to prevent constriction. This last layer of cast padding allows for easy removal of the final layer of loosely applied elastic bandage or self-adherent elastic tape.

Variances to this method are similar to sugar-tong splint application described above. For instance, some practitioners prefer to layer the wet plaster splint with 5 thicknesses of padding and apply the padded splint directly to the limb. This has advantages in minimizing circumferential wrapping of the limb with cotton; yet great care is needed to prevent inadvertent bunching or slipping of the padding.

Spica Cast Application

Spica casts can be applied from infants to adolescents and the location of application can vary according to age and clinical problem. For instance, infants and most children with painful injuries will require sedation and application in the supine position on a spica table. In contrast, a single leg spica cast can be used as an adjunct to internal fixation for femur fracture in large children or adolescents. These latter casts can be applied in a supine or even a standing position with a compliant and comfortable patient. Because of the size of the casts, most spica casts are constructed with synthetic cast material; plaster of Paris still has utility in small infants where a more intimate mold is used and where it's hard to conform fiberglass rolls.

Spica cast application in children is performed on a well-padded spica table which should be firmly attached to the OR bed or cart; one person should be responsible for managing the torso and making sure the child does not fall off the table; one to two assistants will support the legs while the anesthesia team manages the head and airway—this leaves the last of a four- to five-person team to apply the cast.

Before placing the child on the spica table a waterproof pantaloon or stockinet is applied to the torso and legs in some centers. Place a 2- to 4-in thick towel or other pad on the stomach and under the liner or stockinette, that will be removed when the cast is dry to have room for food and respiration. Note that if the patient starts to desaturate during spica cast application pulling out the abdomen padding frequently resolves this. The child is lifted onto the table and 3 to 6 thicknesses of padding are applied, with more at bony prominences such as over the patella and heels. It is also wise to completely cover the perineum with padding and high over the thorax; it is extremely hard to add padding once the cast material is applied (Fig. 4-41). After padding is appropriately applied, the thorax is wrapped with synthetic cast material (Fig. 4-9) and extended down over the uninjured thigh; care is needed to cover the "intern's triangle," this is the posterior area of the cast at the junction of the thigh, buttock, and thorax. Once the uninjured leg portion is hardened the injured leg is casted from proximal to distal. We recommend casting from the thorax, over the hip and to the distal thigh then extending over the knee and onto the distal leg as soon as the hip and thigh portion is firm; once the knee and leg portion is hardened then extend it down to include the foot and ankle. Care must be taken not to apply a short leg cast first, and use it to apply traction across the femur as this is associated with soft tissue problems and compartment

FIGURE 4-41 This 5-year-old child with a femur fracture is supported with three to four assistants as cotton padding is applied to the patient's body which is covered with a waterproof liner over a stack of towels placed as a spacer for his belly. (*Property of UW Pediatric Orthopaedics.*)

FIGURE 4-43 When finished the spica edges are well padded and incorporated into the cast. A small diaper is placed into the perineal region and then another diaper will be placed over this to hold it in place. (*Property of UW Pediatric Orthopaedics.*)

syndrome. In general we include the foot in neuromuscular patients who are prone to develop an equinus contracture and whose distal tibia is osteoporotic and prone to fracture at the level of the distal trimline. The risk of including the foot in a spica cast is soft tissue problems over the dorsal ankle. Once the final cast is hardened the perineal region is trimmed out and patient is removed from the spica table. The abdominal pad is removed and in some children a hole can be cut for further room (Fig. 4-42). Next appropriate radiographs are obtained and the trimlines are padded from rolling back the under padding and lining and incorporated with trim fiberglass. The decision to apply a bar from leg to leg is made based on the structural integrity of the cast. Usually this is not needed in small children and infants. Should a bar be needed then it is wise to wait until the cast is fully cured and the chance of a pressure sore is decreased. Nontoilet-trained infants and children need to have an absorbent pad (small diaper, ABD pad, or sanitary napkin) placed in the perineal region and then a diaper is placed over this (Fig. 4-43). Simply placing a diaper over the cast will not absorb the waste material, as the diaper will not be in contact before it tracks under the cast.

For length-stable diaphyseal femoral shaft fractures, many centers are now moving toward a single leg spica cast, which does not include the contralateral thigh and positions the hip and knee in less flexion and give the child the opportunity to ambulate with a walker or crutches.

Bone Remodeling

Fracture management in children affords the unique opportunity to correct residual deformity with remodeling as growth occurs. The mechanism whereby bone remodeling occurs is

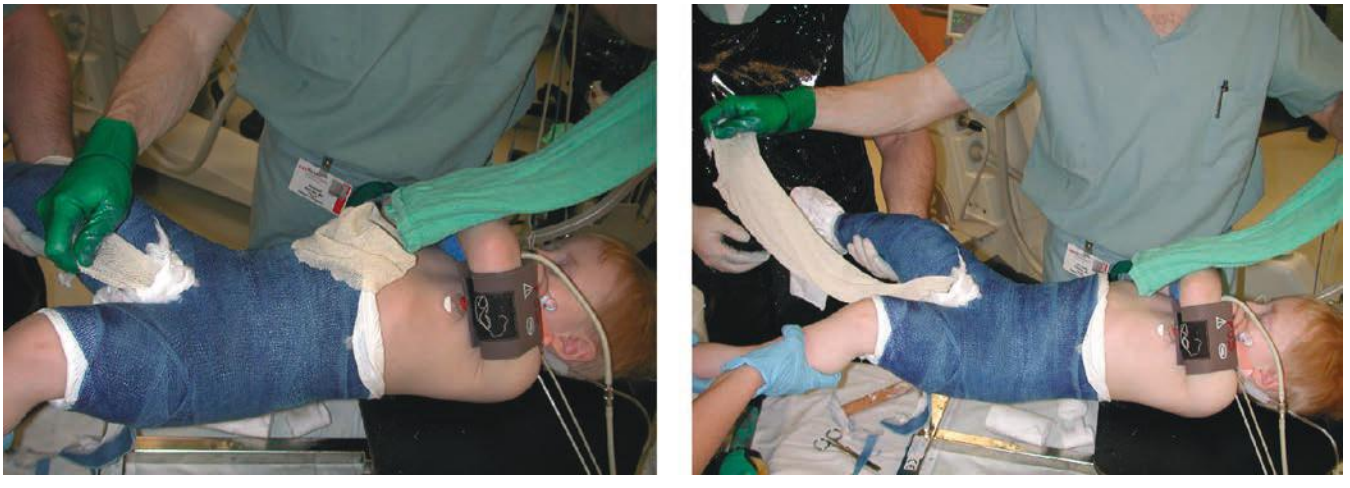

FIGURE 4-42 The abdominal pillow is removed after trimming away the perineal region.

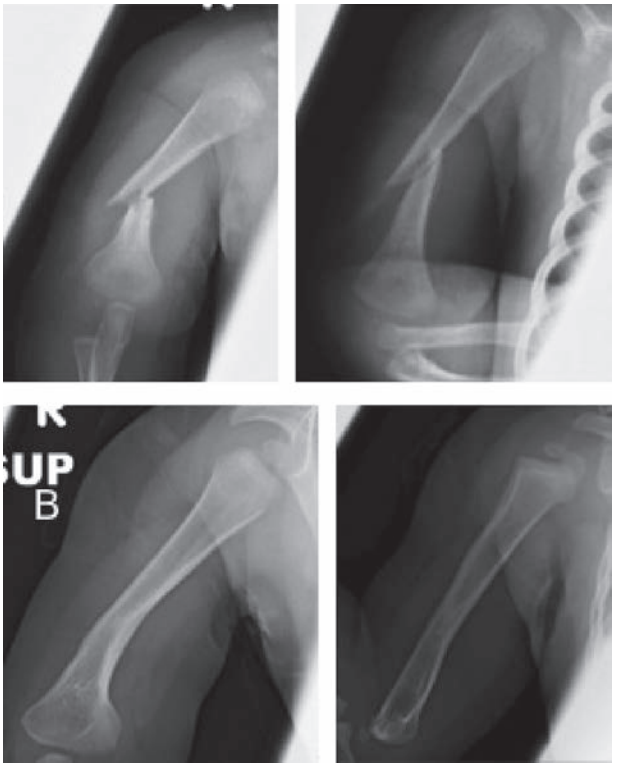

FIGURE 4-44 **A:** Alignment at 1 week in a newborn with a fracture sustained at birth. **B:** After 6 months significant remodeling has occurred, and no functional deficits are noted clinically. (*Property of UW Pediatric Orthopaedics.*)

discussed in the chapter on Bone Biology, but includes asymmetric growth of the physis in angular deformity resulting in overgrowth of the physis on the concave side of the deformity.[85] Seventy-five percent of remodeling occurs at the level of the physis, and remodeling at the level of the fracture also occurs through resorption along the convex side of the deformity with ossification along the concave side.[100] Angular deformities, translational deformities, and apposition undergo a relatively predictable path of remodeling that allows for acceptance of certain amounts of malalignment rather than needing to pursue surgical correction to restore anatomic alignment prior to fracture healing.[41] One notable exception is that rotational deformities may not remodel well and anatomic relationship within the axial plane should occur from the outset of fracture management.[22]

Deformities closer to rapidly growing physes retain greater remodeling potential (proximal humerus remodels well, whereas distal humerus remodels little, if at all), as do angular deformities that occur within the plane of motion of the closest joint (e.g., sagittal plane deformity corrects better than coronal plane deformity at a flexion–extension joint, such as the wrist or finger). Much of the remodeling likely takes place in the first year after fracture; a rate as high as 2.5 degrees per month for metaphyseal radial fractures, with a rate of 1.5 degrees per month for diaphyseal fractures.[79] Newborns, as expected, have the greatest ability for remodeling because 100% of bone mineral content turns over in the first year of life, resulting in remodeling of even dramatic deformity[53] (Fig. 4-44). As a child approaches skeletal maturity the ability to remodel decreases—

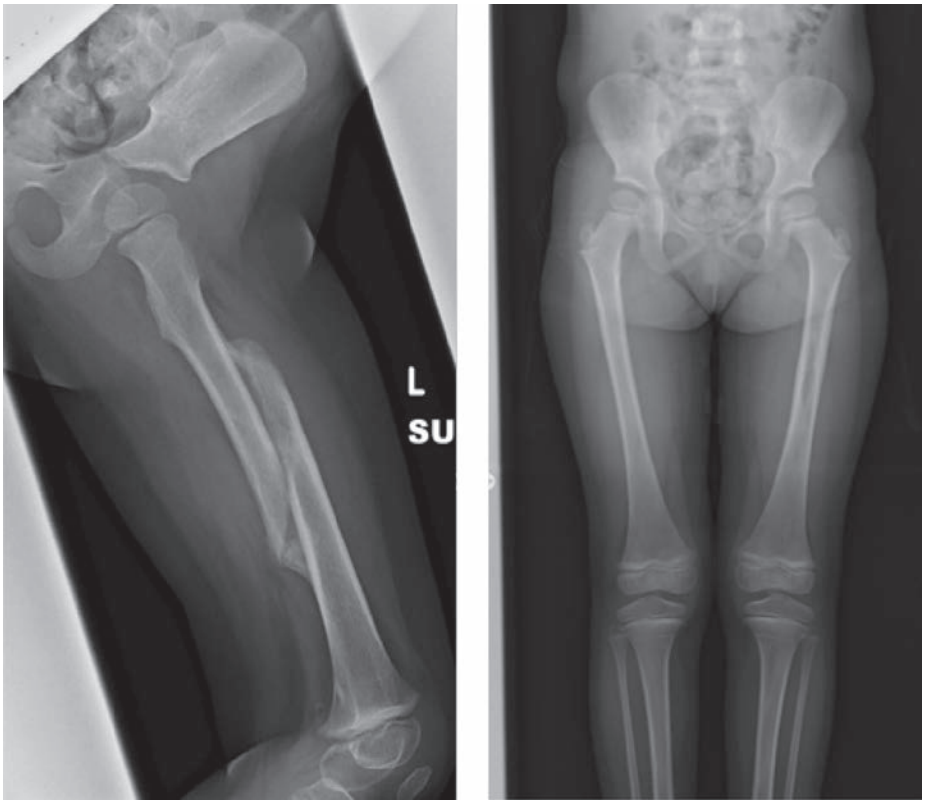

FIGURE 4-45 **A:** Femoral diaphyseal fracture that healed in 2 cm of shortening. **B:** After 1 year, femoral length has been almost fully restored through regrowth. (*Property of UW Pediatric Orthopaedics.*)

a child nearing skeletal maturity has minimal ability for remodeling so fracture alignment should be near-anatomic. As a result, acceptable, or allowable, deformity differs across various age ranges and anatomic locations of fractures. In general, 15 degrees of angulation is acceptable for fractures at nearly any location in a prepubertal child. Greater degrees of deformity may correct in younger children; although healing with malunion is not desired, it is likely more prudent, and cost-effective, to allow ample opportunity to remodel before undertaking surgical correction of deformity.[28]

One of the most extreme examples of the power of growth in the skeletally immature child is the ability of femur fractures, and occasionally tibia fractures, to "overgrow."[67,87] This may result in limb length discrepancy when the fracture heals at length, but provides opportunity for equalization of limb discrepancy when the fracture heals in a foreshortened position (Fig. 4-45). Overgrowth following fracture may occur through increased activity at the physes of the fractured, and possibly adjacent, bone(s).[32]

Top 15 Fractures to Avoid Missing, Underappreciating, or Undertreating

1. A 15-year-old hockey player is tripped and slides into the boards. He arises with the complaint of right-sided chest pain and mild shortness of breath. Tenderness is noted at the right sternoclavicular joint with minimal deformity. X-rays at urgent care were read as normal (Fig. 4-46A). He was experiencing some difficulty swallowing and slight shortness of breath, both of which improved over the next 3 weeks. After following-up in clinic, the correct diagnosis was suspected and a computed tomography (CT) obtained (Fig. 4-46B, C).

   Posteriorly displaced sternoclavicular fractures, as with dislocations, frequently result in restriction of cardiorespiratory function, occasionally nerve injury and, rarely, even death. Diagnosis by plain radiographs is difficult because of obscuration by the ribs on standard clavicle views and lack of a good orthogonal image. In the setting of traumatic

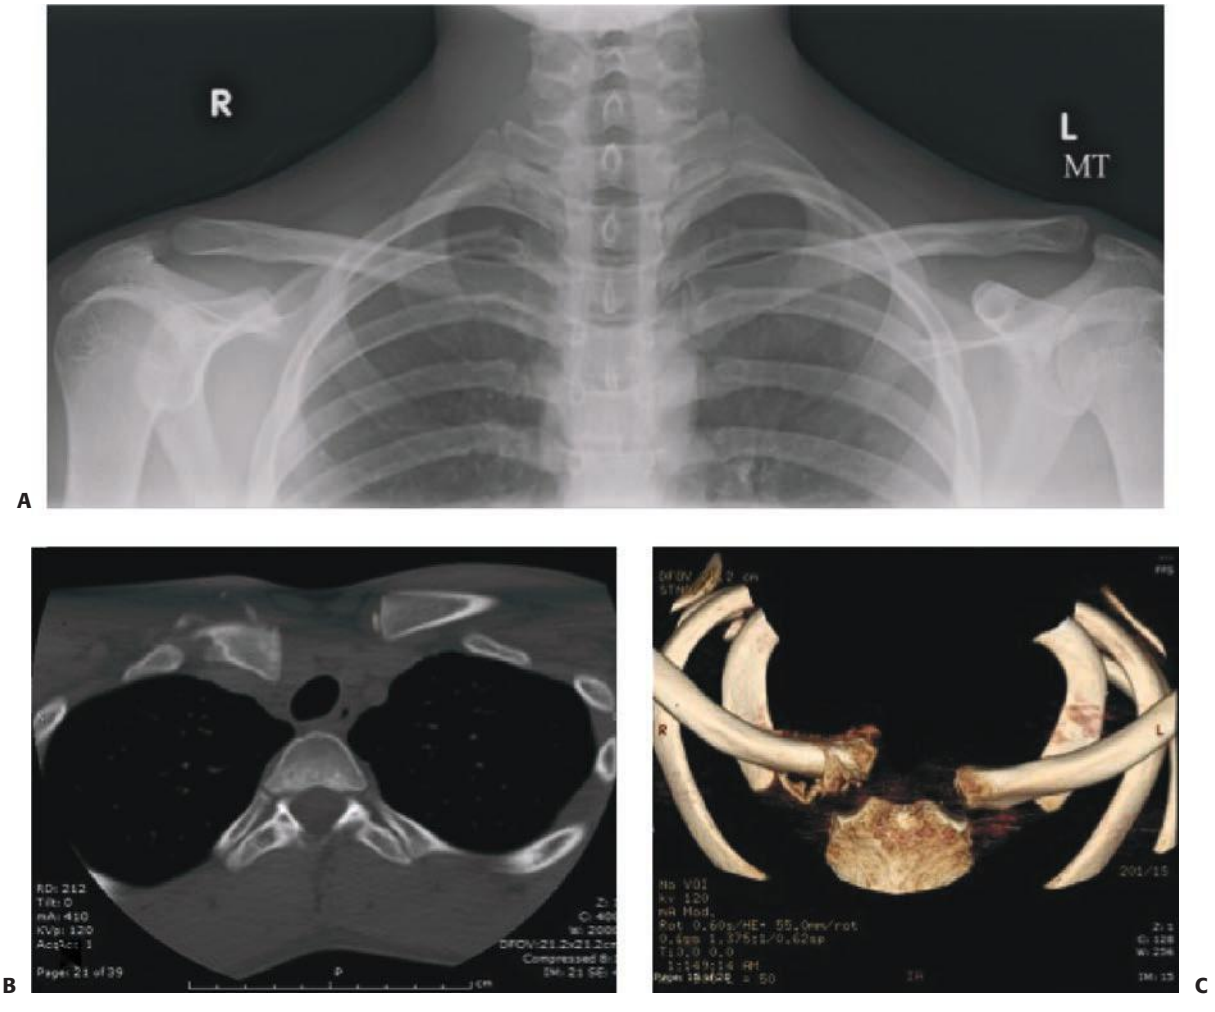

FIGURE 4-46 **A:** AP view of both clavicles does not demonstrate any obvious abnormality. **B:** Computed tomography 4 weeks later demonstrates posteriorly displaced proximal clavicle fracture, more fully appreciated on three-dimensional reconstruction **(C).** (*Used with permission from the Children's Orthopaedic Center, Los Angeles.*)

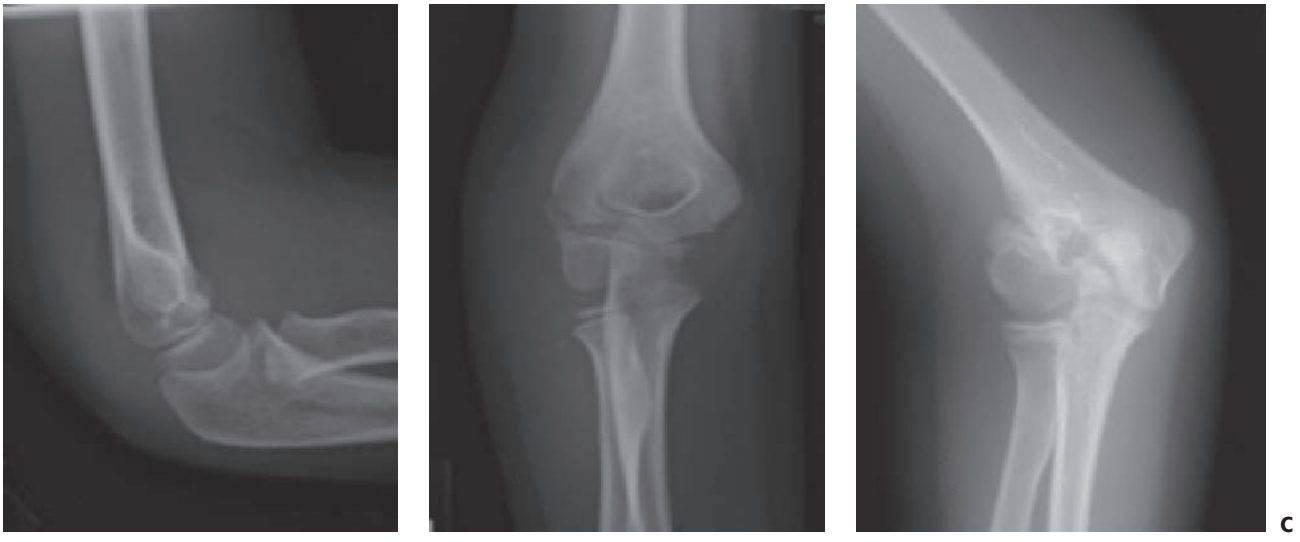

FIGURE 4-47 **A:** Lateral and **(B)** AP views at presentation demonstrating a minimally displaced lateral condyle fracture in a 4-year-old. **C:** AP radiograph in a 10-year-old with a prior lateral condyle fracture, now with nonunion and valgus deformity. (*Property of UW Pediatric Orthopaedics.*)

FIGURE 4-48 **A:** AP and **(B)** lateral of the unaffected right elbow with the medial epicondyle in anatomic position (*arrows*). The medial epicondyle is seen to be entrapped in the joint on both **(C)** AP and **(D)** lateral views (*arrowheads*). (*Property of UW Pediatric Orthopaedics.*)

onset of sternoclavicular pain, clinical suspicion should lead CT, the imaging modality of choice.[96]

2. A 4-year-old girl presents with right elbow pain after experiencing an injury from landing on the mat when jumping on a trampoline with her 13-year-old brother. AP and lateral radiographs demonstrated a nondisplaced lateral condyle fracture. After 4 weeks of casting the patient was released from care. Six years later she returns with clinical and radiographic deformities (Fig. 4-47).

   Stability of lateral condyle fractures may be difficult to discern on initial radiographs. Lateral condyle fractures with extension to the joint have a high propensity for displacement and nonunion. Additional views such as the internal oblique view, and close monitoring, are necessary to identify displacement and need for surgical fixation.[90]

3. A 10-year-old female dislocated her elbow and it popped back in place by her physician father. She has swelling throughout the elbow, bruising and tenderness medially to palpation. Radiographs reveal an ossific density overlying the distal humerus (Fig. 4-48).

   Medial epicondyle fractures occur in 50% of elbow dislocations or may occur as isolated injuries.[36] Dislocations create an opportunity for the avulsed medial epicondyle to become entrapped in the joint. Contralateral films or CT scan will help with identification.

4. A 2-year-old boy has an undefined elbow injury after a fall from his bed; radiographs were considered questionable for a distal humerus fracture, and an MRI was performed by his treating physician. This was suggestive of a distal humerus fracture, he was taken to the OR where an arthrogram demonstrated the injury and he underwent closed reduction and pinning (Fig. 4-49A–C).

   The distal humerus is the most common location for a transphyseal fracture. Transphyseal fractures may occur in the presence of a difficult extraction of a neonate or nonaccidental trauma, rarely occurring via other mechanisms. Infants commonly present with pseudoparalysis of the extremity, fussiness, and often a swollen joint. Radiographs appear normal as the fracture is an avulsion of the nonossified epiphysis through the physis with a minimal or no metaphyseal fragment. Neonates may do well[54] but at any other age, missed fractures have a high rate of avascular necrosis (AVN) of the medial condyle and subsequent cubitus varus.[74]

FIGURE 4-49 **A:** Less than optimal plain radiograph of an anxious crying 2-year-old is nondiagnostic for injury. **B:** Because of difficulty obtaining standard films and contralateral comparison films an MRI was obtained which demonstrates likely transphyseal fracture. **C:** Arthrogram before pinning demonstrates extension of the distal fragment. (*Property of UW Pediatric Orthopaedics.*)

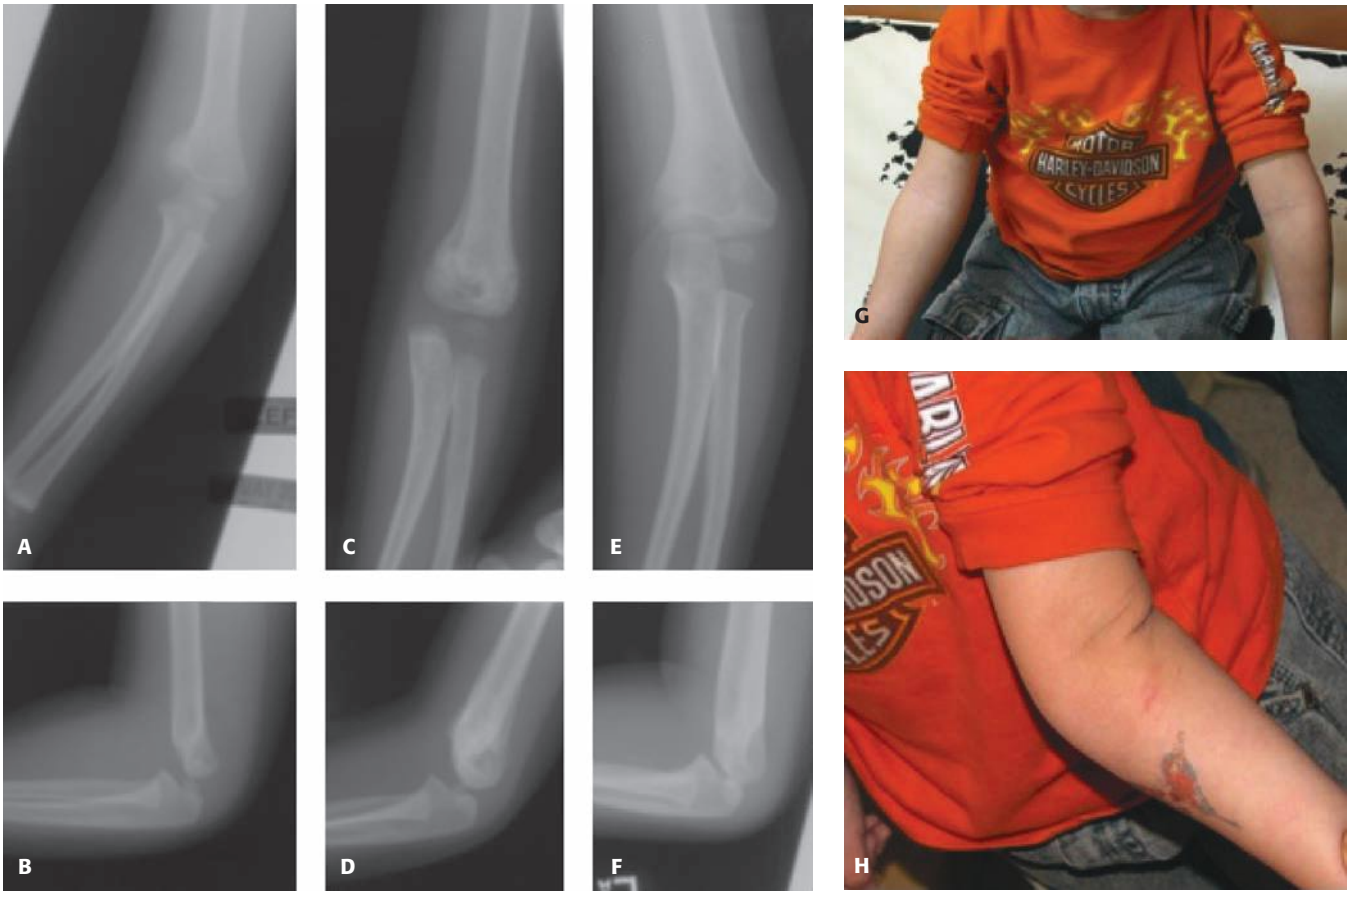

FIGURE 4-50 **A:** AP and **(B)** lateral views of the elbow demonstrating a type 2 supracondylar humerus fracture at presentation. **C** and **D:** Showing healing in varus and hyperextension. **E** and **F:** Imaging 3 years later shows persistent varus and extension without evidence of remodeling. Clinically, the patient has a gunstock deformity **(G)** and hyperextension **(H).** (*Property of UW Pediatric Orthopaedics.*)

5. A 5-year-old male presents with his parents with concerns regarding elbow deformity after a fracture at 2 years old. He has a gunstock deformity to his left elbow, which also hyperextends. Review of old radiographs, and new imaging, reveals a supracondylar humerus fracture treated conservatively that healed in extension and varus (Fig. 4-50).

   Type 2 supracondylar humerus fractures may rarely be amenable to nonsurgical treatment. Before doing so, alignment in the coronal and sagittal planes should be carefully assessed using contralateral films and measurement of Baumann angle to make sure the fracture is not in varus/valgus malalignment and/or hyperextension that requires reduction and/or surgical intervention.[102]

6. A 4-year-old female presents with arm deformity after falling off her bike. Neurovascular examination is normal. Radiographs reveal a diaphyseal ulna fracture. She is casted and goes on to good healing at 4 weeks. Six months later she returns with difficulty pronating and supinating her forearm; radiographs reveal malalignment of the radiocapitellar joint (Fig. 4-51).

   Numerous variations exist, but Monteggia fractures and their equivalents involve an ulnar fracture with associated radial head dislocation. Focus on the forearm frequently results in missing the radiocapitellar component either through ordering only forearm radiographs, excluding orthogonal visualization of the elbow, or a lack of proper interpretation of elbow radiographs. Missed or delayed diagnoses require surgical correction often with an increased risk of complications.[82]

7. A 12-year-old male presents with wrist pain and deformity after falling off a skateboard when going down a hill. He undergoes reduction of his distal radius metaphyseal fracture and goes on to full healing. Three years later he returns with wrist pain. Radiographs reveal ulnar shortening and growth arrest (Fig. 4-52).

   Nearly 50% of distal ulnar physeal fractures undergo growth arrest.[11] Nondisplaced ulnar physeal fractures may not be appreciated on initial imaging but will demonstrate evidence of healing 2 to 4 weeks after injury. When identified, follow-up imaging 6 to 9 months after injury helps identify growth arrest before it becomes clinically significant.

8. A 10-year-old male presents with pain and swelling about his 2nd finger after throwing a pass and getting his finger stuck in another player's face mask. Radiographs reveal a

FIGURE 4-51 **A:** AP and **(B)** lateral views of the forearm demonstrating ulnar diaphyseal fracture. Radial head dislocation can be appreciated on these views. **C** and **D:** Follow-up imaging did not include the elbow. **E:** Radial head dislocation is appreciated 6 months later. (*Property of UW Pediatric Orthopaedics.*)

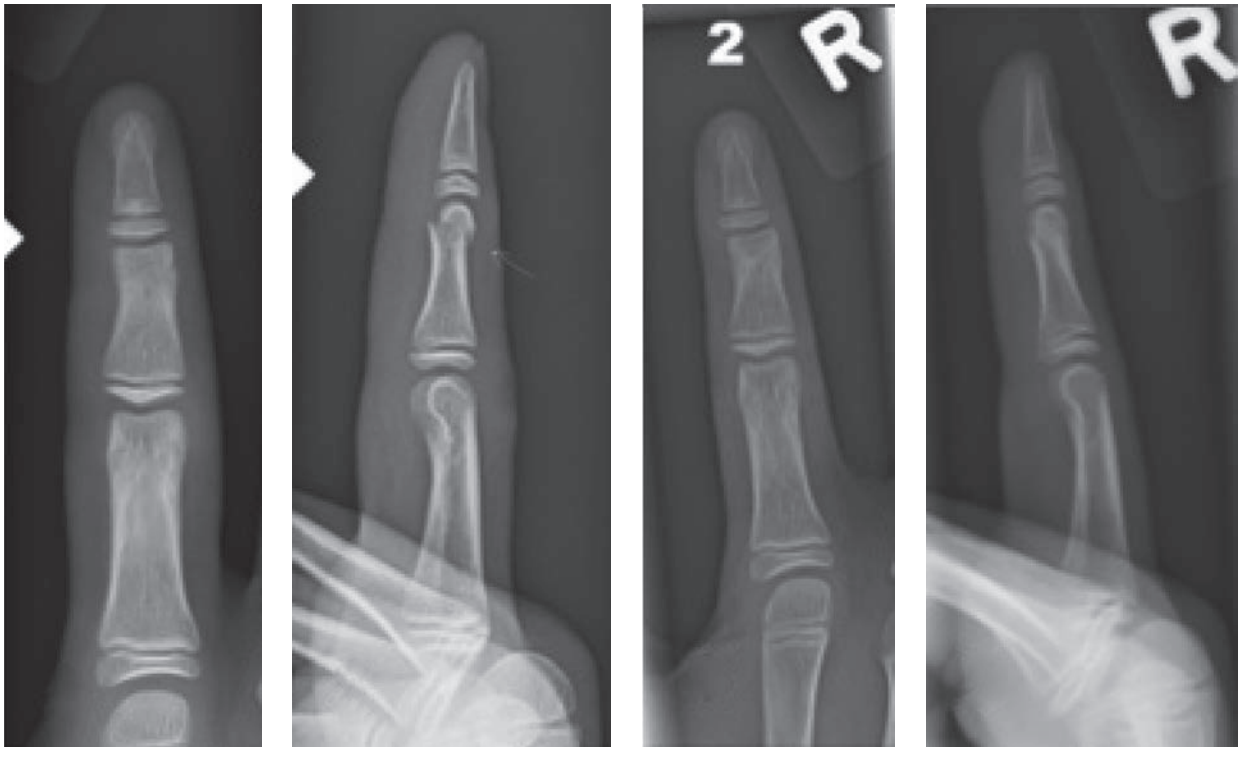
fracture through the distal phalangeal neck. He is reduced and splinted 3 months later he returns with no pain, but slightly limited flexion. Radiographs reveal adequate healing (Fig. 4-53).

Phalangeal neck fractures lead to limitation in motion because of fracture extension of the articular surface which leads to a block to flexion into the subcondylar fossa.[21] Remodeling is minimal, so radiographs require critical evaluation to determine need for reduction and fixation.

9. A 6-year-old male presents with right anterior distal thigh pain after a weekend at a local water park. No injury was noted. Radiographs of his knee are normal. He is told to follow up with orthopedics. One week later he presents with slightly improved discomfort, but persistent limp. Examination is remarkable for limited hip abduction and internal rotation. Radiographs of the pelvis reveal sclerosis of the proximal femur with confirmation of a suspected fracture on MRI (Fig. 4-54).

A B

FIGURE 4-52 **A** and **B:** Distal radius and ulna injury and at follow-up a growth arrest of the distal ulna presenting 3 years after initial injury. (*Property of UW Pediatric Orthopaedics.*)



A, B C, D

FIGURE 4-53 **A:** AP and **(B)** lateral views of index finger at presentation demonstrating phalangeal neck fracture. **C:** AP and **(D)** lateral views 3 months later show good healing, but the patient still has slight limitation of flexion. (*Property of UW Pediatric Orthopaedics.*)

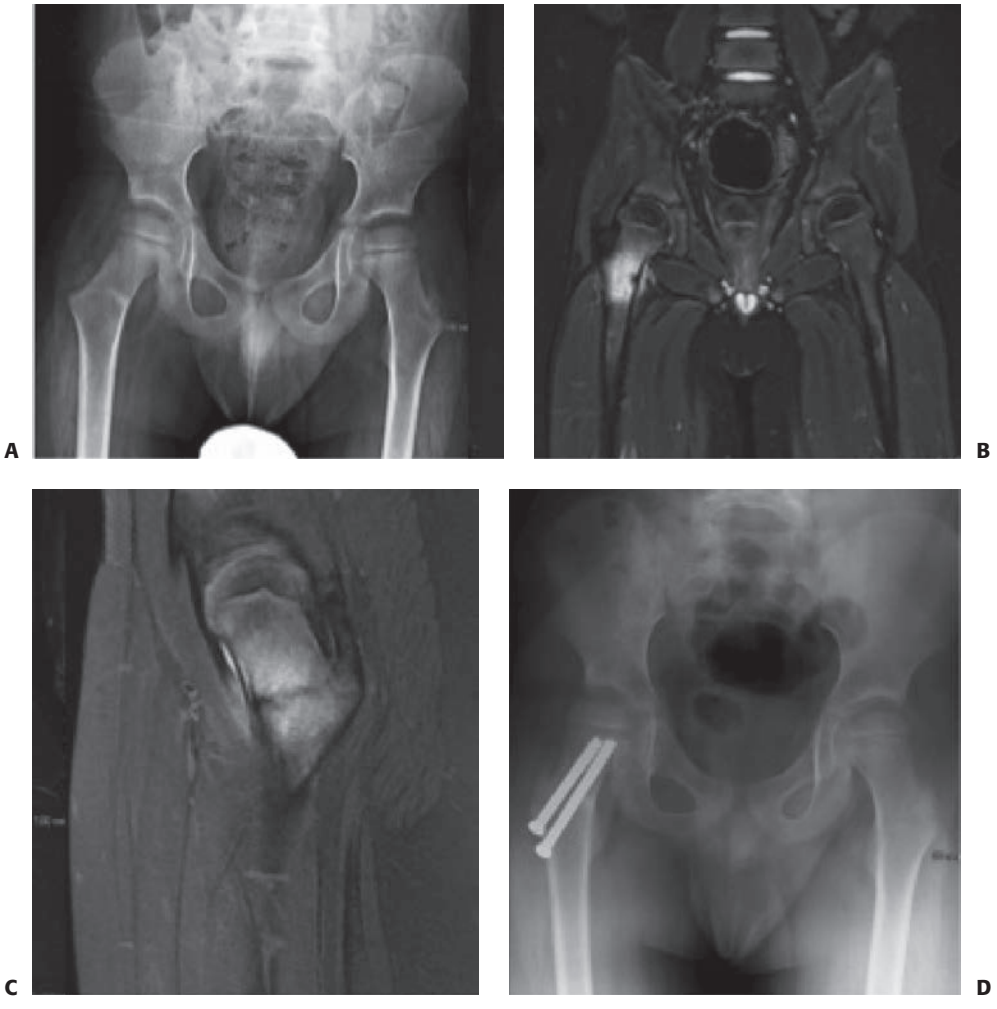


FIGURE 4-54 **A:** AP pelvis including both hips 1 week after onset of right knee pain demonstrating sclerosis at the inferior portion of the right femoral neck. **B** and **C:** MRI demonstrates a propagating fracture prompting **(D)** surgical fixation to prevent complete fracture and displacement. (*Property of UW Pediatric Orthopaedics.*)

Femoral neck fractures have catastrophic sequelae because of AVN.[24] Early recognition and intervention is necessary to prevent further displacement and AVN.

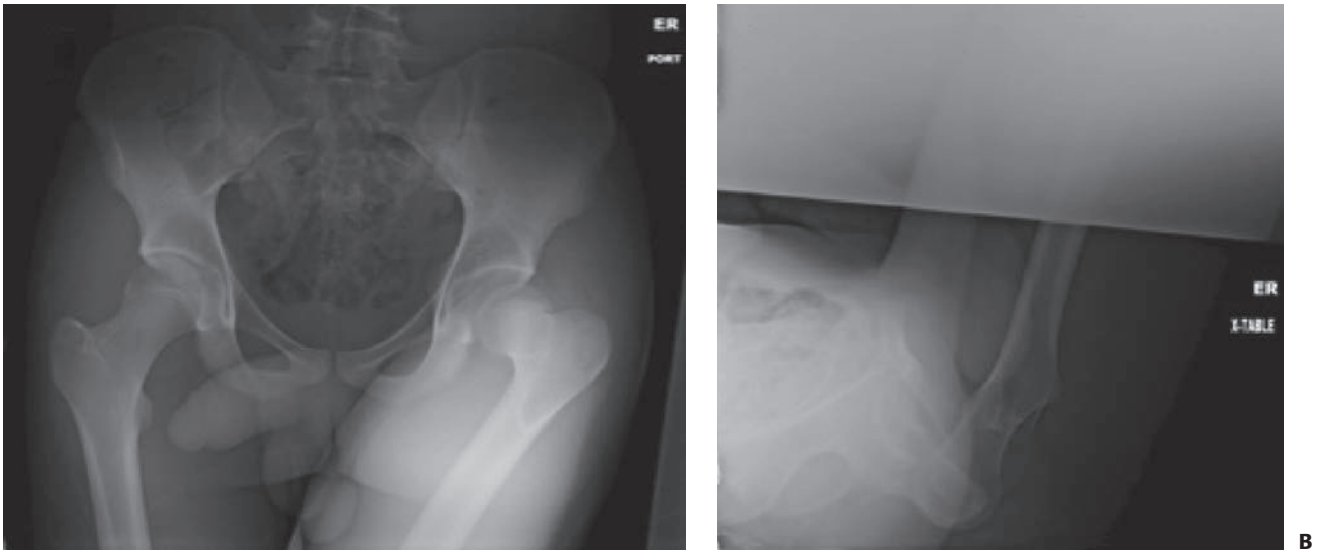
10. A 15-year-old male presents with acute onset of hip pain after being tackled while playing football and having his left thigh forcefully flexed up to his chest when landed on by another player. Radiographs demonstrate a left hip dislocation (Fig. 4-55).

    AP radiographs may be difficult to interpret, but lateral films usually confirm the dislocation. Prompt diagnosis and reduction under deep sedation or general anesthesia is critical to decrease the risk of subsequent AVN. Fluoroscopic imaging is used during reduction to detect concomitant physeal fracture during the reduction. Forced reduction (as would be encountered with poor sedation) and without radiographic monitoring could displace the femoral head through an unrecognized and injured physis in a skeletally immature child or adolescent.[49]

11. A 14-year-old female presents with swelling of her knee after coming down from a rebound in a basketball game. She is swollen throughout her knee but more so over her tibial tubercle. Radiographs identify a displaced avulsion fracture involving the anterior epiphysis and tubercle (Fig. 4-56). She is placed into a splint in extension and told to follow up with the orthopedist the next day. She returns to the emergency department 6 hours later with increased pain, paresthesias, and inability to move her foot or toes.

    Tibial tubercle fractures result in disruption of the extensor mechanism of the knee. Displaced fractures require surgical fixation and carry a risk of development of compartment syndrome.[70] As a result, patients should be admitted for observation.

12. A 12-year-old male presents to his primary physician with knee pain after falling while riding his bicycle. On examination he has an effusion, no areas of focal tenderness,



A B

FIGURE 4-55 **A:** AP pelvis of a patient with a traumatic left hip dislocation, the AP image does not clearly define the displacement posteriorly. **B:** Cross-table lateral views better demonstrate the posterior positioning of the femoral head. (*Property of UW Pediatric Orthopaedics.*)

and a negative Lachman maneuver. He is diagnosed with a sprain and placed into a knee immobilizer for comfort. He comes to clinic 4 weeks later because of persistent pain and swelling. Radiographs demonstrate a fracture involving the tibial eminence (Fig. 4-57).

FIGURE 4-56 Lateral view of the knee demonstrating a type III tibial tubercle fracture. (*Property of UW Pediatric Orthopaedics.*)

As opposed to adults who tear their anterior cruciate ligament (ACL), skeletally immature children who experience the same mechanism of trauma can avulse the tibial eminence. Any child with knee swelling following hyperextension trauma should undergo careful radiographic study. Radiographs should be closely scrutinized for displacement of the tibial spine to identify lesions that benefit from surgical intervention,[1] or immobilization. Despite the fact that the attachment of the ACL is disrupted, the Lachman test may be negative.

13. A 3-year-old male presents with pain in his leg after being fallen on by another child in a bounce house. Radiographs

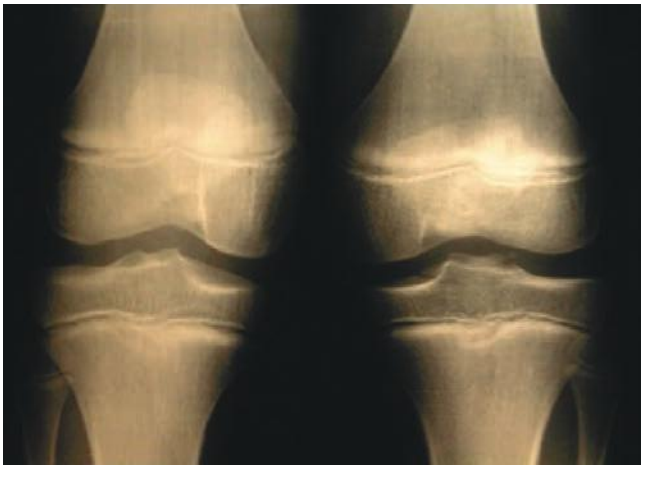


FIGURE 4-57 AP views of both knees demonstrating lucency through base of the tibial eminence of the left knee as well as a small avulsion off the lateral tibial spine. (*Property of UW Pediatric Orthopaedics.*)

FIGURE 4-58 A: AP and **(B)** lateral knee x-rays demonstrating a transverse fracture through the proximal tibia that underwent surgical reduction and fixation **(C).** Clinically, the patient developed a progressive valgus deformity of the left leg **(D). E:** Radiographs confirm a valgus deformity through the proximal tibia. (*Property of UW Pediatric Orthopaedics.*)

reveal a transverse fracture of the proximal tibial metaphysis that undergoes reduction and fixation in anatomic alignment. Twelve months later he returns with his parents for a "crooked leg." Radiographs reveal valgus angulation of the proximal tibia (Fig. 4-58).

Fractures of the proximal tibia can grow into valgus at the proximal growth plate over time. Progressive valgus alignment can occur after surgical or nonsurgical treatment. Alignment is likely to correct with continued bone growth[95,103] without intervention so observation for at least a year is indicated in most cases. However, surgical correction via hemiepiphysiodesis is occasionally needed. Awareness on the part of the physician and parents helps alleviate anxiety or need to pursue surgical correction when deformity occurs.

14. A 13-year-old female presents with ankle pain and swelling after tripping in the backyard when running after some friends. She says that she stepped in a depression in the ground while running down hill, lost her balance and fell. Radiographs are obtained demonstrating a Tillaux fracture of the distal tibia (Fig. 4-59).

    Transitional fractures of the distal tibial physis include the Tillaux fracture and the triplane fracture (Fig. 4-60), which occur as the physis begins to close. Vertical components in the sagittal plane may be difficult to identify. Plain radiographs often underestimate the true amount of fracture displacement, which is best seen on CT.[31,50]

15. A 2-year-old female presents following an injury to her fourth finger after being slammed in a car door. The nail is avulsed

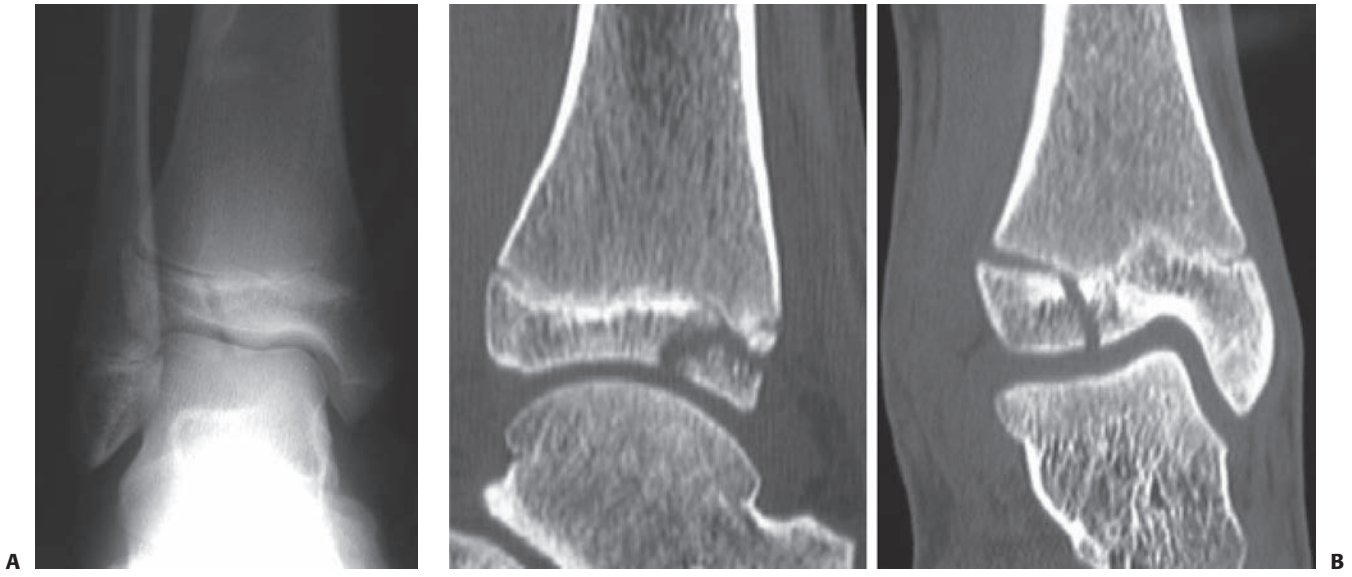

FIGURE 4-59 **A:** AP view demonstrating a Tillaux fracture with vertical, sagittal epiphyseal and horizontal, axial physeal components. **B:** Computed tomography is useful for defining transitional fracture pattern. In Triplane fractures there is a sagittal split (similar to that in Tillaux fractures) with a transverse fracture through the growth plate and an ascending coronal split up the metaphysis. (*Property of UW Pediatric Orthopaedics.*)

proximally with bleeding from the nail bed. Radiographs reveal a fracture of the distal phalanx with slight volar angulation (Fig. 4-61).

The eponymous Seymour fracture of the distal phalanx may occur in the hand or the foot and include a paraphyseal or physeal fracture of the distal phalanx with avulsion of the nail bed and often entrapment of the germinal matrix or extensor sheath within the fracture. Risk of infection and malunion occurs if the soft tissue component is not repaired.[30]

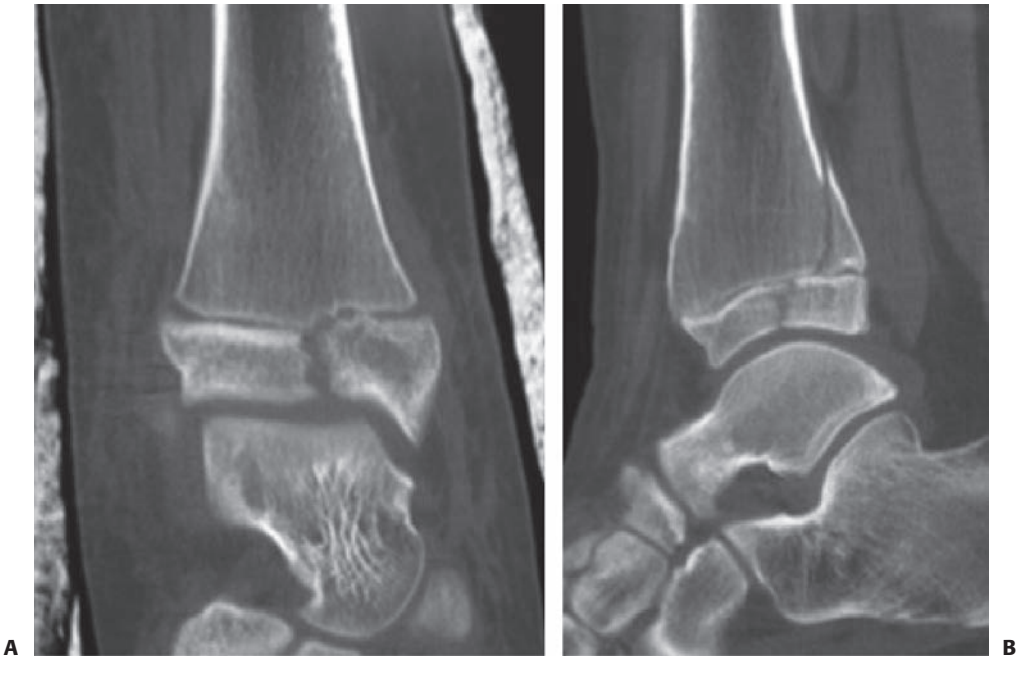

FIGURE 4-60 Computed tomography of a triplane fracture of the distal tibia which typically is involving vertical sagittal (epiphyseal), horizontal axial (physeal), and vertical coronal (metaphyseal) components. (*Property of UW Pediatric Orthopaedics.*)

FIGURE 4-61 **A:** Paraphyseal fracture lucency is seen as part of a distal phalanx fracture with nail bed avulsion. **B:** Lateral view reveals deformity. (*Property of UW Pediatric Orthopaedics.*)

CONCLUSION

In this chapter we highlight the pearls and pitfalls of cast and splint application in children with pediatric orthopedic trauma. This orthopedic subspecialty is one of the few in which an injury is more likely treated with these methods than surgical treatment. A dearth of prospective studies means that much art and personal preferences remain in cast and splint application. As time moves along and there are more innovative methods to treat fractures with surgery, the role of casting will not be supplanted, there will always be a need for a technically well-done cast that helps speed recovery in pediatric trauma. In our minds the many complications result from inappropriate use of the cast or splint to *obtain* correction; in contrast the cast or splint should be used to *maintain* reduction achieved either open or closed. Tight casts and bandages are also commonly associated with compartment syndrome. Problems such as tight casts, wet casts leading to infection, foreign objects in casts, and pressure ulcers are not uncommon. It is important to educate parents that small children may not adequately communicate problems occurring under a cast. It is good for us all to remember that in the words of Chad Price, MD, "there are no hypochondriacs in a cast."

5 MANAGEMENT OF THE MULTIPLY INJURED CHILD

Susan A. Scherl and Robert M. Kay

Role of the Pediatric Trauma Center

Key Concepts

- The American College of Surgeons has established specific criteria for pediatric trauma centers, which include the same principles of rapid transport and rapid treatment by an in-house surgical team as in adult trauma centers.
- Rapid assessment and treatment during the "golden hour" decreases mortality.
- There is increasing evidence that pediatric trauma centers do provide improved outcomes for severely injured children, but there are relatively few such centers, and many children will be stabilized or treated definitively at adult trauma centers.

After the rapid transport of wounded soldiers to a specialized treatment center proved effective in improving survival in the military setting, trauma centers, using the same principles of rapid transport and immediate care, have been established throughout the United States. These trauma centers are supported by the states on the premise that the first hour (the "golden hour")[42] after injury is the most critical in influencing the rates of survival from the injuries. Rapid helicopter or ambulance transport to an onsite team of trauma surgeons in the trauma center has led to an improvement in the rates of acute survival after multiple injuries have occurred.

The first trauma centers focused on adult patients because more adults than children are severely injured. However, pediatric trauma centers have been established at numerous medical centers across the United States with the idea that the care of pediatric polytrauma patients differs from the care given to adults and that special treatment centers are important for optimal results.[69,72,89] The American College of Surgeons has established specific criteria for pediatric trauma centers, which include the same principles of rapid transport and rapid treatment by an in-house surgical team as in adult trauma centers. A pediatric general surgeon is in the hospital at all times and heads the

pediatric trauma team. This surgeon evaluates the child first, and the other surgical specialists are immediately available. General radiographic services and computed tomography (CT) capability must be available at all times for patient evaluation, and an operating room must be immediately available.

There is increasing evidence that survival rates and outcomes for severely injured and younger children are improved at a pediatric trauma center compared to a community hospital.[3,47,50,120,133,179,185] However, the costs associated with such a center (particularly the costs of on-call personnel) have limited the number of existing pediatric trauma centers. Therefore, pediatric trauma patients are often stabilized at other hospitals before transfer to a pediatric trauma center, or treated definitively at an adult trauma center. One European cohort study comparing 2,961 pediatric polytrauma patients to 21,435 adults, found that the "golden hour" for pediatric patients often elapses in the field, or is consumed during transfer between hospitals.[216]

Larson et al.[100] reported that there did not appear to be better outcomes for pediatric trauma patients flown directly to a pediatric trauma center than for those stabilized at nontrauma centers before transfer to the same pediatric trauma center. Other centers have documented the need for improved transfer coordination.[159,182]

Knudson et al.[97] studied the results of pediatric multiple injury care in an adult level 1 trauma center and concluded that the results were comparable to national standards for pediatric trauma care. Sanchez et al.[162] reported that adolescent trauma patients admitted to an adult surgical intensive care unit (SICU) had similar outcomes to comparable patients admitted to a pediatric intensive care unit (PICU) in a single institution. However, those admitted to the SICU were more likely to be intubated and to have a Swan–Ganz catheter placed and had longer ICU stays and longer hospital stays.[162] The use of a general trauma center for pediatric trauma care may be an acceptable alternative if it is not feasible to fund a separate pediatric trauma center.

Initial Resuscitation and Evaluation

Key Concepts

- Regardless of the mechanism causing the multiple injuries, the initial medical management focuses on the life-threatening, nonorthopedic injuries to stabilize the child's condition.[122]
- Initial resuscitation follows the Advanced Trauma Life Support (ATLS) or Pediatric Advanced Life Support (PALS) protocols.
- The primary survey comprises the "ABCs": Airway, Breathing, Circulation, Disability (neurologic), and Exposure and screening radiographs (cervical spine, chest, and pelvis).
- Hypovolemia is the most common cause of shock in pediatric trauma patients so early and adequate fluid resuscitation is critical.[165]

Initial Evaluation

The initial steps in resuscitation of a child are essentially the same as those used for an adult.[6,43,122] The primary survey begins with assessment of the "ABCs," Airway, Breathing, Circulation, Disability (neurologic), and Exposure, followed by screening radiographs (cervical spine, chest, and pelvis). In severe injuries, the establishment of an adequate airway immediately at the accident site often means the difference between life and death. The cervical spine needs to be stabilized for transport if the child is unconscious, there is facial trauma, or if neck pain is present (Fig. 5-1). A special transport board with a cutout for the occipital area is recommended for children younger than 6 years of age because the size of the head at this age is larger in relation to the rest of the body. Because of this larger head size, if a young child is placed on a normal transport board, the cervical spine is flexed, a position that is best avoided if a neck injury is suspected.[77]

FIGURE 5-1 Temporary cervical spine stabilization is imperative in any child with multitrauma, especially those who are unconscious or complain of neck pain.

Fluid Replacement

Once an adequate airway is established, the amount of hemorrhage from the injury, either internally or externally, is assessed. This blood loss is replaced initially with intravenous (IV) crystalloid solution. In younger children, rapid IV access may be difficult. In this situation, the use of intraosseous fluid infusion via a large bore needle into the tibial metaphysis can usually be placed within 1 to 2 minutes and has been found safe and effective for IV fluids and drug delivery during resuscitation. Bielski et al.,[16] in a rabbit tibia model, likewise demonstrated no adverse effects on the histology of bone or the adjacent physis with intraosseous injection of various resuscitation drugs and fluids.

Because death is common if hypovolemic shock is not rapidly reversed, the child's blood pressure must be maintained at an adequate level for organ perfusion. Most multiply injured children have sustained blunt trauma rather than penetrating injuries, and most of the blood loss from visceral injury or from pelvic and femoral fractures is internal and may be easily underestimated at first. The "triad of death," consisting of acidosis, hypothermia, and coagulopathy, has been described in trauma patients as a result of hypovolemia and the systemic response to trauma.[212] Peterson et al.[142] reported that an initial base deficit of eight portends an increased mortality risk.

Despite the need to stabilize the child's blood pressure, caution needs to be exercised in children with head injuries so that overhydration is avoided because cerebral edema is better treated with relative fluid restriction. Excessive fluid replacement also may lead to further internal fluid shifts, which often produce a drop in the arterial oxygenation from interstitial pulmonary edema, especially when there has been direct trauma to the thorax and lungs. In some instances, to accurately assess the appropriate amount of fluid replacement, a central venous catheter is inserted during initial resuscitation. A urinary catheter is essential during the resuscitation to monitor urine output as a means of gauging adequate organ perfusion.

Evaluation and Assessment

Key Concepts

- Trauma rating systems have two functions: To aid in triage, and to predict outcomes.
- There are many rating systems, each with strengths and weaknesses.
- Of the commonly used systems, both the Injury Severity Score (ISS) and Glasgow Coma Score have predictive value for prognosis.
- The secondary survey is a systematic examination of the patient from head to toe.
- It includes a complete history, physical examination, focused radiographs, and adjunctive imaging studies such as CT and MRI scans.

Trauma Rating Systems

After initial resuscitation has stabilized the injured child's condition, it is essential to perform a quick but thorough check for other injuries. At this point in the evaluation, a trauma rating is often performed. The purpose of the trauma rating is twofold: To aid in triage, and to predict outcomes. Several trauma rating systems have been validated for the pediatric population,[5,21,34,54,147,149,167,168,178,193] but the most commonly utilized are the Glasgow Coma Scale (GCS), the Injury Severity Score (ISS), and the Pediatric Trauma Score (PTS). Each of the scoring systems has strengths and weaknesses. The ISS is a valid, reproducible rating system that can be widely applied in the pediatric polytrauma setting (Table 5-1).[211] It is an ordinal, not a linear scale (i.e., a score of 40 is not twice as bad as a score of 20). It has been found to be a valid predictor of mortality, length of hospital stay, and cost of care.[24] Another injury rating system for children that has been shown to be valid and reproducible is the PTS (Table 5-2).[211] It has good predictive value for injury severity, mortality, and the need for transport to a pediatric trauma center; however, it is a poor predictor of internal injury in children with abdominal blunt trauma.[160] The injury rating system chosen varies among trauma centers, but whether the ISS or PTS is used, each allows an objective means to assess mortality risk at the time of initial treatment, as well as allowing some degree of prediction of future disability.[138,186,218]

Head injury is most often evaluated and rated by the GCS, which evaluates eye opening (1 to 4 points), motor function (1 to 6 points), and verbal function (1 to 5 points) on a total scale of 3 to 15 points (Table 5-3).[192] There are some limitations in the use of the GCS in children who are preverbal or who are in the early verbal stages of development, but in other children this rating system has been a useful guide for predicting early mortality and later disability. A relative head injury severity scale (RHISS) has been validated[44] and is available in trauma registries, thus is useful for comparative studies of large populations. As a rough guide in verbal children, a GCS score of less than 8 points indicates a significantly worse chance of survival for these children than for those with a GCS of more than 8. The GCS should be noted on arrival in the trauma center and again 1 hour after the child arrives at the hospital. Serial changes in the GCS correlate with improvement or worsening of the neurologic injury. Repeated GCS assessments over the initial 72 hours after injury may be of prognostic significance. In addition to the level of oxygenation present at the initial presentation to the hospital, the 72-hour GCS motor response score has been noted to be very predictive of later permanent disability as a sequel to the head injury.[70,125,219]

Physical Assessment

The secondary survey starts with a full history and physical examination. In a child with multiple injuries, a careful abdominal examination is essential to allow early detection of injuries to the liver, spleen, pancreas, or kidneys. Ecchymosis on the abdominal wall must be noted, because this is often a sign of significant visceral or spinal injury.[29,175] In one series, 48% (22/46) of children with such ecchymosis required abdominal exploration,[29] whereas in another series 23% (14/61) of children were noted to have spine fractures.[175]

Swelling, deformity, or crepitus in any extremity is noted, and appropriate imaging studies are arranged to evaluate potential extremity injuries more fully. If extremity deformity is present, it is important to determine whether the fracture is open or closed. Sites of external bleeding are examined, and pressure dressings are applied if necessary to prevent further blood loss. A pelvic fracture combined with one or more other skeletal injuries has been suggested to be a marker for the presence of head and abdominal injuries.[206] Major arterial injuries associated with fractures of the extremity are usually diagnosed early by the lack of a peripheral pulse. However, abdominal venous injuries caused by blunt trauma are less common and are less commonly diagnosed before exploratory laparotomy. About half of abdominal venous injuries have been reported to be fatal, so the trauma surgeon needs to consider this diagnosis in children who continue to require substantial blood volume support after the initial resuscitation has been completed.[59]

Initial splinting of suspected extremity fractures is routinely done in the field. However, once the injured child is in the hospital, the orthopedist should personally inspect the extremities to determine the urgency with which definitive treatment is needed. Most important are whether a vascular injury has occurred, whether the fracture is open or closed.

TABLE 5-1 Injury Severity Score

Abbreviated Injury Scale (AIS)

The AIS classifies injuries as moderate, severe, serious, critical, and fatal for each of the five major body systems. The criteria for each system into the various categories are listed in a series of charts for each level of severity. Each level of severity is given a numerical code (1–5). The criteria for severe level (Code 4) is listed below.

Severity Code	(AIS) Severity Category/ Injury Description	Policy Code
4	Severe (Life-threatening, Survival Probable)	B

General

Severe lacerations and/or avulsions with dangerous hemorrhage; 30–50% surface second- or third-degree burns.

Head and Neck

Cerebral injury with or without skull fracture, with unconsciousness >15 min, with definite abnormal neurologic signs; posttraumatic amnesia 3–12 h; compound skull fracture.

Chest

Open chest wounds; flail chest; pneumomediastinum; myocardial contusion without circulatory embarrassment; pericardial injuries.

Abdomen

Minor laceration of intra-abdominal contents (ruptured spleen, kidney, and injuries to tail of pancreas); intraperitoneal bladder rupture; avulsion of the genitals.
Thoracic and/or lumbar spine fractures with paraplegia.

Extremities

Multiple closed long-bone fractures; amputation of limbs.

Injury Severity Score (ISS)

The injury severity score (ISS) is a combination of values obtained from the AIS. The ISS is the sum of the squares of the highest AIS grade in each of the three most severely injured areas. For example, a person with a laceration of the aorta (AIS = 5), multiple closed long-bone fractures (AIS = 4), and retroperitoneal hemorrhage (AIS = 3) would have an injury severity score of 50 (25 + 16 + 9). The highest possible score for a person with trauma to a single area is 25. The use of the ISS has dramatically increased the correlation between the severity and mortality. The range of severity is from 0–75.

Adapted from Committee on Medical Aspects of Automotive Safety. Rating the severity of tissue damage. I. The abbreviated scale. *JAMA*. 1971;215(2):277–280; Baker SP, O'Neill B, Haddon W Jr, et al. The Injury Severity Score: A method for describing patients with multiple injuries and evaluating emergency care. *J Trauma*. 1974; 14:187–196.

The back and spine should be carefully examined. If there is noopen fracture and if the peripheral vascular function is normal, there is less urgency in treating the fracture and splinting will suffice until the other organ system injuries are stabilized.

Splinting decreases the child's pain while the child is resuscitated and stabilized and minimizes additional trauma to the soft tissue envelope surrounding the fracture. Splinting also facilitates transport of the child within the hospital while the trauma workup, including appropriate imaging studies, is completed. If the child is to be transferred to a trauma center, splints are invaluable for patient comfort and safety during transfer.

Any evident neurologic deficit is noted to document the extremity function before any treatment. It is important to remember that a detailed neurologic examination may not be possible because these are often young and scared children who are in pain and may have a central nervous system injury. The inability to obtain a reliable examination should also be documented.

Head injuries and extreme pain in certain locations can result in some injuries being missed initially. In a series of 149 pediatric polytrauma patients, 13 injuries were diagnosed an average of 15 days following the initial accident, including five fractures (one involving the spine), four abdominal injuries, two aneurysms, one head injury, and one facial fracture.[85,109] Given this

TABLE 5-2 Pediatric Trauma Score

	Category		
Component	+2	+1	–1
Size	≥20 kg	10–20 kg	<10 kg
Airway	Normal	Maintainable	Unmaintainable
Systolic Blood Pressure	≥90 mm Hg	90–50 mm Hg	<50 mm Hg
Central Nervous System	Awake	Obtunded/LOC	Coma/decerebrate
Open Wound	None	Minor	Major/penetrating
Skeletal	None	Closed fracture	Open/multiple fractures

This scoring system includes six common determinants of the clinical condition in the injured child. Each of the six determinants is assigned a grade: +2, minimal or no injury; +1, minor or potentially major injury; –1, major, or immediate life-threatening injury. The scoring system is arranged in a manner standard with advanced trauma life support protocol, and thereby provides a quick assessment scheme. The ranges are from –6 for a severely traumatized child to +12 for a least traumatized child. This system has been confirmed in its reliability as a predictor of injury severity.

Adapted from Tepas JJ 3rd, Mollitt DL, Talbert JL, et al. The Pediatric Trauma Score as a predictor of injury severity in the injured child. *J Pediatr Surg.* 1987;22(1):14–18, with permission.

9% incidence of delayed diagnosis, it is imperative that polytrauma patients be reexamined once they are more comfortable to reassess for potential sites of injury. In some cases, despite careful inpatient reevaluations, some pediatric injuries escape detection until later follow-up visits. In addition, children with head injuries need to be reassessed once they awaken enough to cooperate with reexamination. Families and patients need to be informed of the frequency of delayed diagnosis of some injuries in polytrauma patients so that they can partner with the medical team in recognizing such injuries (often evident as previously undetected sites of pain or dysfunction).

TABLE 5-3 Glasgow Coma Scale

Response	Action	Score
Best motor response	Obeys	M6
	Localizes	5
	Withdraws	4
	Abnormal flexion	3
	Extensor response	2
	Nil	1
Verbal response	Oriented	V5
	Confused conversation	4
	Inappropriate words	3
	Incomprehensible sounds	2
	Nil	1
Eye opening	Spontaneous	E4
	To speech	3
	To pain	2
	Nil	1

This scale is used to measure the level of consciousness using the eye opening, best verbal, and best motor responses. The range of scores is from 3 for the most severe to 15 for the least severe. This is a measure of level and progression of changes in consciousness.

Adapted from Jennett B, Teasdale G, Galbraith S, et al. Severe head injuries in three countries. *J Neurol Neurosurg Psychiatry.* 1977;40(3):291–298, with permission.

Imaging Studies

Radiographs

Imaging studies should be obtained as quickly as possible after the initial resuscitation and physical examination. Any extremity suspected of having a significant injury should be examined on radiograph. Primary screening radiographs classically consist of a cross-table lateral cervical spine, anteroposterior chest, and anteroposterior pelvis.[53,150] In some centers, a lateral cervical spine radiograph is obtained only if the child has a head injury or if neck pain is noted on physical examination. Some centers evaluate the cervical spine with a CT scan in children with polytrauma who have neck pain, a traumatic brain injury (TBI), or who have been drinking alcohol.[161] Further workup with cervical spine magnetic resonance imaging (MRI) is necessary before cervical spine clearance in those who have persistent neck pain or tenderness despite normal plain films and CT, and should be considered in patients who remain obtunded (see "Magnetic Resonance Imaging").

If a cervical spine injury is present, the lateral radiograph of this area will detect it in 80% of cases.[105] If there is suspicion of a cervical spine injury on the neutral lateral view, a lateral flexion radiograph of the cervical spine taken in an awake patient will help detect any cervical instability. The cervical spine of a young child is much more flexible than the cervical spine in an adult. Under the age of 12 years, the movement of C1 on C2 during flexion of the neck can normally be up to 5 mm, whereas in adults, this distance should be less than 3 mm. Likewise in this young age group, the distance between C2 and C3 is up to 3 mm. No forward movement of C2 on C3 should be present in a skeletally mature individual when the neck is flexed. This so-called pseudosubluxation of C2 on C3 in a child should not be diagnosed as instability that requires treatment because this is a normal finding in young children.[33] Because it is difficult to detect a fracture of the thoracic or lumbar spine clinically, radiographs of this area, primarily a lateral view, should be carefully evaluated, particularly in a comatose child.

Computed Tomography

CT is essential in evaluating a child with multiple injuries. If a head injury is present, CT of the head will detect skull fractures and intracranial bleeding. With abdominal swelling, pain, or bruising, CT of the abdomen with IV contrast provides excellent visualization of the liver and spleen and allows quantification of the amount of hemorrhage present. Because most hepatic and splenic lacerations are treated nonoperatively,[29,79,155] the CT scan and serial hematocrit levels are used to determine whether surgical treatment of these visceral lacerations is needed.

CT of the pelvis is more sensitive for pelvic fractures than is a screening pelvic radiograph (Fig. 5-2). In one study, a screening pelvic radiograph demonstrated only 54% of pelvic fractures identified on CT scan.[66] CT also is useful for thoroughly evaluating fracture configuration and determining appropriate treatment options, both surgical and nonsurgical. If abdominal CT is being done to evaluate visceral injury, it is simple to request that the abdominal CT be extended distally to include the pelvis. CT of a fractured vertebra will provide the information needed to classify the fracture as stable or unstable and determine whether operative treatment is needed.

Intravenous Pyelography

There is a strong correlation of urologic injury with anterior pelvic fractures, as well as with liver and spleen injury. Although CT and ultrasonography are used to evaluate renal injuries, the IV pyelogram still has a role in helping to diagnose bladder and urethral injuries.[136] Regardless of the methods of imaging, the anatomy of the urethral disruption often cannot be accurately demonstrated preoperatively.[4]

Radionuclide Scans

Bone scans have a limited role in the acute evaluation of a child with multiple injuries. In conjunction with a skeletal survey, a technetium-99m bone scan is sometimes used in children with suspected child abuse to detect previously undetected new or old fractures.[75,94,123]

Heinrich et al.[75] reported that bone scans in 48 children with multiple injuries often demonstrated an unsuspected injury. Nineteen previously unrecognized fractures were identified by obtaining radiographs of the areas with increased isotope uptake. In addition, there were 66 false-positive areas of increased uptake in the 48 patients. Of their 48 patients, six had a change in their orthopedic care as a result of this bone scan, although this treatment was usually simple cast immobilization of a nondisplaced fracture. In some instances, the bone scan can be useful to differentiate a normal variation in skeletal ossification (normal uptake) from a fracture (increased uptake), particularly in an extremity or a spinal area where pain is present. Areas of increased uptake require further imaging studies to determine if orthopedic treatment is required.

FIGURE 5-2 CT is an excellent addition to radiographs for evaluation of pelvic fractures.

Magnetic Resonance Imaging

MRI is used primarily for the detection of injury to the brain or the spine and spinal cord. In young children, the bony spine is more elastic than the spinal cord. As a result, a spinal cord injury can occur without an obvious spinal fracture in children with multiple injuries, particularly in automobile accidents.[9,22,57] In the spinal cord injury without radiographic abnormality (SCIWORA) syndrome, MRI is valuable in demonstrating the site and extent of spinal cord injury and in defining the level of injury to the disks or vertebral apophysis. A fracture through the vertebral apophysis is similar to a fracture through the physis of a long bone and may not be obvious on planar radiographs. MRI in obtunded and intubated pediatric trauma patients has been reported to lead to a quicker cervical spine clearance with a resulting decrease in hospital stay and cost.[61]

MRI is also useful in evaluating knee injuries,[118] particularly when a hemarthrosis is present. If blood is present on knee arthrocentesis, MRI can assist in diagnosing an injury to the cruciate ligaments or menisci. In addition, a chondral fracture that cannot be seen on routine radiographs may be demonstrated by MRI.

Ultrasonography

Ultrasound evaluation has been shown to be an accurate means of detecting hemopericardium and intraperitoneal fluid following injury. Some trauma centers have replaced peritoneal lavage and laparoscopy with serial ultrasound evaluations to monitor liver, spleen, pancreas, and kidney injury in children with multiple injuries.[27,79,155] The protocol most typically used is called "Focused Assessment with Sonography for Trauma" (FAST). FAST consists of a rapid ultrasound examination of four areas: The right upper abdominal quadrant, the left upper abdominal quadrant, the subxiphoid area, and the pelvis. The role of FAST in the evaluation of pediatric trauma patients is still being established.[39,55,80,81,184] As a result, CT is more often used for assessment and monitoring of visceral injury in children sustaining multiple injuries. Comparisons of CT and ultrasonography have demonstrated the superiority of CT for diagnosing visceral injury in children with polytrauma,[39,131,152,187] but there is evidence that hemodynamically unstable children with a positive FAST should be taken for laparotomy rather than for CT scanning.[113]

Nonorthopedic Conditions in the Multiply Injured Child

Key Concepts

- Head injury severity is the principle determinant of morbidity and mortality in a multiply injured child.
- Children often make substantial recovery from even severe head trauma.
- Management of orthopedic injuries in children with head trauma should be based on the presumption of full recovery from the head injury.
- Spasticity and contracture are common sequelae of brain injury, and should be addressed early.
- There is an association between pediatric pelvic fractures and both intra-abdominal and genitourinary injuries.
- Motion at the site of a long-bone fracture results in increased intracranial pressure (ICP). To control ICP, it is imperative that long-bone fractures are immobilized until definitive fracture care can be provided.

Head Injury

Prognosis for Recovery

Head injuries occur in children with multiple injuries even more often than orthopedic injuries. In a review of 494 pediatric polytrauma patients, Letts et al.[109] reported closed head injuries in 17% and skull fractures in 12%, whereas Schalamon et al.[166] reported injuries to the head and neck region in 87% of pediatric polytrauma patients. It has been clearly demonstrated that a child recovers more quickly and more fully from a significant head injury than does an adult.[40,112,214] Even children who are in a coma for hours to days often recover full motor function. Mild cognitive or learning deficits may persist, so educational testing needs to be considered for children who have had head injury and coma. Two factors that have been linked to poorer functional recovery and more severe permanent neurologic deficits are a low oxygen saturation level at the time of presentation to the hospital and a low GCS score 72 hours after the head injury. In fact, the severity of TBI is the single most important determinant of long-term outcome in polytraumatized children.[87] Because children with head injuries are often transported long distances, evacuation of a cerebral hematoma within 4 hours is not always possible.[190]

Despite the fact that excellent motor recovery is expected in most children after a head injury, children are often left with significant residual cognitive deficits. Many children who sustain TBIs are unaware of their residual cognitive limitations and tend to overestimate their mental capacities.[71] Children who have had a TBI also often have behavioral problems, the presence of which may be predictive of behavioral problems in uninjured siblings as well.[188] Greenspan and MacKenzie[65] reported that 55% of children in their series had one or more health problems at 1-year follow-up, many of which were relatively minor. Headaches were present in 32% and extremity complaints in 13% of patients. The presence of a lower extremity injury with a head injury led to a higher risk of residual problems.

Because of the more optimistic outlook for children with head injuries than for adults with similar injuries, timely orthopedic care should be provided, and the orthopedist should base the orthopedic care on the assumption of full neurologic recovery. Waiting for a child to recover from a coma is not appropriate, and comatose children tolerate general anesthesia well. Unless the musculoskeletal injuries are treated with the assumption that full neurologic recovery will take place, long-bone fractures may heal in angled or shortened positions. In the absence of optimal orthopedic care, once neurologic recovery occurs, the primary functional deficit will be from ill-managed orthopedic injuries rather than from the neurologic injury.

Intracranial Pressure

After a head injury, ICP is commonly monitored to prevent excessive pressure, which may lead to further permanent disability or death. Normally, ICP does not exceed 15 mm Hg, and all attempts should be made to keep the pressure under 30 mm Hg after a head injury. This is accomplished by elevating the head of the bed to 30 degrees, lowering the PCO2, and restricting IV fluid administration. Ventilator assistance is used to lower the PCO2, which helps lessen cerebral edema. Fluid restriction also is recommended if peripheral perfusion can be maintained despite the polytrauma. Elevation of serum norepinephrine has been shown to correlate well with the severity of head injury in patients with injury of multiple organ systems.[215]

Motion at the site of a long-bone fracture results in increased ICP. To control ICP, it is imperative that long-bone fractures are immobilized until definitive fracture care can be provided. Initial immobilization is usually accomplished by splinting or casting of the fractures, or by use of traction for femoral shaft fractures. Fracture stabilization with internal or external fixation facilitates dressing changes for the treatment of adjacent soft tissue injury as well as allowing inhospital transport for imaging studies and other necessary treatments.[196,197]

Secondary Orthopedic Effects of Head Injuries

A head injury can have later impact on the management of musculoskeletal injuries, even after the acute phase has passed. Persistent spasticity, the development of contractures, heterotopic bone formation in soft tissue, and changes in fracture healing rates are all sequelae of a head injury in children.

Spasticity. Spasticity may develop within a few days of head injury. The early effect of this spasticity is to cause shortening at the sites of long-bone fractures if traction or splint or cast immobilization is being used. If fracture displacement or shortening occurs in a circumferential cast, the bone ends may cause pressure points between the bone and the cast, leading to skin breakdown at the fracture site, with a higher risk for deep infection. Even with skeletal traction for femoral fractures, fracture shortening and displacement will occur as the spasticity overcomes the traction forces. Once spasticity develops and long-bone fractures displace, internal or external fixation is needed to maintain satisfactory reduction. This operative stabilization should be done as soon as the spasticity becomes a problem for fracture reduction because fracture healing is accelerated by a head injury.[195,197]

Contractures. The persistence of spasticity in the extremities often leads to subsequent contractures of the joints spanned by the spastic muscles. Contractures can develop quickly, and early preventative stretching or splinting should begin while the child is in the intensive care unit. Nonselective mass action muscle activity associated with brain injury can be used to help prevent these early contractures. If the child lies in bed with the hips and knees extended, there will usually be strong plantarflexion of the feet at the ankles. If the hip and knee are flexed, it will be much easier to dorsiflex the foot at the ankle, so part-time positioning in this way will prevent early equinus contractures from developing. Stretching and splinting can often be effective in preventing contractures, and casting may be needed if contractures develop. If these measures are not successful and are interfering with rehabilitation, these contractures may need to be released surgically.

Heterotopic Bone Formation. Heterotopic bone may form in the soft tissues of the extremity as early as a few weeks after a head injury with persistent coma.[96] Although any joint can be affected, the most common sites are the hip and the elbow. There is some evidence that heterotopic bone formation can be stimulated by surgical incisions. In head-injured teenagers who undergo antegrade reamed femoral intramedullary nailing of femoral fractures, heterotopic bone that later restricts hip motion can form at the nail insertion site.[92] A sudden increase of alkaline phosphatase a few weeks after the onset of coma, even with fractures coexisting, may mean that heterotopic bone is starting to form and a more careful examination of the extremities is indicated.[127] Technetium-99 bone scans show increased isotope uptake in the soft tissue where heterotopic bone forms, and this imaging study should be considered if new swelling is noted in the extremity of a comatose child. Other diagnoses that must be considered in a comatose child with new swelling of the extremity are a new long-bone fracture and deep venous thrombosis.[181]

Observation and excision are the two primary approaches taken in managing heterotopic bone formation in an injured child. If the child remains comatose, usually little treatment is administered. There are no conclusive data to support medical treatment because diagnosis of heterotopic bone formation is typically made after the inflammatory stage of heterotopic bone formation. In theory, it might be useful to try to block some of the heterotopic bone formation by the use of salicylates or nonsteroidal anti-inflammatory medication if the diagnosis were established very early. If the child has recovered from the head injury and has heterotopic bone that does not interfere with rehabilitation, no intervention is required. If there is significant restriction of joint motion from the heterotopic bone, this bone should be excised to facilitate rehabilitation. The timing of the heterotopic bone excision is controversial, but resection should be considered whenever heterotopic bone significantly interferes with rehabilitation, rather than waiting for 12 to 18 months until the bone is more mature. After surgical excision, early postoperative prophylaxis with local low-dose radiation therapy or medications (salicylates or nonsteroidal anti-inflammatory drugs) decreases the risk of recurrence. Mital et al.[127] reported success in preventing recurrence of heterotopic bone after excision by use of salicylates at a dosage of 40 mg/kg/day in divided doses for 6 weeks postoperatively.

Fracture Healing Rates. Long-bone fractures heal more quickly in children and adults who have associated head injuries.[222] It has been demonstrated that polytrauma patients in a coma have a much higher serum calcitonin level than do conscious patients with similar long-bone fractures, but how or whether this finding influences fracture healing is still unclear.[48]

Peripheral Nerve Injuries

Although TBI most often accounts for persistent neurologic deficits in a child with multiple injuries, peripheral nerve injury should be considered as well during the rehabilitation process. In one clinical review of brain-injured children, 7% had evidence of an associated peripheral nerve injury documented by electrodiagnostic testing.[144] For closed injuries, the peripheral nerve injury is typically associated with an adjacent fracture or with a stretching injury of the extremity. In most cases, observation is indicated because these injuries often recover spontaneously. However, if the nerve injury is at the level of an open fracture, then exploration of the nerve is indicated at the time of the initial surgery. In children being observed following a nerve injury, if function does not return within 2 to 3 months, then electrodiagnostic testing should be undertaken. It is important to recognize these injuries because surgical peripheral nerve repair with nerve grafts offers an excellent chance of nerve function recovery in young patients.

Abdominal Injuries

Studies have reported abdominal injuries in 8%[109] to 27%[51] of pediatric polytrauma patients. Abdominal swelling, tenderness, or bruising are all signs of injury. CT evaluation has largely replaced peritoneal lavage or laparoscopy as the initial method of evaluation of abdominal injury.[191] Abdominal injury is common if a child in a motor vehicle accident (MVA) has been wearing a lap seat belt, regardless of whether a contusion is evident.[29,201] Bond et al.[20] noted that the presence of multiple pelvic fractures strongly correlated (80%) with the presence of abdominal or genitourinary injury, whereas the child's age or mechanism of injury had no correlation with abdominal injury rates. Although hepatic and splenic injuries are much more common, 22% of pediatric cases of pancreatitis result from trauma.[15]

The usual practice is to treat hepatic and splenic lacerations nonoperatively, by monitoring the hematocrit, by repeating the abdominal examination frequently, and by serial CT scans or ultrasound examinations.[31,36,37,38,108,191,203] Once the child's overall condition has stabilized, and the child is stable to undergo general anesthesia, the presence of nonoperative abdominal injuries should not delay fracture care.

Genitourinary Injuries

Genitourinary system injuries are rare in the pediatric polytrauma population, with Letts et al.[109] reporting an incidence of 1% in these patients. However, genitourinary injuries have been reported in 9%[172] to 24%[198] of children with pelvic fractures.

FIGURE 5-3 Most injuries to the bladder and urethra are associated with anterior pelvic ring fractures and should be suspected with these injuries.

Most injuries to the bladder and urethra are associated with fractures of the anterior pelvic ring (Fig. 5-3).[12] Such injuries are more common in males and usually occur at the bulbourethra, but the bladder, prostate, and other portions of the urethra can also be injured.[12,136] Although less common following pelvic fracture in girls, such injuries are often associated with severe injuries, including those to the vagina and rectum, with long-term concerns regarding continence, stricture formation, and childbearing.[146,158] If the iliac wings are displaced or the pelvic ring shape is changed, it may be necessary to reduce these fractures to reconstitute the birth canal in female patients. There are increased rates of cesarean section in young women who have had a pelvic fracture.[41] Adolescent females with displaced pelvic fractures should be informed of this potential problem with vaginal delivery. If the injury is severe, kidney injury may also occur, but most urologic injuries that occur with pelvic fractures are distal to the ureters.[1]

Fat Embolism and Pulmonary Embolism

Although fat embolism and acute respiratory distress syndrome are relatively common in adults with multiple long-bone fractures, they are rare in young children.[115,154] When fat embolism occurs, the signs and symptoms are the same as in adults: Axillary petechiae, hypoxemia, and radiograph changes of pulmonary infiltrates appearing within several hours of the fractures. It is likely that hypoxemia develops in some children after multiple fractures, but the full clinical picture of fat embolism seldom develops. If a child with multiple fractures without a head injury develops a change in sensorium and orientation, hypoxemia is most likely the cause, and arterial blood gases are essential to determine the next step in management. The other primary cause of mental status change after fracture is overmedication with narcotics.

If fat embolism is diagnosed by low levels of arterial oxygenation, the treatment is the same as in adults, generally with endotracheal intubation, positive pressure ventilation, and hydration with IV fluid. The effect of early fracture stabilization, IV alcohol, or high-dose corticosteroids on fat embolism syndrome has not been studied well in children with multiple injuries.

Deep venous thrombosis and pulmonary thromboembolism also are rare, but are increasingly reported in children.[10,11,46,114,200] The risk of deep venous thrombosis and pulmonary embolism is increased in children older than 9, those with an ISS greater than or equal to 25, and/or a GCS lower than or equal to 8, and those with central venous catheters[34,155] The role of prophylaxis for pediatric deep venous thrombosis and pulmonary thromboembolism is unclear.[23,156,163,200]

Nutritional Requirements

Pediatric polytrauma patients have high caloric demands. If an injured child requires ventilator support for several days, caloric intake through a feeding tube or a central IV catheter is necessary to avoid catabolism, improve healing, and help prevent complications. The baseline caloric needs of a child can be determined based on the weight and age of the child. Children on mechanical ventilation in a PICU have been shown to require 150% of the basal energy or caloric requirements for age and weight.[194] The daily nitrogen requirement for a child in the acute injury phase is 250 mg/kg.

Orthopedic Management of the Multiply Injured Child

Key Concepts

- Most fractures in multiply injured children can be splinted initially, and undergo definitive treatment urgently, not emergently.
- Pelvic fractures in children can typically be treated nonoperatively, but may require fixation if the child is hemodynamically unstable.
- Tetanus toxoid and antibiotics should be provided for all open fractures, though routine culture is unnecessary.
- The timely administration of IV antibiotics and appropriate irrigation and debridement are the most important steps in the treatment of open fractures.
- There are many options for stabilization of open fractures. In each case stabilization should be planned to allow easy access for further treatment of the soft tissue injury.
- Children will often heal open fractures that would necessitate amputation in an adult.
- If amputation is necessary, preserve as much stump length as possible.

Timing

Because fractures are rarely life-threatening, splinting generally suffices as the initial orthopedic care while the child's overall condition is stabilized. Loder[116] reported that, in 78 children with multiple injuries, early operative stabilization of fractures

within the first 2 or 3 days after injury led to a shorter hospital stay, a shorter stay in the intensive care unit, and a shorter time on ventilator assistance. In addition, there were fewer complications in those who had surgical treatment of the fractures less than 72 hours after injury. In a more recent study, Loder et al.[117] reported a trend toward a higher rate of complications of immobilization (including pulmonary complications) in fractures treated late (after 72 hours), but the difference did not reach statistical significance. In this more recent study, age greater than 7 years and Modified Injury Severity Score (MISS) ≥140 were predictive of an increased rate of complications of immobilization. A mixed series of adults and children demonstrated comparable results for early (within 24 hours) and late (after 24 hours) fixation of fractures in the setting of blunt trauma and severe head injuries.[207]

Pelvic Fractures

Pelvic fractures are common in children and adolescents with multiple injuries and have been reported in up to 7% of children referred to level 1 regional trauma centers.[180,209] Survival is related to ISS and type of hospital.[209] In two series, 60% to 87% of pelvic fractures involved a pedestrian struck by a motor vehicle.[172,183] Other common mechanisms include being a passenger in an MVA or falling from a height.[172,183] Although many of these pelvic injuries are stable, unstable patterns have been reported in up to 30% of cases.[18]

Injuries to the axial skeleton have been reported to be associated with the most intense hospital care and higher mortality rates than other injury combinations.[26] In their series of 166 consecutive pelvic fractures, Silber et al.[172] reported associated substantial head trauma in 39%, chest trauma in 20%, visceral/abdominal injuries in 19%, and a mortality rate of 3.6% (Fig. 5-4). In this same series,[172] 12% (20/166) had acetabular fractures, whereas in another series, 62% of children (8/13) with pelvic fractures had other orthopedic injuries.[183]

Control of bleeding, either from the retroperitoneum near the fracture or from the peritoneum from injured viscera, may present an immediate threat.[86] However, death of children with pelvic fractures appears to be caused more often by an associated head injury rather than an injury to the adjacent viscera or vessels.[130]

FIGURE 5-4 Bilateral superior and inferior pubic rami fractures. Genitourinary and abdominal injuries must be ruled out with severe pelvic fractures.

Anterior pelvic ring fractures are the primary cause of urethral injury,[1,12,146,158] although urethral injuries are reported to occur less frequently in children than in adults.[172] Bilateral anterior and posterior pelvic fractures are most likely to cause severe bleeding,[124] but death from blood loss in children is uncommon.[49,130] Injury to the sciatic nerve or the lumbosacral nerve roots may result from hemipelvis displacement through a vertical shear fracture. Nonorthopedic injuries associated with pelvic fractures led to long-term morbidity or mortality in 31% (11/36) of patients in one review of pediatric pelvic fractures.[62] Most pelvic fractures in children are treated nonoperatively. However, in a child or preadolescent, an external fixator can be used to close a marked pubic diastasis or to control bleeding by stabilizing the pelvis for transport and other injury care. The external fixator will not reduce a displaced vertical shear fracture, but the stability provided is helpful to control the hemorrhage while the child's condition is stabilized.[151,189] Another option for acute pelvic stabilization in the emergency department is a simple pelvic binder.[87] Though reported to be safe for children, the C-clamp is not typically utilized for the pediatric population.[82] Operative treatment can result in healing by 10 weeks with a low complication rate.[90]

Open Fractures

Background

Most serious open fractures in children result from high-velocity blunt injury involving vehicles. Penetrating injuries are much less common in children than in adults; however, many low-energy blunt injuries can cause puncture wounds in the skin adjacent to fractures, especially displaced radial, ulnar, and tibial fractures. In children with multiple injuries, approximately 10% of the fractures are open.[26,166] When open fractures are present, 25% to 50% of patients have additional injuries involving the head, chest, abdomen, and other extremities.[166]

Wound Classification

The classification used to describe the soft tissues adjacent to an open fracture is based on the system described by Gustilo and Anderson[67] and Gustilo et al.[68] Primary factors that are considered and ranked in this classification system are the size of the wound, the degree of soft tissue damage and wound contamination, and the presence or absence of an associated vascular injury (Table 5-4).

Type I. Type I fractures usually result from a spike of bone puncturing the skin (from the inside to the outside). The wound is less than 1 cm in size, and there is minimal local soft tissue damage or contamination.

Type II. A type II wound is generally larger than 1 cm and is typically associated with a transverse or oblique fracture with minimal comminution. There is adjacent soft tissue injury, including skin flaps or skin avulsion, and a moderate crushing component of adjacent soft tissue usually is present. Skin grafts or flaps should not be needed for coverage.

Type III and Subgroups. The most severe open fractures are classified as type III, with associated subgroups A, B, or C; the letters indicate increasing severity of injury.

TABLE 5-4 Classification of Open Fractures

Type I	An open fracture with a wound <1 cm long and clean
Type II	An open fracture with a laceration >1 cm long without extensive soft tissue damage, flaps, or avulsions
Type III	Massive soft tissue damage, compromised vascularity, severe wound contamination marked fracture instability
Type IIIA	Adequate soft tissue coverage of a fractured bone despite extensive soft tissue laceration or flaps, or high-energy trauma irrespective of the size of the wound
Type IIIB	Extensive soft tissue injury loss with periosteal stripping and bone exposure; usually associated with massive contamination
Type IIIC	Open fracture associated with arterial injury requiring repair

Adapted from Gustilo RB, Mendoza RM, Williams DN. Problems in the management of type III (severe) open fractures: A new classification of type III open fractures. *J Trauma.* 1984;24(8):742–746; Gustilo RB, Anderson JT. Prevention of infection in the treatment of 1025 open fractures of long bones: Retrospective and prospective analyses. *J Bone Joint Surg Am.* 1976;58(4):453–458.

These fractures typically result from high-velocity trauma and are associated with extensive soft tissue injury, a large open wound, and significant wound contamination. In a type IIIA fracture, there is soft tissue coverage over the bone, which is often a segmental fracture. In a type IIIB fracture, bone is exposed at the fracture site, with treatment typically requiring skin or muscle flap coverage of the bone. Type IIIC fractures are defined as those with an injury to a major artery in that segment of the extremity, regardless of wound size or the other soft tissue disruption. Although these injuries are commonly associated with extensive soft tissue loss and contamination, a type IIIC injury may, in fact, be associated with even a small wound in some cases. Also, key distinguishing factors between type II and type III fractures are the amount of periosteal stripping of the bone, and the severity of the damage to the surrounding soft tissues, as opposed to the size of the skin laceration per se (Fig. 5-5). Some of the factors which determine the correct classification of the open fracture may not be known until the time of surgery; as such, the grade the orthopedic surgeon assigns to the open fracture may change at the time of surgery.

This classification is widely used and has been shown to correlate in adults with sequelae of the injury, including the potential for infection, delayed union, nonunion, amputation, and residual impairment. However, studies have shown that the Gustilo classification has only moderate interobserver reliability.[25,83,134] The Orthopaedic Trauma Association[137] has proposed a new classification system that evaluates five parameters: Skin injury, muscle injury, arterial injury, contamination, and bone loss. It has not yet been fully validated. The final functional results of type III fractures in children appear to be superior to results after similar fractures in adults, likely because of their better peripheral vascular supply and the regenerative potential of pediatric periosteum.

Author's Preferred Method

Three Stages

The treatment of open fractures in children is similar to that for open fractures in adults. The primary goals are to prevent infection of the wound and fracture site, although allowing soft tissue healing, fracture union, and eventual return of optimal function. Initial emergency care includes the ABCs of resuscitation, application of a sterile povidone-iodine dressing, and preliminary alignment and splinting of the fracture. If profuse bleeding is present, a compression dressing is applied to limit blood loss. In the emergency department, masks and gloves should be worn as each wound is thoroughly inspected. Tetanus prophylaxis is updated as needed, and the initial dose of IV antibiotics is given. The dose of tetanus toxoid is 0.5 mL intramuscularly to be given if the patient's immunization status is unknown, or if it is more than 5 years since the last dose. The second stage of management is the primary surgical treatment, including initial and (if necessary) repeat débridement of the tissues in the area of the open fracture until the entire wound appears viable. The fracture is reduced and stabilized at this time. If the bone ends are not covered with viable soft tissue, muscle or skin flap coverage is considered. Vacuum-assisted closure (VAC) therapy (Kinetic Concepts, Inc., San Antonio, TX) may be a useful adjunct to facilitate coverage and obviate the need for flaps in some patients.[76,129,210] VAC has been shown to shorten the time of healing of wounds associated with open fractures.[107] The third and final stage of this management is bony reconstruction as needed if bone loss has occurred and followed by rehabilitation of the child.

Cultures

Previous studies have demonstrated poor correlation of growth on routine cultures with wound infections.[104,205] Lee[104] reported that neither pre- nor postdébridement cultures accurately predicted the risk of infection in open fractures. He noted that only 20% of wounds (24/119) with positive predébridement cultures and only 28% (9/32) with positive postdébridement cultures became infected.[104] Although postdébridement cultures were more predictive of infection, these cultures identified the causative organism in only 42% (8/19) of infected wounds. Valenziano et al.[204] found that cultures at the time of presentation to the trauma center also were of no value, with only 2 of 28 patients (7%) with positive cultures becoming infected, in comparison to 5 of 89 patients (6%) with negative initial cultures. Initial cultures were positive in only two of seven cases that became infected. Open fractures do not need to be routinely cultured. Cultures should be obtained only at the time of reoperation in patients with clinical evidence of infection.

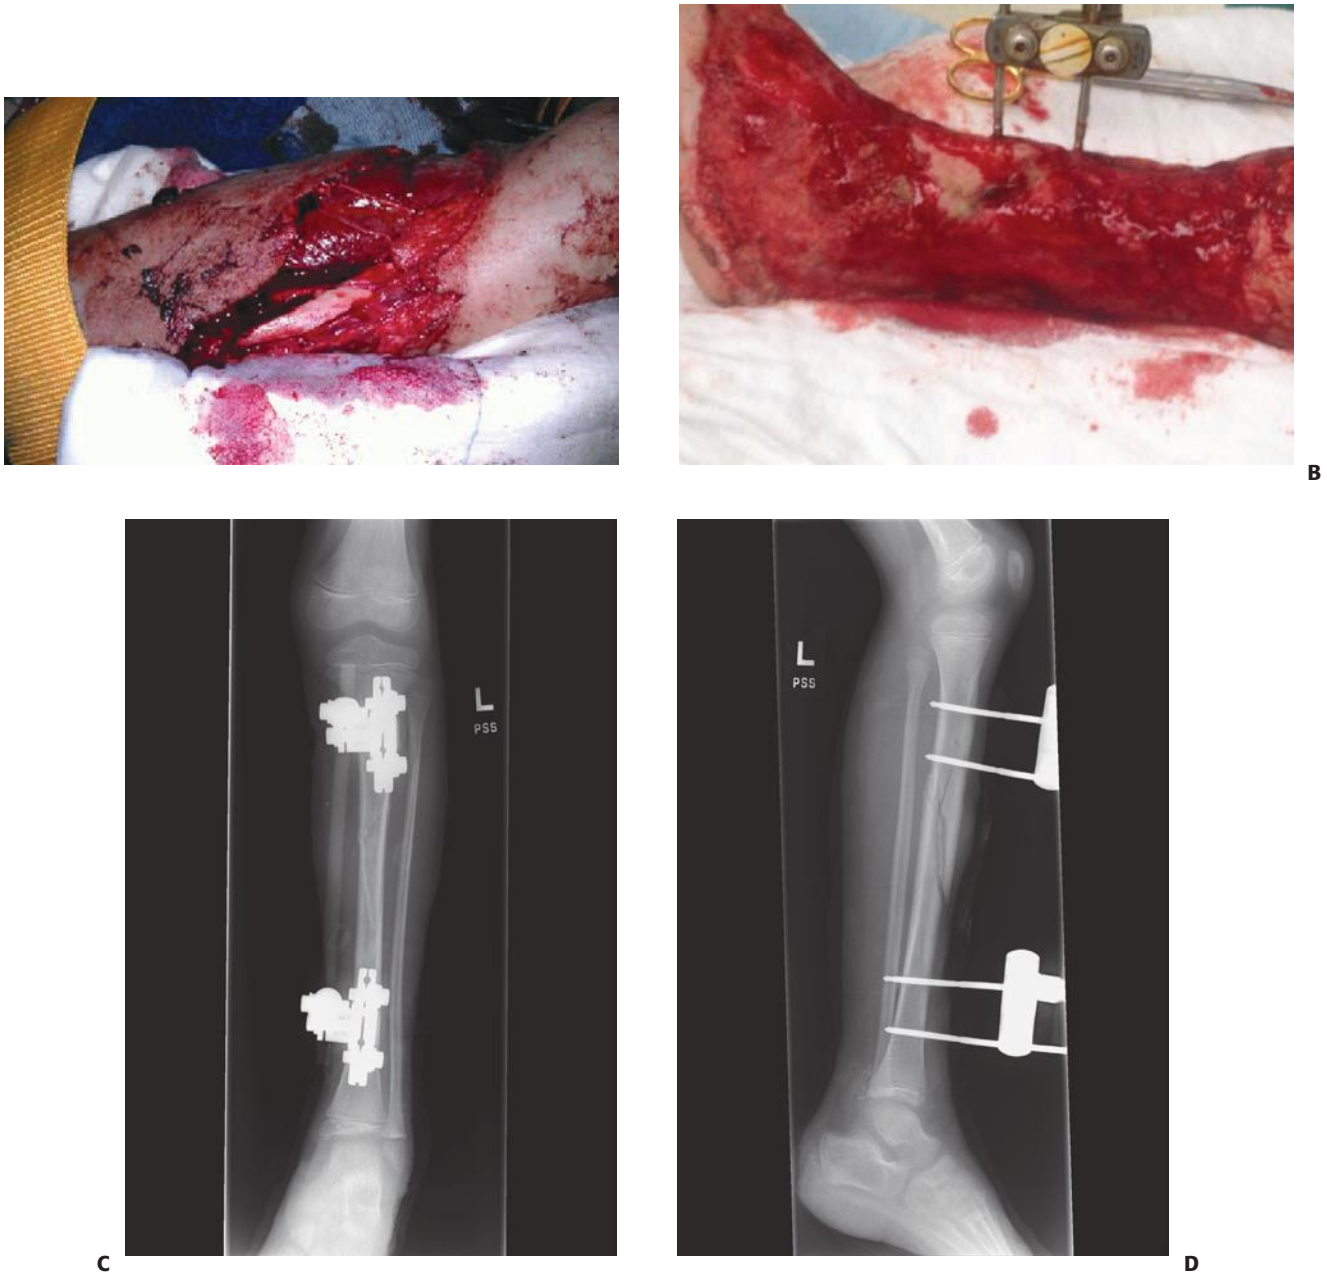

FIGURE 5-5 **A:** Grade IIIC open tibia fracture in a 9-year-old boy hit by a bus. **B:** Appearance of the wound after several debridements. **C, D:** AP and lateral radiographs showing external fixation of the fracture. Note the vascular clips distally, where an autologous vein graft from the popliteal trifurcation was anastomosed to the posterior tibial artery.

Antibiotic Therapy

Antibiotic therapy decreases the risk of infection in children with open fractures. Wilkins and Patzakis[213] reported a 13.9% infection rate in 79 patients who received no antibiotics after open fractures, and a 5.5% rate in 815 patients with similar injuries who had antibiotic prophylaxis. Bacterial contamination has been noted in 70% of open fractures in children, with both Gram-positive and Gram-negative organisms noted, depending on the degree of wound contamination and adjacent soft tissue injury. We limit antibiotic administration generally to 48 hours after each surgical treatment of the open fracture.[103]

For all type I and some type II fractures, we use a first generation cephalosporin (cefazolin 100 mg/kg/day divided q8h, maximal daily dose 6 g).[103] For more severe type II fractures and for type III fractures, we use a combination of a cephalosporin and aminoglycoside (gentamicin 5 to 7.5 mg/kg/day divided q8h).[103]

For farm injuries or grossly contaminated fractures, penicillin (150,000 units/kg/day divided q6h, maximal daily dose

24 million units) is added to the cephalosporin and aminoglycoside. All antibiotics are given intravenously for 24 to 72 hours. Although there is a trend toward a shorter duration (24 hours) of antibiotic prophylaxis, there is currently a lack of evidence-based medicine to support specific regimens of duration of antibiotic prophylaxis in children. Oral antibiotics are occasionally used if significant soft tissue erythema at the open fracture site remains after the IV antibiotics have been completed. Gentamicin levels should be checked after four or five doses (and doses adjusted as necessary) during therapy to minimize the risk of ototoxicity.

An additional 48-hour course is given around subsequent surgeries, such as those for repeat irrigation and débridement, delayed wound closure, open reduction and internal fixation of fractures, and secondary bone reconstruction procedures.

It should be noted, however, that the guidelines above were developed prior to the widespread prevalence of community-acquired methicillin-resistant *Staphylococcus Aureus* (MRSA). If the patient is at risk for MRSA, consideration should be given to adding clindamycin or vancomycin to the regimen. Moreover, evidence-based guidelines published in 2006 found that the available data support the conclusion that a short course of a first generation cephalosporin, combined with appropriate orthopedic management, does decrease risk of subsequent infection in open fractures. However, the data were inadequate to either support or refute additional practices such as adding an aminoglycoside for Gustilo type II fractures, or increasing the duration of antibiotic administration.[73]

Débridement and Irrigation

After antibiotics are given, débridement and irrigation of the open fracture in the operating room is the next critical step in the primary management of open fractures in children. Some authors have reported that significantly higher infection rates occurred if débridement and irrigation were done more than 6 hours after open fractures in children.[98] A multicenter report, however, demonstrated an overall infection rate of 1% to 2% after open long-bone fractures, with no difference in infection rates between groups of patients treated with irrigation and débridement within 6 hours of injury and those treated between 6 and 24 hours following injury.[176] Another study of pediatric type I open fractures reported a 2.5% infection rate with nonoperative treatment.[85] One likely reason for the low rates of infection in these two series is the early administration of IV antibiotics in both groups. Although up to a 24-hour delay does not appear to have adverse consequences regarding infection rates, it may be necessary to perform an earlier irrigation and débridement to minimize compromise of the soft tissue envelope. The débridement needs to be performed carefully and systematically to remove all foreign and nonviable materials from the wound. The order of débridement typically is (a) excision of the necrotic tissue from the wound edges, (b) extension of the wound to adequately explore the fracture ends, (c) débridement of the wound edges to bleeding tissue, (d) resection of necrotic skin, fat, muscle, and contaminated fascia, (e) fasciotomies as needed, and (f) thorough irrigation of the fracture ends and wound.

Because secondary infection in ischemic muscle can be a major problem in wound management and healing, in adults, all ischemic muscle is widely débrided back to muscle that bleeds at the cut edge and contracts when pinched with the forceps. In children, who generally heal better and have fewer comorbidities than adults, it is often possible to do a less aggressive debridement at the initial surgery, and wait until questionable tissue declares itself at a second look to determine the definitive necessary extent of debridement.

When débriding and irrigating an open diaphyseal fracture, we typically bring the proximal and distal bone ends into the wound to allow visual inspection and thorough irrigation and débridement. This often necessitates extension of the open wound, which is preferable to leaving the fracture site contaminated. We carefully remove devitalized bone fragments and contaminated cortical bone with curettes or a small rongeur. If there is a possible nonviable bone fragment, judgment is needed as to whether this bone fragment should be removed or left in place. Small fracture fragments without soft tissue attachments are removed, whereas very large ones may be retained if they are not significantly contaminated. Reconstruction of a large segmental bone loss has a better outcome in children than in adults because children have a better potential for bone regeneration and a better vascular supply to their extremities. Nearby major neurovascular structures in the area of the fracture are identified and protected. Débridement is complete when all contaminated, dead, and ischemic tissues have been excised; the bones' ends are clean with bleeding edges; and only viable tissue lines the wound bed.

Although a high-pressure lavage system can be used for irrigation, there have been reports of complications, including acute compartment syndrome, using these devices.[102,173] Therefore, gravity lavage using wide-bore cystoscopy tubing is a reasonable alternative. Several recent studies, including the multicenter, randomized, blinded Fluid Lavage of Open Wound (FLOW) study have found that low-pressure lavage is safer and more effective than high-pressure lavage.[139,143] These studies also examined lavage solutions. Although there were the same number of reoperations in patients treated with saline versus soap (13 in each group), the total number of post-op infections, both operative and nonoperative, and both deep and superficial, was higher in the soap group. The difference approached, but did not reach, statistical significance ($p = .019$). We routinely use 3 to 9 L of normal saline (with or without soap as per surgeon preference) for the lower extremities and 2 to 6 L in the upper extremities because of the smaller compartment size. Note that high-powered lavage is >70 psi. Many "powered" lavage systems are low pressure, (around 12 psi) so one must consult the manufacturer's data for the details of the particular system in use.

After the débridement and irrigation are complete, local soft tissue is used to cover the neurovascular structures, tendons, and bone ends. If local soft tissue coverage is inadequate, consideration should be given to local muscle flaps or other coverage methods, including VAC. The area of the wound that has been incised to extend the wound for fracture inspection can be primarily closed. The traumatic wound should either be

left open to drain or may be closed over one or more drains. Wounds that are left open can be dressed with a moistened povidone-iodine or saline dressing, but are probably better treated with a VAC. Types II and III fractures are routinely reoperated on every 48 to 72 hours for repeat irrigation and débridement until the wounds appear clean and the tissue viable. This cycle is repeated until the wound can be sutured closed or a split-thickness skin graft or local flap is used to cover it. If flap coverage is necessary, this is optimally accomplished within 1 week of injury.

Fracture Stabilization

Fracture stabilization in children with open fractures decreases pain, protects the soft tissue envelope from further injury, decreases the spread of bacteria, allows stability important for early soft tissue coverage, decreases cerebral pressure, and improves the fracture union rate.

Principles for stabilization of open fractures in children include allowing access to the soft tissue wound and the extremity for débridement and dressing changes, allowing weight bearing when appropriate, and preserving full motion of the adjacent joints to allow full functional recovery.

The concept of "damage-control" orthopedics, in which an external fixator is used to temporarily stabilize a long-bone fracture until the patient is systemically stable enough to undergo definitive fracture fixation, is well studied and accepted in the adult literature.[140,164,189,202] There is essentially no pediatric literature on "damage-control" orthopedics, except for one case series of three patients with femur fractures, initially treated with an external fixator, and subsequently revised to submuscular plating.[128] External fixators can be put on quickly and safely in the ICU or at bedside without fluoroscopy for pelvic, femur, tibia, and other fractures for initial stabilization, with the understanding that definitive alignment can be achieved later.

Although casts or splints can be used to stabilize isolated type I fractures and occasionally type II fractures with relatively small wounds and minimal soft tissue involvement, difficulties with soft tissue management and loss of alignment as swelling subsides are common with such closed treatment. Most of these injuries involve the radius or ulna in the upper extremity or the tibia in the lower extremity. Splint or cast immobilization is generally not satisfactory for the more unstable type II and most type III injuries.

For diaphyseal forearm fractures, a flexible intramedullary implant in the radius and/or ulna commonly provides enough stability of the fracture to allow dressing changes through the cast or splint. For intramedullary fixation, we prefer 2- to 4-mm diameter flexible titanium implants for stabilizing open fractures in the forearm when reduction of either the radial or ulnar fracture is unstable. Since the ulnar canal is straight, the implant chosen is often at least 80% of the narrowest canal diameter, whereas the implant for the radius is generally 50% to 60% of the narrowest canal diameter. The ulnar implant is inserted antegrade, and the radial implant is inserted retrograde just proximal to the distal radial physis. One or both bones can be stabilized, and the implants can be removed easily after fracture healing.

For distal forearm fractures, percutaneous pinning of the radius (and, occasionally, the ulna) is generally appropriate and provides sufficient stability. A short-arm cast usually is sufficient to maintain appropriate alignment following such fixation. The pins are removed in the office at 3 to 4 weeks, but the cast is used for a total of 6 weeks.

We also use flexible intramedullary nails for most open fractures of the femoral shaft. For type III fractures, especially if there is a large or contaminated soft tissue wound present, external fixation may be indicated. Trochanteric-entry antegrade nails are gaining popularity and may be considered in children ≥10 years old or those who weigh ≥50 kg (110 lb).

For most open tibial and femoral fractures in children, flexible intramedullary rod fixation has replaced external fixation as our treatment of choice. Both intramedullary rodding and external fixation allow access to the wound for débridement and dressing changes as well as any soft tissue reconstruction needed.[132] Wound access, however, may be limited with external fixators, especially when there are extensive soft tissue wounds. Intramedullary rods generally are better tolerated by patients and families, do not require daily care, leave more cosmetic scars, and are load-sharing devices. With intramedullary rodding, the child is allowed to weight bear as tolerated following transverse or short oblique fractures, but weight bearing is protected for 4 to 6 weeks following comminuted or spiral fractures.

External fixation is preferable for fractures with segmental bone loss, and ring fixators may even be used in such instances for bone transport. External fixation allows weight bearing relatively soon after the injury. We find that a uniplanar frame is best for most fractures and is relatively easy to apply. For some segmental fractures in the metaphysis and diaphysis, as well as soft tissue injuries, a multiplanar or ring fixator may be a better choice.

We use open reduction and internal fixation for open intraarticular fractures. When feasible, fixation should be parallel to (and avoid) the physis. Cannulated screws often are used in such instances. Screws or threaded pins should not cross the physis. If fixation across the physis is necessary, smooth pins are used; they should be removed 3 to 4 weeks after injury to minimize the risk of growth disturbance.

For fractures that involve both the metaphysis and diaphysis, open reduction and internal fixation can be combined with external fixation. For diaphyseal fractures in skeletally immature children, we prefer flexible intramedullary nails to compression plates for internal fixation of type I, type II, and some type III fractures. The superiority of intramedullary or external fixation for type IIIB fractures has not been firmly established. For treatment of a floating joint, usually the knee or elbow, we almost always stabilize both fractures operatively.[19,111]

Wound Management

Serial irrigation and débridement are done every 2 to 3 days until the wounds are clean and all remaining tissue appears viable. Fracture fixation at the time of initial surgery (as described previously) facilitates wound management. We prefer to provide soft tissue coverage of the open fracture and adjacent soft tissue defect by 5 to 10 days after the injury to limit the risk of later infection.

Most type I wounds heal with local dressing changes. For some type II and type IIIA fractures, we use delayed wound closure or a split-thickness skin graft over underlying muscle cover.

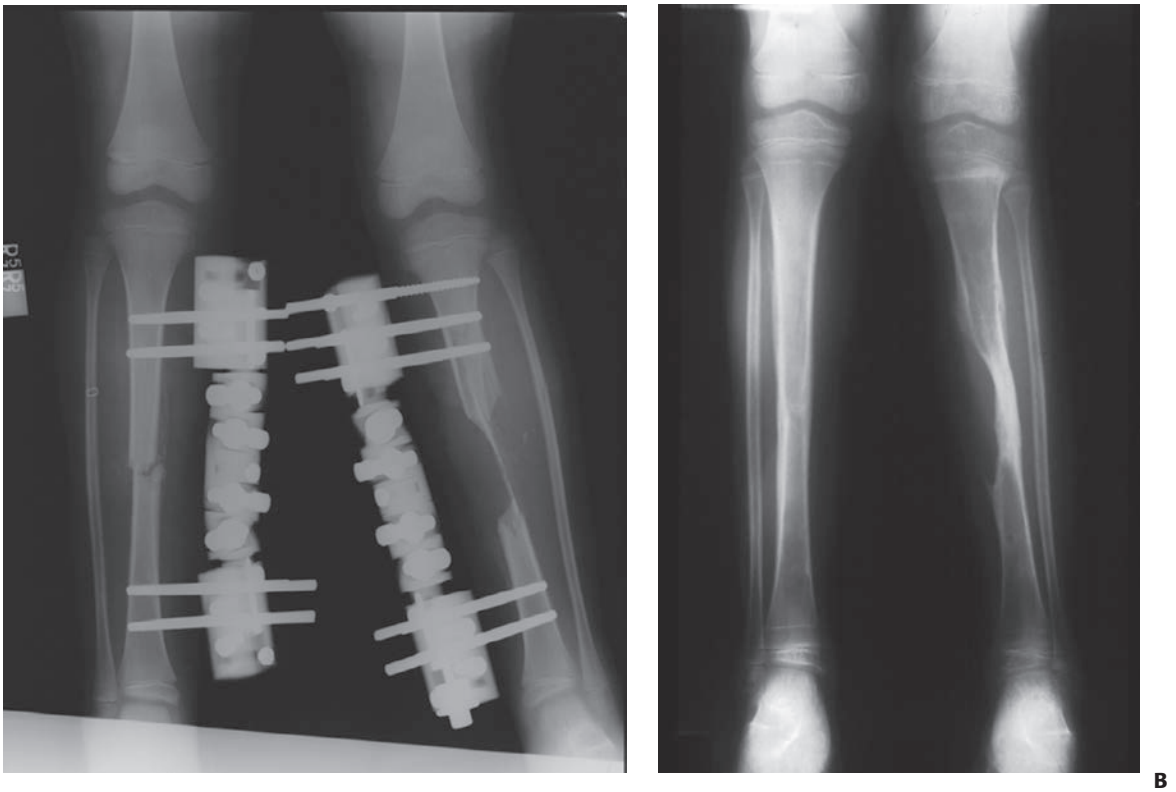
Large soft tissue loss is most often a problem with types IIIB and IIIC fractures. In the proximal tibia, plastic surgeons may be needed to provide a gastrocnemius rotational flap, followed by secondary coverage of the muscle with a skin graft. In the middle-third of the leg, a soleus flap is used with skin graft coverage, and a vascularized free muscle transfer is necessary if local coverage is inadequate. Free flaps may be required for coverage of the distal third of the tibia, especially in adolescents,[153] although there is a 60% postoperative complication rate. VAC sometimes can reduce the need for free tissue transfers. The VAC can convert wounds that need free tissue to ones that need split-thickness skin graft or can heal completely.[32,129]

The flaps and grafts used for reconstructing severe injuries are either muscle flaps or composite grafts. For a massive loss of soft tissue and bone, composite grafts of muscle and bone often are necessary. The younger the child, the better the likelihood that autogenous graft will fill in a bone defect if there is a well-vascularized bed from the muscle flap. Free flaps, especially from the latissimus dorsi, are useful in the midtibial and distal tibial regions to decrease infection rates and improve union rates. Vascularized fibular grafts rarely are used acutely to reconstruct bone defects, but may be useful after soft tissue healing.

For the rare case of significant bone defect in a child, we rely on the healing capacity of young periosteum and bone and the vascular supply of a child's extremity (Fig. 5-6). An external fixator is used to hold the bone shortened about 1 to 2 cm to decrease the size of the bone loss. In a growing child, 1 to 2 cm of overgrowth can be expected in the subsequent 2 years after these severe injuries, so the final leg length will be satisfactory. Autogenous bone graft can be used early, but if there is surviving periosteum at this site, spontaneous bone formation often is surprisingly robust and may preclude the need for bone grafting. In teenagers with bone loss, once the soft tissue has healed, bone transport using either a uniplanar lengthening device or a circular thin wire external fixator is our preferred method of reconstruction, although use of an allograft or vascularized fibular graft may be considered.

Amputation

In children, attempts should generally be made to preserve all extremities, even with type IIIC open fractures that are usually treated with primary amputation in adults. Wounds and fractures that do not heal in adults often heal satisfactorily in children and preservation of limb length and physes are important in young children. Although the Mangled Extremity Severity Score (MESS) correlates well with the need for amputation in adults, the correlation is less in children.[58] In one series,[58] the



A B

FIGURE 5-6 **A:** AP radiograph of a 6-year-old boy with bilateral open fractures, fixed with external fixators. Note the bone loss on the left, with only a thin piece of cortical bone remaining. However, his periosteum was preserved. **B:** Result at 1 year, with healing and hypertrophy of the cortical bone, without bone grafting.

MESS predicted limb amputation or salvage correctly in 86% (31/36) of children, with 93% accuracy in salvaged limbs but only 63% in amputated limbs.

If amputation is absolutely necessary, as much length as possible should be preserved. For example, if the proximal tibial physis is preserved in a child with a below-knee amputation at age 7 years, 3 to 4 in more growth of the tibial stump can be expected by skeletal maturity. Thus, even a very short tibial stump in a skeletally immature child may grow to an appropriate length by skeletal maturity. As a result, even a short below-knee amputation at the time of injury would likely be superior to a knee disarticulation in final function.

Although amputations to treat congenital limb deficits usually are done through the joint to limit bone spike formation (overgrowth) at the end of the stump, we prefer to maintain maximal possible length if amputation becomes necessary as a result of a severe injury.

Management of Other Fractures

When a child with an open fracture is brought to the operating room for irrigation and débridement of the open fracture, the orthopedist may use this opportunity to treat the other fractures as well, whether operative treatment or closed reduction and casting are needed. In the setting of pediatric polytrauma, most long-bone fractures are treated surgically, to facilitate patient care and rehabilitation.

Stabilization of Fractures

Key Concepts

- Fracture stabilization aids in the overall care of the multiply injured child.
- There are many different operative techniques and implants available and useful to the pediatric orthopedic surgeon.
- Although about 22% of children who sustain polytrauma have some residual disability, optimal treatment of their orthopedic injuries in a timely fashion decreased their burden of musculoskeletal disability.
- The best predictor of long-term disability was the Glasgow Outcome Scale 6 weeks after injury and later.[205]

Beneficial Effects

Fracture stabilization also provides a number of nonorthopedic benefits to a child with multiple injuries. Among the potential benefits are ease of patient mobilization, ease of nursing care, decreased risks of pressure sores, and better access to the wounds. Pulmonary contusions at the time of injury often lead to increasing respiratory problems in the first few days after injury.[145] If the lungs have been severely contused, protein leaks into the alveolar spaces, making ventilation more difficult. This may be exacerbated by the systemic inflammatory response syndrome, which is commonly seen following severe trauma.[154,212] Surfactant dysfunction follows and is most abnormal in patients with the most severe respiratory failure.[108] As the time from the injury increases, pulmonary function deteriorates and general anesthesia becomes more risky. Orthopedic surgical treatment before such pulmonary deterioration limits the anesthetic risks in these patients. In patients with severe pulmonary contusions and multiple fractures, the use of extracorporeal life support may be the only treatment available to allow patient survival.[170]

In adults with multiple injuries, early operative stabilization of fractures decreases pulmonary and other medical complications associated with prolonged bed rest that is a part of nonoperative fracture treatment.[14] Most adult trauma centers follow the treatment protocol of early fracture stabilization, even though Poole et al.[148] reported that, despite early fracture stabilization simplifying patient care, pulmonary complications in patients with marked chest trauma were not prevented and the course of the head injury was not affected. In children, medical complications are less common, so the recommendations that mandate early fracture stabilization are somewhat more difficult to support in young patients. Nonetheless, bruises on the chest or rib fractures should alert the orthopedist to potential pulmonary contusions as a part of the injury complex.[141] Initial chest radiographs may not clearly demonstrate the degree of pulmonary parenchymal injury, and arterial blood gas determinations are more useful in estimating the anesthetic risk of these patients during operative care of the fractures.

Timing

As noted, splinting is needed at the time of the initial resuscitation. In a child with multiple closed fractures, definitive treatment should proceed expeditiously once the child's condition has been stabilized. Loder[116] reported that operative stabilization of fractures within the first 2 or 3 days after injury led to fewer complications, shorter hospital and intensive care unit stays, and a shorter time on ventilator assistance in children with multiple injuries. A more recent study by Loder et al.[117] reported a trend toward a higher rate of complications in fractures treated after 72 hours. Although there appear to be other factors besides the timing of surgery that affect the eventual outcomes of polytrauma patients, the timing of surgery is a variable that can be controlled by the surgeon, and it seems prudent to complete fracture stabilization within 2 to 3 days of injury when possible.

Operative Fixation

The type of operative stabilization used in multiply injured children commonly depends on the training, experience, and personal preference of the orthopedist. The most common methods used are intramedullary rod fixation, external fixation, compression plating, and locking plating; Kirschner wires or Steinmann pins may be used in conjunction with casts.

Intramedullary Rod Fixation

There has been an increase in the use of 2- to 4-mm diameter flexible titanium intramedullary rods for stabilization of long-bone fractures of the upper and lower extremities in children. Intramedullary rodding is most commonly used for unstable closed fractures of the radius and ulna in patients through adolescence and for femoral shaft fractures in patients between the ages of 5 and skeletal maturity.[197,208] A trochanteric-entry

antegrade nail is often a viable option in children of 10 years old or older or in those with comminuted or length-unstable femoral fractures. The tibia also can be fixed with intramedullary rods in children with an open fracture, polytrauma, a "floating knee" injury (concurrent femur fracture), or a high-energy, unstable injury (especially during adolescence). A diaphyseal fracture of the humerus can be treated with intramedullary fixation in the presence of a "floating" shoulder or elbow.[157]

Common indications for intramedullary fixation of forearm fractures include unstable diaphyseal fractures (especially in adolescents) and open fractures.[64,101,106,119] Forearm fractures can generally be treated with closed reduction, with the intramedullary implant passed across the fracture site under fluoroscopy for stabilization.[101] In one study,[106] 23% (10/43) of closed forearm fractures treated with intramedullary rod fixation required open reduction. The ulnar implant is placed in antegrade fashion and can be inserted through the lateral proximal metaphyseal area or the tip of the olecranon. The radial implant is inserted retrograde and is contoured to conform to the normal radial bow before insertion. The insertion point is proximal to the distal radial physis and the rod can be inserted from the radial aspect of the distal radius or dorsally (slightly ulnar to Lister tubercle). Stability of both fractures may be achieved by instrumenting only the radius or the ulna in younger children, but both bones are more commonly fixed in adolescents. Intramedullary fixation of open forearm fractures appears to decrease the rate of loss of reduction.[64,119] In one series,[106] reduction was maintained in all 27 patients treated with rodding of both bones or of only the radius, compared with loss of reduction in 32% (7/22) of patients in whom only the ulna was rodded. The high rate of failure may be because of the small diameter pins (1.6 or 2 mm) used to fix the ulna in this series.[106] A cast is used for further immobilization.

The implants are easily removed from the wrist area and the elbow region 6 to 12 months after insertion. Despite the utility of flexible intramedullary implants for stabilizing forearm fractures in children, the radius and ulna in young patients have significant remodeling capacity and not all fractures require anatomic reduction. A closed reduction and cast immobilization may suffice. Displaced distal forearm fractures in polytrauma patients are often well treated with closed reduction and percutaneous pinning; thus affording sufficient stability for use of a short-arm cast in these polytrauma patients.

In a series of 20 pediatric patients treated with intramedullary rodding of forearm fractures, 50% of patients had complications including loss of reduction, infection, hardware migration, nerve injury, and delayed union, although 95% (19/20) of patients had excellent or good results at follow-up.[45] In another series,[220] compartment syndromes occurred in 6 of 80 (7.5%) patients with forearm fractures treated with intramedullary fixation; risk factors in this study were reported to be increased operative time and increased intraoperative use of fluoroscopy.

If flexible intramedullary nails are used in the femur, the most common technique is retrograde insertion from the medial and lateral metaphyseal region of the distal femur, 2 to 3 cm proximal to the physis. Two rods are used to cross the fracture site and obtain purchase in the proximal femur, usually with one at the base of the femoral neck and the other at the base of the greater trochanter. Rod diameter is generally 40% of the intramedullary diameter of the femoral isthmus, up to a maximum rod size of 4 to 4.5 mm (depending on manufacturer). A cast is not necessary postoperatively, although a fracture brace can be used to help control rotation at the fracture site and provide some patient comfort during early walking, especially for proximal third fractures or those with significant comminution. The implants usually are removed within 1 year of the fracture.[74,84] One study showed that intramedullary nailing of the femur had more complications in comminuted fractures and children weighing over 100 lb,[60] whereas another noted higher complication rates in children of 10 years old or older at the time of surgery.[78]

The use of reamed antegrade intramedullary rods to treat femoral shaft fractures in the pediatric population should be reserved for those with a closed proximal femoral physis. In younger children, rod insertion at the piriformis fossa may interfere with the vascular supply to the femoral epiphysis leading to avascular necrosis (AVN), may cause growth arrest of the greater trochanter (i.e., apophysis with resultant coxa valga), or may interfere with the appositional bone growth at the base of the femoral neck, thereby thinning this region and potentially predisposing the child to a femoral neck fracture.[13,30,110,126,135] Some authors have advocated rigid intramedullary rodding using an entrance point at the tip of the greater trochanter.[88,119] Nails designed to be inserted through the lateral aspect of the greater trochanter, not the tip, have also shown good results.[63,91] A recent meta-analysis of rigid nailing in the pediatric population found an AVN rate of 2% for the piriformis entry site, 1.4% for the trochanteric tip, and no cases of AVN when the lateral trochanteric entry site was used.[121] AVN of the femoral head can be a catastrophic iatrogenic injury best avoided.

Flexible intramedullary rod fixation is becoming increasingly common for diaphyseal tibial fractures. The most common indications currently are open fractures, "floating knee" injuries, and unstable diaphyseal fractures in adolescents. The rods are inserted in antegrade fashion, with medial and lateral entrance points distal to the physis and avoiding the tibial tubercle. As with femoral fractures, rod diameter is 40% of the narrowest intramedullary diameter, with a maximum rod size of 4 to 4.5 mm (depending on implant manufacturer). A short-leg walking cast or fracture boot often is used for comfort for the first 4 to 6 weeks postoperatively, although a splint may be used initially to allow access to wounds associated with an open fracture or degloving injury.

Compression Plates

Some authors have advocated the use of compression plates to stabilize long-bone fractures, especially in the femoral shaft, in children with multiple injuries.[28,99] Kregor et al.[99] reported an average overgrowth of the femur of 9 mm, and all fractures healed in a near anatomic position. Caird et al.[28] noted that 3% of patients (2/60) had a limb length discrepancy of greater than 2.5 cm following femoral plating, including a 5-cm discrepancy in one child. The disadvantages of compression plating include

FIGURE 5-7 Stabilization of femoral shaft fractures in children with multitrauma can be obtained with several methods. Minimally invasive percutaneous submuscular plating techniques can occasionally be used. (Courtesy of Steven T. Morgan, MD, Denver, CO.)

the need for more extensive operative exposure at the site of the fracture, the fact that they are not load-sharing devices, and the usual need to remove the plate through a relatively long incision once healing is complete. Minimally invasive percutaneous submuscular plating techniques have eliminated some of the problems associated with traditional plating (Fig. 5-7).[89,174] Refracture may occur through the screw holes left after plate removal if physical activity is resumed too quickly.[89] Stiffness of adjacent joints is rarely a problem in children unless there has been an associated severe soft tissue injury. The number of cortices the screws cross on each side of the fracture may be fewer in children than in adults, because a cast or splint is routinely used in young patients. Kanlic et al.[89] reported an 8% incidence of leg length discrepancy after submuscular bridge plating.

Although some authors have recommended open reduction and compression plate fixation of displaced radial and ulnar fractures,[217] we prefer flexible intramedullary nails in children, as noted earlier. The use of compression plates in the forearm requires a larger operative incision with a resultant scar, a second extensive procedure for plate removal, and a significant risk of refracture following hardware removal. We do not believe that the healing capability of the young child requires the rigid fixation of compression plating to obtain fracture union.

External Fixation

Traditional indications for external fixation in a child with multiple injuries are open fractures with significant soft tissue injury, fractures in children with a head injury and coma, and "floating knee" fractures of the femur and tibia.[7,8,17,19,95,111,157,169,196,221] With advances in intramedullary rod techniques, external fixation is now less common. A unilateral fixator generally is sufficient to hold the fracture reduced in this age group.

If external fixation is used, the caliber of the pin should be less than 30% of the diameter of the bone into which it is to be inserted to minimize the risk of fracture through a pin site. The distal and proximal pins must be inserted at a level to avoid the physis, and we recommend leaving at least 1 to 2 cm between the pin and physis, partly to avoid any adverse effect on the physis should a pin track infection occur. The proximal tibial physis is more distal anteriorly below the tibial tubercle, and this area must be avoided or a recurvatum deformity of the proximal tibia and knee will result. The external fixator is usually left in place until fracture healing is complete, but it can be removed once the reason for placement has resolved (such as waking from coma or healing of a skin wound).[56,214] If the fixator is removed early, a walking cast is applied. Transverse open fractures reduced out to length take longer to heal than do oblique fractures reduced with slight overlap. Refracture is a well-described risk following fixator removal. However, refracture rates have been variable, with a 21% rate noted in a series in which a rigid transfixion type of fixator was used[195] and a 1.4% rate in a series with more flexible unilateral frames.[17] One report indicated that if three of the four cortices at the fracture site appear to be healing on anteroposterior and lateral radiographs of the fracture, the refracture rate after frame removal should be low.[177]

Laboratory studies have suggested that dynamization of external fixators may stimulate early fracture healing.[35,100] We prefer to dynamize the fixator early to stimulate callus formation, although the effect of dynamization on refracture rates is unclear.[52,93]

Outcomes of Treatment of the Multiply Injured Child

In one review of 74 children with multiple injuries, 59 (80%) survived, but after 1 year, 22% were disabled, mainly from a brain injury.[205] At 9 years after the injuries, 12% had significant physical disability, whereas 42% had cognitive impairment. In this group, however, the SF-36 or functional outcome survey did not differ from the control population. The best predictor of long-term disability was the Glasgow Outcome Scale 6 weeks after injury and later.[205] Letts et al.[109] reported that 71.6% of multiply injured children made a full recovery, with a mean of 28 weeks until full recovery. Of the 53 residual deficits in 48 patients, the common deficits were neurologic (38%), psychosocial (34%), and musculoskeletal (24%).[109] Outcomes of children with pelvic fractures were near normal at 6 months.[171]

Whether operative or nonoperative fracture treatment is chosen for a child with multiple injuries, it is important that an orthopedist be involved in the care of the child from the start. Although recognizing the need to care for the other organ system injuries the child has sustained, it is important to advocate for the expeditious and appropriate treatment of the fractures that are present. Failure to do so will leave the multiply injured child with musculoskeletal disability once healing of the other injuries occurs.

After multiple injuries, the most common long-term problems relate to either sequelae of the head injury or of the orthopedic injuries.

6 COMPARTMENT SYNDROME IN CHILDREN

Paul D. Choi, Frances Sharpe, and Milan V. Stevanovic

Introduction

The serious and potentially devastating complications associated with compartment syndrome in adults occur in children as well. Similar to adults, compartment syndrome in children is characterized by sustained increased pressures within an osseofascial compartment resulting in circulatory impairment, ischemia, cellular anoxia, and ultimately tissue death. Failure to diagnose and treat this condition in an expeditious manner can lead to permanent disability in the affected limb. The importance of timely diagnosis and treatment is critical not only to optimize clinical outcomes but also to minimize medicolegal liability, that is, risk of malpractice claim. Delayed or missed diagnosis of compartment syndrome is one of the most common causes of litigation against medical professionals in North America.[3]

Similar to adults, compartment syndrome is three to four times more prevalent in boys than in girls.[2,15] A variety of injuries and medical conditions, including fractures, soft tissue injuries, burns, animal and insect bites, external compression by tight dressings, casts, antishock garments, penetrating trauma, and bleeding disorders can lead to compartment syndrome and can involve the hand, forearm, foot, lower leg, and thigh (Table 6-1). The most common mechanism of injury is trauma—secondary to motor vehicle accidents, falls, and sports.[15] The majority of cases of compartment syndrome are associated with a fracture. Soft tissue injury without fracture can also commonly lead to compartment syndrome (especially in the setting of an underlying bleeding disorder or with the use of anticoagulants). It is important to maintain a high index of suspicion in soft tissue injuries without fracture. Compartment syndrome in this setting has been associated with a high rate of disability, likely associated with a delay in diagnosis and treatment.[17,30] Both high- and low-energy injuries can result in compartment syndrome. Compartment syndrome can occur even in the presence of an open wound, and in one study of compartment syndrome in children, open fractures were associated with a higher incidence of compartment syndrome than closed injuries.[15] Open fractures are generally associated with higher-energy injuries and the associated fascial disruption does not result in adequate decompression of all compartments.

Historically, acute compartment syndromes (ACSs) were more commonly reported in the forearm associated with supracondylar humerus (SCH) fractures and in the lower extremity associated with femur fractures. Likely, this was related to historical treatment methods, including casting of the elbow in hyperflexion (>90 degrees) for SCH fractures and the use of Bryant traction for the treatment of femur fractures. With advancing treatment methods, such as operative stabilization and immediate spica casting, the incidence of these causes of compartment syndromes has decreased.

Currently, ACS in the pediatric population most commonly involves the lower leg associated with fractures of the tibia and/or fibula.[12,15] Adolescents in particular are at risk and have an 8.3% rate of compartment syndrome after tibial fractures.[9] In

TABLE 6-1 Causes of Compartment Syndrome

Intrinsic	Extrinsic
Fracture	Compressive casts, dressings
Soft tissue trauma without fracture	Pneumatic antishock garments
Vascular injury	
Penetrating trauma	
Burns	Burn eschar
Animal + insect bites	
Fluid infusion secondary to intravenous (or intraosseous) extravasation (also arthroscopy)	
Bleeding disorders	
Reperfusion injury following prolonged ischemia	
Elective orthopedic procedure—osteotomy	

the upper extremity, ACS most commonly involves the forearm typically associated with both bone fractures of the forearm and SCH fractures.[4,12,15,20] Based on a national database review, the incidence of forearm compartment syndrome following upper extremity injuries has been estimated at 1%.[15] High-risk fracture patterns include displaced SCH fractures with concomitant ipsilateral forearm fractures with a rate of compartment syndrome as high as 33%[4] or supracondylar fractures with a median nerve injury, which can mask the pain of compartment syndrome.[25] One study found displaced fractures of the forearm that undergo multiple passes of intramedullary nails may be at a higher risk for compartment syndrome.[53]

Diagnosis

The diagnosis of ACS is challenging and can be more difficult in children, especially infants, who are too young to cooperate, nonverbal, or apprehensive and crying. A high index of suspicion is recommended, especially in the setting of at-risk injuries and conditions.

Pain, pressure, pallor, paresthesia, paralysis, and pulselessness (the six Ps) have been described as clinical markers of compartment syndrome. The reliability of these clinical findings is questionable; however, as they may be difficult to obtain in the pediatric or obtunded patient or may present too late (only after irreversible tissue damage has already occurred). Instead, the three As may be more useful in making a diagnosis of compartment syndrome in the pediatric population: *Anxiety* (or restlessness), *agitation* (or crying), and an increasing *analgesia* requirement.[2,21]

Pain out of proportion to the injury, especially aggravated by passive motion of the involved, ischemic compartment, remains as one of the most sensitive and early physical findings of compartment syndrome.[27] In particular, an increasing analgesia requirement (both in dose and frequency) can be a helpful early marker.[2] Pain perception may be diminished or absent; however, and cases of "silent" compartment syndrome (i.e., absence of pain in a compartment syndrome) have been reported.[1,27] Restlessness, agitation, and anxiety may be present instead, as children may not be able to report or express pain. *Pressure,* swelling, and tenseness may be the only objective findings of early compartment syndrome; however, these findings also tend to be unreliable physical markers of compartment syndrome.[27,40] *Paralysis* is a late and poorly sensitive finding of compartment syndrome, and once a motor deficit develops, full recovery is rare. Pulse oximetry usually is not helpful.

Diagnosis or exclusion of compartment syndrome on clinical grounds alone may be impossible. In these questionable clinical situations, compartment pressure measurements are recommended. In the pediatric setting, compartment pressures usually are best measured under conscious sedation or anesthesia. Accurate placement of the needle is essential. Multiple measurements at different sites and depths within each compartment are recommended. Compartment pressure measurements close to the level of fracture may be most accurate. Although controversial, the thresholds/indications for fasciotomy are an absolute pressure greater than 30 to 40 mm Hg or pressures within 30 mm Hg of either the diastolic blood pressure or the mean arterial pressure.[43] Recently, normal baseline compartment pressures have been shown to be higher in (the legs of) children (13 to 16 mm Hg) compared to adults (5 to 10 mm Hg). The clinical application of this data remains unclear.

Delayed diagnosis of compartment syndrome in children is not uncommon. This may be related to the challenges in making the diagnosis clinically in children. Other risk factors that may delay diagnosis are altered conscious level, associated nerve injury, polytrauma, and altered pain perception (possibly related to certain types of analgesia [regional]). Certain anesthetic techniques, including local anesthetics, regional anesthesia (epidural, nerve blocks), and systemic analgesics, may obscure early signs of a developing compartment syndrome and have been shown to increase the likelihood of missed compartment syndromes.[2,27,52] Delay in diagnosis may also be related to longer elapsed time between the initial injury and peak compartment pressures in the pediatric setting.[12] Extended close monitoring (after injury) is recommended in light of the sometimes later diagnosis of compartment syndrome in children.

In the future, near-infrared spectroscopy (NIRS) may prove to be useful in the earlier diagnosis of compartment syndrome, as NIRS is noninvasive and capable of measuring the oxygenation state of at-risk tissues.[41]

Overall, the entire clinical picture must be considered, and a high index of suspicion, especially in children who are difficult to examine, obtunded patients with blunt head injuries, or patients who are sedated, must always be maintained.

Classification

Acute Compartment Syndrome: ACS occurs when tissue pressures rise high enough within an osseofascial compartment to

cause tissue ischemia. The exact time of onset of ACS is difficult to determine. It can therefore be difficult to know the duration of tissue ischemia in a given patient.

Exercise-induced or Exertional Compartment Syndrome: Exercise-induced compartment syndrome is a reversible tissue ischemia caused by a noncompliant fascial compartment that does not accommodate muscle expansion occurring during exercise. It has been described in both the upper and lower extremities.[51]

Neonatal: Both neonatal compartment syndrome and neonatal Volkmann contracture have been reported. To our knowledge, this has only been reported in the upper extremity. It is possible that this diagnosis exists for the lower extremity but has been attributed to other causes. Awareness of this diagnosis is important, as early recognition and treatment can improve the functional outcome and growth in these patients. Although established neonatal Volkmann contracture cannot be improved by emergent intervention, awareness of this diagnosis can aid in counseling of the family and treatment of the patient (Fig. 6-1A, B).

Volkmann Ischemic Contracture: Volkmann ischemic contracture is the end result of prolonged ischemia and associated with irreversible tissue necrosis.

Several classification systems have been described for upper extremity Volkmann contracture. Most are based on the clinical severity of the presentation and are used to help direct the appropriate treatment for the identified disability. Most authors recognize the tremendous variability of the clinical presentations and the subsequent limitations of the classification system.[38,48,49,54]

Seddon was the first to introduce the concept of the ellipsoid infarct involving the muscles of the proximal forearm. He further described a spectrum of contracture from mild to severe. The mild type responds to splinting with little to no residual sequelae, with the possible recurrence of contracture as a young child grows to maturity. The most severe type was described as a limb, which "apart from its envelope is gangrenous and whose treatment is futile."[38] Between these two extremes, he described three separate patterns of presentation: *(1) Diffuse but moderate ischemia; (2) intense but localized muscle damage, and (3) widespread necrosis or fibrosis.*

Zancolli noted the significant variability in the involvement of the hand. His classification system was entirely based on the involvement of the intrinsic muscles.[54] Types I to IV describe the severity of the intrinsic muscle involvement. The variability in presentation depends on the ischemic insult and recovery potential to the median and ulnar nerves.

The most commonly used and our preferred classification system is that of Tsuge.[48] He classified established Volkmann contracture into mild, moderate, and severe types, according to the extent of the muscle involvement.

The *mild type,* also described as the localized type involves the muscles of the deep flexor compartment of the forearm, usually involving only the flexor digitorum profundus of the ring or middle fingers. It can involve all the flexor digitorum profundus and the flexor pollicis longus as well. Nerve involvement is absent or mild, typically involving sensory changes which resolve spontaneously. With wrist flexion, the fingers can be fully extended. The majority of the mild type resulted from direct trauma either from crush injury or forearm fractures, and was typically seen in young adults.

In the *moderate type,* the muscle degeneration includes all or nearly all of the flexor digitorum profundus and flexor pollicis longus with partial degeneration of the flexor superficialis muscles. Neurologic impairment is always present. Sensory impairment is generally more severe in the median than in the ulnar nerve, and the hand demonstrates an intrinsic minus posture. Moderate-type injury was most commonly the result of SCH fractures in children between ages 5 and 10.

The *severe type* involves degeneration of all the flexor muscles of the fingers and of the wrist. There is central muscle necrosis, and varying involvement of the extensor compartment

A

B

FIGURE 6-1 **A:** Neonatal compartment syndrome. Note the sentinel lesion in the forearm described by Ragland et al.[31] **B:** Neonatal Volkmann's seen in a 5-day-old child. Necrosis present from time of birth. (Courtesy of Dr. M. Stevanovic.)

FIGURE 6-2 Appearance of the hand and forearm with a Tsuge *severe* type Volkmann contracture. (Courtesy of Dr. M. Stevanovic.)

(Fig. 6-2). Neurologic deficits are severe, including complete palsy of all the intrinsic muscles of the hand. Tsuge categorized as severe those cases with moderate involvement that are complicated by fixed joint contractures, scarred soft tissue, or previously failed surgeries. As with the moderate cases, the severe cases were most commonly the result of SCH fractures in children.

Within each classification type, there is a broad range of clinical presentation. This heterogeneity of presentation makes it difficult to apply a specific treatment based solely on classification systems, and makes it nearly impossible to provide meaningful outcome and comparison studies.

Treatment

Potentially devastating complications may be avoidable with early recognition and prompt intervention. The goal of treatment is to prevent tissue necrosis, neurovascular compromise, and permanent functional deficits.

The first step is to remove all possible extrinsic causes of pressure, including circumferential dressings, cast padding, and casts. Remember that excessive limb elevation may be counterproductive; the affected limb should not be elevated higher than the patient's heart to maximize perfusion while minimizing swelling; however, a little elevation is probably better than risking a dependent limb. Optimizing overall medical management is also recommended, as shock and hypoxia may lower tissue pressure tolerance.[15]

Ultimately, emergent surgical decompression (fasciotomy, i.e., release of the fascia overlying the affected compartments) is recommended for established cases. At times, release of the epimysium is also necessary. Clearly necrotic tissue should be excised as it may become a nidus for infection, but in young children questionable tissue should be left in place for a second look at a later date as discussed below. Late fibrosis of necrotic muscle can lead to compression of the adjacent nerves and result in disability of the extremity. Other procedures may be indicated based on the etiology of the compartment syndrome, including vascular thrombectomy, repair, or grafting; nerve exploration, if indicated; and fracture reduction and stabilization. Nerve repair or reconstruction when necessary should be performed at the time of definitive wound closure.

Late diagnosis increases the risk for severe complications, including infection, neurologic injury, need for amputation, and death. Concerns about increased risk of infection have led to some recommendations not to perform fasciotomy after 24 hours of onset of symptoms. Good results however may be possible in children even when fasciotomy is performed as late as 72 hours after the injury (within acute swelling phase).[12] Dramatic, essentially full, recovery has been reported following compartment syndrome of the lower leg in children even after delayed presentation.[6] The potential for recovery of muscle function may be greater in a child than in an adult. This is consistent with the increased potential for recovery observed from other types of injuries in children, such as fractures, traumatic brain injuries, and articular cartilage injuries.[6] As has been suggested in open fractures in children, if in doubt as to the viability of soft tissue, we recommend not to debride questionable tissue at the initial fasciotomy because the potential for tissue recovery in a child is much greater than that of an adult.[11]

In the case of a delayed (or late) compartment syndrome, where fasciotomy is not indicated, for example, no demonstrable muscle function in any segment of the involved limb, the limb can be splinted in a functional position. For the upper extremity, if the resources are available for immediate reconstruction with functional free muscle transfer, then early debridement and reconstruction can reduce the incidence of late contracture and improve neurologic recovery.[36,44,45] Supportive care, usually in the form of vigorous intravenous hydration, should be given for the potential risk of myoglobinuria. Myoglobinuria, as well as metabolic acidosis and hyperkalemia, can also occur during reperfusion and requires medical management especially to prevent sequelae such as renal failure, shock, hypothermia, and cardiac arrhythmias and/or failure.

Lower Extremity

Thigh

Compartment syndromes involving the thigh are particularly rare but have been reported in the pediatric population after blunt trauma, external compression with antishock trousers, and vascular injury with or without fracture of the femur. Historically, children with femoral shaft fractures treated by skin or skeletal traction were also at risk for compartment syndrome.

Three compartments—anterior, medial, and posterior—are described in the thigh (Table 6-2). In the thigh, a long single

TABLE 6-2 Compartments of the Thigh

Compartment	Contents
Anterior	Quadriceps muscle Femoral artery, vein, and nerve
Medial	Adductor muscles Obturator nerve
Posterior	Hamstring muscles Sciatic nerve

TABLE 6-3 Compartments of the Lower Leg

Compartment	Contents

Central (deep [or calcaneal])	Quadratus plantae
Medial	Abductor hallucis brevis Flexor hallucis brevis
Lateral	Flexor digiti minimi Abductor digiti minimi

lateral incision can adequately decompress the anterior and posterior compartments (Fig. 6-3). Occasionally, a medial adductor incision is required as well.

Lower Leg

The most common presentation of ACS in children involves the lower leg following a tibia and/or fibula fracture. Compartment syndrome is also a well-known complication following tibial osteotomies for angular and/or rotational correction.

In the lower leg, a one- or two-incision technique can be employed for decompressive fasciotomy of all four compartments—anterior, lateral, superficial posterior, and deep posterior (Table 6-3). In the two-incision technique (Fig. 6-4A), the anterolateral incision allows access to the anterior and lateral compartments. The posteromedial incision must be lengthy enough to allow for decompression of the superficial posterior compartment (more proximal) and deep posterior compartment (more distal). The soleus origin should be detached from the medial aspect of the tibia. All four compartments of the lower leg can also be adequately decompressed with a single-incision technique (Fig. 6-4B). The long lateral incision typically extends 3 to 5 cm within either end of the fibula. First, identification of the septum between anterior and lateral compartments allows access to these compartments. Next, by elevating the lateral compartment musculature, the posterior intermuscular septum is visualized and access to the superficial and deep posterior compartments is possible.

Foot

Compartment syndromes of the foot in children are usually caused by crush injuries, such as a car tire running over a foot, and may not be associated with a fracture.[42] Neurovascular deficit is infrequent. Compartment syndrome in the foot is commonly associated with a LisFranc fracture-dislocation but has been reported with fractures of the metatarsals and phalanges as well.

In the foot, nine compartments—interosseus (4), adductor, central (2), medial, and lateral—have been described (Table 6-4).

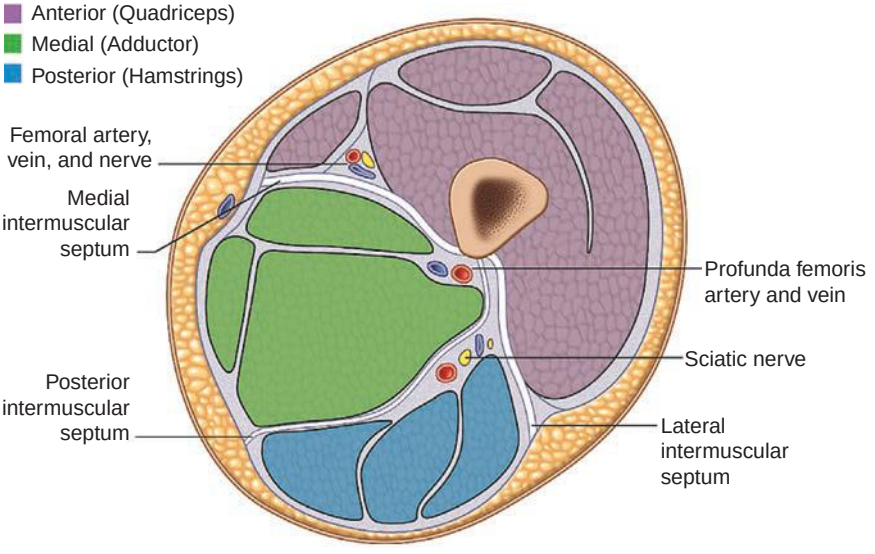

FIGURE 6-3 Cross-sectional anatomy of the thigh. Note the anterior (quadriceps), posterior (hamstrings), and medial (adductor) compartments. Entry sites for compartment pressure measurements should take into consideration the relationship between the intermuscular septa and the neurovascular structures of each compartment. (Modified from Schwartz JT, Brumback RJ, Lakatos R, et al. Acute compartment syndrome of the thigh. A spectrum of injury. *J Bone Joint Surg Am.* 1989;71:392–400 [reprinted with permission from *J Bone Joint Surg,* Inc.]. From Choi PD, Rose RKT, Kay RM, et al. Compartment syndrome of the thigh in an infant: A case report. *J Orthop Trauma.* 2007;21:587–590. [Courtesy of Dr. P. Choi.])

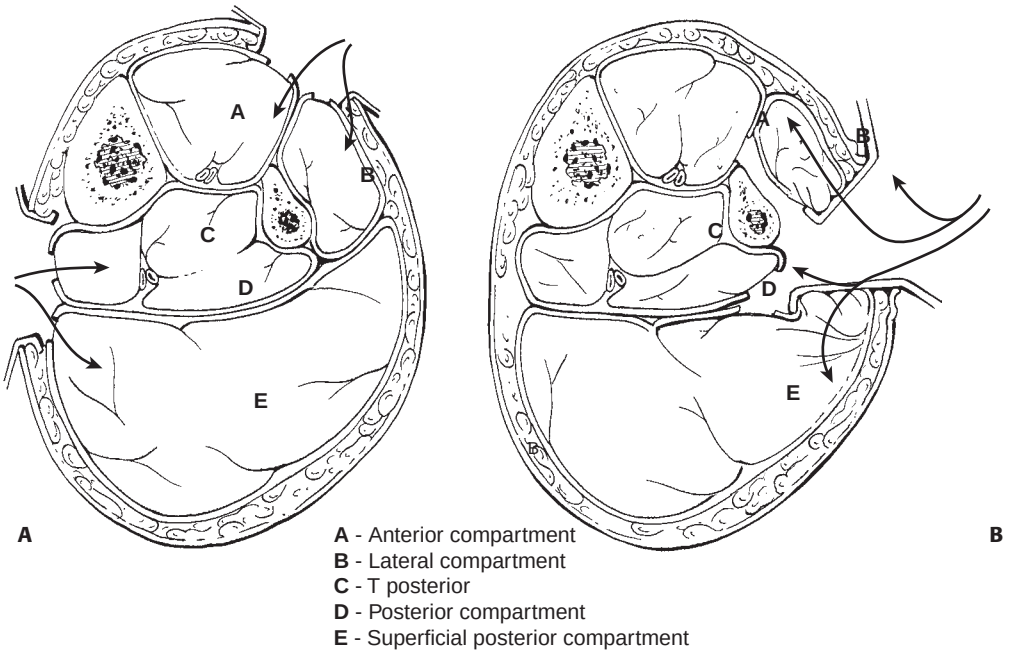

FIGURE 6-4 Decompressive fasciotomy of the lower leg. **A:** Two-incision approach. The anterolateral incision allows decompression of the anterior and lateral compartments. The medial incision allows decompression of the superficial posterior and the deep posterior compartments. **B:** One-incision approach. A single lateral incision allows decompression of all four compartments in the lower leg. (Courtesy of Dr. P. Choi.)

A dorsal approach through two longitudinal incisions centered over the second and fourth metatarsals may allow for adequate decompression of all nine compartments (Fig. 6-5), though many authors recommend a third incision for the medial compartment.

Upper Extremity

The surgical incision for fasciotomy of the arm and forearm is extensile from the brachium to the carpal tunnel. The extent of the release performed is tailored to the clinical and intraoperative findings. Release of the dorsal forearm and compartments of the hand require separate incisions when indicated (Table 6-5). Separate incision for dermotomies of each of the fingers may also be added to prevent skin necrosis and loss of the fingers.

Arm

The anterior and posterior compartments of the arm can be decompressed through a single medial incision. This allows access to the neurovascular structures of the arm, the medial fascia of the biceps and brachialis in the anterior compartment,

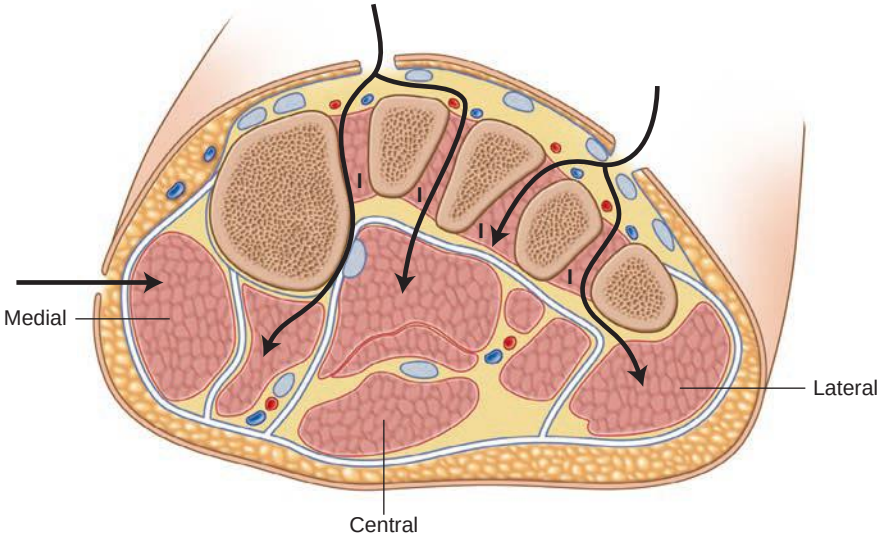

FIGURE 6-5 Decompressive fasciotomy of the foot. Through a dorsal approach, two longitudinal skin incisions over the second and fourth metatarsals can be utilized to decompress all nine compartments of the foot. The superficial fascia is divided over each interspace to decompress the interosseous (I) compartments (× 4) (caution: Interosseous veins and the distal dorsalis pedis arterial branches in the first interspace). Next, the adductor, central (superficial and deep), medial, and lateral compartments are decompressed through each interspace. Many authors, however, recommend a third medial incision to decompress the medial/calcaneal compartment.

TABLE 6-5 Compartments of the Upper Extremity

Compartments			Contents
Arm	Anterior		Biceps and brachialis, brachial artery, and median nerve
	Posterior		Triceps, ulnar nerve, and radial nerve
Forearm	Volar	Superficial	FCR, PL, pronator teres, FCU, and FDS
		Deep	FDP, FPL, and pronator quadratus Anterior interosseous nerve and artery
	Dorsal	Mobile wad	Brachioradialis, ECRL, ECRB
		Extensor	EDC, ECU, EPL, APL, EPB, EIP, EDM, supinator[a], posterior interosseous nerve
		Anconeus[b]	Anconeus
Hand	Thenar		Abductor pollicis brevis, opponens pollicis, and flexor pollicis brevis
	Hypothenar		Abductor digiti minimi, flexor digiti minimi, and opponens digiti minimi
	Adductor pollicis		Adductor pollicis (2 heads)
	Dorsal interossei (4)		Each separate compartments
	Volar interossei (3)		Each separate compartments
Fingers			[c]

[a]Supinator is not typically a component of extensor compartment syndrome, but decompression can be done through the brachioradialis/ECRL interval.

[b]Not typically listed as a separate compartment, but should be assessed.

[c]Not technically a compartment, but compression of the neurovascular structures by rigid Cleland and Grayson's ligaments can lead to skin necrosis and/or loss of the finger.

and the fascia of the triceps. Excision of the medial intermuscular septum will provide additional decompression of both compartments (Fig. 6-6). The incision can be easily extended to the elbow crease and incorporated with the incision for decompression of the forearm. This also allows release of the lacertus fibrosus and evaluation of the distal portion of the brachial artery. When there is no anticipated need to evaluate and decompress the neurovascular structures or extend the incision into the forearm, a straight midline anterior and posterior fasciotomies may be performed to decompress the flexor and extensor compartments, respectively.

Forearm

Several skin incisions have been described for the forearm. Since the surgical incisions are long and extensile, almost any incision can be used to decompress the forearm compartments (Fig. 6-7). Because the incisions are left open, we prefer the incision described in the figure below, as this minimizes exposure of neurovascular structures and can be extended proximally into the medial arm and distally into the carpal tunnel (Fig. 6-8C, D). After the skin incision is made, the antebrachial fascia is opened longitudinally from lacertus fibrosis to the wrist flexion crease. This decompresses the superficial flexor compartment. The deep flexor compartment is most easily and safely exposed through the ulnar side of the forearm.[34] We start at the mid to distal forearm and identify the interval between flexor carpi

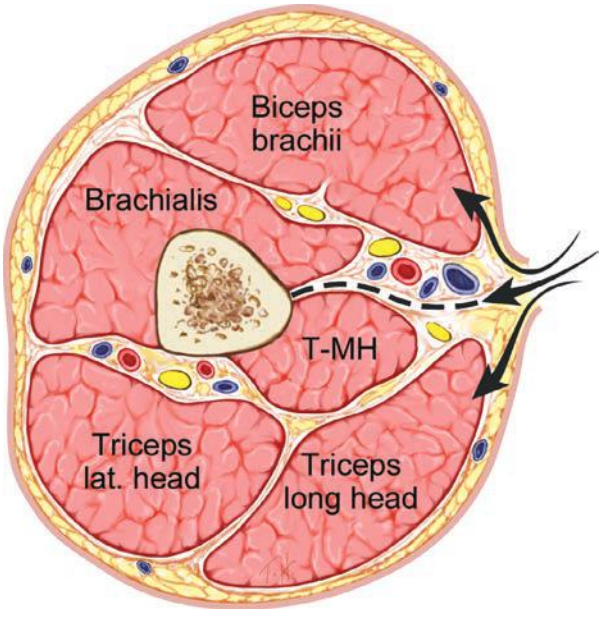

FIGURE 6-6 Cross-sectional anatomy of the arm is shown. The *dotted line* represents the plane of dissection for decompression of the anterior and posterior compartments through a medial incision. The intermuscular septum can be excised which further decompresses both compartments. Alternatively, a straight anterior and posterior incision may be used to separately decompress the anterior and posterior compartments. (Courtesy of Dr. M. Stevanovic.)

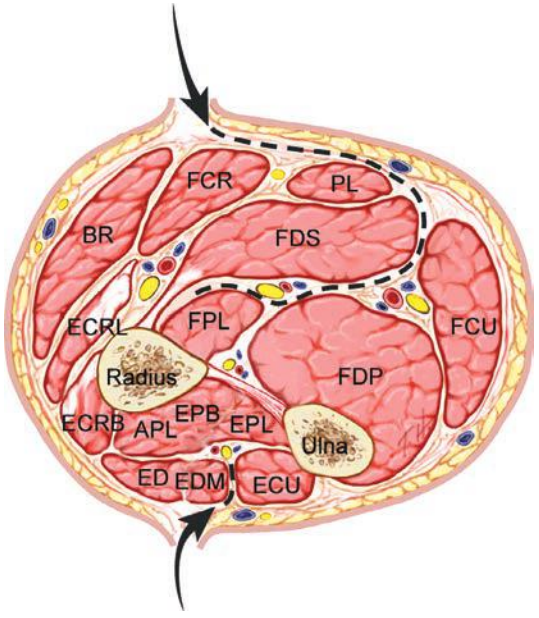

FIGURE 6-7 Cross-sectional anatomy of the forearm is shown. The *dotted lines* represent the plane of dissection for dorsal and volar compartments. The superficial flexor compartment can be released in the midline or any location, trying to avoid an incision over the radial or ulnar artery or median nerve. The deep flexor compartment is best released by opening the interval between flexor carpi ulnaris and the flexor digitorum superficialis. (Courtesy of Dr. M. Stevanovic.)

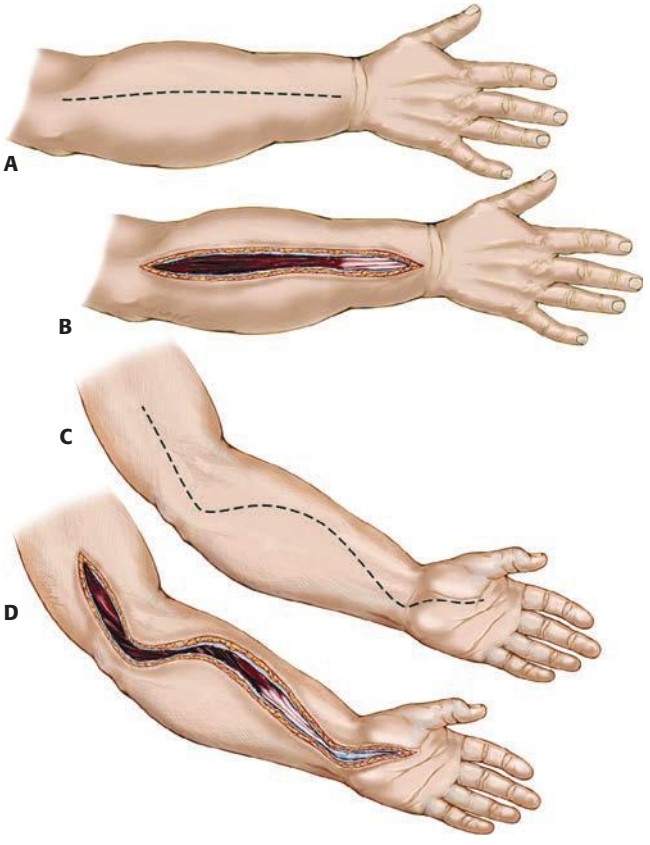

FIGURE 6-8 **A:** Dorsal (extensor) incision for forearm fasciotomy. **B:** Release of the extensor compartment. **C:** Volar (flexor side) incision for forearm fasciotomy. This incision can be extended proximally into the medial arm and distally into the carpal tunnel as indicated by intraoperative findings. **D:** Release of the flexor compartment and carpal tunnel. (Courtesy of Dr. M. Stevanovic.)

ulnaris and flexor digitorum superficialis. The flexor digitorum profundus and flexor pollicis longus fascia are exposed and released through this interval. This is the most important component of this procedure, as the deep flexor compartment is usually the first and most affected by increased compartmental pressure. Through the same interval, the fascia overlying the pronator quadratus is also released.

During the dissection, if the muscles appear pale after release of the fascia, then additional release of the epimysium of the pale muscle should be performed. For these muscles, reperfusion injury will lead to more swelling in the muscle that will lead to further muscle injury if the epimysium is not released.

Clinical evaluation at this time of the remaining tension in the dorsal forearm compartment and/or hand should be done to determine whether additional release of the extensor compartments and hand should be added (Fig. 6-9).

The extensor compartments are released through a midline longitudinal dorsal incision extending from the lateral epicondyle to the distal radioulnar joint. This will allow release of the mobile wad and the extensor compartment (Fig. 6-8A, B).

Hand

The hand has 10 separate compartments. It is rarely necessary to release all 10 compartments, and intraoperative assessment and/or measurement of compartment pressures should be used to determine the extent of release needed (Figs. 6-10 and 6-11).

Volar Release

Decompression should start with an extended carpal tunnel release. This usually will adequately release Guyon's canal without formally opening and decompressing the ulnar neurovascular structures. The carpal tunnel incision can be extended to the volar second web space. In the distal portion of the incision, the volar fascia of the adductor pollicis muscle can be released. Also, the fascia tracking to the long finger metacarpal (separating the deep radial and ulnar midpalmar space) can be decompressed. This will help decompress the volar interosseous muscles. The thenar and hypothenar muscles are decompressed through separate incisions as needed (Fig. 6-12C, D).

Dorsal Release

The dorsal interosseous muscles (and volar interosseous muscles) are decompressed through dorsal incisions between the second and third metacarpals and the fourth and fifth metacarpals. The first dorsal interosseous muscle is decompressed through an incision placed in the first dorsal web space. The dorsal fascia of the adductor pollicis can also be released through this incision (Fig. 6-12A, B).

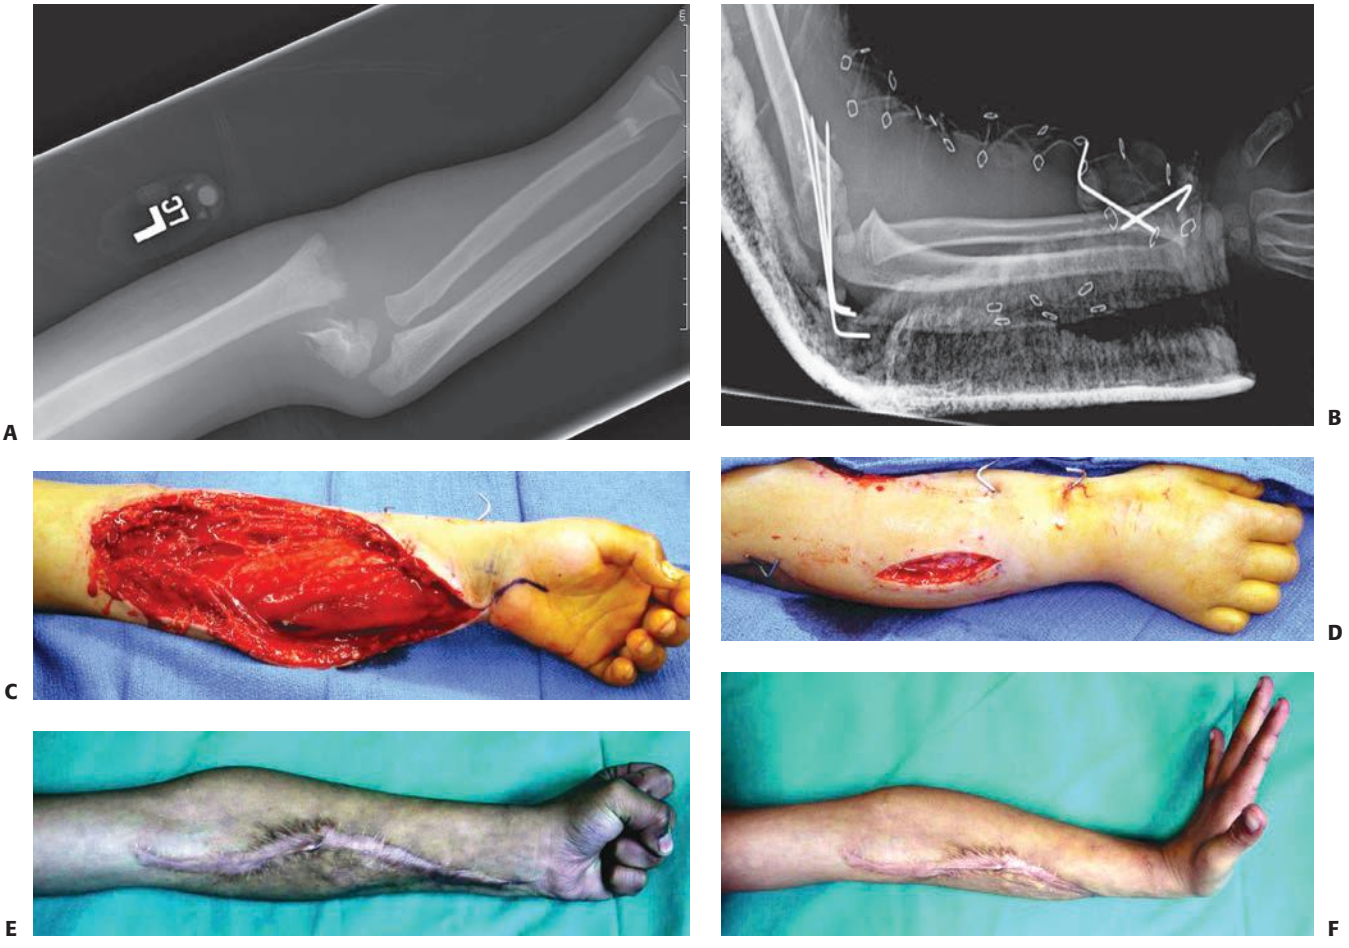

FIGURE 6-9 This 7-year-old patient fell while riding a bicycle, sustaining an ipsilateral displaced SCH fracture and distal radius fracture. He was seen about 4 hours after his initial injury. He was diagnosed with a compartment syndrome on presentation and taken emergently to the operating room for surgical stabilization and fasciotomy. **A:** Injury films showing displaced SCH fracture and distal radius fracture. **B:** Postoperative reduction and stabilization. **C:** Volar fasciotomy. **D:** Dorsal fasciotomy. **E:** Finger flexion at 1 year postinjury. **F:** Wrist and finger extension at 1 year postinjury. (Courtesy of Dr. M. Stevanovic.)

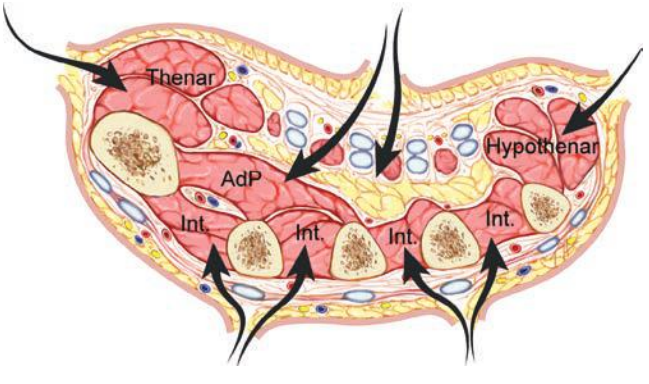

FIGURE 6-10 Cross-sectional anatomy of the hand. The *arrows* show the planes of dissection for decompression of the compartments of the hand. (Courtesy of Dr. M. Stevanovic.)

Fingers

Tense swollen fingers can result in skin and subcutaneous tissue necrosis. The tight fibers of Cleland and Grayson's ligaments can compress and obstruct the digital arteries. Dermotomy of all involved fingers reduces the risk of necrosis of the skin and possible loss of the digit. Dermotomies should be done in the midaxial plane to prevent subsequent contracture. When possible, the dermotomy should be performed on the side that will cause the least amount of scar irritation. The preferred locations for finger and thumb dermotomies are shown in Figure 6-8A–D.

Postoperative

All surgical incisions are left open. We do not like the use of retention sutures in children. Even if there is minimal swelling of the muscle(s) during the primary release, muscle swelling

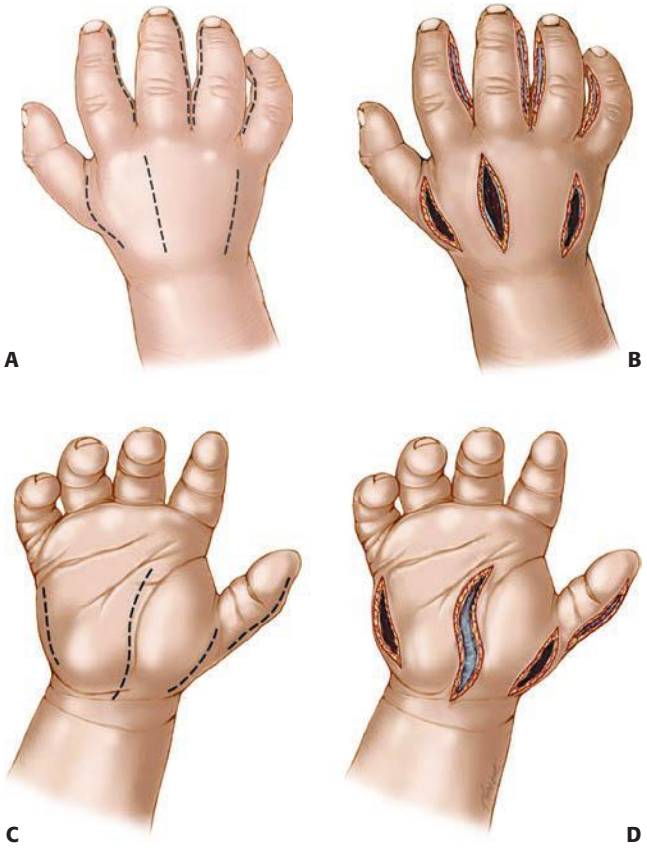

FIGURE 6-11 **A** and **B:** Dorsal incisions for fasciotomy of the hand and dermotomies of the fingers. **C** and **D:** Volar incisions for release of the thenar and hypothenar compartments, carpal tunnel release, and dermotomy of the thumb. (Courtesy of Dr. M. Stevanovic.)

will usually increase after perfusion has improved. If nerves and arteries are not exposed, a negative pressure wound dressing (e.g., VAC) can be used. If nerves or arteries are exposed, we prefer to use a moist gauze dressing. Dressing changes should be done in the operating room at 24 to 48 hours. Partial delayed primary wound closure can be performed at that time if swelling is decreased and/or to provide coverage over open neurovascular structures. Definitive wound closure should be performed only after swelling has decreased. In the hand, only the incision for the carpal tunnel release should be considered for delayed primary wound closure. The other palmar and dorsal incisions as well as the dermotomy incisions will close quickly healing by secondary intention. If the skin cannot be closed without tension, then split thickness skin grafting with or without dermal substitutes should be used.

Therapy should be started immediately postoperatively to maintain maximum active and passive range of motion of the fingers. Splinting should be done as long as needed for soft tissue stabilization or for treatment of other associated injuries. Therapy may need to be temporarily discontinued during healing of skin grafts, but should be resumed as soon as tissue healing allows. Once the soft tissues are adequately healed, we continue nighttime splinting to prevent contractures of the wrist and fingers. Splinting is continued until scars and soft tissues are mature and supple.

Established Contracture (Volkmann's)

Treatment of established Volkmann contracture depends on the severity of the contracture and neurologic deficits and the resultant functional losses. The classification system of Tsuge provides some guidance in establishing a treatment algorithm. However, each patient has unique deficits and needs. Reconstruction should take into consideration their deficits, residual motor and sensory function, and the patient's needs. Surgical treatment should not be undertaken before soft tissue equilibrium is present.

Nonoperative Management

Nonoperative management should be instituted early in most cases of established Volkmann contracture. In children, there may be more recovery of nerve and muscle function over time than in adults, and we do not advocate immediate surgical intervention. A formal program of splinting and therapy can improve the outcome of later surgical intervention and may result in less extensive surgical corrections. Therapy should be directed toward maintenance of passive joint motion, preservation and strengthening of remaining muscle function, and correction of deformity through a program of splinting. We prefer the use of static progressive splinting or serial casting for fixed contractures of the wrist, fingers, and thumb web space. Mild contractures with minimal to no nerve involvement can often be treated only with a comprehensive program of hand therapy and rehabilitation. For moderate to severe involvement where surgery is anticipated, therapy is indicated only as long as necessary to achieve supple passive motion of the fingers. Preoperative therapy is also helpful in establishing a good patient and parent rapport with the therapist and in gaining an understanding of the postsurgical therapy program.

Operative Treatment

A variety of surgical procedures have been used to treat Volkmann ischemic contracture. These have included both bone and soft tissue management.

Bone Reconstruction: Shortening procedures including shortening osteotomy of the radius and ulna and proximal row carpectomy have been used to match the skeletal length to the shortened fibrotic muscle.[14,33] Generally, we do not like shortening procedures in children, because the forearm is already relatively shortened by the initial ischemic insult to the bone and growth plates. Further, the principal contracture is usually on the flexor surface. Shortening the forearm indiscriminately lengthens the muscle resting length of both the flexor and extensor muscles, neglecting the predominant involvement of the contracture within the flexor compartment. Bony reconstructive procedures for long-standing contractures or for distal reconstruction required for neurologic injury include wrist fusion, trapeziometacarpal joint fusion, or thumb metacarpophalangeal joint fusion, which should be done after skeletal maturity. These may be considered in conjunction with some of the soft tissue procedures listed below.

FIGURE 6-12 This 4-year-old girl placed a rubber band around her wrist before going to bed. She was brought to the emergency room the following morning because of swelling of her hand. She was taken immediately to the operating room for compartment release. **A:** Volar hand prior to fasciotomy. **B:** Dorsal hand prior to fasciotomy. **C:** Volar release. **D:** Dorsal release. **E:** Finger flexion at 6 months. **F:** Finger extension at 6 months. (Courtesy of Dr. M. Stevanovic.)

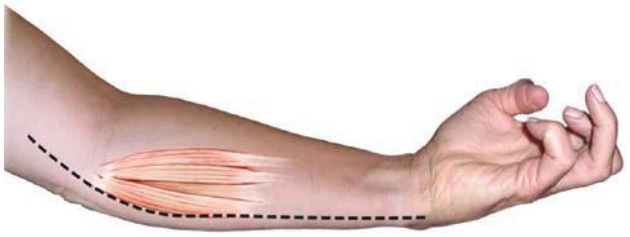

FIGURE 6-13 Extended ulnar incision.

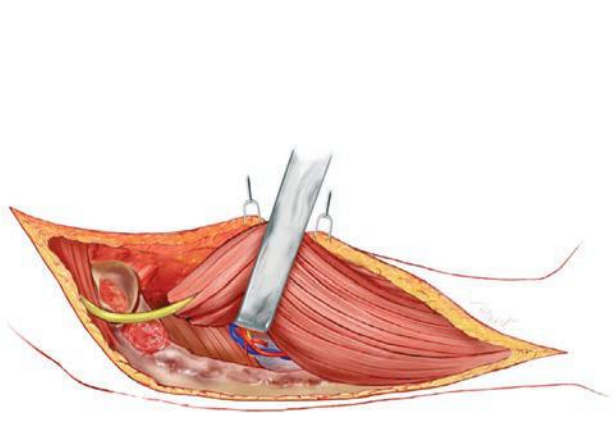
Soft Tissue Procedures: Soft tissue procedures have included excision of the infarcted muscle, fractional or z-lengthening of the affected muscles, muscle sliding operations (flexor origin muscle slide), neurolysis, tendon transfers, and functional free tissue transfers, as well as combinations of the above procedures.[7,8,10,14,16,19,22,23,32,37,46,48,49,55] Excision of scarred fibrotic nerves without distal function followed by nerve grafting has been described to try and establish some protective sensation in the hand.[18] Fixed contractures of the joints can be addressed with soft tissue release including capsulectomy and collateral ligament recession or excision, depending on the joints involved.

Author's Preferred Methods

Our preferred methods of treatment depend on the general classification of severity of contracture, individualized to the patient presentation.

Mild (localized) Type (Deep flexor compartment without neurologic deficit): For mild contractures which have failed to respond to nonsurgical management, our preferred treatment is a muscle sliding operation initially described by Page and subsequently used and endorsed by several others.[23,26,29,35,37,39,48,49] We have found this procedure effective as long as there is clinically good finger flexion. We do not combine this procedure with infarct excision, nor have we found it necessary to release the distal insertion of the pronator teres to correct pronation contracture.[23,49]

We differ with Tsuge in our surgical incision and favor the technique initially described by Page (Fig. 6-13). The surgical incision begins on the ulnar distal arm and continues along the ulnar border of the forearm all the way to the wrist. The ulnar nerve is identified and mobilized out of the cubital tunnel and for several centimeters proximal to the medial epicondyle. Three to four centimeters of intermuscular septum is excised. The flexor pronator mass is elevated off of the medial epicondyle, taking care to preserve the medial collateral ligament and elbow joint capsule. The origins of the flexor carpi ulnaris, flexor digitorum longus, and flexor digitorum superficialis are carefully mobilized off of the ulna and interosseous membrane. The dissection is carried out above the periosteum toward the radius. The common interosseous artery arises as a branch of the ulnar artery, crossing the flexor digitorum profundus. Here it bifurcates into the anterior and posterior interosseous arteries. The posterior interosseous artery crosses to the posterior compartment at the proximal edge of the interosseous membrane, and can be easily injured in this area. As this is the dominant blood supply to the extensor compartment, it is important to protect this branch (Fig. 6-14A, B). Working toward the radius, the origin of the flexor pollicis longus is released from proximal to distal. Throughout the procedure, the wrist and fingers are manipulated to check whether the contracture is improving and to help localize where there is still tightness within the muscle origin. The dissection must often be carried down to the level of the wrist to release adhesions between the flexor tendons and pronator quadratus before full correction is achieved. If necessary, the carpal tunnel should be opened and tendon adhesions released in this area as well. Slight under correction, which can be addressed by postoperative splinting and rehabilitation may decrease the reduction in muscle power resulting from the muscle slide. When a pronation contracture is present and not corrected by the release of the flexor–pronator origin, we release the pronator quadratus from the distal ulna. Even with a complete release of both pronators and dorsal distal radioulnar joint capsule, complete correction of the pronation deformity may not be possible because of fibrosis and contracture of the interosseous membrane. At the completion of the muscle slide, the ulnar nerve is transposed to an anterior subcutaneous position. The hand is splinted and



A

B

FIGURE 6-14 Flexor slide with muscle elevation and showing the posterior interosseous artery branching from the common interosseous artery. **A:** Diagram. **B:** Clinical photo.

subsequently casted in a position of forearm supination, wrist and finger extension. We continue this immobilization for a period of 6 weeks to allow the flexor–pronator origin to heal adequately to its new origin (Fig. 6-15).

A limited flexor slide may be done for mild deformity, affecting only a portion of the flexor digitorum profundus. In this case, the surgical incision is the same; however, the flexor pronator mass does not have to be released from the medial epicondyle, and the ulnar nerve does not have to be mobilized and transposed. We do not usually perform a neurolysis, because by definition of the mild type, there is little to no nerve involvement. We think that this surgical approach limits its potential scarring and vascular compromise to the remaining muscles and nerves in the flexor compartment, and that

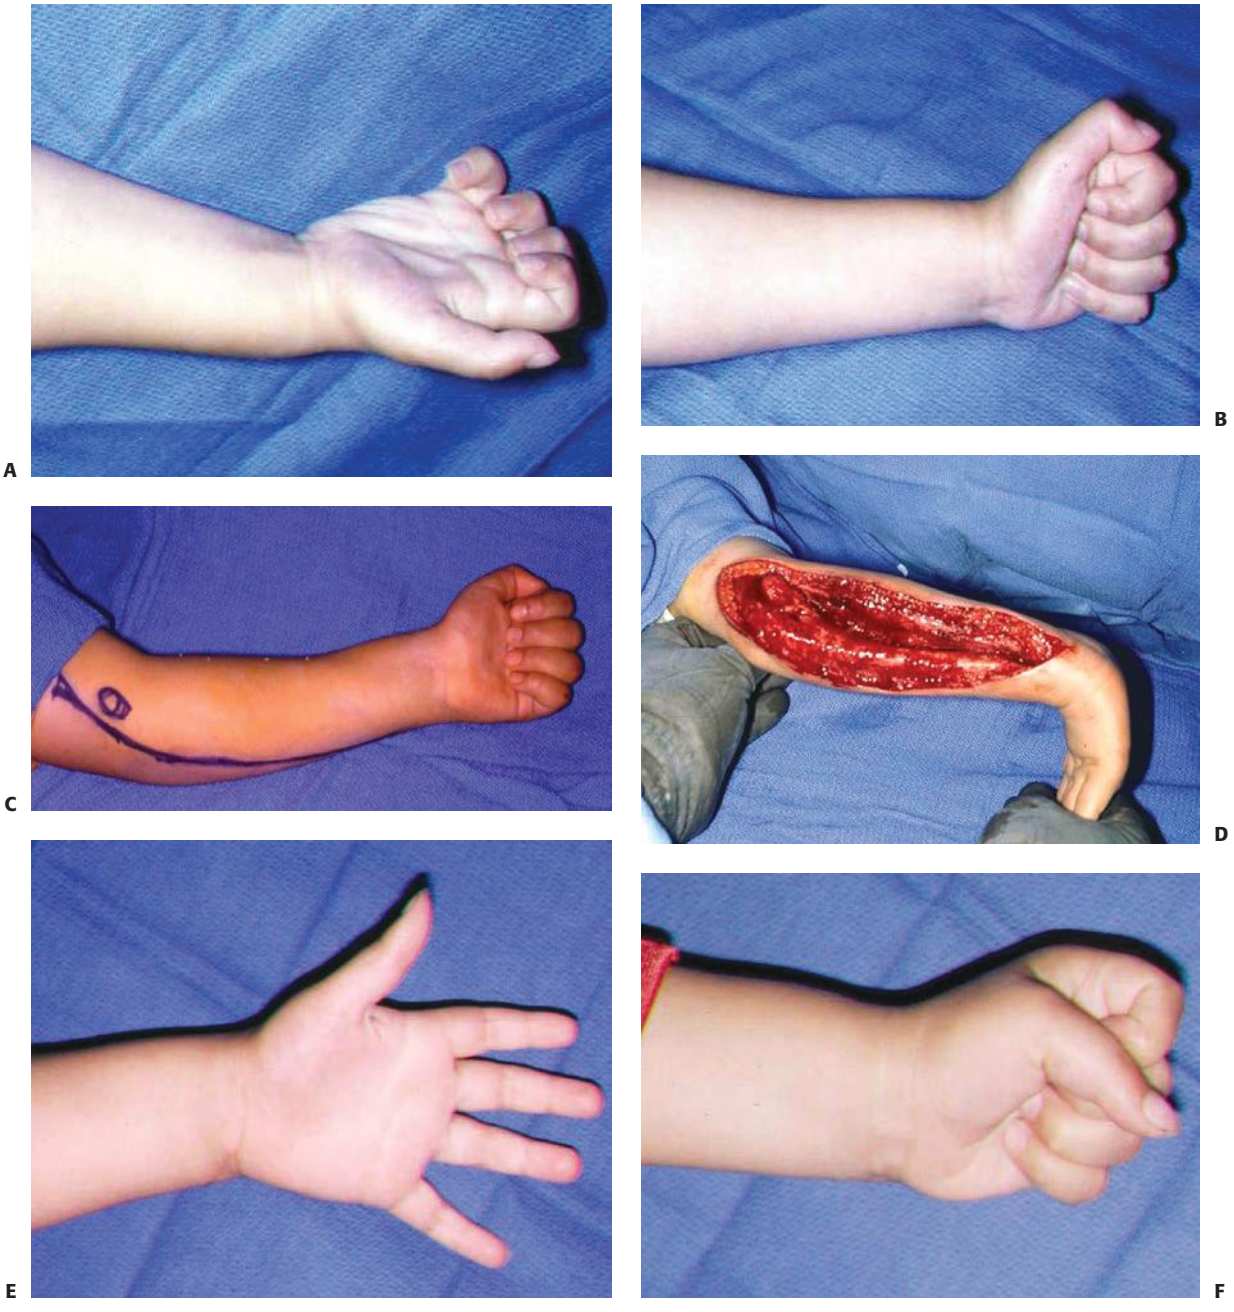


FIGURE 6-15 This 7-year-old boy sustained an SCH fracture after a fall from a tree. He was treated with closed reduction and pinning. He presented 1 year after his injury with inability to extend his fingers and thumb. **A:** Preoperative maximum extension. **B:** Preoperative maximum flexion. **C:** Extended ulnar incision. **D:** Intraoperative flexor slide. At the completion of the flexor slide, the patient has full extension of the elbow, wrist, and fingers. **E:** 1-year postoperative extension. **F:** 1-year postoperative flexion.

the superficial veins are better preserved in the subcutaneous tissue.

Moderate Type (Deep and superficial flexor compartment with neurologic deficit): For moderate deformity, we still prefer the muscle slide operation to correct the tightness of the flexors, provided that there is still adequate remaining strength in the flexors. Since neurologic impairment is characteristic of the moderate injury, we combine the flexor slide with neurolysis of both the median and ulnar nerves. A separate incision to release the carpal tunnel may also be done. Depending on the functional deficits, tendon transfer can be combined with flexor slide, usually as a staged procedure.

Reconstruction of Thumb Function: Our preferred transfers for thumb flexion is to use brachioradialis or extensor carpi radialis longus to the flexor pollicis longus. Extensor indicis proprius is used for thumb opposition.

Reconstruction of Finger Flexion: When the finger flexors are very weak or absent, a functional free muscle transfer may produce a better functional result than tendon transfers. However, if functional free muscle transfer is not an option, tendon transfers include: Biceps brachii elongated with autograft (fascia lata or superficialis tendon) to the flexor digitorum profundus. Extensor carpi radialis longus, brachioradialis, extensor carpi ulnaris, and extensor indicis proprius can also be used as donor muscles for reconstruction of finger flexion. These donor muscles do not have sufficient excursion to match the flexor muscles, but in the absence of other options, they can provide adequate improvement in grasp.

Nerve Reconstruction: When sensory impairment is severe and there has been no recovery, the nerve should be carefully evaluated at surgery. If there is a densely scarred atrophic nerve, resection of the nerve to healthy appearing fascicles followed by sural nerve graft reconstruction may restore protective sensation to the hand.

Severe Type (superficial and deep flexor compartments, extensor compartment, and severe neurologic deficits): Severe type contractures are best treated with functional free muscle transfers.[7,8,19,22,55] The donor vessels are usually either the radial or anterior interosseous artery as an end-to-end anastomosis, or end-to-side to the brachial artery. The donor motor nerve is the anterior interosseous, which should be resected back to healthy appearing fascicles. Our preference for the donor muscle is the gracilis. Appropriate marking of the muscle resting length and establishing a strong muscle origin and insertion are critical to achieving good functional results.[45] Zuker has described using separate motor fascicles of the gracilis to restore independent flexor digitorum profundus and flexor pollicis longus motor function.[55]

For severe type contractures with extensive involvement of the extensor compartment, a double-free muscle transfer should be considered. As with the moderate type, tendon transfer, nerve graft reconstruction, and late osseous reconstructive procedures may improve final functional outcomes.

Postoperative: Both operative and nonoperative treatment requires splinting and therapy (whether formal or informal) through skeletal maturity.

Outcomes

The duration of elevated tissue pressures before definitive surgical decompression may be the most important factor in determining outcome. In adults, prolonged ischemic insult to compartment musculature greater than 8 hours increases the risk of permanent sequelae.[12] Favorable outcomes can be expected if decompression is accomplished in less than 8 to 12 hours.[24] Full functional recovery within 6 months has been reported with timely management of compartment syndrome in the pediatric population.[2] The development of compartment syndrome does not seem to delay fracture healing.

Complications associated with compartment syndrome include functional muscle loss, contracture, neurologic deficit (both motor and sensory distal to the level of injury), cosmetic deformity, growth arrest, and infection. Less commonly, loss of limb, rhabdomyolysis, multiorgan system failure, and death can be seen, especially in the setting of crush injury with severe large volume muscle necrosis.

Permanent and disabling outcomes are a real and significant risk of compartment syndrome. Early recognition of the diagnosis and expeditious treatment may minimize long-term functional disability; however, even promptly treated compartment syndrome can have permanent residual deficits.[5,13,28]

Outcomes following Volkmann contracture in the upper extremity are difficult to assess. Studies are limited by small numbers of patients, great variability in initial presentations, use of varied surgical techniques, and difficulty in compliance with the long-term follow-up necessary to track patients through skeletal maturity. Ultee and Hovius attempted to provide some information regarding outcomes. They found that all patients who had developed the contracture during childhood had a relatively shortened extremity. Substantial improvements in hand function were noted in those patients who underwent functional free muscle transfer. Tendon lengthening alone often resulted in recurrence of contracture. Finally, in patients who had sufficient remaining muscle, procedures which combined infarct excision, tenolysis, neurolysis, and tendon transfer when necessary produced good hand function.[50] Sundararaj and Mani noted improvement in sensory function in conjunction with neurolysis. Additional procedures were done simultaneously, and little analysis of outcomes of those other procedures was given.[47] In our experience, mild and moderate contractures can have significant functional improvement following flexor muscle slide and nerve reconstruction when indicated. Normal function is not anticipated, but a hand with protective sensation and functional grasp can often be achieved. Functional free muscle outcomes can also restore gross grasp and have a much better outcome in patients with good intrinsic function.

7 PHYSEAL INJURIES AND GROWTH DISTURBANCES

Karl E. Rathjen and Harry K.W. Kim

INTRODUCTION

One of the unique aspects of pediatric orthopedics is the presence of the physis (or growth plate), which provides longitudinal growth of children's long bones. Physeal injuries are a common and unique feature of children's bony injuries, in part because the physis is structurally more susceptible to loads that would produce metaphyseal or juxta-articular fractures in adults.[15,28,63,81,112,117,135,137,141] Physeal injury may occur in a variety of ways in addition to trauma.[14,15,19,23,26,32,38,52,65,78,88,91,123,125,136,150,154,156] Although physes, similar to the children with them, are resilient to permanent injury, uneventful outcomes are by no means assured.[1,10,17,20,25,29,61,76,90,104,106,110,113,122,134,143] In this discussion of management of physeal injuries and associated growth disturbances the term *physis* is used rather than "growth plate."

PHYSEAL ANATOMY

Normal Physeal Anatomy

Gross

Five regions characterize long bones: The bulbous, articular cartilage-covered ends (epiphyses) tapering to the funnel-shaped metaphyses, with the central diaphysis interposed between the metaphyses. During growth, the epiphyseal and metaphyseal regions are separated by the organized cartilaginous physis, which is the major contributor to longitudinal growth of the bone. The larger long bones (clavicle, humerus, radius, ulna, femur, tibia, and fibula) have physes at both ends, whereas the smaller tubular bones (metacarpals, metatarsals, and phalanges) usually have a physis at one end only.

At birth, with the exception of the distal femur and occasionally the proximal tibia, all of the epiphyses which are mentioned above are purely cartilaginous. At various stages of postnatal growth and development, a secondary ossification center forms within the epiphysis. This development helps define the radiolucent zone of the physis, which persists until the physis closes at skeletal maturation. Typical ages for appearance of the major secondary ossification centers and physeal closure are summarized in Figures 7-1 and 7-2.

Microscopic Structure

Physis is highly organized, yet dynamic structure that consists of chondrocytes undergoing proliferation, differentiation, and formation of complex extracellular matrix. The extracellular matrix is composed of type II collagen fiber network, aggrecans, and noncollagenous proteins, such as cartilage oligomeric protein

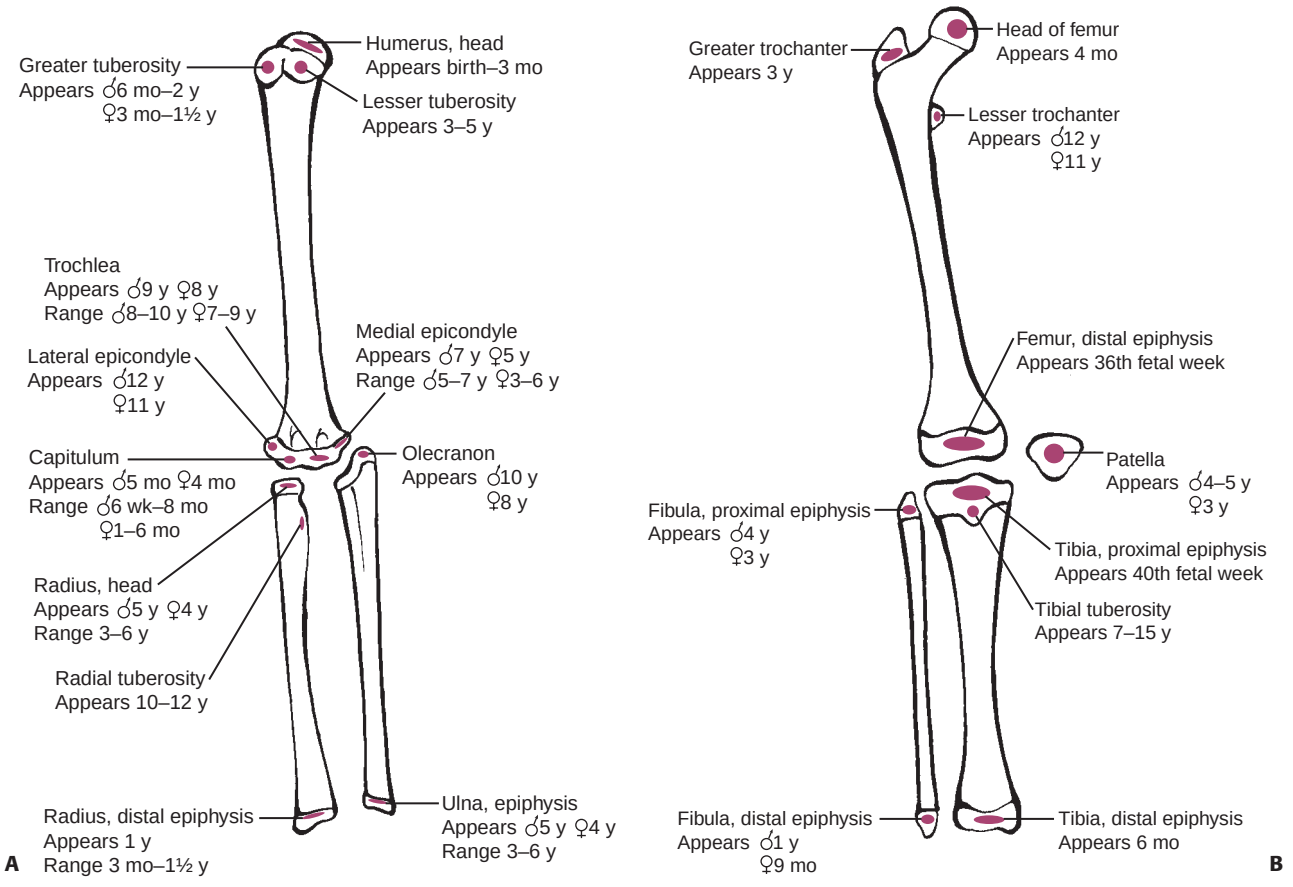

FIGURE 7-1 Typical age (and range) of development of the secondary ossification centers of the epiphyses in the **(A)** upper extremity and **(B)** lower extremity.

and matrilin-3. Type IX and XI collagens are minor collagens found in the physis. Type X collagen is also found in the physis; however, its synthesis is limited to the hypertrophic zone and is a distinguishing feature of hypertrophic chondrocyte.

Understanding of physeal injuries requires knowledge of normal physeal morphology.[135] Histologically, the physis is divided into four zones oriented from the epiphysis to the metaphysis: Germinal (reserve), proliferative, hypertrophic, and provisional calcification (Fig. 7-3). The proliferative zone is the location of cellular proliferation, whereas the hypertrophic and provisional calcification zones are characterized by extracellular matrix production, cellular hypertrophy, apoptosis, extracellular matrix calcification, and vascular invasion of the lacunae of the terminal hypertrophic chondrocytes. Collagen fiber orientation is horizontal in the germinal zone whereas it is vertical in the proliferative and hypertrophic zones, in line with growth and columnar arrangement of cells.[8] Collagen content is lower in the proliferative and hypertrophic zones compared with the germinal zone. The differences in the collagen content and fiber orientation of different physeal zones have important implications in the mechanical behavior of each zone to mechanical loading.[9] For instance, greater strains are observed in the proliferative and hypertrophic zones compared with the germinal zone following compression loading.

The peripheral margin of the physis comprises two specialized areas important to the mechanical integrity and peripheral growth of the physis (Fig. 7-3). The zone (or groove) of Ranvier is a triangular microscopic structure at the periphery of the physis, containing fibroblasts, chondroblasts, and osteoblasts. It is responsible for peripheral growth of the physis. The perichondral ring of LaCroix is a fibrous structure overlying the zone of Ranvier, connecting the metaphyseal periosteum and cartilaginous epiphysis, and has the important mechanical function of stabilizing the epiphysis to the metaphysis.

The epiphysis and secondary ossific nucleus must receive blood supply for viability.[155] Dale and Harris[46] identified two types of blood supply to the epiphysis (Fig. 7-4). Type A epiphyses (such as the proximal humeral and proximal femoral epiphyses) are nearly completely covered with articular cartilage; therefore, most of the blood supply to the epiphysis must enter from the perichondrium in a distal to proximal direction. The blood supply to these epiphyses may be easily compromised by epiphyseal separation. A complete disruption of the epiphyseal vasculature, however, may not produce an extensive ischemic damage to the physis if the metaphyseal vasculature is intact.[87] The studies using multiphoton microscopy also suggest that growth plate nutrition is not unidirectional from the epiphysis to the metaphysis as traditionally believed but is

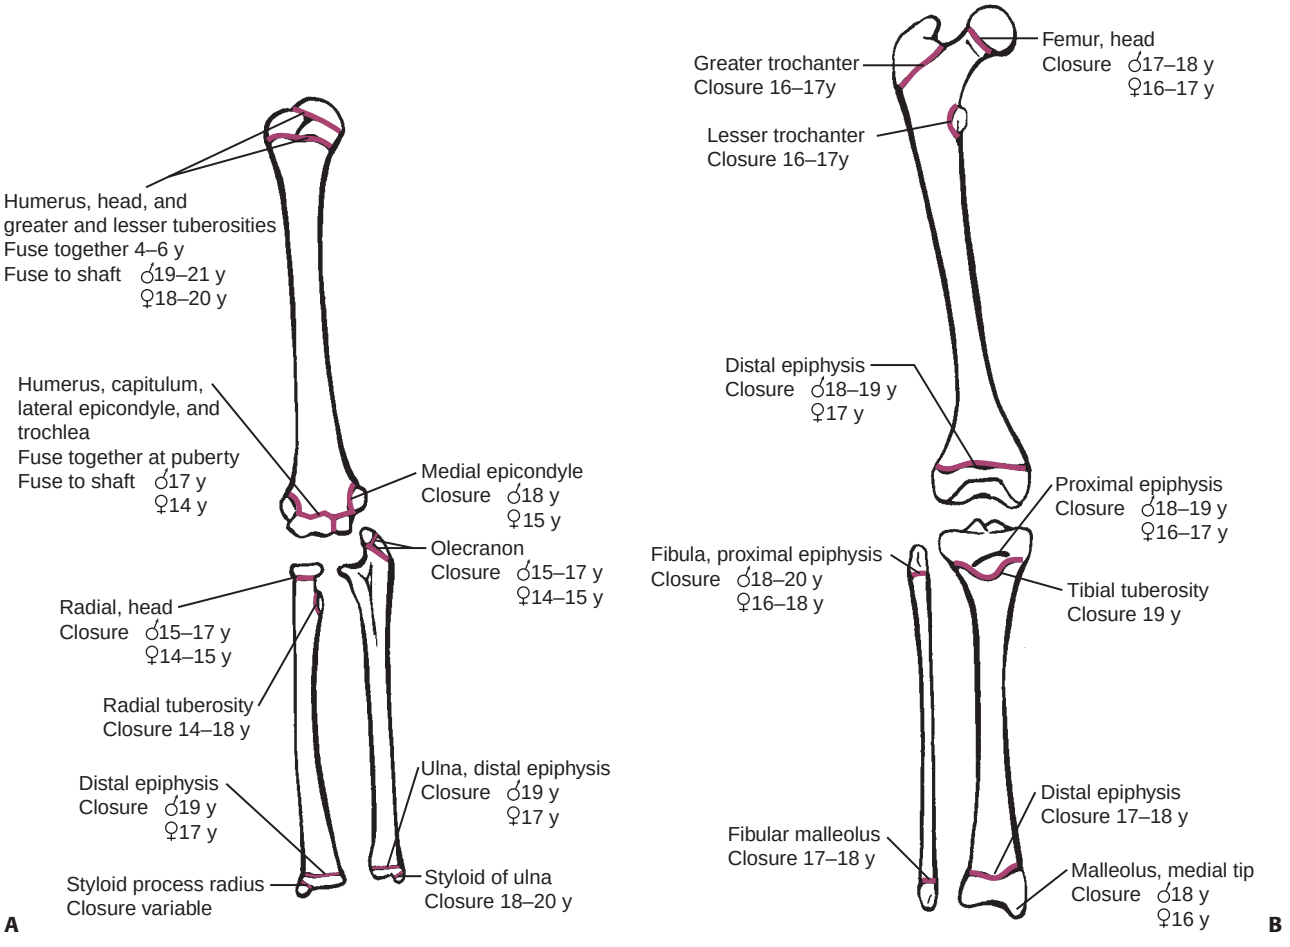

FIGURE 7-2 Typical age (and range) of closure of physes in the **(A)** upper extremity and **(B)** lower extremity.

contributed by the epiphyseal, metaphyseal, and circumferential perichondrial vasculature.[53,161] Type B epiphyses (such as the proximal and distal tibia and the distal radius) have only a portion of their surface covered with articular cartilage and are theoretically less susceptible to devascularization from epiphyseal separation.

Regulation of Growth

Various systemic (hormonal) and local (paracrine) factors, as well as the mechanical factors, regulate and influence the longitudinal growth.[115] Systemic factors that influence physeal function include growth and thyroid hormones, androgen, estrogen, vitamin D, and glucocorticoids. Estrogen and not androgen controls the growth spurt and normal physeal closure at skeletal maturity in both sexes.[149] Local factors that influence chondrocyte proliferation and differentiation include parathyroid hormone-related protein, Indian hedgehog protein, transforming growth factor-B, insulin-like growth factor-1, and fibroblast growth factor. In a physis, chondrocyte hypertrophy contributes most to the longitudinal growth followed by extracellular matrix production and cell division.[163] The physes with more rapid growth, such as the proximal tibial physis in comparison to the proximal radial physis, have a larger increase in cell size. Experimental studies show that static, sustained loading decreases chondrocyte proliferation, cell height, and the thickness of the hypertrophic zone.[158] Hueter–Volkmann law states that abnormal compression inhibits growth whereas distraction stimulates it. A varying degree of dynamic physiologic loading, however, has not been shown to significantly alter longitudinal bone growth.[114]

Contributions to Longitudinal Growth and Maturation Characteristics of Selected Physes

Growth of long bones is more complex than simple elongation occurring at their ends. However, as a generality, the physes at the end of long bones contribute known average lengths in percentage of total bone growth and percentage contributions to the total length between two physes at either end of a long bone. This information has come from observations of longitudinal growth by a number of authors.[11-13,64,71,102] Knowledge of this information is paramount for the surgeon managing physeal injuries to long bones. Figure 7-5 outlines the generally accepted percentage of longitudinal growth contribution of pairs of physes for each long bone in the upper and lower

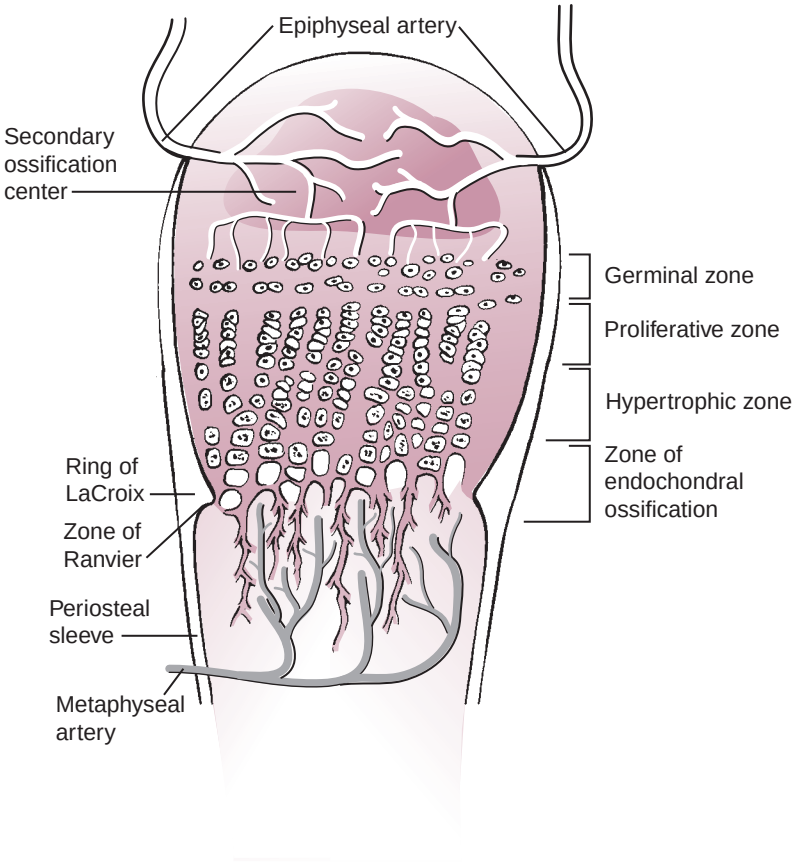

FIGURE 7-3 Schematic diagram of the organization of the physis. Four zones are illustrated: The germinal, proliferative, hypertrophic, and provisional calcification (or enchondral ossification) layers. Note also the groove of Ranvier and the perichondral ring of LaCroix.

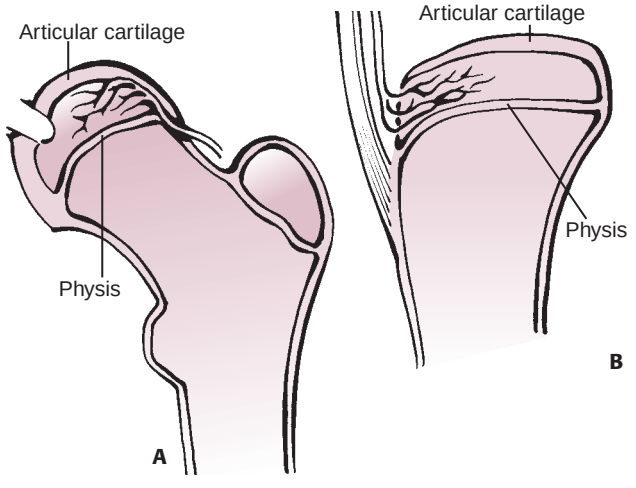

FIGURE 7-4 Classification of epiphyseal blood supply according to Dale and Harris. **A:** Type A epiphyses are nearly completely covered by articular cartilage. Blood supply must enter via the perichondrium. This blood supply is susceptible to disruption by epiphyseal separation. The proximal femur and proximal humerus are examples of type A epiphyses. **B:** Type B epiphyses are only partially covered by articular cartilage. Such epiphyses are more resistant to blood supply impairment by epiphyseal separation. The distal femur, proximal and distal tibia, and distal radius are clinical examples of type B epiphyses.

extremities. Table 7-1 outlines the average amount of growth in millimeters per year of skeletal growth contributed by the same physes mentioned above. These are estimations only, and growth tables should be consulted when more specific information is required.[12,13,64,71,102]

Mechanical Features of the Physis and Patterns of Injury

An understanding of the microscopic characteristics of the physeal zones permits an understanding of the theoretical line of least resistance (and hence fracture) within the physis. The germinal and proliferative zones are characterized by an abundance of extracellular matrix, whereas the hypertrophic and provisional calcification zones are primarily cell hypertrophy, apoptosis, and vascular channels. As a consequence, fracture lines can be predicted to pass through the hypertrophic and provisional calcification zones, a finding that Salter and Harris reported in their experimental investigation in rats.[138] Theoretically, Salter–Harris types I and II fractures should involve these zones only, not affecting the germinal and proliferative zones, and thus should be at lower risk for subsequent growth disturbance. However, types III and IV physeal fractures traverse the entire physis, including the germinal and proliferative zones. In addition, displacement between bone fragments containing portions of the physis may occur. Consequently, growth disturbance is more likely from type III or IV injuries.

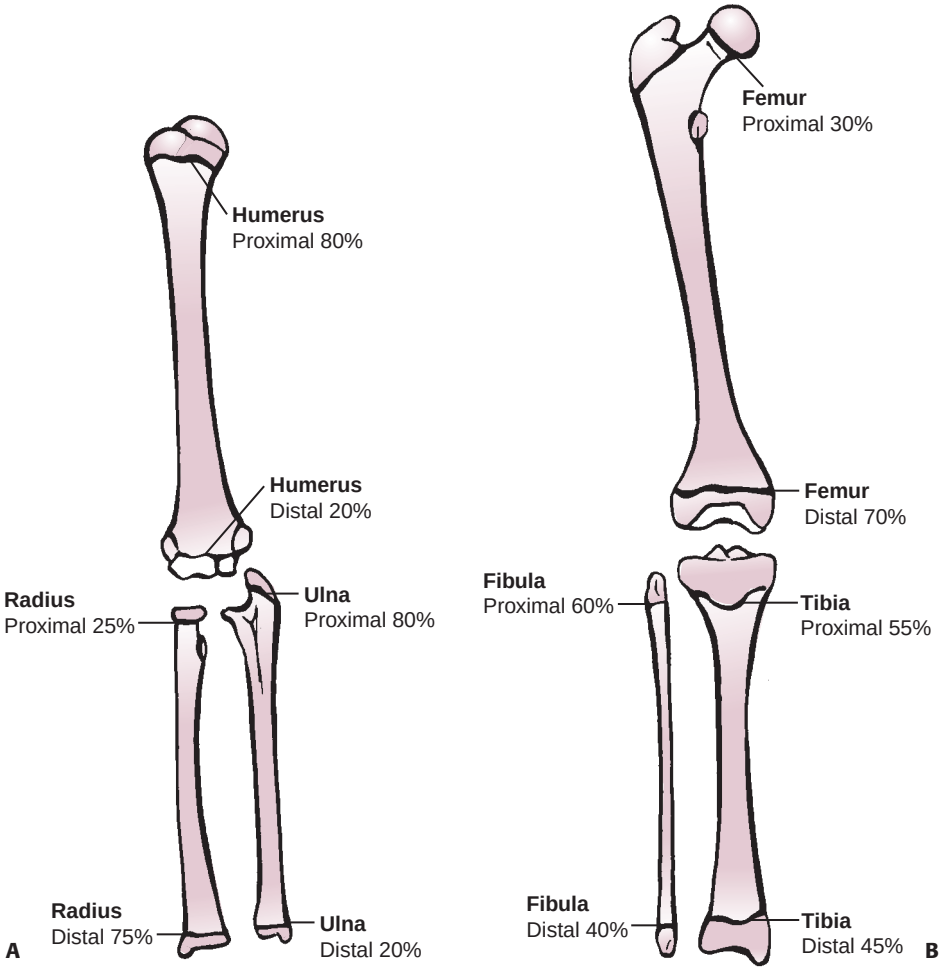

FIGURE 7-5 Approximate percentage of longitudinal growth provided by the proximal and distal physes for each long bone in the upper **(A)** and lower **(B)** extremities.

Not surprisingly, mechanical and clinical studies of microscopic fracture patterns have demonstrated that fracture lines through the physeal layers are more complex than this simplistic view, and often undulate through the various zones.[28,63,80,112,148,159] Smith et al.[148] reported a Salter–Harris type I fracture of the distal tibia examined microscopically after associated traumatic lower leg amputation. In this high-energy injury, they found that the fracture line involved all four layers of the physis, in part because of the relatively straight plane of fracture and the undulations of the physis. Bright et al.[28] in a study of experimentally induced physeal fractures in immature rats, found that not only was the fracture line usually complex, involving all four layers of the physis, but also that the physis contained a number of horizontal "cracks" separate from the fracture itself. They also observed a statistically significant lower force required to produce a physeal fracture in male and prepubescent animals, which might have clinical relevance to the epidemiologic aspects of physeal fractures (see "Epidemiology"). The rate, direction, and magnitude of force are also factors that contribute to the histologic pattern of physeal fractures. Moen and Pelker,[112] in an experimental study in calves, found that compression forces produced fractures in the zone of provisional calcification and metaphysis, shear caused fractures in the proliferative and hypertrophic zones, and torque produced fracture lines involving all four layers of the physis. Finally, the energy of injury is a factor in the extent of physeal injury. Distal femoral physeal fractures are a good example of the overriding significance of the energy of injury in potential for subsequent growth disturbance. High-energy mechanisms of injury are frequent in this region, and the risk of subsequent growth disturbance is high.[99,134]

Our current understanding of how a bone bridge forms following a physeal injury is limited. The experimental studies show a sequence of inflammatory, fibrogenic, and osteogenic responses in the time course of bone bridge formation following a drill hole injury to the proximal tibial physis in a rat model.[165] More in-depth study using microarray analysis showed that several molecular pathways including those involved with skeletal development, osteoblast differentiation, BMP signaling, and Wnt signaling are involved in the bone bridge formation.[100] A better understanding of mechanisms involved with the bone bridge formation may lead to new treatments that can prevent this complication.

Physeal Injuries

Etiology of Physeal Injuries

Physes can be injured in many ways, both obvious and subtle. Obviously, the most frequent mechanism of injury is fracture.

TABLE 7-1 Average Growth per Year (in mm) of Specific Physes of the Upper and Lower Extremities[a]

Location	Average Growth (mm/y)
Proximal humerus	7
Distal humerus	2
Proximal radius	1.75
Distal radius	5.25
Proximal ulna	5.5
Distal ulna	1.5
Proximal femur	3.5
Distal femur	9
Proximal tibia	6
Distal tibia	5
Proximal fibula	6.5
Distal fibula	4.5

[a]Estimations only. Gender, skeletal age, percentile height, and epiphyseal growth all influence magnitude of individual bone growth. Growth tables should be consulted when specific calculations are required. Adapted from growth studies.

Most commonly, physeal injury is direct, with a fracture involving the physis itself. Occasionally, physeal injury from trauma is associated with a fracture else wherein the limb segment, either as a result of ischemia[125] or perhaps compression[1,10,25,76,107,113,157] (see discussion of Salter–Harris type V physeal fractures below). Other mechanisms of injuries to the physes include infection,[19,23,91,123] disruption by tumor, cysts,[150] and tumor-like disorders, vascular insult,[125] repetitive stress,[7,26,39,40,98,168] irradiation,[34,136] and other rare etiologies.[18,32,38,141,168]

Infection

Long bone osteomyelitis or septic arthritis (particularly of the shoulder, hip, and knee) can cause physeal damage resulting in either physeal growth disturbance or frank growth arrest.[14,19,23,52,65,78,88,91,123] These septic injuries may be further complicated by joint disruption resulting from associated epiphyseal destruction, articular cartilage damage, and capsular adhesions, particularly in the hip and shoulder.

Multifocal septic arrests can produce significant deformity requiring multiple surgical procedures. The most common causes are fulminant neonatal sepsis, particularly in premature infants or those with neonatal sepsis associated with maternal diabetes, and multiple septic arrests associated with meningococcemia (Fig. 7-6). In the latter case, physeal damage may also result from the cardiovascular collapse and disseminated intravascular coagulation known as purpura fulminans.[14,65,78,88]

FIGURE 7-6 Standing anteroposterior lower extremity radiograph of a 12-year-old boy with multifocal physeal disturbance from purpura fulminans associated with meningococcemia. Radiograph abnormalities are present in the left proximal femur; both distal femoral epiphyses, including partial arrest of the left distal femoral physis; and both distal tibial epiphyses. The patient also has digital amputations and extensive soft tissue scarring resulting from this septic event.

Tumor

Both malignant and benign tumors and tumor-like disorders can disrupt normal physeal architecture, resulting in direct physeal destruction. In the case of malignant tumors, the extent of growth lost as the result of local irradiation or limb salvage surgery must be taken into consideration in planning and recommending the therapeutic reconstruction to be undertaken.

Benign tumors and tumor-like conditions can result in destruction of all or part of a physis. Examples include enchondromata, either isolated or multiple (Ollier disease) (Fig. 7-7), and unicameral bone cysts.[150] Growth disturbance as a consequence of physeal damage from these disorders generally cannot be corrected by surgical physeal arrest resection (see "Physeal Arrests"), and other treatment strategies must be adopted as clinically indicated.

FIGURE 7-7 Valgus deformity of the distal femur associated with the presence of an enchondroma of the distal lateral femur involving the lateral physis.

Vascular Insult

Known vascular insult is a rare cause of physeal injury.[125] Partial or complete growth arrests can occur from a pure vascular injury to an extremity (Fig. 7-8). Unrecognized vascular insult may represent the mechanism of subsequent growth disturbance after an injury in an adjacent part of a limb and may play a role in Salter–Harris type V injuries; the most common location for this is the tibial tubercle after femoral shaft or distal femoral physeal fractures. In addition, ischemia may be the cause of physeal damage associated with purpura fulminans.[14,65,78,88]

FIGURE 7-9 Stress injury of the distal radius and ulna in both wrists of a competitive gymnast. There was no history of specific injury. The wrists were tender to touch. Note distal radial and ulnar physeal widening and irregularity.

Repetitive Stress

Repetitious physical activities in skeletally immature individuals can result in physeal stress–fracture equivalents.[7,39,40] The most common location for such injuries is in the distal radius or ulna, as seen in competitive gymnasts (Fig. 7-9); the proximal tibia, as in running and kicking sports such as soccer (Fig. 7-10); and the proximal humerus, as in baseball pitchers.[39] These injuries should be managed by rest, judicious resumption of activities,

A

B

FIGURE 7-8 Physeal injury from presumed vascular insult. **A:** The patient's leg was caught under heavy pipes rolling off a rack, resulting in stripping of the soft tissues from the distal thigh, open comminuted fracture of the distal femur, and popliteal artery injury. **B:** In follow-up, after arterial and soft tissue reconstruction, the patient has physeal growth arrests of the distal femur and proximal tibia. The mechanism of injury to the proximal tibial physis was presumed to be vascular because of the associated femoral artery injury.

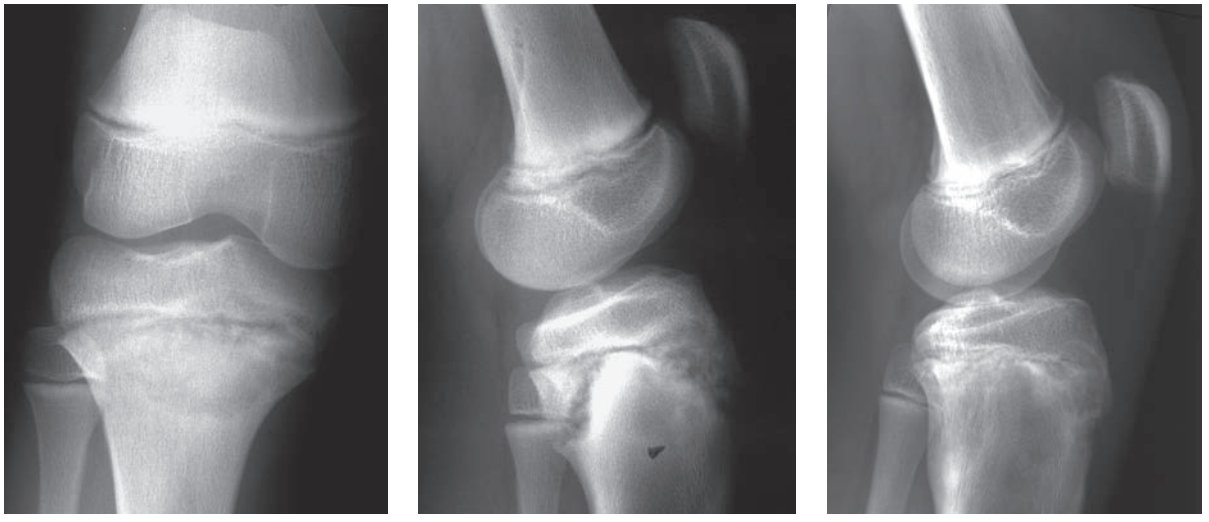

FIGURE 7-10 Stress injury of the proximal tibia in an elite soccer player. **A:** Anteroposterior radiograph film demonstrates subtle proximal tibial physeal widening. **B:** Lateral radiograph shows widening, a metaphyseal Thurston–Holland fragment, and some posterior displacement of the proximal epiphysis. **C:** Significant radiograph improvement noted after discontinuing athletic activities for 3 months.

and longitudinal observation to monitor for potential physeal growth disturbance.

Miscellaneous (Irradiation, Thermal Injury, Electrical, Unrecognized)

Rare causes of physeal injury, usually recognized from consequent growth disturbance, include irradiation (Fig. 7-11)[34,136]; thermal injury, especially phalangeal physeal injury from frostbite (Fig. 7-12)[32,38]; burns; and electrical injuries. A recent report noted progressive genu valgum associated with obesity and theorized that repetitive microtrauma superimposed on genetic factors might play a role in growth disturbance.[168] On other rare occasions, physeal growth disturbance noted on clinical findings and radiographs has no identifiable cause. Presumably, such events represent unrecognized trauma, infection, or vascular insult involving the physis.

FIGURE 7-11 Proximal tibial physeal growth disturbance with angular deformity after irradiation for Ewing sarcoma.

Historical Review of Physeal Fractures

Physeal fractures have been recognized as unique since ancient times. Hippocrates is credited with the first written account of this injury. Poland (see "Classification of Physeal Fractures") reviewed accounts of physeal injuries in his 1898 book,

FIGURE 7-12 Premature closure of the distal phalangeal physes after a frostbite injury to the digits.

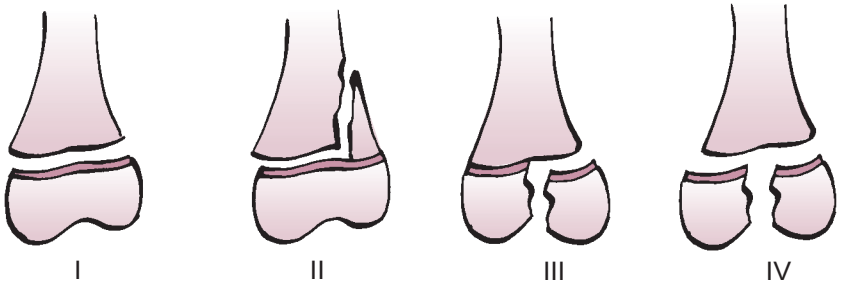

FIGURE 7-13 Poland classification of physeal fractures compared to the Salter–Harris classification. Poland type I: Epiphyseal separation without metaphyseal fragment, or extension into the epiphysis. Poland type II: Physeal fracture line extends into the metaphysis. Poland type III: Fracture extends from the articular surface to the physis and continues peripherally through the physis. Poland type IV: T-condylar fracture of the epiphysis and physis.

Traumatic Separation of the Epiphysis.[132] Poland is also credited with the first classification of the patterns of physeal fracture, and the publication of his text closely followed Roentgen's discovery of radiographs in 1895.

Classification of Physeal Fractures

Poland[132] proposed the first classification of physeal fractures in 1898. Modifications to Poland's original scheme have been proposed by a number of authors,[2-5,46,49,101,117,119,126,127,130,138] including Aitken,[4] Salter and Harris,[138] Ogden et al.[119,107] and Peterson.[126,127] Classifications of physeal fractures are important because they alert the practitioner to potentially subtle radiographic fracture patterns, can be of prognostic significance with respect to growth disturbance potential, and guide general treatment principles based on that risk and associated joint disruption. To some extent, fracture pattern provides some insight into mechanism of injury and the extent of potential physeal microscopic injury ("Normal Physeal Anatomy" and "Mechanical Features of the Physis and Patterns of Injury").

Currently, the Salter–Harris classification, first published in 1963,[138] is firmly entrenched in the literature and most orthopedists' minds. Therefore, evolution and specifics of the nature of physeal fractures of the various classification schemes are discussed relative to the Salter–Harris classification. The reader also should be aware of some deficiencies in that classification, as pointed out by Peterson.[126-128]

Poland Classification of Physeal Fractures

Poland's classification, published in 1898,[132] consisted of four types of physeal fractures (Fig. 7-13). Types I, II, and III were the foundation of the Salter–Harris classification, as described below. Poland's type IV fracture was effectively a T-condylar fracture of the epiphysis and physis.

Aitken Classification of Physeal Fractures

Aitken[4] in 1936 included three patterns of physeal fracture in his classification (Fig. 7-14). His type I corresponded to Poland and Salter–Harris type II fractures, his type II to Poland and Salter–Harris type III fractures, and his type III was an intra-articular transphyseal metaphyseal–epiphyseal fracture equivalent to a Salter–Harris type IV fracture.

Salter–Harris Classification of Physeal Fractures

Salter and Harris published their commonly used five-part classification of physeal injuries in 1963.[138] The first four types were adopted from Poland (types I, II, and III) and Aitken (Aitken type III became Salter–Harris type IV) (Fig. 7-15). Salter and Harris added a fifth type, which they postulated was an unrecognized compression injury characterized by normal radiographs and late physeal closure. Peterson and Burkhart challenged the existence of true type V injuries,[128] but other authors have subsequently documented its existence in some form.[1,10,17,25,74,76,86,128,157] Because we believe that delayed physeal closure can occur after some occult injuries, we have chosen to retain this type of injury in our preferred classification scheme.

Type I. Salter–Harris type I injuries are characterized by a transphyseal plane of injury, with no bony fracture line through either the metaphysis or the epiphysis. Radiographs of undisplaced type I physeal fractures, therefore, are normal except for associated soft tissue swelling, making careful patient examination particularly important in this injury. In the Olmstead County Survey of physeal fractures,[129] type I fractures occurred most frequently in the phalanges, metacarpals, distal tibia, and distal ulna. Epiphyseal separations in infants occur most commonly in the proximal humerus, distal humerus, and proximal femur. If an urgency to make the diagnosis is deemed necessary for patients suspected of having a type I injury, further imaging by ultrasound, magnetic resonance imaging (MRI),[36,44,79,130,147]

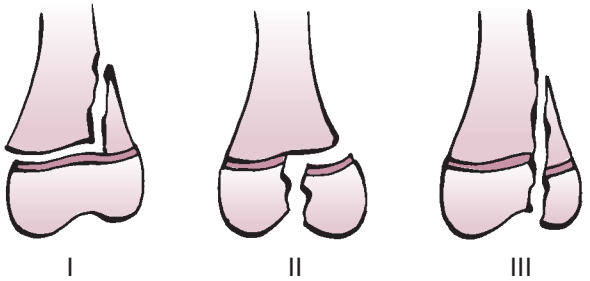

FIGURE 7-14 Aitken classification of physeal fractures: Types I, II, and III. Type III is equivalent of Salter–Harris type IV.

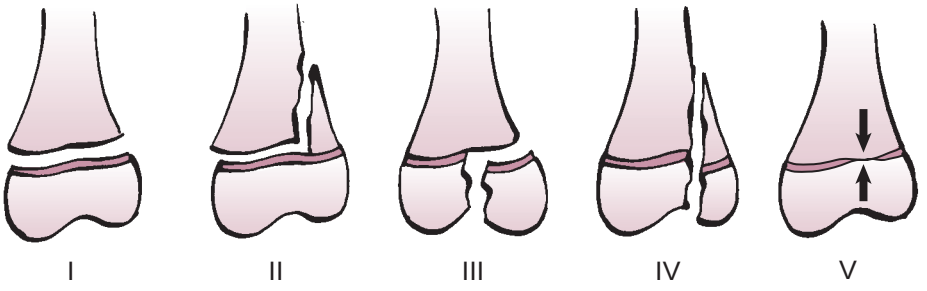

FIGURE 7-15 Salter–Harris classification of physeal fractures. In Salter–Harris type I fractures, the fracture line is entirely within the physis, referred to by Poland as type I. In Salter–Harris type II fractures, the fracture line extends from the physis into the metaphysis; described by Poland as type II and Aitken as type I. In Salter–Harris type III fractures, the fracture enters the epiphysis from the physis and almost always exits the articular surface. Poland described this injury as type III and Aitken as type II. In Salter–Harris type IV, the fracture extends across the physis from the articular surface and epiphysis, to exit in the margin of the metaphysis. Aitken described this as a type III injury in his classification. Salter–Harris type V fractures were described by Salter and Harris as a crush injury to the physis with initially normal radiographs with late identification of premature physeal closure.

or intraoperative arthrography may be helpful.[6,67,105] Stress radiographs to document displacement are generally unnecessary and probably unwise. Ultrasound is particularly helpful for assessing epiphyseal separations in infants (especially in the proximal femur and elbow regions) without the need for sedation, anesthetic, or invasive procedure.[30,48,50,73,140]

The fracture line of type I injuries is usually in the zone of hypertrophy of the physis, as the path of least resistance during the propagation of the injury (see "Normal Physeal Anatomy") (Fig. 7-16). As a consequence, in theory, the essential resting and proliferative zones are relatively spared, and, assuming that there is no vascular insult to these zones as a consequence of the injury, subsequent growth disturbance is relatively uncommon. As discussed above, however, studies have shown this to be a simplistic view of the fracture line through a physis, and that, because of uneven loading and macroscopic undulations in the physis, any zone of the physis can be affected by the fracture line.[27,80,112,137,141,148]

Because the articular surface and, at least in theory, the germinal and proliferative layers of the physis are not displaced, the general principles of fracture management are to secure a gentle and adequate reduction of the epiphysis on the metaphysis and stabilize the fragments as needed.

Type II. Type II injuries have physeal and metaphyseal components; the fracture line extends from the physeal margin peripherally across a variable portion of the physis and exits into the metaphysis at the opposite end of the fracture (Fig. 7-17). The epiphyseal fragment thus comprises all of the epiphysis and some portion of the peripheral metaphysis (the Thurston–Holland fragment or sign). The physeal portion of this fracture has microscopic characteristics similar to those of type I injuries, but the fracture line exits the physis to enter the metaphysis (i.e., away from the germinal and proliferative layers) at one margin. Similar to type I injuries, these fractures should have a limited propensity to subsequent growth disturbance as a consequence

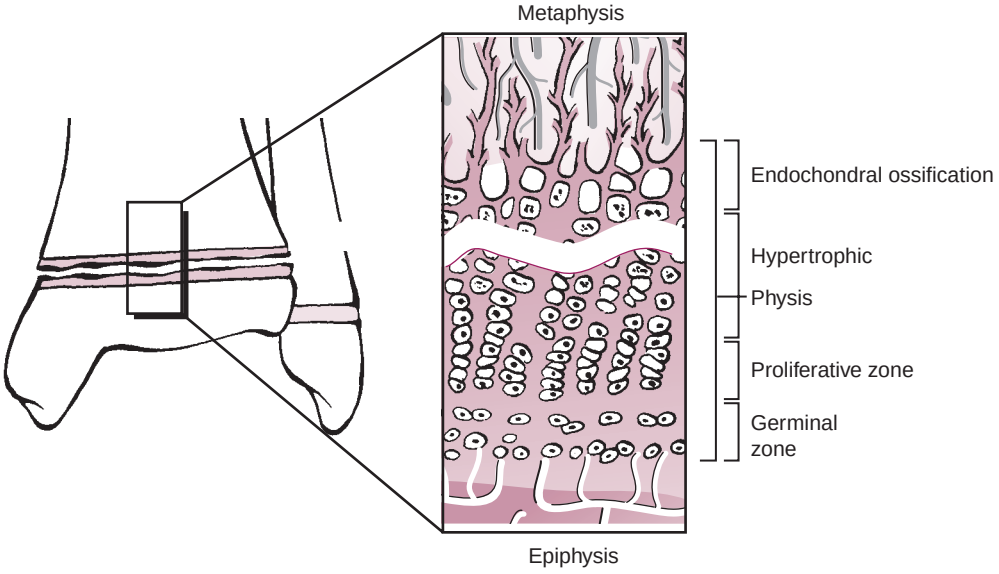

FIGURE 7-16 Scheme of theoretic fracture plane of Salter–Harris type I fractures. Because the hypertrophic zone is the weakest zone structurally, separation should occur at this level. Experimental and clinical studies have confirmed that the fracture plane is more complex than this concept and frequently involves other physeal zones as well.

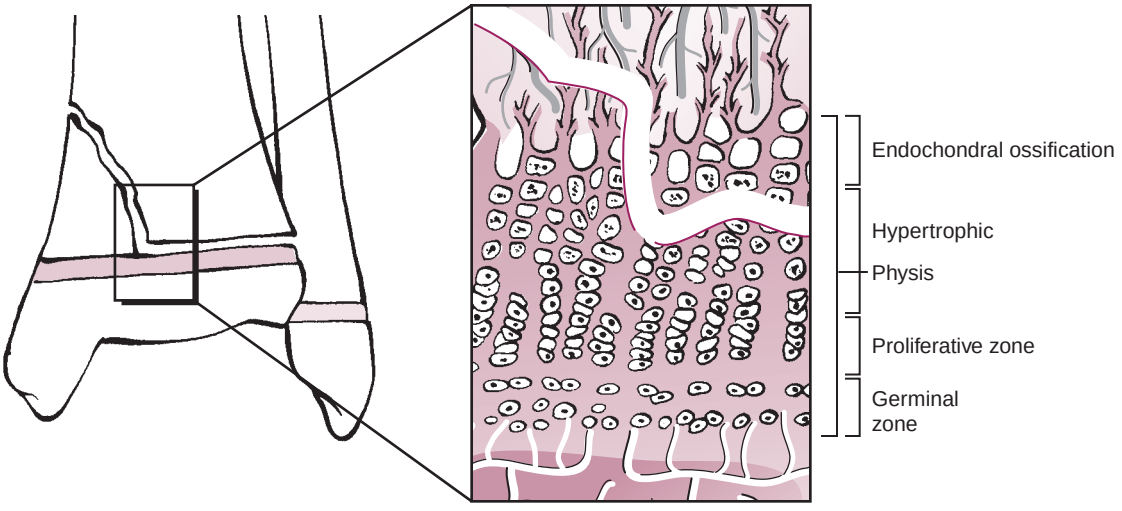

FIGURE 7-17 Fracture plane of Salter–Harris type II fractures. The fracture extends from the physis into the periphery of the metaphysis.

of direct physeal injury. However, the metaphyseal "spike" of the diaphyseal/metaphyseal fragment may be driven into the physis of the epiphyseal fragment, which can damage the physis (Fig. 7-18). Similar to type I injuries, the articular surface is not affected and the general principles of fracture management are effectively the same.

Type III. Salter–Harris type III fractures begin in the epiphysis (with only rare exception) as a fracture through the articular surface and extend vertically toward the physis. The fracture then courses peripherally through the physis (Fig. 7-19). There are two fracture fragments: A small fragment consisting of a portion of the epiphysis and physis, and a large fragment consisting the remaining epiphysis and long bone. This fracture pattern is important for two main reasons: The articular surface is involved (Fig. 7-20) and the fracture line involves the germinal and proliferative layers of the physis. In addition, type III injuries are often associated with high-energy or compression mechanisms of injury, which imply greater potential disruption of the

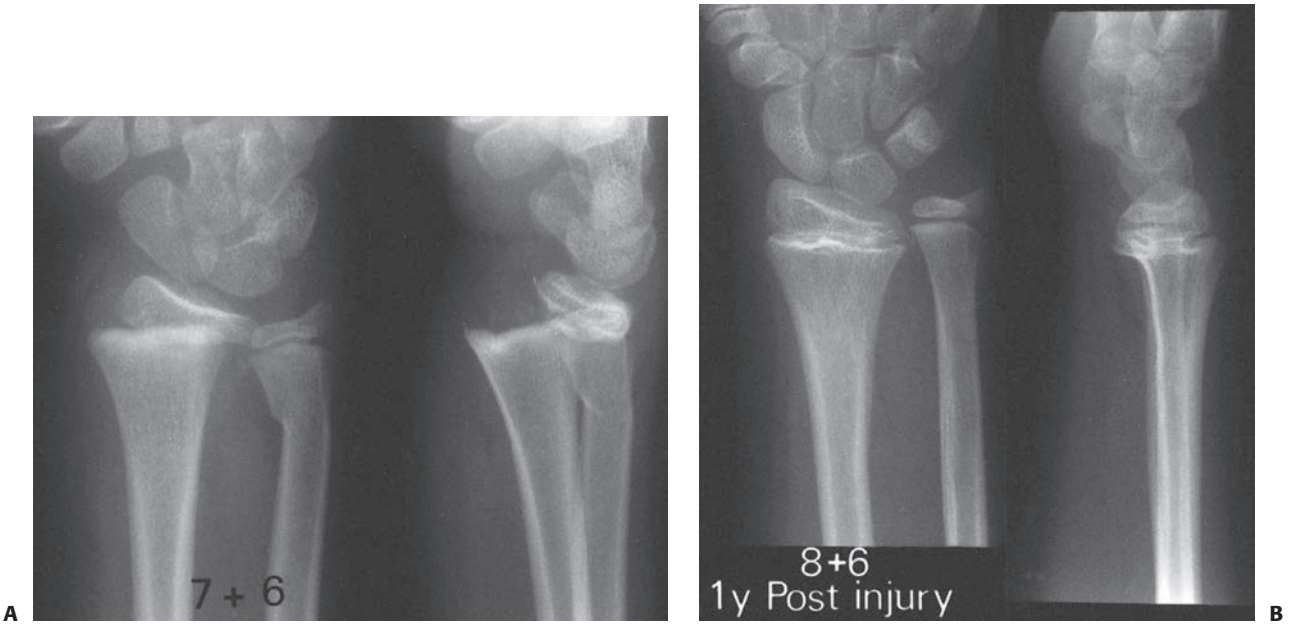

FIGURE 7-18 Potential mechanism of physeal arrest development after Salter–Harris type II fracture of the distal radius. **A:** Dorsally displaced type II fracture of the distal radius. Note the evidence of impaction of the epiphyseal fragment (with the physis) by the dorsal margin of the proximal fragment metaphysis. **B:** One year later, there is radiographic evidence of physeal arrest formation in the distal radial physis.

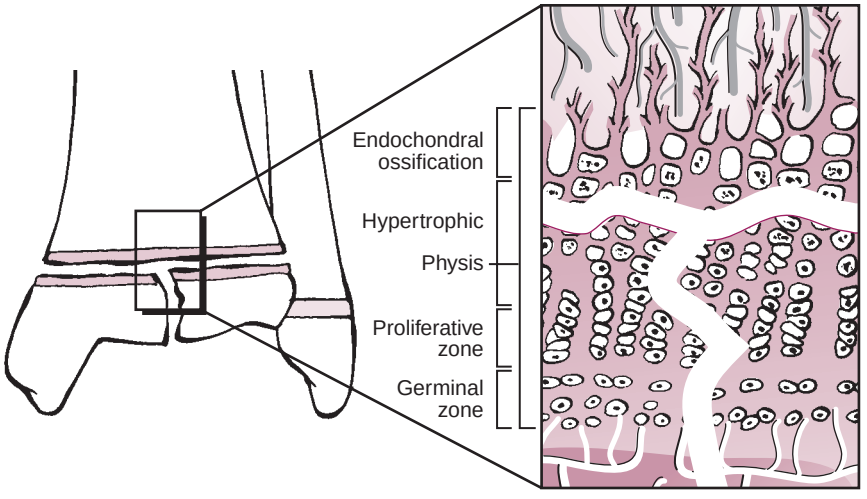

FIGURE 7-19 Scheme of fracture plane in Salter–Harris type III fractures. The fracture plane extends from the physis into the epiphysis and articular surface. "Extra-articular" type III fractures in which the articular surface is intact have been reported but are quite rare.

physis and higher risk of subsequent growth disturbance. Anatomic reduction (usually open) and stabilization are required to restore the articular surface and to minimize the potential for growth disturbance.

On occasion, particularly in the distal femur and the distal humerus, high-energy injuries produce either a T-condylar or other complex pattern of injury, with at least three fragments, resulting in a combination of physeal and epiphyseal injuries (Fig. 7-21).

Type IV. Type IV fractures are effectively vertical shear fractures, extending from the articular surface to the metaphysis (Fig. 7-22A). These fractures are important because they disrupt the articular surface, violate all the physeal layers in crossing from the epiphysis to the metaphysis, and, with displacement, may result in metaphyseal–epiphyseal cross union (Fig. 7-22B).[41,62] The latter occurrence almost invariably results in subsequent growth disturbance. This fracture pattern is frequent around the medial malleolus, but may occur in other epiphyses. Lateral condylar fractures of the distal humerus and intra-articular two-part triplane fractures of the distal tibia may be thought of as complex Salter–Harris type IV fractures.

General treatment principles include obtaining anatomic reduction and adequate stabilization to restore the articular surface and prevent metaphyseal–epiphyseal cross union.

Type V. The type V fracture described by Salter and Harris was not described by Poland or Aitken. Salter and Harris postulated that type V fractures represented unrecognized compression injuries with normal initial radiographs that later produced premature physeal closure. The existence of true type V injuries was questioned by Peterson[128] and subsequently became a subject of debate.[1,10,17,25,74,76,86,157] We believe that delayed physeal closure clearly occurs. The most common example of such an injury is closure of the tibial tubercle, often with the development of recurvatum deformity of the proximal tibia, after fractures of the femur or distal femoral epiphysis (Fig. 7-23).[25,74,76] Although the mechanism of such injuries may be unclear (perhaps vascular rather than compression trauma), the traditionally held view that such injuries occurred as a result

FIGURE 7-21 Complex fracture of the distal femur. There is a Salter–Harris type II fracture of the distal femoral physis. In addition, there is an additional coronal plane epiphyseal fracture of the major portion of the lateral femoral condyle, not involving the physis, which was not recognized at the time of initial treatment. The type II component was treated by closed reduction and cross-pinning. The epiphyseal fracture was treated separately and subsequently by open reduction and headless screw fixation. **A:** Initial anteroposterior radiograph showing what appears to be simple Salter–Harris type II fracture of the distal femur. **B:** Lateral radiograph after reduction appears acceptable; however, careful review demonstrates the coronal plane, intra-articular fracture of the lateral condyle. **C:** CT scan demonstrates the epiphyseal fracture of the lateral femoral condyle. **D, E:** Radiograph appearance after healing of the fractures. Patient was asymptomatic and recovered full knee motion. In follow-up, the patient developed symmetric distal physeal closure not requiring further treatment.

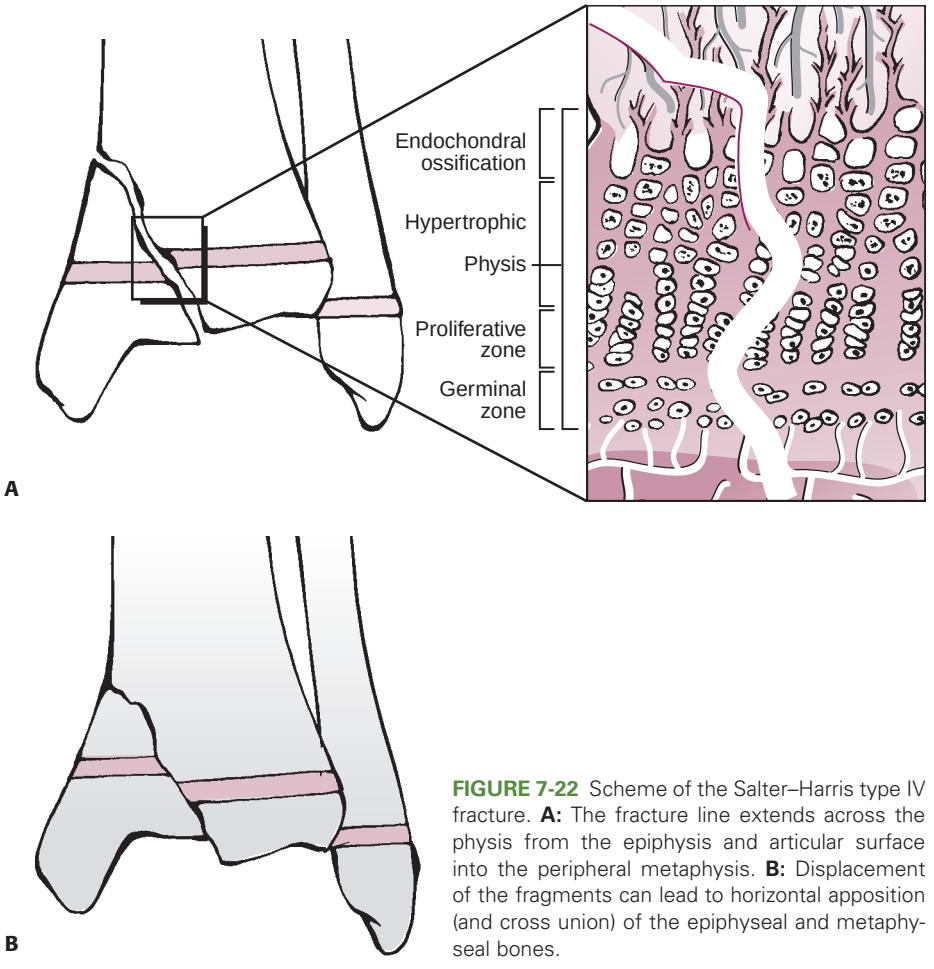

FIGURE 7-22 Scheme of the Salter–Harris type IV fracture. **A:** The fracture line extends across the physis from the epiphysis and articular surface into the peripheral metaphysis. **B:** Displacement of the fragments can lead to horizontal apposition (and cross union) of the epiphyseal and metaphyseal bones.

FIGURE 7-23 Posttraumatic closure of the anterior proximal tibial physis after displaced Salter–Harris type II fracture of the distal femoral physis. **A:** Lateral radiographs after reduction. No injury to the proximal tibia was noted at the time of treatment of the distal femoral injury. **B:** At follow-up, distal femoral physeal growth disturbance with flexion deformity is apparent. **C:** At skeletal maturity, proximal tibial extension deformity with sclerosis of the tibial tubercle area is evident, suggestive of arrest in this area. The patient has undergone a distal femoral extension osteotomy.

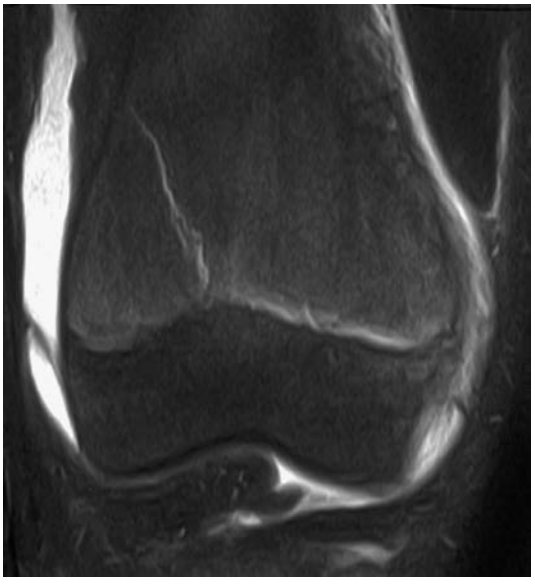

FIGURE 7-24 MRI of patient after injury with normal radiographs. MRI clearly documents the presence of a Salter–Harris type II fracture of the distal femur.

of inadvertent direct injury during the insertion of proximal tibial skeletal traction pins has been unequivocally discounted in some cases.[25,74,76] Other locations and case reports of late physeal closure after extremity injury and apparently normal initial radiographs exist in the literature.[1,10,17,19,111,157] By definition, this pattern of injury is unrecognized on initial radiographs. Undoubtedly, more sophisticated imaging of injured extremities (such as with MRI) will identify physeal injuries in the presence of normal plain radiographs (Fig. 7-24). Although the mechanism of injury in type V injuries may be in dispute, in our opinion, the existence of such injuries is not.

Peterson Classification of Physeal Fractures

In an epidemiologic study of physeal injuries, Peterson et al.[128] identified several deficiencies of the Salter–Harris classification and subsequently developed a new classification of physeal fractures (Fig. 7-25). They were not able to identify any Salter–Harris type V injuries caused by compression in this epidemiologic study, challenged their existence, and excluded that type from the classification. This classification retained Salter–Harris types I to IV as Peterson types II, III, IV, and V and added two new types.[126,127] It is important to be cognizant of the two new patterns that Peterson et al. described, because they are clinically relevant.

Peterson's type I is a transverse metaphyseal fracture with a longitudinal extension to the physis (Fig. 7-26). This pattern of injury is subclassified into four types, based on the extent of metaphyseal comminution and fracture pattern.

Peterson's type VI is a partial physeal loss (Fig. 7-27). Unfortunately, this pattern of injury currently is common, largely as a consequence of lawnmower or "road-drag/abrasion" injuries. Soft tissue loss, neurovascular injury, and partial physeal loss (usually including the epiphysis so that articular impairment also results) further complicate this often devastating injury.

Author's Preferred Treatment

We believe that the Salter–Harris classification remains an easily recognized and recalled classification scheme embracing most physeal injuries and continue to use it to describe most physeal fracture patterns. It provides generally useful prognostic and treatment guidelines. We encourage the continued recognition of the Salter–Harris type V physeal injury as a delayed, indirect, or occult injury–induced physeal closure, whose mechanism may be compression, other unrecognized direct injury,

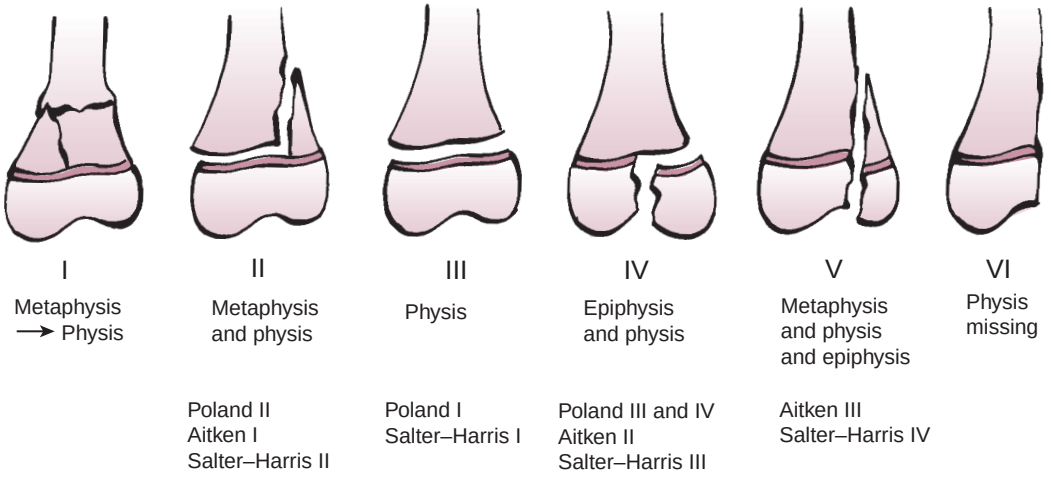

FIGURE 7-25 Peterson classification of physeal fractures. Type I is a fracture of the metaphysis extending to the physis. Types II to V are the equivalents of Salter–Harris types I, II, III, and IV, respectively. Peterson type VI is epiphyseal (and usually articular surface) loss. Lawnmower injuries are a frequent mechanism for type VI injuries (see text for further discussion).

FIGURE 7-26 Peterson type I injury of the distal radius. These injuries typically have a benign course with respect to subsequent growth disturbance.

or vascular insult. We also believe that Peterson types I and VI physeal fractures are not classifiable by the Salter–Harris scheme and refer to them as Peterson types I and VI fractures, respectively.

Epidemiology of Physeal Fractures

In several population surveys reporting the frequency and distribution of childhood fractures, including physeal injuries,[101,111,129,164] 20% to 30% of all childhood fractures were physeal injuries. The phalanges represent the most common location of physeal injuries.

In our opinion, the most useful epidemiologic study of physeal fractures is the Olmstead County Survey.[129] This study of the frequency of physeal fractures in a stable population base was performed between 1979 and 1988, in Olmstead County, Minnesota. The most relevant components are summarized in Tables 7-2 and 7-3. During the study period, 951 physeal

Modified from Peterson HA, Madhok R, Benson JT, et al. Physeal fractures: Part I. Epidemiology in Olmsted County, Minnesota, 1979–1988. *J Pediatr Orthop.* 1994;14:423–430.

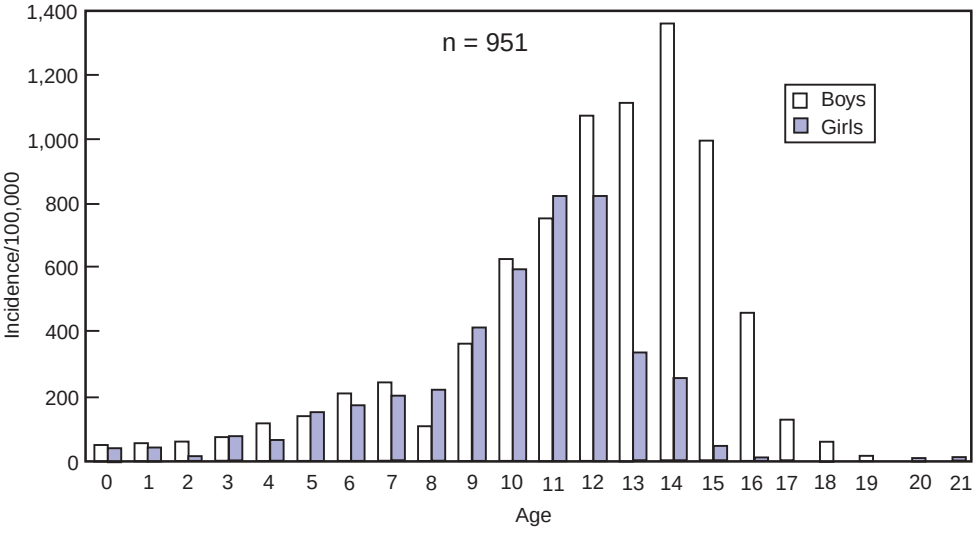

FIGURE 7-28 Relative frequency of physeal fractures by age and sex according to the Olmstead County survey by Peterson et al. Peak incidence age 14 in boys, and 11 to 12 in girls. (From Poland J, ed. *Traumatic Separation of the Epiphysis*. London: E. Smith and Company; 1898.)

fractures were identified: 37% of fractures occurred in the finger phalanges, with the next most common site the distal radius; 71% fractures occurred in the upper extremity; 28% in the lower; and 1% in the axial skeleton. Other salient findings of the Olmstead County survey included a 2:1 male-to-female ratio and age-related incidence by gender (peak incidence at age 14 in boys and 11 to 12 in girls) (Fig. 7-28). The Adelaide, Australia, survey by Mizuta et al.[111] had similar findings: 30% of physeal fractures were phalangeal, males outnumbered females approximately 2:1, and the prepubertal age groups had the highest relative frequency of physeal fracture.

Evaluation of Physeal Fractures

Modalities available for the evaluation of physeal injuries include plain radiographs, computed tomography (CT) scans, and MRI scans[36,44,60,79,80,130,147] arthrography,[6,47,67,105,166] and ultrasound.[30,48,50,73,140] Plain radiographs remain the preferred initial modality for the assessment of most physeal injuries. Radiographs should be taken in true orthogonal views and as a default include the joint both above and below the fracture unless clinical examination rules out areas of pathology, that is, a very distal both bone fracture may not need radiographs of the elbow if clinical examination of the elbow is normal. If a physeal injury is suspected, dedicated views centered over the suspected physis should be obtained to decrease parallax and increase detail. Oblique views may be of value in assessing minimally displaced injuries.

Although plain radiographs provide adequate detail for the assessment and treatment of most physeal injuries, occasionally greater anatomic detail is necessary. CT scans provide excellent definition of bony anatomy, particularly using reconstructed images. They may be helpful in assessing complex or highly comminuted fractures, as well as the articular congruency of minimally displaced fractures (Fig. 7-29). MRI scans are excellent for demonstrating soft tissue lesions and "bone bruises" which may not be seen using standard radiation techniques. Arthrography, MRI, and ultrasound have been used to assess the congruency of articular surfaces. Arthrography and MRI may help define the anatomy in young patients with small or no secondary ossification centers in the epiphyses.[6,47,67,105,166] Ultrasonography is occasionally useful for diagnostic purposes to identify epiphyseal separation in infants (Fig. 7-30).[30,47,48,50,73]

Treatment

The general tenets of physeal fracture management are essentially the same as those for injuries not involving the physis,

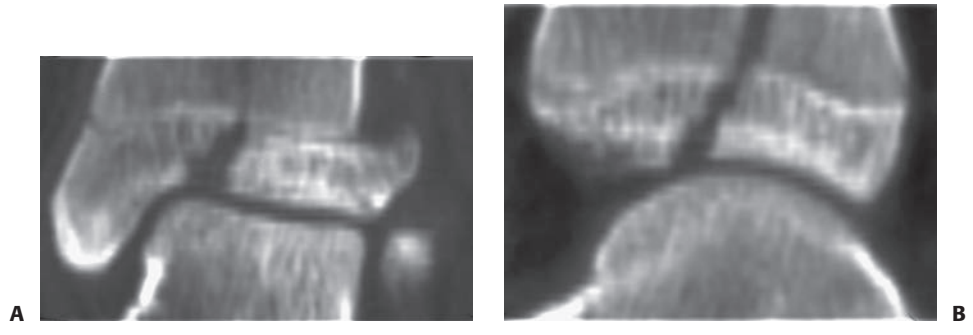

FIGURE 7-29 CT scans with or without reconstructed images can be helpful in the assessment of physeal fractures. Coronal **(A)** and sagittal **(B)** plane reconstructions of a triplane fracture of the distal tibia.

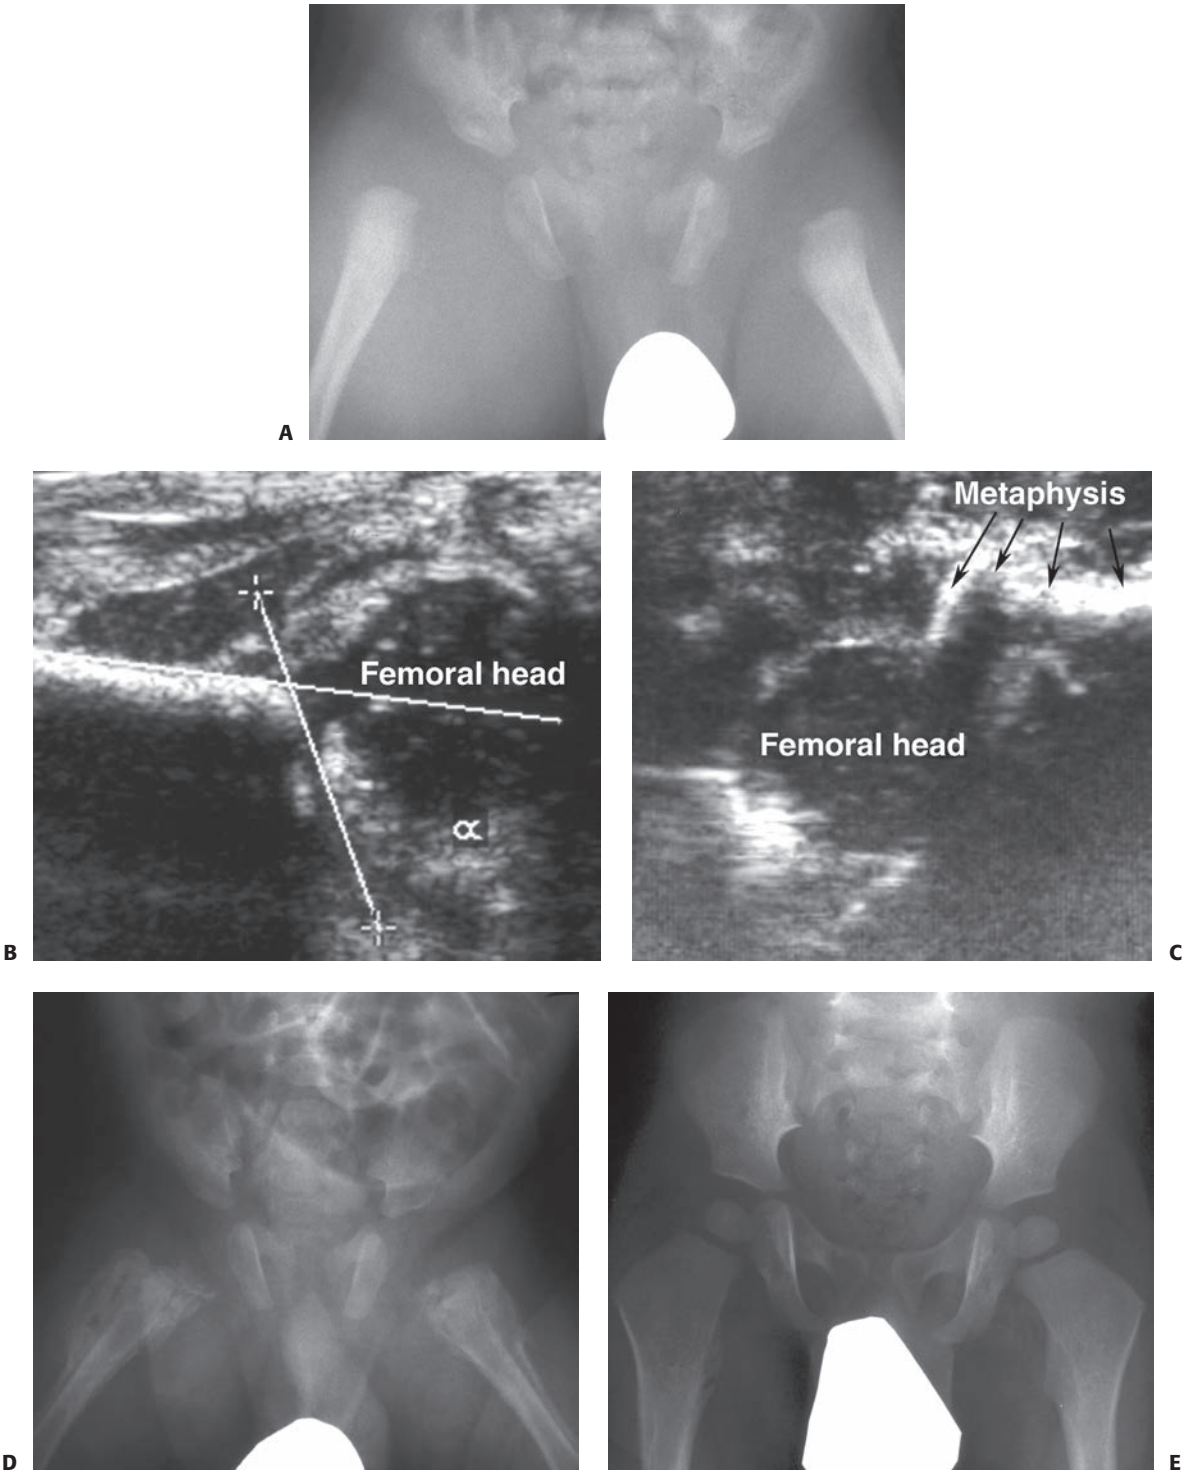

FIGURE 7-30 Ultrasonography can be useful as a noninvasive investigation confirming intra-articular effusion or epiphyseal separation, particularly in infants. **A:** Anteroposterior radiograph of a 2-month-old infant with bilateral hip pain and generalized irritability. Septic arthritis is included in the differential diagnosis. **B:** Ultrasonographic image of the right hip demonstrates a femoral head contained in the acetabulum, without significant hip effusion. **C:** This ultrasonographic image demonstrates separation of the proximal epiphysis from the femoral metaphysis. The diagnosis is nonaccidental trauma. **D:** One month later, radiograph demonstrates extensive periosteal reaction bilaterally. **E:** At 18 months of age, radiograph demonstrates remarkable remodeling, without evidence of physeal growth disturbance or epiphyseal abnormality.

including radiographs of all areas with abnormal physical findings. Physeal injuries involving neurovascular compromise or impending compartment syndrome should be managed emergently. In most cases, stabilization of the physeal fractures will help facilitate management of the soft tissue injury.

General Principles of Treatment

In general, fractures in children, including physeal injuries, heal more rapidly than in adults, and they are less likely to experience morbidity or mortality from prolonged immobilization. In addition, children are also often less compliant with postoperative activity restrictions, making cast immobilization a frequently necessary adjunct to therapy.

Physeal fractures, like all fractures, should be managed in a consistent methodical manner that includes a general assessment and stabilization of the polytraumatized patient, evaluation of the neurovascular and soft tissue status of the traumatized limb; what constitutes an "acceptable" reduction is dictated in part by the fracture pattern and remodeling potential of the fracture. Intra-articular fractures (such as Salter–Harris types III and IV) require anatomic reduction to restore the articular surface and prevent epiphyseal–metaphyseal cross union. Salter–Harris types I and II fractures, particularly those that are the result of low-energy injuries, have minimal risk of growth disturbance (excepting injuries of the distal femur and proximal tibia) and excellent remodeling potential in most patients; in such patients, the surgeon must be cautious not to *create* physeal injury by excessively forceful or invasive reductions. When performing a closed reduction of physeal fractures the aphorism "90% traction, 10% translation" is useful to minimize iatrogenic injury to the physis which may occur as a physis grinds against a sharp bony metaphysis.

Complications of Physeal Fractures

Except for the possibility of subsequent growth disturbance, the potential complications of physeal injuries are no different than other traumatic musculoskeletal injuries. Neurovascular compromise and compartment syndrome represent the most serious potential complications.[29,122] It is important to remember that, although a high degree of suspicion and diligence may avoid some of these potentially devastating complications, they can occur even with "ideal" management. Infection and soft tissue loss can complicate physeal fracture management, just as they can in other fractures. The one complication unique to physeal injuries is growth disturbance. Most commonly, this "disturbance" is the result of a tethering (physeal bar or arrest) that may produce angular deformity or shortening. However, growth disturbance may occur without an obvious tether or bar and growth acceleration also occurs (Fig. 7-31). Finally, growth disturbance may occur without recognized injury to the physis.

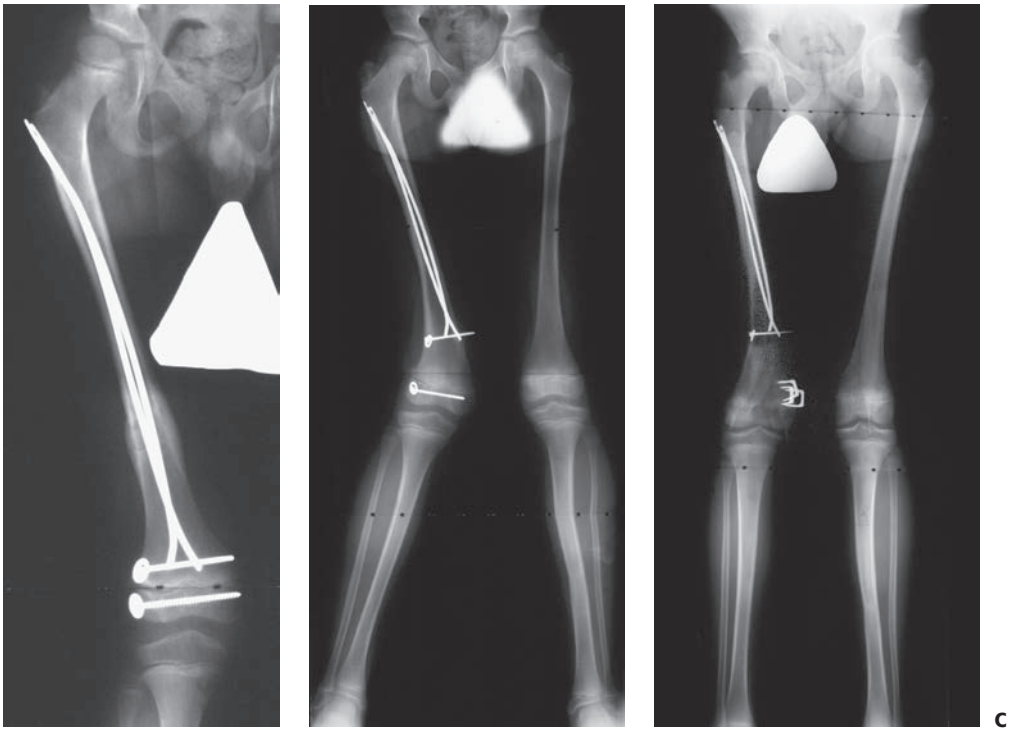

FIGURE 7-31 Growth deceleration in the absence of a true physeal arrest. This patient sustained concurrent ipsilateral femoral shaft and Salter–Harris type IV distal femoral epiphyseal fractures. **A:** Anteroposterior radiograph of the healed femur. Both fractures were treated with internal fixation. **B:** The patient developed valgus deformity of the distal femur because of asymmetric growth of the distal femoral physis. Note that the distance between the screws on either side of the physis has increased asymmetrically, confirming asymmetric growth rather than cessation of growth laterally. **C:** The angular deformity was treated with medial distal femoral epiphyseal stapling.

Physeal Growth Disturbance

An uncommon but important complication of physeal fracture is physeal growth disturbance.[106,113,134] The potential consequences of physeal growth disturbance include the development of angular deformity, limb length inequality, epiphyseal distortion, or various combinations of these. Development of these abnormalities, if any, depends on the physis affected, location within the affected physis, the duration of time present, and the skeletal maturity of the patient. Frequently, further surgery, often repeated and extensive, is required to correct or prevent deformity caused by an established growth disturbance.[27,31,69,84,89,93,139,162]

Etiology

Disturbance of normal physeal growth may result from physical loss of the physis (such as after Peterson type VI injuries), from disruption of normal physeal architecture and function without actual radiograph loss of the physis, or by the formation of a physeal arrest, also called bony bridges or physeal bars.[159] Careful identification of the nature of physeal growth disruption is important, because treatment strategies may differ based on the etiology of growth disturbance and the presence or absence of a true growth arrest.

Growth disturbance as a result of physeal injury may result from direct trauma (physeal fracture)[106,113,134] or associated vascular disruption.[125] Infection,[19,23] destruction by a space-occupying lesion such as unicameral bone cyst or enchondroma,[150] infantile Blount disease,[18] other vascular disturbances (such as purpura fulminans),[14,65,78,88] irradiation,[17,136] and other rare causes[21,32,38] also may result in physeal growth disturbance or physeal arrest.

Evaluation

Physeal growth disturbance may present as a radiographic abnormality noted on serial radiographs in a patient known to beat risk after fracture or infection, clinically with established limb deformity (angular deformity, shortening, or both), or occasionally incidentally on radiographs obtained for other reasons. The hallmark of plain radiographic features of physeal growth disturbance is the loss of normal physeal contour and the sharply defined radiolucency between epiphyseal and metaphyseal bones. Frank physeal arrests typically are characterized by sclerosis in the region of the arrest. If asymmetric growth has occurred, there may be tapering of a growth arrest line to the area of arrest,[68,118] angular deformity, epiphyseal distortion, or shortening (Fig. 7-32). Physeal growth disturbance without frank arrest typically appears on plain radiographs as a thinner or thicker physeal area with an indistinct metaphyseal border because of alteration in normal enchondral ossification. There may be an asymmetric growth arrest line indicating angular deformity, but the arrest line will not taper to the physis

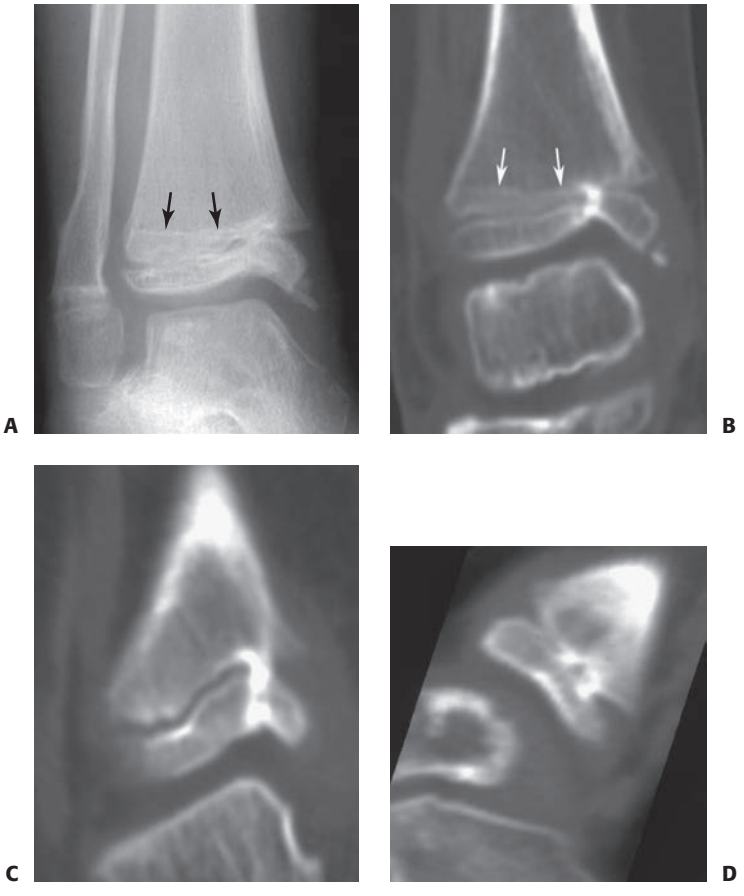

FIGURE 7-32 Harris growth arrest line tapering to the physis at the level of the growth arrest can serve as an excellent radiograph confirmation of the presence of the true growth arrest. Although most commonly noted on plain radiographs, these arrest lines can be seen on CT scans and MRIs as well. **A:** Anteroposterior radiograph of the distal tibia after Salter–Harris type IV fracture demonstrates a Harris growth arrest line (*arrows*) tapering to the medial distal tibial physis, where a partial physeal arrest has formed. **B:** Harris growth arrest line (*arrows*) as noted on CT. CT scans with coronal **(C)** and sagittal **(D)** reconstructions corrected for bone distortion provide excellent images of the location and size of arrest.

FIGURE 7-33 Asymmetric growth arrest line that does not taper to the physis is a strong indication of the presence of physeal growth disturbance without frank physeal arrest. In this case, the asymmetric growth arrest line is noted in the proximal tibial metaphysis on CT scan.

itself (Fig. 7-33).[118] This indicates altered physeal growth (either asymmetric acceleration or deceleration) but not a complete cessation of growth. This distinction is important, because the consequences and treatment are different from those caused by complete growth arrest.

If a growth arrest is suspected on plain radiographs in a skeletally immature child, further evaluation is often warranted. CT scanning with sagittal and coronal reconstructions (orthogonal to the area of interest) may demonstrate clearly an area of bone bridging the physis between the epiphysis and the metaphysis (Fig. 7-32C,D). MRI is also a sensitive method of assessing normal physeal architecture (Fig. 7-34).[36,51,60] Revealing images of the physis and the region of physeal growth disturbance can be obtained using three-dimensional spoiled recalled gradient echo images with fat saturation or fast spin echo proton density images with fat saturation (Fig. 7-35). MRI has the additional advantage of the opportunity to assess the organization of the residual physis that may indicate its relative "health." This assessment may be helpful in cases of infection, irradiation, or tumor to determine if arrest resection is feasible based on the integrity of the remaining physis. With either CT or MRI, physeal arrests are characterized by an identifiable bridge of bone between the epiphysis and the metaphysis, whereas growth disruption without arrest demonstrates some degree of loss of normal physeal contour and architecture without the bony bridge or physeal bar.

FIGURE 7-34 MRI scan of a patient with traumatic lateral distal femoral partial growth arrest. Note Harris arrest line tapering to the site of the arrest.

FIGURE 7-35 MRI scan (three-dimensional spoiled recalled gradient echo images with fat saturation) provides excellent visualization of the affected area and some sense of the integrity of the residual physis. This patient has infantile Blount disease.

Although definitive assessment of physeal growth disturbance or arrest may require advanced imaging, further evaluation by plain radiographs is also beneficial. Radiographs of the entire affected limb should be obtained to document the magnitude of angular deformity. Existing limb length inequality should be assessed by scanogram. An estimation of predicted growth remaining in the contralateral unaffected physis should be made based on a determination of the child's skeletal age and reference to an appropriate growth table.[11-13,64,71,72,102]

Physeal Arrests

Whenever a bridge of bone develops across a portion of physis, tethering of the metaphyseal and epiphyseal bone together may result (Table 7-4). Partial physeal arrests can result in angular deformity, joint distortion, limb length inequality, or combinations of these, depending on the location of the arrest, the rate and extent of growth remaining in the physis involved, and the health of the residual affected physis. Although these partial arrests are not common, their presence usually requires preventive or corrective surgical treatment to minimize the long-term sequelae of the disturbance of normal growth they can create (Fig. 7-36).

FIGURE 7-36 Physeal arrests create variable amounts of limb shortening, angular deformity, and epiphyseal distortion, depending on the duration of the arrest, the physis affected, and the size of the arrest. A long, standing film of the lower extremities with the hip, knee, and ankle joints included provides an overall assessment of angular deformity and shortening.

Classification

Partial physeal arrests can be classified by etiology and by anatomic pattern. Potential etiologies of physeal arrest are summarized in Table 7-4 and include physeal fracture, Blount disease, infection, tumor, frostbite, and irradiation. Physeal arrests also can be classified based on the anatomic relationship of the arrest to the residual "healthy" physis. Three basic patterns are recognized (Fig. 7-37): Central, peripheral, and linear. A *central* arrest is surrounded by a perimeter of normal physis, like an island within the remaining physis. Central arrests are most likely to cause tenting of the articular surface, but also may result in angular deformity, if eccentrically located, and limb length inequality (Fig. 7-38). A *peripheral* arrest is located at the perimeter of the affected physis. This type of arrest primarily causes progressive angular deformity and variable shortening. A *linear* arrest is a "through-and-through" lesion with anatomic characteristics of both a central and peripheral arrest; specifically, the affected area starts at the perimeter of the physis and extends centrally with normal physis on either side of the affected area. Linear arrests most commonly develop after Salter–Harris type III or IV physeal fractures of the medial malleolus.

TABLE 7-4 Potential Causes of Physeal Arrest Formation

Physeal fracture
Traumatic vascular disruption
Transphyseal infection
Vascular collapse associated with infection (purpura fulminans)
Infantile Blount disease
Irradiation
Unicameral bone cyst
Enchondroma

Management

Several management alternatives are available. It is important to be aware of these and to weigh carefully the appropriateness of each for the individual situation.

Prevention of Arrest Formation. Ideally, the surgeon should be proactive in the prevention of physeal arrest formation. Most commonly, this can be accomplished by adhering to the general treatment principles of physeal fractures: Gentle, anatomic, and secure reduction of the fracture, especially Salter–Harris types III and IV injuries. Damaged, exposed physes can be protected by immediate fat grafting,[57] similar to the principle of interposition material insertion for the resection of established arrests (see following discussion). Although there is little evidence to support the practice, the most common situation in which this technique is utilized during open reduction of medial malleolar fractures, where comminution or partial physeal damage is identified during reduction.

Some experimental work[152] indicates that nonsteroidal anti-inflammatory medications (specifically indomethacin) given

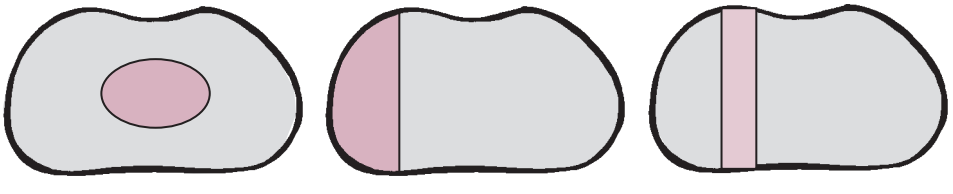

FIGURE 7-37 Anatomic classification of physeal arrests. Central arrests are surrounded by a perimeter of normal physis. Peripheral arrests are located at the perimeter of the physis. Linear arrests are "through-and-through" lesions with normal physis on either side of the arrest area.

FIGURE 7-38 Central arrests are characterized by tenting of the articular surface. Variable shortening and angular deformity will develop, depending on the size and location of the arrest.

for a period of time after physeal injury may prevent formation of physeal arrest. There is, however, no clinical study supporting this experimental study, so the use of nonsteroidal anti-inflammatory medications is empiric and not common clinical practice.

Partial Physeal Arrest Resection. Conceptually, surgical resection of a physeal arrest (sometimes referred to as *physiolysis* or *epiphysiolysis*) restoring normal growth of the affected physis is the ideal treatment for this condition.[27,31,41,59,84,89,92,93,106,121,161] The principle is to remove the bony tether between the metaphysis and the physis and fill the physeal defect with a bone reformation retardant, anticipating that the residual healthy physis will resume normal longitudinal growth.[27,59,89,92,93,121] However, this procedure can be technically demanding, and results in our practice are modest (see comment below). To determine if this procedure is indicated, careful consideration must be given to the location and extent of the arrest and the amount of longitudinal growth to be potentially salvaged (see discussion below).

Physeal Distraction. Physeal arrests have been treated with the application of an external fixator spanning the arrest and gradual distraction until the arrest "separates."[35,45] Angular deformity correction and lengthening can be accomplished after separation as well. However, distraction injury usually results in complete cessation of subsequent normal physeal growth at the distracted level.[55] Furthermore, the fixation wires or half pins may have tenuous fixation in the epiphysis or violate the articular space, risking septic arthritis. Thus, this modality is rarely used.

Repeated Osteotomies During Growth. The simplest method to correct angular deformity associated with physeal arrests is corrective osteotomy in the adjacent metaphysis. Of course, neither significant limb length inequality nor epiphyseal distortion that may result from the arrest is corrected by this strategy. However, in young patients with a great deal of growth remaining in whom previous physeal arrest resection has been unsuccessful or is technically not possible, this treatment may be a reasonable interim alternative until more definitive completion of arrest and management of limb length inequality is feasible.

Completion of Epiphysiodesis and Management of Resulting Limb Length Discrepancy. An alternative strategy for the management of physeal arrests is to complete the epiphysiodesis to prevent recurrent angular deformity or epiphyseal distortion and manage the existing or potential limb length discrepancy appropriately. Management of the latter may be by simultaneous or subsequent lengthening of the affected limb segment or contralateral epiphysiodesis if the existing discrepancy is tolerable and lengthening is not desired. We believe that this course of management is specifically indicated if arrest resection has failed to result in restoration of longitudinal growth and in patients in whom the amount of growth remaining does not warrant an attempt at arrest resection. In our opinion, this treatment should be considered carefully in all patients with a physeal arrest.

Physeal Arrest Resection

Based on our experience with the results of physeal arrest resection, the factors discussed in the following sections should be considered before determining if physeal arrest resection is indicated.

Etiology of the Arrest

Arrests caused by trauma or infantile Blount disease have a better prognosis for resumption of normal growth, compared to those secondary to infection, tumor or tumor-like conditions, or irradiation are less likely to demonstrate growth after resection.

Anatomic Type of the Arrest

Central and linear arrests have been reported to be more likely to demonstrate resumption of growth after resection,[31] but our experience has not supported this observation.

Physis Affected

Because proximal humeral and proximal femoral lesions are difficult to expose, a technically adequate resection is less likely in these areas. In our institutional experience, (currently unpublished) distal femoral bars have a poorer prognosis for growth after resection, whereas those of the distal tibia have a more favorable prognosis for the resumption of growth.

Extent of the Arrest

The potential for resumption of longitudinal growth after arrest resection is influenced by the amount of physeal surface area affected.[27,31,84] Arrests affecting more than 25% of the total surface area are unlikely to grow, and, except in patients in whom significant growth potential remains, alternative treatment strategies should be used.

Amount of Growth Remaining in the Physis Affected

Some authors[31,84,89,92,93,124] have stated that 2 years of growth remaining based on skeletal age determination is a prerequisite for arrest resection to be considered. Based on our results with

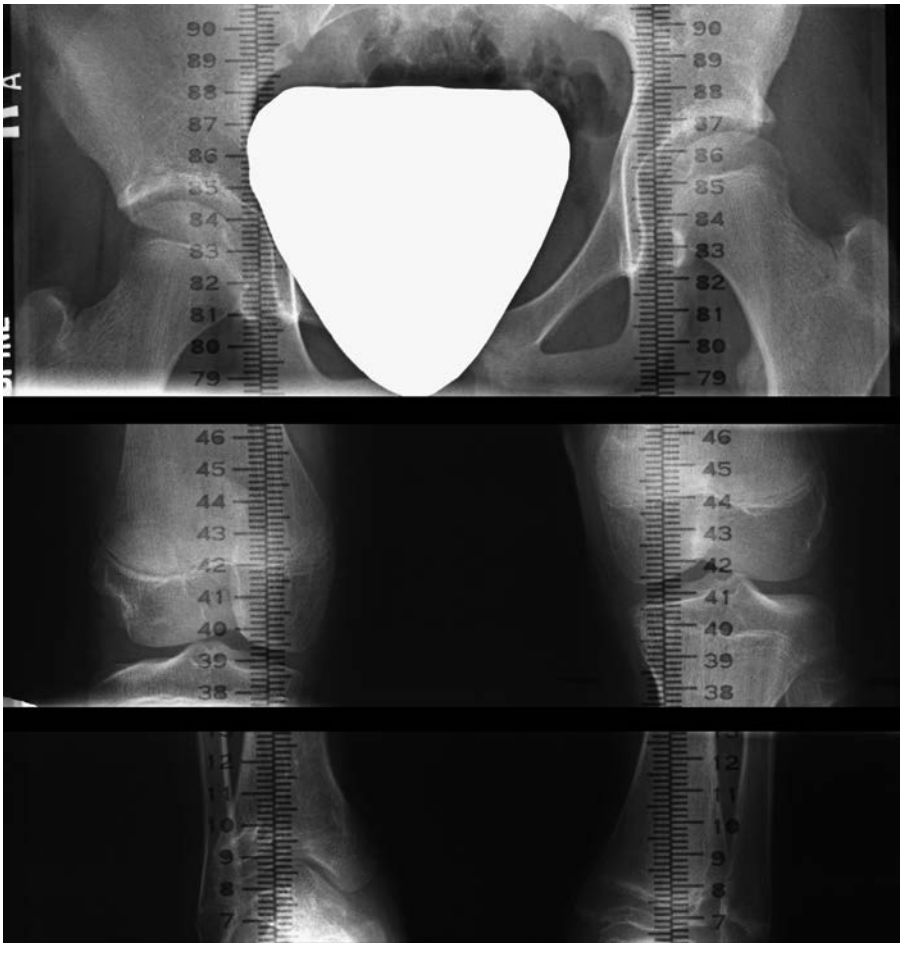

FIGURE 7-39 Scanogram indicates the existing limb length inequality.

this procedure, we find that 2 years of growth remaining is an inadequate indication for physeal arrest resection. We believe that the decision to perform arrest resection should be made on a combination of the calculated amount of growth remaining in the affected physis and the likelihood of resumption of growth. Scanogram (Fig. 7-39) will document the existing discrepancy, determination of skeletal age and consultation with the growth remaining tables for the affected physis[11-13,61,74,102] will allow calculation of the predicted discrepancy.

Preoperative Planning and Surgical Principles

If physeal arrest resection is considered appropriate, some planning is required to maximize the opportunity for resumption of longitudinal growth.

First, the extent and location of the arrest relative to the rest of the physis must be carefully documented. The most cost-effective method to accurately evaluate an arrest is with reconstructed sagittal and coronal CT images to provide views orthogonal to the affected physis. MRI may also be used and, with recent advancements in the capability to identify and quantify physeal arrests, may soon become the imaging study of choice. We currently prefer three-dimensional spoiled recalled gradient echo images with fat saturation or fast spin echo proton density images with fat saturation to visualize the physis. CT images allow precise delineation of bony margins and, at the current time, is cheaper than MRI. An estimation of the affected surface area can be computed with the assistance of the radiologist using a modification of the method of Carlson and Wenger (Fig. 7-40).[37] The procedure should be planned with consideration of the principles discussed in the following section.

Minimize Trauma. The arrest must be resected in a manner that minimizes trauma to the residual physis. Central lesions should be approached either through a metaphyseal window (Fig. 7-41) or through the intramedullary canal after a metaphyseal osteotomy. Peripheral lesions are approached directly, resecting the overlying periosteum to help prevent reformation of the arrest. Intraoperative imaging (fluoroscopy) is needed to keep the surgeon oriented properly to the arrest and the residual healthy physis. Care to provide adequate visualization of the surgical cavity is essential, because visualization is usually difficult even under "ideal" circumstances. A brilliant light source, magnification, and a dry surgical field are very helpful. An arthroscope can be inserted into a metaphyseal cavity to permit a circumferential view of the resection area.[103] A high-speed burr worked in a gentle to-and-fro movement perpendicular to the physis is usually the most effective way to gradually remove the bone composing the arrest and expose the residual healthy

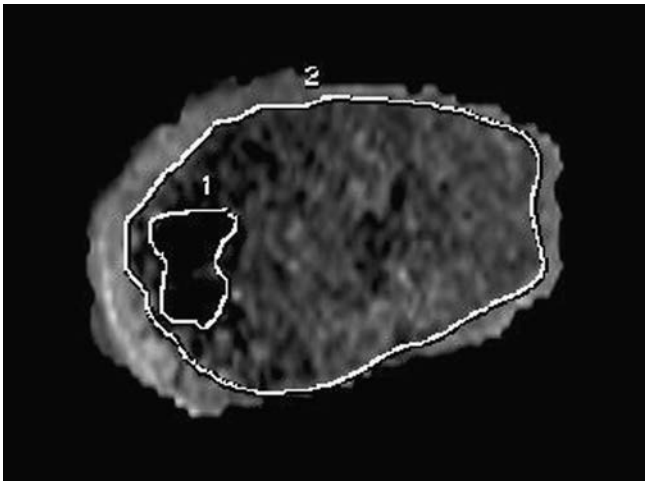

FIGURE 7-40 Reconstructed MRIs allow estimation of the percentage of surface area of the physis affected by a growth arrest. This workstation reconstruction delineates the perimeter of normal physis (*border 2*) and that of the physeal arrest (*border 1*). Surface area affected can be calculated from these reconstructions.

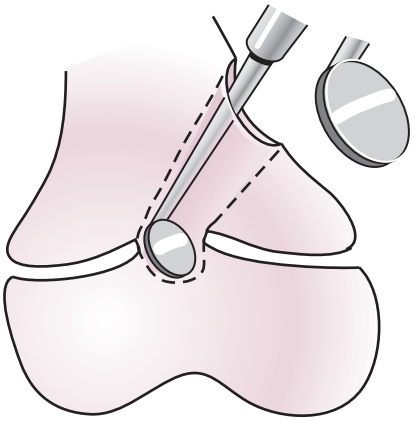

FIGURE 7-42 After complete resection, the healthy physis should be evident circumferentially within the cavity produced by the arrest resection.

physis (Fig. 7-42). By the end of the resection, all of the bridging bone between the metaphysis and the epiphysis should be removed, leaving a void in the physis where the arrest had been, and the perimeter of the healthy residual physis should be visible circumferentially at the margins of the surgically created cavity (Fig. 7-43). Recently, intraoperative CT has been reported to be an effective adjuvant to guide bar resection.[83]

Prevent Reforming of Bridge Between Metaphysis and Epiphysis. A bone-growth retardant or "spacer" material should be placed in the cavity created by the arrest resection to prevent reforming of the bony bridge between the metaphysis and the epiphysis. Four compounds have been used for this purpose either clinically or experimentally: Autogenous fat,[31,84,89,92-95,162] methyl methacrylate,[22,84,124] silicone rubber,[27] and autogenous cartilage.[16,18,56,66,85,97] Silicone rubber is no longer available and, to our knowledge, autogenous cartilage has been used only experimentally as a press-fit plug or cultured chondroblasts. Currently, only autogenous fat graft, harvested either locally or from the buttock, and methyl methacrylate are used clinically. Autogenous fat has at least a theoretic advantage of the ability to hypertrophy and migrate with longitudinal and interstitial growth (Fig. 7-44).[94,95] Methyl methacrylate is inert, but provides some immediate structural stability.[33] This feature may be important with large arrest resections in weight-bearing areas, as in the proximal tibia in association with infantile Blount disease (Fig. 7-45). However, embedded methyl methacrylate, especially products without barium to clearly delineate its location on radiograph, can be extremely difficult to remove and can jeopardize bone fixation if subsequent surgery is required. Pathologic fracture associated with methyl methacrylate migration from the metaphysis to diaphysis has also been reported.[142] A number of recent studies have looked at the possibility of "grafting" the resected area of physis with chondrocytes or stem cells. Although promising, these techniques have not yet

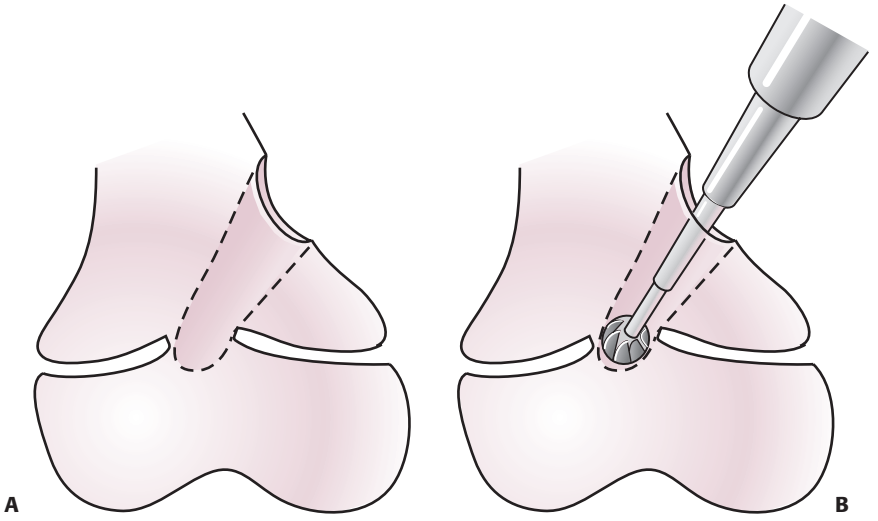

FIGURE 7-41 **A:** Central arrests are approached through a metaphyseal "window" or the medullary canal after metaphyseal osteotomy. **B:** The arrest is removed, leaving in its place a metaphyseal–epiphyseal cavity with intact physis surrounding the area of resection.

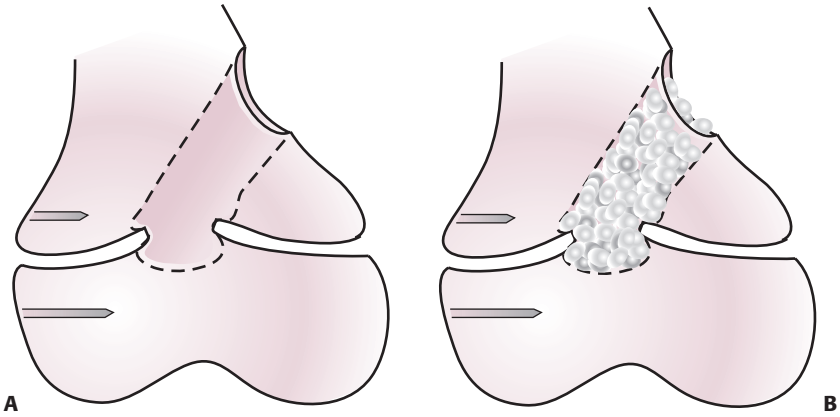

FIGURE 7-43 **A:** After the bar is resected, metallic markers are inserted in the epiphysis and metaphysis. **B:** Following marker placement fat graft is placed in the resection bed.

become clinically available and remain predominantly a research endeavor in laboratory animals.[43,75,96,131,153,167]

Marker Implantation. Metallic markers should be implanted in the epiphysis and metaphysis at the time of arrest resection to allow reasonably accurate estimation of the amount of longitudinal growth that occurs across the operated physis, as well as to identify the deceleration or cessation of that growth (Fig. 7-46). We believe that precise monitoring of subsequent longitudinal growth is an important aspect of the management of patients after arrest resection. First, resumption of longitudinal growth may not occur despite technically adequate arrest resection in patients with good clinical indications. Perhaps more importantly, resumption of normal or even accelerated longitudinal growth may be followed by late deceleration or cessation of that growth.[69] It is imperative that the treating surgeon be alert to those developments, so that proper intervention can be instituted promptly. Embedded metallic markers serve those purposes admirably.

Author's Observation. It has been our clinical observation that even patients who have significant resumption of growth following arrest resection will experience premature cessation of longitudinal growth of the affected physis relative to the contralateral uninvolved physis. We believe that even if growth resumes after bar resection, the previously injured physis will cease growing before the contralateral physis. Thus, the percent of predicted growth might be expected to decrease over the length of follow-up.

Our experience with physeal arrest resection prompted several conclusions and treatment recommendations.

- On average, approximately 60% of physeal arrests demonstrate clear radiograph evidence of resumption of longitudinal growth of the affected physis after physeal arrest resection.
- There is a correlation between the amount of surface area of the physis affected and the prognosis for subsequent longitudinal growth after arrest resection. Physeal arrests affecting

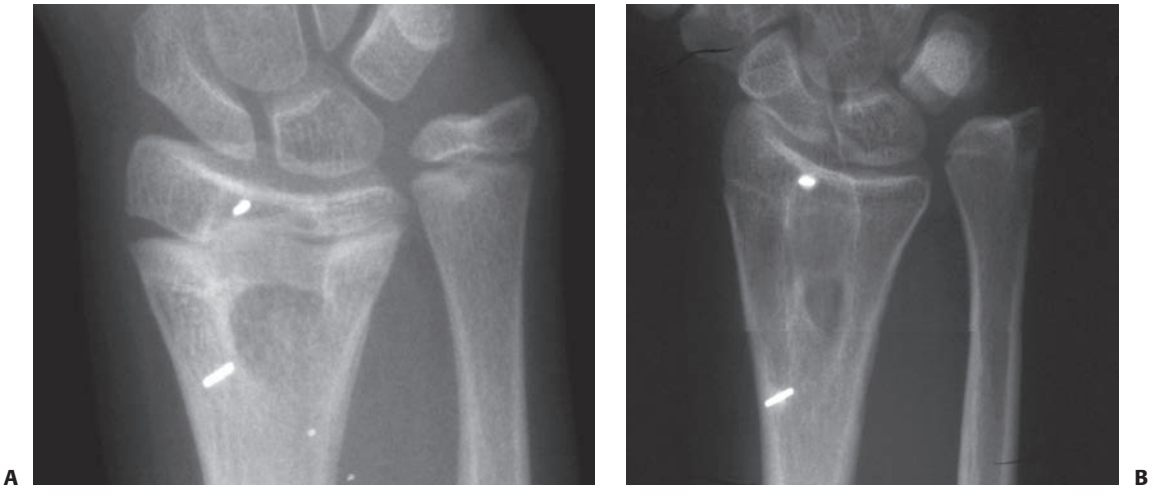

FIGURE 7-44 Fat used as an interposition material in partial physeal arrest resection can persist and hypertrophy during longitudinal growth. **A:** Radiograph appearance after traumatic distal radial physeal arrest resection. **B:** Appearance 5 years later. Longitudinal growth between the metallic markers is obvious. The fat-filled cavity created at physeal arrest resection has persisted and elongated with distal radial growth.

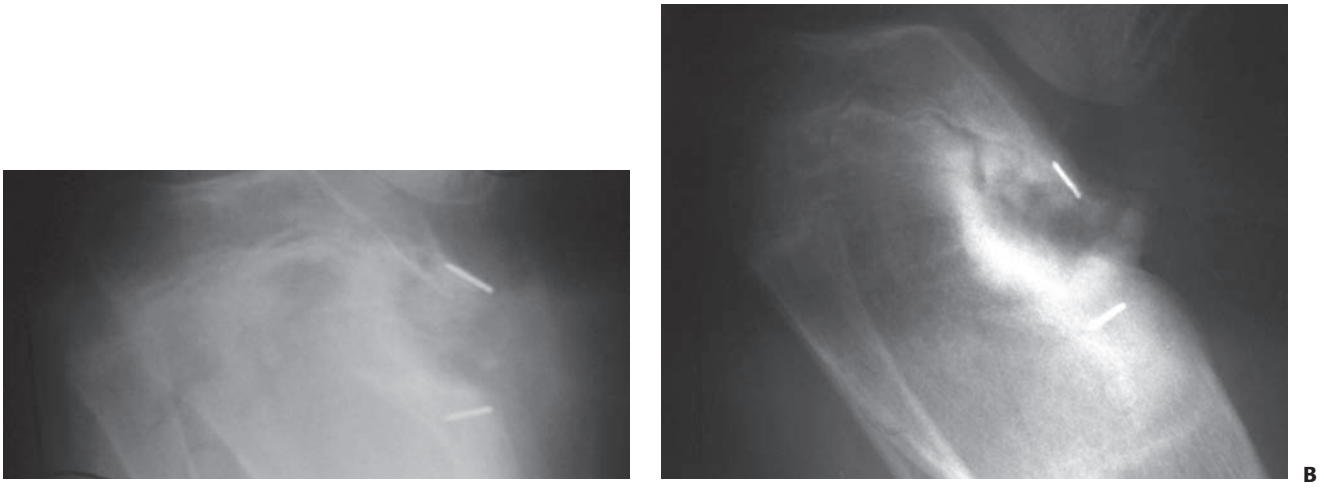

FIGURE 7-45 Resection of substantial physeal arrests in weight-bearing areas may allow subsidence of the articular surface. This is of particular concern in the proximal tibia of patients with infantile Blount disease. **A:** Early postoperative radiograph after partial physeal arrest resection in an obese patient with infantile Blount disease. **B:** One year later, the metallic markers are actually closer together, in addition to demonstrating increased varus. Subsidence of the medial proximal tibial articular surface is the likely explanation of this radiograph finding. Protected weight bearing or methyl methacrylate as the interposition material may be indicated in such cases.

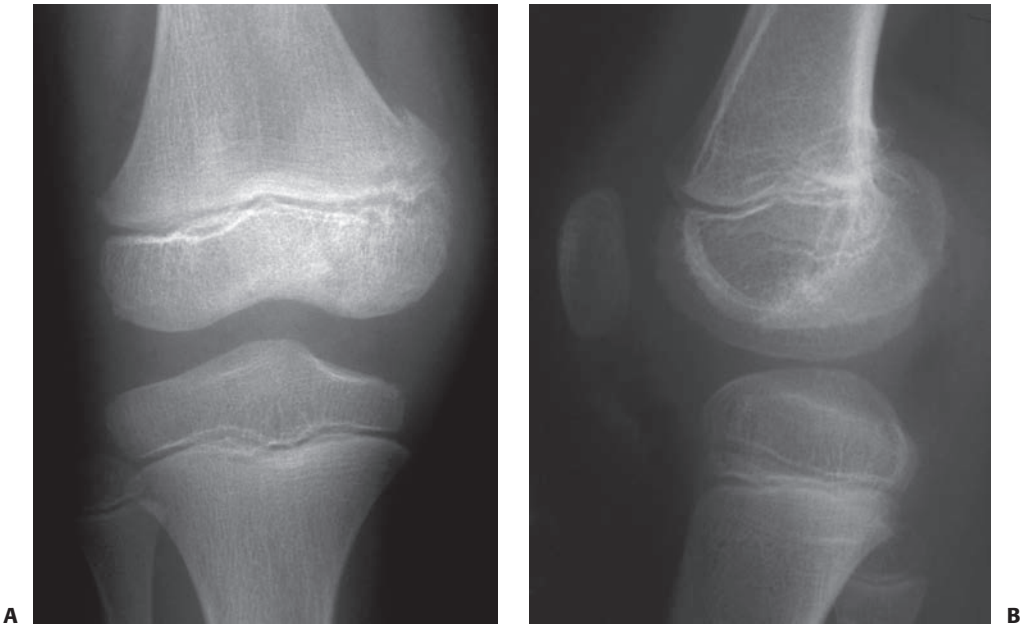

FIGURE 7-46 Intraosseous metallic markers in the epiphysis and metaphysis spanning the area of arrest resection allow sensitive radiographic documentation of the presence and extent of growth after arrest resection and permit early detection of the cessation of restored longitudinal growth. This patient had a small central arrest of the lateral portion of the distal femoral physis after a Salter–Harris type IV fracture. **A:** Injury films show a mildly displaced Salter–Harris type IV fracture of the lateral distal femur. **B:** Several years later, a small central arrest has developed involving a portion of the lateral distal femoral physis. A tapering growth arrest line is faintly visible.

FIGURE 7-46 (*continued*) **C:** The posterior location of the partial arrest can be seen on the sagittal CT reconstructions. **D:** After arrest resection through a metaphyseal window, a cavity is evident in the region of the original bar. Metallic markers have been placed in the metaphysis and epiphysis. **E:** Three years after arrest resection, substantial growth has occurred, as documented by the increased distance between the markers. However, on radiographs taken at 4 years postoperatively, no further growth was documented. This event was treated by completion of the epiphysiodesis and contralateral distal femoral epiphysiodesis to prevent the development of limb length discrepancy from developing.

less than 10% of the surface area of the physis have a better prognosis than larger arrests.

- Langenskiöld stage VI infantile Blount disease has results comparable to posttraumatic physeal arrests.
- Etiologies other than posttraumatic and infantile Blount disease have poor prognoses for subsequent growth.
- Central and peripheral arrests have equivalent prognoses with respect to resumption of growth.
- Early growth resumption may be followed by cessation of longitudinal growth before skeletal maturity. As a consequence, patients must be evaluated regularly until skeletal maturity with some reliable method (such as metaphyseal and epiphyseal radiograph markers) to detect such development as promptly as possible.

We believe that physeal bar resection has a role to play in patients with significant longitudinal growth remaining. However, the benefits of such surgery must be weighed against the actual amount of growth remaining, and the etiology, location, and extent of the physeal arrest must be considered. The appropriate time to add a corrective osteotomy to bony bar resection is controversial. Generally, when the angular deformity is more than 10 to 15 degrees from normal, corrective osteotomy should be considered.

Growth Disturbance Without Arrest

Recognition

Growth disturbance may also occur without physeal arrest. Both growth deceleration and, less frequently, acceleration have been reported. Growth deceleration without arrest is characterized radiographically by the appearance of an injured physis (usually relative widening of the physis with indistinct metaphyseal boundaries). There may be associated clinical or radiographic deformity if the disturbance is severe and long standing. It is important to make a distinction between growth deceleration without complete cessation and true physeal arrest, because

management and outcome are typically different in these two disorders. The concept of growth deceleration without arrest is most readily appreciated in patients with adolescent Blount disease and the milder stages of infantile Blount disease. Recently, growth deceleration without physeal arrest has also been reported to produce distal femoral valgus deformity in obese adolescents.[146] Growth deceleration may also occur after infection and physeal fracture. In contrast to physeal arrests, there is no sclerotic area of arrest on plain radiographs (Fig. 7-33). A growth arrest line, if present, may be asymmetric but will not taper to the physis, thereby suggesting growth asymmetry but not complete arrest. Furthermore, in some cases, deformity will not be relentlessly progressive and can actually improve over time.

Growth acceleration most classically occurs following proximal tibial fracture in young patients resulting in valgus deformity which usually spontaneously resolves.[77,82,120,145,146,169] Interestingly, it has also recently been reported to occur in patients younger than 10 years who have had curettage of benign lesions of the proximal tibial metaphysis.[70]

Management

The diagnosis of physeal growth disturbance is usually made incidentally by noting physeal abnormality on radiographs during physeal fracture follow-up or after a diagnosis of frank physeal arrest has been excluded during the evaluation of a patient with angular deformity and physeal abnormality on plain radiographs. Once a growth disturbance has been identified in a patient, its full impact should be assessed by determining the presence and extent of limb length inequality and the calculated amount of potential growth remaining for the affected physis.

In some cases, the radiographic abnormality is stable and only longitudinal observation is required. This observation must be regular and careful, because progressive deformity will require treatment. If angular deformity is present or progressive, treatment options include hemiepiphysiodesis or physeal "tethering" with staples, screws, or tension plates[24,42,54,58,108,109,116,144,151,160] and corrective osteotomy, with or without completion of the epiphysiodesis. In the absence of frank arrest formation, hemiepiphysiodesis or "tethering" the affected physis with staples, screws, or tension plates on the convex side may result in gradual correction of the deformity. If correction occurs, options include completion of the epiphysiodesis (with contralateral epiphysiodesis if necessary to prevent the development of significant leg length deformity) and removal of the tethering device with careful longitudinal observation for recurrence or overcorrection of deformity. Although there have been numerous publications regarding the various techniques and implants for physeal tethering, there is to date no solid evidence to support one technique. One pitfall to avoid is that a "tethering" technique (staples, plate, screw) opposite a known partial physeal arrest is unlikely to lead to correction of angular deformity, and is likely to lead to a complete growth arrest.

Corrective osteotomy is the other option for the management of growth disturbance with established angular deformity. Angular deformity correction in the early stages of infantile and adolescent Blount disease is known to result in resolution of the physeal growth disturbance in some patients, both on radiographs and clinically. We are unaware of confirmation of similar outcome when the etiology of growth disturbance is infection or trauma, although it may occur. Thus, the treating surgeon must decide whether to perform epiphysiodesis of the affected physis (with contralateral epiphysiodesis, if appropriate) to prevent recurrence or to ensure careful longitudinal observation of the growth performance of the affected physis until skeletal maturity.

SUMMARY

Physeal fractures are one of the unique aspects of pediatric orthopedics. These injuries are common and usually have a favorable outcome without long-term sequelae. Physeal fractures must be treated gently and expertly to maximize restoration of normal limb function and longitudinal growth. Depending on the severity and nature of physeal injury, longitudinal follow-up to identify the development of physeal growth disturbance is important.

8 PATHOLOGIC FRACTURES

Alexandre Arkader and John P. Dormans

INTRODUCTION

In normal circumstances, children and adolescents are prone to fractures caused by forces encountered during their high level of activity. Whenever the structural characteristics and strength of the bone are compromised, by a localized or generalized process, the risk of fractures is increased. The definition of a pathologic fracture is one that occurs through abnormal bone. The combination of a previous bone abnormality and a fracture poses special challenges in the decision-making and management of these injuries. Pathologic fractures may result from a localized or generalized bone weakness, resulting from an intrinsic or extrinsic process. Examples of localized bone weakness caused by an intrinsic process are tumors or tumor-like lesions; generalized causes because of an extrinsic process include osteopenia or osteoporosis of different etiologies.

The evaluation of a child with a pathologic fracture starts with detailed history and physical examination. The past medical history, use of medications, and prodromic symptoms may lead to the diagnosis. Some key points include the patient's age, as some predisposing conditions are more common in specific age groups (Table 8-1); and the presence of pain, which can raise suspicion toward a bone lesion or localized weakening process. Radiographic evaluation is the next step, and helps differentiating between a localized (e.g., tumor) and a generalized process (e.g., osteoporosis). If a bone lesion is identified the five questions should be answered for a differential diagnosis.

1. Where is the lesion? Different bone lesions are seen more frequently in specific areas of the body and the bone (Figs. 8-1 and 8-2).
2. What is the lesion's size and extent? Aggressive lesions tend to be larger and grow faster. Exceptions include fibrous dysplasia (FD) that may involve not only the entire bone but also several bones at the same time and nonetheless is a benign condition. Multiple lesions or generalized bone weakness may pose another challenge in the prevention and management of pathologic fractures.
3. What is the lesion doing to the bone? The pattern of bone involvement and/or destruction plays an important role in the bone strength. For example, lytic lesions (e.g., unicameral bone cyst [UBC]) put the bone at a much higher risk of pathologic fracture than blastic lesions (e.g., osteoblastoma).
4. What is the bone's response? If the bone has time to "compensate" for its destruction caused by a lesional process, new bone formation and cortical thickening may be observed and will to some point prevent or delay apathologic fracture.
5. Soft tissue mass? The presence of an associated soft tissue mass may be an indication of a more aggressive, perhaps malignant process; furthermore, the cortical adjacent to the associated soft tissue mass will often be severely weakened or destructed.

One of the challenges dealing with a "weakened" bone is to predict the likelihood of fracture. The combination of bending and torsional rigidity measured noninvasively with quantitative

TABLE 8-1 Common Predisposing Factors for Pathologic Fractures by Peak Age Incidence

Age (Years)	Benign Lesions	Malignant Tumors	Generalized Causes
0–5	Eosinophilic granuloma Osteomyelitis	Metastatic tumors (neuroblastoma, Wilm) Leukemia Ewing sarcoma	Neuromuscular diseases (medications, disuse osteopenia) Osteogenesis imperfecta
5–10	Unicameral bone cyst Aneurysmal bone cyst Nonossifying fibroma Osteochondroma Fibrous dysplasia Enchondromatosis/Ollier Neurofibromatosis/ Congenital pseudarthrosis of the tibia	Leukemia Osteogenic sarcoma Ewing sarcoma	Neuromuscular diseases (medications, disuse osteopenia) Osteogenesis imperfecta Other medications (e.g., steroids) Rickets Dietary deficiencies Osteopetrosis Bone marrow diseases
10–20	Unicameral bone cyst Aneurysmal bone cyst Nonossifying fibroma Osteochondroma Fibrous dysplasia Chondroblastoma Giant cell tumor	Leukemia Lymphoma Osteogenic sarcoma Ewing sarcoma	Neuromuscular diseases (medications, disuse osteopenia) Other medications (e.g., steroids) Stress fractures Dietary deficiencies Bone marrow diseases

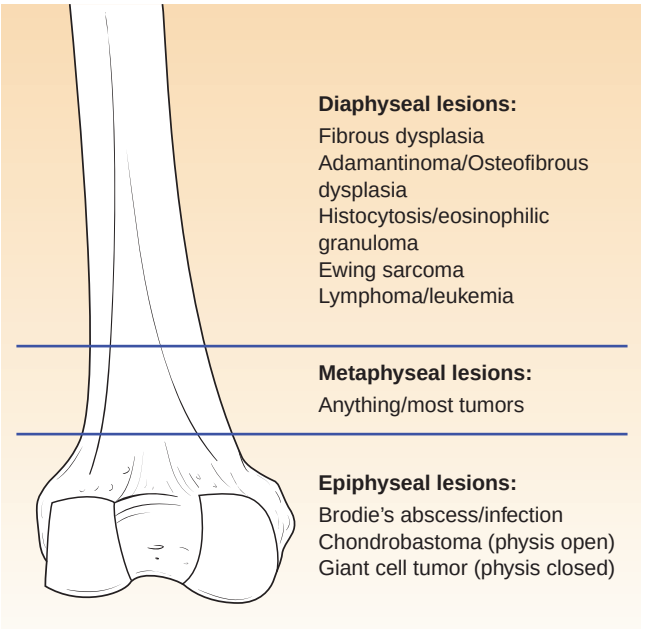

FIGURE 8-1 Schematic distribution of the most common benign and malignant bone lesions seen in the long bones in children.

CT was found to be more accurate for predicting pathologic fracture through benign bone lesions in children than the standard radiographic criteria (42% to 61% accuracy).[129,253]

An important consideration in the management of pathologic fracture is that the underlying cause often needs to be addressed to achieve fracture healing; therefore, the treatment plan must consider both the treatment of the fracture and its underlying cause, at times deviating from the classic principles of pediatric fractures.

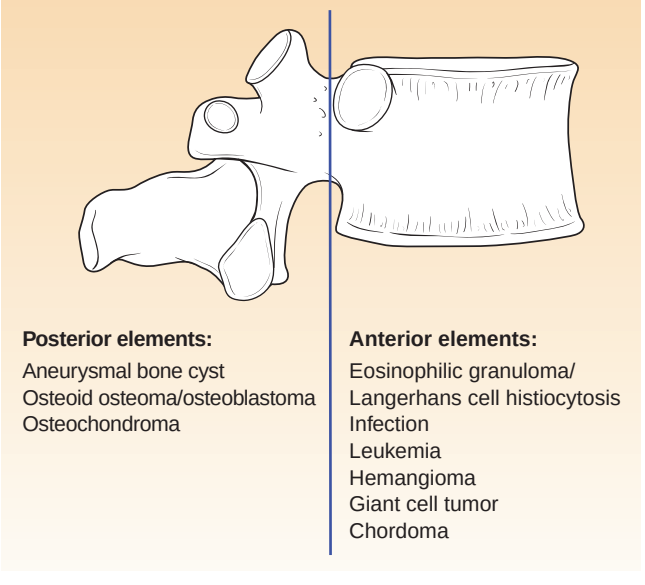

FIGURE 8-2 Schematic distribution of the most common benign and malignant bone tumors seen in the spine in children.

This chapter describes the clinical and radiographic features of the most common causes of pediatric pathologic fractures, including specific patterns of injury and special concerns of treatment. The goals are to warn and prepare the orthopedic surgeon for the correct diagnostic approach and management of these lesions.

Tumors or Tumor-Like Processes

Benign tumors can be classified according to their aggressiveness (Table 8-2). Stage 1, or latent benign lesions, are usually asymptomatic, discovered incidentally, and seldom associated with pathologic fracture. Stage 2 lesions are intermediate in behavior, and stage 3, or aggressive benign lesions, are usually symptomatic, grow rapidly, and may be associated with pathologic fracture.

Unicameral Bone Cyst

Unicameral bone cyst (UBC), also known as simple bone cyst, is a benign, active or latent, solitary cystic lesion that usually involves the metaphysis or metadiaphysis of long bones. In the order of decreasing frequency, UBCs are most commonly seen in the proximal humerus, proximal femur, proximal tibia, distal tibia, distal femur, calcaneous, distal humerus, radius, fibula, ilium, ulna, and rib.[201,202] Although the etiology is unknown, one of the most accepted theories is that UBC is caused by obstruction of the drainage of interstitial fluid.[54,57]

UBCs are classified based on their proximity to the adjacent growth plate. Active cysts are close to the physeal line, and inactive or latent cysts have "migrated" away from the growth plate as longitudinal growth occurs and therefore are far from the epiphysis.[202,202]

The vast majority of patients are younger than 20 years old.[54,275] The male-to-female ratio is about 2:1.[46,202] UBCs are often asymptomatic and, in approximately 80% of cases, the initial presentation is with a pathologic fracture following minor trauma.[49,76,77,275] The fractures are usually incomplete or minimally displaced, and tend to heal uneventfully. In approximately 10% of the cases the cyst heals following the fracture.[5,73,75] Lower

TABLE 8-2 Classification of Benign Lesions According to Their Aggressiveness

Stage 1, Latent Benign
Asymptomatic
Often discovered incidentally
Seldom associated with pathologic fracture
Stage 2, Active Benign
Majority
Tend to grow steadily
May be symptomatic
Stage 3, Aggressive Benign
Generally symptomatic
Discomfort, usually tender
May be associated with pathologic fracture
Growth rapid

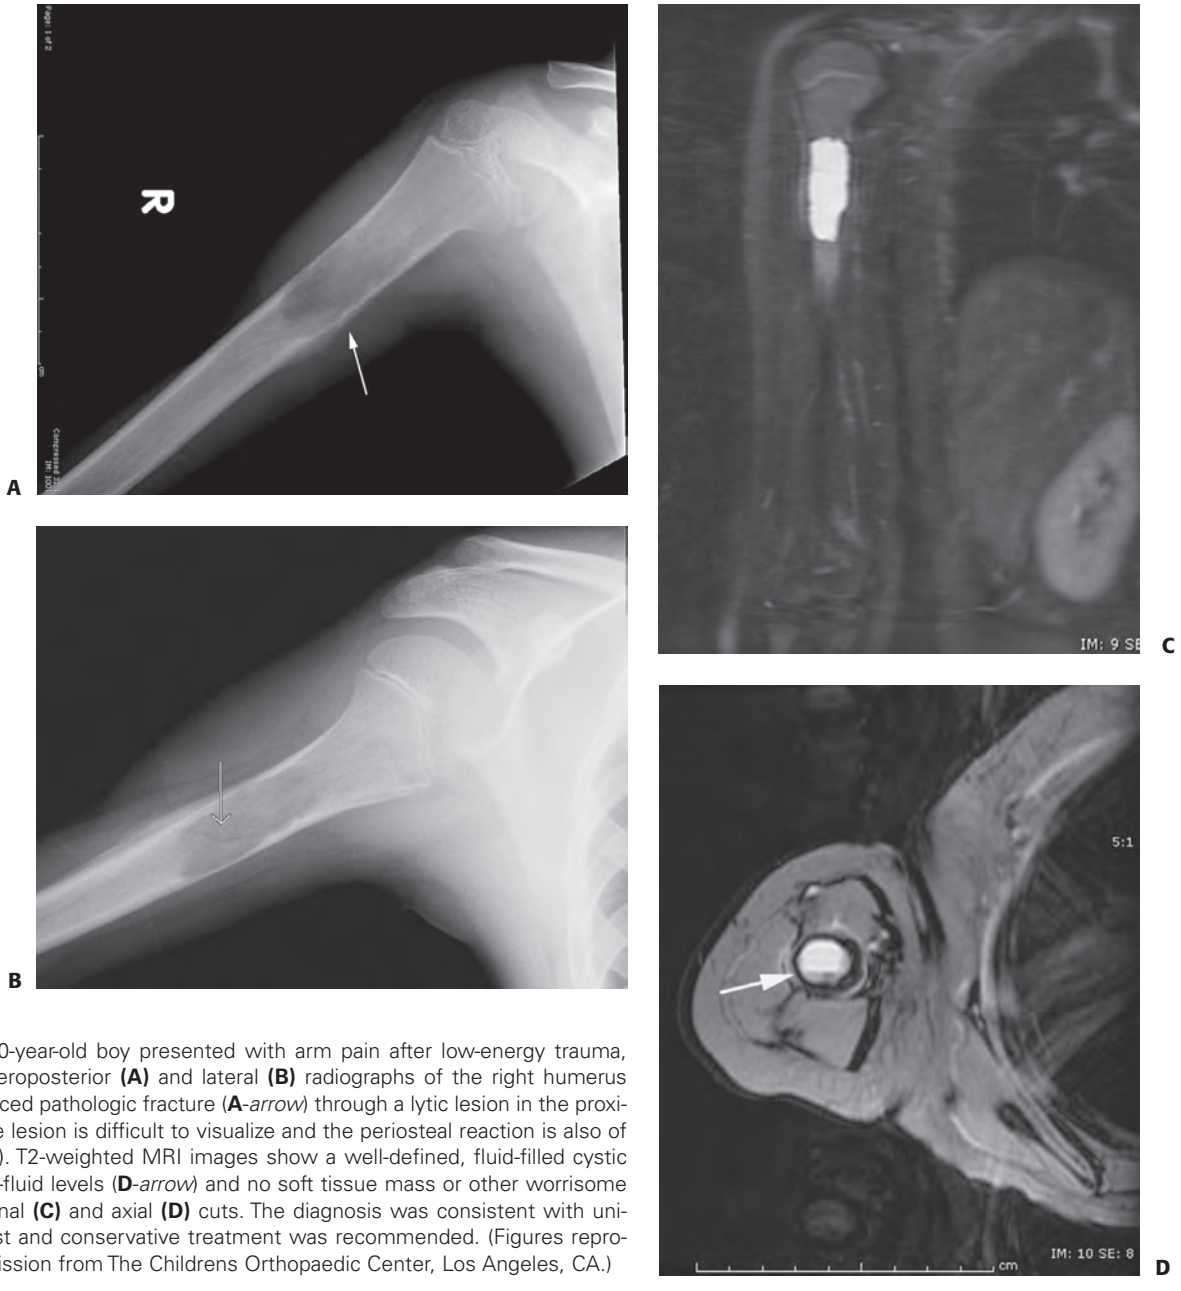

FIGURE 8-3 A 10-year-old boy presented with arm pain after low-energy trauma, 5 days prior. Anteroposterior **(A)** and lateral **(B)** radiographs of the right humerus show a nondisplaced pathologic fracture (**A**-*arrow*) through a lytic lesion in the proximal humerus. The lesion is difficult to visualize and the periosteal reaction is also of concern (**B**-*arrow*). T2-weighted MRI images show a well-defined, fluid-filled cystic lesion, with fluid–fluid levels (**D**-*arrow*) and no soft tissue mass or other worrisome signs in the coronal **(C)** and axial **(D)** cuts. The diagnosis was consistent with unicameral bone cyst and conservative treatment was recommended. (Figures reproduced with permission from The Childrens Orthopaedic Center, Los Angeles, CA.)

extremity fractures, particularly around the hip, often need surgical intervention.

Plain radiographs are usually diagnostic; UBC is a well-defined, centrally located, radiolucent/lytic cystic lesion with narrow zone of transition. Cortical thinning and mild expansion are common. When a pathologic fracture occurs, there is periosteal reaction and occasionally the typical "fallen fragment" sign is visualized (fragment of bone "floating" inside the fluid-filled cystic cavity). CT is useful for lesions located in areas that are of difficult visualization on plain films (e.g., spine, pelvis) and to rule out minimally displaced fractures. Magnetic resonance imaging (MRI) is sometimes used for differential diagnosis of atypical UBCs. Although the characteristics are nonspecific, UBCs usually present as low-to-intermediate signals on T1-weighted images and a bright and homogeneous signals on T2-weighted images (Fig. 8-3).[184]

The differential diagnosis includes aneurysmal bone cyst (ABC), nonossifying fibroma, FD (especially for diaphyseal tumors), brown tumor of hyperparathyroidism, and osteomyelitis.

With time, UBCs tend to stabilize in size and "migrate" away from the growth plate. Although some lesions heal or disappear spontaneously at puberty,[201,202] the majority will persist into adulthood (Table 8-3).

Lesions that have the typical radiographic appearance and therefore do not warrant biopsy for diagnostic confirmation,

TABLE 8-3 Staging of Unicameral Bone Cysts

	Active	Inactive or "Latent"
Age of the patient	<10–12 years	>12 years
Location	Abutting the physis	Separated from physis by a zone of normal cancellous bone
Radiographic appearance	Single cavity	Multiloculated cavity
Intralesional pressure	>30 cm H_2O	6–10 cm H_2O
Pathology	Thin shiny membrane, few osteocytes, little or no hemosiderin, osteoclasts	Thick membrane, frequent giant cells, cholesterol slits, hemosiderin, osteoblasts

particularly those lesions in non–weight-bearing bones, can be followed with serial radiographs.

Large lesions that involve more than 50% to 80% of the bone diameter and lesions that are associated with marked cortical thinning are at high risk of fractures and may warrant prophylactic treatment.[126,254] Lesions of weight-bearing bones, especially around the hip, are best addressed before a fracture (Fig. 8-4). Although several attempts have been made to predict the true risk of pathologic fracture associated with bone cysts, most of the data are related to other lesions, particularly among adults (Fig. 8-5). CT has been shown to be useful for predicting the likelihood of fracture. This method uses a

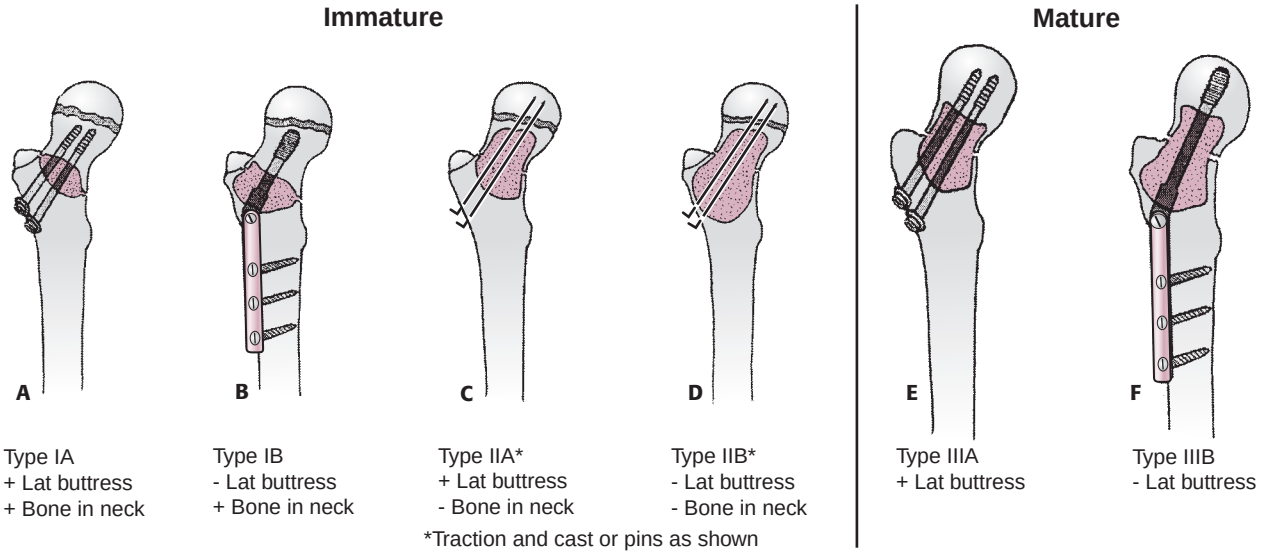

FIGURE 8-4 Classification system for the treatment of pathologic fractures of the proximal femur associated with bone cysts in children. **A:** In type IA, a moderately sized cyst is present in the middle of the femoral neck. There is enough bone in the femoral neck and lateral proximal femur (lateral buttress) to allow fixation with cannulated screws, avoiding the physis, after curettage and bone grafting. **B:** In type IB, a large cyst is present at the base of the femoral neck. There is enough bone proximally in the femoral neck but there is loss of lateral buttress, so a pediatric hip screw and a side plate should be considered rather than cannulated screws after curettage and bone grafting. **C, D:** In type II A-B, a large lesion is present in the femoral neck, so there is not enough bone beneath the physis to accept screws. There are two options for treatment of these bone cysts: (i) after curettage and bone grafting, parallel smooth pins across the physis can be used in combination with spica cast; (ii) the patient can be treated in traction until the fracture heals (with subsequent spica cast) followed by curettage and bone grafting. **E, F:** In type IIIA-B, the physis is closing or closed. The lateral buttress is present in type IIIA hips, so cannulated screws can be used to stabilize the fracture after curettage and bone grafting. In type IIIB hips, the loss of lateral buttress makes it necessary to use a pediatric hip screw and a side plate following curettage and bone grafting. In all types, we recommend spica cast immobilization after surgery.

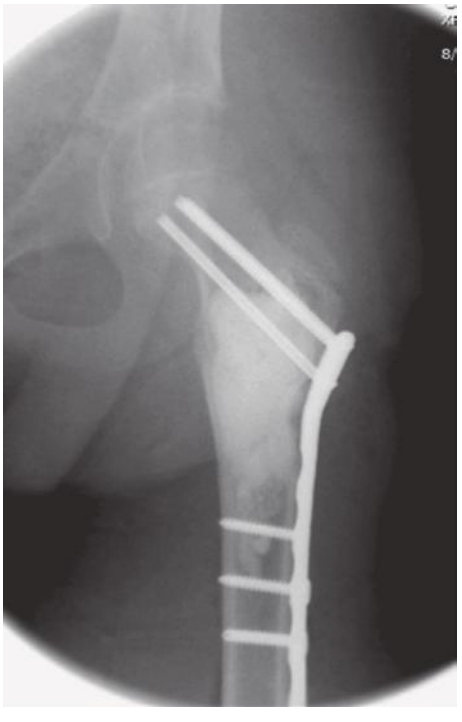
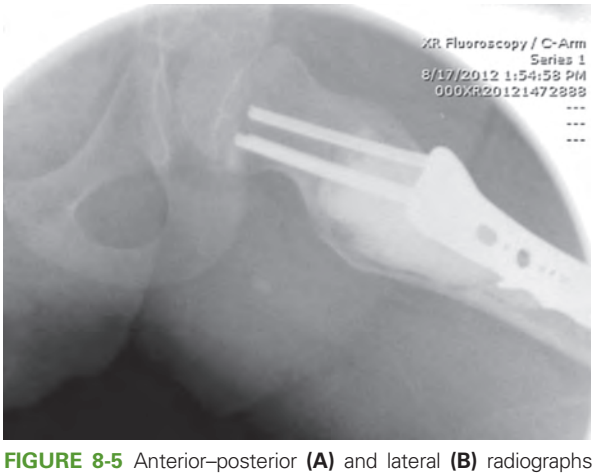
B



C



D

FIGURE 8-5 Anterior–posterior **(A)** and lateral **(B)** radiographs of a 10-year-old who came in with chronic hip pain of several weeks duration. There is a well-defined, lytic lesion in the proximal femur, presenting with cortical thinning and some periosteal reaction, suggesting a healing stress pathologic fracture through a unicameral bone cyst. The patient underwent biopsy to confirm the diagnosis, followed by curettage and bone grafting, supplemented by internal fixation to improve the lateral buttress **(C** and **D).** (Figures reproduced with permission from The Children's Orthopaedic Center, Los Angeles, CA.)

computerized regression system and may help deciding which cysts warrant intervention.[254]

Although spontaneous resolution of UBCs following fracture may occur in up to 15% of the cases (Fig. 8-6), pathologic fractures associated with UBCs do not always heal uneventfully; malunion, growth arrest, and avascular necrosis are some of the reported complications.[142,182]

Author's Preferred Method

We recommend treating the fracture conservatively prior to definitive treatment of the cyst. The main reasons are to allow possible spontaneous healing of the cyst and to make it easier to treat a

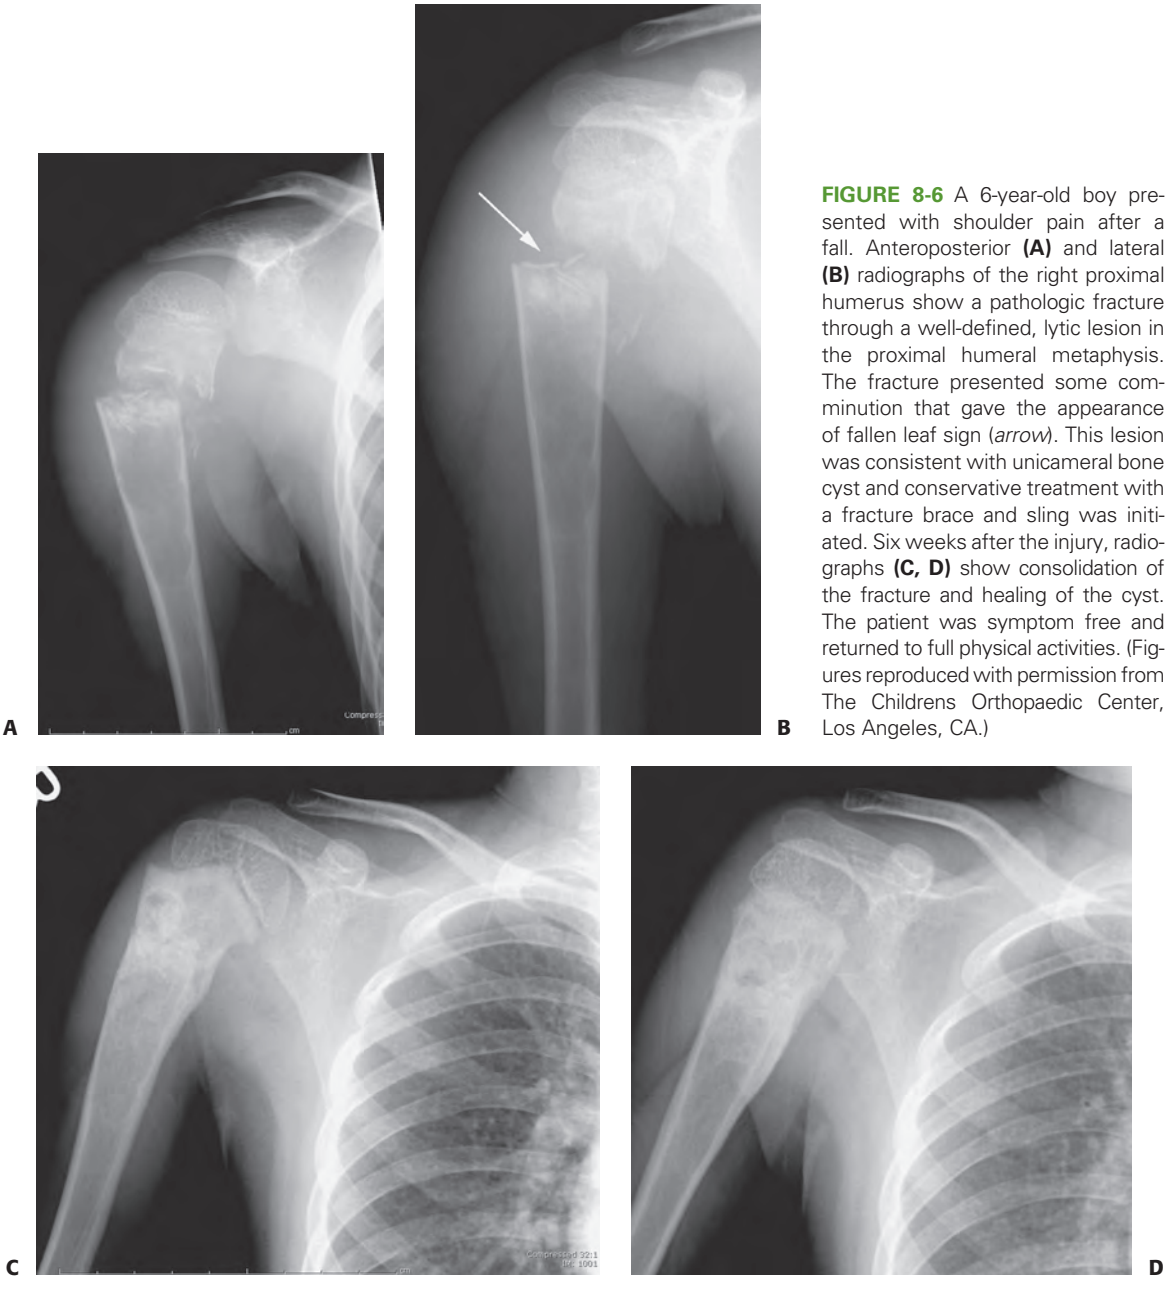


FIGURE 8-6 A 6-year-old boy presented with shoulder pain after a fall. Anteroposterior **(A)** and lateral **(B)** radiographs of the right proximal humerus show a pathologic fracture through a well-defined, lytic lesion in the proximal humeral metaphysis. The fracture presented some comminution that gave the appearance of fallen leaf sign (*arrow*). This lesion was consistent with unicameral bone cyst and conservative treatment with a fracture brace and sling was initiated. Six weeks after the injury, radiographs **(C, D)** show consolidation of the fracture and healing of the cyst. The patient was symptom free and returned to full physical activities. (Figures reproduced with permission from The Childrens Orthopaedic Center, Los Angeles, CA.)

stable bone, rather than two moving parts. The exception is select proximal femur fractures that may need rigid internal fixation.

Our preferred technique is a minimally invasive approach that combines aspiration, cystogram, biopsy, curettage, intramedullary decompression, and grafting with medical-grade calcium'.[73,76] Complete cyst healing is achieved in over 80% of the cases.

Surgical Technique

- Under fluoroscopic guidance, a Jamshidi trocared needle (CardinalHalth, Dublin, OH) is percutaneously inserted into the cyst cavity, preferably in the middle of the cyst.
- The cyst is aspirated to confirm the presence of straw-colored fluid.
- Three to 10 mL of Renografin dye (E.R. Squibb, Princeton, NJ) is injected to perform a cystogram and confirm the single fluid-filled cavity.
- A 0.5-cm longitudinal incision is then made over the site of the aspiration and a 6-mm arthroscopy trocar is advanced into the cyst cavity through the same cortical hole. The cortical entry is then enlarged manually.
- Under fluroscopic guidance, percutaneous removal of the cyst lining is done with curved curettes and a pituitary rongeur.
- An angled curette and/or flexible intramedullary nail is used to perform the intramedullary decompression in one direction (toward diaphysis) or in both directions (if the growth plate is far enough to avoid injury).

- Bone grafting is done with medical-grade calcium sulfate pellets (Osteoset, Wright Medical Technology, Arlington, TN) inserted through the same cortical hole and deployed to completely fill the cavity. The pellets do not offer structural support but act as scaffolding for new bone formation and cyst healing. Angled curettes can be used to advance pellets into the medullary canal, which also confirms adequate decompression. Tight packing of the cyst is preferred.
- The wound is closed in a layered fashion.

Aneurysmal Bone Cyst

ABCs are benign, locally aggressive bone tumors.[257] They are well-defined, eccentric, expansile, osteolytic, blood-filled lesions usually seen in the metaphyseal region of long bones (65% of cases) or in the posterior elements of the spine. ABCs have a tendency to expand beyond the width of the epiphyseal plate. Approximately 75% of ABCs are seen in patients younger than 20 years old, and 50% are seen in individuals between 10 and 20 years of age.[46,62] The estimated incidence is of approximately 1.4 cases per 100,000, representing 1.5% of all primary bone tumors.[62]

In the order of decreasing frequency, the most commonly involved bones in the appendicular skeleton are the femur (~20%), tibia (~17%), spine (~15%), humerus (~13%), pelvis (~8%), and fibula (~7%).[62] The spine is involved in up to 27% of the cases,[46,62] with the posterior elements being the most common site with frequent extension into the vertebral body.[39,98] The lumbar vertebrae are the most commonly affected.[39]

The etiology of ABCs is still unknown. The neoplastic basis of primary ABCs has been in part demonstrated by the chromosomal translocation t(16; 17)(q22; p13) that places the ubiquitin protease USP6 gene under the regulatory influence of the highly active osteoblast cadherin 11 gene, which is strongly expressed in bones.[210] There is a fairly high incidence of ABCs associated with other benign and malignant tumors such as UBCs, nonossifying fibromas, FD, and osteogenic sarcoma.[65,174,186] The most common presenting symptom is localized pain and/or swelling of less than 6 months duration; spinal lesions may present with radicular pain.[46,69,98,104,159]

On plain radiographs, ABCs present as an eccentric lytic lesion. Although usually the overlying cortex is intact, sometimes cortical disruption is identified. When that occurs, periosteal reaction is seen.[37,159] Cystic septation is common, giving rise to the so-called soap bubble or honeycomb appearance. Lesions in the short tubular bones, such as the metacarpals and metatarsals, are commonly more central. Lesions near the growth plate tend to expand beyond the width of the adjacent epiphysis (Fig. 8-7), which can be a useful way to differentiate ABCs from UBCs which do not commonly expand as much beyond the width of the epiphysis. MRI is often helpful in obtaining better definition of axial lesions and in demonstrating the characteristic double density fluid level, septation, low signal on T1 images, and high intensity on T2 images; however, these findings are not pathognomonic for ABC.[262]

Campanacci et al.[46] have classified ABCs into three groups. An aggressive cyst has signs of reparative osteogenesis with ill-defined margins and no periosteal shell. An active cyst has an incomplete periosteal shell and a defined margin between the lesion and the host bone. An inactive cyst has a complete periosteal shell and a sclerotic margin between the cyst and the long bone (Fig. 8-8).

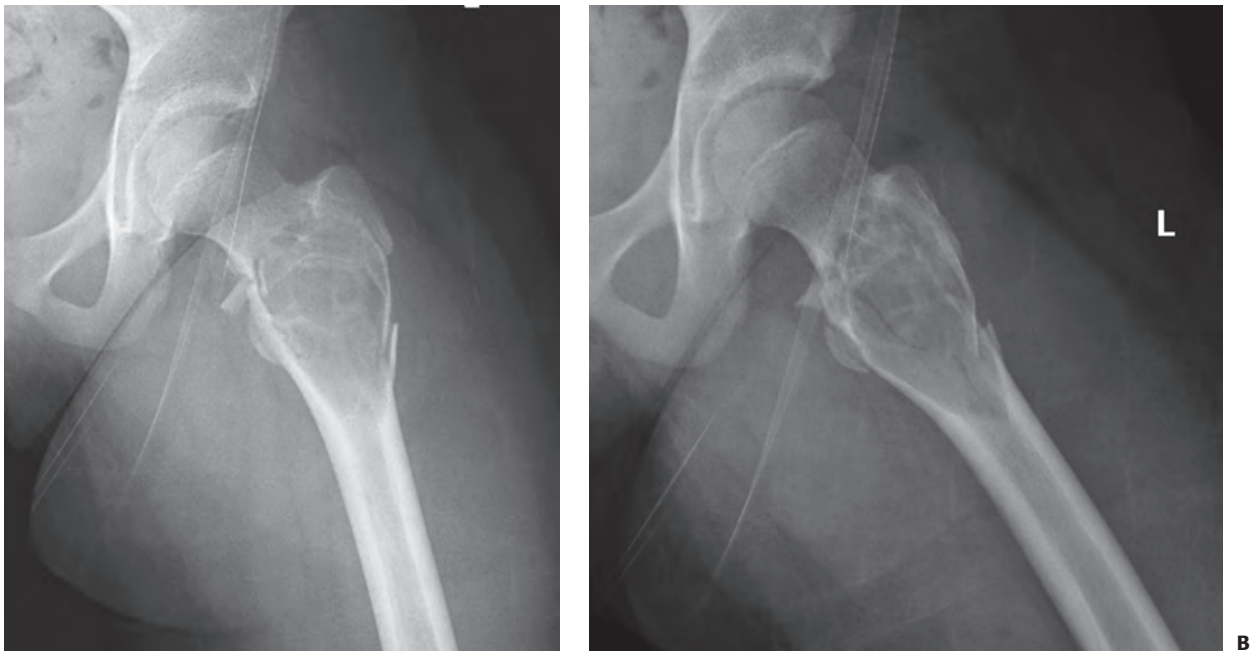

FIGURE 8-7 Anterior–posterior **(A)** and lateral **(B)** radiographs of a 12-year-old who suffered a fall and developed acute left hip pain and inability to ambulate. There is a pathologic fracture through a well-defined, lytic and loculated lesion in the proximal femur, with cortical thinning, no soft tissue mass or periosteal reaction.

FIGURE 8-7 (*continued*) The patient underwent biopsy confirming the diagnosis of aneurysmal bone cyst, followed by curettage and allografting, supplemented by internal fixation with a variable hip screw and a cannulated antirotational screw **(C, D).** The 4 years follow-up, short after hardware removal, shows no signs of recurrence or persistence of the lesion **(E** and **F).** (Figures reproduced with permission from The Children's Orthopaedic Center, Los Angeles, CA.)

Pathologic fractures occur in 11% to 35% of long bone lesions.[98,159] The humerus and femur are the most common sites of pathologic fracture.[98,158] The incidence of pathologic fracture associated with spinal lesions is approximately 20%.[39,69,104] Conservative treatment with immobilization is usually inappropriate as a definitive treatment for pathologic fractures of ABCs. Although the pathologic fracture will heal, ABCs do not spontaneously heal and may enlarge; furthermore, tissue sampling is often needed for diagnosis confirmation.

Recurrence rates following intralesional curettage and bone grafting are as high as 30%.[74,109,269] Several authors have shown that the recurrence is higher among younger children.[24,60,74,98] Freiberg et al.[98] treated ABCs with curettage and bone grafting in seven patients younger than 10 years of age and noted

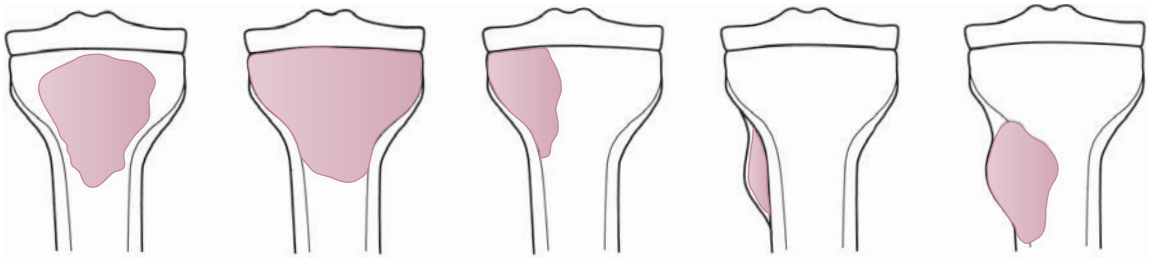

FIGURE 8-8 Classification of morphologic types of aneurysmal bone cyst. (From Campanna R, Bettelli G, Biagini R, et al. Aneurysmal cysts of long bones. *Ital J Orthop Traumatol.* 1985;XI:421–429, with permission.)

recurrence in five of the seven patients at an average of 8 months after the first procedure. Because of this high recurrence rate, several authors attempted the use of adjuvant, such as cryosurgery and cementation.[183,239]

Author's Preferred Method

Four-Step Approach Resection

This technique has been previously described with reported recurrence rate for appendicular lesions around 8%.[74,104] We recommend the use of headlamps for enhanced illumination and loupes for magnification. An image intensifier is available for intraoperative confirmation of complete tumor excision and appropriate bone grafting. Diagnostic tissue confirmation is an essential part of this technique. For large spinal tumors, preoperative embolization is recommended (Fig. 8-9). If instrumentation is needed after spine tumors resection, we recommend titanium or cobalt chrome instrumentation that gives a much better visualization of the spine on future MRIs (less artifact) than stainless steel (Fig. 8-10).

Surgical Technique

- Under fluoroscopic guidance, a small longitudinal incision is made over the cyst. No flaps are created, and the dissection is carried down to the lesion level. The cyst wall is usually easily penetrated with curettes. Care should be taken to control eventual significant bleeding at the time of cyst penetration.
- Lesional tissue is than retrieved and sent for frozen section for diagnostic confirmation.
- Upon diagnostic confirmation, the cortical window is enlarged using roungers or a high-speed burr to allow appropriate visualization and excision. Using angled and straight curettes of different sizes, the intralesional resection/curettage is performed (Step 1).
- After the first step, the high-speed burr is used to extend the intralesional margins as well to excise any residual tumoral cells (Step 2).
- Step 3 entails the use of electrocautery. This has two goals: First, it helps identify residual tumor pockets and second, has the theoretical capability of killing residual tumor cells.
- Adjuvant in the form of phenol solution 5% is used for appendicular lesions (Step 4).
- The lesion is now completely excised and bone grafting is performed, usually using a combination of allograft cancellous cubes and demineralized bone matrix paste. Tight packing of the cyst is preferred. Alternatively a bone substitute, such as tricalcium phosphate, may be used for immediate structural support.
- Internal fixation is done on case-by-case basis. Lesions of weight-bearing bones, particularly of the proximal femur, and some large vertebral lesions may warrant internal fixation/instrumentation following the four-step approach.
- The wound is closed in a layered fashion. Drain is used as needed and should exit the skin in line with the excision.

Fibrous Cortical Defects and Nonossifying Fibromas

Fibrous cortical defects (FCDs) are the most common bone tumor or tumor-like condition seen in the growing child. Both FCDs and the larger variant known as nonossifying fibroma (NOF) may be associated with pathologic fractures in children. Pathologic fractures through these lesions occur more commonly in boys between 6 and 14 years old.[64]

FCDs are small, well-defined, intracortical, metaphyseal lesions surrounded by a sclerotic rim with localized cortical thinning, ranging from 1 to 2 cm in diameter and most commonly found in the distal femur, proximal tibia, and fibula. FCDs can be incidentally found on radiographic studies of the lower extremity in approximately 25% of pediatric patients.[64] In view of their usually asymptomatic nature, it is difficult to estimate the true incidence. They usually require no treatment other than observation.

NOFs present at a similar age as FCDs and follow a similar distribution of bone involvement; however, multiple lesions are present in approximately one-third of patients.[79] Radiographically, they present as a well-defined, eccentric radiolucent cyst-like lesion of the metaphysis that may be mostly intracortical or intramedullary and are usually larger than 4 cm,[15] sometimes extending across a substantial portion of the width of the long bone.[64] NOFs are also usually asymptomatic unless a pathologic fracture is present.[15,64]

Several authors have suggested that FCDs and NOFs may regress spontaneously with time.[79,83] Typically, this tumor

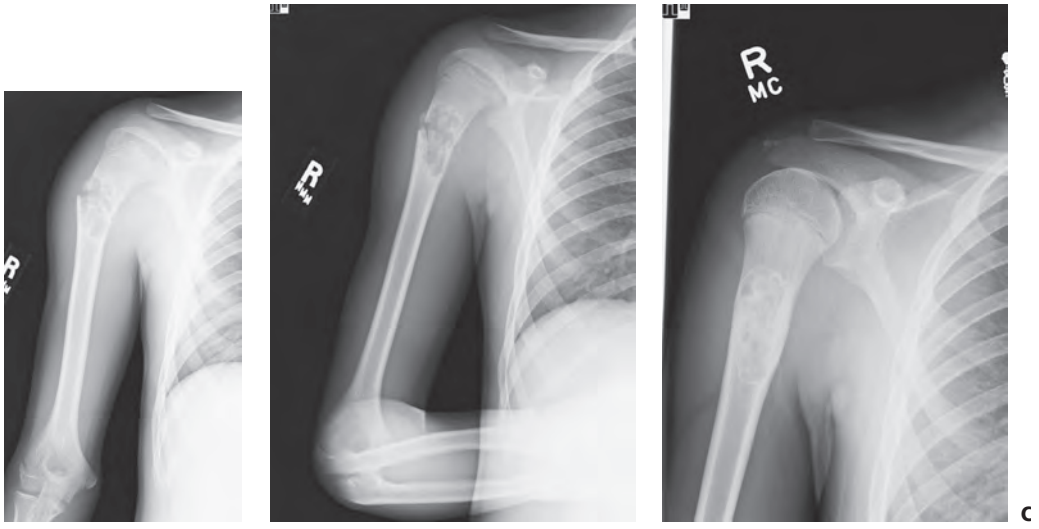
remains asymptomatic and is commonly an incidental radiographic finding. However, lesions with extensive cortical involvement can cause pain because of pathologic fractures. Fractures through NOFs heal uneventfully but the lesion persists, and refracture may occur, but the incidence is low (Fig. 8-11).[15,64,79,83]

The size of the lesion seems to correlate directly to the risk of pathologic fracture.[15] Arata et al.[15] noted that all pathologic fractures associated with NOFs in the lower extremity occurred through lesions involving more than 50% of the transverse cortical diameter. These large lesions were defined as exhibiting more than 50% cortical involvement on anteroposterior (AP) and lateral radiographic studies and a height measurement of more than 33 mm.[15] In their series, 43% of the pathologic fractures through NOFs were in the distal tibia. Although the authors recommended careful observation of these large NOFs, they suggested that "prophylactic curettage and bone grafting be considered if there is a reasonable chance of fracture."[15] Their series does not include any large lesion meeting their size criteria that did not fracture, and their hypothesis has never been tested in any published series. Drennan et al.[79] suggested that large NOFs causing pain might predispose to fracture and recommended prophylactic curettage and bone grafting for select larger lesions.



A, B C

FIGURE 8-11 A 13-year-old girl sustained a fall from her own height and developed pain and deformity around the right shoulder. Anterior–posterior **(A)** and lateral **(B)** plain films show a pathologic fracture through a well-defined, eccentric, cortical based lesion in the proximal humerus metaphysis. There is sharp sclerotic rim and the lesion was clinically diagnosed as nonossifying fibroma. After 4 weeks of conservative treatment, the fractured healed **(C, D)** in a few degrees of varus and the lesion persisted.

D

FIGURE 8-11 (*continued*)

Easley and Kneisel[83] reported that although absolute size parameters were helpful in predicting pathologic fracture, they did not imply a requirement for prophylactic curettage and bone grafting. In their series, 13 (59%) large NOFs had not had pathologic fracture despite exceeding the previously established size threshold. In the nine (41%) patients in whom pathologic fracture occurred, healing was uneventful after closed reduction and cast immobilization, and no refractures occurred. They suggested that most patients with large NOFs can be monitored without intervention, because previous studies support spontaneous resolution of most of these lesions.[15,64,79] All fractured NOFs in their series healed with closed reduction and immobilization.

Fractures are usually treated with immobilization until healing is obtained. Surgery is necessary only if the residual lesion of significant size to predispose the patient to further pathologic fractures, if there is chronic pain suggesting a stress fracture, or if there is doubt about the nature of the lesion.[15,83]

Author's Preferred Method

Treatment is based on the size and location of the lesion and the type of pathologic fracture. Small lesions without fracture can be observed and may require 1 to 3 years to spontaneously resolve. Large lesions of the lower extremity in active children, even if they are assymptomatic, should either be followed carefully with serial radiographic studies or should undergo curettage and bone grafting to avoid pathologic fracture. Although absolute size parameters may be useful in predicting pathologic fracture, they do not imply a requirement for prophylactic curettage and bone grafting. Most patients with large NOFs can be monitored without surgical intervention, and fractures can be successfully managed with nonoperative treatment. Our experience is that a considerable number of incidentally discovered large NOFs do not fracture. Although we cannot readily identify an accurate denominator, we infer that many large NOFs remain unindentified and nonproblematic. Patient and family wishes and the individual's activity demands also influence the decision. Given the historic evidence for spontaneous resolution and favorable healing characteristics of NOFs, patients with lesions larger than 50% of the width of the bone should be approached individually, especially in the presence of clinical symptoms (Fig. 8-12).

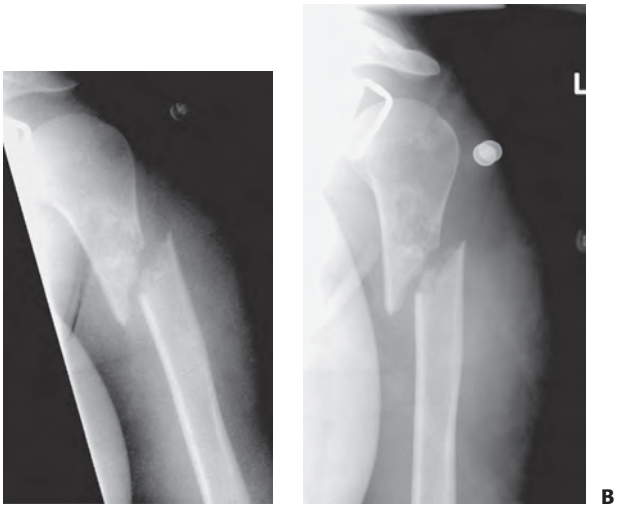
Enchondroma

Enchondromas are latent or active benign cartilaginous tumors. These lesions are often incidentally found, but the most common presenting symptom is pain associated at times with swelling. The most common sites of involvement in decreasing order of frequency are the phalanges, metacarpals, metatarsals, humerus, and femur. Pathologic fracture is commonly the presenting symptom for enchondromas located in the phalanges of the hands or feet, but is rare for enchondromas in other locations.[105]

On plain radiographs, enchondromas are usually central intramedullary lesions with stippled calcification of the cartilage tumor matrix. Larger lesions may cause cortical thinning and scalloping and predisposal to pathologic fractures (Fig. 8-13).

Children may present with multiple enchondromas or enchondromatosis (Ollier disease), which is commonly seen between 2



A B

FIGURE 8-13 A 17-year-old girl with developmental delays sustained a fall and developed pain and deformity around the right proximal humerus. Radiographs of the proximal humerus **(A, B)** demonstrated a pathologic fracture through a right proximal humerus metaphyseal lesion. There is some matrix formation with speckled calcification, some cortical thinning/ scalloping, but no soft tissue mass, gross cortical disruption, or other worrisome signs. The lesion was clinically consistent with enchondroma. (Figures reproduced with permission from The Childrens Orthopaedic Center, Los Angeles, CA.)

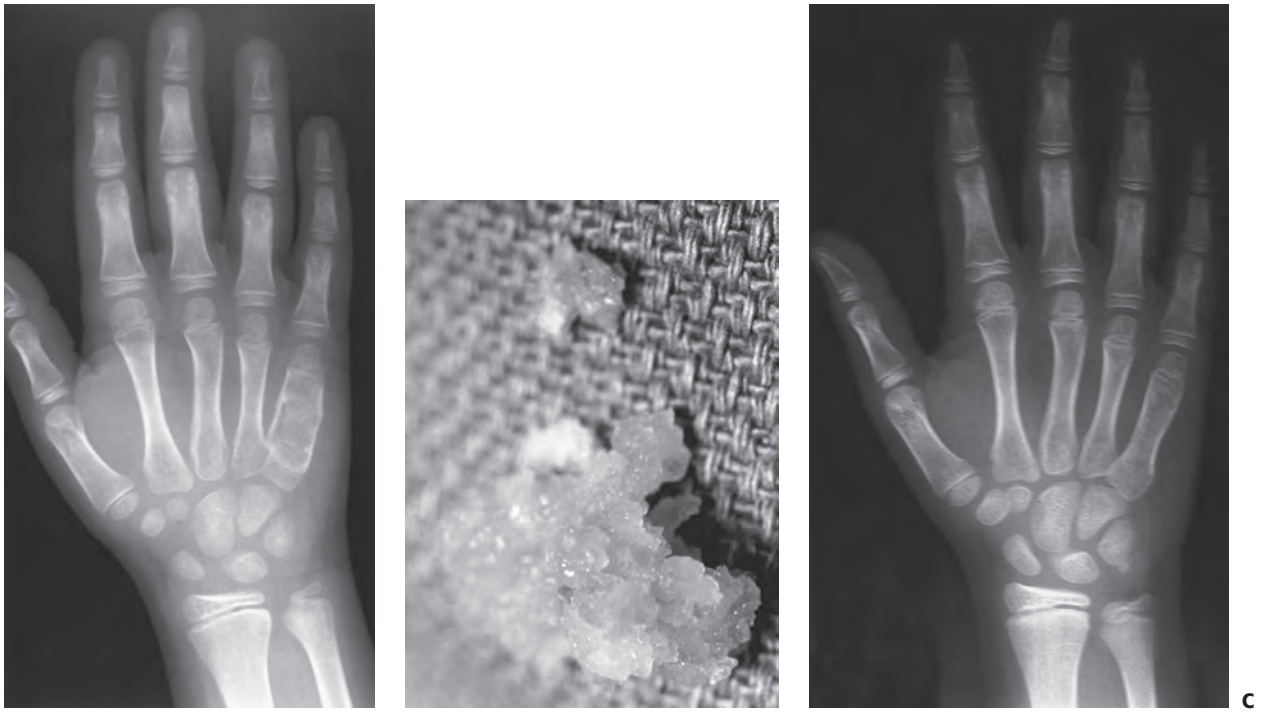
and 10 years of age. Although the lesion itself is similar to a solitary enchondroma, deformity and shortening of the extremity because of growth disturbance may occur (Fig. 8-14).[273] A typical radiographic finding of enchondromatosis is the presence of linear radiolucencies extending from the metaphysis down the shaft of the long bone, frequently seen in the hands.

When enchondromatosis is associated with multiple hemangiomas, it is known as Maffucci syndrome.[175] In this syndrome, 30% of patients have one or more pathologic fractures.[175] Approximately half of these fractures go on to delayed union or nonunion. Skeletal deformities tend to stabilize at maturity (Fig. 8-15). Sarcomatous degeneration has been reported in approximately 15% of patients.[175]

Asymptomatic lesions can be observed. Biopsy may be necessary when the identity of the lesion is uncertain. Symptomatic lesions respond well to curettage and bone grafting.[105,273] Treatment should be individualized for displaced fractures.

Author's Preferred Method

For asymptomatic patients with small lesions with classic radiographic findings, biopsy is not necessary. Curettage and bone grafting are necessary for those lesions with acute or impending pathologic fracture, or in cases of continued pain. Fixation



A, B C

FIGURE 8-14 An 8-year-old boy presented with pain and swelling of the ulnar border of his right hand. **A:** Radiographic studies showed an expansile, lucent lesion of the diaphysis of the patient's right fifth metacarpal with microfractures. The patient had an open incisional biopsy with frozen section, which was consistent with enchondroma with subsequent curettage and bone grafting. **B:** Gross appearance of material removed at the time of surgery, which is consistent with enchondroma. **C:** At 6-month follow-up, the fracture is well healed, and there is no sign of recurrent tumor.

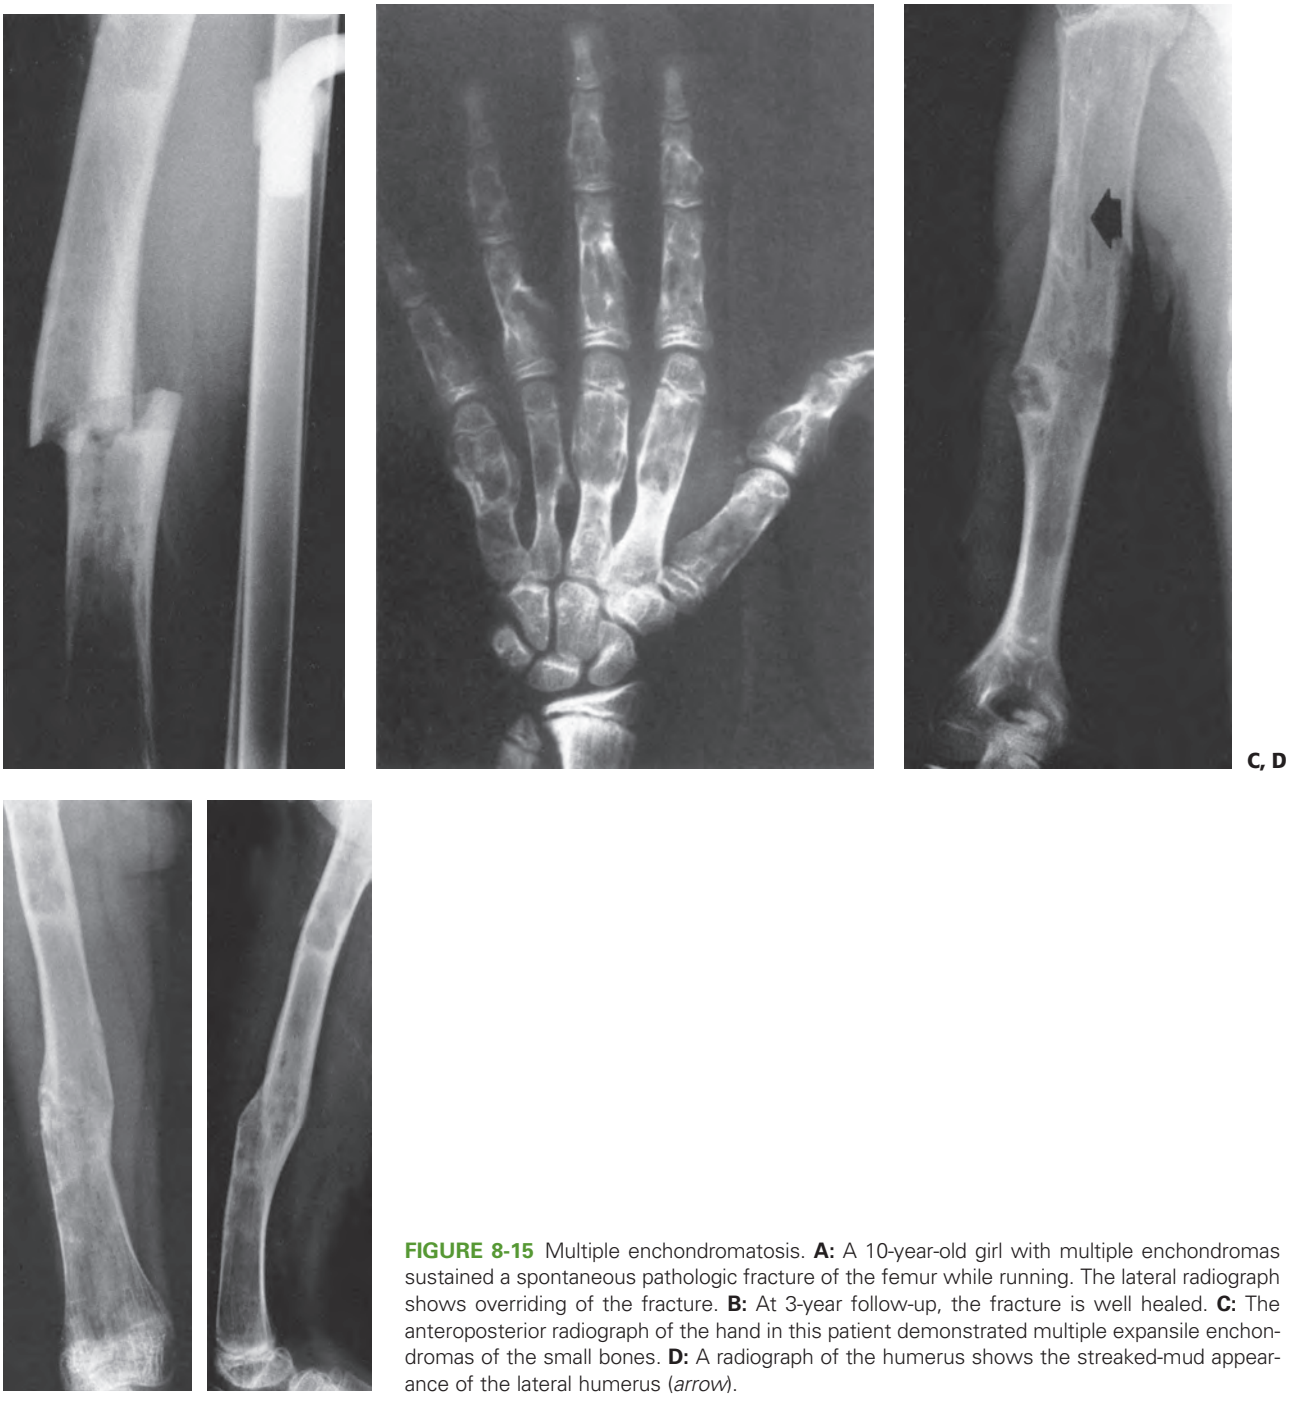


FIGURE 8-15 Multiple enchondromatosis. **A:** A 10-year-old girl with multiple enchondromas sustained a spontaneous pathologic fracture of the femur while running. The lateral radiograph shows overriding of the fracture. **B:** At 3-year follow-up, the fracture is well healed. **C:** The anteroposterior radiograph of the hand in this patient demonstrated multiple expansile enchondromas of the small bones. **D:** A radiograph of the humerus shows the streaked-mud appearance of the lateral humerus (*arrow*).

is not necessary for lesions of the short tubular bones but may be necessary for lesions of the proximal femur or long bone of the lower extremity. Standard fracture care is adequate to treat most pathologic fractures, but the bone quality may be compromised by the tumor and it may be difficult fixation.

Osteochondroma

Osteochondromas are one of the most common tumors of bone in children, and clinical symptoms are usually related to irritation of the surrounding soft-tissue structures. The radiographic appearance is pathognomonic, with a continuity of the host bone cortex with the outer cortex of the lesion and intramedullary cavities, in the same fashion. Although fractures associated with osteochondromas are rare, they may occur through the base or stalk of a pedunculated tumor (Fig. 8-16).[51] Fractures through osteochondromas should be treated conservatively; however, excision in the acute phase may be considered because the fragment is "floating free" in the soft tissues. The

FIGURE 8-16 A 13-year-old girl presented with right knee pain following direct trauma to that area 10 days prior. On anteroposterior **(A)** and lateral **(B)** radiographs, there was a pathologic fracture through the base of a pedunculated osteochondroma (*arrow*). The patient was very tender around that area and elected surgical excision. Immediately after excision **(C, D),** there was improvement of the symptoms. Four weeks later, she returned to full activities. (Figures reproduced with permission from The Childrens Orthopaedic Center, Los Angeles, CA.)

cartilage cap surrounding the lesion should always be removed to avoid the risk of recurrence.

Langerhans Cell Histiocytosis

Langerhans cell histiocytosis (LCH) is a rare group of disorders with a wide spectrum of clinical presentation, where the constant pathologic finding is the "Langerhans cell." The present nomenclature defines solitary osseous lesion as eosinophilic granuloma (EG). The annual incidence of LCH is at 6 per million children per year.[31] Males are affected to a slightly higher degree than females.[43,133] It is predominantly a disease of childhood, with more than 50% of cases diagnosed between the ages

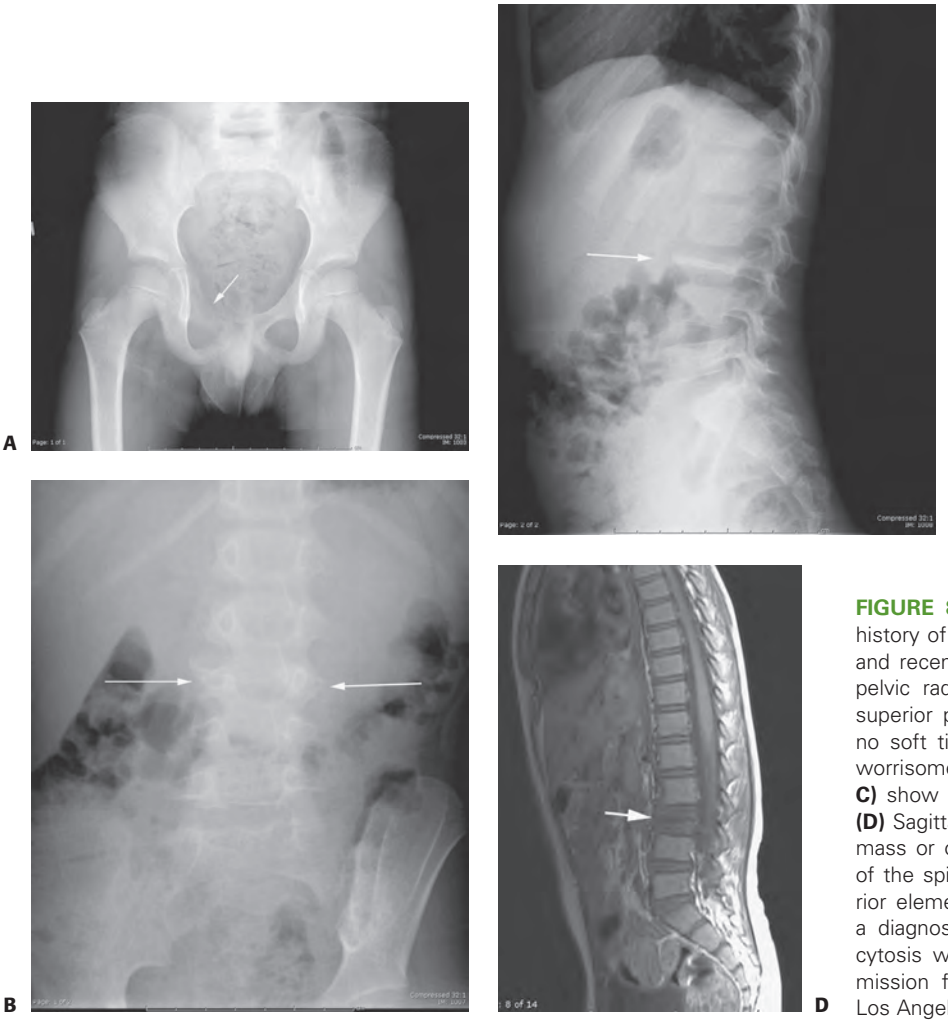

FIGURE 8-17 A 5-year-old boy presented with a history of several months of intermittent back pain and recent development of right inguinal pain. On pelvic radiographs **(A)** a lytic lesion of the right superior pubic rami is visualized (*arrow*). There is no soft tissue mass, periosteal reaction, or other worrisome signs. The lumbar spine radiographs **(B, C)** show a classic "vertebra plana" of L3 (*arrow*). **(D)** Sagittal T1-weighted MRI shows no soft tissue mass or other associated lesions, no compromise of the spinal canal and no extension to the posterior elements. The pelvic lesion was biopsied and a diagnosis of polyostotis Langerhans cell histiocytosis was made. (Figures reproduced with permission from The Childrens Orthopaedic Center, Los Angeles, CA.)

of 1 and 15, and peak in incidence between the ages of 1 and 4.[31,43] The clinical course of the disease is quite variable, with some forms undergoing seemingly spontaneous remission. The disease can be localized to a bone or single system, or multifocal involving multiple bones and/or systems.

Bone pain is the initial symptom in 50% to 90% of the patients with osseous lesion.[72] Other reported symptoms in osseous LCH include swelling, tenderness, pathologic fractures, diminished hearing, and otitis media (mastoid lesions) or loose teeth (mandible lesions). Vertebral collapse may produce pain and spasm, torticollis may be seen with cervical spine lesions, and kyphosis might develop with thoracic lesions but neurologic symptoms are uncommon.[97,174,224]

The radiographic appearance is highly variable, but often lesions are radiolucent with well-defined margins, with or without surrounding sclerosis. Skeletal lesions may be solitary or multiple. Most long bone lesions involve the diaphysis or metaphysis, with destructive osteolysis and overlying expansion by periosteal layering.[43] Epiphyseal involvement is rare but may occur.

Vertebral destruction with complete collapse of the vertebral body is classically referred to as "vertebra plana." Adjacent intervertebral disc height is usually maintained (Fig. 8-17). Spinal lesions can be classified based on the amount and pattern of maximal vertebral collapse[103]: Grade I (0% to 50% of collapse), grade II (51% to 100%), or grade III (limited to the posterior elements); and A (symmetric collapse) or B (asymmetric collapse).

Biopsy is usually necessary to confirm the diagnosis and also to differentiate LCH from malignancies that may present with similar radiographic appearance. Biopsy can usually be done minimally invasively through the pedicle. One should not violate posterior ligaments or progressive kyphosis will result. If nonspine sites are biopsy-proven LCH, and the spine involvement is classic for vertebra plana, a biopsy of the spine may not be needed. Once the diagnosis is established, treatment options include observation or curettage and bone grafting.[43,108,133] Surgical intervention is uncommon. Localized kyphosis is present, but can usually be treated with a brace (TLSO) for approximately 3 months. Chemotherapy with prednisone and vinblastine is indicated for cases of multiple bone involvement or visceral disease.[16] Pathologic fracture is uncommon in patients with LCH. Standard fracture care is usually sufficient for pathologic fractures.

Malignant Bone Tumors and Metastasis

Pathologic fractures can sometimes be the presenting symptom of a malignant bone tumor (Fig. 8-18). The two most common primary bone malignancies in children are osteosarcoma and Ewing sarcoma. Destructive bone lesions can also be caused by metastasis, being more common than primary tumors in certain age groups. Careful staging and biopsy[20,250] are critical in the approach to children with bone tumors. However, biopsy is not done without risks. One of the main complications following biopsies is pathologic fracture caused by a decrease in

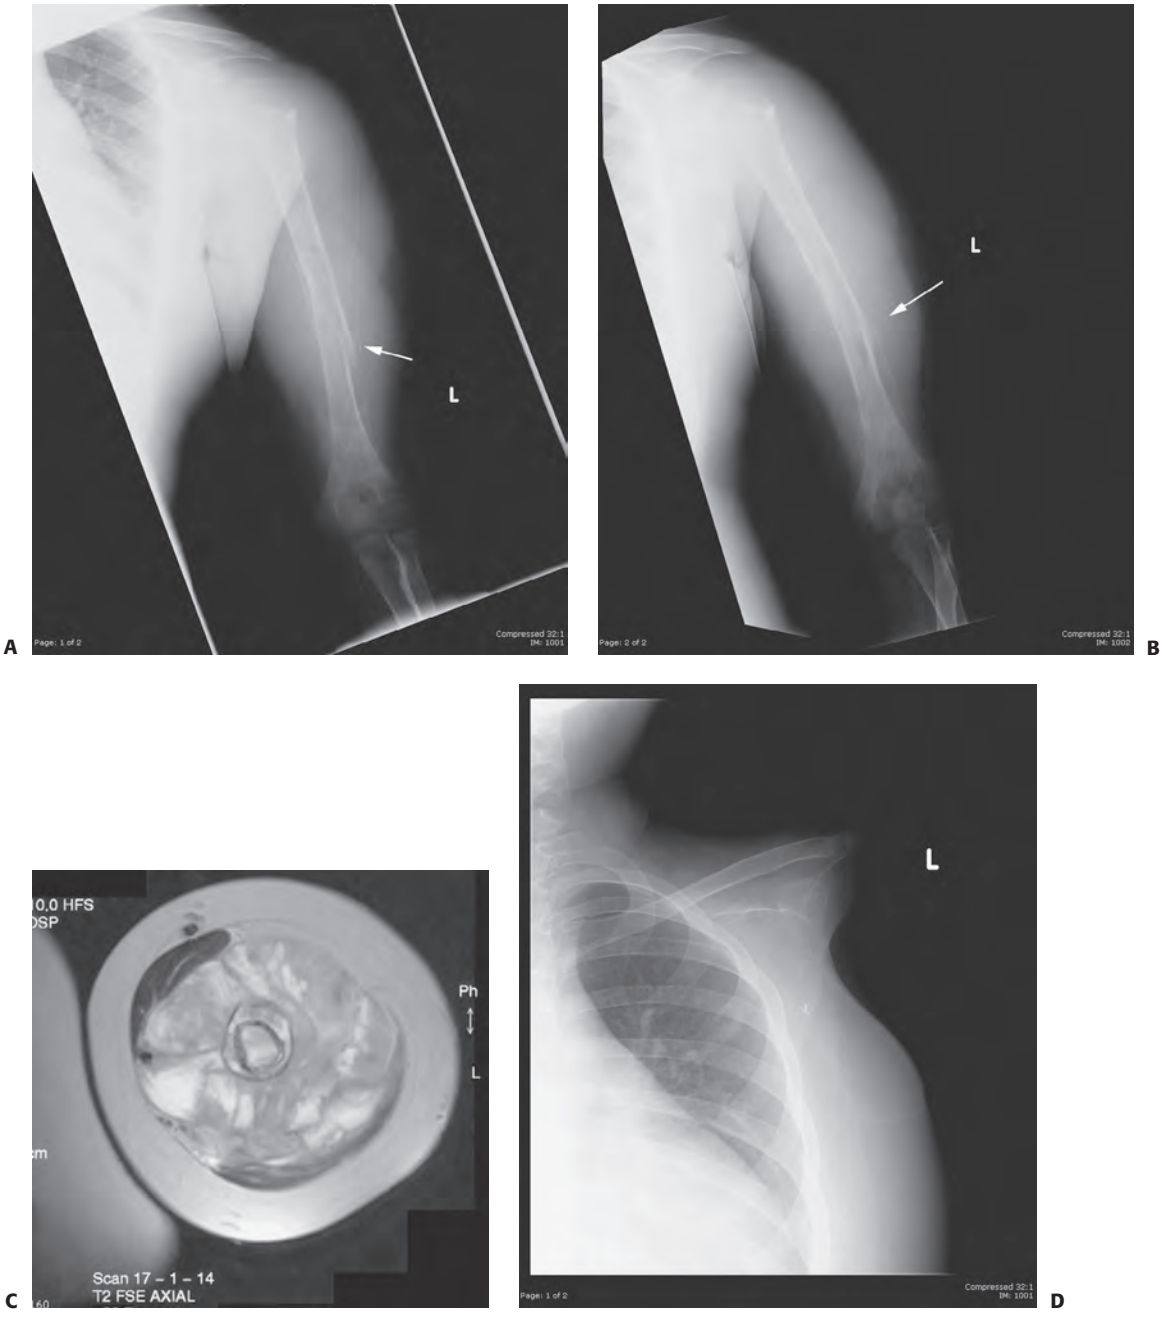

FIGURE 8-18 A 13-year-old boy presented with several months history of right arm pain and recent increase in pain following minor trauma. Anteroposterior **(A)** and lateral **(B)** radiographs show a minimally displaced midshaft humeral pathologic fracture (*arrow*) through a poorly defined, permeative, aggressive-looking diaphyseal lesion. **C:** T2-weighted axial MRI shows a huge soft tissue mass associated with the bone lesion and involvement of the neurovascular bundle. The patient was diagnosed with Ewing sarcoma, received neoadjuvant chemotherapy, and had a shoulder disarticulation **(D),** followed by postoperative chemotherapy. (Figures reproduced with permission from The Childrens Orthopaedic Center, Los Angeles, CA.)

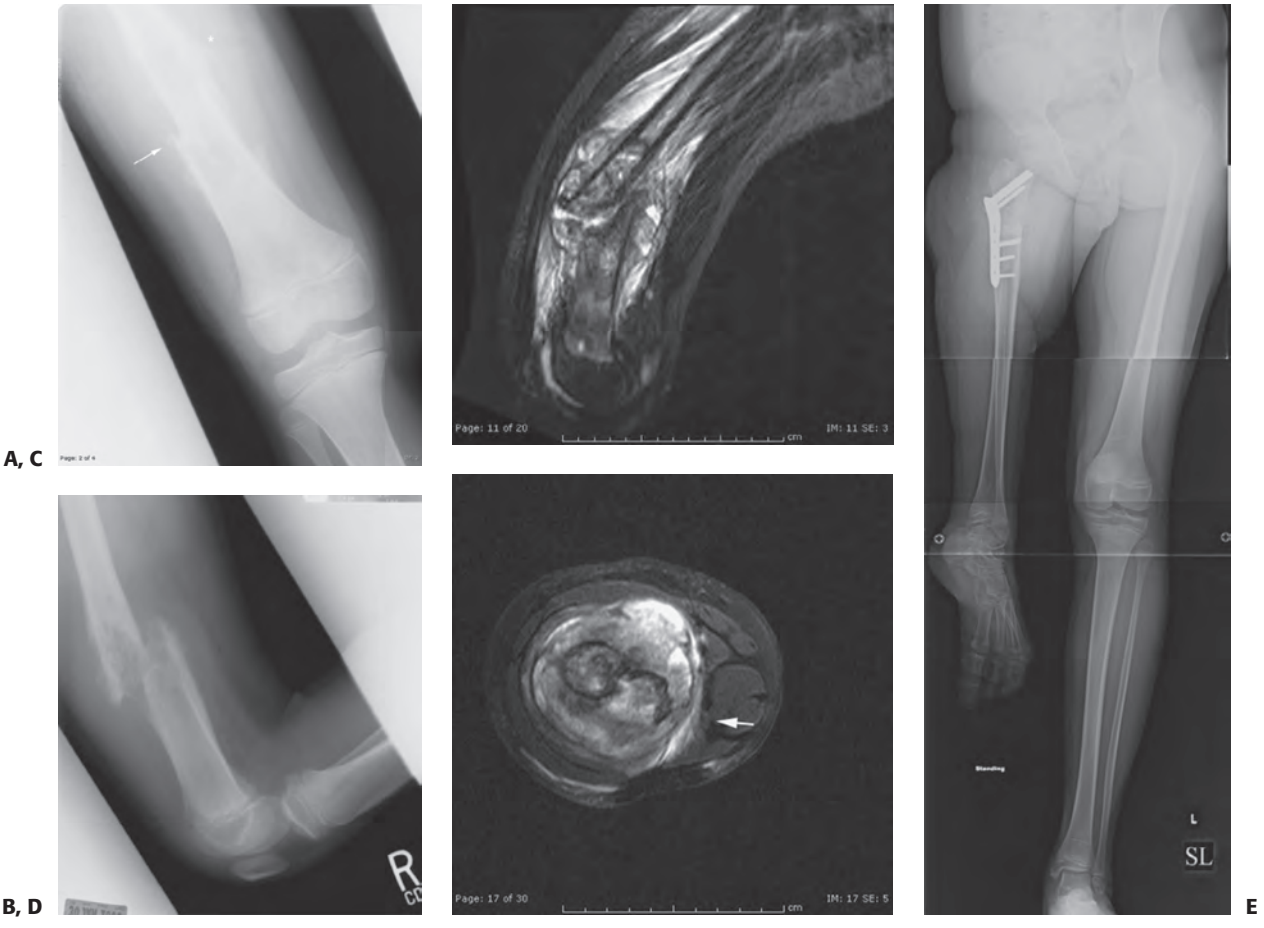

FIGURE 8-19 An 8-year-old girl sustained a pathologic fracture of the femur after falling off her bicycle. She denied symptoms previous to this injury. The radiographs **(A, B)** showed a grossly displaced fracture through a poorly defined, mixed lesion in the midshaft of the femur (*arrow*); there is disorganized periosteal reaction with sunburst sign. T2-weighted coronal **(C),** and axial **(D)** MRI showed extensive soft tissue mass; the neurovascular bundle (*arrow*) does not seem do be involved by the tumor mass. The patient underwent biopsy that confirmed osteogenic sarcoma and fracture stabilization with an external fixator at a referring institute. Note that the external fixator pins were inappropriately placed too far from the tumor and fracture site **(E)** postoperative appearance following Van Ness rotationplasty. The patient is continuously free of disease, 5 years after surgery.

the torsional strength of the bone following cortical drilling. To prevent a pathologic fracture, an oval hole with smooth edges should be used, preferably in areas of less stress for weight-bearing bones. Sometimes, the biopsy hole can be filled with bone cement or other grafting material. Because most bone sarcomas are associated to a large soft-tissue mass that can be sampled, drilling of the bone may be avoided.

One of the major advances in the care of children with extremity sarcoma has been the development of limb-sparing surgical techniques for local control of the tumor. Pathologic fracture has previously been cited as a contraindication to limb salvage because of concerns about tumor dissemination by fracture hematoma, and inability in obtaining free margins following resection. Several studies, however, have shown that pathologic fractures eventually heal during neoadjuvant chemotherapy and may not preclude limb salvage, or affect survival rates (Fig. 8-19).[89,278] Abudu et al.[1] reviewed the surgical treatment and outcome of pathologic fractures in 40 patients with localized osteosarcoma and found that limb-sparing surgery with adequate margins could be achieved in many patients but that there was a 19% recurrence rate, without compromising overall survival. Scully et al.[241] reviewed the surgical treatment of 18 patients with osteosarcoma and pathologic fractures. Of the 10 patients who had limb-sparing surgery, three had local recurrences and six had distant recurrences. Although the distant recurrence rate for patients undergoing amputation was no different from the rate for those undergoing limb salvage, the difference in local tumor control approached statistical significance. All patients who developed local recurrence died. The authors stated that surgical treatment should be individualized. Bacci et al.[21] compared the disease-free survival and overall survival of 46 patients with non-metastatic osteogenic sarcoma of the extremity and pathologic

F **G**

fracture to a cohort of 689 patients without pathologic fracture and found no significant difference. Limb-sparing surgery was possible and appropriate in carefully selected patients as long as wide margins could be safely achieved.

Pathologic fracture after limb-sparing surgery is another major complication, occurring most commonly after allograft reconstruction but also after limb salvage with endoprosthetic reconstruction.[30,272] Berrey et al.[30] reviewed 43 patients with fractures through a massive allograft used for limb reconstruction after resection of tumors. Four fractures healed with immobilization alone, and the remainder of patients attained satisfactory results with open reduction and grafting, replacement of the internal fixation device, or total joint replacement. San-Julian and Canadell[238] reported on 12 patients with 14 fractures (10.2% of 137 patients with allograft for limb-sparing surgery in their series). They recommended intramedullary fixation whenever possible to reduce the incidence of allograft fracture.

Pathologic fractures can also occur in children with metastatic disease but are less common than in adults. Furthermore, most are microfractures and can be successfully managed conservatively.

Author's Preferred Method

For all suspicious lesions, careful staging and biopsy are the appropriate initial approach. Experience in the management of children with musculoskeletal sarcomas, and access to special diagnostic modalities, such as immunohistochemistry and cytogenetics, will decrease the chances of mismanagement and misdiagnosis. The decision for or against limb-sparing surgery in patients with pathologic fracture associated with a bone sarcoma should be individualized based on factors such as the fracture displacement, fracture stability, histologic and radiographic response to chemotherapy, and, most important, the ability to achieve wide margins for local tumor control. Pathologic fractures that occur after reconstruction through allograft or endoprosthetic reconstruction often can be successfully treated with bone grafting or exchange of allograft or endoprosthesis.

Fibrous Dysplasia

FD is a benign bone abnormality characterized by replacement of normal bone and marrow by fibrous–osseous tissue (woven bone formed by metaplasia with poorly oriented bone trabeculae) resulting in decrease of strength, deformity, and pathologic fracture. The disease may involve a single bone (monostotic FD) or several (poliostotic FD). When bone disease is associated with café-au-lait skin hyperpigmentation and endocrine dysfunction, it is referred as McCune–Albright syndrome.[209]

The diagnosis of FD is usually made between 5 and 15 years of age. Often, the lesions are asymptomatic and a pathologic fracture may be the presenting symptom. Fractures of long bones are generally minimally displaced or incomplete, many being microfractures and presenting with pain and swelling.[171] The bones most commonly affected are the femur, tibia, humerus, radius, facial bones, pelvis, ribs, and phalanges. The sites of fracture in decreasing order of frequency are the proximal femur, tibia, ribs, and bones of the face. The age of first fracture, number of fractures, and fracture rate are related to the severity of the metabolic derangement. The endocrinopathies are often associated with phosphaturia that causes a rickets-type effect on the normal skeleton and is related to increased incidence of fractures.[171] Although the fractures heal rapidly, endosteal callus is poorly formed and periosteal callus is normal. With mild deformity, the cortex thickens on the concave side of the long bone. Nonunion is rare in monostotic FD, but can occur in polyostotic disease. Spine involvement occurs with polyostotic FD, and limb-length discrepancy is common.[121] In one series of 37 patients with polyostotic FD, nearly 85% had at least one fracture and 40% had an average of three fractures.[121]

On plain radiographs, FD is seen as well-defined, mostly lytic and central lesion, located in the metaphysis or diaphysis of long bones. The borders are commonly sclerotic and

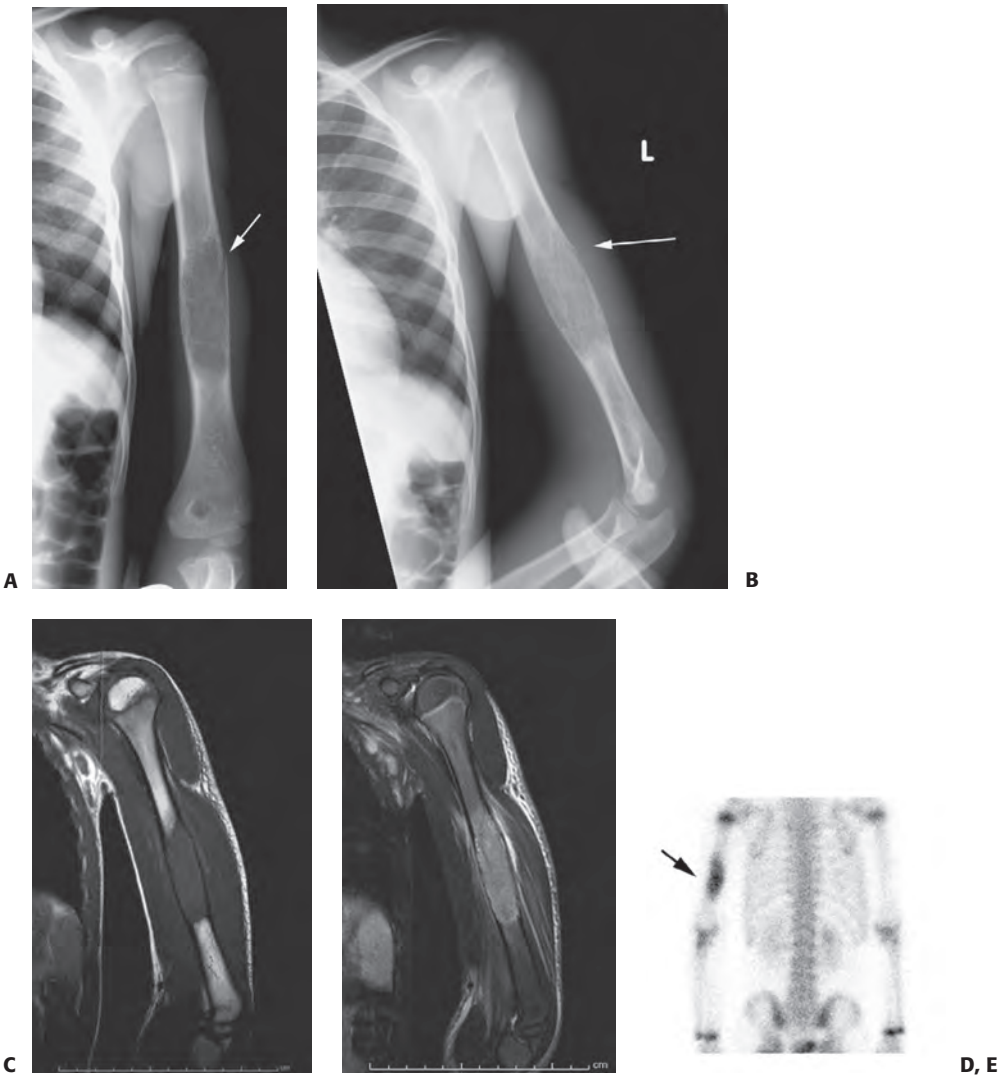

FIGURE 8-20 A 6-year-old girl presented with right arm acute pain after hitting the elbow in the bathtub. Radiographs of the humerus **(A, B)** show a nondisplaced pathologic fracture through a humeral diaphyseal lesion (*arrow*). The lesion is well defined, mostly lytic but with definite matrix, cortical thinning, no periosteal reaction. MRI T1-**(C)** and T2-weighted **(D)** coronal images demonstrate absence of soft tissue mass or other aggressiveness signs. Bone scan shows increased activity at the lesion and fracture site (*arrow*) **E:** The patient underwent open incisional biopsy that confirmed the diagnostic of fibrous dysplasia. (Figures reproduced with permission from The Childrens Orthopaedic Center, Los Angeles, CA.)

the metaplastic woven bone comprising the lesion creates the classic "ground-glass" appearance (Fig. 8-20). Bowing and/or angular deformity of tibia and femur are often seen. In distinguishing polyostotic from monostotic FD, skeletal surveys and sometimes technetium bone scans are recommended.

Conservative treatment with immobilization is indicated for most fractures that occur in conjunction with monostotic FD. Surgery is indicated for fractures through severely deformed long bones (especially in the lower extremities), and those through large cystic areas. Fractures in polyostotic disease often require more aggressive treatment.

Fractures of the femur can be treated conservatively in young patients, but after adolescence, recurrent deformity after surgery is less common, and curettage and grafting with internal fixation should be considered, especially for large lesions through deformed bones.[121] Stephenson et al.[258] found that in patients younger than 18 years of age, closed treatment or curettage and bone grafting alone of lower extremity fractures gave unsatisfactory results, but internal fixation produced more satisfactory outcomes.

Proximal femoral pathologic fractures are especially troublesome because of the propensity for malunion with coxa vara resembling a shepherd's crook.[71] For fractures through small lesions, either cast immobilization or curettage with grafting can be used[100]; for larger lesions, internal fixation is necessary. For severe shepherd's crook deformity, medial displacement valgus

osteotomies with internal fixation may be needed to restore the biomechanical stability of the hip. Both painful lesions without fracture and impending pathologic fractures can be treated with internal fixation. Spine fractures are rare but can be treated with bed rest followed by immobilization with an orthosis.[114]

The main challenge in bone grafting FD is the potential for resorption and transformation into FD. Autogenous cancellous graft has the higher likelihood to become FD, and cortical allograft is the least likely to be transformed.[71] The use of bisphosphonates, primarily pamidronate, may offer hope for a medical treatment for patients with severe FD. Pamidronate is a second-generation bisphosphonate that has had documented success in selected patients with the disease. It is a potent inhibitor of bone resorption and has a lasting effect on bone turnover. The major effect is decreased bone pain. Improved bone density with pamidronate therapy has also been demonstrated.[209]

Author's Preferred Method of Treatment

Conservative treatment with immobilization is indicated for most fractures in children with monostotic FD, especially in the upper extremities. Because fractures in patients with polyostotic FD usually occur through very abnormal bone and can result in marked deformity, internal fixation is often needed.

Curettage and grafting are indicated for fractures through severely deformed long bones and those through large cystic areas, with appropriate internal fixation for the location and age. Bone graft is often reabsorbed and transformed into FD, allograft has a lower likelihood to be reabsorbed than autograft. Recently, the use of coral as bone substitute has been shown to be an alternative.[71]

For proximal femur pathologic fractures one must be vigilant and ready to intervene at any sign of varus deformity. Femoral neck fractures can be stabilized in situ with a cannulated screw or compression screw and side plate. Varus deformity is best treated with valgus osteotomy of the subtrochanteric region and internal fixation early in the course of the disease to restore the normal neck shaft angle and mechanical axis. Intramedullary load-sharing fixation is preferred for juvenile patients with femoral shaft fractures, total bone fixation is the ideal and second-generation intramedullary nails should be used when possible.

Osteofibrous Dysplasia

Osteofibrous dysplasia (OD) is a rare developmental tumor-like fibro-osseous condition. Most patients present before the age of 5 years, ranging from 0 to 15 years of age.[47,216] Clinically, there is usually a painless enlargement of the tibia with slight to moderate anterior or anterolateral bowing. The disease process is almost always confined to one tibia, but the ipsilateral fibula can also be involved. Although distal and proximal lesions can occur, midshaft involvement is the most frequent. Pathologic fractures occur in approximately one-third of patients; but are usually incomplete (e.g., stress fractures, microfractures) or minimally displaced and heal well with conservative treatment.[47] Pseudarthrosis is rare but sometimes delayed union may be a problem.

OD presents as a well-defined, eccentric, intracortical, lytic lesion usually located in the middle third of the tibia, extending proximally or distally.[216] The cortex overlying the lesion is expanded and thinned, and in the medullary canal, a dense band of sclerosis borders the lesion with narrowing of the medullary canal. Single areas of radiolucency may be present and have a ground-glass appearance, but often there are several areas of involvement with a bubble-like appearance (Fig. 8-21). Intralesional curettage and grafting lead to local recurrence in over 60% of the cases.[47] Wide extraperiosteal resection can be performed for aggressive lesions and present with lower rate of recurrence.[168] Some authors[6,155] recommend bracing until skeletal maturity.

Pathologic fractures heal conservatively. In cases of recurrent fracture or rapid progression, wide extraperiosteal resection and grafting may be indicated.[47] Open reduction with bone grafting and internal fixation may be recommended for fractures with angular deformity. Bracing is recommended to prevent fractures and angular deformity.

Neurofibromatosis

Neurofibromatosis (NF), also known as von Recklinghausen disease (NF type-1), is an autosomal dominant condition with variable penetrance that occurs in one in 2,500 to 3,000 live births.[63] It affects neural tissue, vascular structures, skin, and the skeleton. The clinical diagnosis is based on the presence of at least two of these signs: Multiple café-au-lait spots (six or more >5 mm); family history of NF (first degree relative); biopsy-proven neurofibroma (two or more neurofibromas or one plexiform neurofibroma); skeletal deformity (e.g., pseudarthrosis of the tibia, hemihypertrophy, or a short, angular scoliosis); Lisch nodules (two or more); axillary or inguinal freckling.[63]

Approximately 20% of normal children have one or two café-au-lait spots with a diameter of more than 0.5 cm, therefore five or more café-au-lait spots are needed to suggest the diagnosis of NF.[63] Café-au-lait spots are not usually seen until 5 or 6 years of age.[63] The presence of a biopsy-proven neurofibroma is a valuable criterion for diagnosis, but tends not to be clinically apparent until the child is 12 years or older.[63] Approximately 5% of NF patients develop pseudarthrosis of long bones; the tibia is the most commonly affected. On the other hand, 55% of the cases of congenital pseudarthroses of the tibia are thought to be associated with NF.[63] The appearance of pseudarthroses and their resistance to treatment may be associated to a deficiency of bone formation secondary to mesodermal dysplasia. Anterior bowing of the leg develops at an average age of 8 months and fracture and pseudarthrosis at an average of 1 year. Therefore, the term congenital pseudarthrosis is misleading because the majority of patients do not have pseudarthrosis at birth.[199] Pseudarthroses may also occur in the radius, ulna, femur, clavicle, and humerus.[27,44,199]

Children with NF-type 1 have a general tendency toward osteopenia and osteoporosis, suggesting an abnormal underlying bone phenotype. This may be a reason as why there is a high incidence of pseudarthrosis, nonunion, and poor bone healing associated with NF.[82]

FIGURE 8-21 Anterior–posterior and lateral radiographs **(A** and **B)** of a 10 year-old female who sustained a ground level fall at school and developed acute pain in the midshaft tibia. Note the eccentric, well-defined nature of this mostly lytic lesion in the diaphysis. There is an incomplete transverse fracture and the posterior cortex is spared. The lesion was consistent with osteofibrous dysplasia and the child did well with conservative treatment as seen in the images 3 months and 12 months after the pathologic fracture **(C** and **D).** (Figures reproduced with permission from The Children's Orthopaedic Center, Los Angeles, CA.)

The radiographic presentation of tibial involvement is with anterolateral bowing and loss of the medullary canal, or cystic lesion, followed by fracture.[44,63,82] Patients with established pseudarthroses present with narrowing or obliteration of the medullary, sclerosis, and anterolateral angulation. Pseudarthrosis of the fibula may also be present and leads to valgus deformity of the ankle.

Tibia bowing in an infant or child tends to eventually fracture; however, simple osteotomy to correct angular deformity accelerates the progression to pseudarthrosis and is usually not indicated as a stand-alone treatment. Bracing may be helpful in preventing fracture and angular deformity, but is ineffective in the treatment of an established pseudarthrosis. Once pathologic fracture occurs, casting will likely fail but may

be attempted. Surgical treatment of pseudarthrosis includes excision of the hypotrophic bone ends followed by grafting and internal and/or external fixation. Grafting alternatives include auto (e.g., vascularized fibula, iliac crest) or allografting and periosteal grafting. Fixation is done through intramedullary nailing, or external fixation for compression of the pseudarthrosis and concurrent callotastic lengthening. All of these methods may be complicated by further pathologic fracture and nonunion. The rate of success ranges from 7% to 90%. A prophylactic bypass grafting of the prepseudarthrotic tibia in NF has been performed with some success (Fig. 8-22).[261] More recently, authors have been reporting on the use of recombinant human bone morphogenetic protein with promising results.[92,166]

FIGURE 8-22 **A:** A 2-year-old boy with neurofibromatosis presented with anterolateral bowing, sclerosis, and partial obliteration of the medullary canal of the tibia without fracture. **B:** A modified McFarland technique for prophylactic bypass grafting was performed as shown. **C:** Immediate postsurgical radiographs of the tibia after prophylactic bypass grafting. **D:** Three years later, radiographs show continued growth of the tibia without fracture but some absorption of the allograft and relative loss of structural support by the allograft related to continued growth. (From Dormans JP. Modified sequential McFarland bypass procedure for prepseudarthrosis of the tibia. *J Orthop Tech.* 1995;3:176–180, with permission.)

Amputation should be considered and discussed with the family early when previous operative interventions have been unsuccessful. Amputation is usually Syme's, with prosthetic fitting around the pseudarthrosis. In a gait analysis study, Karol et al.[144] compared 12 patients with previously operated and healed congenital pseudarthroses of the tibia with four children with amputations for final treatment of congenital pseudarthroses of the tibia. They found marked disturbance of gait and muscle strength in patients with healed congenital pseudarthroses of the tibia. They concluded that patients with early onset of disease, early surgery, and trans-ankle fixation had more inefficient gaits than amputees.

Patients with forearm pseudarthroses can be pain free and function may be satisfactory with observation or splinting. However, persistence of an ulnar pseudarthrosis in a growing child may lead to bowing of the radius and posterior lateral subluxation or dislocation of the radial head. Union after conventional bone grafting and fixation has been reported in only a small number of patients with congenital pseudarthrosis of the forearm.[27] Many of these patients require multiple conventional bone grafting procedures and often years of immobilization. The results of treatment of congenital pseudarthrosis of the forearm in NF by free vascularized fibular grafts are encouraging.[187] Other surgical options include excision of the ulnar pseudarthrosis to avoid a later tethering effect on the growing radius and fusion of the distal radius and ulnar joint.[7]

Extreme care should be taken in the surgical treatment of children with NF, as complications are common. Hypertension is present in up to 16% of children with NF.[270] The periosteum is less adherent to the bone, and extensive subperiosteal hemorrhage may result from a trauma, an osteotomy, or other surgical procedure.[279]

Author's Preferred Method of Treatment

The treatment of congenital pseudarthrosis of the tibia remains controversial. When a child presents with prepseudarthrosis (angulation without fracture), either bypass grafting with fibular allograft or bracing are reasonable options. Once pseudarthrosis has developed, our preference is inserting an intramedullary rod and bone grafting of both the tibia and fibula when possible (Fig. 8-23). If these procedures fail, free vascularized fibula transfer or resection and bone transport with circular frame techniques can be considered. Amputation and prosthetic fitting should be considered early in patients with failure of the techniques mentioned above and severe shortening and a stiff ankle and foot. Conservative options, such as bracing or observation, for upper extremity pseudarthroses may be justified in a patient with a nonprogressive deformity and a satisfactory functional use of the extremity. Conventional bone grafting and fixation procedures for treatment of pseudarthrosis of the upper extremity have very limited success, and other approaches should be considered.

Congenital Insensitivity to Pain

Congenital insensitivity to pain is a rare hereditary sensory neuropathy disorder characterized by the absence of normal subjective and objective responses to noxious stimuli in patients with intact central and peripheral nervous systems. The cause is unknown, but sporadic reports have appeared in the orthopedic literature.[23,117,161]

The orthopedic manifestations of congenital insensitivity to pain include recurrent fractures, osteomyelitis, and neuropathic joints. Although the lower extremities are most commonly affected, the spine may also be involved with gross and unstable spondylolisthesis. Limb-length discrepancy may occur from chronic physeal damage. Lack of pain perception is associated with the development of Charcot joints, which may lead to later neuropathic arthropathy, especially around the knees and ankles. Although fracture healing usually occurs, the arthropathy is progressive, eventually resulting in gross deformity and instability. In addition to the absence of deep pain, the patients have impaired temperature sensation.

The differential diagnosis includes a spectrum of closely related sensory disorders including congenital sensory neuropathy, hereditary sensory radicular neuropathy, familial sensory neuropathy with anhidrosis, and familial dysautonomia (Riley–Day syndrome). Acquired conditions with pain insensitivity include syringomyelia, diabetes mellitus, tabes dorsalis, alcoholism, and leprosy. Loss of protective sensation promotes self-mutilation, burns, bruises, and fractures. The disease often comes to light when the child develops teeth and then bites his or her tongue, lips, and fingers.

Management should aim at education and prevention of injury. Prevention of joint disease is the best early option.[23,117] Joint injury should be recognized and treated early to prevent progression to gross arthropathy. Early diagnosis and treatment of fractures is important, usually by conservative manners.[117,161] In a severely unstable, degenerated joint, arthrodesis may eventually be appropriate; however, poor healing, nonunion, and pseudarthrosis are common in neuropathic joints (Fig. 8-24). Infection rate is also increased, and it is important to make the differentiation between fracture and infection.[23] The condition appears to improve with time with the gradual recovery of pain sensation.

Diseases of the Bone Marrow

Gaucher Disease

Gaucher disease is a hereditary disorder of lipid metabolism. It is the most common lysosomal storage disease and is caused by deficient production and activity of the lysosomal enzyme beta-glucosidase (glucocerebrosidase), resulting in progressive accumulation of glucosylceramide (glucocerebroside) in macrophages of the reticuloendothelial system in the spleen, liver, and bone marrow. The most common sphingolipidosis, is inherited as an autosomal recessive trait,[146] with most cases noted in Ashkenazic Jews of eastern European origin. There are three types of Gaucher disease: Type I represents more than 90% of all cases and is the most common type seen by orthopedic surgeons—it presents as a chronic nonneuropathic

FIGURE 8-23 A 19-month-old girl presented with right leg bowing and recent inability to bear weight on that extremity. The patient has neurofibromatosis type 1 with associated café-au-lait spots **(A).** Anteroposterior **(B)** and lateral **(C)** radiographs of the tibia and fibula show pseudarthrosis of the tibia diaphysis associated with intramedullary obliteration and bone thinning at the pseudarthrosis level. The fibula presents anterior-lateral deformity and partial obliteration of the medullary canal without fracture. Postoperative images **(D, E)** following excision of the pseudarthrosis, fibular osteotomy, iliac bone graft and periosteum grafting, and fixation with a William rod. (Figures reproduced with permission from The Childrens Orthopaedic Center, Los Angeles, CA.)

FIGURE 8-24 This 6-year-old child with anhidrosis, congenital insensitivity to pain, and attention deficit disorder presented with a history of swollen ankles and knees. Anteroposterior **(A)** and lateral **(B)** radiographs show Charcot changes in the subtalar joint with calcaneal and distal fibular fractures. Anteroposterior **(C)** and lateral **(D)** radiographs of the right knee show large, loose osteochondral fragments, medial subluxation of the femur on the tibia, and extensive periosteal new bone formation in the distal femur. Soft tissue shadows are consistent with her huge knee hemarthrosis. More than 100 mL of sterile serosan guineous fluid was aspirated from the knee at her initial visit. The effusion quickly returned in the days following the aspiration. Because management with casts at another hospital resulted in significant skin breakdown, we stabilized the knees with removable hinged braces. The effusions improved but did not resolve.

disease with visceral (spleen and liver) and osseous involvement, also known as the adult form, although patients present during childhood[146]; Type II is an acute, neuropathic disease with central nervous system involvement and early infantile death; and Type III is a subacute nonneuropathic type with chronic central nervous system involvement. Types II and III are both characterized as either infantile or juvenile, and are notable for severe progressive neurologic disease, usually being fatal.

Osseous lesions are a result of marrow accumulation and present with Erlenmeyer flask appearance of the metaphyseal bone, osteonecrosis (ON) (particularly of the femoral head), and pathologic fractures, especially of the spine and femoral neck. Bone lesions are most common in the femur, but they also occur in the pelvis, vertebra, humerus, and other locations. Infiltration of bone by Gaucher cells leads to vessel thrombosis, compromising the medullary vascular supply and leading to localized ON of the long bones. ON of the femoral head occurs in most patients in whom the disease is diagnosed in childhood.

Pathologic fractures, especially of the femoral neck or shaft after biopsy, and of the spine, are usually best managed conservatively. Katz et al.[146] reported 23 pathologic fractures in nine children with Gaucher disease; seven had multiple fractures. In decreasing order of frequency, the site of involvement included the distal femur, basilar neck of the femur, spine, and proximal tibia. Fractures of the long bones were transverse and usually in the metaphysis. Fractures of the spine were either wedge-shaped or centrally depressed at the end plate. The factors predisposing these children to fracture included significant medullary space infiltration, cortical bone erosion, ON, and associated disuse osteoporosis.[146]

In another report of 53 patients with Gaucher disease aged 9 to 18 years,[148] 11 children had vertebral fractures, usually at two or three sites in each patient, with either anterior wedging, central vertebral collapse, or total rectangular collapse. Most patients had relief of their pain after 1 to 4 months of conservative treatment; two required decompression laminectomies, and one had a posterior lateral fusion to stabilize the spine.

Katz et al.[147] found that fractures of the upper extremities in Gaucher disease were prone to occur in areas of prior crisis. Although external callus formed in 6 to 8 weeks in most patients, complete healing with internal callus took almost 2 years in some. Both delayed union and nonunion[233] have been reported in older patients with Gaucher disease.

Pathologic femoral neck fractures with minimal associated trauma in children with Gaucher disease often heal with a varus malunion and minimal subsequent remodeling; ON of the femoral head also can be associated with femoral neck fractures.[112] Goldman and Jacobs[112] described the presence of a mixed density of the femoral neck on radiograph with narrowing of the medial cortex as a risk factor for fracture.

Author's Preferred Method of Treatment

Conservative immobilization with nonweight bearing is suggested for long bone fractures when appropriate. Stable fractures of the femoral neck should be treated by immobilization with frequent follow-up radiographs; internal fixation should be used in unstable femoral neck fractures. Preoperative planning is important, and the anesthesiologist must recognize that patients with Gaucher disease may be prone to upper airway obstruction because of infiltration of the upper airway with glycolipids and abnormal clotting function, even when clotting tests are normal.[264]

Sickle Cell Disease

The term sickle cell disease (SCD) characterizes conditions caused by the presence of sickle cell hemoglobin (HbS). The most common type of SCD, HbS-S, is a homozygous recessive condition in which individuals inherit the HbS globin gene from each parent. SCD has systemic effects particularly on splenic function and on the central nervous, renal, hepatic, and musculoskeletal systems. SCD affects approximately one in 400 African Americans. Sickle cell trait affects 8% to 10% of the African American population and other groups less frequently. With sickle cell trait, each individual has inherited a beta-S globin gene and a beta-A globin gene. Clinical manifestations of sickle cell trait usually are not apparent. The presence of this abnormal hemoglobin in red blood cells causes them to be mechanically fragile, and when they are deoxygenated, the cells assume a sickle shape, which makes them prone to clumping with blockage of the small vessels of the spleen, kidneys, and bones. Chronic hemolytic anemia is present in most severely affected patients, and marrow hyperplasia is found in both the long bones and the short tubular bones. The prevalence of osteopenia and osteoporosis in young adults with SCD is extremely high and that can be related or predisposed to pathologic fractures.[196] These disorders are diagnosed by hemoglobin electrophoresis.

Pathologic fractures of the long bones in SCD occur frequently[28,85] and may be the first symptom of the disorder. Children with SCD often have undiagnosed osteopenia or osteoporosis (Fig. 8-25).[196] Pathologic fractures are often seen in association with osteomyelitis.[85] In a series of 81 patients with 198 long bone infarcts with occasional concurrent osteomyelitis, Bohrer[36] found a 25% incidence of fractures associated to femoral lesions, and 20% with humeral lesions. Ebong[85] reported pathologic fractures in 20% of patients with SCD and osteomyelitis. The most common site was the femur. The fractures are transverse and commonly located in the shaft of the long bone, and although minimal trauma is needed to cause them, they often have significant displacement.[36] The exact mechanism for pathologic fracture in these patients is unclear; and although it is often associated with bone infarct, the fracture is seldom through the infracted area. Marrow hyperplasia may be a major contributing factor; not only does the hypercellular bone marrow expand the medullary canal with thinning of both trabecular and cortical bone, but it also extends into widened Haversian and Volkmann canals. This process may weaken the bone leading to fractures. Finally, children with SCD have significant deficits in the whole body bone mineral content that persist despite adjustment for poor growth and decreased lean mass; therefore, these children maybe at increased risk for fragility fractures and suboptimal peak bone mass.[45] The healing process seems unaffected, and union usually occurs at the usual rate.

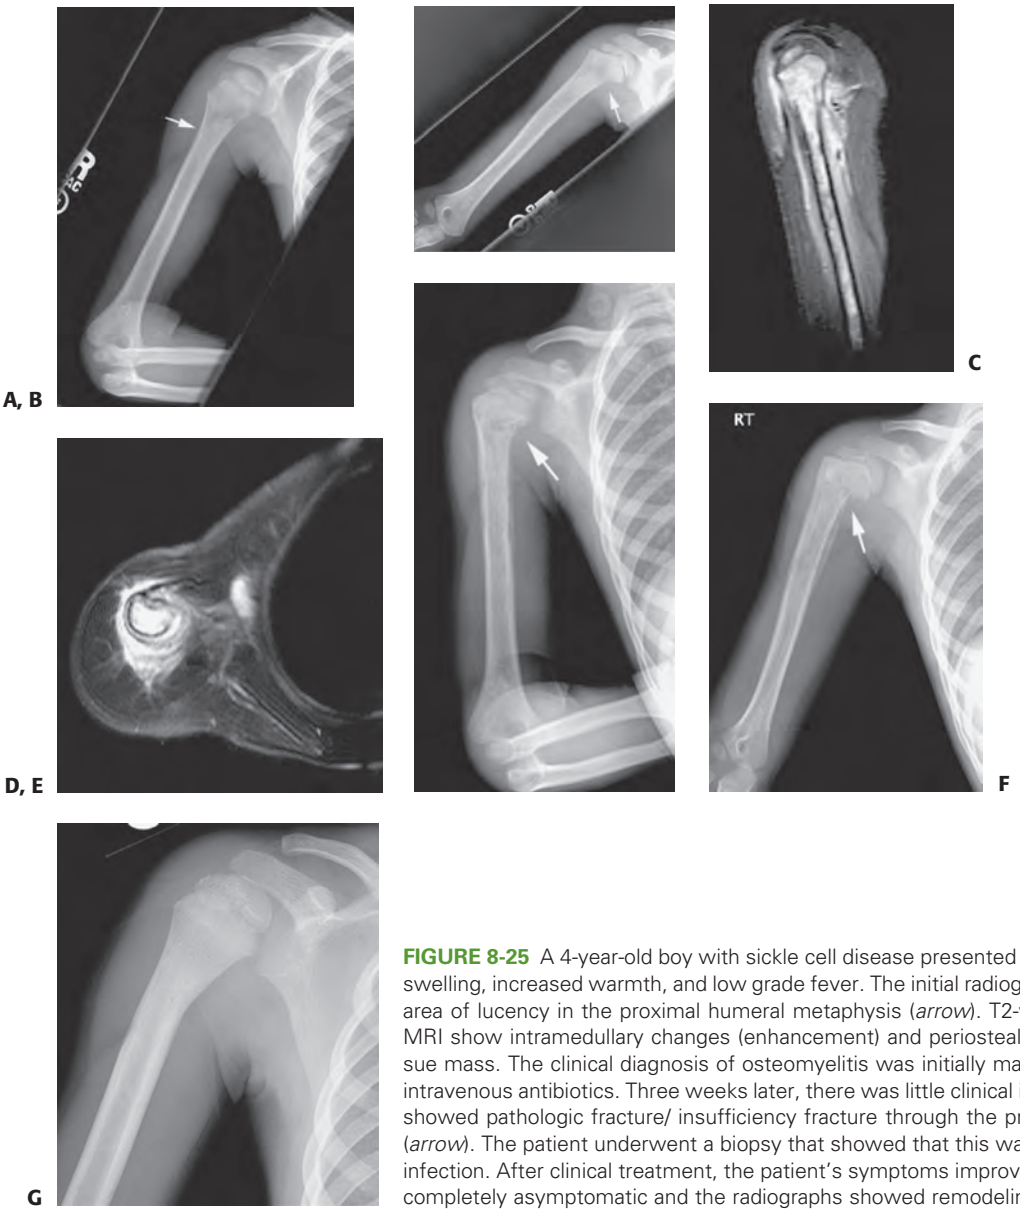

FIGURE 8-25 A 4-year-old boy with sickle cell disease presented with acute onset of right arm pain, swelling, increased warmth, and low grade fever. The initial radiographs **(A, B)** show a poorly defined area of lucency in the proximal humeral metaphysis (*arrow*). T2-weighted sagittal **(C)** and axial **(D)** MRI show intramedullary changes (enhancement) and periosteal reaction/abscess with no soft tissue mass. The clinical diagnosis of osteomyelitis was initially made and the patient was started on intravenous antibiotics. Three weeks later, there was little clinical improvement and new radiographs showed pathologic fracture/ insufficiency fracture through the proximal humeral metaphysis **(E, F)** (*arrow*). The patient underwent a biopsy that showed that this was an infarct with no superimposed infection. After clinical treatment, the patient's symptoms improved. At 6-months follow-up, he was completely asymptomatic and the radiographs showed remodeling and continued growth **(G).**

Author's Preferred Method of Treatment

Pathologic fractures in patients with SCD usually heal with conservative treatment. Furthermore, operative management may be hazardous. Extreme care must be taken to oxygenate the patient's tissues adequately during the procedure, and ideally, elective procedures should be preceded by transfusion regimen to raise hemoglobin levels to 10 g/dL and prevent perioperative complications. Intravenous hydration is very important, with one and a half to two times the daily fluid requirements needed in addition to routine replacement of fluid losses. The use of a tourniquet in surgery for patients with SCD is somewhat controversial.

ON of the femoral head is an especially difficult problem in patients with SCD. Treatment options range from conservative measures such as physical therapy and rest, to surgery such as core decompression, although some have shown no difference in the final outcome.[204] Patients with total head involvement may require femoral or pelvic osteotomies, and total joint replacement is occasionally needed in young adults.

Leukemia

Leukemia accounts for over 30% of cases of childhood cancer. Acute lymphocytic leukemia is one of the most common malignant diseases in childhood and accounts for 80% of pediatric leukemias. There is an increased occurrence of lymphoid leukemias in patients with Down syndrome, immunodeficiencies, and ataxic telangiectasia. The peak incidence occurs at 4 years of age.

Leukemic involvement of bones and joints is common. Skeletal lesions occur more frequently in leukemic children than in adults because leukemic cells can quickly replace the smaller marrow reserves in children. Approximately 50% to

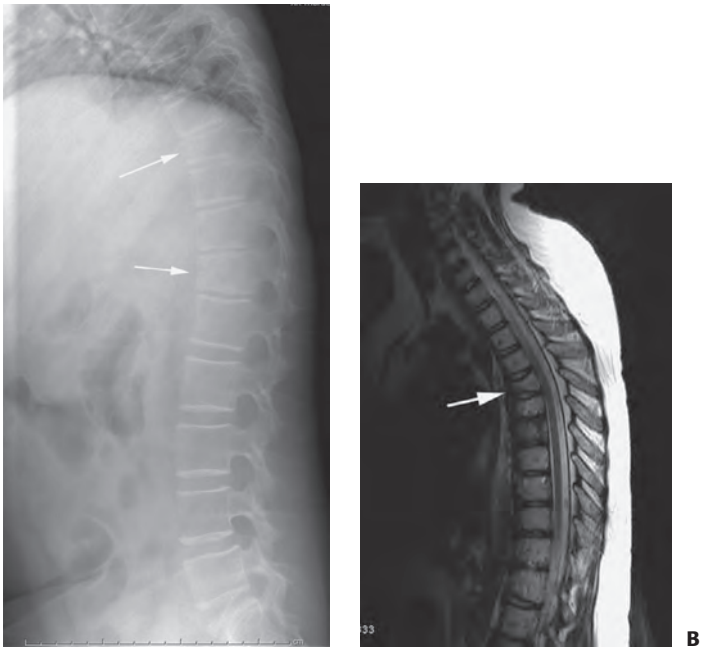

FIGURE 8-26 This 8-year-old girl presented with back pain, fever, malaise, and weight loss. Lateral radiographs **(A)** of the spine showed diffuse osteopenia and compression/insufficiency fractures of the vertebral body (*arrows*). T1-weighted sagittal MRI **(B)** confirms disease process within the vertebral body (*arrow*) and no soft tissue mass or intraspinal involvement. She was diagnosed with acute lymphoblastic leukemia. (Figures reproduced with permission from The Childrens Orthopaedic Center, Los Angeles, CA.)

75% of children with acute leukemia develop radiographic skeletal manifestations during the course of their disease; however, there are no pathognomonic osseous manifestations.[232,250] Pathologic fractures can be seen in up to a third of the patients.[154,232,250] Diffuse osteopenia is the most frequent radiographic finding (Fig. 8-26).[250] Nonspecific juxtaepiphyseal lucent lines are often seen and are a result of generalized metabolic dysfunction. Sclerotic bands of bone trabeculae are more typical in older children. Lucencies and periostitis may mimic osteomyelitis. A characteristic lesion seen within a month of onset of symptoms is a radiolucent metaphyseal band adjacent to the physis[232,250]; these are usually bilateral and vary from 2 to 15 mm in width. Osteolytic lesions with punctate areas of radiolucency are found in the metaphysis and can either appear moth-eaten or as a confluent radiolucency. Periosteal reaction often is present with osteolytic lesions and is most common in the posterior cortex of the distal femoral metaphysis, the medial neck of the femur, and the diaphysis of the tibia and fibula.[250] Most bone lesions in leukemia improve after treatment and tend to progress with worsening of the disease.

The risk of pathologic fractures usually decreases with treatment. Fracture is most commonly associated with osteoporosis of the spine, resulting in vertebral collapse (compression fracture). The thoracic vertebrae are the most commonly involved. Fractures occasionally occur at other locations and usually after minor trauma.[192,205] A bone scan may aid in identifying clinically silent areas but may not correlate with areas of obvious destruction on radiographs.

Author's Preferred Method of Treatment

Prompt diagnosis and initiation of chemotherapy is the main step in the treatment of pathologic fractures associated to leukemia. Most fractures are stable microfractures and can be treated with conservative immobilization with emphasis on early ambulation to avoid further osteopenia. For vertebral fractures, a back brace or thoracolumbosacral orthosis is often used to alleviate symptoms.

Hemophilia

Hemophilia is a sex-linked recessive disorder of the clotting mechanism that presents most commonly as a functional deficiency of either factor VIII (hemophilia A) or factor IX (hemophilia B). Classic hemophilia, or hemophilia A, has an incidence of 1 per 10,000 live male births in the United States.[4] Christmas disease, or hemophilia B, occurs in 1 per 40,000 live births.

When hemophilia is suspected, screening tests should be performed, including platelet count, bleeding time, prothrombin time, and partial thromboplastin time. Deficiency of factor VIII, the most common form of hemophilia, causes a marked prolongation in the partial thromboplastin time. Specific factor assays can document the type of hemophilia. The severity of the deficiency correlates with the circulating levels of factors VIII and/or IX. The disease is classified as severe when clotting activity is less than 1%, moderate when clotting activity is 1% to 5%, and mild when clotting activity is more than 5% (Table 8-4). Early diagnosis and aggressive management are the keys to lessening complications.

Musculoskeletal involvement includes acute hemarthroses (knee, elbow, and ankle, in decreasing order of frequency), soft tissue and muscle bleeds, acute compartment syndrome, carpal tunnel syndrome, femoral nerve neuropraxia, early degenerative arthritis, and fractures (Table 8-5).

Should a child with hemophilia require operative management, the orthopedist and the hematologist should work closely together. Preoperatively, the patient should be tested for the presence of inhibitor and a test dose of factor replacement should be given to determine the biologic half-life of that factor for that

TABLE 8-4 Severity of Hemophilia Correlated with Plasma Factor Activity Levels

Degree of Hemophilia	Percentage of Factor	Clinical Characteristics
Mild	20–60%	Usually clinically occult, excessive bleeding after major trauma or surgery
Moderate	5–20%	Excessive bleeding during surgery and after minor trauma
Moderately severe	1–5%	Excessive bleeding with mild injury and infrequent spontaneous hemarthrosis
Severe	>1%	Frequent excessive bleeding with trauma and spontaneous bleeding into the soft tissue and joints

particular patient.[4] Elective surgery is usually contraindicated in the presence of inhibitor. Most authors recommend a level of factor activity during surgery ranging from 70% to 100%,[4,221] although others believe that 50% is adequate.[217] Tourniquets are recommended for extremity surgery. The use of routine drains is not advised, but 24 hours of suction drainage is favored by some.[4,221] Factor levels are checked immediately after surgery and then at least daily. Factor VIII is given every 6 hours, and factor IX is given every 8 hours. In the immediate postoperative period, factor levels are maintained at 30% to 40%, and maintained at that level until sutures are removed. During the rehabilitative period, maintenance levels should range from 20% to 50% immediately before sessions of physical therapy.[4,217,221] Intramuscular injections should be avoided, as should aspirin compounds and nonsteroidal anti-inflammatory medications that affect platelet function. Acetaminophen, celecoxib, and codeine are safe oral analgesics.[145] In the past, hemophiliac patients had an increased risk of operative infections and delayed wound healing, but aggressive replacement therapy has minimized those problems.[221]

Fracture risk does not seem to be increased in patients with hemophilia,[35,231] but decreased bone density is frequent. Most authors have noted that healing of fractures proceeds primarily with endosteal callus and very little periosteal callus.[96] Joint dislocations are rare in hemophiliac patients. Most fractures are treated conservatively with immobilization.[169] Factor replacement is important especially during the first week, and recommended levels vary from 20% to 50%.[3,4,35,96,132] Circumferential casting is associated with the risk of swelling from bleeding, leading to subsequent compartment syndrome and skin necrosis. A splint, or well-padded, soft dressing may be preferable immediately after injury, and a cast should be applied once active swelling has stopped.[132] Fractures of the femur can be treated with traction and subsequent spica casting.[35,169] Nonetheless, some authors consider skeletal traction hazardous because of the risk of infection or bleeding.[4,132] Replacement therapy is advisable whereas fractures are manipulated and casts are changed. Most authors think that open reduction and internal fixation should be performed in hemophiliac patients for fractures that would customarily be treated with such methods.[4,35] External fixators are not commonly used for patients with hemophilia; however, Lee et al.[170] described the use of external fixators for nine patients undergoing arthrodesis of infected joints, or treatment of open fractures. One major complication occurred in a patient who developed inhibitors. They concluded that external fixators can be used safely in hemophilic patients without inhibitors and prolonged factor replacement is not required.[170]

TABLE 8-5 Grades of Articular Involvement

Grade 1	Transitory synovitis; no bleeding sequelae and with no more than three episodes in 3 months
Grade 2	Permanent synovitis with increased joint size, synovial thickening, and limitation of movement
Grade 3	Chronic arthropathy with axial deformity and muscular atrophy
Grade 4	Ankylosis

Author's Preferred Method of Treatment

Collaboration between the orthopedist and the hematologist is important in providing care for children with hemophilia. Most fractures in children with hemophilia can be treated with either traction or cast techniques. Care must be taken to avoid complications related to compression in these patients, and a mono- or bivalved, well-padded cast is safe. Operative treatment should be reserved for fractures that normally require surgery, and the usual pre- and perioperative precautions for hemophiliac patients are observed.

Osteomyelitis

The pattern of pediatric osteomyelitis in North America has changed during the past several decades. Although the typical clinical picture of acute onset of pain, associated with fever and inability, or refusal to bear weight is still seen, subtle presentations and more aggressive ones have become frequent. Among the potential reasons for these changes are the increased use of empiric antibiotics, and the increased number of aggressive community-acquired pathogens such as methicillin-resistant *Staphylococcus aureus* (MRSA). Osteomyelitis can be classified according to the age of onset (neonatal, childhood, and adult osteomyelitis); causative organism (pyogenic and granulomatous infections); onset (acute, subacute, and chronic); and routes of infection (hematogenous and direct inoculation). Although the acute form is still the most common, subacute osteomyelitis, or Brodie abscess, and chronic recurrent multifocal osteomyelitis are seen more frequently.[141] Chronic osteomyelitis is defined as symptoms present for longer than 1 month (Fig. 8-27 and Table 8-6).

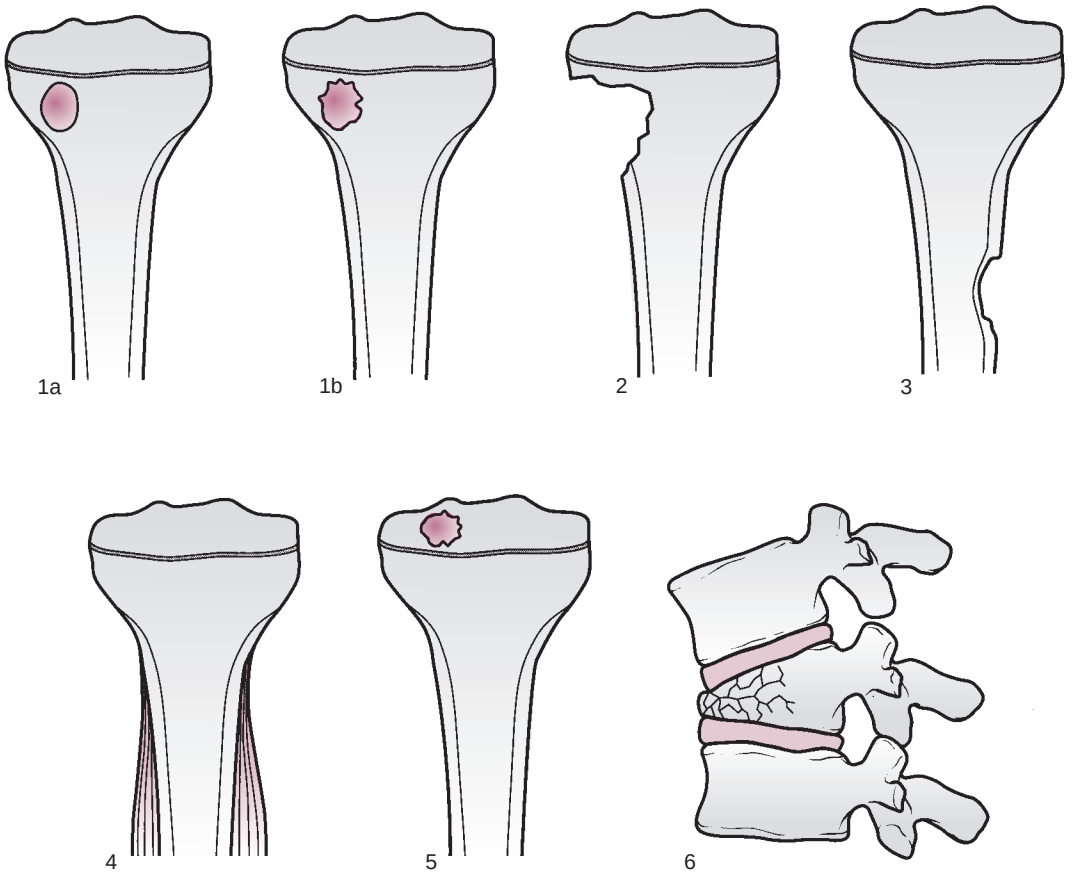

FIGURE 8-27 Classification of subacute osteomyelitis. Type 1A, punched-out radiolucency suggestive of eosinophilic granuloma. Type 1B, similar but with sclerotic margin; classic Brodie abscess. Type II, metaphyseal lesion with loss of cortical bone. Type III, diaphyseal lesion with excessive cortical reaction. Type IV, lesion with onionskin layering of subperiosteal bone. Type V, concentric epiphyseal radiolucency. Type VI, osteomyelitic lesion of vertebral body. (From Dormans JP, Drummond DS. Pediatric hematogenous osteomyelitis: new trends in presentation, diagnosis, and treatment. *J Am Acad Orthop Surg.* 1994;2:333–341, with permission.)

TABLE 8-6 Comparison of Acute and Subacute Hematogenous Osteomyelitis

Presentation	Subacute	Acute
Pain	Mild	Severe
Fever	Few patients	Majority
Loss of function	Minimal	Marked
Prior antibiotics	Often (30–40%)	Occasional
Elevated white blood cell count	Few	Majority
Elevated erythrocyte sedimentation rate	Majority	Majority
Blood cultures	Few positive	50% positive
Bone cultures	60% positive	85% positive
Initial x-ray study	Frequently abnormal	Often normal
Site	Any location (may cross physis)	Usually metaphysis

From Dormans JP, Drummond DS. Pediatric hematogenous osteomyelitis: new trends in presentation, diagnosis, and treatment. *J Am Acad Ortho Surg.* 1994;2:333–341.

Changes in plain radiographs are only present in 20% of patients in the first 2 weeks of disease; the earliest finding is soft-tissue swelling/loss of defined deep soft tissue planes. Because of this early insensitivity of plain radiographic studies, isotope-scanning techniques have been used to aid in diagnosis with varying rates of success. MRI has up to 98% sensitivity and 100% specificity for early detection of osteomyelitis.[158] MRI detects increased intramedullary water and decreased fat content, which occurs when there is inflammatory exudate, edema, hyperemia, and ischemia, all of which are present in infection.[158] In proven osteomyelitis, abnormal technetium scans are seen in 63% to 90% of patients.[134]

In 1932, Capener and Pierce[50] reviewed 1,068 patients with osteomyelitis and found only 18 pathologic fractures (~1.7% incidence), 13 of which occurred in the femur. They thought these fractures were because of delayed recognition of the infection or inadequate treatment. Other factors include disuse osteopenia, presence of a weak involucrum, and excessive surgical removal of involved bone. In that preantibiotic era, most of the fractures were sustained after surgical treatment of the osteomyelitis, and the authors believed that conservation of the involucrum and proper immobilization could have prevented these injuries. Daoud and Saighi Bouaouina[67] reported on 34 patients with hematogenous osteomyelitis complicated by pathologic fracture, pseudarthrosis, or significant segmental bone loss. The tibia was affected in 24 cases, the femur was affected in 8 cases, and the humerus was affected in 2 cases. Pathologic fracture of the proximal femoral has been reported in neonatal osteomyelitis.[20] Although rare, hematogenous osteomyelitis has also been reported at the site of a closed fracture.[48,242] Canale et al.[48] reported three children with osteomyelitis after closed fracture. They pointed out that progressive pain and swelling at a fracture site during healing are suggestive of possible osteomyelitis. Daoud et al.[66] reported 35 children with proximal femur osteomyelitis with associated septic arthritis. The incidence of ON of the femoral head was approximately 50% both in the group that was treated with arthroscopy and in the group in which no surgery had been done. They postulated that ON of the femoral head may be because of compression by abscess of the vessels lying on the posterior superior femoral neck. The complications of fracture, dislocation, and displacement of the capital femoral epiphysis occurred in two-thirds of their patients, and these usually were patients who presented long after an acute phase of the disease. They recommended surgical drainage of septic hips, and reduction and stabilization of hips with ON using skin traction and plaster immobilization for 40 to 60 days. Atypical osteomyelitis associated with bone lesion and risk of fracture has been described in rubella and cytomegalic inclusion disease.[235]

Pathologic fractures associated with osteomyelitis are usually associated with neglected or chronic osteomyelitis, neonatal osteomyelitis, or septic arthritis. They may be difficult to treat and be associated with complications, such as malunion and growth disturbance (Fig. 8-28). Tudisco et al.[267] reported on 26 patients with chronic osteomyelitis with average follow-up of 23 years. Approximately 15% had shortening and angular deformity of the affected limb. In children with chronic osteomyelitis, the purulent material elevates the periosteum and a supportive involucrum develops. Sequestrectomy of a portion of the necrotic diaphysis while leaving the supportive involucrum is often needed to bring the infection under control. Daoud and Saighi-Bouaouina[67] recommended early

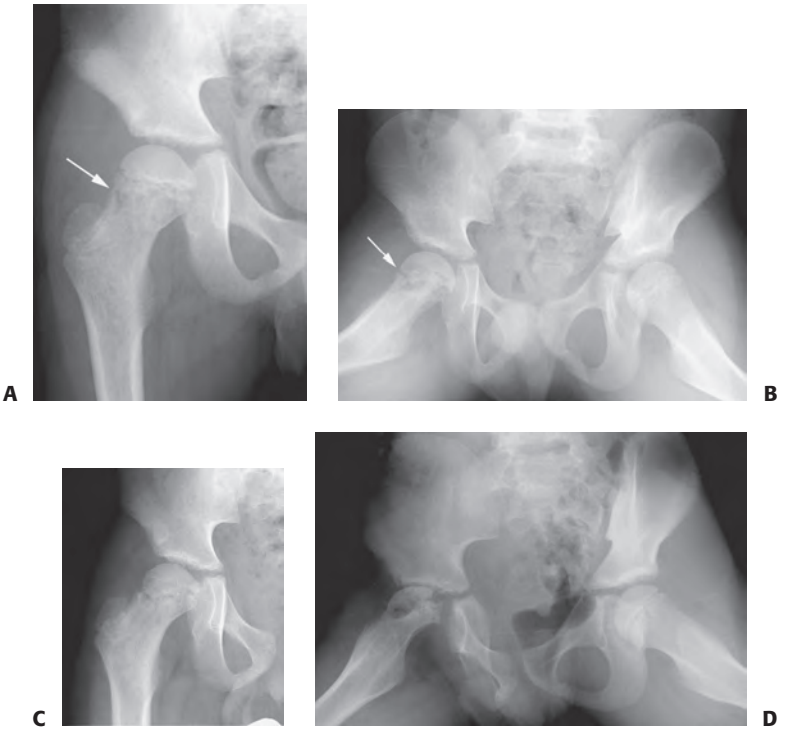

FIGURE 8-28 A 7-year-old boy presented with classic picture of septic arthritis of the right hip. He underwent promptly irrigation and débridement of the hip. On follow-up just a few weeks later, plain radiographs demonstrated a lytic area in the femoral neck **(A, B)** (*arrow*) and blood work showed increased creative protein and sedimentation rate. The patient underwent repeated irrigation of the hip and drilling of the lytic area (osteomyelitis) in the femoral neck. Two months later, he developed collapse (pathologic fracture) of the femoral head with gross deformity of the proximal femur **(C, D),** especially in the lateral views **(D)** with decreased range of motion. (Figures reproduced with permission from The Childrens Orthopaedic Center, Los Angeles, CA.)

debridement followed by antibiotic therapy for up to 6 months. Prolonged cast immobilization was necessary. They obtained healing in 33 of 34 patients with pathologic fractures or pseudarthroses caused by osteomyelitis. The mean healing time of fractures was 5 months in patients with involucrum. Patients with active infection and without involucrum required debridement, antibiotics, and subsequent treatment with corticocancellous iliac graft, for a mean healing time of 8.7 months; whereas patients without active infection and without involucrum were treated with prolonged immobilization, cancellous bone graft, and supplemented by fixation.

Author's Preferred Method of Treatment

With early recognition and appropriate treatment, acute osteomyelitis rarely leads to a pathologic fracture. When pathologic fracture occurs (Fig. 8-29), it is usually associated to a neglected chronic osteomyelitis or, rarely, neonatal osteomyelitis or septic arthritis. The most important step in the treatment of fracture associated with osteomyelitis is to control the underlying infection. This requires biopsy for culture and sensitivities, drainage and debridement of the infection with appropriate immobilization and antibiotic therapy (Table 8-7). In advanced infections, sequestrectomy may be necessary. MRI is useful in identifying the sequestrum; an attempt should be made to leave as much supporting involucrum as possible at the time of sequestrectomy. Bone transport and lengthening may be valuable in certain cases. Prolonged immobilization with either plaster casts or external fixation devices may be needed, and segmental bone loss can be treated with bone transport or grafting.

Pathologic Fractures after Limb Lengthening

Limb lengthening has evolved dramatically over the past several decades. Surgeons experienced with lengthening techniques can now correct problems that previously had no satisfactory solution. Complications with the Wagner method, popular 20 to 30 years ago, were as high as 92%.[130,181] Newer techniques, using gradual lengthening with either monolateral fixators or fine wire fixators, such as the Ilizarov fixator, have decreased the complication rate.

FIGURE 8-29 This lateral radiograph of the humeral shaft of a 17-year-old boy shows a pathologic fracture through chronic osteomyelitis of the humerus. (Case courtesy of B. David Horn, MD.)

Fractures that occur in association with limb lengthening fall into three general categories: (1) fractures through pin tracks, (2) fractures through regenerated bone, or (3) fractures through bone weakened by disuse osteoporosis. Fractures that occur through holes left after removal of screws or fine wires generally occur a few weeks after device removal. The incidence of these fractures can be minimized by protective weight bearing after removal of the device and using the smallest possible screw diameter that is appropriate for the fixation device

TABLE 8-7 Initial Antibiotic Therapy for Osteomyelitis

Patient Type	Probable Organism	Initial Antibiotic
Neonate	Group B Streptococcus, *S. aureus,* Gram-negative rods (*H. influenza*)	Cefotaxime (100–120 mg/kg/ 24 h) or oxacillin and gentamicin (5–7.5 mg/kg/24 h)
Infants and children	*S. aureus* (90%) if allergic to penicillin* if allergic to penicillin and cephalosporins*	Oxacillin (150 mg/kg/24 h) Cefazolin (100 mg/kg/24 h) Clindamycin (25–40 mg/kg/24 h) or Vancomycin (40 mg/kg/24 h)
Sickle cell disease	*S. aureus* or Salmonella	Oxacillin and ampicillin or chloramphenicol or cefotaxime (100–120 mg/kg/24 h)

*Overall 80% because of *S. aureus.*

needed. Fractures through regenerated bone are true pathologic fractures. The bone that is formed by distraction callotasis must be subjected to normal weight-bearing forces over a period of time before normal bony architecture is established. Fractures that occur through the lengthening gap can occur either soon after removal of the fixator or years later (Fig. 8-30). Various reports describe fractures through regenerative bone occurring as late as 2 to 8 years after lengthening.[181,200] The incidence of fractures has been reported to be as high as 50% for Wagner lengthening, but only 3% for newer techniques.[90,130,179,200,212,223] At present, most lengthenings are performed through the metaphysis, which has a larger bone diameter and better blood supply than the diaphysis (where Wagner lengthening was done).[179,213] When fractures occur in regenerated bone, they can be treated with simple cast immobilization. However, because this method further promotes osteopenia, many surgeons reapply a fixator, correct any malalignment caused by the fracture, and compress at the fracture site until healing. To ensure that the regenerated bone can bear the forces of normal activity, a variety of imaging methods have been used.[33] When the regen-

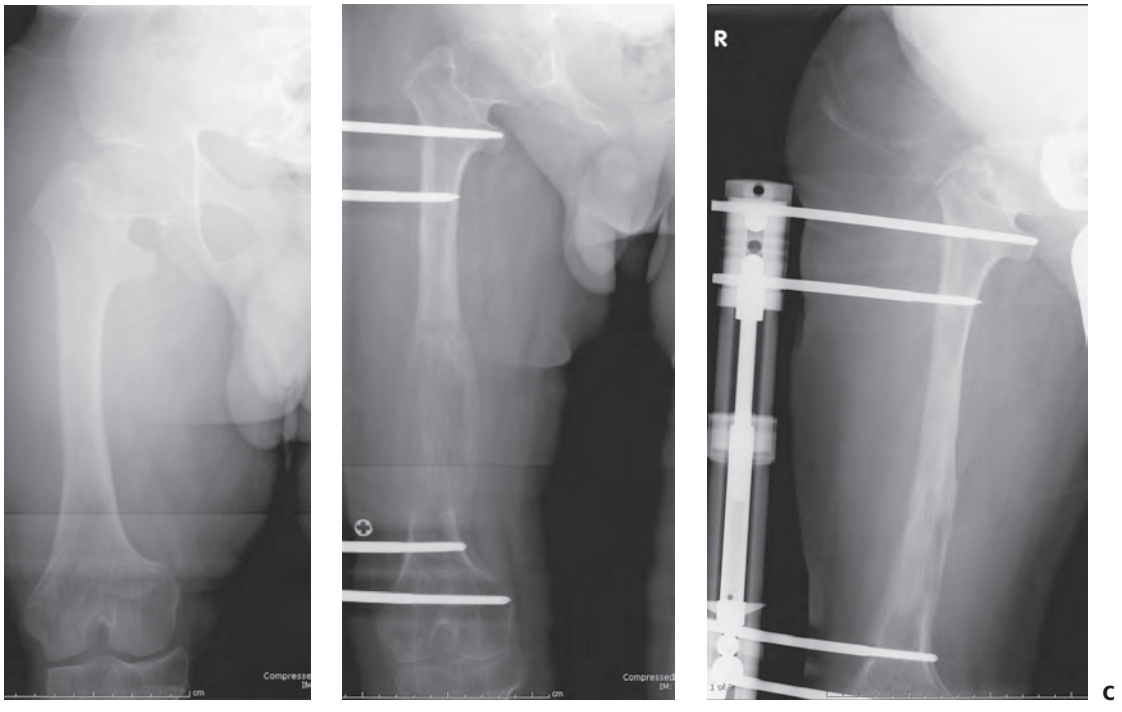

FIGURE 8-30 Radiograph of a 15-year-old boy with achondroplasia **(A)** who underwent femoral lengthening with a monolateral external fixator for limb-length discrepancy **(B).** The procedure and the lengthening were uneventful and the device was removed after four cortices were visualized on radiographs **(C, D).** Less than 2 months after external fixator removal, the patient fell and had a pathologic femoral fracture through the regenerated bone **(E).**

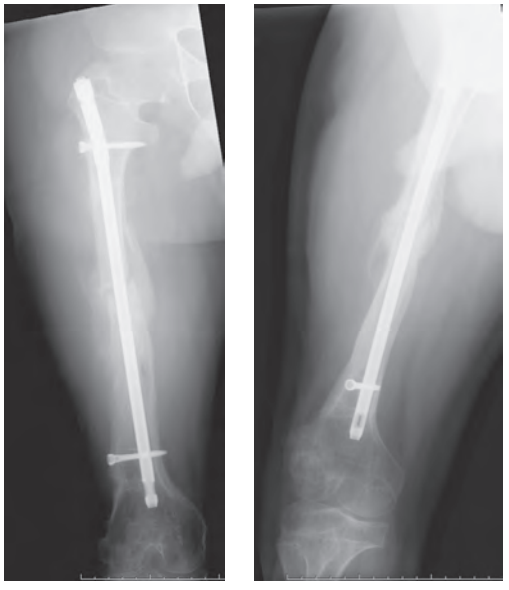

F G

FIGURE 8-30 (*continued*) He underwent open reduction and internal fixation with an intramedullary device and the fracture healed in approximately 3 months **(F, G).** (Figures reproduced with permission from The Childrens Orthopaedic Center, Los Angeles, CA.)

erated bone attains the density and ultrastructural appearance (development of the cortex and the medullary canal) of the adjacent bone, fixator removal is generally safe. Some authors have reported on decreased incidence of fractures combining lengthening with internal fixation (intramedullary nail or submuscular plating).[138,214]

Pathologic fracture can also be caused by osteopenia and joint contractures that can occur after months in an external fixation device. Some children, because of pain or anxiety, are reluctant to bear sufficient weight on their fixator devices, putting them at risk for disuse osteoporosis. Joint contractures can be related to either the lengthening or insufficient rehabilitation during and after lengthening. Many of the fractures caused by these causes are avoidable; when they do occur, appropriate immobilization or internal fixation is used.

Fractures in Conditions that Weaken Bone

Osteogenesis Imperfecta

Osteogenesis imperfecta (OI) are a heterogeneous group of inherited disorders in which the structure and function of type I collagen is altered. The fragile bone is susceptible to frequent fractures and progressive deformity. OI is identifiable in 1 in 20,000 total births, with an overall prevalence of approximately 16 cases per million index patients.[59] The wide spectrum of clinical severity—from perinatal lethal forms to clinically silent forms—reflects the tremendous genotypic heterogeneity (more than 150 different mutations of the type I procollagen genes COL1A1 and COL1A2 have been described). Most forms of OI are the result of mutations in the genes that encode the pro alpha1 and pro alpha2 polypeptide chains of type I collagen.[208] Histologic findings reveal a predominance of woven bone, an absence of lamellar bone, and thinning of the cortical bone with osteopenia. As the molecular basis of this continuum of severity is further elucidated, the phenotypic groupings of the various classifications and subclassifications may seem arbitrary. From a practical viewpoint of orthopedic care, patients with OI can be divided into two groups. One group of patients with severe disease who develop long-bone deformity through repetitive fractures often needing surgical treatment, and another group of patients with mild disease with frequent fractures, but most injuries responding well to closed treatment.

Children with severe OI may present with a short trunk, marked deformity of lower extremities, prominence of the sternum, triangular faces, thin skin, muscle atrophy, and ligamentous laxity, some develop kyphoscoliosis,[119,198] basilar impression,[245] and deafness (caused by otosclerosis).[120] Children with OI usually have normal intelligence. Blue sclera, a classic finding in certain forms of OI, can also be present in normal infants, as well as in children with hypophosphatasia, osteopetrosis, Marfan syndrome, and Ehlers–Danlos syndrome. Children with OI also have a greater incidence of airway anomalies, thoracic anatomy abnormalities, coagulation dysfunction, hyperthyroidism, and an increased tendency to develop perioperative malignant hyperthermia.[260] Pathologic fractures may present with swelling of the extremity, pain, low-grade fever, and a radiograph showing exuberant, hyperplastic, callus formation. The callus may occur without obvious fracture and can have a distinct butterfly shape, as opposed to the usual fusiform callus of most healing fractures. The femur is the most common site of pathologic fractures.[228]

The radiographic findings vary (Fig. 8-31). In severe OI, there is marked osteoporosis, thin cortical bone, and evidence of past fracture with angular malunion. Both anterior and lateral bowing of the femur and anterior bowing of the tibia are common. Spinal radiographs may show compression of the vertebrae between the cartilaginous disc spaces (so-called codfish vertebra).

The diagnosis of OI is based on clinical and radiographic findings. There is no specific laboratory diagnostic test, although fibroblast cell culture can detect the collagen abnormality in 85% of OI patients.[58] In the absence of multiple fractures, the initial radiographic diagnosis can be difficult. It is crucial, but often difficult, to distinguish OI from nonaccidental injury.[153,197] Unexplained fractures in mild, undiagnosed OI can drag a family through unnecessary legal proceedings; conversely, a child with OI may be abused but not exhibit classic fracture patterns (e.g., corner fractures) owing to the fragility of their bones.

Fractures tend to occur before skeletal maturity. Most pathologic fractures are transverse, diaphyseal, minimally displaced, and heal at a relatively normal rate.[245] Moorefield and Miller[198] reported on 951 fractures in a series of 31 patients, 91% of which occurred before skeletal maturity. Fractures of the femur and tibia predominated, followed by the humerus. Recurrent fractures may result in coxa vara, genu valgum, and leg-length discrepancy. Olecranon sleeve (apophysis) avulsion fractures are essentially pathognomonic of OI (Fig. 8-32).[260] Zionts and Moon[281] reviewed 17 fractures of the olecranon apophysis in 10 children with mild OI; 15 of these were treated operatively. The

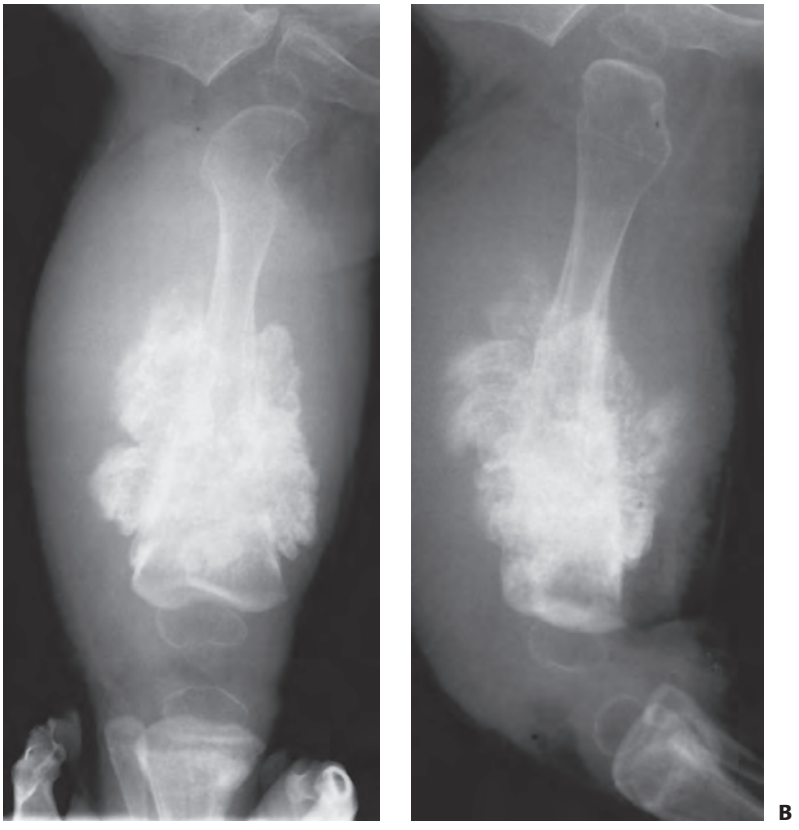

FIGURE 8-31 This 10-month-old boy with a history of osteogenesis imperfecta presented with a right thigh pain and swelling and refusal to bear weight. Anteroposterior **(A)** and lateral **(B)** radiographs of the right femur show the extraordinarily abundant, hyperplastic callus—with the characteristic butterfly shape—that can occur in osteogenesis imperfecta. This appearance may be mistaken for an infection or a neoplastic process.

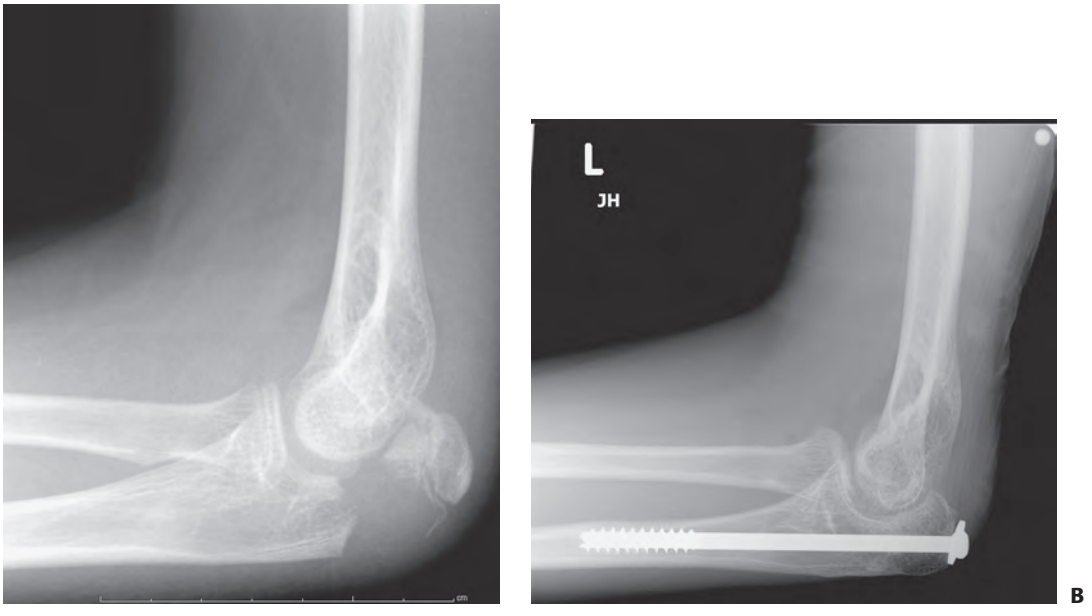

FIGURE 8-32 A 13-year-old boy with mild osteogenesis imperfecta presented after a fall on an outstretched arm, with inability to move his elbow, pain, and swelling. Radiographs showed a displaced olecranon fracture **(A).** This fracture pattern is commonly seen in children with osteogenesis imperfecta and is quite uncommon in healthy children. The patient underwent open reduction and internal fixation. The fracture healed after 6 weeks **(B).** (Figures reproduced with permission from The Childrens Orthopaedic Center, Los Angeles, CA.)

same injury presented in the opposite extremity 1 to 70 months after the initial fracture in seven of the 10 patients. All fractures had healed by the time of cast removal; however, two refractured. The authors concluded that with careful follow-up, cast immobilization can be used for minimally displaced fractures, but operative management is suggested for displaced fractures. The high rate of bilaterality suggests that children who sustain this fracture should be counseled about the possible risks of injury to the opposite extremity.[281] Displaced fractures of the apophysis of the olecranon should be treated with open reduction and internal fixation using tension band technique or compression screw fixation.[260]

Although nonunion may occur, callus formation is usually adequate in OI and most nonunions seem to be associated with inadequate fixation after osteotomies and fractures.[2] Gamble et al.[101] emphasized the problem with a report of 12 nonunions in 10 patients. Sub-optimal treatment of the initial fracture was identified in half of the patients.

The role of medical therapy in the prevention of fractures associated to OI has been well established. Bisphosphonates are a potent inhibitor of bone resorption and have been used with good results. Among the advantages of using bisphosphonates are good short-term safety (particularly with regard to renal function), significant reduction in chronic bone pain, decrease in the rate of fractures, gain in muscle force, increase in density and size of vertebral bodies, thickening of bone cortex, and increase growth rate.[13,110,111,280] Some of the reported negative effects, include decrease in bone remodeling rate, growth plate abnormalities, and delay in the healing of osteotomy.[110] Glorieux et al.[111] and Zeitlin et al.[280] showed that administering cyclical intravenous pamidronate to children with OI reduces bone pain and fracture incidence and increase bone density and level of ambulation, with minimal side effects. Falk et al.[94] concurred with most of these findings, but concluded that long-term follow-up is required to prove whether bisphosphonate therapy will decrease fracture rates and increase mobility in children with moderate-to-severe OI.[94] Sakkers et al.[235] reported a reduction of long bones fracture risk using oral treatment with olpadronate at a daily dose of 10 mg.

Gene therapy for OI has been attempted; however, because most of the mutations in OI are dominant negative, supplying the normal gene without silencing the abnormal gene may not be beneficial.[208] Nonetheless, potential new therapies for OI have been tested in cell culture systems, animal models, and patients and may offer hope for the future development of successful therapies.

The orthopedist caring for children with OI must balance standard fracture care with the goal of minimizing immobilization to avoid a vicious circle: Immobilization, weakness, and osteopenia, then refracture.[8,198] Plaster splints and casts, braces, and air splint have all been used.[34,106,198] Protected weight bearing with customized splints and/or braces can add support to limbs weakened by fragile and deformed bone, and is thought to reduce the incidence of lower extremity fractures.

Load-sharing devices (such as intramedullary rods) are used for internal fixation of long bone fractures or osteotomies in children with OI. Plates and screws should be avoided. In patients with severe OI and angular deformities and/or recurrent fractures, osteotomy and internal fixation may improve function and reduce the incidence of fractures in weight-bearing bones (Fig. 8-33). Porat et al.[220] reported an increased number of ambulatory patients (from 45% to 75%) after intramedullary rodding. The amount of bowing that requires osteotomy has not been defined. Traditionally, multiple osteotomy and rodding procedures (Sofield technique) involved extensive incisions with significant soft-tissue stripping and blood loss. Sijbrandij[247] reported a percutaneous technique in which the deformity is straightened by closed osteoclasis and Rush pins are inserted along the proximal axis of the long bones, partially transfixing them to stabilize them in a new alignment. Most centers now use limited incisions, thus minimizing blood loss and periosteal stripping, while ensuring optimally placed osteotomies and efficient, controlled instrumentation. The choice of fixation device should be based on the age of the patient and the width of the medullary canal of the bone. Both fixed-length rods[220,255] and extensible or telescoping rods[22,101,206,220] are used. Skeletally mature patients and patients with very small medullary canals are best treated with nonelongating rods, whereas skeletally immature patients with adequate width of the medullary canal are best treated with extensible rods.[101] Complications after osteotomies and intramedullary fixation include fracture at the rod tip, migration of the fixation device, joint penetration, loosening of components of extensible rods, and fractures through the area of uncoupled rods.

Postoperative bracing is suggested for lower extremity fractures. Upper extremity fractures may also undergo prolonged splinting after removal of fracture fixation. Immobilization also may be adequate to treat stable, minimally displaced fractures just distal or proximal to the intramedullary rods.[101]

Author's Preferred Method of Treatment

Protected weight bearing is the goal for patients with severe OI. Close follow-up is necessary in the first few years of life, with protective splinting or soft cast for fractures. Orthoses are constructed for bracing of the lower extremities to aid in both standing and ambulation. Standing frames are also used. Once ambulatory, the child is advanced to the use of a walker or independent ambulation. Bisphosphonates should be considered at an early age, prior to fractures and deformity. The length of treatment is still debatable. Severe bowing of the extremities especially after recurrent fractures is an indication for osteotomy and intramedullary rodding. Whenever possible, surgery is delayed until 6 or 7 years of age to allow for better fixation and decrease the chance of recurrence. We recommend extensible rods in skeletally immature patients and nonelongating rods in older patients.

Osteopetrosis

Osteopetrosis is a condition in which excessive density of bone occurs as a result of abnormal function of osteoclasts.[17,219] The resultant bone of these children is dense, brittle, and highly

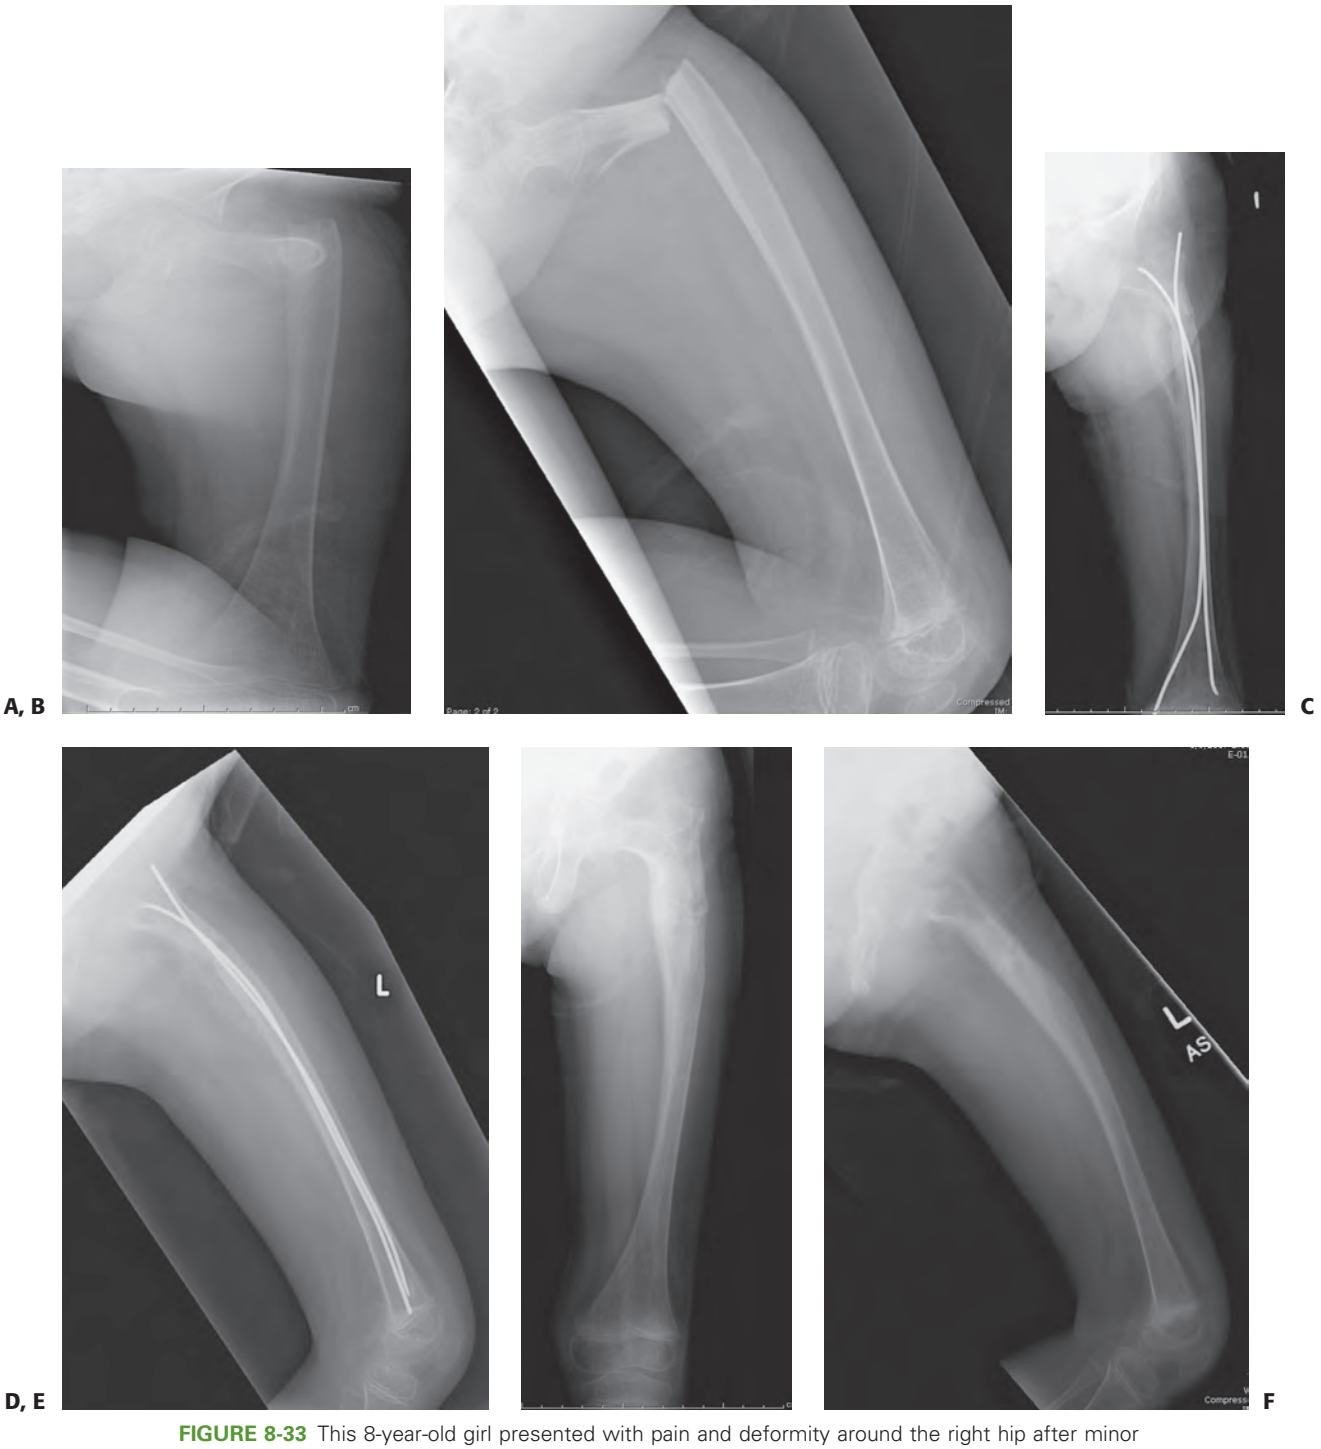

FIGURE 8-33 This 8-year-old girl presented with pain and deformity around the right hip after minor trauma. The patient had a known history of osteogenesis perfecta. Initial radiographs **(A, B)** showed grossly displaced fracture of the proximal femur in the subtrochanteric area. The patient underwent closed reduction and internal fixation with titanium elastic nails, and the fracture healed after 5 weeks, with good alignment in both anteroposterior **(C)** and lateral **(D)** views. The nails were slightly prominent and the family elected removal of the hardware **(E, F).**

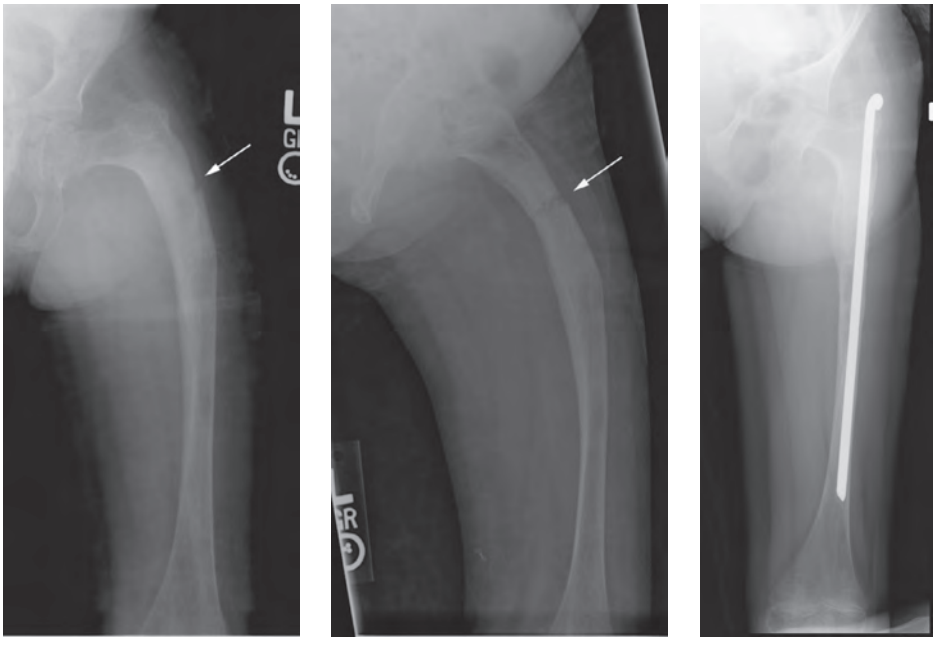

G, H I

J

FIGURE 8-33 (*continued*) Three months after removal of the hardware, the patient presented with new trauma to that region followed by pain. Radiographs showed a minimally displaced transverse fracture in the subtrochanteric region (*arrow*) associated with varus and anterior angulation of the proximal femur **(G, H).** The patient underwent a Sofield procedure with Rush rods as the internal fixation. Ten weeks after the procedure, there was complete healing at the osteotomy/fracture site and adequate femoral alignment **(I, J).** (Figures reproduced with permission from The Childrens Orthopaedic Center, Los Angeles, CA.)

susceptible to pathologic fracture. The incidence of osteopetrosis is approximately 1 per 200,000 births. The inherent problem is a failure of bone resorption with continuing bone formation and persistent primary spongiosa. Osteopetrosis is classified into three main forms: Malignant autosomal recessive, intermediate autosomal recessive, and benign autosomal dominant; and basically presents as a severe infantile type or a milder form that presents later in life. Although the number of osteoclasts present in the affected bone is variable, in the severe form of this disease, the osteoclasts may be increased but function poorly.[243]

Radiographically, the bones have a dense, chalk-like appearance (Fig. 8-34). The spinal column may have a sandwich or "rugger jersey" appearance because of dense, sclerotic bone at each end plate of the vertebrae and less involvement of the central portion. The long bones tend to have a dense, marble-like appearance and may have an Erlenmeyer flask shape at their ends owing to deficient cutback remodeling. Radiolucent transverse bands may be present in the metaphysis of the long bones, and these may represent a variable improvement in the resorption defect during growth of the child. There may be bowing of the bones because of multiple fractures, spondylolysis, or coxa vara.[123,219] The small bones of the hands and feet may show a bone-within-bone appearance with increased density around the periphery. The unusual radiographic appearance may initially obscure occult nondisplaced fractures.

Pathologic fractures are quite common in patients with osteopetrosis (Fig. 8-35).[38,143,219,243] Patients with a severe form of the disease have more fractures than those with presentation

FIGURE 8-34 Anteroposterior radiograph of the pelvis of an 8-year-old boy with osteopetrosis. Note the typical increased bone density and obliteration of the medullary canal. (Figures reproduced with permission from The Childrens Orthopaedic Center, Los Angeles, CA.)

FIGURE 8-35 This 2-year-old with osteopetrosis presented with forearm pain. An anteroposterior radiograph shows the characteristic increased bone density and absence of a medullary canal, especially in the distal radius and ulna. There is a typical transverse, nondisplaced fracture (*arrow*) in the distal ulnar diaphysis.

later in childhood. Patients with autosomal dominant osteopetrosis with rugger jersey spine and endobones of the pelvis (type II) are six times more likely to have fractures than patients with only sclerosis of the cranial vault (type I).[38]

Patients with the severe, congenital disease have transverse or short oblique fractures of the diaphysis, particularly the femur. Distal physeal fractures with exuberant callus may be confused with osteomyelitis.[195] Common locations for fractures include the inferior neck of the femur, the proximal third of the femoral shaft, and the proximal tibia.[17,195] Upper extremity fractures are also frequent.[17] The onset of callus formation after fracture in osteopetrosis is variable.[17] Although some believe that fractures in osteopetrosis heal at a normal rate[219] others report delayed union and nonunion.[17] Hasenhuttl[123] observed that in one patient with recurrent fractures of the forearm, each succeeding fracture took longer to heal, with the last fracture taking nearly 5 months to unite.

The orthopedist treating fractures in children with osteopetrosis should follow the principles of standard pediatric fracture care, with additional vigilance for possible delayed union (Fig. 8-36).[123,243] Immobilization is prolonged when delayed union is recognized. Armstrong et al.[17] surveyed the membership of the Pediatric Orthopaedic Society of North America and compiled the combined experience of 58 pediatric orthopedic surgeons with experience treating pathologic fractures in osteopetrosis. In this comprehensive review, they concluded that nonoperative treatment should be strongly considered for most diaphyseal fractures of the upper and lower limbs in children, but surgical management is recommended for femoral neck fractures and coxa vara. Open treatment of osteopetrotic fractures with fixation is technically difficult because of bone rigidity/density, and absence of intramedullary canal/ sclerosis. Armstrong et al.[17] cautioned, "the surgeon should expect to use several drill bits and possibly more than one power driver."

In addition to these technical difficulties, patients with osteopetrosis are at risk for excessive bleeding and infection, related to the hematopoietic dysfunction caused by obliteration of the marrow cavity.[243] Procedures should be avoided if the platelet count is less than 50,000 mm, and preoperative platelet transfusions may be necessary.[243] Prophylactic antibiotic coverage is advised. Minor procedures should be performed percutaneously whenever possible.[243]

In the past, primary medical treatment for osteopetrosis included transfusions, splenectomy, calcitriol, and adrenal corticosteroids, but these techniques have proved ineffectual.[227,268] Stimulation of host osteoclasts has been attempted with calcium restriction, calcitriol, steroids, parathyroid hormone, and interferon. Bone marrow transplantation for severe infantile osteopetrosis has proved to be an effective means of treatment for some patients; however, it does not guarantee survival, and it may be complicated by hypercalcaemia.[53,56,107]

Pyknodysostosis

Pyknodysostosis, also known as Maroteaux-Lamy syndrome, is a rare syndrome of short stature and generalized sclerosis of the entire skeleton. The dense brittle bones of affected

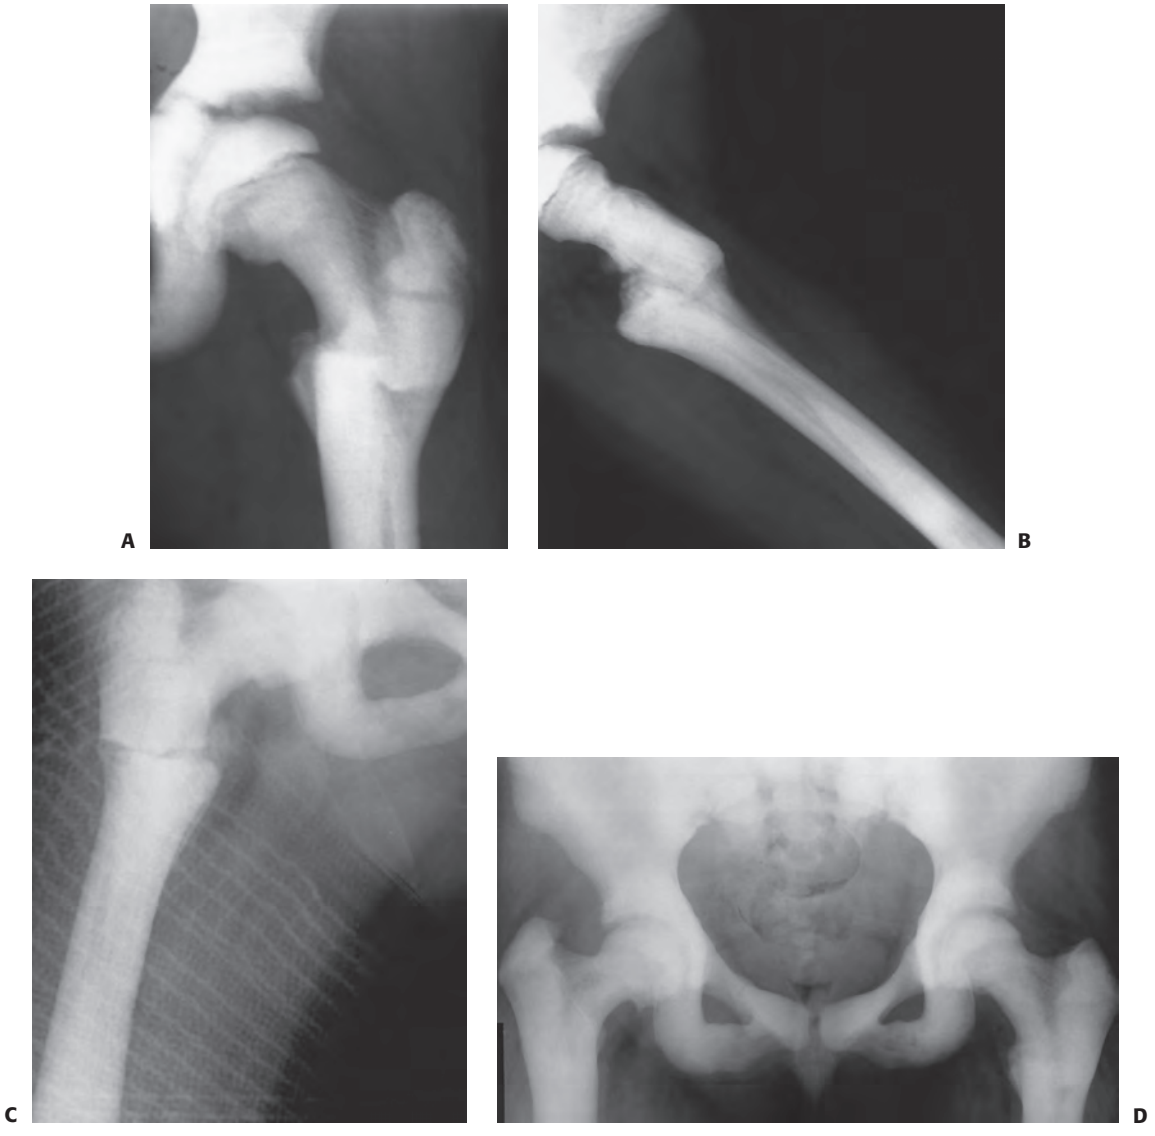

FIGURE 8-36 **A:** This 9-year-old with osteopetrosis sustained similar bilateral subtrochanteric fractures of the femur over a 2-year period. Anteroposterior **(A)** and lateral **(B)** femoral radiographs show a healing transverse subtrochanteric fracture of the left femoral. **C:** One year later, at age 10, she sustained a similar right transverse minimally displaced subtrochanteric femur fracture, which was treated with reduction and a spica cast. **D:** This anteroposterior radiograph taken at age 14 years shows that both proximal femoral fractures have healed and there is mild residual coxa vara, especially on the right side.

children are highly susceptible to pathologic fractures. Pyknodysostosis is inherited as an autosomal recessive trait, with an incidence estimated as 1.7 per 1 million births. Mutations in the gene encoding cathepsin K, a lysosomal cysteine protease localized exclusively in osteoclasts is responsible for this disease.[99] The long bones are sclerotic with poorly formed medullary canals; histologic sections show attenuated Haversian canal systems. Patients with pyknodysostosis have short stature, a hypoplastic face, a nose with a parrot-like appearance, and both frontal and occipital bossing. Bulbous distal phalanges of the fingers and toes with spooning of the nails are common. Coxa vara, coxa valgum, genu valgum, kyphosis, and scoliosis may be present. Results of laboratory studies usually are normal.

Radiographs show a sclerotic pattern very similar to that of osteopetrosis. In pyknodysostosis, however, the medullary canal is present but poorly formed, and a faint trabecular pattern is seen. Such sclerotic bone is also seen in Engelmann's disease, but clinically those patients are tall and eventually develop muscle weakness. The distal femur in a patient with pyknodysostosis usually has an Erlenmeyer flask deformity similar to that found in patients with Gaucher disease.[29]

Although pathologic fractures are thought to be less common in pyknodysostosis than in OI, almost all patients with

pyknodysostosis reported in the literature have had pathologic fractures.[25] Edelson et al.[86] reported 14 new cases of pyknodysostosis from a small Arab village. They described a hangman fracture of C2 in a 2-year-old child that went on to asymptomatic nonunion. There was 100% incidence of spondylolysis in their patients aged 9 years or older, with most located at L4 to L5. Lower extremity fractures are the most common, and clinical deformity of both the femur and tibia is frequent. The fractures are usually transverse and diaphyseal, and heal with scanty callus.[194] The fracture line can persist for nearly 3 years after clinical union, with an appearance similar to a Looser line. Overall, fractures tend to heal readily in childhood, but nonunion can be a problem in adulthood.

Rickets

Rickets is a disease of growing children caused by either a deficiency of vitamin D or an abnormality of its metabolism. The osteoid of the bone is not mineralized, and broad unossified osteoid seams form on the trabeculae. With failure of physeal mineralization, the zone of provisional calcification widens and the ingrowth of blood vessels into the zone is disrupted. In the rickets of renal failure, the effects of secondary hyperparathyroidism (bone erosion and cyst formation) are also present. Before widespread fortification of common foods, vitamin D deficiency was a common cause of rickets, but other diseases affecting the metabolism of vitamin D have become a more common cause. Regardless of the underlying cause, the various types of rickets share similar clinical and radiographic features (Fig. 8-37). Although many of the metabolic findings are the same, there are some differences.

Both pathologic fractures[215,252] and epiphyseal displacement[113] can occur in rickets. The treatment of rickets depends on identification of the underlying cause. In addition to nutritional rickets, many other diseases can affect vitamin D metabolism, and their treatment is necessary before the clinical rickets can be resolved (Table 8-8).

Nutritional Rickets Inadequate dietary vitamin D and lack of exposure to sunlight can lead to a vitamin D deficiency. Pathologic fractures from vitamin D deficiency rickets also occur in children on certain diets: Unsupplemented breast milk, diets restricted by religious beliefs, and fat diets.[87,165] Fractures are treated with both cast immobilization and correction of the vitamin deficiency by oral vitamin D supplementation. Oral calcium supplements also may be necessary, and patients should consume a vitamin D-fortified milk source.

FIGURE 8-37 Lower extremity radiograph of an 18-month-old boy with rickets. Note the severe bowing, physeal irregularities and widening with flaring of distal tibial metaphysis. (Figures reproduced with permission from The Childrens Orthopaedic Center, Los Angeles, CA.)

Rickets in Malabsorption Celiac disease caused by gluten-sensitive enteropathy affects intestinal absorption of fat-soluble vitamins (such as vitamin D), resulting in rickets. Biopsy of the small intestine shows characteristic atrophy of the villi. Treatment is oral vitamin D and a gluten-free diet. Infants with short gut syndrome may have vitamin D-deficiency rickets. This

TABLE 8-8 Rickets: Metabolic Abnormalities

Disorder	Cause	$1,25(OH)_2$ Vitamin D	Parathyroid Hormone	Calcium	P	Alkaline Phosphate
Vitamin D deficiency rickets	Lack of vitamin D in the diet	↓	↑	↓ or →	↓	↑
Gastrointestinal rickets	Decreased gastrointestinal absorption of vitamin D or calcium	↓ or →	↑	↓	↓	↑

Vitamin D-resistant rickets—end-organ insensitivity	Intestinal cell insensitivity to vitamin D causing decreased calcium absorption	↑ or →	↑	↓	↓	↑
Renal osteodystrophy	Renal failure causing decreased vitamin D synthesis, phosphate retention, hypocalcemia, and secondary hyperparathyroidism	↓↓	↑↑	↓	↑	↑

syndrome may develop after intestinal resection in infancy for volvulus or necrotizing enterocolitis, in intestinal atresia, or after resection of the terminal ileum and the ileocecal valve.[265] Pathologic fractures have been reported, and treatment is immobilization and administration of vitamin D_2 with supplemental calcium gluconate.

Hepatobiliary disease is also associated with rickets.[128,157] With congenital biliary atresia, the bile acids, essential for the intestinal absorption of vitamin D, are inadequate. By the age of 3 months, nearly 60% of patients with biliary atresia may have rickets.[157] Intravenous vitamin D is often needed for effective treatment of these patients. After appropriate surgical correction of the hepatic syndrome, the bone disease gradually improves (Fig. 8-38). The pathologic fractures that develop in these disorders[128] can be treated with immobilization.

Epilepsy may affect bone in a number of ways such as restriction of physical activity, cerebral palsy, or other coexisting morbidities. Also, the use of anticonvulsant therapy can interfere with the hepatic metabolism of vitamin D and result in rickets and pathologic fractures.[237] Fewer fractures occur in institutionalized patients receiving vitamin D prophylaxis.[244]

Ifosfamide, a chemotherapeutic agent used for treatment of different sarcomas, can cause hypophosphatemic rickets in children. The onset of rickets may occur anywhere from 2 to 14 months after chemotherapy and can be corrected with the administration of oral phosphates.[263] Other mineral deficiencies such as magnesium (a cofactor for parathyroid hormone) can cause rare forms of rickets.

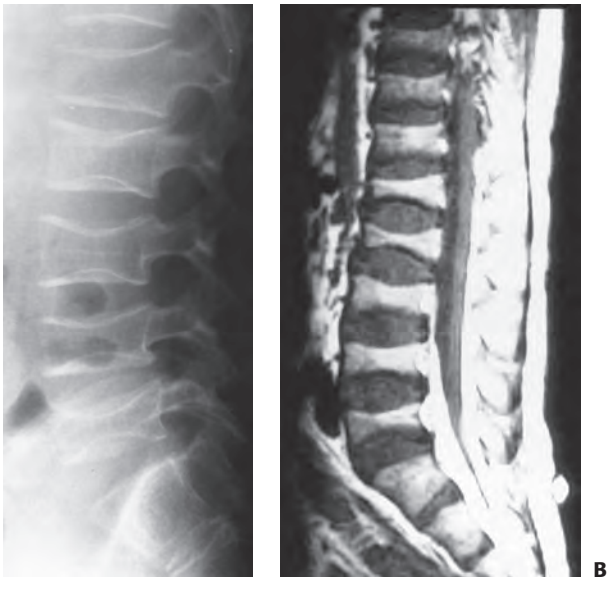

FIGURE 8-38 This 18-year-old boy with sclerosing cholangitis and a history of steroid use presented with several months of worsening low back pain. **A:** Lateral radiograph of his lumbar spine shows marked osteopenia, collapsed codfish vertebrae with sclerotic end plates and widened disc spaces and Schmorl nodes. **B:** This MRI shows flattened concave vertebrae that are smaller in most locations than the adjacent intervertebral discs. He was successfully treated with 3 months in a thoraco-lumbar-sacral-orthosis brace, followed by weaning from the brace and conditioning exercises.

Rickets and Very-Low–Birth-Weight Infants Very-low–birth-weight infants (1,500 g or less) can have pathologic fractures. In one study of 12 very-low–birth-weight infants, the incidence of pathologic fracture was 2.1%, nearly twice the rate of other premature infants with a birth weight of more than 1,500 g.[9] The fractures are likely caused by a nutritional osteomalacia that may evolve into frank rickets in nearly 30% of very-low–birth-weight infants.[9,156] Eighty percent of both calcium and phosphorus is acquired during the last trimester of pregnancy, when the intrauterine growth rate is exponential, and almost two-thirds of the birth weight is gained.[149,229] Bone loss can be graded by either loss of cortical bone of the humerus or loss of bone of the distal radius.[156] Other than craniotabes (thinning and softening of the skull bone with widening of the sutures and fontanelles), the clinical signs of rickets are generally lacking in these patients. The risk factors predisposing these patients to both rickets and fractures include hepatobiliary disease,[157,263] prolonged total parenteral nutrition, chronic lung disease,[9] necrotizing enterocolitis, patent ductus arteriosus, and physical therapy with passive range-of-motion exercises.[156] In a prospective study of 78 low-birth-weight infants, Koo et al.[156] observed a 73% incidence of rickets with associated pathologic fractures in patients with a birth weight of 800 g or less and only a 15% incidence of rickets with fractures in patients with a birth weight ranging from 1,000 to 1,500 g. In most cases, pathologic fractures in very-low–birth-weight infants are found incidentally on chest radiograph or gastrointestinal studies. The fractures may be suspected when physical examination reveals swelling and decreased movement of an extremity. The differential diagnosis of these fractures is limited but important: OI, copper deficiency syndrome, child abuse, and pathologic fracture from overzealous physical therapy.

In the series reported by Amir et al.,[8,9] (1.2%) of 973 preterm infants had fractures; 11 of 12 had more than one fracture. Radiographically, osteopenia is first seen at the fourth week of life. Typically, rib fractures are next seen at 6 to 8 weeks of life, then fractures of the long bones at 11 to 12 weeks.[229] In one study, 54% of fractures were in the upper extremities, 18% in the lower extremities, 22% in the ribs, and approximately 6% in either the scapula or the clavicle.[156] Most long bone fractures are metaphyseal and may be transverse or green-stick with either angulation or complete displacement.[9] Callus is seen at the fracture site in less than a week, and complete remodeling occurs in 6 to 12 months.[9,156] Passive range-of-motion exercises for these infants, by both physical therapists and parents should be avoided. Rib fractures have been associated with vigorous chest physiotherapy. Care also should be taken even with routine manipulation of the extremities during nursing care, and special care should be taken in restraining the extremities during surgical procedures.[156] Splinting and soft dressing are choices for pathologic fractures of the long bones in very-low–birth-weight infants. The prognosis is excellent for most of these fractures because they go on to complete remodeling within 12 months. Preventive measures are important to minimize the risk of fracture in low-birth-weight infants. Their nutritional need for high levels of calcium, phosphorus, and vitamin D

should be recognized. Alternating high levels of calcium with low levels of phosphorus in hyperalimentation solutions can help meet these needs. Because growth arrest is possible after fractures, follow-up over the first 2 to 3 years of life is advised.

Rickets and Renal Osteodystrophy Renal osteodystrophy is common in patients with end-stage renal failure, typically developing 1 to 2 years after the diagnosis of kidney disease.[135] The clinical syndrome is a combination of rickets and secondary hyperparathyroidism with marked osteoporosis. Affected children develop renal rickets as a result of chronic nephritis, pyelonephritis, congenitally small kidneys, or cystinosis.[252] They present with short stature, bone pain, muscle weakness, delayed sexual development, and bowing of the long bones. Identification of the renal disorder is important because patients presenting with rickets caused by obstructive uropathy may respond to surgical treatment of the renal disease.

Specific deformities include genu valgum (most common), genu varum, coxa vara, and varus deformities of the ankle.[14,68] These deformities are most common in patients diagnosed before 3 years of age. Davids et al.[68] showed that periods of metabolic instability, characterized as an alkaline phosphatase of 500 U for at least 10 months, were associated with progression of deformity. With the adolescent growth spurt, osseous deformities can accelerate rapidly over a matter of weeks.[68]

Radiographs show rickets and osteopenia with osteitis fibrosa cystica.[14] Osteoclastic cysts (brown tumors) may form. Metaphyseal cortical erosions occur in the lateral clavicle, distal ulna and radius, neck of the humerus, medial femoral neck, medial proximal tibia, and middle phalanges of the second and third fingers.[135] In renal osteodystrophy, the Looser zone may represent a true stress fracture and, with minor trauma, may extend across the full thickness of the bone with development of a true fracture (Fig. 8-39). Callus may be scanty in patients with fractures who have untreated renal disease, but in patients on hemodialysis, abundant callus may form at the fracture site.[14] Phalangeal quantitative ultrasound may be a useful method to assess bone quality and fracture risk in children and adolescents with bone and mineral disorders.

In renal osteodystrophy, pathologic fractures of the long bones, rib fractures, vertebral compression fractures, and epiphyseal displacement of the epiphyses occur frequently. Fractures occur in areas of metaphyseal erosion or through cysts. Immobilization is used to treat pathologic fractures through both generalized weakened bone and brown tumors. Once the underlying bone disease is under control, open procedures such as curettage of cysts with bone grafting and open reduction of fractures may be considered when appropriate. Internal fixation is preferable to external fixation. Preoperative tests needed for these patients include electrolytes, calcium, phosphorus, and alkaline phosphatase. Before surgery they may need dialysis, phosphate adjustment, either medical correction of hyperparathyroidism, or chelation therapy for aluminium toxicity. Postoperative infection may be more common in patients who are on corticosteroid therapy after renal transplantation.[202]

The incidence of epiphyseal displacement in children with renal osteodystrophy ranges from 20% to 30%.[152] Sites

FIGURE 8-39 This 12-year-old girl with rickets associated with chronic kidney disease presented with complaints of knocked knees and wrist pain. Hip to ankle radiographs **(A)** showed typical rickets changes with valgus deformity at the knee level. Looser lines around the distal femur, and physeal widening. Wrist images **(B, C)** demonstrated marked physeal widening and metaphyseal flare of the distal radius and ulna. (Figures reproduced with permission from The Childrens Orthopaedic Center, Los Angeles, CA.)

of involvement include the distal femur, proximal femur, and proximal humerus, the heads of both the metatarsals and metacarpals, and the distal radial and ulnar epiphyses.[152] In the proximal femur, both femoral neck fractures and slipped capital femoral epiphysis occur.[113] Possible explanations for displacement of the proximal femoral epiphysis include metaphyseal erosion with subsequent fracture,[113,152] and a layer of fibrous tissue that forms between the physis and the metaphysis because of the destructive effects of the renal osteodystrophy. The warning signs and risk factors for slipped capital femoral epiphysis in renal osteodystrophy include subperiosteal erosion of the medial femoral neck, increasing width of the physis, bilateral coxa vara, male gender, and an age between 10 and 20 years (Fig. 8-40).[113] With erosion of the cortex of the inferior medial femoral neck, the femoral head collapses, decreasing the neck shaft angle, and subjecting the physis to shear forces as it assumes a vertical orientation. The slip is bilateral in up to 95% of the patients and it is usually stable.[178,210]

The aggressive medical treatment of renal osteodystrophy, including administration of vitamin D, calcitriol, hemodialysis, renal transplantation, and parathyroidectomy, has improved the long-term survival and quality of life for these patients. Temporary limitation of weight bearing is recommended if there is little metaphyseal erosion, minimal coxa vara, and if fusion of the physis is expected within 1 to 2 years. Continuing displacement of the proximal femoral epiphysis may occur even after pinning, because the fixation holds poorly, possibly because the wide radiolucent zone of the femoral neck in this disorder is

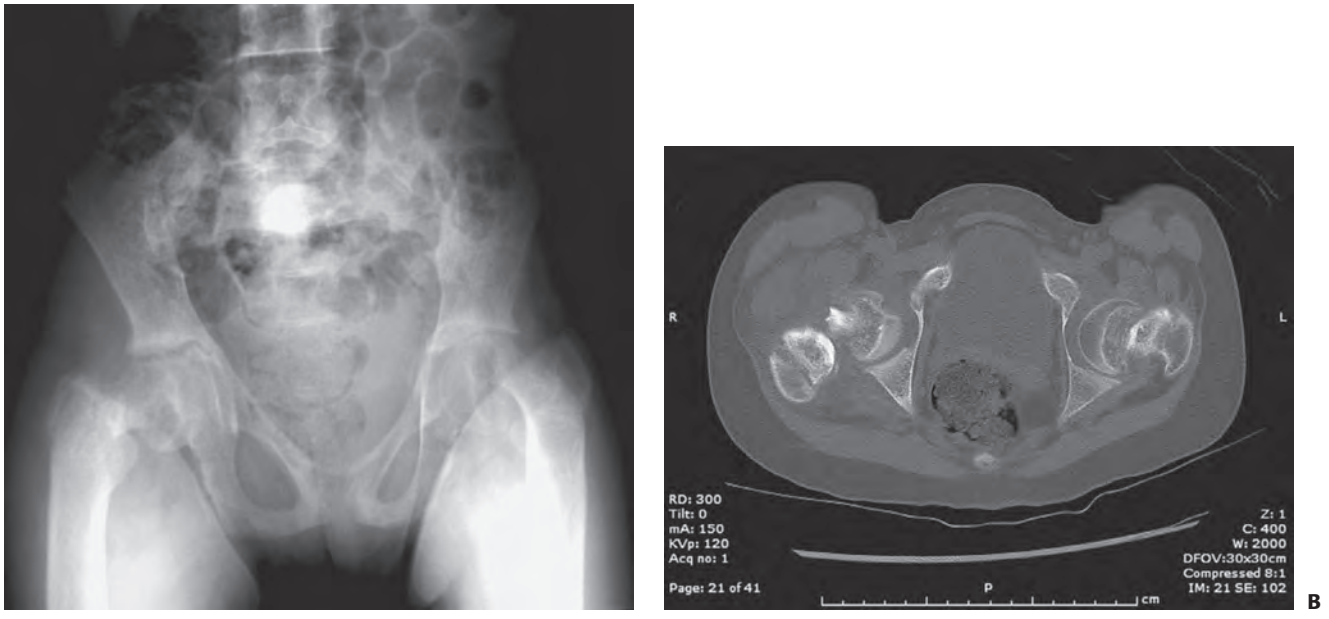

FIGURE 8-40 This 13-year-old boy with renal osteodystrophy presented with bilateral hip and thigh pain. **A:** Anteroposterior pelvic radiograph shows widening of the proximal femoral physes with sclerosis. Slipped capital femoral epiphyses were diagnosed. **B:** This anteroposterior pelvic radiograph taken 9 months after surgery shows narrowing of the physis and no evidence of further displacement of the capital femoral epiphyses. (Figures reproduced with permission from The Children's Orthopaedic Center, Los Angeles, CA.)

not true physis, but rather poorly mineralized woven bone and fibrous tissue.

Smooth pins can be used to stabilize the epiphysis temporarily until medical treatment resolves the underlying bone disease and avoids definitive physeal closure.[178] For patients younger than 5 years, Hartjen and Koman[122] recommended treatment of slipped capital femoral epiphysis with reduction through Buck traction and fixation with a single specially fabricated 4.5-mm cortical screw. The distal threads of the screw were machined off so that only the smooth shank of the screw extended across the physis. Subtrochanteric osteotomy with fixation or total hip arthroplasty may be necessary in older patients with severe coxa vara after slipped capital femoral epiphysis.[113]

Renal Osteodystrophy Complicated by Aluminium Toxicity Oppenheim et al.[211] noted the contribution of aluminium toxicity to the development of fractures in renal osteodystrophy. Because phosphorus restriction is important in children with renal disease, aluminium hydroxide has been commonly used as a phosphate binder.[11] Aluminium intoxication causes defective mineralization. Multiple pathologic fractures may occur with poor healing. Serum aluminium levels are not diagnostic, but the use of deferoxamine, a chelation agent, in an infusion test may provide the diagnosis. A bone biopsy is often necessary. After treatment of the renal disease with correction of the aluminium toxicity by chelation agents, acute fractures will heal. Severe bowing of the long bones caused by fractures can be treated with multiple osteotomies with intramedullary Rush rod or plate fixation.[211] Recurrence of the syndrome is prevented by use of aluminium-free phosphate-binding agents such as calcium carbonate.[237]

Author's Preferred Method of Treatment

Recognition of the underlying metabolic abnormalities is the most important aspect in the care of all of these injuries. Most fractures of the long bones respond readily to cast or splint immobilization, with concurrent aggressive medical treatment of the underlying metabolic disease. Slipped capital femoral epiphysis may be the first presenting sign of renal failure.[113] A slipped capital femoral epiphysis should be stabilized with in situ screw fixation in older children, and multiple screws should be considered because the underlying metaphyseal bone is quite soft. For treatment of progressive slipped capital femoral epiphysis in very young children, some form of unthreaded fixation seems most logical. Femoral neck fractures are treated with anatomic reduction and internal fixation. The underlying bone disease should be medically treated to ensure success of open procedures. Significant cysts should be treated with curettage and bone grafting. Angular deformities of the long bones should be corrected when the patient is close to maturity.

Idiopathic Osteoporosis

Osteoporosis in children is generally associated with congenital diseases such as OI or metabolic disorders such as Cushing syndrome. Rarely, children develop idiopathic osteoporosis with pathologic fractures. The etiology in healthy children is likely multifactorial and incompletely understood. Poor calcium intake during the adolescent growth spurt may play some role. Symptoms can persist for 1 to 4 years after diagnosis,

with spontaneous resolution in most patients after the onset of puberty. The only consistent metabolic abnormality is a negative calcium balance with high rates of fecal excretion of calcium.[131] This finding supports the hypothesis that idiopathic juvenile osteoporosis results from intestinal malabsorption of calcium. Biopsy specimens show a quantitative decrease in the amount of bone that has been linked to both increased resorption[139] and primary failure bone formation.[251]

Idiopathic osteoporosis is characteristically seen 2 years prior to puberty, but age at presentation may range from 4 to 16 years.[251] It usually presents with bone pain, deformities, and fractures. Although many children present with back pain as the only complaint, the most severely affected present with generalized skeletal pain.[139,251] Patients may have difficulty walking, and their symptoms may be initiated by mild trauma. Unique metaphyseal impaction fractures are a hallmark of this disorder.[131] In a review of 40 patients with idiopathic osteoporosis, Smith[251] observed that 87% had vertebral fractures and 42% had metaphyseal fractures.

Generally, 30% of bone mass must be absent before osteoporosis is detected on radiographs.[163] Radiographs of the spine show decreased density in the central areas of the vertebral bodies, and clarity of the dense vertebral end plates is increased. The long bones lose trabecular anatomy and show thinning of the cortex.[131,249] Some authors have noticed that it is mostly a disorder of cancellous bone, reflecting a decreased modelling activity on the endocortical surface of the internal cortex.[226] Some of the issues when dealing with idiopathic osteoporosis in children include the usually difficult interpretation of bone densitometry and turnover markers and poorly established guidelines regarding prevention and treatment of bone fragility. Once symptoms begin, a mildly lucent area of newly formed bone, so called neo-osseous porosis, is observable in the metaphysis (Fig. 8-41). This is considered weaker than the surrounding bone, which formed before onset of the disease.[252]

Serum calcium, phosphorus, and alkaline phosphatase levels are usually normal.[131] Low plasma calcitriol, a vitamin D

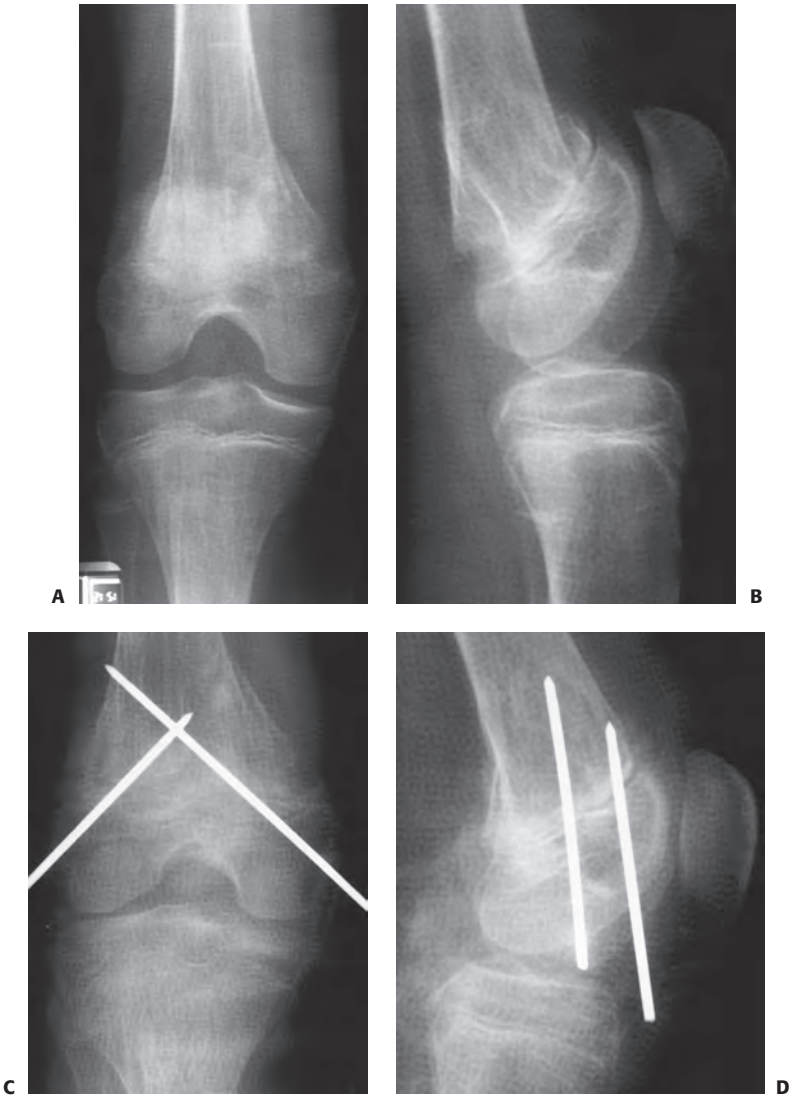

FIGURE 8-41 **A:** Multiple pathologic fractures in a previously healthy teenage boy who developed idiopathic osteoporosis. FIGURE 8-41 (*continued*) **E:** A few months later, he sustained a left proximal femoral fracture, which was treated with a spica cast. **F:** This anteroposterior pelvic radiograph taken 3 years later shows healed proximal femoral fractures with varus angulation and severe osteopenia of the pelvis and femora with profusion of both acetabuli.

metabolite that aids calcium absorption in the gut, has been observed in juvenile osteoporosis.[185]

Lower extremity and vertebral fractures are common, but fractures of the proximal humerus, radius, ulna, and ribs may also occur.[131] Metaphyseal fractures can start as hairline cracks that gradually extend across the width of the shaft, and with further collapse in the femoral shaft, the cracks may telescope into the distal femur, with later distortion of the femoral condyle.[131] Long bone shaft fractures are either transverse or oblique, and the callus formed seems to be normal.[131] No clear-cut effective medical treatment has been found for idiopathic juvenile osteoporosis.[131,139] Many patients have been treated by both vitamin D and calcium supplements with equivocal benefit, and usually mineralization of the skeleton does not improve until puberty, when the disease spontaneously resolves. Low-dose pamidronate may be indicated in the treatment of childhood osteoporosis.[102]

Iatrogenic Osteoporosis

Osteoporosis Associated with Cancer Treatment Osteoporosis is commonly seen in children who are undergoing cancer therapy. The cause of reduced bone mineral density is multifactorial. The disease itself may play a role (e.g., acute lymphoblastic leukemia, malignant bone tumors), but specifically the treatment including corticosteroids, chemotherapy (e.g., methotrexate, ifosfomide), and radiation (such as brain radiation that can reduce growth hormone secretion and cause hypogonadotropic hypogonadism), can contribute to the development of osteoporosis.[236] Methotrexate, for example, is believed to inhibit osteogenesis, causing both delayed union and nonunion of fractures.[224] The incidence of pathologic fractures after methotrexate use ranges from 19% to 57%.[163,224,256]

Generalized demineralization of the skeleton is seen with marked radiolucency of the metaphyseal regions of the long bones. Radiographic changes in the metaphysis and epiphysis resemble those seen in scurvy.[224] Minimally displaced transverse fractures occur in the long bones of both the upper and lower extremities and the small bones of the feet.[224,256]

Schwartz and Leonidas[239] cautioned that stress fractures of the long bones that can occur after methotrexate therapy can be mistaken for recurrence of leukemia. If feasible from an oncologic viewpoint, methotrexate should be discontinued to allow these fractures to heal in a cast. The cast immobilization itself may result in additional osteopenia and fractures even though methotrexate is discontinued.[239] Patients with severe osteoporosis and bone pain without fracture also respond to a halt in methotrexate therapy.[224] Prevention is the key and physical activity, adequate vitamin D intake, and sometimes bisphosphonates are some of the options.[236]

Immobilization Osteoporosis Immobilization of an extremity for fracture treatment can result in loss of as much as a 44% of mineralization of trabecular bone. Immobilization leads to bone resorption, especially in unstressed areas.[163] Osteoporosis may persist for 6 months after an injury, but bone density returns to normal in most by 1 year.[91] Nilsson and **Westlin**[207] found a residual decrease in bone mineralization of the distal femur of 7% at nearly 11 years of follow-up in a study of 30 patients. Persistent osteoporosis after cast immobilization for fracture can also contribute to refracture.

Primary Hyperparathyroidism

Primary hyperparathyroidism in childhood is extremely rare. Although the exact incidence remains unknown, it results from hyperplasia of the parathyroid gland. Symptoms are associated with high serum calcium and inappropriate parathyroid hormone level, causing increased osteoclastic activity, leading to general demineralization of the skeleton and hypercalcemia. In

severely affected patients, osteitis fibrosa cystica may develop with fibrous tissue replacement of bone and formation of cysts. In a large retrospective study, among the 44 children and adolescents, ranging in age from 6 to 18 (mean 13) years, 83% were symptomatic and 43% had nephrolithiasis. Two had multiple endocrine neoplasias.[182]

A particularly severe form of primary hyperparathyroidism seen in infants is congenital primary hyperparathyroidism, which results from an autosomal recessive trait[84] and is lethal without parathyroidectomy. These patients may present with difficulty breathing, hypotonia, poor feeding with constipation, and failure to thrive. Serum calcium is markedly increased in most patients, but a gradual rise above normal serum levels may occur in some infants with serial measurements. Radiographs reveal demineralization of the skeleton. Marked resorption is present in the femoral necks and distal tibias, with decreased trabeculae and poorly defined cortices.[84] Periosteal elevation is common, and when it is severe, the long bones may actually look cloaked with new bone (Fig. 8-42). Periosteal resorption of the bone of the middle phalanges is believed to be characteristic of this disease. Brown tumors are rare in infancy.

In older children and adolescents, the clinical presentation is subtler. Weakness, anorexia, and irritability are present in 50% of patients, and constipation is present in 28%.[32] Renal calculi also are present in 25% of patients, and polyuria, excessive thirst, bone pain, abdominal distension, pancreatitis, and swelling of the knees are occasionally present.[32] Approximately 50% of older patients have osteopenia and other osseous signs of hyperparathyroidism.[32] The serum calcium is only moderately elevated in many patients, but 24-hour urine calcium excretion is abnormally high.[32] If the diagnosis is uncertain, selective venous catheterization for parathyroid hormone can be done, localizing the gland by either ultrasound, CT, or MRI.

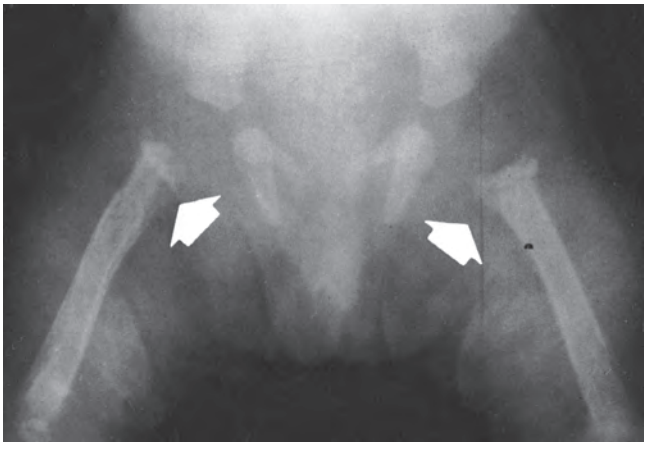
Pathologic fractures of the long bones are common in patients with hyperparathyroidism, especially in infancy. Vertebral fractures, which occur in 4.4% of adult patients,[55] are rare in infancy. Increased levels of parathyroid hormone results in decreased function and numbers of osteoblasts, and hence delayed union of pathologic fractures may occur, mostly in adults.[162] Most fractures are successfully treated with simple immobilization. Occasionally, a fracture through a cyst or brown tumor requires curettage and bone grafting after a period of initial healing.[276]

Cushing Syndrome

Endogenous Cushing syndrome in children is a rare disorder that is most frequently caused by pituitary or adrenocortical tumors, resulting in excessive production of cortisol and its related compounds. If the hyperactivity of the adrenal cortex is caused by pituitary gland stimulation, the syndrome is known as Cushing disease. In children, hypercortisolism is most often caused by carcinoma, adenoma, hyperplasia of the adrenal cortex,[189] or exogenous corticosteroid therapy. The elevated adrenal corticosteroids inhibit the formation of osteoblasts, resulting in increased resorption of the bone matrix and decreased bone formation.[140]

Presenting symptoms include failure to thrive, short stature with excessive weight gain, moon faces, presence of a buffalo hump, hirsutism, weakness, and hypertension.[140,173,189] Cutaneous striae are rare, and the genitalia are of normal size. Mortality is over 50%.[189] In older children, the clinical picture is somewhat different: Truncal obesity, short stature, a lowered hairline, acne, weakness, emotional lability, hirsutism, cutaneous striae, hypertension, and ecchymosis.

Radiographic findings may include severe osteopenia and a retarded bone age. Fractures of the ribs, vertebrae, and long bones have been reported in children with Cushing syndrome.[189] In terms of diagnostic studies, it has been shown that a single



A

B

FIGURE 8-42 **A:** Newborn with hyperparathyroidism. There is marked demineralization of bone, and marked resorption is present in the proximal femurs (*arrows*). **B:** Periosteal elevation is present along the ulna (*arrows*). (Courtesy of Bruce Mewborne, MD.)

cortisol value at midnight followed by overnight high-dosage dexamethasone test led to rapid and accurate confirmation and diagnostic differentiation, respectively, of hypercortisolemia caused by pituitary and adrenal tumors.[26]

The primary treatment of Cushing syndrome of childhood is total adrenalectomy.[189] The associated fractures usually can be treated with standard immobilization techniques, but care should be taken not to increase the extent of osteopenia through excessive immobilization. In patients taking steroids, dose modification is attempted when possible. Also, children and adolescents who have Cushing syndrome may have significant alterations in body composition that result in a small but significant decrease in bone mass and increase in visceral adiposity. Long-term monitoring of body fat and bone mass should be mandatory after treatment.[173]

Scurvy

Scurvy occurs in children who eat inadequate amounts of fresh fruit or vegetables leading to depletion in vitamin C. It takes up to 6 to 12 months before symptoms arise, and those may include asthenia, vascular purpura, bleeding, and gum abnormalities. In 80% of cases, the manifestations of scurvy include musculoskeletal symptoms consisting of arthralgia, myalgia, hemarthrosis, and muscular hematomas.[93] Because vitamin C is essential for normal collagen formation, deficiency results in defective osteogenesis, vascular breakdown, delayed healing, and wound dehiscence. Children may experience severe lower limb pain related to subperiosteal bleeding. Although scurvy is often caused by a dietary deficiency of vitamin C,[203] both aspirin and phenytoin are associated with decreased plasma levels of ascorbic acid. Vitamin C deficiency may also be present in myelomeningocele, although its contribution to fracture in that population is unclear. Infants with scurvy may present with irritability, lower extremities tenderness, weakness, pseudoparalysis, and possibly bleeding gums (if teeth have erupted). Subperiosteal hemorrhages may exist as well as hemorrhage into the subcutaneous tissues, muscles, urinary system, and gastrointestinal tract.[248] Anemia is also a common finding. In developing countries, older children with scurvy presenting with inability to walk may be misdiagnosed as having poliomyelitis.[225]

Radiographs may show osteolysis, joint space loss, ON, osteopenia, and/or periosteal proliferation. Trabecular and cortical osteoporosis is common.[93] Profound demineralization is evident. In advanced disease, the long bones become almost transparent with a ground-glass appearance and extreme thinning of the cortex. Calcium accumulates in the zone of provisional calcification adjacent to the physis and becomes densely white (Fränkel line). Fractures generally occur in the scurvy line (Trummerfeld zone)—the radiolucent juxtaepiphyseal area above Fränkel line where the matrix is not converted to bone. Dense lateral spurs, known as the Pelken sign, may be seen.[240,248] A characteristic finding of scurvy is the corner sign in which a peripheral metaphyseal defect exists where fibrous tissue replaces absorbed cortex and cartilage.[115] Cupping of the metaphysis is common in both scurvy and rickets; in rickets, the metaphysis is ragged, whereas in scurvy, the metaphysis is sharply outlined.[115] The epiphysis becomes ringed with a thin, dense line (Wimberger sign). The periosteal elevation caused by hemorrhage calcifies within 10 days of treatment with vitamin C (Fig. 8-43).

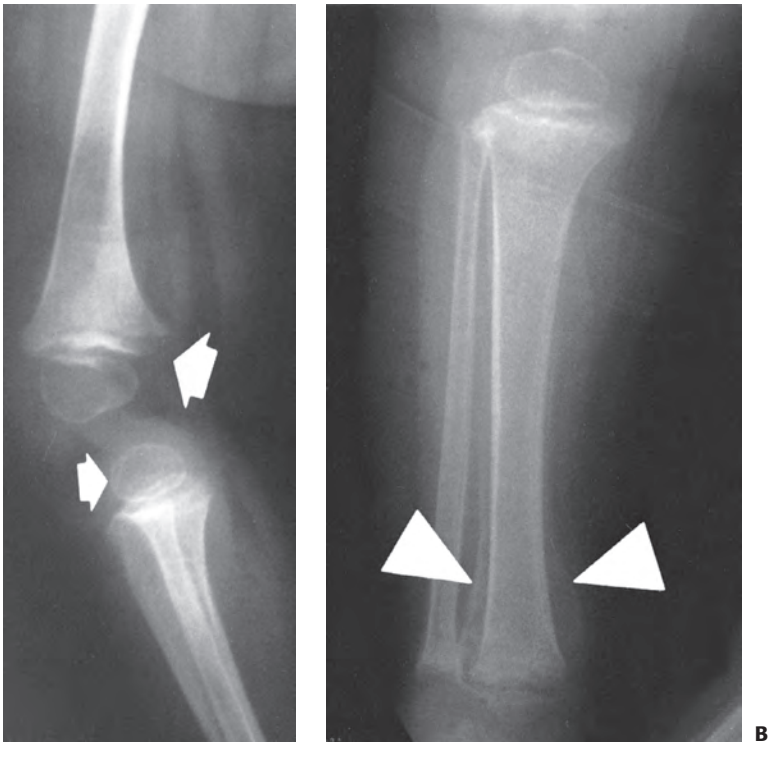


FIGURE 8-43 Scurvy. **A:** A 10-month-old boy presented with a 2-week history of refusal to walk with tenderness of the lower extremities. He had a history of milk and cereal intake only. There are signs of scurvy in the metaphysis (*large arrow*). The dense white line in the zone of the provisional calcification of the distal femur is known as the Fränkel line. The radiolucent juxtaepiphyseal line above the white line is known as the scurvy line. The peripheral metaphyseal defect, where fibrous tissue replaces absorbed cortex in cartilage, is known as the corner sign. Wimberger sign is a thin, dense line surrounding the epiphysis (*small arrow*). **B:** This is a child with healing scurvy. There is marked periosteal calcification around the distal tibia (*arrows*).

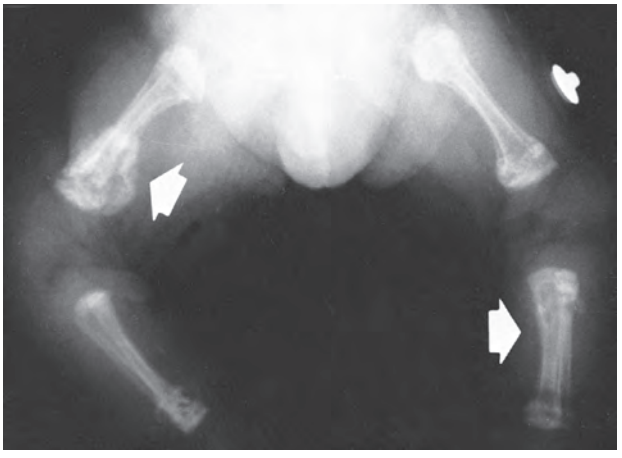
(*continues*)



C

FIGURE 8-43 (*continued*) **C:** A newborn with scurvy. Periosteal hemorrhage has become calcified in the bones of the lower extremity (*arrows*). (Courtesy of Bruce Mewborne, MD.)

Fractures and epiphyseal displacement may occur in both infants and older children with scurvy.[115,180,240,248] The most common sites of fracture, in the order of frequency, are the distal femur, proximal humerus, costochondral junction of the ribs, and distal tibia.[115] Fractures of the long bones generally are nondisplaced metaphyseal buckle fractures with mild angulation. In contrast, marked epiphyseal displacement occurs with a moderate amount of callus present even in untreated patients. Exuberant callus forms once vitamin C is administered. Standard immobilization, with administration of vitamin C, is adequate for most fractures. Remodeling potential is high in these patients.[240] Even healed fractures that may appear to have undergone growth arrest should be observed, because there is potential for continued growth with medical treatment.[248] For infants who are older than 12 months of age and have begun weight bearing, spine films are recommended to rule out vertebral fractures.[180]

The literature regarding fracture treatment in scurvy consists primarily of case reports. Hoeffel et al.[127] reported on a 14-month-old girl with scurvy with bilateral distal femoral epiphysis displacement. This condition resolved after treatment with vitamin C, but limb-length discrepancy developed on one side. In two patients with distal femoral fractures, healing led to cupping of the metaphysis with an appearance similar to that in central growth arrest.[248]

Copper Deficiency and Scurvy-Like Syndrome

Copper is a vital trace element needed in the production of collagen. Copper deficiency results in a decreased number of collagen crosslinks, with adverse effects on both bone and blood vessels.[116] Copper deficiency can occur by 3 months in low–birth-weight infants[125] and after prolonged total parenteral nutrition. Copper deficiency can also develop as a result of excessive supplemental zinc ingestion.[40] Another cause of copper deficiency is disruption of one gene on the X chromosome causing a defect in the process of copper absorption, with consequent deficiency of available copper at the cellular level, resulting in abnormalities of collagen formation and brain maturation, leading to early death.[271]

Infants at risk for nutritional copper deficiency are those who are primarily milk fed and are on semistarvation diets with concurrent vomiting and diarrhea.[61] Both rib and wrist enlargement are frequent,[116] and neutropenia is common.[125] The diagnosis is commonly based on clinical presentation and decreased levels of serum copper.

Rarely, disruption of the copper controlling gene on chromosome 13 is associated with accumulation of excess copper in the body, initially in the liver and brain. With time, copper accumulates in the kidneys, causing renal damage and osteoarticular changes (e.g., osteoporosis, osteomalacia, and pathologic fractures).[271]

Radiographic findings in copper deficiency syndrome are very similar to those in rickets, including metaphyseal cupping, flaring, demineralization of the skeleton, and subperiosteal elevation with calcification.[61,116] There are some radiographic differences between scurvy and copper deficiency syndrome. The corner sign is frequently absent in copper deficiency, the metaphyseal spurs are not strictly lateral but sickle shaped, and radiolucent bands of the metaphysis are absent.[116] Bone age also is frequently retarded. Pathologic fractures have been reported in copper deficiency syndrome. Cordano et al.[61] noted prompt healing of a distal femoral fracture in an infant, but the fracture recurred before treatment of the copper deficiency. Such injuries can be treated like those in scurvy, with simple immobilization and concurrent correction of the copper deficiency.

Fractures in Neuromuscular Disease

Cerebral Palsy

Neuromuscular diseases, such as cerebral palsy (CP) may be associated with osteoporosis. The main causes of low bone density and osteoporosis in children and adolescents with CP are lack of activity, nutritional, and pharmacologic treatments (e.g., anticonvulsivants drugs).[218]

In a review of 1,232 institutionalized patients with cerebral palsy, Mclvor and Samilson[191] documented 134 extremity fractures, primarily in quadriplegics. When the mechanism of injury was known, most of these fractures were the consequence of a fall, often associated with seizure activity. Approximately 46% of these fractures involved the femoral shaft, 6% were fractures of the head or neck of the femur, 15% involved the tibia and fibula, and 13% were humeral fractures. These authors believed that contracture or paralytic dislocation of the hip joint predisposed these patients to femoral fractures. Presedo et al.[222] reported on 156 children with CP who were treated for fractures. The mean age at the time of the first fracture was 10 years; 66% of patients had spastic quadriplegia, of those 83% were nonambulatory. Most fractures (82%) occurred in the lower limbs. The main risk factor was nonambulatory CP child on anticonvulsant therapy.[223] In another large multicenter study including 364 children with moderate-to-severe motor impairment, the rate of fracture was 4% per year. Children with greater body fat, feeding gastrostomy, and history of fracture

were at highest risk of fractures.[259] Leet et al.[172] reported on 418 children with CP: 243 (58%) had quadriplegia, 120 (29%) had diplegia, and 55 (13%) hemiplegia. Of these, 366 were spastic, 23 mixed tone, 13 athetoid, and 16 classified as others. Pathologic fractures were seen in 50 children (12%). Older age at first fracture and use of valproic acid were predictive of fractures and defined a group of children who may benefit from treatment interventions to increase bone density.

The diagnosis may be delayed because patients are often noncommunicative. Anticonvulsant therapy may contribute to osteoporosis; low levels of serum vitamin D were seen in 42% of patients in one series.[167]

Although long-bone fractures in patients with cerebral palsy heal quickly with abundant callus, their treatment through either closed or open methods can be quite difficult. In a large series of patients, McIvor and Samilson[191] recommended closed treatment through skeletal traction, hip spica cast, or long-leg cast. Approximately 65% of the femoral shaft fractures and 86% of distal femoral fractures went on to malunion. Despite malunion, most patients regained their prefracture function. Nearly 21% of their patients had refractures, and the authors believed that this was because of disuse osteopenia, inadequate reduction, or joint contractures. Closed treatment of these fractures can be complicated by the development of decubitus ulcers. Closed fractures, especially those of the femur, can become open injuries during treatment, owing to spasticity or inadequate immobilization.[191] The healing time of femoral fractures treated through immobilization varies from 1 to 3.5 months.[191] Fractures of the humerus have been treated with light hanging-arm casts or sling-and-swath bandages. Hip nails with side plates, compression plates, and intramedullary fixations also have been used for femoral shaft fractures in patients with CP. The mean healing time has been 5.3 months.[191]

Heinrich et al.[124] treated four femoral fractures in young patients with CP with flexible intramedullary nails with good outcomes. Femoral neck fractures may require in situ pinning, but observation may be adequate in asymptomatic bedridden patients. Although he advocated open fixation of some lower extremity fractures in patients with developmental delays, Sherk[244] cautioned that some patients may have inadequate motivation to resume ambulation even with successful healing of their injuries. Medical management of these patients must also be emphasized. In patients with cerebral palsy and multiple fractures, Lee and Lyne[167] recommended metabolic supplementation, along with traditional fracture care.

In a randomized controlled trial of standing program impact on bone mineral density in nonambulant children with CP, participation in 50% longer periods of standing (in either upright or semiprone standing frames) improved vertebral but not proximal tibial volumetric trabecular bone mineral density. The authors concluded that such intervention might reduce the risk of vertebral fractures but is unlikely to reduce the risk of lower limb fractures in children with CP.[52]

Fractures of the distal pole of the patella have been reported in children with CP caused by spasticity of the extensor mechanism of the knee in the presence of established knee flexion contracture.[176,234] Lloyd-Roberts et al.[176] reported on eight patients with this injury who presented with deterioration in walking and decreased endurance. All had knee flexion contractures. Seven of the eight patients complained of pain and local tenderness at the distal pole of the patella. In a series of 88 patients, fragmentation was seen in only 8%.[234] Children predisposed to distal pole patellar fractures are spastic ambulalors with flexion contractures of the knees, patella alta, and a history of falls. Extension casting maybe helpful in symptomatic patients.[234] If conservative treatment is unsatisfactory, then hamstring lengthening with correction of the knee flexion contracture can result in both healing of the fracture and relief of symptoms.[176,234] Some authors[176] also have excised the avulsed distal pole of the patella to relieve chronic symptoms.

Although less common than metaphyseal and diaphyseal fractures, epiphyseal separations may occur. In a report of nine epiphyseal separations involving the distal femur and proximal humerus, in four severely affected children with spastic quadriplegic CP, the clinical-radiologic features confirmed the cause to be scurvy. The fractures healed nicely with treatment with vitamin C and splintage.[18]

Author's Preferred Method of Treatment

Prevention is an important part of managing fractures in children with CP. Traditionally, long-leg casts or spica casts were used after multiple muscle lengthening or hip osteotomies, then after several weeks, the cast was removed and therapy had begun. After cast treatment, however, the osteopenia was worse, the joints were stiff, and fractures—especially in the distal femoral metaphysis—occurred during therapy or transfers. Foam abduction pillows and knee immobilizers and an intensive therapy program in the immediate postoperative period may avoid the deconditioning, osteopenia, and joint stiffness that develop after prolonged cast immobilization. In ambulatory children who need hip osteotomies, use of rigid internal fixation allows standing and gait training within 2 weeks, preventing not only osteopenia but also the risk that the child may never regain the full level of preoperative function after a prolonged period of cast immobilization.

The goal of fracture care in CP is to restore the child to his or her prefracture level of function. In nonambulatory children with CP, one goal should be to preserve the ability to transfer. In children with severe CP, some degree of both malunion and shortening may be accepted. The patients' spasticity and inability to communicate make them prone to skin problems, so casts should be properly applied and well padded, usually with felt and polyurethane foam. Extra padding should be placed over the patella, anterior ankle, and heel, and a snug cast mould should be placed above the calcaneus to prevent proximal migration of the heel. If the patient is ambulatory, conventional forms of fracture treatment may be used (Fig. 8-44). When indicated fixation with titanium elastic intramedullary nails can be a very effective way to treat femoral fractures (Fig. 8-45).

Distal femoral buckle fractures in nonambulatory children are safely treated with a knee immobilizer. For metaphyseal

distal femur fractures adjacent to contracted knee, casting can be used to improve limb alignment (pseudo-osteotomy). If a long-leg cast is used for a fracture of the lower extremity and the joint of the involved side is dislocated, the rigid cast may function as a lever arm, with the posterior fracture of the proximal femur beyond the cast (Fig. 8-46).

Myelomeningocele

Children with myelomeningocele are at a high risk of pathologic fractures of the lower extremities. The etiology is multifactorial but results from decreased bone mineral density because of disuse (nonambulators), immobilization after reconstructive surgical procedures, and increased urinary calcium loss.[177] Numerous other factors predispose these patients to fracture. For example, children with flail limbs tend to pick up one leg and drop it out of the way when they roll over in bed or twist around while in a sitting position, and this may be enough force to cause a fracture. Because protective sensation is absent, the child can neither anticipate impending injury nor be aware of injury once it has occurred.

The incidence of fractures in children with myelomeningocele ranges from 12% to 31%.[80,81] The location of these fractures, in the order of decreasing frequency, are midshaft of the femur, distal femur, midshaft of the tibia, proximal femur, femoral neck, distal femoral physis, and proximal tibia.[80] Fractures may involve any segment of the bone, it's usually a result of a minor trauma, and often incomplete or impacted.[177] They tend to heal rapidly, except for physeal fractures, and nonunion is rare.[80,274]

The level of neurologic involvement also affects the incidence of fractures. In a series of 76 fractures, Lock and Aronson[177] found that 41% occurred with neurologic deficit at the thoracic level, 36% occurred with deficit at the upper lumbar level, and only 13% occurred in patients with lower lumbar or sacral deficits. Nearly 86% of these fractures occurred before 9 years of age, and 76% were associated with cast immobilization. Most fractures after immobilization occur within 4 weeks of cast rem oval.[81,177,193] In addition to the inherent disuse osteoporosis from immobilization, casting causes stiffness of joints with concentration of force on the osteoporotic bone adjacent to the joints.[177] Boytim et al.[42] reported neonatal fractures in six infants with myelomeningocele and concluded that the risk of fracture was 17% for patients with thoracic or high lumbar level deficits with significant contracture of the lower extremities. The authors cautioned that particular care must be used to avoid fractures in these patients during physical therapy, positioning for radiographs, or surgical procedures. Fractures associated with spina bifida are, however, most commonly seen in early adolescence.[19]

Norton and Foley (1959)[209] stated that "the quality of bone developed by activity appears to be the best protection against pathologic fractures," and the orthopedist should assist spina bifida patients in maintaining the highest activity level possible. Stable fractures of the long bones may not require complete or rigid immobilization.[81] Femoral shaft fractures have been treated with padding and sandbags, skin traction of anesthetic limbs may cause massive skin necrosis and is contra-indicated.[80] Skeletal traction usually is inadvisable because of problems with decubitus ulcers and poor fixation to atrophic bone.[80] Preventive measures include limiting cast immobilization after reconstructive surgery. Solid side cushions may prevent fractures that occur when patients catch their lower extremities in bed rails.

Fractures of the physes in patients with myelomeningocele are relatively uncommon and difficult to diagnose.[150] The clinical presentation may mimic infection, with elevated temperature and swelling, redness, and local warmth at the fracture site.[230,266] Fractures of the proximal tibia may be confused with septic arthritis of the knee, with swelling up to the midthigh and limited knee flexion. Both the white blood cell count and erythrocyte sedimentation rate are often elevated. Immobilization of these injuries usually results in a dramatic decrease in swelling and redness of the extremity within 2 to 3 days of casting. With healing, the radiographic picture can be alarming, with epiphyseal plate widening, metaphyseal fracture, and periosteal elevation. The radiographic differential diagnoses should include osteomyelitis, sarcoma, leukemia, and Charcot joint.[88] Physeal fractures require lengthy immobilization with strict avoidance of weight bearing to avoid destructive repetitive trauma to the physis.[88] Either a plaster cast or a snug-fitting total-contact orthosis is suggested for immobilization, and union can be determined by return of the physis to normal width on radiographs. Kumar et al.[160] emphasized that application of a long-leg cast for 8 to 12 weeks is necessary to obtain satisfactory healing of physeal fractures of the tibia, and weight bearing is to be avoided until union occurs.

Recurrent trauma to the physis, from either continued walking or passive joint motion after injury, results in an exuberant healing reaction (Fig. 8-47).[88] Repetitive trauma delays resumption of normal endochondral ossification, resulting in abnormal thickening of the cartilage in the zone of hypertrophy and the physeal widening seen on radiographs. In a study of 19 chronic

physeal fractures, Rodgers et al.[231] compared MRI with histology and found that adjacent to this thickened, disorganized zone of hypertrophy is juxtametaphyseal fibrovascular tissue that enhances gadolinium on MRI. Delayed union is common, and premature growth arrest occurs in 29% to 55% of patients.[177]

Anschuetz et al.[12] reported a unique syndrome in three patients with myelomeningocele and fracture. These children sustained fractures of the lower extremities during long-term immobilization and with cast removal went on to dramatic cardiopulmonary distress with increased pulse rate, hypotension, and increased respiratory rate. Fever also developed with decreased hematocrit levels. They suggested that the etiology of this problem was loss of intravascular volume into the fracture sites and recommended intravenous replacement of fluid losses, along with careful splinting of associated fractures.

Lock and Aronson[177] used Webril immobilization for an average of 1 to 3 weeks in their patients with fractures and discontinued immobilization when callus was visible. They found similar outcomes in patients treated with Webril dressings and those treated with casts; however, there was much less difficulty with pressure sores in the group treated with Webril dressings. Kumar et al.[160] used a polyurethane padded long-leg posterior plaster splint for metaphyseal and diaphyseal fractures for 3 weeks, followed by bracing. Drennan and Freehafer[80] recommend a well-padded cast for 2 to 3 weeks for infants with fracture and braces or Webril immobilization for incomplete fractures that followed surgery. Injuries with deformity were placed in a cast. Mobilization was begun as soon as practical to prevent further osteopenia, as early as 2 weeks after injury. Lock and Aronson[177] cautioned that brace treatment of acute fractures may cause pressure sores. Drummond et al.[81] reported on 18 fractures treated by closed techniques that resulted in three malunions, two shortenings, and two episodes of pressure sores; one patient had four refractures. Drabu and Walker[78] noted a mean loss of knee movement of 58 degrees in 67% of fractures about the knee. The stiffness began 2 months after fracture and was well established by 6 months but resolved almost completely in all patients 3 years after injury. They suggested that aggressive physical therapy to restore knee motion is probably not necessary in these injuries.

Operative fixation of fractures in children with myelomeningocele is associated with a high rate of infection. Bailey-Dubow rods may be valuable in multiple recurrent pathologic fractures of the femoral or tibial shaft. If operative treatment is necessary, it should be noted that the incidence of malignant hyperthermia is higher in patients with myelomeningocele than in other children.[10]

Life-threatening anaphylactic reactions caused by latex allergy in children with myelomeningocele have been reported with increasing frequency.[77,177] Minor allergic reactions, such as rash, edema, hives, and respiratory symptoms, are common when children with myelodysplasia are exposed to latex products such as gloves, catheters, and balloons. Between 18% and 40% of children with myelodysplasia are allergic to latex.[95] Meeropol et al.[193] emphasized that every child with myelomeningocele should be screened for latex allergy, and those with a positive history should be evaluated individually by the anesthesiologist for preoperative prophylaxis. Current preoperative prophylaxis begins 24 hours before surgery and is continued for 24 hours after surgery. Medications used include diphenhydramine 1 mg/kg every 6 hours (maximum 50 mg), methylprednisolone l mg/kg every 6 hours (maximum 125 mg), and cimetidine 5 mg/kg every 6 hours (maximum 300 mg). A latex-free environment must also be provided throughout the hospitalization.

Author's Preferred Method of Treatment

In nonambulatory patients, mild malunion and shortening can be tolerated, and stable or minimally angulated fractures can be treated with either polyurethane splints or Webril dressings. Fractures with significant deformity may require reduction and immobilization in a cast heavily padded with polyurethane foam. In children who walk, fractures should be carefully aligned with heavily padded casts that allow continued protective weight bearing, if possible. Hip spica casts may be necessary for femoral shaft fractures. Fractures of the proximal femur should be treated by immobilization and any later deformity corrected by osteotomy. Any patient considered for operative intervention should be treated prophylactly with latex-free gloves and equipment. Physeal fractures are best treated with semi-rigid fiberglass or immobilizer for short period of time (2–3 weeks) to avoid further osteopenia and other fractures. Long-term follow-up is encouraged for physeal injuries because of the risk of growth arrest.

Muscular Dystrophy

Fractures of the lower extremity in children with Duchenne muscular dystrophy must be managed so as not to cause premature loss of the ability to walk[190] or transfer.[137] In patients 9 to 10 years old, increasing muscle weakness and joint contractures contribute to falls, and a loss of normal muscle bulk and fat limit the cushioning on impact.[246] Patients in lower extremity braces seem to sustain fewer fractures in falls, probably because the overlying orthoses provide some protection.[246] Patients confined to a wheelchair can fall because they have poor sitting balance, and fractures are frequent because these patients are more osteoporotic than ambulatory individuals.[246]

Corticosteroid therapy given to children with Duchenne muscular dystrophy to prolong mobility has been shown to increase the rate of osteoporosis and consequently, increase the risk of fracture. In a chart review of 143 boys with genetically confirmed dystrophinopathies, boys treated with steroids ambulated independently 3.3 years longer than the untreated group and had a lower prevalence of scoliosis. However, vertebral compression fractures occurred in 32% of the treated group, whereas no vertebral fractures were seen in the nontreatment group; long-bone fractures were 2.6 times greater in steroid-treated patients.[151] A study of 33 boys with Duchenne muscular dystrophy demonstrated the incidence of vertebral fractures in these patients after the initiation of corticosteroid treatment;

40 months after commencement of steroids the first vertebral fracture emerged, and by 100 months of treatment, approximately 75% of patients had sustained a vertebral fracture.[41]

Concentric "osseous atrophy" occurs in the long bones of patients with Duchenne muscular dystrophy; osteoporosis is also common.[188] Osteoporosis is most profound in the lower extremities and begins to develop early while still ambulating. Consequently, frequent fractures may result in loss of ambulation.[164] Larson and Henderson[164] reported that bone density in the proximal femur was profoundly diminished even when gait was minimally affected, and then progressively decreased to nearly four standard deviations below age-matched normal. Fractures are seldom displaced and are frequently minimally painful because there is minimal muscle spasm.[246] Fractures tend to heal rapidly. The most commonly fractured bone is the femur followed by the proximal humerus.[137,246]

There are two goals of fracture care in children with muscular dystrophy: Limb stability and maintenance of maximal function during fracture healing. In ambulatory patients, treatment methods should allow children to maintain the ability to walk as the fracture heals. When ambulatory ability is tenuous, even minor bruises or ankle sprains may end walking ability. As little as 1 week in a wheelchair can prematurely end ambulation; patients at bed rest for more than 2 weeks will likely lose the ability to ambulate.[190] Hsu[136] reported that 25% of ambulatory patients with muscular dystrophy lost the ability to walk after sustaining fractures. In one of these patients, the ankle was casted in 20 degrees of plantarflexion, and the resulting contracture prevented ambulation at the end of treatment.

Treatment of specific fractures should be individualized. Upper extremity fractures can be treated with lightweight slings.[246] Lower extremity fractures can be treated with either light walking casts or long-leg double upright braces.[246] Splints also can be used until the patients are pain free. Routine activities are begun as soon as possible. Protected standing and ambulation with physical therapy are crucial in maintaining independent ambulation (Fig. 8-48).

Hsu and Garcia-Ariz[137] reported on 20 femoral fractures in 16 patients with muscular dystrophy. Six of the seven ambulatory patients were able to walk after treatment. In the nonambulatory patients in this series, most had supracondylar femoral fractures which were splinted for 2 to 3 weeks, with emphasis on physical therapy to maintain functional abilities. Although union was achieved rapidly, hip and knee flexion contractures often increased in these patients and up to 20 degrees of angulation of the fracture was routinely accepted. One patient with slipped capital femoral epiphysis was treated successfully with pinning in situ.

Author's Preferred Method of Treatment

The first goal of fracture treatment in children with muscular dystrophy is to avoid making matters worse. The patient should be mobilized as soon as possible in a lightweight cast or orthosis. Aggressive physical therapy should be used to maintain functional status. In a very young child, midshaft femoral fractures can be treated by traction and hip spica techniques, but in an older patient, ambulatory cast bracing might be a better choice.

Arthrogryposis

Arthrogryposis is a group of rare and heterogeneous disorders affecting children in whom there are at least two or more joint contractures in multiple body areas. There are at least a few hundred arthrogrypotic syndromes. Arthrogryposis has an incidence of 3 in 10,000 live births.[277] Although the etiology is unknown and likely multifactorial, there is a lack of fetal joint movement after initially normal development, leading to

collagen proliferation, fibrotic replacement of muscle, a marked thickening of joint capsules, taut ligaments, and capsular tightness resulting in joint stiffness.[118] Dislocations can occur with severe shortening of the involved muscles.

Fractures may occur in 25% of infants with arthrogryposis.[70] A difficult delivery or forceful manipulation of the extremities can lead to fracture.[70] Diamond and Alegado[70] reported 16 fractures in nine infants with arthrogryposis; an ipsilateral dislocated hip was present in 35% of patients. Most fractures involved the femur, with the remainder mostly tibial fractures, one humeral fracture, and one clavicle fracture. Epiphyseal separations occurred in the proximal tibia, distal femur, and proximal humerus. Clinical symptoms included poor feeding, irritability, and fussiness when handled. The involved extremity was thickened, and there was often an increased white blood cell count. Plain radiographs after acute injury, especially with epiphyseal separations, were not helpful, and arthrogram was used in one patient to evaluate a distal femoral epiphyseal separation. With healing, these fractures develop exuberant callus with rapid union and ready remodeling of angulated midshaft fractures.

Short-term immobilization is adequate to treat nondisplaced fractures in these patients (Fig. 8-49). Postnatal fractures are most common in patients with either knee contracture or dislocation of the hip, and postnatal injury could possibly be reduced by avoidance of forceful manipulation of these extremities. Older patients with lower extremity contractures do not seem to have increased risk for pathologic fractures.

9 THE ORTHOPEDIC RECOGNITION OF CHILD MALTREATMENT

Richard M. Schwend, Laurel C. Blakemore, and Kristin A. Fickenscher

Introduction

Terminology

Child maltreatment is any act or failure to act on the part of a parent or caretaker which results in death, serious physical or emotional harm, sexual abuse or exploitation, or an act or failure to act which presents an imminent risk of serious harm.[272] Child maltreatment includes all types of abuse and neglect that occur among children under the age of 18 years.[221] The four common types of maltreatment include physical, sexual, and emotional abuse as well as child neglect.[130] Maltreatment can be acute or chronic over a number of years, with worse outcomes when inflicted over a number of years with multiple events.[137] Neglect is the most frequently encountered type of child maltreatment.[79] Psychological maltreatment is increasingly recognized to be as harmful as other types of maltreatment.[116] Recent terminology for a battered child, physical abuse, or child abuse include child maltreatment, nonaccidental injury (NAI), inflicted injury, or nonaccidental trauma (NAT).[93] Child maltreatment occurs when a parent or caregiver is the perpetrator; whereas bullying involves maltreatment by another child.[146]

Epidemiology

The National Child Abuse and Neglect Data System (NCANDS) was initiated in response to Public Law 93–247 to collect and analyze child abuse statistics.[271] NCANDS documents

that the epidemic of child abuse continues to worsen in the United States, with approximately 3.6 million reports (47.8 per 1,000 children) filed in federal fiscal year 2006 compared to 1.2 million in 1982.[272] Approximately one-quarter of these children who received an investigation were confirmed to have been abused or neglected. This represents a victim rate of 12.1 per 1,000, totaling 905,000 US children in 2006.[272] Approximately 60% of confirmed cases are neglect, 16% physical abuse, 10% sexual abuse, and 7% psychological abuse.[221] Reports by professionals are more likely to be confirmed. Although children under the age of 4 years are at greatest risk for maltreatment, the victim rate is highest for infants, totaling 91,278 (23.2 per 1,000 population over the course of less than a year).[53] Newborns in the first week of life may be at the highest risk, with a total of 29,881 reported cases, 70% of which were reported for neglect.[221] One of every 1,000 abused children in the United States die.[135] Three children die of abuse or neglect each day,[274] with 50% to 80% having evidence of a prior injury. The World Health Organization estimates that 57,000 children worldwide die from maltreatment, while more than 1,500 die in the United States.[166] However, mortality rates are commonly underestimated.[69,114] Nineteen percent of maltreatment fatalities occur in infants; whereas, newborns in the first week of life have greatest risk of death.[221] Abuse is second only to sudden infant death syndrome (SIDS) for mortality in infants 1 to 6 months of age and second only to accidental injury in children older than 1 year. The incidence of abuse is three times that of developmental dysplasia of the hip or clubfoot. Fortunately, there is some evidence that abusive fracture incidence may be decreasing over the past 24 years, possibly because of a general increase in recognition of child maltreatment and more preventive services available to families.[174]

The estimated national cost of child abuse for the child welfare system is 14 billion dollars, law enforcement 24 million, and the court system 341 million.[274] The long-term social costs of child abuse are substantial: One-third of the victims of child abuse grow up to be seriously dysfunctional, neglectful, or abusive parents; one-third are at high risk for eventually becoming abusive parents; and only one-third do not repeat the destructive patterns they were exposed to as children.[206,252] Exposure to adverse childhood experiences has a high probability of both recent and lifetime depressive disorders.[59] Direct and indirect total estimated national costs of child abuse, including special education for learning disorders of abused children, maternal mental and health care, legal costs of juvenile delinquency, lost productivity to society of abused and neglected children as unemployed adults, and later adult criminality of abused and neglected children in 2012 is 124 billion dollars.[54]

The orthopedist becomes involved in the care of 30% to 50% of abused children.[5] Early recognition by the orthopedist is critical because children returned to their homes after an unrecognized episode of child abuse have a 25% risk of serious reinjury and a 5% risk of death.[230] Jenny and Isaac[133] have noted a threefold increased mortality rate of children who have been listed on state abuse registry for all types of abuse. The mortality rate is highest for those who are physically abused, especially infants.[133]

Overview

In 1946, Caffey[45] described six infants with long-bone fractures, chronic subdural hematomas, and intraocular bleeding without a history of trauma to explain the injuries; however, he did not speculate about the etiology of the children's injuries. Although his work is cited as the first report in the English literature of child abuse, it was Ambroise Tardieu, the prolific French forensic physician, who during the mid-1800s described in great detail the condition of sexual abuse in children, as well as the battered child syndrome.[168] In 1953, Silverman[240] characterized the unique metaphyseal fractures found in abused children and clearly emphasized that these were because of NAT. Altman and Smith[8] published the first series in the orthopedic literature of injuries caused by child abuse in 1960. General public awareness of child abuse increased with the 1962 publication of a report by Kempe et al.[145] characterizing the problems as the battered child syndrome. In 1974, Caffey[46] introduced the term "whiplash-shaken infant syndrome" to the literature to emphasize the etiology of subdural hematomas in infants caused by shaking episodes. In 1974, Congress acknowledged the national importance of the prevention of child abuse by the passage of the Child Abuse Prevention and Treatment Act.[271] Because pediatric personnel and hospital-based child protection teams must be aware of reporting requirements for child maltreatment, there are published guidelines for the establishment and management of hospital-based child protection teams.[193]

The Risk Factors for Child Abuse

The Home at Risk

In assessing where child abuse may occur, households in turmoil from marital separation, job loss, divorce, family death, housing difficulties, or financial difficulties are more likely to have abusive episodes.[81] When one twin is abused, the second twin is at higher risk to be concurrently abused than a nontwin sibling or contact.[180] One of the most important predictors of abuse is the presence of a nonrelated adult living in the household. Compared to single parent families, death caused by child abuse was noted to be 50 times higher in households that had unrelated adults; the perpetrator was the unrelated adult in 83.9% of these cases.[231] Families with two unplanned births are 2.8 times more likely to have an episode of child abuse than families with no unplanned births.[285] Stepparents, babysitters, boyfriends, relatives, and even larger siblings may be abusers.[4,115,207,236] Young, unmarried mothers are more likely to have an infant death from intentional injury, with a peak incidence of 10.5 intentional deaths per 10,000 live births.[237] In a study of 630 fractures in 194 abused children, the perpetrator was identified in 79% of cases.[248] Sixty-eight percent of the perpetrators were male, and 45% of the time the biologic father was responsible. Abused infants were significantly younger (4.5 months of age) when a male had abused the child, than when a female was the abuser (10 months of age). The parents of battered children may themselves have been abused when they were children.[100] High levels of parental stress and belief in corporal punishment are associated with child abuse.[68] Parental substance abuse, whether alcohol or other drugs, makes child

TABLE 9-1 Parental Predictors of Child Abuse

General
- Unrelated adult living in the home[a]
- Parent history of child abuse
- Divorce or separation of mother's parents
- Maternal history of being separated from mother, parental alcohol, or drug abuse
- Maternal history of depression
- Child attends a home day care

Mother
- Age less than 20 years
- Lower educational achievement
- History of sexual abuse
- Child guidance issues
- Absent father during childhood
- History of psychiatric illness

Father
- Age less than 20 years
- Lower educational achievement
- Child guidance issues
- History of psychiatric illness

[a]Fifty times the risk of death during infancy because of nonaccidental trauma.

Adapted from Sidebotham P, Golding J. The ALSPAC Study Team: Child maltreatment in the "Children of the Nineties"—a longitudinal study of parental risk factors. *Child Abuse Negl.* 2001;25:1177–1200, with permission.

abuse more likely.[111] The risk of physical abuse is fivefold more likely with maternal cocaine use.[275] Violence in the home is not directed solely toward the child. In one study of families with substantiated child abuse, 30% of the mothers had also been abused.[47] Although the youngest, poorest, most socially isolated, and economically frustrated caretakers are the most likely to act violently toward their children,[280] any adult from any social or economic level may abuse a child.[4] Day care may be an at-risk environment in situations when there is poor supervision of the child caregivers. However, in an analysis of 1,362 deaths in day care, home day care was a much higher risk than was a formal institutional day care because of less training and supervision of the adult caregivers and the absence of adult witnesses.[281] Primary parental predictors of child abuse are listed in Table 9-1.

The Child at Risk

Most reported cases of child abuse involve children younger than 3 years of age.[96] In one report of abused children,[30] 78% of all fractures reported were in children younger than 3 years of age and 50% of all fractures occurred in children younger than 1 year of age. Infants younger than 1 year are especially at risk for infant homicide, the most severe form of child abuse.[76,151] The problem may be more widespread than suspected. In one report,[35] covert video recordings of adults attending their children who were hospitalized for suspicious illness documented 14 separate instances of caretaker attempts to cause upper airway obstruction. An infant may present to the emergency room dead or near dead after an apparent "life-threatening event." In these cases, it is important to be open to all diagnostic possibilities and use a multidisciplinary team approach to the evaluation.[201] Possible explanations for these events include SIDS, metabolic disease, cardiac disease, infection, as well as accidental or nonaccidental suffocation. Up to 11% of infants treated in the emergency room for apparent life-threatening events are later confirmed to be victims of child abuse.[39] Firstborn children, premature infants, stepchildren, and disabled children are at a greater risk for child abuse, as are twins and children of multiple births.[30] Benedict et al.,[31] in a longitudinal study of 500 disabled children followed from birth to age 10 years, documented a 4.6% incidence of physical abuse. The most severely disabled children were less likely to be abused, whereas marginally functioning children were at greater risk, with parental frustration considered to be a factor.

The Risk for Child Abuse that Occurs in a Medical Setting

Children who are repeatedly presented by parents for medical assessment of vague illness and have a history of multiple diagnostic or therapeutic procedures for unclear reasons are at risk for having a form of child abuse known as "child abuse that occurs in the medical setting."[251] This term has replaced the previously used "Munchausen Syndrome by Proxy,"[193] named after Baron von Munchausen, an eighteenth-century mercenary whose exaggerated tales of adventure were viewed with great suspicion. In child abuse that occurs in a medical setting, children become the victims of this adult behavior when misguided parents fabricate a wide range of illnesses for their children, often subjecting them to needless diagnostic workups and treatment.[193] Symptoms of the child's "illness" are based on an imaginary medical history given by the parent, with signs of the illness either simulated or induced by the parent. For example, a child may be brought into the emergency room by a parent with a complaint of vomiting. This complaint may either be a total fabrication by the parent or the parent may simulate the complaint by producing "vomitus" from some source as proof of illness. In one report, bloodstained material was presented by a caretaker as proof of a child's "gastrointestinal bleeding," but DNA testing revealed that the source was actually from the caretaker.[276] Conjunctivitis from a caustic agent placed on an infant by a caretaker has been reported.[28] Children have been given clozapine and clonidine by caretakers to simulate illness.[27] A parent has caused vomiting in a child by the administration of salt[191] or ipecac. In other extreme cases, a rodenticide-induced coagulopathy was seen in a 2-year-old child,[18] a deliberate self-induced preterm labor was caused by a parent,[98] and another repeatedly gave insulin to a 1-year-old child.[193] Over half of reported cases of child abuse in the medical setting involve induced symptoms, whereas 25% involve a combination of both simulation and induction of symptoms.[39] In less severe cases, the parent's anxiety can cause them to obtain unnecessary and harmful or potentially harmful medical care, even though the parent believes that he or she is acting in the child's best interest. Physicians need to be vigilant so as not to be an unwary participant of this form of child maltreatment.

The biologic mother is almost always the perpetrator of child abuse in the medical setting,[227] but men can be responsible.[192] Caretakers often have a medical background: 35% to 45% are nurses, 5% are medical office workers, 3% are social workers, and 1% are orderlies.[227] The perpetrator of the child's illness

denies the knowledge of its etiology; however, the acute signs and symptoms of the child's illness will resolve if the syndrome is recognized and the child is separated from the parent.[227] Follow-up of families with this disorder is crucial. Failure to diagnose this condition places a child at risk for either serious long-term sequelae or death in approximately 9% of cases.

The diagnosis of child abuse in the medical setting remains difficult. Health care workers must have a high degree of suspicion when children present with repetitive illness with no physiologic explanation. Physicians need to recognize that their perseverance in finding an explanation to a child's illness may contribute to the inflicted harm to the child. When possible, a pediatrician with experience in child abuse should become involved in the evaluation as well as the hospital or community-based multidisciplinary child protection team. A thorough review of all the medical care received by the child and communication among team members is necessary to establish the diagnosis and to recognize patterns of parental behavior that may harm the child. Covert video surveillance (CVS) of caretakers with their children may be a valuable means to substantiate or disprove this diagnosis. Hall et al.[102] reported that CVS with audio surveillance allowed diagnosis in 56% of patients monitored and was supportive of the diagnosis in another 22% of children. The approach is expensive, is not covered by third-party payers, and so is infrequently used. Effective treatment generally involves assuring the safety of all children in the family and addressing ongoing dysfunctional family behaviors.

The Risk for Sexual Abuse

Although the orthopedist usually considers child abuse in the context of fractures and other obvious injuries, an increasingly important situation to recognize is sexual abuse. It is estimated that 25% of abused or neglected children have been sexually abused.[167] Physically abused children have a one in six chance of being sexually abused, whereas sexually abused children have a one in seven risk of being physically abused.[117] Children living with nonbiologic parents or with caretakers who are substance abusers are most at risk. The child usually discloses sexual abuse under three types of circumstances: The child may have just experienced an argument with the abuser and may "accidentally" reveal the existence of the abusive relationship, the child is permanently separated from the abuser, or the abusive adult is shifting attention to a younger sibling.[279] Up to 25% to 83% of children with a disability have been reported to be abused.[257]

Obtaining the History

The history is critical in the diagnosis of child abuse, which is a team effort with the consulting pediatrician, social worker and other personnel from the hospital's child protective team, child protective services worker, law enforcement, and the appropriate consulting service. The orthopedic surgeon is involved if the child has an injury to the musculoskeletal system. The history is usually taken in the chaotic environment of a busy emergency room, so it is important to find a quiet area for the interview to be conducted calmly and with minimal distractions. The orthopedic surgeon should focus on the facts of the injury, including the child's ability to get into the injury scenario, details of when, where, and what happened, the child's position and action before the injury, position after the injury, how the child reacted, and how promptly the caregiver responded appropriately. Such detailed interview skills rarely are taught during residency training. In a survey of pediatric residents, 42% of them had 1 hour or less in training for detection of child abuse, and most orthopedic residents likely have even less.[80] In a study comparing the documentation of physical abuse between 1980 and 1995 in a teaching hospital, very little improvement was noted.[179] Little progress has been made in how frequently physicians inquire about basic historic information such as the timing of the injury and who were the witnesses.[14] The type of hospital that an injured child visits also influences the likelihood that a diagnosis of abuse will be made.[269,270] General hospitals were less likely to diagnose a case of abuse compared to children's hospitals. Use of a structured clinical form can increase the information collected to support the diagnosis of child abuse.[24] Having received recent continuing medical education focused on child abuse was the most important factor for a physician to properly recognize and report child abuse.[90] Precise documentation in child abuse is vital for reasons beyond medical care. Although most subpoenas for testimony by physicians in child abuse cases do not result in courtroom appearances,[212] all documentation in child abuse cases may become evidence in courtroom proceedings. Thus, detailed records are helpful to all in courtroom testimony by physicians.[105] The history needed to document child abuse is termed the investigative interview, is a team effort, and should be led by members of the child protective team and the police when potential child abuse is investigated.

The Orthopedic Interview

When involved, the orthopedic surgeon performs a detailed musculoskeletal history and physical examination to characterize the features and mechanism of the obvious injury and to discover evidence of additional undocumented injuries. The interview documents the history (or the lack of history) of the presenting injury and attempts to uncover enough details about the child's life so that plausible scenarios can be evaluated that might explain the injury. The team should determine how the injured child lives, find out which family members, friends, or other caretakers have access to the child, and how likely it is that they might have contributed to the child's injuries. A detailed history of injury is obtained individually from each adult family member in a private setting. If the patient and siblings can communicate, they should be interviewed separately from the parents and other members of the family. The location where the injury occurred and which individuals were actually present are documented. The interviewer should follow a systematic review of symptoms: What happened, who was there, when the injury was recognized, and how long before medical treatment was sought. To avoid provoking emotions, any additional soft tissue or skeletal trauma discovered should be brought up at the end of the interview for explanation once the presentation injury has been thoroughly discussed.

Delay in seeking medical care for an injured child is very suggestive of child abuse.[81] An infant who has sustained abusive

head trauma (AHT) typically will develop immediate neurologic change and will invariably show symptoms within a few hours.[37] For a child with head trauma, a caregiver's story that there was a long period after the injury in which the child had no symptoms is suspicious. When central nervous injury in child abuse is significant or severe, it is immediately symptomatic; thus, the last caretaker who witnessed the reported injury or found the child immediately after the injury is highly suspected of being the perpetrator.[23] Inconsistencies are not challenged during the interview. Leading questions are avoided in favor of open-end questions. Medical terms should be explained in plain English, with care taken to avoid medical jargon. More plausible explanations for the injury are not volunteered. Open prompts can enhance the interview.[209] If the injury was observed, the caregiver should be able to give a detailed description of the injury mechanism that fits the energy of the fracture and the clinical picture.[218,219] The crucial questions to be answered are not only whether the given history of trauma is sufficient to explain the severity of injury, but also what other possible scenarios could explain the injury if the volunteered explanation is not plausible. This requires obtaining a working knowledge of the child's environment, which team members can obtain by asking specific, detailed questions (Table 9-2).

When interviewing injured children, it is essential to be as gentle as possible, asking how they got hurt rather than who hurt them. Questions asked should be appropriate for the child's age. The child's account of what he or she was doing at the time of injury should be compared with the accounts of the adult witnesses. If possible, the siblings of the injured child should be interviewed because they are also at risk for child abuse. Nonvisual cues during the interview should be noted (Table 9-2).

To make the diagnosis of child abuse, the orthopedic surgeon or child abuse team must determine if the history of trauma is adequate to explain the severity of injury.[56] This should be based on the experience in the care of fractures with knowledge of their mechanisms of injury and special insight into the types of trauma most likely to cause significant injury. In addition, it is extremely important to have knowledge of the developmental abilities of a child when a caretaker states the child's injuries are self-inflicted.[135] For example, if the parents explain that a 4-month-old infant's femoral fracture occurred in a fall while the infant was standing alone, this history is inconsistent with the child's developmental ability.

Details given as the reason for the injury should be carefully considered. Although it is not unusual for a young child to sustain an accidental fall, it is unusual to sustain a serious injury from that fall alone. Infants fall from a bed or a raised surface during a diaper change fairly frequently. In a study of 536 normal infants,[165] nearly 50% of them had fallen accidentally from an elevated surface, usually after the first 5 months of life, when the children were able to roll over and were more active. Significant injury in such falls is, however, extremely rare. Combining two studies of 782 children younger than 5 years of age who accidentally fell off an elevated surface, such as bed or sofa, reveals that injuries were limited to three clavicle fractures, six skull fractures, one humeral fracture, and one subdural hematoma.[112,163] In another report, a much higher rate of fracture was seen in falls from furniture with 98% having fractures, mostly in the upper extremity, because of the child catapulting during play activity rather than sustaining a simple short-height fall.[113] More severe injuries occur in falls from greater heights. Stairway falls usually result in low-energy injuries, but there is increased risk of injury if the child is being carried by the caregiver. In a report of 363 stairway injuries,[145] 10 were infants who were dropped by their caretakers and four of those sustained skull fractures. In patients 6 months to 1 year of age, 60% were using walkers at the time of the stairway injury. Only 4% of patients had extremity fractures and 1% had skull fractures. Reported short-height falls (<1.5 m) are rarely documented to cause death.[55] A review of child mortality in infants and young children in California showed the following causes of death/1 million children/year: Prematurity 165, congenital malformation 316, neoplasms 33, respiratory 38, accidents 121, homicide 22, and short-height falls 0.48 (a total of six cases, all occurring in the home). Although short-height falls are a rare cause of death, there has been no reported case

TABLE 9-2 Child Abuse: Investigative Interview

Environmental Issues

Primary Caretakers
- Unsupervised
- Responsible for feeding, discipline, toilet training
- Easy or difficult child

Home Environment
- Place of residence
- Living conditions
- Adults employed or unemployed
- Sleeping arrangements
- Marital status of parents
- Boyfriend or girlfriend of single parent
- Substance abuse

Home Stress Level
- Recent job loss
- Marital problems (separation or divorce)
- Death in the family
- Housing problems
- Inadequate funds for food

Parental or Caregiver Responses and Attitudes
- Evasive, not readily responsive to questions
- Irritated by questioning
- Contradictory in responses
- Hostile and critical toward child
- Fearful of losing child or criminal prosecution, or both
- Unconcerned about child's injuries
- Disinterested in treatment and prognosis
- Intermittently unavailable for interview (without valid reason)
- Unwilling to give medical information
- Unwilling to give consent for tests
- Indifferent to child's suffering (seldom touches or looks at child)

Adapted from Akbarnia BA. The role of the orthopaedic surgeon in child abuse. In: Morrissy RP, ed. *Lowell and Winter's Pediatric Orthopaedic.* Philadelphia, PA: JB Lippincott; 1990; Green FC. Child abuse and neglect: A priority problem for the private physician. *Pediatr Clin North Am.* 1975;22(2):329–339, with permission.

of shortfall death in an institution-type day care setting, where witnesses are typically present. A fatally injured child from a reported short-height fall at home must receive expert postmortem investigation for child abuse.

Additional information about the child and the family may be obtained by a review of past medical records or by contacting the patient's primary physician and social workers who may have been involved with the family. The physician or social worker should be asked if there has been any previous pattern of injury, illness, ingestion of objects or medications, or noncompliance with health care recommendations; whether the family is receiving counseling or other support from any community groups; and whether the family has any previous involvement with child protective services or law enforcement.[80]

Documentation Requirements

Careful documentation is critical. Chart notes may later be presented as evidence in court for either custodial hearings or criminal trial.[179] Defending inaccurate or partial chart notes in court can be extremely embarrassing as well as placing the child at additional risk. Each account should be recorded in as much detail as possible, using quotation marks for exact quotes and specifying who is giving the history. Particularly with crucial answers, the exact question preceding the response should be documented. In a study of subsequent confessions, the initial history, although not consistently true, did reveal some elements of truth.[88] In addition, the general emotional state of the individual providing the account, as well as the individual's reaction to emotionally charged questions should be documented to assist in later evaluation of the credibility of the account. If the family wishes to change their story after the initial account, no changes should be made to the earlier record, but an addendum should be placed detailing the new account. The completed record should include several specific items such as the timing and mechanism of the injury, who found the child, timing of events, family history of underlying conditions such as osteogenesis imperfecta (OI), radiographs, and documentation of protective services involvement.

Physical Examination

After the initial musculoskeletal evaluation for acute fracture assessment, a detailed physical examination should follow, systematically evaluating from head to toes, to detect any signs of additional acute or chronic injury. Acute and subacute fractures may cause local tenderness and swelling, whereas chronic fractures may produce swelling from the presence of callus and clinical deformity from malunion. Radiographs are obtained to confirm clinically suspected fractures. A skeletal survey must be performed in children under 2 years of age when there is reasonable suspicion of abuse[12]: It should be considered an extension of the physical examination for this age group. A thorough examination should focus on the body areas commonly involved in child abuse including the skin, central nervous system (CNS), abdomen, and genitalia.[207] Careful evaluation for signs of previous injury is useful because 50% of verified abuse cases show evidence of prior abuse.[100]

Soft Tissue Injuries

In addition to examination of the soft tissue around the acute fracture site for swelling and bruising, the patient's entire body should be systematically evaluated to detect acute and chronic soft tissue trauma. Deliberate soft tissue injuries are present in 81% to 92% of abused patients,[96,190,159] making them the most common abuse-related physical examination finding. The types of skin lesions commonly encountered include bruises, welts, abrasions, lacerations, scars, and burns.

The number and location of bruises relate to the child's development. Seventeen percent of mobile infants, 53% of toddlers, and most school children have bruises.[185] Young infants have a much lower prevalence of accidental bruising (seen in 1%) compared to mobile toddlers.[185] Accidental bruises in babies are also typically noted over bony prominences.[49] The toddler may have multiple accidental bruises over bony prominences such as the chin, brow, knees, and shins.[4,230,255] Bruises on the back of the head, neck,[4] arms, legs, buttocks, abdomen, cheeks, or genitalia may be suspicious for abuse, although accidental bruises can also occur in all these locations.[8] Accidental bruising of the face is much less common and should be carefully evaluated.[185] In the dentistry literature, in a series of 266 children suspected of being abused, Jessee and Rieger[134] reported that bruises were the most common soft tissue injury, with the most common facial. In nonabused children, only 7% had accidental soft tissue injuries of the face and head, with the peak incidence of 17% seen in toddlers; whereas, soft tissue injuries were present on the lower extremities and buttocks in 31% of children and on the upper extremities in 9%.[225] In a study of 1,467 patients seen for reasons other than trauma at a medical center over a 1-year period, 76.6% had at least one skin lesion of recent onset, 17% had at least five, 4% had at least 10, and fewer than 1% had more than 15 recent lesions.[169] In children less than 9 months of age, skin lesions were uncommon and were concentrated on the head and face, whereas in children over 9 months of age, the skin lesions were mostly on the lower extremities.[169] Although any number of bruises may be present in any child, the location and configuration of the bruises and the mobility of the child, taken together with the rest of the medical and social history determines the suspicion for abuse (Fig. 9-1 and Table 9-3).

Although the configuration of abusive bruises may resemble the implement used to inflict the injury, the soft tissue injuries of abuse are weapon specific in fewer than 10% of patients.[190] The weapons used to abuse children often include belt buckles, staplers, ropes, switches, coat hangers, ironing cords, and the open or closed human hand.[136,258] Bruises inflicted by an open hand may appear on the face or a flat area of skin and grasp marks may appear as ovoid lesions when the fingertips are deeply embedded in the extremities or the shoulders of the child during extreme shaking.[123] The injury pattern and the severity of the bruising depend on the amount of force used, how directly the instrument made contact, and the specific type of implement used to strike the child.[123]

Other types of skin lesions may be noted. Welts are more complex skin lesions in which swelling accompanies bruising from injury through lashing or whipping. Lacerations, scars, and burns

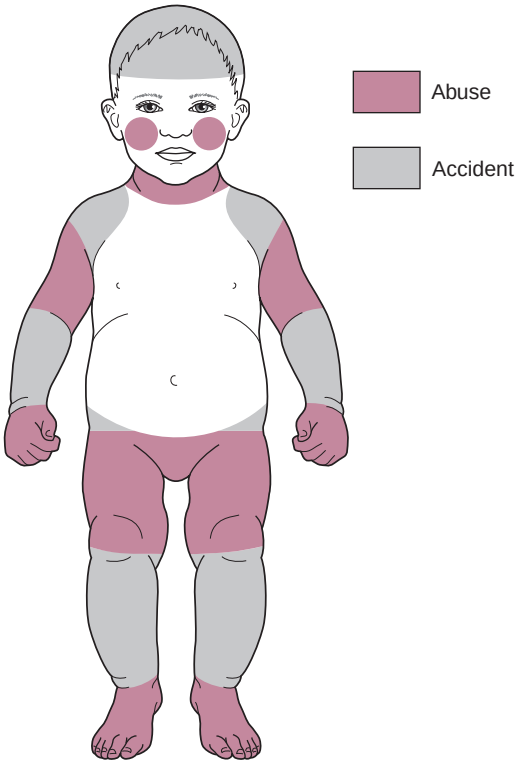

FIGURE 9-1 Schematic illustrates distribution of abusive versus accidental bruising. (Redrawn from original courtesy of Samir Abedin, MD.)

are seen in older abused children, whereas bruises are seen in all ages.[190] Like bruises, the laceration configuration can resemble the weapon used to inflict the injury on the child. Although minor lacerations around the eye are fairly common, multiple scars from either lacerations or burns are suspicious.[222,265] Displaced fractures may have associated bruising, with or without abuse. Deep bruising after abuse can be so extensive that rhabdomyolysis can occur, detectable by urine dipstick.[216]

TABLE 9-3 Evaluating Bruising in a Child—Implications for Practice

A bruise must never be interpreted in isolation and must always be assessed in the context of medical and social history, developmental stage, explanation given, full clinical examination, and relevant investigations.

Patterns of bruising that are suggestive of physical child abuse:

- Bruising in children who are not independently mobile
- Bruising in babies
- Bruises that are seen away from bony prominences
- Bruises to the face, back, abdomen, arms, buttocks, ears, hands
- Multiple bruises in clusters
- Multiple bruises of uniform shape
- Bruises that carry the imprint of implement used or a ligature

Adapted from Maguire S, Mann MK, Sibert J, et al. Are there patterns of bruising in childhood which are diagnostic or suggestive of abuse? A systematic review. *Arch Dis Child.* 2005;90(2):182–186.

The age of a bruise can be roughly estimated by a change in color over the 2 to 4 weeks following injury, with fading of the lesions beginning at the periphery. Acute contusions are blue or reddish purple, gradually changing to green, then to yellow, with final resolution as a brownish stain as hemoglobin is finally broken down.[278] Langlois and Gresham[171] noted that a yellowish bruise must be older than 18 hours; a red, purple, blue, or black coloration of the bruise may be present from 1 hour after injury to resolution; red is always present in bruises regardless of the age; and bruises of identical age and etiology on the same person may be of different appearances and may change at different rates. A deep contusion may take some time to rise to the skin surface because of intervening fascial planes and thus delay its appearance. Although the color of a bruise may roughly aid in determining the length of time it has been present, dating bruises based on appearance should be done with caution.[232,250]

Natural skin lesions should not be mistaken for bruises. Mongolian spots, more common in black or Asian infants, are deep-blue pigmented areas that are present on the lower back at birth, usually just proximal to the buttocks.[17] They do not change in color and gradually resolve as the child matures.[123] Cultural differences should be considered when unusual skin lesions are noted. Vietnamese children may be subjected to the folklore medical practice known as cao gio, which places scratches and bruises on the back of the trunk and may be mistaken for child abuse.[45] Other conditions can mimic inflicted bruising: Eczema, coagulation disorders, vasculitis, impetigo, Ehlers–Danlos syndrome, vascular malformations, dye stains, and others.[259] In cases where bruising or bleeding is the only finding of abuse, a family history for bleeding diathesis, using established protocols for hematologic evaluation for an underlying bleeding disorder and involvement of a hematologist, is advised before child maltreatment is diagnosed.[172,262]

Burns

Burns are found in approximately 20% of abused patients[96] and are most likely to occur in patients younger than 3 years of age.[190] Burn evaluation should include configuration, approximate percentage of body surface area, location, distribution, uniformity, length of time the child was in contact with the burning agent, temperature of the burning agent, and presence or absence of splash marks when hot liquids are involved.[123]

Scalds are the most frequent type of abusive burns and are caused either by a spill or an immersion.[164] Accidental spill burns are generally located on the trunk and proximal upper extremities (Fig. 9-2). Most accidental pour or spill burns occur on the front of the child, but accidental burns can also occur on the back as well. In accidental flowing liquid burns, the injury usually has an arrowhead configuration in which the burn becomes shallower and more narrow as it moves downward, and there may be splash marks surrounding the lesion.[123] The pattern in accidental burns may also be indicative of flowing water.[224] Abuse should be suspected when deep second- or third-degree burns are well demarcated with circumferential definition. The typical child abused by scalding burns is an undernourished 2-year-old child with 15% to 20% of the body involved, usually the buttocks, and has a 10% to 15% mortality rate from secondary sepsis.[224]

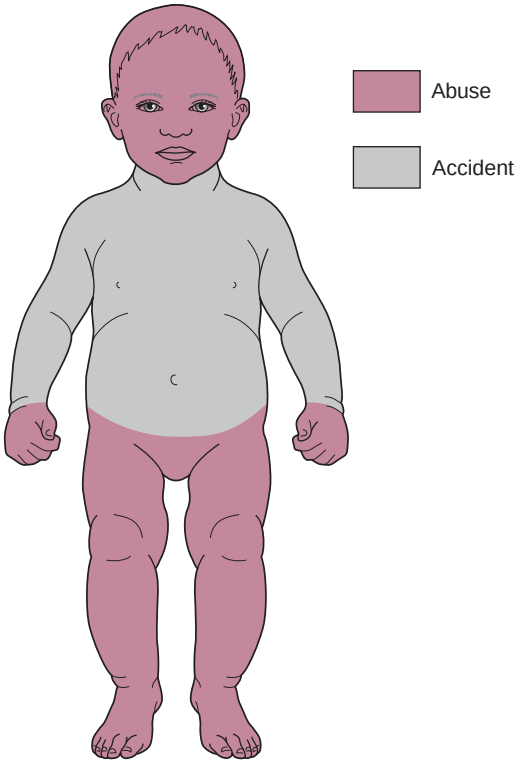

FIGURE 9-2 Schematic illustrates location of accidental versus abusive burns. Note the buttock and lower extremity distribution of nonaccidental immersion burns compared to thoracic distribution accidental burns. (Redrawn from original courtesy of Samir Abedin, MD.)

In accidental hot water immersion, an indistinct stocking or glove configuration may be seen with varying burn depths and indistinct margins. In deliberate immersion burns such as occurs when a child's buttocks are immersed in hot water, the burn demarcation has uniform depth and a well-demarcated water line.[123] The gluteal crease of the buttocks may be spared, giving a doughnut-like appearance to the burn. In accidental hot water immersion, the child is uniformly scalded about the lower extremities as the legs are quickly extended by the child to climb out of the water, but in deliberate, abusive immersion the child is lowered into the water and instinctively flexes the hips and knees, thus sparing the popliteal area.[96]

Burns can be inflicted by many objects commonly found in the household. Intentional burns by cigarettes are circular, deeply excavated, and sometimes repetitive, usually about 8 mm in diameter.[123] Impetigo may resemble scalds or cigarette burns, but is more superficial. Severe eczema may mimic burns suspicious for child abuse.[110] Contact with heated objects may cause burns of unique shape that allow identification of their etiology. Children accidentally grasping curling irons sustain burns of the palms, whereas burns on the dorsum of the hands are more suspicious for abuse.[135] Hair dryers can be used to inflict burns on children, and full-thickness skin burns can result from the heated air or from contact with the grill up to 2 minutes after it has been turned off.[220] Abuse burns have also been inflicted by stun guns.[94] These devices deliver a high-voltage impulse of up to 100,000 V at 3 to 4 mA, incapacitating the individual and leaving hypopigmented burn scars on the skin 0.5 cm apart. Circular scars above the wrists may be because of rope burns when children are restrained for beatings.[135] Full-thickness skin burns have been reported in small children who were placed in microwave ovens.[7] Certain folklore practices may cause lesions simulating abusive burns. Round burns on the abdomen, buttock, or between the thumb and forefinger of Southeast Asian children may be because of a variant on the Chinese medical practice of moxibustion. Folk medical practitioners' burn balls of the moxa herb on the surface of the skin for therapeutic purposes, and both cigarettes and yarn have been similarly used in refugee camps. The knowledge of these practices may help to avoid inappropriate accusations of child abuse.[86]

The orthopedic surgeon must examine and carefully document all soft tissue injuries that are present before treating acute fractures. Casts applied in the treatment of fractures, especially a spica cast, may obscure potentially incriminating skin lesions and will preclude other members of the child advocacy team from being able to identify or document them. Photographs taken to document skin lesions must be done before cast placement.

Abusive Head Trauma

Several terms have been used to describe head trauma related to abuse, including the older term shaken baby syndrome (SBS) and the preferred newer terms AHT,[37] inflicted traumatic brain injury (ITBI), inflicted head trauma (IHT), or nonaccidental head trauma.[201] These terms have been used to describe a form of physical NAT in infants with a triad of subdural hemorrhage, retinal hemorrhage, and encephalopathy occurring with an inconsistent or inappropriate history, commonly associated with other inflicted injuries.[106] The American Academy Committee on Child Abuse and Neglect recommends the term "abusive head trauma" to be used in the medical record. Pediatric AHT is defined as "an injury to the skull or intracranial contents of an infant or young child, less than 5 years of age, because of an inflicted blunt impact and/or violent shaking.[61,214] Recent excellent review articles discuss fatal AHT[95] and the diagnosis of pediatric head trauma in general.[125,126] The rate of hospitalization for AHT (36 per 100,000) is similar to that of fractures from NAT (25 to 32 per 100,000).[175]

A child under the age of 3 years who suffers head trauma from abuse is more likely to have sustained a noncontact injury mechanism (acceleration–deceleration or shaking) resulting in deeper brain injury, cardiorespiratory compromise with diffuse cerebral hypoxia–ischemia, and a worse outcome at 6 months than a child who is accidentally injured.[126] Head injuries can be from indirect noncontact forces such as in shaking or from direct contact from a blow to the head such as occurs when the child is thrown against an object. Indirect trauma is felt to be responsible for the most severe injuries, although the actual injury may be from both mechanisms. Symptoms typically occur early rather than later, although secondary or delayed brain injury may occur with edema and the brain's neurotoxic injury response.

In physical abuse, the most common cause of death is head trauma.[223] In Kleinman's[154] classic postmortem study of 31 infants with an average age of 3 months, head trauma was the cause of death in 18. For children less than 2 years of age dying from a traumatic brain injury, 80% of the deaths are from abuse, with the highest incidence at 6 months.[93] For a child with AHT, the mortality rate is approximately 20%, and

TABLE 9-4 Criteria for Categorizing the Etiology of Head Injuries

Category	Criteria
Noninflicted	Cases in which the child's primary caregiver described an accidental head injury event that was developmentally consistent, historically consistent with repetition over time, could be linked to the child's acute clinical presentation for traumatic cranial injuries, and occurred in the absence of any noncranial injuries considered moderately or highly specific for abuse[a]. Cases in which an accidental head injury event was witnessed independently and could be linked to the child's acute clinical presentation for traumatic cranial injuries (e.g., motor vehicle accident).
Inflicted	Cases in which the child's primary caregiver admitted abusive acts that could be linked to the child's acute clinical presentation for traumatic cranial injuries. Cases in which an independent witness verified abusive acts that could be linked to the child's acute clinical presentation for traumatic cranial injuries. Cases in which a child not yet cruising or walking became clearly and persistently ill with signs of acute cardiorespiratory compromise[b] linked to his or her traumatic cranial injuries while in the care of a primary caregiver who denied any knowledge of a head injury event. Cases in which the child's primary caregiver provided an explanation for the child's head injury event that was clearly developmentally inconsistent with the parents' description of their child's developmental capabilities. Cases in which the child's primary caregiver provided an explanation for the child's head injury event that was highly inconsistent with repetition over time. Cases in which the head-injured child also revealed at least two noncranial injuries considered moderately or highly specific for abuse[a].
Undetermined	Cases meeting criteria for both inflicted and noninflicted etiology. Cases not meeting any criteria for either inflicted or noninflicted etiology.

[a]Including classic metaphyseal lesion(s); fractures of the rib(s), scapula, sternum, spinous process(es), or digit(s); vertebral body fracture(s) or dislocation(s); epiphyseal separation(s); noncranial bruising; abrasion(s) or laceration(s) in location(s) other than the knees, shins, or elbows; patterned bruise(s) or dry contact burn(s); scalding burns with uniform depth, clear lines of demarcation, and a paucity of splash marks; intra-abdominal injuries; retinal hemorrhages described by an ophthalmologist as dense, extensive, covering a large surface area of the retina, or extending to the periphery of the retina; and retinoschisis diagnosed by an ophthalmologist.

[b]Including breathing difficulty, respiratory distress, infrequent respirations, apnea, or cyanosis; clinical manifestations of shock, delayed capillary refill, or cardiac arrest; any requirement for mouth-to-mouth breathing, bag-mask ventilation, intubation, chest compressions, rapid volume expansion, or epinephrine therapy; occurring at the scene of injury, during transport, in the emergency department, or at the time of hospital admission; documented by medical personnel or reported by the child's primary caregiver.

Adapted from Hymel KP, Makoroff KL, Laskey AL, et al. Mechanisms, clinical presentations, injuries, and outcomes from inflicted versus noninflicted head trauma during infancy: Results of a prospective, multicentered, comparative study. *Pediatrics*. 2007;119(5):922–929.

survivors have a higher rate of permanent and significant disability than is seen with accidental trauma.[140]

When an infant presents with altered mental status, AHT should be suspected (Table 9-4). Jenny et al.[132] reported that 31.2% of cases of AHT were misdiagnosed on initial presentation to the emergency room, with a delay averaging 7 days until a correct diagnosis was made. Although early diagnosis of an infant with AHT is essential, primary prevention is the most important new development to occur nationally. There is correlation between peak incidence of infant crying and peak incidence of AHT that occurs 4 to 6 weeks later, suggesting that repeat and prior injuries occur.[25] Dias et al.,[77] utilizing an early postnatal hospital-based program for new parents to learn about shaking impact syndrome and how to appropriately deal with an inconsolable infant, found a 47% decrease in SBS, whereas intervention programs after abuse was recognized having much less success.[182]

As a general principle, a typical short fall in the home is highly unlikely to cause generalized CNS injury or subdural or retinal hemorrhage, although isolated skull fracture or epidural hemorrhage may be seen. The young infant who is not developmentally mobile enough to cause a fall from a height, having a relatively large head, immature brain, and weak neck muscles, is very vulnerable to the whiplash effects of inflicted violent shaking (Fig. 9-3). In 25% to 54% of confirmed cases of AHT, the abuser described an indirect mechanism by shaking the infant without the head contacting a surface, with resulting immediate onset of symptoms.[36,247] Indirect trauma is responsible for the most severe injuries. There is sudden angular acceleration and deceleration with associated rotation of the head and neck in relation to the thorax, producing inertial shear strain deformation and

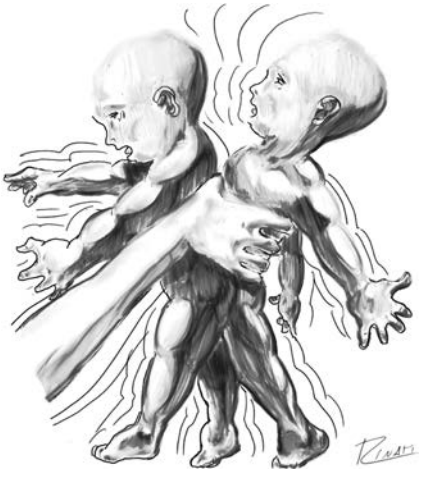

FIGURE 9-3 Illustration of acceleration–deceleration injury sustained by a shaken infant. Shaken infants suffer whiplash injuries due in part to their disproportionately large heads in relation to their bodies. This mechanism is believed responsible for the common association of subdural hematomas, retinal hemorrhages, and posterior rib fractures. (Artwork courtesy of Gholamreza Zinati, MD.)

disruption leading to diffuse injury.[23] Whereas accidental trauma causes subdural hemorrhage from the translational forces of an impact, IHT from rotational and shearing forces may result in more diffuse subdural or intrahemispheric hemorrhage.[120]

The eye of a young infant has a soft sclera: The globe can more easily deform during shaking. This causes vitreoretinal traction leading to direct hemorrhage in the retina and in the optic nerve sheath.[282] Fundoscopic examination confirms and documents retinal optic nerve as well as orbital hemorrhage.[46] Retinal hemorrhages of abuse classically are multilayered, more anterior, closer to the ora serrata, and are numerous and bilateral. Retinoschisis is a splitting of the layers of the macula forming a cystic cavity caused by shearing and pulling forces of the strong vitreous attachments to the retinal surface and is classic for AHT.[229] Unilateral retinal hemorrhages may occur in 10% to 16% of cases, so unilateral does not rule out SBS.[16] Although retinal hemorrhages resulting from normal vaginal birth are present in 34% of newborns, these resolve by 16 days of age.[121]

Previous clinical studies on SBS do not typically address injury to the cervical spine, so it is not known how frequently the spine also is injured with this mechanism.[21] In very young infants (2 to 3 months of age), forces may be directed to the upper cervical spine leading to spinal cord injury without obvious radiographic abnormality (SCIWORA), cervicomedullary junction cord injury, apnea, and cardiorespiratory arrest.[97,126] Direct head injuries may also occur when the child's head is slammed onto a soft surface such as a mattress.[83] On impact, deceleration forces approaching 400 Gs may occur, tearing the bridging vessels between the skull and the brain and producing intracranial hemorrhage and cerebral edema. Skull fractures are rare unless the child is thrown onto a hard object.

A complete neurologic examination is required for any child suspected of being abused. This should include assessment of the child's mental status, motor function, sensation, reflexes, and gait, if possible. Any abnormal findings warrant further investigation. Also included should be a dilated fundoscopic examination by an ophthalmologist looking for retinal hemorrhages. For the child with acute neurologic findings suspicious for AHT, a noncontrast computed tomography (CT) scan is done to evaluate for conditions that may benefit from prompt medical and neurosurgical treatment, such as intracranial hemorrhage—acute parenchymal, subarachnoid, subdural, or epidural (Fig. 9-4). If the head CT scan includes upper cervical spine-associated injuries, pre-existing bony conditions such as Klippel–Feil syndrome or occipital cervical assimilation may be detected.[119] Anteroposterior (AP) and lateral skull and spinal radiographs are always included as part of the routine skeletal survey for the child less than 2 years of age and should be performed for any aged child with suspected AHT (Table 9-5). CT scans alone may occasionally miss in-plane axial skull fractures. However, these fractures are usually easily seen on the accompanying skeletal survey. Although fine-cut three-dimensional CT skull reconstructions may reveal subtle skull fractures, they may increase delivered radiation by up to 30% over standard head CT. New CT scanners and reformatting algorithms allow for 3D images of the calvarium at no extra radiation dose. Magnetic resonance imaging (MRI) is best used to fully assess various intracranial pathology and has become the imaging modality of choice for evaluating asymptomatic, nonacute parenchymal brain lesions and for fully documenting the abuse. MRI is also effective for diagnosis of related conditions in the cervical spine, including ligamentous injury and intraspinal injuries such as SCIWORA.

FIGURE 9-4 Interhemispheric subdural hematoma in an 8-month-old female presenting with seizures caused by nonaccidental trauma. Axial CT image shows high attenuation blood along the left aspect of the posterior falx (*arrow*).

Even in abused children without neurologic findings or retinal hemorrhages, occult head injury should always be suspected. At risk children with obvious neurologic findings should be urgently screened with head CT for acute pathology. At risk children without obvious neurologic findings are best imaged initially with MR brain imaging (ACR guidelines).[12] MRI is sensitive for diagnosing small parenchymal hemorrhages[83] and offers the highest sensitivity and specificity for the diagnosis of subacute and chronic head injuries.[12] Diffusion- and susceptibility-weighted imaging sequences are

extremely sensitive for detecting subtle hypoxic–ischemic brain injury and parenchymal hemorrhage[213,256] and are routinely included in imaging protocols when available. MR venography may be used if venous sinus thrombosis is suspected. MR spectroscopy may detect lactate levels, an indicator of prognosis.[87]

Infants with acute head injuries may have fever, bulging fontanelles, and macrocephaly. Paresis may be present, and reflexes may be increased. Older infants and children may have subdural hemorrhages and musculoskeletal injuries.[97] Classic infant AHT with multilayered retinal hemorrhages and acute subdural hematomas has been noted in an autopsy series of four older children between 2.5 and 7 years of age.[229] Cerebral edema may be lethal,[60] so emergency neurosurgical consultation may be needed. Barnes and Krasnokutsky[23] reviewed the radiographic evaluation of a young child with a suspected nonaccidental head injury, including mimicking of conditions, such as accidental injury from short falls, acute CNS infections, coagulopathies, venous thrombosis, metabolic abnormalities, and neoplasms. The diagnosis of these mimics may require more extensive workup before a diagnosis of AHT is confirmed (Table 9-6).[242] Oehmichen et al.[204] have presented very practical principles for diagnosing AHT (Table 9-7).

Disability after AHT is frequent and ranges from mild to severe. Common late sequelae after AHT include developmental delays, sensory and motor deficits, feeding difficulties, recurrent seizures, attention deficits, and intellectual, educational, and behavioral dysfunctions.[126] In a long-term outcome study, 69% of children had an abnormality and 40% had severe dysfunction.[22] Approximately 50% had visual impairment and another 50% had behavior disorder.[22] Some children seemed normal until 5 years after the inflicted injury, then showed learning disorders, so long-term follow-up is essential. Repeat abuse when AHT is not recognized and the child is returned to the home is too common.[97]

Abdominal Injuries

After AHT, trauma to the abdomen is the second most common reason for death from abuse.[39] In a review of the National Pediatric Trauma Registry, 16% of all blunt abdominal trauma in children 0 to 4 years of age was attributable to child abuse.[268] The pediatric thorax and pelvis are very compliant. The abdominal muscles are pliable with little subcutaneous and omental fat, so there is less protection to the internal abdominal, chest, and pelvic organs. Whereas shaken infants sustain head trauma, toddlers receive abdominal injuries as they are more often punched and beaten. Inflicted abdominal trauma may be because of beatings with the hand, fist, or when the child is thrown into a fixed object. The compliant pediatric abdominal wall does not absorb much of the injury energy, so abdominal bruising is present in only 12% to 15% of major intra-abdominal injury cases.[123] Children with inflicted injuries are more likely to be of a younger age, malnourished, have a pancreatic or hollow viscous injury, have an associated traumatic brain injury, and have higher mortality compared to victims of accidental abdominal injury.[268]

Children with abdominal injury from child abuse may have a wide range of symptoms depending on the organ involved and the severity of the injury. Fever, vomiting, anemia, abdominal distention, localized involuntary spasm, and bowel sounds may be absent.[207] The liver is the most commonly injured solid organ. With a damaged liver, right shoulder pain from hemidiaphragm irritation (Kehr sign) may be associated with abdominal pain and fatal hypovolemic shock.[266] Liver function tests may reveal occult liver injury. In one study,[64] elevated aspartate aminotransferase, alanine aminotransferase, and lactic dehydrogenase enzyme levels were useful markers for occult liver lacerations in abused children who had false-negative abdominal examinations. Blows

TABLE 9-7 Principles of Diagnosing Inflicted Traumatic Brain Injury in Children

1. Simple injuries are caused by simple mechanism; extreme violence (blows, shaking, impact) is necessary to cause life-threatening injuries.
2. Life-threatening injuries are characterized by the rapid onset of serious clinical symptoms (coma, circulatory and respiratory arrest) without a lucid interval.
3. If a parent or caregiver attributes a severe traumatic brain injury in a child to a household fall, the claim should be regarded as suspect until proven otherwise.
4. If a child is injured by a fall, the parent or caregiver will immediately seek medical care and express extreme anxiety regarding the fate of the child. But if a child is injured by abuse, the perpetrator often waits to see if the child will recover spontaneously.
5. The diagnosis of shaking trauma is rarely based on a confession, more on the implausibility of an explanation. Shaking is hardly ever witnessed.
6. The following symptom complex is highly specific to shaking trauma:
   - Intracranial hemorrhage, especially subdural or subarachnoid
   - Retinal hemorrhage
   - Dural bleeding of the cervical cord
   - Bleeding of the throat and neck muscles
   - Gripping marks on the thorax and shoulders
   - Symptoms of recurrent trauma

Adapted from Oehmihen M, Meissner C, Saternus KS. Fall or shaken: Traumatic brain injury in children caused by falls or abuse at home—a review on biomechanics and diagnosis. *Neuropediatrics.* 2005;36:240–245.

to the abdomen often injure the pancreas as it is violently compressed against the spine. Blunt pancreatic injury caused by NAI commonly presents with contusion, transaction, or laceration, all of which are associated with pancreatitis and elevated blood amylase. A pancreatic pseudocyst may form, causing obstructive symptoms several weeks after initial injury.[123] Splenic and renal injuries, rare in child abuse, have a 45% risk of mortality from hemorrhagic or septic shock if care is delayed.[67]

Hollow organ injuries to the upper or lower gastrointestinal tract or bladder are infrequent in accidents but common in child abuse, particularly in the younger child (mean age 2.5 years).[173] Hollow organ abuse injuries, as is true for most abdominal injuries caused by NAI, presented for medical attention late, with an inconsistent or vague history. In a young child with unexplained hollow organ injury, abuse should be suspected and investigated.

Child abuse is the leading cause of duodenal injury in children less than 4 years of age.[267] Intramural duodenal hematoma may cause obstruction and bilious vomiting.[123] CT, ultrasound imaging, and/or upper gastrointestinal radiography may be diagnostic (Fig. 9-5). More severe trauma may cause duodenal avulsion or transection with nausea, vomiting, and clinical acute abdomen.[181] Frequently, the radiologist first suggests the possibility of NAT by finding a duodenal hematoma with no history by the caregiver of trauma. Blunt trauma to the abdomen may also cause intestinal perforation, usually involving the small intestine, and the physical examination may suggest peritonitis. Previously, plain radiographs were used to search for free air in suspected hollow organ injuries; however, only 19% of radiographs were diagnostic.[41] Today, CT with intravenous contrast enhancement is used for the trauma evaluation. CT imaging better reveals free fluid, focal bowel wall thickening, inflammation, or ileus. Associated spine injuries, such as Chance flexion–distraction lumbar spine fracture, should be evaluated.

The Academy of Pediatrics Section on Radiology[12] recommends CT scans with nonionic intravenous contrast to define injury to abdominal organs. Contrast should not be used if there is a history of iodine allergy or renal failure. The use of oral contrast is debatable with CT scans and may place the patient at risk of aspiration. Ultrasound and upper gastrointestinal series are most often used to evaluate duodenal hematoma. When abdominal injury is suspected in an abused child, the hematocrit and hemoglobin levels are checked, the child is typed and crossmatched for blood, and two large intravenous lines are placed in anticipation for surgical treatment. General surgery consultation is obtained. The overall mortality rate associated with visceral injury in child abuse is 40% to 50%.[64] In fatal cases with liver injury, hepatic glycogen staining may be helpful in establishing time of death for legal reasons.[261] Occult abdominal trauma is easily missed, so a high index of suspicion

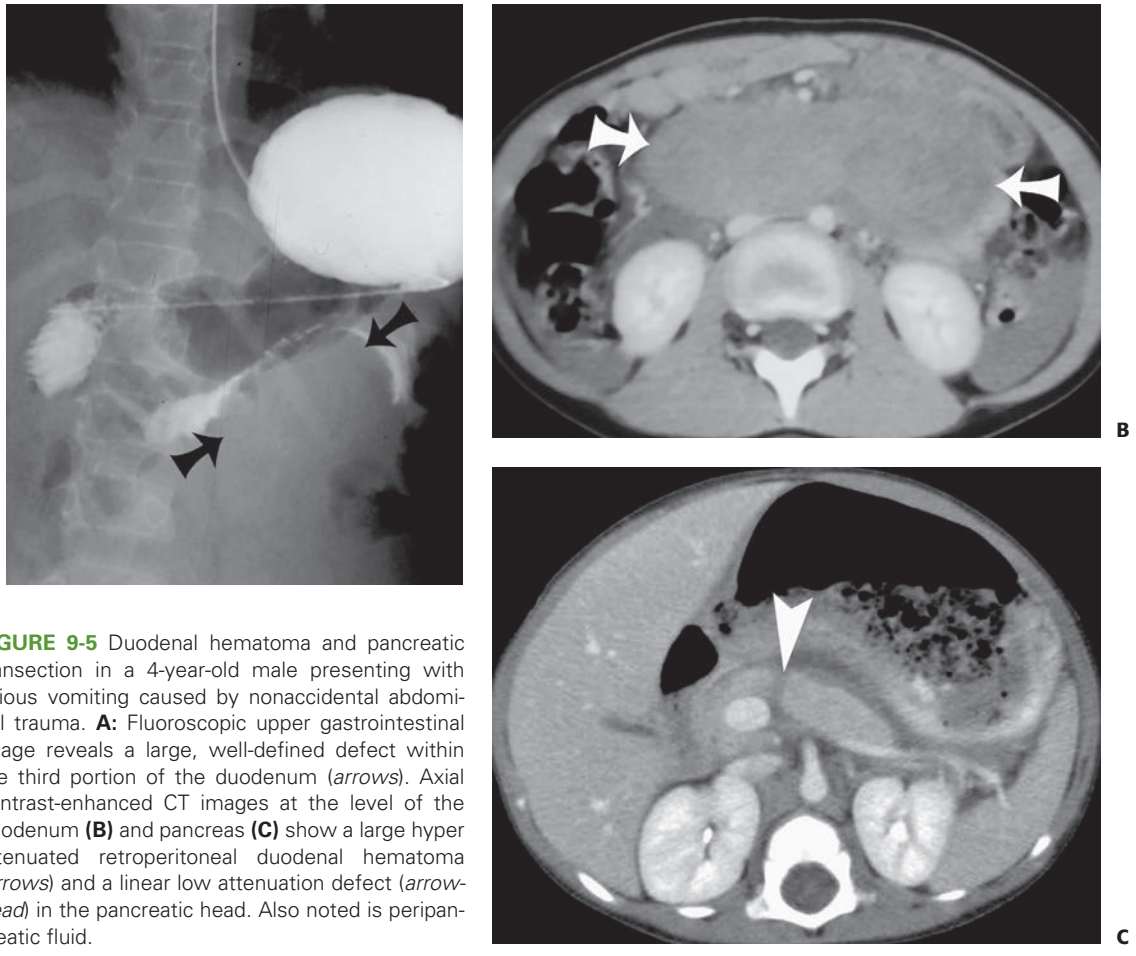

FIGURE 9-5 Duodenal hematoma and pancreatic transection in a 4-year-old male presenting with bilious vomiting caused by nonaccidental abdominal trauma. **A:** Fluoroscopic upper gastrointestinal image reveals a large, well-defined defect within the third portion of the duodenum (*arrows*). with serial abdominal examination and liberal use of abdominal CT should be used in the suspected abused child.[120]

Genital Injuries

Sexual abuse should always be considered when evaluating a physically abused child. Specific guidelines for the evaluation for sexual abuse were revised and published in 2005.[2] Children who have been sexually abused can have symptoms of bed wetting, fecal incontinence, painful defecation, pelvic pain, abdominal pain, vaginal itching and bleeding, sexually transmitted diseases, and pregnancy in postmenarche adolescents. Sexually transmitted diseases found in abused children include gonorrhea, syphilis, chlamydia, trichomoniasis, and lymphogranuloma venereum. Although the percentage of sexually assaulted children with obvious physical trauma to the genitalia is low, failure to document such findings is a serious matter. Sexual abuse is always a criminal offense and must be reported to legal authorities. The physical signs of sexual abuse, including genital trauma, sexually transmitted diseases, or presence of sperm, are present in only 3% to 16% of verified sexual assaults,[29,241] but even this minority of patients will be undiagnosed if sexual abuse is not considered when a child presents with musculoskeletal injury resulting from abuse.

The orthopedic surgeon should be aware of the proper procedure for handling suspected sexual abuse, but is not expected to manage this evaluation. When sexual abuse is suspected, consultation with an experienced medical team will assure competent assessment of the child's physical, emotional, and behavioral needs, manage reporting and legal requirements, and interact with appropriate professionals to provide comprehensive treatment and follow-up.[2] The child's genitalia should always be examined and documented in a chaperoned setting by an appropriate physician consultant such as a pediatrician or a gynecologist. If the sexual assault occurred within 72 hours of evaluation, then a rape kit must be used by the evaluating physician or nurse examiner to provide medical evidence of the attack.[167] However, detecting semen on examination for forensic evidence decreases markedly after 24 hours.[211]

Patterns of injury that suggest, but are not specific for, sexually motivated assault include bruises, scratches, and burns around the lower trunk, genitalia, thighs, buttocks, and upper legs, including the knees. Pinch or grip marks may be found where the child was held. Attempted or achieved penetration may involve the mouth, vagina, or anus.[117] Sexually abused boys may have poor rectal sphincter tone, perianal scarring, or urethral discharge. Female genital examination findings that are consistent with sexual abuse include chafing, abrasion, or bruising of the inner thighs or genitalia, distortion of the hymen, decreased or absent hymen, scarring of the external genitalia, and enlargement of the hymenal opening.[11] The size of the transverse hymenal orifice does not correlate as a marker of child abuse.[127] The examination of the female genitalia can be normal even when there has been penetration, because hymen tissue is elastic and there can be rapid healing. In a study of 36 adolescent pregnant girls evaluated for sexual abuse, only 2 of 36 had genital changes diagnostic of penetrating trauma, suggesting that injuries either may not occur or may heal completely.[141] There is also a wide variability of appearance of normal female genitalia,[48,60] but posterior hymen disruption is rare and should raise suspicion for abuse.[33]

Fractures in Child Abuse

Overview

After skin lesions, fractures are the second most common physical presentation of abuse. Fractures, documented on plain radiographs or CT, are present in 11% to 55% of abused children and are most common in children younger than 3 years of age.[4,73,100] The child abuse literature shows varying incidence of abuse-related fractures, depending on the age of the study population, institution, study entry criteria, selection bias, and time period when the study was published.[174] The younger the child with a fracture, especially under 18 months of age, the more likely abuse is the cause.[62,65,143] Fractures resulting from abuse should be suspected in young children if a caretaker brings the child for evaluation but reports no history of accidental trauma, especially if the caretaker reports a change in the child such as extremity swelling or decreased movement of the limb. Particularly concerning is a bone that fractures under tension with torsion, rather than the physiologic loading of compression of normal childhood activity or falls. Pierce et al.[219] recommend that the clinician determine if the observed injury of a long bone and the stated mechanism are consistent (Table 9-8).

TABLE 9-8 Considerations When Evaluating a Child with a Long-Bone Fracture

1. What are the biodynamics of the injury event, the energies generated by the event, and how could certain factors of the injury environment contribute to the likelihood of injury?
2. What injuries are expected, and what is the likelihood that the event generated the specific load required to cause each and all of the injuries?
3. Did the energy of the event exceed the injury threshold, or was there a biologic abnormality such as decreased bone density that resulted in a lowering of the actual threshold for injury? Is there evidence of bone weakness or disease?
4. Is the fracture morphology consistent with the direction, magnitude, and rate of loading of the described mechanism?
5. Is the facture pattern unusual, and one that requires an extremely unusual loading condition, as is the case with a classic metaphyseal lesion (also termed corner or bucket-handle fracture)?
6. What are the child's developmental capabilities, and could the child have generated the necessary energy independent of "outside" forces to cause the observed injury?
7. Does the fracture reflect a high-energy fracture? Did the event generate enough energy to cause a high-energy fracture? Or is the fracture a small cortical defect, or hairline crack, reflecting a smaller amount of energy required for propagation of the fracture type?
8. What regions of the bone have been injured and what are the structural components that affect the ultimate pattern of fracture that is being observed? Were there structural factors that contributed to the likelihood of fracture?

TABLE 9-9 Specificity of Skeletal Trauma for Abuse

High Specificity
- Classic metaphyseal lesions
- Posterior rib fracture
- Scapular fracture
- Spinous process fracture
- Sternal fracture

Moderate Specificity
- Multiple fractures, especially bilateral
- Fractures in various stages of healing
- Epiphyseal separation
- Vertebral body fracture or subluxation
- Digital fracture
- Complex skull fracture

Low Specificity
- Clavicular fracture
- Long-bone shaft fracture
- Linear skull fracture

Adapted from O'Connor JF, Cohen J. Dating fractures. In: Kleinman PK, ed. *Diagnostic Imaging of Child Abuse*. Baltimore, MD: Williams & Wilkins; 1987:168–177, with permission.

Kleinman ranked the specificity of skeletal fractures for abuse (Table 9-9) based on the location and type of fracture. He emphasized that both moderate and low specificity radiographic findings become more specific when there is an inadequate or inconsistent explanation for the injury. The location and the type of fracture can aid in distinguishing between an accident and child abuse, but is only one piece of information.

All types of fractures have been reported in the child abuse literature, and it is often the presence of multiple fractures that indicates NAT (Fig. 9-6). In one of the largest series, King et al.[147] reported 429 fractures in 189 abused children. Fifty percent of these patients had a single fracture, and 17% had more than three fractures. Approximately 60% of fractures were found in roughly equal numbers in the humerus, femur, and tibia. Fractures also occurred in the radius, skull, spine, ribs, ulna, and fibula, in order of decreasing frequency. Another study[207] found a similar incidence of fractures of the humerus, femur, and tibia in abused children, with skull fractures seen in 14%. In contrast, Akbarnia et al.[3] found that rib fractures in abused patients were twice as prevalent as fractures of any one long bone; the next most frequently fractured bone was the humerus, followed by the femur and the tibia. Nearly a third of these patients had skull fractures. Loder and Bookout[181] reported the tibia to be the bone most commonly fractured in their series of abused children, followed by the humerus, the femur, the radius, and the ulna. In a classic study of 31 postmortem infants, the fracture pattern was very different from clinical studies in living children.[154] Highly detailed skeletal, specimen, and histopathologic analysis revealed 165 total fractures, most commonly in ribs, distal femur, the ends of the tibia, and skull (Fig. 9-7). The fact that 29 of the 31 infants had evidence of a healing fracture provides sobering evidence of the need to aggressively diagnose NAT before an infant is killed.

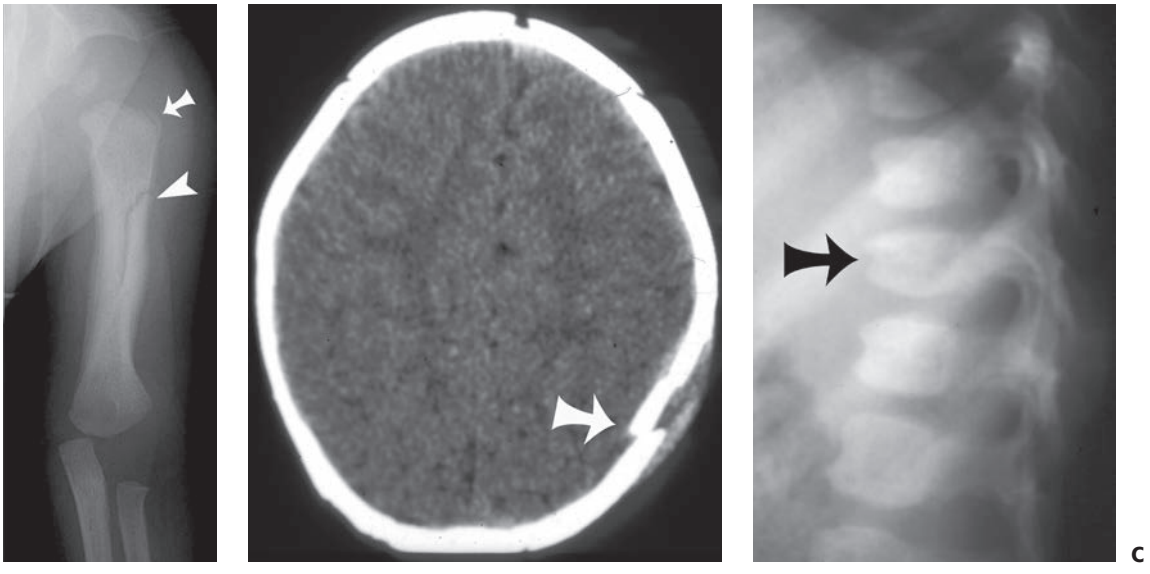

FIGURE 9-6 Multiple fractures in a 3-month-old female victim of inflicted injury. **A:** Frontal radiograph of the humerus shows proximal metaphyseal irregularity consistent with a corner fracture (*arrow*) and an oblique diaphyseal fracture with extensive periosteal reaction and healing (*arrowhead*). **B:** Axial CT image reveals a depressed left calvarial fracture (*arrow*). **C:** Lateral thoracolumbar radiograph suggests a T12 compression fracture (*arrow*), which is confirmed on nuclear bone scintigraphy **(D)** as a region of increased uptake (*arrow*). Bone scan also confirms left parietal (*arrowhead*) and humeral (*curved arrow*) fractures.

TABLE 9-10 Pearls and Pitfalls of Nonaccidental Trauma

- Be particularly cautious of a young infant with an injury.
- It is unusual for a young child to sustain a life-threatening injury from a fall alone, and he or she is highly unlikely to die from a short-height fall.
- Caregiver should be able to describe in detail the mechanism that is consistent with the observed injury.
- Multiple rib fractures, fractures in various stages of healing, and classic metaphyseal fractures are highly specific.
- Injury mechanism stated by the parents should agree with the type and energy of the fracture.
- Failure to diagnose child abuse may result in 25% risk of repeat abuse and 5% chance of death.
- Concerning bruises and skin lesions are the most common presentation of abuse. However, the child with such bruises should receive a proper evaluation for bleeding disorder.
- Unexplained fractures are much more likely to represent abuse and not a rare disease such as osteogenesis imperfecta (OI). Always consider OI when multiple fractures are seen.
- Obtain skeletal survey in all children younger than 2 years old, and individualize for 2–5-year-olds when child abuse is suspected. Repeat in 2 weeks.
- Involve the hospital child protective team early in the evaluation.
- Prepare records as though everything will be reviewed and read in court.

Physician education in child abuse is necessary to properly identify and report child abuse,[170] as there are many pitfalls to avoid (Table 9-10). There are several medical conditions that result in weakened bone and predisposition to fracture, such as OI, that should be considered in the evaluation of a young child with multiple fractures.[129] Some metabolic diseases cause metaphyseal abnormalities that should not be confused for metaphyseal fractures. One must also be aware of the normal physiologic diaphyseal periosteal reaction that is frequently present in infants younger than 6 months. In contrast to healing fractures, this is typically symmetric, diaphyseal only, and seen on the long bones of the extremities.[217]

Compared to healthy term infants, premature infants are more susceptible to fractures, both related to their prematurity and to increased risk of child abuse.[51] They may have underlying genetic, metabolic, and nutritional deficiency that predispose to fractures. Underlying osteopenia may lead to insufficiency fractures, both acute and chronic, in various stages of healing. Higher parental stress from caring for a sick or disabled infant may result in higher risk of NAT. In the premature infant with multiple fractures, investigation of the bone health as well as for child abuse is necessary, depending on the clinical context and findings.

The Skeletal Survey

In addition to standard radiographic studies of the acute injury, a complete skeletal survey should be used to screen for additional fractures in all children younger than age 2 years when abuse is suspected.[12,142] Use of the skeletal survey in children

suspected of abuse yielded positive findings in 10.8% of cases, most commonly in children with AHT, a life-threatening event, and in infants under 6 months of age in which the physical examination is less reliable.[82] Besides the index child, children under the age of 2 years in the same household of the injured abused child have a 11.9% risk of a positive skeletal survey, so are also recommended to have a skeletal survey.[180] The standard views obtained on a skeletal survey recommended by the American College of Radiology[13] are listed in Table 9-5. A suspected metaphyseal lesion of the extremity is more likely to be detected when a lateral view is done in addition to the AP view.[139] Lateral views coned to the joints may help in diagnosing classic metaphyseal lesions (CMLs). Lateral views of the entire spine must always be included in the skeletal survey. Bilateral oblique views of the thorax are for the diagnosis of subtle rib fractures.[142] The American Academy of Pediatrics Section on Radiology[12] cautioned that a "baby gram" has no place in diagnosing fractures of child abuse because the obliquity of the angle at which the radiographs transverse the skeleton may obscure many subtle fractures.[66]

Screening skeletal survey (Table 9-5) is the standard of care for imaging suspected child abuse in children less than 2 years of age. A radionucleotide bone rarely is used as a complementary and confirmatory test for problem solving some difficult cases.[66] Neither a skeletal survey nor a technetium bone scan alone will detect all occult fractures.[142] In Kleinman's postmortem infant study of fractures diagnosed by detailed histopathology, 58% of these fractures were seen on skeletal survey and 92% were seen by specimen radiographs. Because of a false-negative rate of 12% with skeletal surveys, Sty and Starshak[254] suggested in 1983 that a technetium bone scan be used as an initial screening test. However, technetium bone scintigraphy is currently used much less frequently in tertiary children's hospitals. Technetium bone scintigraphy is useful in the diagnosis of occult rib fractures[66]; however, there is inconsistent interpretation in children younger than 18 months of age. Bone scintigraphy is not useful for areas that are normally active such as the physis and metaphysis, but is very good when imaging areas away from the physis, such as the shaft of a long bone. Scintigraphy is not reliable to detect skull fractures.[196] Bone scan and skeletal survey may be considered complementary rather than competing imaging modalities; however, the skeletal survey is performed first. Jaudes[128] found that when results of either a bone scan or a skeletal survey were normal in a known abused child, the use of both tests often revealed additional occult fractures. Technetium scans are not useful for dating fractures because increased isotope uptake may occur at a fracture as early as 24 hours after injury and scan abnormalities may persist for years.[92]

Follow-up skeletal survey at 2 weeks increases the diagnosis of occult fractures, because some fractures, especially of the ribs, may not be seen until callus appears at 10 to 14 days. Oblique thoracic films obtained on 2-week follow-up skeletal survey increased diagnostic yield, with 46% of repeat surveys revealing additional fractures.[156,284] The second look skeletal survey better defines the fracture seen on the original survey and may help determine the age of the fracture.[142] Kleinman et al.[156] reported that a follow-up skeletal survey 2 weeks after the initial series detected 27% more fractures and provided assistance in dating 20% of previously detected fractures. In an effort to decrease radiation dose, a limited 15-view follow-up survey that excludes views of the skull and coned views of the joints has proven to be adequate to gain the necessary follow-up information.[107] Fractures or questionable fractures diagnosed on the initial screening skeletal survey should be reimaged on the follow-up survey. Almost 10% of children who sustained suspected abuse have a normal initial skeletal survey, but have significant findings on a 2-week follow-up survey, suggesting that all potential victims should have a repeat skeletal survey.[32]

The sensitivity of skeletal surveys diminishes in patients older than 2 years of age. They have less value for children older than age 5 years because the older child can describe where the pain is located. For children between the ages of 2 and 5 years, the test should be individualized.[12] The cost-effectiveness of skeletal surveys in the older child appears to be low, but may be helpful for the child with a disability who cannot cooperate with the physical examination. In one study of 331 children, only eight patients without overt physical signs of child abuse had occult fractures revealed by the survey[85]; however, the use of the skeletal survey in these few patients possibly prevented both reinjury and death. Digital radiography through picture archiving and communication system has replaced standard film-screen imaging in most hospitals and is comparable to high-detail film-screen imaging.[157,283] High-quality images with excellent image detail and spatial resolution are required to diagnose subtle skeletal abnormalities. The image acquisition and display parameters should be optimized for high diagnostic performance. Skeletal surveys should be supervised by a radiologist to ensure diagnostic quality.

Dating Fractures

Radiographic proof of unexplained fractures in various stages of healing is believed to be strong evidence of child abuse (Fig. 9-8).[3] The orthopedist often is asked to determine the age of fractures with some certainty to corroborate a history of injury given by caretakers. Experienced orthopedists and radiologists can roughly estimate the age range of fractures by their radiographic appearance and their experience reading many radiographs of known dated injuries. Although specific guidelines have been established for estimating the age of fractures in children,[78] there is limited evidence-based data for accurately predicting the age of healing fractures.[221] By studying healing clavicle fractures in newborns, Walters et al. concluded that subperiosteal new bone formation was present at 8 to 10 days and callus was present by 10 to 16 days. This can be used as a guide in dating fractures in cases of abuse. CMLs are acute until periosteal reaction appears at about 14 days; however, not all CML develop visible callus, so dating in the absence of callus should be done with caution.[273] Skull fractures generally cannot be dated.

In a review of studies that met minimal evidence-based inclusion criteria, the following conclusions were reached: The science of fracture dating is inexact and periosteal reaction is seen as early as 4 days and is present in at least 50% of cases by 2 weeks with remodeling peaking at 8 weeks after the fracture. The most difficult fractures to date are those that are completely

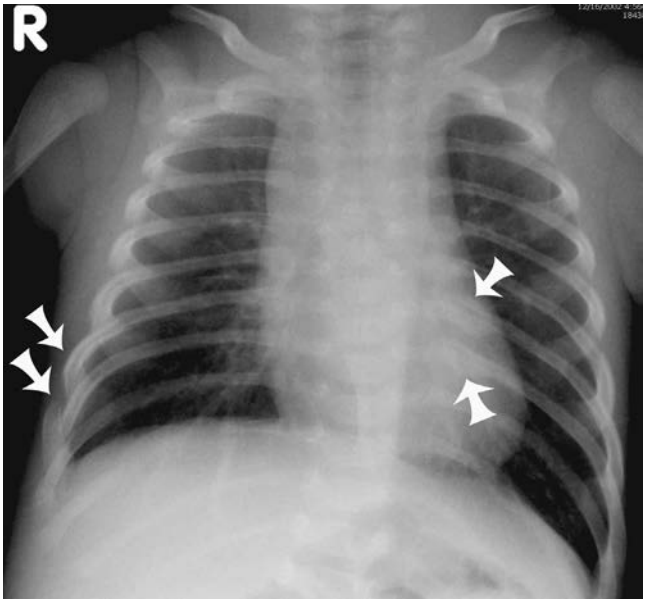

FIGURE 9-8 Rib fractures in multiple stages of healing in a 4-month-old female victim of nonaccidental injury. Frontal chest radiograph reveals acute (no periosteal reaction or healing) and subacute/healing (positive periosteal reaction) rib fractures (*arrows*).

healed, with substantial remodeling, and often the only sign of a healed fracture is a thickened cortex.

Skull Fractures

Infants in the first year of life with fractures of the skull or the extremities have an equal risk of the etiology being either accident or abuse.[188] However, 80% of skull fractures from abuse are seen in infants less than 1 year of age. Skull fractures were the most commonly reported fracture in one series.[190] Detailed postmortem analysis of 31 abused infants, with an average age of 3 months, observed confirmed skull fractures in 13.[154] Skeletal surveys missed 26% of skull fractures confirmed on CT scan.[229] Skull fractures are nonspecific and the morphology of the fracture does not distinguish accidental from inflicted trauma.[23] Simple linear skull fractures are usually accidental; however, 80% of inflicted skull fractures are also linear.[176] Complex skull fractures without a history of significant trauma, including comminuted, diastatic (separated sutures), displaced fractures, and fractures crossing suture lines, are suspicious, but not diagnostic for abuse.[39] Skull fractures cannot be dated.

Extremity Fractures

There is no predominant pattern of diaphyseal fracture in child abuse. Traditionally, a midshaft spiral fracture such as in the femur was believed to be caused by a violent abusive twisting injury. However, this is not typically the case. In a study of 23 long-bone fractures in abused children, spiral fractures were found in 78%.[115] However, others found that 71% of diaphyseal fractures were transverse in abused children.[96] Loder and Bookout[181] reviewed 69 long-bone fractures in abused children and noted that 56% were transverse, 36% oblique, and only 8% spiral. In another study of 429 fractures,[86] 48% of fractures were transverse and 26% were spiral. Most of these long-bone fractures were in either the middle or distal third of the shaft. Transverse fractures are most commonly associated with either a violent bending force or a direct blow to the extremities, whereas spiral or oblique fractures of the long bones are caused by axial-loaded, twisting injuries, such as in a fall. Humeral shaft fractures in children under 3 years of age have an 18% risk of being because of probable abuse.[234] In delayed medical care, long-bone fractures may show exuberant callus because of lack of immobilization, and multiple fractures may be present in different stages of healing.[6] Juxtacortical calcification may be seen without fracture when there is diaphyseal periosteal separation resulting from tractional or torsional force when the limb is grasped or pulled along the shaft of the bone.[195]

Femur fractures in infants are especially suspicious for NAT; whereas children old enough to run can fall and accidentally fracture their femurs if there is a significant twisting motion at the time of injury.[264] Despite a high likelihood of NAT in an infant with a femoral fracture, an infant with a femur fracture may have accidental trauma as the cause, if the parent's reported mechanism is consistent with the injury. In a recent case series from Alberta, Canada, only 17% of femoral fractures in infants less than 1 year of age were from abuse, whereas the author's review of eight previous reports showed that NAT was the cause for 42% to 93% of cases.[122] As children get older and more active, a femur fracture is more likely to be from accidental injury than from abuse. Schwend et al.[233] reported that while 42% of femoral fractures in infants not walking were related to NAI, only 2.6% of femoral fractures in ambulatory toddlers were related to NAI. Blakemore et al.[38] noted that only 2% of femoral fractures from age 1 to 5 years were caused by abuse. Risk factors for abuse were age younger than 12 months, the child not yet walking, a questionable mechanism, and other associated injuries.

Humeral shaft fractures are frequently seen in NAT (Fig. 9-9). Fractures in unusual locations such as the distal clavicle, scapula, acromial tip, proximal humeral metaphysis, or distal humeral physis may result from violent blows or upper extremity traction injury and are suggestive of abuse in young children.[10] Infants may normally have a separate ossification center adjacent to the tip of the acromion, simulating a fracture,[160] but a true fracture

FIGURE 9-9 Humeral fracture in a 3-week-old male after a difficult delivery. Radiograph shows a transverse mid diaphyseal fracture with extensive callus (*arrow*).

has sharp, demarcated edges, may be positive on bone scan, and will show callus or healing. Although Kleinman[148] described fractures of the sternum to be specific for child abuse, accidental midsternal fractures in children have been reported.[109]

Fractures of the hands and feet are commonly because of accidental trauma in older children,[196] but are suspicious for abuse in infants. Nimkin et al.[203] reviewed 11 hand and foot fractures in abused children younger than 10 months of age and found mostly torus fractures either of the metacarpals or the proximal phalanges of the hand and similar fractures of the first metatarsals of the feet (Fig. 9-10). Clinical signs of fracture were present in only one patient, and bone scans were insensitive to the presence of the fractures in all patients. These injuries are best seen on the oblique views standard in the skeletal survey.

Metaphyseal and epiphyseal fractures of the long bones are classically associated with child abuse.[45,240] In infants and toddlers, these fractures can occur when the child is violently shaken by the extremities with direct violent traction or rotation of the extremity (Fig. 9-9).[196] Buckle fractures may occur at multiple sites, seldom producing exuberant callus. Repeated injury may cause irregular metaphyseal deformities. Periosteal avulsion typically produces new bone formation within 2 to 3 weeks of injury and may be confused with osteomyelitis.[6] New bone formation may be delayed, particularly in children with malnutrition or rickets. Metaphyseal fractures constituted 40% of fractures in one series,[96] but fewer than 15% in another.[163]

Kleinman[148] ranked the specificity of skeletal trauma for abuse (Table 9-9). Distinguishing between an accident and child abuse is based on the location and the type of fracture. He emphasized that both moderate- and low-specificity radiographic findings of child abuse become much more specific when there is an inadequate explanation for the injury. The presence of multiple injuries, particularly in the young child, is especially concerning for abuse.

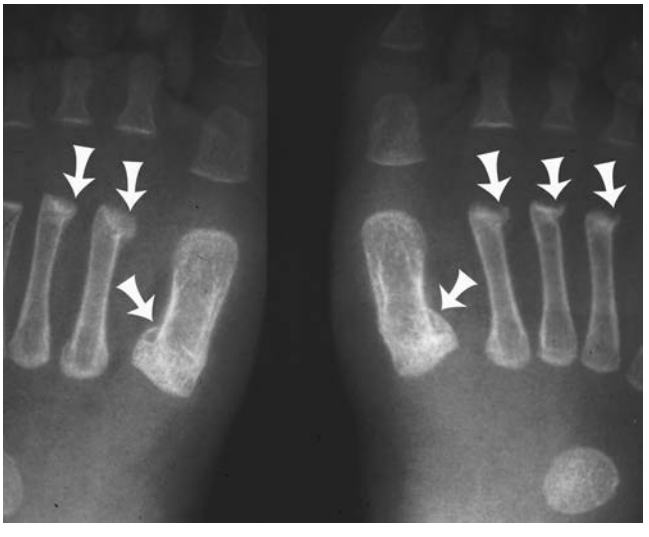

FIGURE 9-10 Metatarsal fractures in a 2-month-old female victim of nonaccidental trauma. Radiographic image from a skeletal survey shows multiple healing, bilateral, and symmetric proximal and distal metatarsal fractures (*arrows*).

Compared to healthy term infants, premature infants are more susceptible to fractures, both related to their prematurity and increased risk of child abuse.[51] They may have underlying genetic, metabolic, and nutritional deficiency that predispose to fractures. Underlying osteopenia may lead to insufficiency fractures, both acute and chronic, in various stages of healing. Higher parental stress from caring for a sick or disabled infant may result in higher risk of NAT. In the premature infant with multiple fractures, investigation of the bone health as well as for child abuse is necessary, depending on the clinical context and findings.

Classic Metaphyseal Lesion of Child Abuse

The almost pathognomonic fracture of child abuse is the CML, commonly termed the "corner" or "bucket-handle fracture."[6] These fractures are almost exclusively seen in NAI, but are not the most common fractures in abused children. The incidence of CML in large series ranges from 15% to 32%.[96,147,163,181] Radiographs show a corner fracture at the edge of the ossified portion of the zone of provisional calcification, *which is the metaphyseal side of the physis as opposed to the epiphyseal side*. If a significant portion of the metaphyseal rim is involved, a bucket-handle fracture pattern is produced. Based on their histopathologic autopsy study of metaphyseal fractures in abused infants, Kleinman et al.[151,153] found that bucket-handle or corner fractures are actually a full-thickness metaphyseal fracture extending through the primary spongiosa of bone just above the zone of provisional calcification (Fig. 9-11). Centrally, the amount of metaphysis remaining attached to the physis was

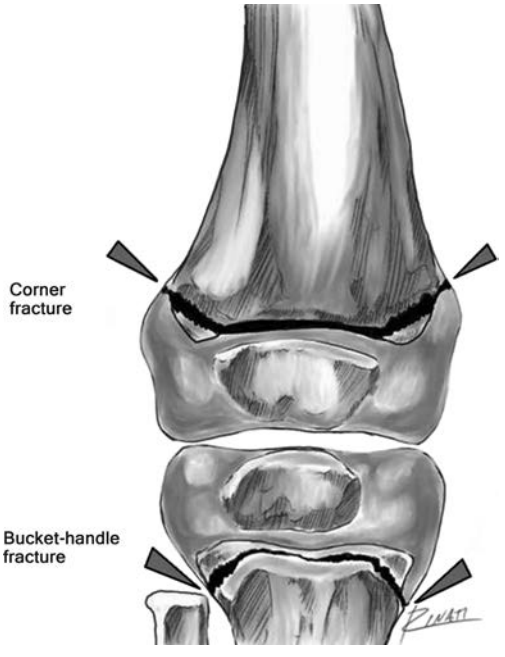

FIGURE 9-11 Schematic representation of classic metaphyseal lesions (CMLs). Illustration demonstrates the path of the CML. Depending upon the angle at which the CML is viewed from, it may appear to extend across the width of the ossified physis (tibia illustrating a bucket-handle fracture) or only the margins of the physis (femur, illustrating a corner fracture). (Artwork courtesy of Gholamreza Zinati, MD.)

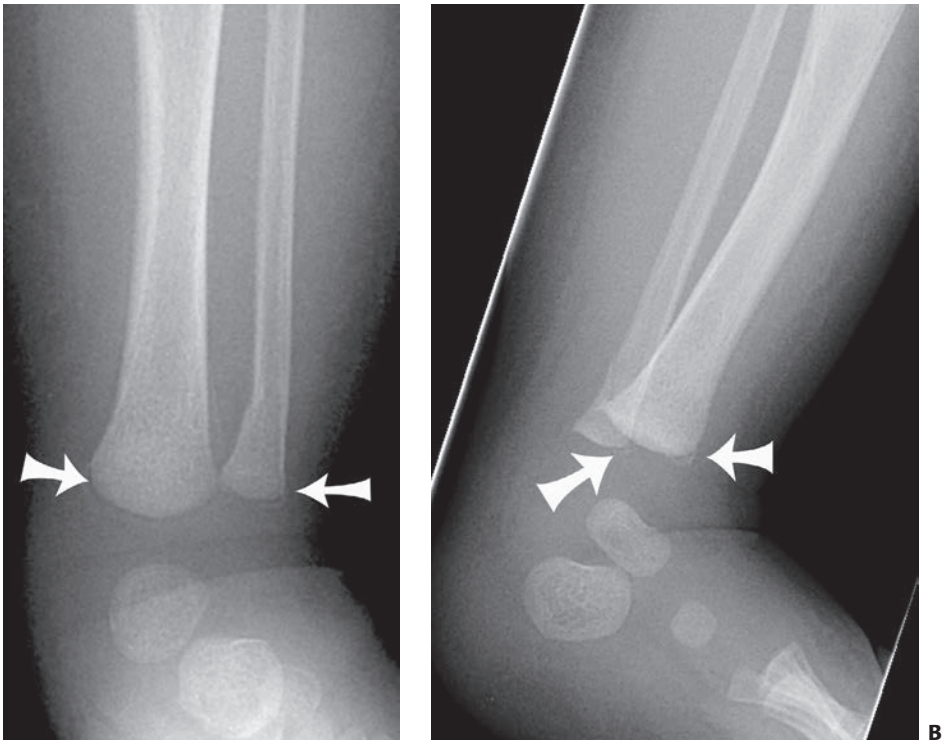

FIGURE 9-12 Classic metaphyseal fracture in a 2.5-month-old male victim of nonaccidental injury. **A:** Frontal radiograph of the tibia and fibula demonstrates transmetaphyseal lucencies or bucket-handle fractures (*arrows*). **B:** A lateral ankle radiograph reveals lucency at the tibial and fibular metaphyseal margins indicating corner fractures (*arrows*).

thin, but peripherally the fracture line curved away from the physis so that a substantial metaphyseal rim remained attached to the physis (Fig. 9-12). On radiographic study, this metaphyseal rim formed the basis for both corner and bucket-handle fractures. In healing fractures, biopsy specimens showed metaphyseal extension of hypertrophied chondrocytes.[210] Metaphyseal corner fractures are most likely caused by either violent shaking or traction injuries to the extremity.[4] Even one CML noted on a skeletal survey is highly suspicious and specific for child abuse.[158] Subepiphyseal–metaphyseal lucency can also be caused by systematic disease such as rickets and leukemia. Lesions resembling corner fractures of the distal radius, ulna, tibia, and proximal humerus also have been reported with one variant of spondylometaphyseal dysplasia.[72] Because fracture callus does not reliably occur, dating the CML lesion is always unreliable. The presence of callus does indicate that the fracture is probably greater than 10 to 14 days.

Rib Fractures

Rib fractures are uncommon in childhood accidents, especially when located posterior and associated with other long-bone fractures. Although no single fracture is specific for abuse, rib fractures are highly suggestive of abuse if there is no plausible trauma or medical explanation.[142] Abusive rib fractures may be caused by squeezing of the chest by a caretaker,[45] hitting the child from behind, or stepping on the chest.[156,244] Kleinman et al.[155] postulated that severe shaking of an infant can cause front-to-back chest compression, which levers the posterior rib over the transverse process of the vertebral body, causing fractures of the posterior rib shaft at the transverse process and of the rib head adjacent to the vertebra (Fig. 9-13). One series showed that fractures of the first rib in children were only seen in abuse.[253] Barsness et al.[26] reported that rib fractures had a positive predictive value of NAI of 95% in children younger than 3 years of age. In this study, rib fracture(s) were the only skeletal manifestation of NAI in 29% of the children. Posterior rib fractures are difficult to diagnose acutely because they lack callus and are rarely displaced. Even with healing, the callus on radiography may be obscured by the overlying transverse process.[152] Oblique views of the chest are included in skeletal surveys because they better show these fractures. Posterior rib fractures are the most common location in child abuse, but fractures may occur anywhere along the arc of the rib, including disruption of the anterior costochondral junction (Fig. 9-14). Posterior rib fractures tend to occur between T4 and T9. Acute anterior costochondral separations of the ribs may be difficult to see on chest radiographs,[243] and with healing, the anterior end of the osseous rib becomes widened and club shaped.[163,207] Anterior rib fractures are commonly associated with abdominal injury and can be detected on CT scan. Healing fractures show callus, but healed fractures may be subtle, with only a fusiform thickening of the rib. Older fractures of the ribs in NAT may form lytic, expansile lesions.[183]

Rib fractures are rarely discovered in abused infants who have undergone resuscitation for cardiac arrest; in which case, there may be confusion about the etiology of the fractures. However, the elasticity of the infant chest allows a high tolerance to compression, having low reported rates of rib fractures from cardiopulmonary resuscitation between 0.3% and 2%, with none being posterior rib fractures.[184] Cardiopulmonary resuscitation is therefore a very rare cause of rib fractures and seldom causes classic posterior rib fractures. Death from cardiac arrhythmia from a blow to the chest has been reported in

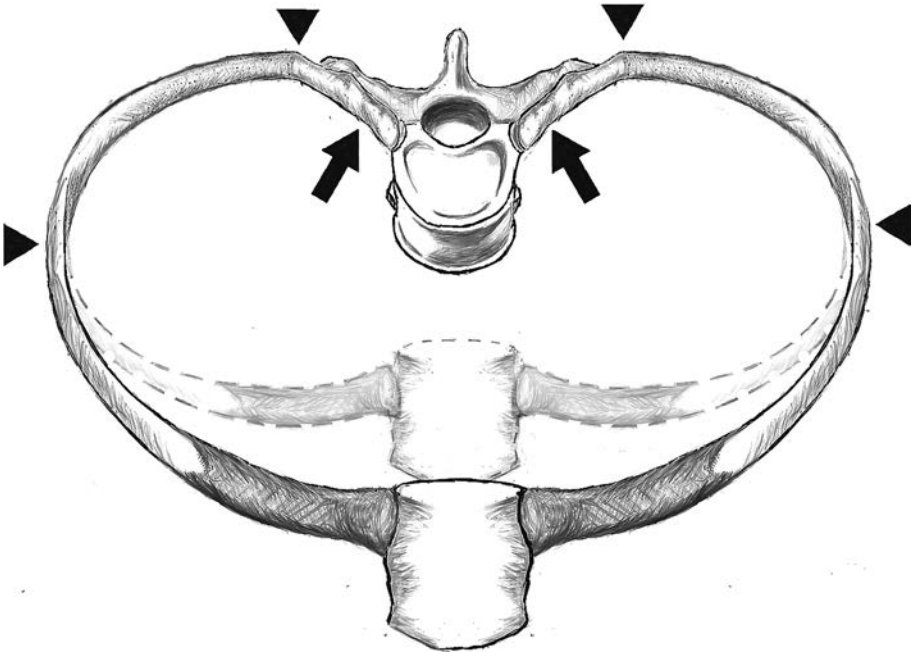

FIGURE 9-13 Schematic representation of rib fracture mechanism. Anterior chest compression causes the posterior ribs to be levered over the transverse processes of the vertebra (*arrows*) causing posterior and lateral rib fractures (*arrowheads*). (Artwork courtesy of Samir Abedin, MD.)

a 7-week-old abused infant whose rib fractures at autopsy were initially thought to be caused by resuscitation efforts.[19] In addition to rib fractures, abused infants can sustain severe lung contusion and respiratory distress from chest wall trauma,[189] with fatal fat embolus reported.[202] Chest physiotherapy for infants with respiratory infection is a very rare cause of multiple rib fractures, about 1 in 1000 infants receiving this treatment.[57]

In infant fatalities of suspicious origin, postmortem high-detailed preautopsy skeletal surveys and specimen radiographs are helpful in fully evaluating and diagnosing child abuse.[149] In a postmortem study of 31 infants who died of inflicted skeletal injury,[154] there were a total of 165 fractures (51% rib fractures, 39% metaphyseal long-bone fractures, 5% long-bone shaft fractures, 4% fractures of the hands and feet, 1% clavicular fractures, and less than 1% spinal fractures). Postmortem thoracic CT is more sensitive than radiography for pediatric anterior and posterior rib fractures.[118] If an abdominal CT is being performed for evaluation of NAT, inclusion of the chest may yield

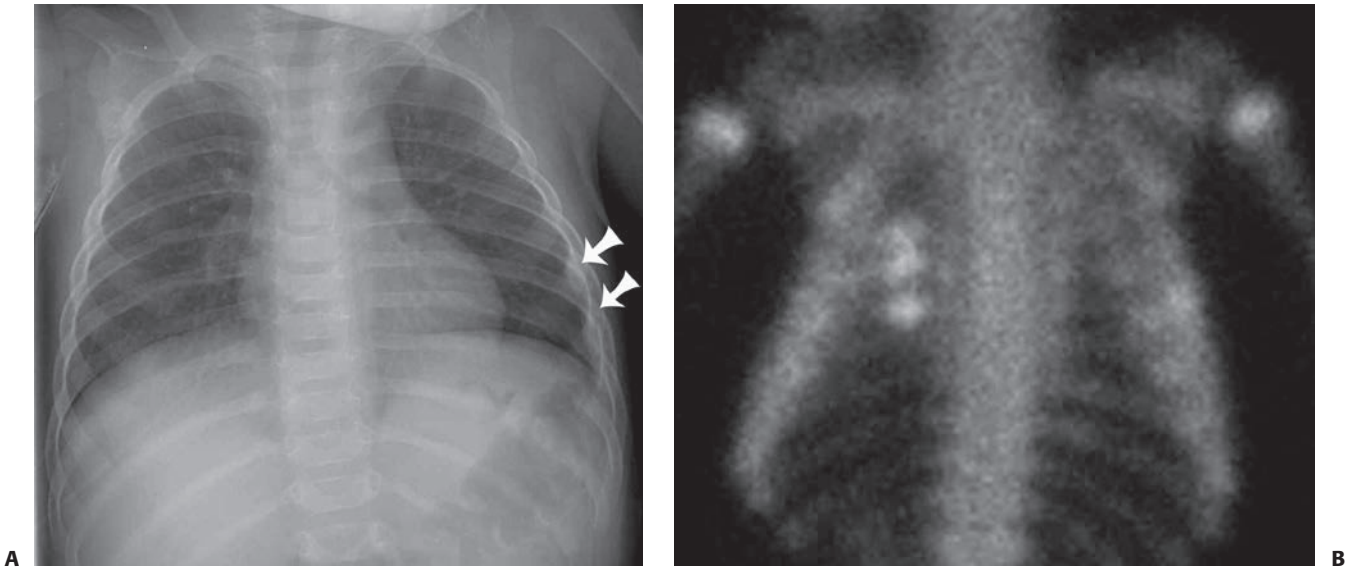

FIGURE 9-14 Rib fractures in a 9-month-old male victim of nonaccidental trauma. **A:** Chest radiograph reveals left lateral sixth and seventh rib fractures (*arrows*). **B:** Nuclear medicine bone scan confirms foci of increased uptake within the left lateral ribs as well as revealing additional hot foci in multiple right posterior lateral ribs.

additional information about rib fractures, but at a cost of additional radiation of approximately 3 mSv.

Spinal Fractures

Spinal fractures in abused children are infrequent but important to recognize. Based on autopsy findings,[150] spinal fractures of fatally abused children generally involve 25% or less compression of the vertebrae. In a report of 103 children with cervical spine injury, only three patients had injury because of abuse and all had SCIWORA.[42] In another study of fractures of the cervical spine, prevertebral soft tissue edema on radiographs was the only sign of cervical injury, because spontaneous reduction of the cervical vertebrae after dislocation was common.[223] Thomas et al.[263] reported a 9-week-old boy with spinal cord injury resulting from cervical spine fracture who presented as a floppy infant. Although routine cervical radiographs were normal, MRI studies showed retropulsion of a fragment of the primarily cartilaginous C3 vertebrae into the spinal canal. Hangman's type fractures of the posterior elements have been described in infants as a result of child abuse.[159] This must be distinguished from C2 primary spondylolysis which may be associated with pyknodysostosis, both of which are rare disorders associated with wormian bones and pencil pointing of the distal phalanges.[71]

CT is helpful in evaluating pediatric cervical trauma. Rooks et al.[226] reported a compression fracture of C5 with anterior subluxation of C4 on C5 in a 3-month-old abused premature twin requiring decompression and cervical fusion. The other twin had a C5 on C6 fracture subluxation treated with casting, but later required surgery to reduce and fuse the subluxation. MRI was very helpful in showing spinal cord compression in both cases. Oral et al.[208] reported on an inflicted avulsion fracture of C2 and interspinous ligament injury in a 4-year-old child.

Vertebral compression fractures can occur when a child's buttocks are forcibly slammed onto a flat surface with hyperflexion of the spine.[5,47] Half of these fractures involved the anterosuperior end plate associated with a compression deformity, 30% had pure compression fractures, and 20% had fractures of the superior end plate without significant compression. Positioning premature infants in extreme hyperflexion for lumbar puncture has been reported to cause iatrogenic lumbar spine fracture.[101] Carrion et al.[50] reported circumferential physeal fractures of the thoracolumbar spine associated with child abuse that required open reduction. Thoracolumbar fracture dislocations may occur in abused children with or without neurologic injury.[177,237] Flexion–distraction Chance fractures and synchondroses injuries (Fig. 9-15) may also be seen in NAT. Although neurologic injury in spinal fractures resulting from child abuse is uncommon,[70] any patient with abusive spinal injury should undergo thorough neurologic examination (Fig. 9-15). Skeletal survey must include a lateral view of the cervical, thoracic, and lumbar spine. Because of the potentially serious consequences of a spinal injury in an infant or young child, clinical or radiographic suggestion of a spinal injury should be further evaluated with MRI. If a patient has evidence of AHT to require MRI, it should include the entire spine.[144]

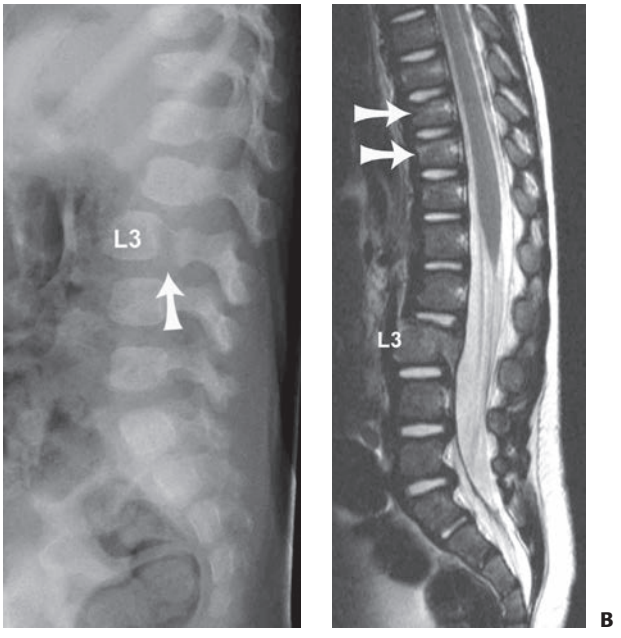

FIGURE 9-15 Lumbar spine fracture in a 16-month-old male victim of nonaccidental trauma. **A:** Lateral lumbar radiograph shows lucency through the L3 synchondrosis (*arrow*) with anterolisthesis of L3 body on L4. **B:** Sagittal T2-weighted MRI reveals hyperintense signal within the bone marrow of the fractured L3. Slight compression fractures of T10 and T11 are also noted (*arrows*).

Laboratory Studies

An abused child should have a complete blood cell count with sedimentation rate, liver function studies, and urinalysis. Clotting studies, including prothrombin time and activated partial thromboplastin time, thrombin time, fibrinogen, factor VIII, factor IX, and von Willebrand factor antigen and activity should be performed in patients with bleeding or ecchymosis to evaluate for bleeding diathesis. If bruising is the only finding of possible abuse, consultation with a hematologist may be necessary to fully evaluate for an unusual bleeding disorder.[262] Infants born prematurely are at risk for rickets and low bone density. Therefore, evaluation of calcium, phosphorous, alkaline phosphatase, and 25-OH vitamin D may be useful in such infants.

Recently, two biomarkers for head injury, neuron-specific enolase S100B and myelin-basic protein, have been found to be released into the peripheral circulation, analogous to cardiac enzyme release after myocardial injury. These two markers when used together are 79% sensitive and 100% specific in diagnosing traumatic brain injury, making them potentially very promising for evaluating suspected mild head trauma.[34] If there is suspicion of substance abuse by any family member, a toxicology screen should also be performed on the patient.[96]

Multidisciplinary Approach

The most important consultation to request for a child with suspected inflicted injury is the child protective services team. In a study by Banaszkiewicz et al.,[20] three tiers of physicians

reviewed the medical records of 74 children under the age of 1 year presenting to the emergency department with fractures: Staff clinicians, orthopedic attendings, and a child protective team pediatrician. In over one-fourth of cases of abuse, the possibility was underestimated during the original evaluation. Any suspected abuse should initiate a minimum evaluation that includes an appropriate radiographic evaluation with a skeletal survey in the younger child, dilated fundoscopic examination by an ophthalmologist, and consultation by a child abuse specialist. Any significant nonorthopedic injury should prompt consultation by the appropriate subspecialty: Neurosurgery, general surgery, plastic surgery, ophthalmology, or urology.[6] In cases of suspected sexual abuse, a thorough genital examination will be required, including a gynecologic consultation for girls. This is typically initiated by the child protective services team.

The Differential Diagnosis

Although it is extremely important not to miss the diagnosis of child abuse, it is equally important to maintain an objective, critical view and not to make the diagnosis in error.[129] Overdiagnosing child abuse can be harmful to the family, with the parents being placed at risk of losing custody of their children and also facing criminal charges.[138] Even direct allegations of child abuse may turn out to be false. Patients or family friends may make false statements about an abuse situation through misinterpretation, confabulation, fantasy, delusions, and other situations.[35] The American Academy of Child and Adolescent Psychiatry[9] has published guidelines for the evaluation of abuse, stating that the possibility of false allegations needs to be considered, particularly if the charges are coming from the parent rather than the child, the parents are engaged in a dispute over custody or visitation, or the child is a preschooler.

Normal metaphyseal variations are seen occasionally and should not be confused with corner fractures of child abuse. These variants are seen most commonly in the proximal tibia, distal femur, proximal fibula, distal radius, and distal ulna. A bony beak may be seen medially in the proximal humerus or tibia, and is usually bilateral. Cortical irregularity in the medial proximal tibia may also be seen in 4% of normal infants and young toddlers and is bilateral in 25%. Beaks may extend beyond the metaphyseal margins in both the distal radius and the lateral aspect of the distal femur, with bilateral normal variants in 25% of infants and young toddlers.[205]

The signs of child abuse found on radiographs can overlap with the findings of systemic diseases such as Caffey disease (infantile cortical hyperostosis), osteomyelitis, septic arthritis, insufficiency fracture, hypophosphatasia (Fig. 9-16), leukemia (Fig. 9-17), metastatic neuroblastoma, OI (Fig. 9-18), scurvy (Fig. 9-19), vitamin D deficient and drug-induced rickets (Fig. 9-20), congenital insensitivity to pain, osteopetrosis, kinky hair syndrome, prostaglandin therapy, osteoid osteoma, and other benign bone tumors.[6] Children with biliary atresia may present with osteopenia and fractures without history of significant injury, which

should not be mistaken for child abuse.[75] There has been an increase in the incidence of syphilis in females of childbearing age, and, although extremely rare, congenital syphilis can mimic fractures of child abuse with diaphysitis, metaphysitis, and multiple pathologic fractures in different stages of healing.[178] Physiologic periostitis, in contrast to lesions from child abuse, is seen in young infants of about 6 months of age, is usually bilateral, symmetric, diaphyseal, located on the long bones – humerus, femur, and tibia – and has no periostitis of the metaphysis.[66] Insufficiency rib fractures may be seen in rickets of prematurity as well as rickets of low birth weight and also have been reported after chest physiotherapy.[56] The presence of metabolic disease and pathologic fractures does not exclude the possibility of child abuse. Duncan and Chandy[84] reported a 3-month-old girl with multiple fractures associated with rickets who died suddenly at 5 months of age. Child abuse was suspected but not proven. Three years later, evidence of child abuse was found in a subsequent sibling in the same family.

Several diseases are commonly brought up in custodial hearings as alternative possibilities to nonaccidental traumatic injuries, and these diseases should be objectively considered in the differential diagnosis. Linear lucencies of the proximal tibia noted after intraosseous vascular access needles may mimic fractures, but careful analysis of the imaging studies can determine the actual cause of the lucency.[108] Metaphyseal corner fractures of the distal tibia and fibula were seen in eight children treated with likely forceful serial casting for clubfoot, with only one potentially related to NAT.[99] Leukemia should always

be considered in a child with diffuse osteopenia or metaphyseal lucencies. McClain et al.[187] reported a 2-year-old child who died of undiagnosed acute lymphoblastic leukemia, having been earlier reported as a possible victim of child abuse. Ecchymosis on the back and extremities did not initiate an appropriate evaluation for leukemia or bleeding disorder. Clinical signs of leukemia, including fever, pallor, petechia, purpura, adenopathy, hepatosplenomegaly, and bone pain, should be sought in children with bruising of unknown origin. Factor XIII deficiency may cause unexplained bleeding from minor trauma and be

mistaken for child abuse because the standard coagulation profile may be negative and factor-specific tests may be negative if performed post transfusion.[200]

Osteogenesis Imperfecta

Undiagnosed OI should always be considered when a child presents with multiple fractures of unknown etiology, but may be a difficult diagnosis to make.[229] Before the diagnosis of OI is made the parents may be presumed to be the cause of the fractures, with temporary removal of a child in 70% of cases.[162] OI caused by spontaneous mutation can occur without a family history.[215] The so-called hallmark of OI is an intensely blue sclerae, but this feature is consistently present only in Sillence type I,[238] may be completely absent in patients with type IV, and is less obvious in type III.[215] Sillence et al.[239] noted that patients with either type II or III OI may have blue sclerae at birth, but the sclerae can become normal by adolescence. The rare Sillence type II OI, termed Congenta A in the Shapiro classification, has normal sclerae, but bone abnormalities and osteopenia are severe and early death is likely.[215] Blue sclerae may be present in normal young infants and can be misinterpreted as a sign of OI. The presence of abnormal teeth, known as dentinogenesis imperfecta, may be helpful in a diagnosis if the child is old enough for teeth to have erupted. Plain radiographs may show long bones of normal density in both types I and IV OI. Another radiographic sign of OI, wormian bones of the skull, is consistently present only in type III and is often absent in types I and IV.[215] Because type IV OI does not have blue sclera or wormian bones and is a milder form of OI than type III, diagnosis may be initially delayed or confused with NAT. Other rare types of OI have been described, which further confounds the medical and legal evaluation. Some authors believe that the presence of metaphyseal fracture is pathognomonic for child abuse and, therefore, helpful to distinguish abuse from OI,[1,15] but others[74,215] believe that there is no particular fracture pattern that renders the diagnosis of OI likely. Children with OI tend to bruise excessively, which overlaps with child abuse.[235] SIDS has also been described in infants with undiagnosed OI.[205]

When the diagnosis of OI cannot be made on clinical grounds, the diagnosis may be made by biochemical assay. Gahagan and Rimsza[95] reported that 87% of children with OI have abnormal procollagen that can be detected by a skin biopsy with fibroblast culture. Fibroblasts are assayed for abnormally low levels of procollagen as well as primary abnormal procollagen.[44] Steiner et al.[249] reported that over a 4-year period, 48 patients were referred for collagen analysis to diagnose OI in cases of suspected child abuse. Only 6 of these 48 children had abnormal collagen test results, and in five of the six patients, the diagnosis of OI could have been made on clinical and radiologic findings. More recently, Marlowe et al.[185] found 11 of 262 samples submitted to rule out OI had alterations in the amount or structure of type I collagen synthesized, consistent with the diagnosis of OI. In 11 others, OI could not be excluded. Referring physicians correctly diagnosed children with OI in 6 of the 11 patients clinically. Four children believed to have OI by physical examination had normal biochemical studies, representing a false-positive clinical diagnosis, attributed mostly to the use of sclera hue as a major diagnostic criterion.[186] The authors concluded that laboratory testing for OI remains a valuable adjunct when determining the etiology of fractures in children. Even when a child has OI or other metabolic bone disorders, fractures may be because of comorbid NAT. Knight

and Bennett[161] reported a young child with OI whose abuse could not be proved until linear bruising of the face from being slapped was documented.

Temporary Brittle Bone Disease

In 1993, Paterson et al.[215] described 39 patients with a variant of OI that they described as a temporary brittle bone disease in which fractures were limited to the first year of life followed by spontaneous improvement. However, an extensive review by the Society for Pediatric Radiology[194] concluded that the entity of temporary brittle bone disease has insufficient scientific evidence to warrant this as a plausible diagnosis. This diagnosis as a plausible explanation for NAT with multiple fractures should be discouraged.[131]

Sudden Unexpected Death in Infancy

The death of an infant is a sentinel event and must be handled appropriately with the medical and the legal systems cooperatively involved.[133] SIDS is a subset of sudden unexpected death in infancy (SUDI) and refers to the death of an infant less than 1 year of age with the onset of the fatal episode apparently occurring during sleep that remains unexplained after a thorough review of the circumstances of death and clinical history.[133,277,278] Because SIDS is more common than infanticide, death by abuse intentional suffocation is very commonly initially attributed to SIDS before the correct diagnosis is made.[124] However, other causes of sudden death such as intracranial bleeds must be excluded. Byard et al.[43] reported a 5-month-old girl who died suddenly from spontaneous subarachnoid hemorrhage from undiagnosed Ehlers–Danlos syndrome. They recommended collagen analysis in patients with unexplained multifocal spontaneous hemorrhages to exclude this rare syndrome. Sperry and Pfalzgraf[246] reported a 9-month-old infant whose diagnosis of SIDS became uncertain when postmortem radiographs showed healing symmetric clavicle fractures and a healing left medial humeral condyle fracture. Subsequent investigation showed that the child had undergone "chiropractic" manipulation 4 weeks before death by an unlicensed therapist to correct "shoulder dislocations," with the parents exonerated of abuse charges. When abuse is suspected in an infant fatality, combined radiology, CT scan, detailed forensic autopsy, and osteologic investigation are required to detect all fractures that are present.[52] Detailed examination of organs, such as the orbit, is also becoming the standard in autopsy protocols.[197]

Postemergency Room Treatment and Legal Reporting Requirements

Once NAT is recognized, the first step in treatment is hospital admission.[199] This is therapeutic in that it places the child in a safe, protected environment, provides the opportunity for additional diagnostic workup, and, more importantly, investigation of the family's social situation by appropriate personnel. In tertiary centers, multidisciplinary teams often are available to evaluate and treat such children, but in other circumstances the orthopedist may be primarily responsible for coordinating both evaluation and treatment. Court custody may be required for children of uncooperative families who refuse admission, and hospitalization should be continued until a full investigation is completed by the appropriate child protective services and a safe disposition is established. In the United States, the physician is required by law to report all suspected abuse to appropriate child protective services or legal authorities. Although physicians have better reporting rates than most other professionals, 27% of injuries considered likely to be caused by abuse and 76% of injuries that were considered possibly related to child abuse were not reported.[89] When the reporting is done in good faith, the physician has immunity against criminal or civil liability for these actions, but in only three states – Ohio, California, and Alabama – does this protection include absolute immunity.[63] The distinction is critical. Absolute immunity means that the physician who reports suspected child abuse cannot ever be held for damages sought by families for allegedly inappropriate reports of child abuse or neglect. The granting of absolute immunity, even for physicians, is not encouraged by the American legal system because in theory it would protect individuals who make false reports of child abuse to harass families and would deprive the injured parties their legal right to seek damages for harmful actions. In contrast, physician immunity based on good faith reporting of suspected child abuse is contingent on the physician having a reasonable belief that abuse or neglect has occurred. Although in theory this protection seems to be quite adequate, recently there has been a dramatic rise in the number of lawsuits filed by families seeking damages for alleged, unfounded reports of child abuse and neglect. Although it is true that by the time these lawsuits are eventually resolved, physicians have almost never been held liable for good faith reports of child abuse, in a substantial number of these cases, the physicians first lost at trial level before eventually prevailing at appeal. Considerable expense, frustration, and loss of time can be experienced by the physician in defending against such allegations as the families and their attorneys pursue multiple forms of legal theories in court and attempt to evade the immunity provisions.[63] On the other hand, the stakes for failure to report suspected child abuse are likely much higher, potentially exposing the physician to charges of malpractice.[4]

All states require physicians to report not only cases of definitive child abuse or neglect but also cases when abuse is just suspected or is considered a possibility. Physicians have been held liable for damages for their negligence in failing to diagnose child abuse when the child subsequently was reinjured by further abuse, and, ironically, the parents also may be able to collect additional compensation for losses resulting from medical expenses. For families to be successful in these lawsuits, they must be able to prove that the failure to make the diagnosis of child abuse was negligent and that, had the diagnosis been made, steps would have been taken to protect the child from additional abuse. Although the probability of a physician being held liable under such circumstances is low, the amount of damages can be high if the family does prevail when the child has suffered permanent sequelae.[63]

After admission, the orthopedist proceeds with care of the child's musculoskeletal injuries and facilitates various medical

consultations. Recommendations for disposition of the child after completion of medical treatment may be a group decision through a multidisciplinary team or, more often, the decision of the primary physician, who may be the orthopedist. Final disposition choices may include return to the family, return to a family member who does not live in the child's home, or placement in a shelter or a foster home setting. The risk of reinjury and death is significant if the abused child is returned to the unsafe home, so the orthopedist must strongly support child protective services in custodial actions when it is believed that a child's injury truly occurred from abuse at home. Not only must the definitive diagnosis of child abuse be documented in the chart, but also a separate notarized affidavit may be necessary. Commonly, custodial actions by child protective services are reviewed in a court hearing in a matter of weeks, and the physician may be called to testify in the hearing. Criminal charges also may be brought against the perpetrator of the child abuse, and the physician likely also serves as a witness in these proceedings.

The Orthopedic Surgeon's Legal Role in Nonaccidental Injury

The orthopedist fills a dual role in the courtroom in child abuse proceedings. First, he or she serves as a material witness whose testimony is confined to the physician's personal involvement in the legal matter of the child's evaluation and treatment. The testimony may include clarification to the court of information contained in the medical record. As a material witness, the physician cannot render opinions about the facts as stated during his or her testimony. In addition, however, the physician may also be sworn in as an expert witness.[103] An expert witness is an individual considered by the court to have special knowledge and experience that qualifies him or her to render opinions about certain facts presented in the courtroom. The limits of the physician's expertise usually are defined by the attorneys in court before the testimony of the expert witness.

Physicians may be reluctant to testify in court for many reasons. The courtroom is an unfamiliar setting for most physicians and the adversarial nature of the American legal system may be perceived as a hostile environment. In the courtroom, opposing attorneys are likely to search for inconsistencies in the testimony or unfamiliarity with the record to discredit the physician witness.

To avoid being a poor witness, the orthopedist should meticulously prepare to give testimony by conducting a thorough review of the child's medical records and a review of recent medical literature on the subject of child abuse.[103] Often, there is a pretestimony discussion with child protective services counsel in family court cases or the district attorney's office in criminal cases. Such meetings should preferably be in person, and the orthopedist's professional training and expertise are examined to determine whether he or she may serve as a material witness, an expert witness, or both. The attorney should be provided the orthopedist's curriculum vitae, and another copy should be made available to the court. If the orthopedist is to serve as a material witness, the factual information of the case as well as the limitations of the physician's knowledge are discussed, as are questions that may be posed during testimony. Orthopedists functioning as expert witnesses should indicate relevant information that should be provided through questioning during testimony. In addition, anticipated testimony from any opposing expert witness and cross-examination questions from the opposing attorney should be discussed. The opposing attorney also may request an informal pretestimony meeting. The orthopedist should request a list of questions that will be asked in this session ahead of time and request that both the prosecution attorney and the opposing attorney be present during the session, which often is recorded.

The next step may be a deposition in which both attorneys question the witness under oath to "discover" the testimony that the witness will provide in court. The primary purpose for a deposition in the discovery process is to keep attorneys from later being surprised in court by testimony of witnesses.[55] Any testimony the physician gives during the deposition will be recorded, and later in court any inconsistencies between testimony and prior depositions are likely to be vigorously attacked by attorneys in cross-examination. Depositions are rarely used in criminal prosecutions[103]; instead, a subpoena is issued requiring a physician witness to appear at the courtroom at a certain time. Often, there may be hours of delay before the testimony actually begins. Through prior arrangements with the attorneys, the orthopedist may be placed "on call" if he or she works within a reasonable distance of the courtroom and can be available a short time before the actual testimony is needed. The physician has no legal right to such treatment and must be prepared to honor the exact conditions of the subpoena if alternative arrangements cannot be made. If significant delays are encountered in giving testimony and the attorneys are not responsive to physician hardship, then the orthopedist should contact the judge directly to remedy the situation.[55] In the courtroom, the orthopedist should be conservatively dressed and appear attentive, competent, poised, and at ease.[55,103]

Once called to the stand, the orthopedist is sworn in and identified. Next follows qualification, direct examination, and then cross-examination. In the qualification process, the attorney asks the physician fairly detailed questions about the orthopedist's training and background to establish whether he or she is a credible witness.[103] The attorney wishes to impress the judge or jury with the orthopedist's qualifications as a witness, whereas the opposing attorney may challenge the witness with questions to cast doubt on his or her expertise.[55] During this phase, the attorneys also may establish the limits of the physician's expertise as an expert medical witness. Next, the attorney will proceed with direct examination. A series of questions are asked that aim at developing a logic and progressive line of thought leading to a conclusion.[55] In child abuse cases, in particular, the testimony will lead to the fact that the abuse has occurred and that it has been appropriately diagnosed. In addition, the physician expert witness may be asked to give an opinion of the risk for subsequent abuse if the child returns to the home where the alleged abuse occurred. The physician witness will almost never be asked about the guilt or innocence of the caretaker accused of abuse, but the orthopedist in certain circumstances will come close to answering the "ultimate

question"[55] by testifying about a child's statement of history if it identifies the abuser. Some states, however, restrict such testimony. In Maryland, a physician may not testify regarding any disclosures made by a child abuse victim unless the disclosure is admissible under a recognized exception to the rule prohibiting hearsay evidence.[255] The orthopedist should ask about any possible restrictions on his or her testimony with the attorney in pretrial discussion. In testimony, the orthopedist will want to use the courtroom setting to advocate for the safety and well-being of the child.[103] Questions regarding medical findings often will be prefaced in the courtroom by the words "reasonable medical certainty," a term that is poorly understood by most physicians. Chadwick[55] offered a definition of reasonable medical certainty as "certain as a physician should be in order to recommend and carry out treatment for a given medical condition." He offered an example that the certainty for the diagnosis and treatment of leukemia must be much higher than that for diagnosis and treatment of a viral upper respiratory tract infection.

During testimony, the orthopedist's words should be carefully chosen and should be understandable by a lay jury. Testimony should be objective, honest, and thorough.[103] Attorneys may frame questions in ways that are difficult to understand, and the orthopedist should not hesitate to ask the attorney to clarify a question.[55] Answers should be brief, without volunteering extra information. The perception listeners will have of the answers should be carefully considered by the orthopedist. In particular, attorneys may phrase yes or no questions that could place misleading words in the mouth of the orthopedist. In such situations, when neither response is appropriate, the orthopedist should answer in a sentence that provides an accurate answer.[103] Language should be straightforward, and visual aids may be used in providing clear testimony. The expert should use testimony as an educational process for the court, in which the common experience and knowledge of the jury is used to build understanding with common sense explanations of medical findings.[55]

Cross-examination by the opposing attorney follows direct examination. The opposing attorney's role is to challenge the material presented by the physician witness to protect the defendant.[103] This may involve an attempt to bring into question the physician's credibility, the medical record, the physician's training or expertise, or the physician's objectivity or composure and clarity of thought before the jury.[103] Attorneys may accomplish this by finding inconsistencies with prior statements, asking leading questions as well as questions that allow only certain desired answers, and minimizing physician qualifications.[55] The attorney may frame a question that contains certain elements that the physician agrees with and others that are misleading, and often the question will end with "Isn't that so, doctor?" or "Is that true?" The physician witness should be firm in answering such questions, clearly stating what in the question he or she agrees with and what he or she does not. It is also common to encounter questions from attorneys based on hypotheses that are extremely unlikely, and the physician needs to point out that unlikelihood.[55] Part of the strategy of aggressive cross-examination is to provoke the physician into arguments or unprofessional behavior that could discredit the physician or his or her testimony before the court. In particular, juries will allow aggression on the part of an attorney, but they expect physician witnesses to respond professionally, even under extreme duress.[73] Inexperienced potential physician witnesses can prepare themselves by either watching trials or participating in mock trials.[55] Brent[40] assembled an excellent series of vignettes of expert medical witness case studies in court and provided detailed instructions with regard to the responsibilities of such experts. Both redirect examination and recross-examination may follow cross-examination at the discretion of attorneys, but usually these procedures are very short.[55]

Disposition Following Custody Hearings

After a hearing or trial, the child historically either remains in the protective custody of the state or returned to home, but the danger of further abuse exists in both situations. In a study of recurrent maltreatment in 10 states based on the NCANDS, Fluke et al.[91] found that the recurrence rate was 13% by 6 months after the first episode of reported abuse and return to the home, increasing to 17% by 12 months. In a report of 206 care and protection petitions brought to the Boston juvenile courts,[198] 31 were dismissed with return of the child to the parents. During a 2-year follow-up of these dismissed cases, 29 had reports of further mistreatment, and 16 were returned to court under another care and protection petition. One risk factor identified by the study was a previous appearance in court; half of dismissed cases with this risk factor returned to court again. Children ordered permanently removed from parental custody by the court may still suffer further abuse by a new caretaker. Another alternative pathway of custody is gaining popularity with the court systems in which the abused child is released to the custody of a relative of the family with consideration given to the wishes of the parents or other prior custodians of the child. Although in theory this approach may help preserve the integrity of the family unit, the child may still be in danger in this sort of arrangement. Handy et al.[104] of the Pediatric Forensic Medicine Program of the Kentucky State Medical Examiner's Office noted evidence of recurrent abuse 2 to 9 months after the original injury in 6 patients out of 316 referrals (1.8%) to the program. They emphasized that in two of these cases, the child was in protective custody of a family relative when the original perpetrator was allowed unsupervised access to the child in violation of court order. It is possible that such reinjuries occur because either the close relatives of the child abuser may not believe that the caretaker committed the original abuse or the relatives are under emotional pressure to allow the caretaker to have access to the child in spite of court order. It is hoped that the court systems can strike a balance between the need to preserve the family unit and the need to protect the child from further abuse.

Prevention of Child Abuse

Prevention of child abuse lies in early intervention. Home visitor programs can contact a mother immediately after the birth of her child and arrange for a visit in which the mother's parenting strengths are assessed. Parents requiring additional support

are linked to community agencies and family resources.[10,245] Practicing Safety, a project sponsored by the American Academy of Pediatrics (AAP) and funded by the Doris Duke Charitable Foundation, works to decrease child abuse and neglect by expanding anticipatory guidance and increasing screening by pediatric practices to parents of children aged 0 to 3 years. The AAP website (http://www2.aap.org/sections/scan/practicingsafety/phase1.htm) also lists resources for physicians and parents.

Parenting education offers instruction in specific parenting skills such as discipline methods, basic childcare, infant stimulation, child development, education, and familiarity with local support services. Such support seems to enhance parent and child interactions, and mothers report a diminished need to punish or restrict their children. Antivictimization programs teach children certain concepts believed to facilitate self-protection, such as identification of strangers, types of touching, saying "no" to inappropriate advances, and telling someone about inappropriate behavior.

Continuing abuse can be prevented by the orthopedist's and trauma team's prompt recognition of child abuse in the emergency department or clinic and appropriate intervention.[58] After protecting the welfare of the child, the most important issue in dealing with child abuse is to help both the child and the family through early recognition of the problem and appropriate therapeutic measures by all health personnel.

ACKNOWLEDGMENTS

Special thanks is given to Sreeharsha V. Nandyala for technical assistance with the manuscript and to Drs. Sami Abedin and Reza Zinati for their medical illustrations.

10 FRACTURES AND DISLOCATIONS OF THE HAND AND CARPAL BONES IN CHILDREN

Nina Lightdale-Miric and Scott H. Kozin

Introduction to Fractures and Dislocations of the Hand and Carpal Bones in Children

Incidence

The pediatric hand is exposed and especially vulnerable to injury as the curious child explores the surrounding world. Young children are often unaware of dangers and place their hands in susceptible situations.[14,86,204,217,218] Hand injuries account for up to 25% of pediatric fractures (Table 10-1).[72,86] The reported annual incidence is approximately 26.4 fractures per 10,000 children.[217]

Pediatric hand fractures occur primarily in a *biphasic* age distribution: The toddler and the adolescent. In toddlers, the injury occurs most often secondary to a crush[10,57,110,204]; for example, a finger caught in a closing door. In teenagers, however, the mechanism is more commonly from a torque, twist, or axial load sustained during contact activities and athletics.[29,60,68,121,165,212,220]

A higher incidence of pediatric upper extremity fractures is associated with certain youth sports, such as snowboarding, football, basketball, and skateboarding.[123] In one study, overweight

TABLE 10-1 Incidence of Pediatric Hand Injuries

Peak age: 13 years
Annual incidence: 26.4 per 10,000 children
Percentage of all pediatric emergency patients: 1.7%
Right side incidence equals left
Male incidence is greater than female incidence
Most common fracture types
- Nonphyseal: Distal phalanx (crush)
- Physeal: Proximal phalanx
- Index and small fingers most commonly injured

adolescents were found to have poorer balance, which may explain a propensity for fracture.[71] Hand fractures in children peak around age 13, coinciding with active participation in organized contact sports, attempted daredevil maneuvers, as well as the occasional emotional outburst (e.g., punching a wall).[15,27,60]

The two most common pediatric hand fractures are distal phalanx crush injuries and Salter–Harris (S-H) II fractures of the proximal phalanx.[72,86,119,158,217,218] The border digits (thumb and small fingers) are the most vulnerable rays.[14,86,119,158,217,218] Dislocations are relatively uncommon in children. Lateral bending forces are more often transmitted through the physis rather than the collateral ligaments in a child's hand because the growth plate is the path of least resistance.[86,110,121,180,217,218] Proximal phalanx S-H II fractures account for nearly 33% of all hand fractures in children. Although rare, the thumb metacarpophalangeal (MCP) joint is the most commonly dislocated joint in the skeletally immature hand.[38,67,113] The proximal interphalangeal (PIP) joint is the most commonly injured articular surface, involving volar plate or collateral ligament avulsion fractures.

Fractures and dislocations about the child's carpus are rare compared to injuries of the adjacent physis of the distal radius.[135,218] The scaphoid is the most frequently injured carpal bone in children.[11,30,76] Pediatric scaphoid fractures have a peak incidence between the ages of 12 and 15 years.[53] Scaphoid fractures are extremely rare during the first decade of life.[16,59,76,107,154,165,180,185,203] Only a few reported cases involve children younger than 8 years of age, and the youngest patient reported is 4 years of age.[53]

Carpal ligament dissociation and tears of the triangular fibrocartilage complex (TFCC) rarely occur in children.[198] These tears are usually associated with distal radial fractures, radial growth arrest, ulnar overgrowth, and ulnar carpal impaction. Most often these children present late after acute trauma with activity-related pain. Rotational forces with axial loading cause tearing of the carpal ligaments or TFCC. In children with a positive ulnar variance, the TFCC is thinner and more susceptible to injury. Similarly, hypertrophic unions and nonunions of the ulnar styloid increase the risk of TFCC injuries.

Applied Anatomy of Hand and Carpal Bones

Adults and children have distinct patterns of hand injury because of age-specific patterns of use as well as differences in underlying skeletal and soft tissue composition. Knowledge of the architecture of the physis, the soft tissue origins and insertions, and the surrounding periosteum is essential for recognition and treatment of children's hand fractures.

Osseous Anatomy of Hand and Carpal Bones

Potential epiphyses exist at both the proximal and distal ends of all the tubular bones. Secondary ossification centers, however, develop only at the distal ends of the metacarpals of the index, long, ring, and small rays, and at the proximal end of the thumb. Conversely, the epiphyses are present only at the proximal ends of the phalanges in all digits.[77,121]

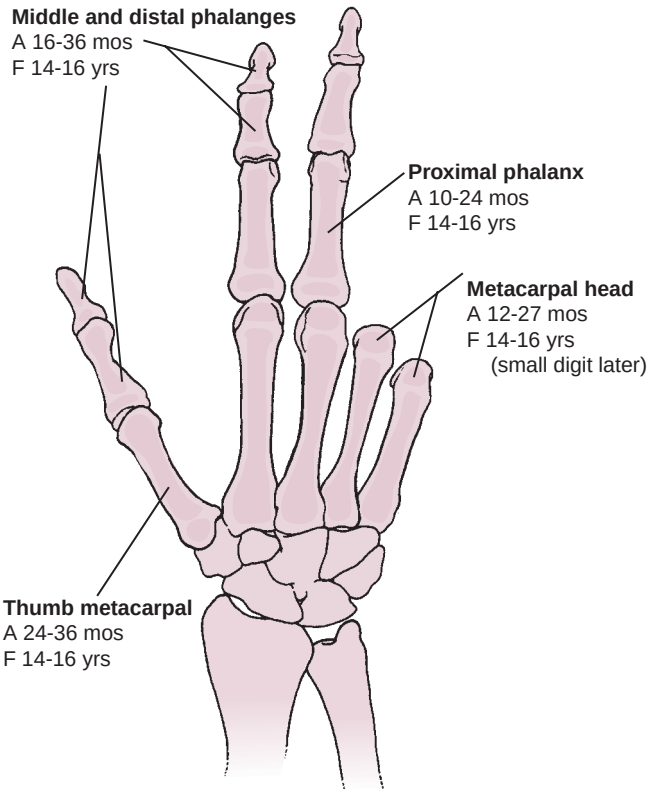

FIGURE 10-1 Appearance of secondary ossification centers (A). Fusion of secondary centers to the primary centers (F).

Secondary Ossification Centers

In boys, the secondary ossification centers within the proximal phalanges appear at 15 to 24 months and fuse by bone age of 16 years (Fig. 10-1).[77,196] In girls, the appearance and closure occur earlier, at 10 to 15 months and bone age of 14 years, respectively. The secondary ossification centers of the middle and distal phalanges appear later in both girls and boys, usually by 6 to 8 months. Fusion of the secondary ossification centers, however, occurs first distally then proximally with maturity.

Within the metacarpal, the secondary ossification centers appear at 18 to 27 months in boys and at 12 to 17 months in girls. The proximal thumb metacarpal secondary ossification center appears 6 to 12 months after the fingers. The secondary centers within the metacarpals fuse between 14 to 16 years of age in girls and boys. Carpal bones classically ossify in a pattern moving counterclockwise when looking at the back of your right hand, starting with the capitate and hamate by 1 year of age.

The pattern of carpal bone ossification and appearance of secondary ossification sites in the metacarpals and phalanges is often used to predict the skeletal bone age and years of remaining growth in children (Fig. 10-2).[77,196] The fetal wrist begins as a single cartilaginous mass. By the 10th week of gestation, the carpus transforms into eight distinct entities with definable intercarpal separations. Although these precursors display minor differences in contour, the anatomical elements greatly resemble the individual carpal bones in their mature form.[111]

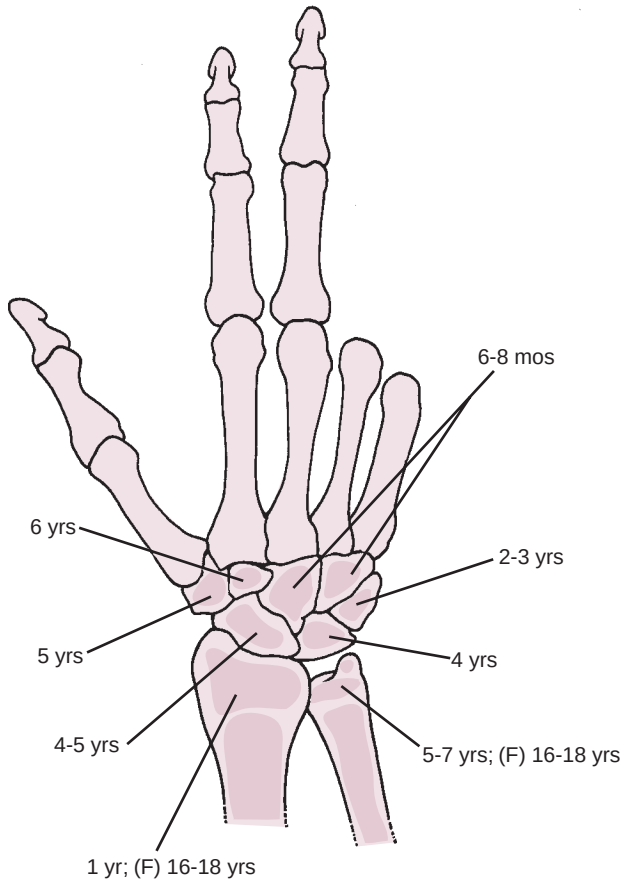

FIGURE 10-2 The age at the time of appearance of the ossific nucleus of the carpal bones and distal radius and ulna. The ossific nucleus of the pisiform (not shown) appears at about 6 to 8 years of age.

The capitate is the first bone to ossify, usually within the first few months of life. The pattern of ossification proceeds stepwise from the distal row to the proximal row in a circular fashion. The hamate appears next, usually at about 4 months of age. The triquetrum appears during the second year, and the lunate begins ossification around the fourth year. The scaphoid begins to ossify in the fifth year, usually slightly predating the appearance of the trapezium.[107] Scaphoid ossification begins at the distal aspect and progresses in a proximal direction.[145] The trapezium and trapezoid ossify in the fifth year, with the trapezoid lagging slightly behind. The ossification pattern usually concludes with the pisiform in the ninth or tenth year. The scaphoid, trapezoid, lunate, trapezium, and pisiform may demonstrate multiple centers of ossification.[116,145] Although these variations are well recognized, they may be confused with acute trauma by the inexperienced observer.

The ossific nucleus of each carpal bone is cloaked in a cartilaginous cover during development, which is thought to provide a unique shelter from injury.[11,72] This observation is supported by epidemiologic studies of scaphoid fractures that highlight the infrequent incidence in children younger than 7 years of age and the marked increase in teenagers.[76,107] The detection of injuries to the immature carpus is problematic because of the difficulties in examining an injured child and the limited ability of radiographs to detail the immature skeleton; therefore, the incidence may be underappreciated.[11,140,167]

Physeal Anatomy of Hand and Carpal Bones

The physis (growth plate) of the long bones of the hand provides longitudinal digital growth. Pediatric hand fracture geometry is the direct result of the histologic anatomy of the physis.[137] The physis is divided into four distinct zones: Germinal, proliferative, hypertrophic, and provisional calcifications (zones I, II, III, and IV, respectively). The zone of chondrocyte hypertrophy (zone III) is the least resistant to mechanical stresses. This zone is devoid of the collagen that provides inherent stabilizing properties. Collagen is present in zones I and II, and the calcium present in zone IV provides similar structural strength.[72,202] Therefore, the fracture often propagates through zone III as the path of least resistance. High-energy injuries, however, may undulate through all four zones of the physis.[137,184]

The irregularity of the physeal zones in the phalanges and metacarpals increases near skeletal maturity.[21] Thus, a fracture line may more often be transmitted through several zones in adolescents. This variable path through irregular topography may contribute to increased risk of partial growth arrest following adolescent fractures that involve the physis.[184] Physeal irregularity also explains the differing patterns of physeal injuries dependent on age: S-H I and II fractures tend to occur in younger patients compared to the rarer S-H III or IV fractures that are more prevalent in children close to skeletal maturity.

Pseudoepiphyses, Double Epiphyses, and Periphyseal Notching of Hand and Carpal Bones

A persistent expression of the distal epiphysis of the thumb metacarpal is called a pseudoepiphysis.[80] The pseudoepiphysis appears earlier than the proximal epiphysis and fuses rapidly. By the sixth or seventh year, the pseudoepiphysis is incorporated within the metacarpal and is inconspicuous. Pseudoepiphyses also have been noted at the proximal ends of the finger metacarpals, usually of the index ray. The only clinical significance is radiologic differentiation from an acute fracture in the setting of incidental injury (Fig. 10-3).

Double epiphyses can be present in any bone of the hand, but these anomalies are more common in the metacarpals of the index finger and thumb. There are variable expressions of double epiphyses, but the true entity is considered only when a fully developed growth mechanism is present on both ends of a tubular bone. Double epiphyses are usually seen in children with other congenital anomalies, but their presence does not appear to influence overall bone growth. When fractures occur in bones with double epiphyses, growth of the involved bone appears to be accelerated.[216]

Periphyseal "notching" should not be confused with double epiphyses, pseudoepiphyses, or fracture.[46,80,206,216] The location of the notches can coincide with the physis or may be slightly more distant from the epiphysis. Notching is a benign condition that does not influence the structural properties of the bone.[216]

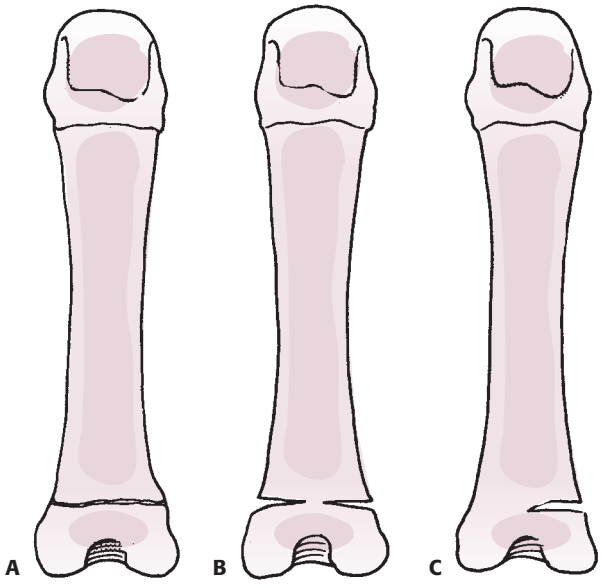

FIGURE 10-3 Abnormal epiphyseal appearance. **A:** Double epiphysis. **B:** Pseudoepiphysis. **C:** Notched epiphysis.

Clinical examination and x-rays of the contralateral noninjured hand are often critical to clarify what is unique individual osseous anatomy versus an acute injury.

Soft Tissue Anatomy of Hand and Carpal Bones

The tensile strength of a younger child's soft tissues usually exceeds that of the adjacent physis and epiphysis.[18,137] For this reason, tendon or collateral ligament avulsions are less common compared to physeal or epiphyseal fractures in the skeletally immature hand.[18,84]

Tendons

The terminal tendon of the digital extensor mechanism and the extensor pollicis longus insert on the epiphyses of the distal phalanx. The central slip of the extensor mechanism inserts onto the epiphysis of the middle phalanx. The extensor pollicis brevis inserts onto the epiphysis of the proximal phalanx of the thumb. The abductor pollicis longus has a broad-based insertion onto both the epiphysis and metaphysis of the thumb metacarpal. The extensor digitorum communis for index through small finger connects into the sagittal band at the MCP joint, which in turn lifts the proximal phalanx into extension by its insertion along the volar plate. These extensor tendinous insertions are broad to the thick periosteum, which predisposes bony avulsion injuries.

The long digital flexor tendons (the flexor digitorum profundus [FDP] and the flexor pollicis longus [FPL]) insert along the metadiaphyseal, not epiphyseal, region of their respective terminal phalanges of the fingers and thumb.[84] The flexor digitorum superficialis (FDS) inserts onto the central three-fifths of the middle phalanx.

Collateral Ligaments

The collateral ligaments at the interphalangeal joint originate from the collateral recesses of the phalangeal head, span the physis, and insert onto both the metaphysis and epiphysis of the middle and distal phalanges (Fig. 10-4). The collaterals also insert onto the volar plate to create a three-sided box that protects the physes and epiphyses of the interphalangeal joints from laterally directed forces.[38,84] This configuration explains

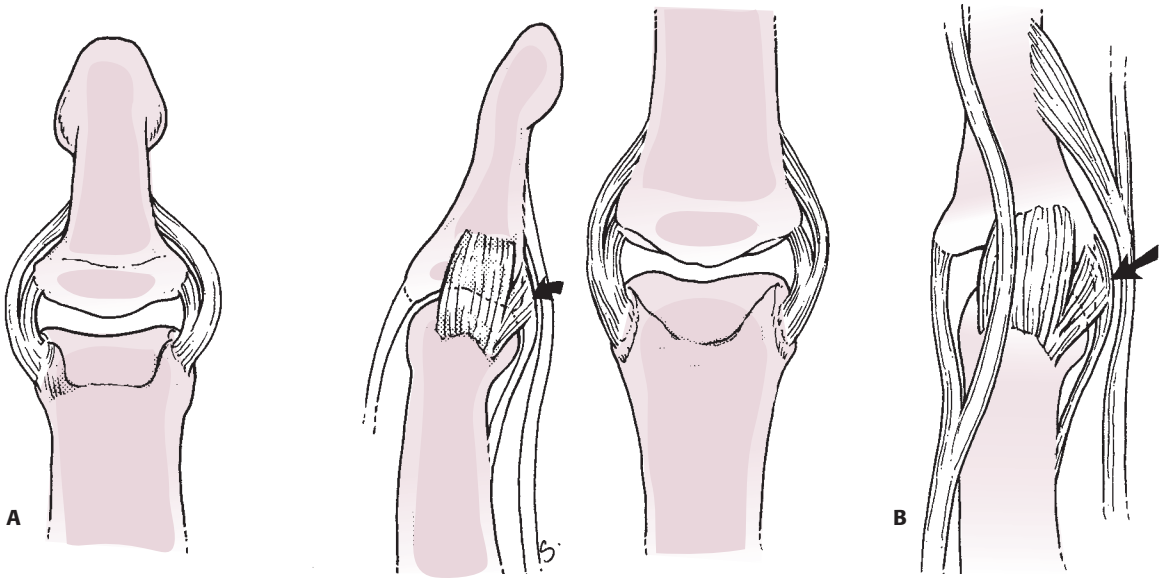

FIGURE 10-4 Anatomy of the collateral ligaments at the distal **(A)** and proximal **(B)** interphalangeal joints. The collateral ligaments at the interphalangeal joints originate in the collateral recesses and insert into both the metaphyses and epiphyses of their respective middle and distal phalanges. Additional insertion into the volar plane (*arrows*) is seen at the interphalangeal joints.

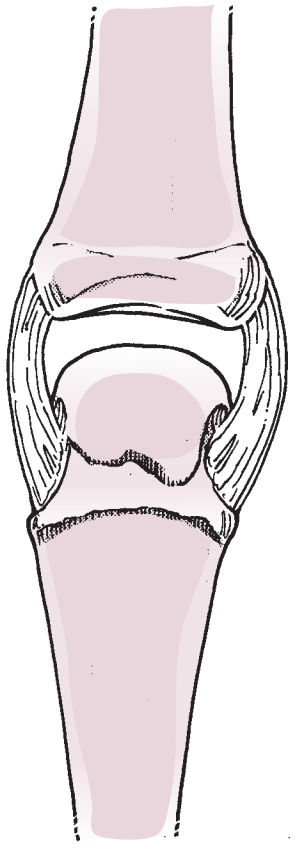

FIGURE 10-5 The collateral ligaments at the MCP joint originate and insert almost exclusively on the epiphyseal regions of the metacarpal and the proximal phalanx.

the rarity of S-H III injuries at the interphalangeal joints. In flexion, the collateral ligaments are stretched because of the shape of the proximal phalanx head. Condyle fractures of the proximal phalanx are therefore at increased risk for displacement with finger motion.

In contrast, the collateral ligaments about the MCP joints originate from the metacarpal epiphysis and insert almost exclusively onto the epiphysis of the proximal phalanx (Fig. 10-5). This anatomic arrangement accounts for the frequency of S-H III injuries at the MCP joint level. The ligamentous anatomy about the thumb MCP joint more closely resembles that of the PIP joints, which mirrors the arrangement of the adjacent physes.

Volar Plate

The volar plate is a stout stabilizer of the interphalangeal joint and MCP joints and resists hyperextension forces. The volar plate originates from the metaphysis of the respective proximal digital segment and inserts onto the epiphysis of the distal segment (Fig. 10-4B). The plate receives insertional fibers from the accessory collateral ligaments to create a three-sided box that protects the joint. Hyperextension of the finger joints often results in avulsion injuries of the epiphysis or S-H III at the volar plate insertion site.

Periosteum

The periosteum is robust in a child's hand and can act as a considerable asset or liability in fracture management. On the positive side, the periosteal sleeve can minimize fracture displacement and aid in fracture reduction. On the negative side, the periosteum can shear off, become interposed between displaced fracture fragments, and prevent reduction.

Nail Matrix

The skin, nail elements, soft tissues, and bone of the distal digit are closely related (Fig. 10-6). The dorsal periosteum of the distal phalanx is the underlying nutritional and structural support for the sterile matrix and nail bed. The germinal matrix is responsible for generating the nail plate. The volar aspect of the distal phalanx anchors the pulp through tough, fibrous septae that stabilize the skin against shear forces.

Remodeling of Hand and Carpal Bones

A young child's ability to remodel displaced fractures in the hand and carpus must be incorporated into injury management decision making. Factors that influence remodeling potential include the patient's age, the proximity of the fracture to the physis, the plane of motion of the adjacent joint, and the presence of malrotation.[17] The remodeling capacity is greater in younger children, fractures that are closer to the physis, and deformity in the plane of motion.[72,73,134,159] Several clinicians have observed remodeling between 20 to 30 degrees in the sagittal plane in children under 10 years of age and up to 10 to 20 degrees in older children.[36,134] Remodeling potential in the coronal or adduction–abduction plane is rarely quantified but is likely greater than or equal to 50% of the remodeling potential in the sagittal plane. Rotational deformity remodeling never occurs and is an absolute indication for fracture management.

The speed of healing in children is remarkable. In the skeletally immature hand, most fractures become clinically stable within 2 weeks. Although this rapid healing potential may allow earlier range of motion and decreased stiffness, delay in treatment of 7 to 10 days may limit a surgeon's ability to perform a successful reduction without osteoclasis.

Assessment of Hand and Carpal Bone Fractures

Hand and Carpal Bone Fracture Injury Mechanisms

Pediatric hand and carpal bone fracture patterns correlate with mechanism of injury. Assessment of each child with a hand fracture should include detailed description of the injury itself (if witnessed), timing of the injury, treatment prior to presentation, history of previous injuries to the same hand, and identification of potential penetrating or embedded materials such as glass, metal, or teeth.

Axial load injuries nearly always occur through the metacarpals or carpometacarpal (CMC) joints. Digital torsion or lateral bending forces most often propagate through the physis of the phalanx into an S-H II injury or may result in avulsion

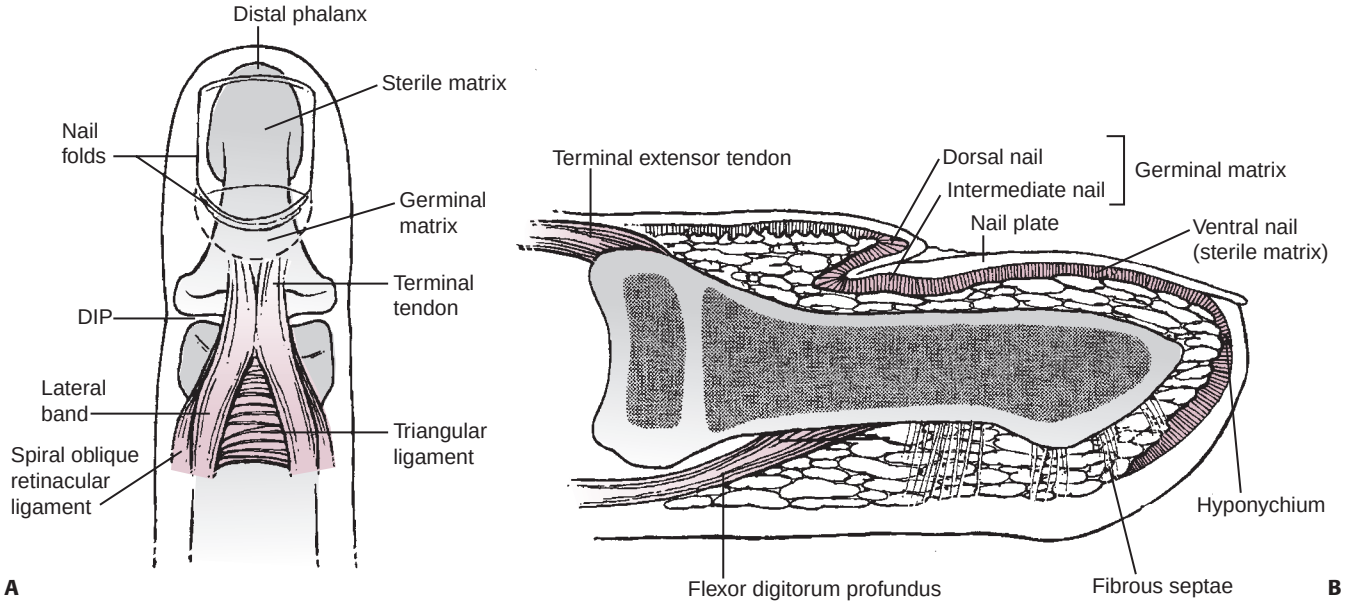

FIGURE 10-6 Anatomy about the distal phalanx. **A:** The skin, nail, and extensor apparatus share a close relationship with the bone of the distal phalanx. Specific anatomic structures at the terminal aspect of the digit are labeled. **B:** This lateral view of the nail demonstrates the tendon insertions and the anatomy of the specialized nail tissues.

fractures. Crush injuries can occur in any hand or carpal bone and may involve the nail matrix or articular surface.

Injuries Associated with Hand and Carpal Bone Fractures

Pediatric hand and carpal bone fractures and dislocations overwhelmingly occur in isolation. Children involved in motor vehicle accidents, contact sports, and falls from a height can sustain hand trauma in the setting of head, cervical spine, wrist, elbow, or shoulder girdle injuries, such as clavicular fractures. In these polytrauma cases, treatment decision making may be driven by a need for earlier stabilization to allow the child the ability to use crutches or prevent fracture displacement during rehabilitation of other injuries.

Children who have sustained hand and carpal bone fractures and dislocations from crush injuries, penetrating trauma, mechanical equipment entrapment, or motor vehicle accidents may also have injuries to the soft tissue envelope of the fingers and hand. Nerve, artery, and tendon repair as well as flap or skin graft coverage may dictate the need for hand fracture stabilization in trauma with associated injuries.

Signs and Symptoms of Hand and Carpal Bone Fractures

The evaluation of a child's hand, especially traumatized infants and toddlers, can be more challenging than that of an adult. The child frequently is noncompliant, unable to understand instructions, and fearful of the physician. The examiner must be patient, engage the child, and often employ the parents to comfort the child as needed. Observation, bribery, and play are the tricks of the trade. The child's hand use, posture, and movements provide clues about the location and severity of the injury as the child interacts with toys, parents, and the environment in the examining area. A hurried examination or a frightened child can lead to an erroneous or missed diagnosis.

Fracture is diagnosed by swelling, ecchymosis, deformity, or limited movement of the fingers or hand. Fracture malrotation is noted by digital scissoring during active grasp or passive tenodesis. Tendon integrity is observed by digital posture at rest and during active grasp around objects of varying size. Passive wrist examination with finger flexion tenodesis is a critical part of the evaluation to accurately diagnose fracture malrotation.

The history, physical examination, and clinical suspicion are the essential elements to diagnosis of a scaphoid or carpus fracture.[153] Although the findings are similar in adults and children, they are more difficult to elicit in children. The relative infrequency of this injury and the difficulty in interpreting radiographs of the immature wrist increase the likelihood of missing a pediatric scaphoid fracture. A distal pole fracture presents with swelling or tenderness over the scaphoid tuberosity. A scaphoid waist fracture presents with pain to palpation within the anatomic snuffbox, scaphoid tubercle, and/or with axial compression of the thumb ray.

For TFCC and carpal ligamentous injuries, pain is localized to the distal ulna and ulnar carpal region. Forearm rotation may be limited and usually reproduces the pain, particularly at the extremes of supination and/or pronation. Compression and ulnar deviation of the carpus against the ulna may reproduce the pain with crepitus. The stability of the distal radioulnar joint should be compared to the contralateral side.[141,198]

After the child is relaxed, the physician may palpate areas of tenderness and move injured joints to assess their integrity. Stress testing should be gentle, and joint stability should be

recorded in the anteroposterior (AP) and lateral directions. Neurologic injuries are especially difficult to detect in a young child. The proper digital artery is dorsal to the proper digital nerve within the finger. Therefore, pulsatile bleeding indicative of a digital artery injury and laceration usually indicates a concomitant digital nerve laceration.

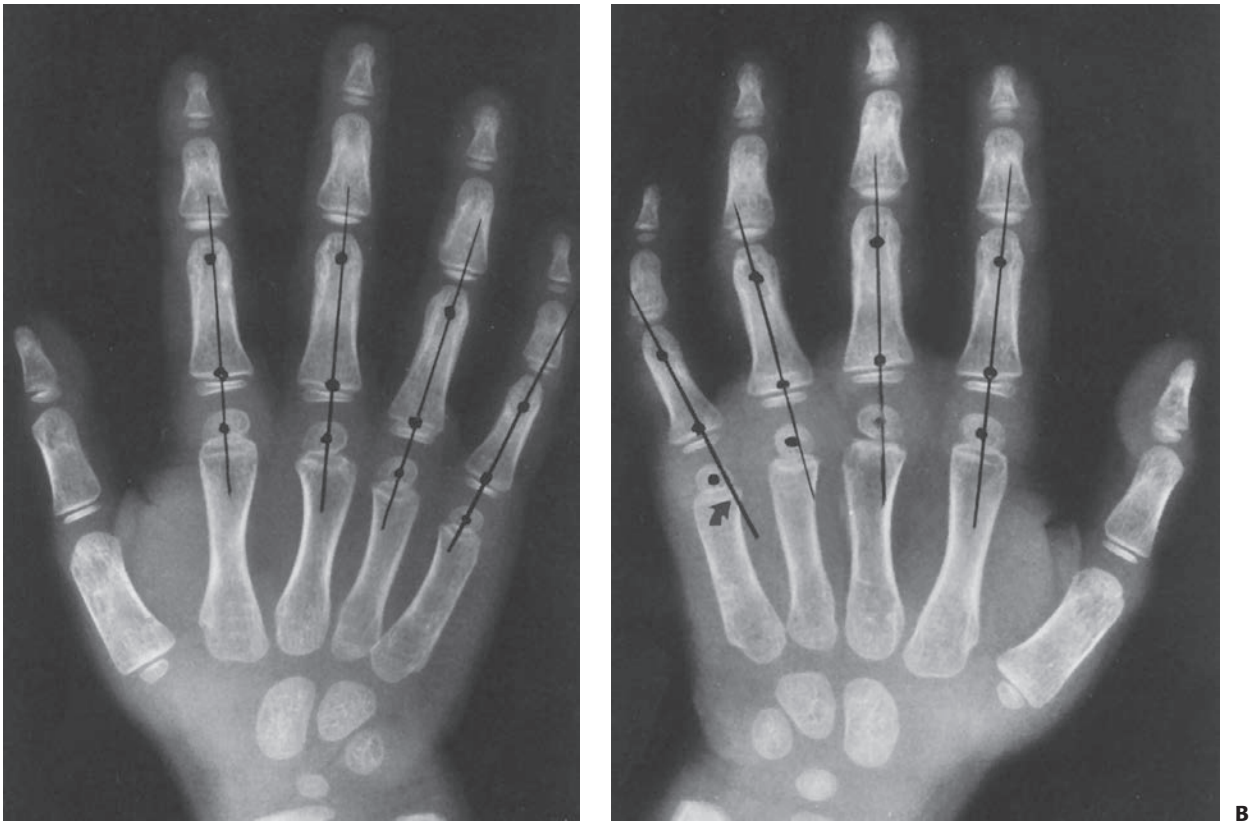
Sensory function is particularly difficult to determine in a young child. Normal discriminatory sensibility does not occur until 5 to 7 years of age. Therefore, meaningful objective data are difficult to obtain in the very young. A clinical clue to sensory impairment is that children often bypass a painful or anesthetic digit during grasp and pinch. A helpful examination maneuver is the wrinkle test. Immersion of an innervated digit in warm water for 5 minutes usually results in corrugation or wrinkling of the volar skin of the pulp. Wrinkling is often absent in a denervated digit. If there is doubt about the integrity of the nerve, operative exploration is imperative.

Comparison to the uninjured hand is invaluable in all aspects of pediatric hand and carpal bone fracture assessment. A thorough upper extremity and whole child examination driven by history and mechanism of injury should be completed for associated injuries. A workup for suspected child abuse or benign neglect may be indicated if the history places a child in a high-risk environment or home alone.

Radiographic Examination of Hand and Carpal Bone Fractures

A careful clinical evaluation is a prerequisite for conducting a proper radiographic examination. Localization of areas of tenderness or deformity directs a focused radiographic assessment. Several pediatric imaging factors complicate interpretation of plain radiographs, including not yet ossified segments and normal variations. Lack of understanding of normal ossification pattern of the immature hand creates problems with the detection of fractures and also promotes false interpretation of ligamentous injuries. Accurate interpretation may require comparison to the uninjured hand or consultation with a pediatric atlas of child development and normal radiographic variants.[77,196]

Complete evaluation of the injured hand or digit requires AP, lateral, and oblique views. The phalangeal line test is useful in recognizing displaced fractures and joint malalignment. A line drawn from the center of the phalangeal neck through the center of the phalangeal metaphysis at the level of the physis, should pass through the exact center of the metacarpal or phalangeal head in a normal finger, regardless of joint flexion (Fig. 10-7).[26] Oblique views are particularly useful for assessing displacement and intra-articular extension. A common radiographic pitfall is failure to obtain a true lateral radiograph of the



A B

FIGURE 10-7 The straight method of assessing alignment about the MCP joint. The long axes of the metacarpal and proximal phalanx should align, as they do in this normal hand **(A).** If there is a fracture in the proximal phalanx, as in this patient's opposite or injured hand **(B, C),** the axes will not be colinear (*arrows*). C

FIGURE 10-7 (*continued*)

injured digit. Isolation of the affected digit on the film or splaying of the fingers projects a true lateral view. Stress views are rarely used for fracture evaluation. If the injury can be clinically isolated to a single digit, individual finger x-rays will demonstrate more detail than a zoomed out image of the entire hand.

To radiographically assess the pediatric carpus, AP, lateral, and scaphoid views in ulnar deviation of the wrist are routine. Middle third scaphoid fractures may or may not be evident on initial radiographs. Distal pole fractures are best seen on the lateral view. A pronated oblique view further highlights the CMC joint and distal pole fracture pattern. A scaphoid view places the scaphoid parallel to the film and reveals the scaphoid in its full size. One must be aware of the pseudo-Terry Thomas sign.[109] The scaphoid ossifies from distal to proximal, so the distance between the ossified lunate and scaphoid decreases as the child develops and approaches adolescence. Thus, the distance between the scaphoid and lunate ranges from the relatively larger 9 mm in a 7-year-old child to 3 mm in a 15-year-old child.[98,109] Failure to appreciate these normal radiographic variants may lead to an erroneous diagnosis of scapholunate dissociation when the apparent gap is filled with normal cartilage and unossified bone. Comparison to contralateral wrist radiographs is extremely useful in distinguishing abnormal from normal patterns; however, one must keep in mind that carpal ossification is not always symmetric. Magnetic resonance imaging (MRI) or computed tomography (CT) scans are usually diagnostic.

If the clinical picture is consistent with a scaphoid fracture but the radiographs are negative, the patient should be immobilized. The child should either be instructed to return in 2 weeks for repeat examination and radiographs, or advanced image studies may be ordered. The use of MRI can help to

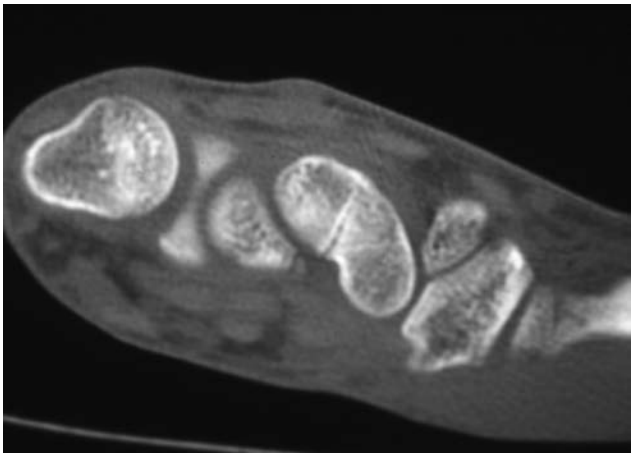

FIGURE 10-8 A CT scan of 16-year-old male with negative radiographs but persistent pain. Sagittal image reveals waist fracture without displacement. (Courtesy of Shriners Hospitals for Children, Philadelphia, PA.)

detect scaphoid fractures that are not visualized on the initial radiographs.[22,35,49,96,118] Johnson et al.[96] evaluated 56 children (57 injuries) with MRI within 10 days of injury. All children had a suspected scaphoid injury but negative radiographs. In 33 (58%) of the 57 injuries, the MRI was normal, and the patients were discharged from care. In 16 cases (28%), a fractured scaphoid was diagnosed, and treatment was initiated. Sedation is required for a young child having MRI, and the modality may be overly sensitive in identifying bone edema that never develops into a fracture.[22,120]

Other advanced imaging studies, such as bone scan, CT, and ultrasound have also been shown to be effective in detecting occult fracture (Fig. 10-8).[53] The role of bone scan has been nearly supplanted by MRI. In the assessment of fracture displacement for operative indications and in the determination of union CT scans are most valuable. For viewing the carpus, CT images must be made along the longitudinal axis of the scaphoid, which is different from CT imaging of the wrist.[169]

If plain radiographs reveal an ulnar styloid fracture, a TFCC tear may be suspected. An acute displaced fracture at the base of the styloid suggests the likelihood of a TFCC tear. Arthrograms and MRI scans will help in the diagnosis.[28,79]

Minifluoroscopy portable units are invaluable and allow a real-time assessment of articular congruity and joint stability. These units have considerable advantages, including the ability to obtain multiple angles, live images, and stress views with low-radiation exposure for the patient and physician. We utilize minifluoroscopy in the child that requires dynamic imaging for accurate diagnosis or when the x-ray technician is having difficulty obtaining orthogonal x-rays.

Differential Diagnosis of Hand and Carpal Bone Fractures

The differential diagnosis in a child who presents with hand trauma includes nontraumatic entities that may be interpreted as acute injuries. These diagnoses are uncommon but may cause swelling, deformity, or decreased motion.

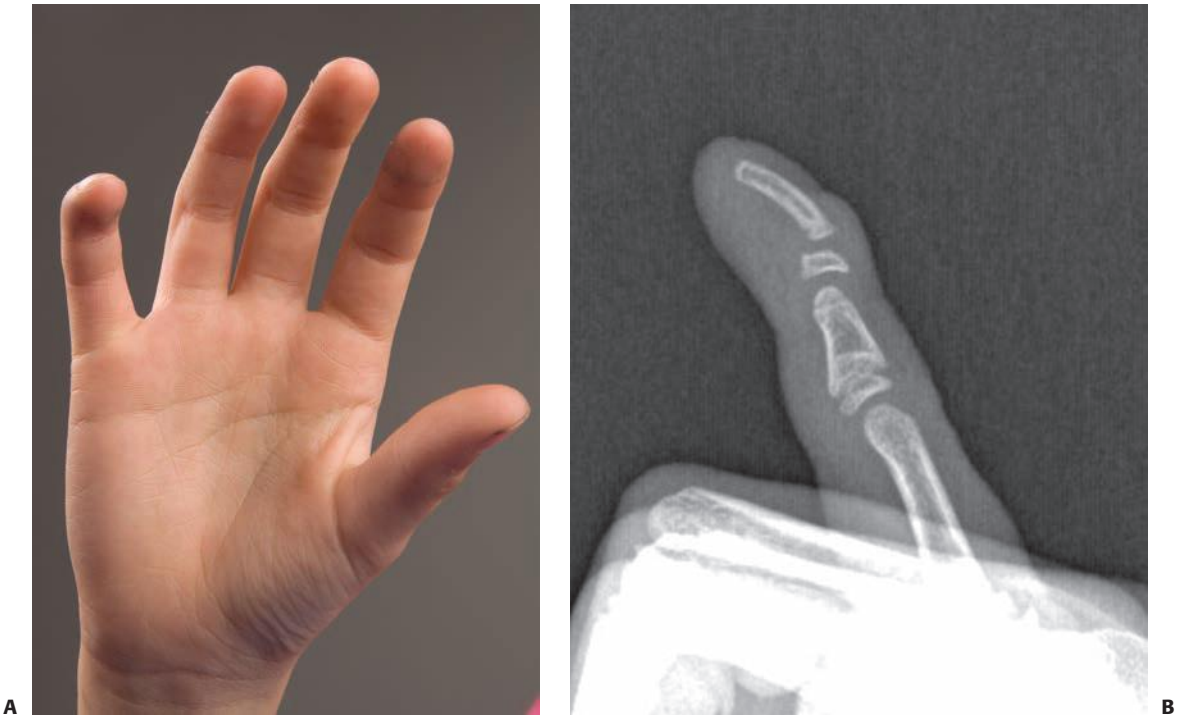

FIGURE 10-9 A–B: A 9-year-old girl with incurving of the tip of the right small finger. Similar findings are noted in family members. The AP and lateral radiographs show radial and palmar incurving of the distal phalanx characteristic of Kirner deformity.

Congenital/Acquired

A Kirner deformity is a palmar and radial curving of the terminal phalanx of the small digit. This deformity occurs spontaneously between the ages of 8 and 14 years and may be confused with an acute fracture or epiphyseal separation (Fig. 10-9).[103] A Kirner deformity, however, is usually bilateral and not associated with trauma.[50] A trigger thumb in a young child is sometimes mistaken for an interphalangeal joint dislocation. This is caused by the fixed flexion posture, near equivalent clinical feel of "joint reduction" with manipulative digital extension, and triggering of the nodule in the FPL through the A1 pulley. The key diagnostic feature or sine qua non of a trigger thumb is the palpable nodule in the FPL over the A1 pulley. Familial camptodactyly or clinodactyly presents predominantly in adolescents when they bump the fifth finger in sports or just notice it is crooked. X-rays consistent with irregular trapezoidal or delta phalanges (a.k.a. longitudinal epiphyseal bracket) and hypoplastic middle phalanx condyles may be hard to distinguish from old or new trauma. Examination of the contralateral side as well as the parents' hands often guides the clinician toward a congenital etiology of the finger deformity.

Thermal Injury

Thermal injury to the growing hand (e.g., frostbite, burns from flame or radiation) may cause unusual deformities from altered appositional and interstitial bone growth. Ischemic necrosis of the physes and epiphyses may occur (Fig. 10-10). The clinical result may yield altered bone width, length, or angulation secondary to the unpredictable thermal effect on the growing elements that make interpretation of subsequent trauma difficult.[81,142]

Osteochondrosis (Thiemann Disease)

Osteochondrosis of the phalangeal epiphyses may cause epiphyseal narrowing and fragmentation, which are characteristic of Thiemann disease. This hereditary entity usually involves the middle and distal phalanges and typically resolves without treatment, though some permanent joint deformity has been reported.[40,173]

Tumors

A tumor may be discovered after fracture of the weakened bone or confused with fracture secondary to swelling and pain. An enchondroma of the proximal phalanx is the classic benign tumor that may fracture after trivial trauma (Fig. 10-11). Malignant bone, cartilage, or muscle tumors are rare. Radiographs reveal intrinsic destructive bony changes in an osteogenic sarcoma or extrinsic compression with adjacent periosteal reaction secondary to an adjacent rhabdomyosarcoma.

Inflammatory and Infectious Processes

Dactylitis from sickle cell anemia can masquerade as a traumatic injury. The affected digit(s) present(s) with fusiform swelling and decreased motion. The medical history usually is positive for sickle cell disease. The inflammatory arthropathies (e.g., juvenile rheumatoid arthritis, psoriatic arthritis, scleroderma, systemic lupus) may be confused with trauma. A joint effusion and tenosynovitis are findings that require further diagnostic evaluation. Aside from standard laboratory testing, MRI is important for diagnosis of an inflammatory synovitis or tenosynovitis. An infectious process often can be mistaken for injury, though local and systemic evaluation usually

FIGURE 10-10 An 11-year-old girl sustained a frostbite injury to the right hand. Radiograph reveals premature fusion of the physis of the distal and proximal phalanges with irregularity of the bases of the shortened phalanges.

ascertains this diagnosis. Advanced skeletal maturity of the involved carpus is a diagnostic finding consistent with inflammatory arthritis.

Hand and Carpal Bone Fracture Outcomes

Outcomes assessment for the results of treatment of pediatric hand and carpal bone fractures include subjective measurements such as stiffness, pain, and the ability to perform activities of daily living. Outcomes instruments such as the Disabilities of the Arm, Shoulder and Hand (DASH), Pediatric Outcomes Data Collection Instrument (PODCI), and Michigan Hand Outcomes Questionnaire (MHQ) can be completed by parents or adolescent children to survey a broad spectrum of long- and short-term results. Newer instruments also try to include assessment of the child's ability to text, type on a computer, and play video games. Objective clinical outcome measurements include rates of complications such as infection, finger or nail deformity, loss of range of motion, and malrotation and shortening. Functional evaluations such as pinch and grip strength, peg board test, in-hand manipulation, and Jebsen–Taylor timed testing are examples of validated instruments in the assessment of hand function in children.

Radiographic outcomes include malunion, nonunion, articular congruity, degenerative joint changes, shortening, and malrotation. Missed days of school, return to sports, and performance of writing activities in the classroom are more elusive but critical outcomes to be considered in the care of pediatric hand and carpal bone fractures. Cost-effectiveness of treatment options can be considered in pediatric hand fractures. Total cost will certainly increase as treatment progresses from "bedside" clinical procedures, to emergency room care, and ultimately to the operating room with general anesthesia.

Fractures of the Distal Phalanx

Distal Phalanx Fracture Classification

Fractures of the distal phalanx in children can be classified into extraphyseal and physeal injuries (Table 10-2). Extraphyseal fractures are common and range from a simple distal tuft fracture to an unstable diaphyseal fracture underlying a nail bed laceration. The extraphyseal fracture pattern can be divided into three types: Transverse, longitudinal split, or comminuted (Fig. 10-12). A transverse fracture (Fig. 10-12A) may occur either at the distal extent of the terminal phalanx or through the diaphysis. Displaced transverse fractures through the diaphysis are almost always associated with a considerable nail bed injury that requires repair. A longitudinal splitting type fracture, much less common, is the result of excessive hoop stress within the tubular distal phalanx at the time of a crush injury (Fig. 10-12B). The "cloven-hoof" appearance of the fracture is characteristic (Fig. 10-13). This type of

FIGURE 10-13 A, B: Extraphyseal fracture of the distal phalanx: The cloven-hoof longitudinal splitting fracture. In this patient, the fracture line (*arrow*) does not appear to extend across the physis.

FIGURE 10-14 **A, B:** Stellate or comminuted extraphyseal fractures and clinical findings.

distal phalanx fracture may be contained within the shaft or can propagate through the physis and even into the joint.[10] Comminuted or stellate fractures of the distal diaphysis also can occur and usually are accompanied by extensive soft tissue injury (Fig. 10-14).

Physeal fractures clinically resemble a mallet finger. There are four basic fracture patterns, and all result in a flexed posture of the distal interphalangeal (DIP) joint (Fig. 10-15). An S-H I or II fracture with flexion of the distal fragment, known as a Seymour fracture, occurs predominantly in young patients less than 12 years of age. The unopposed FDP flexes the distal fragment. The injury is often open and associated with a very proximal nail bed or plate injury.[177] The proximal nail plate may lie on top of the dorsal nail fold, whereas the distal nail plate remains intact. Closed reduction may be blocked by interposition of the nail bed in the dorsal physis deep to the nail plate. Rarely, an S-H I or II fracture causes extrusion of the epiphyseal fragment.[129,207] This "epiphyseal dislocation" is challenging to diagnose with an "invisible" not yet ossified epiphysis. The remaining distal phalanx stays colinear with the axis of the digit, whereas the displaced unossified epiphysis is dorsally dislocated by traction produced by the extensor tendon. A dorsal S-H III fracture of the distal phalanx, "bony mallet finger" occurs in teenagers and results in an extension lag at the DIP joint. Rarely, the epiphysis may also separate from the terminal extensor tendon.[172]

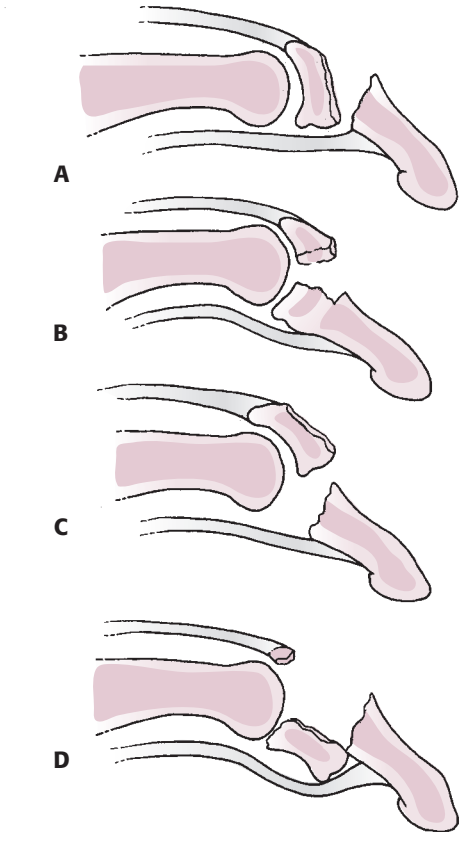

FIGURE 10-15 **A–D:** Mallet-equivalent fracture types.

Distal phalanx fractures can also be described by mechanism of injury including crush, hyperflexion, and hyperextension. A crush injury creates a spectrum of damage from minor tissue disruption with little need for intervention to severe tissue trauma that requires bony fixation, meticulous nail bed repair, and skin coverage (Fig. 10-16). A flexion force applied to the extended tip of the finger results in a malletlike injury to the terminal tendon insertion or physeal separation with nail bed injury as described above. The DIP joint remains flexed whereas active extension is not possible in both types. A hyperextension force can produce a bony avulsion injury of the volar articular surface or rupture of the insertion of the FDP tendon (Jersey finger) (Fig. 10-17).[108,213]

Finally, fractures can be classified into open or closed injuries. A nail bed injury or a subungual hematoma greater than 50% creates a high index of suspicion for an open bony injury and displaced nail bed laceration (Fig. 10-18).[221]

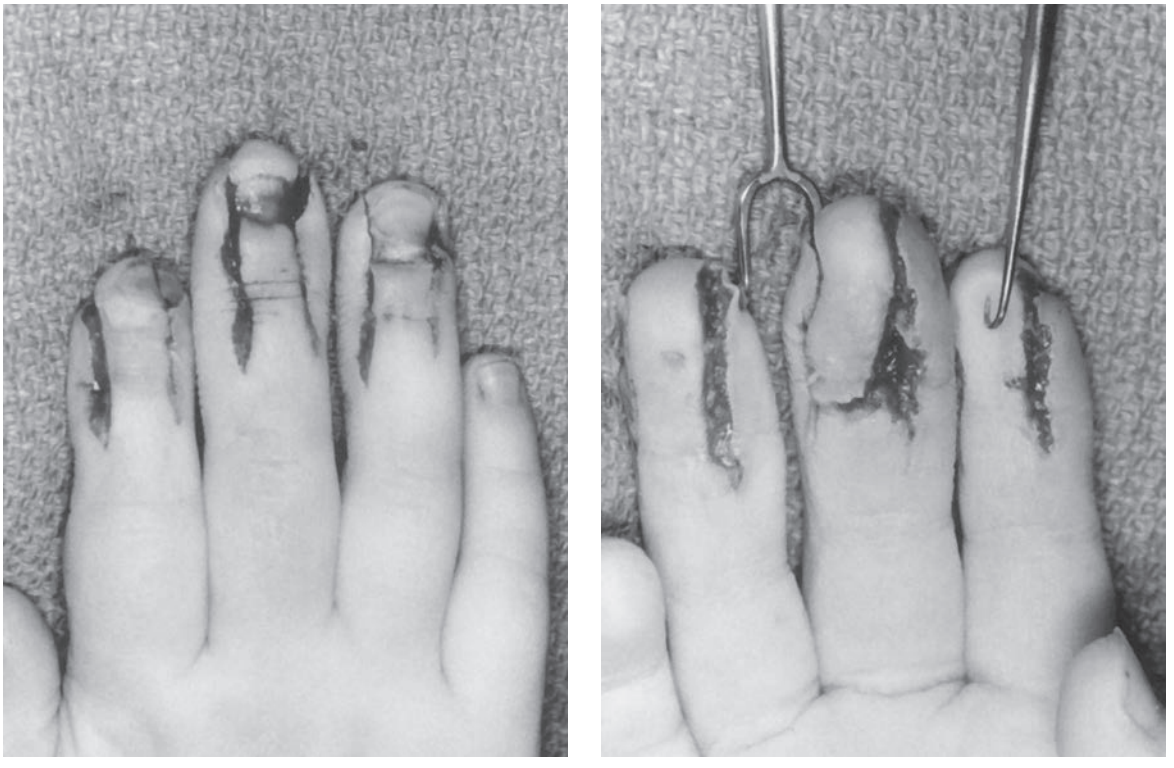

FIGURE 10-16 **A, B:** Crush injury to the fingers of a 4-year-old child with multiple fingernail bed lacerations requiring meticulous repair with absorbable suture.

Distal Phalanx Fracture Treatment Options

Nonoperative Treatment of Distal Phalanx Fractures

Distal phalanx fractures in children are associated with nail bed lacerations. The soft tissue repair may be at the bedside or in the operating room, depending upon the emergency room facilities, operating room availability, and surgeon's preference. Any substantial nail bed laceration requires irrigation, debridement, and repair to prevent nail deformity and osteomyelitis. The pediatric distal phalangeal fracture is assessed for risk of infection, nail deformity, growth arrest, malalignment, and instability. An unstable fracture that cannot support the nail bed necessitates stabilization (Table 10-3).

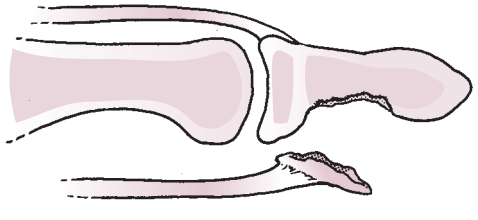

FIGURE 10-17 An FDP avulsion fracture of the distal phalanx (Jersey finger). This bony avulsion is apparent on radiographs, indicating the extent of proximal migration.

Nonoperative Techniques

Immobilization. Most distal phalangeal fractures can be treated with nonoperative measures using a splint or cast. Mild and moderate displacement of extraphyseal fractures will heal without difficulty. Even physeal injuries with mild displacement of the dorsal epiphyseal fragment, "bony mallet finger," have favorable results with hyperextension splinting. Using buddy tape to secure the injured digit to a longer finger or applying plastic bandages for the young child with a crush injury may provide enough immobilization while enabling early range of motion and close monitoring for infection in stable fracture patterns.

Hematoma Evacuation. Indications for a hematoma evacuation, or trephination, include subungual hematoma involving more than 50% of the nail plate or painful pressure under the nail.[41] Decompression can be done with a sterile hypodermic needle or a heated paper clip or cautery tip, but the heat can cause further nail bed injury if penetration is too deep. After 12 to 24 hours, the effectiveness of trephination decreases as the blood coagulates. The use of oral antibiotics in the setting of trephination, although theoretically protective against infection, has not been proven in case series.[43]

Nail Bed Repair. A nail bed repair can be performed at bedside, in a clinical procedure room, or in an emergency room under digital block and/or conscious sedation. A digital tourniquet is often used and needs to be removed after repair. Nail

FIGURE 10-18 **A:** A crush injury to the thumb of a 4-year-old child with a stellate nail bed laceration and fracture of the tuft. **B:** Radiograph reveals a comminuted tuft fracture.

bed repair is required for overt nail bed lacerations and potentially for subungual hematomas that involve more than 50% of the nail plate. After adequate anesthesia and an ideal sterile field are achieved, a blunt Freer elevator is used to remove the nail plate to avoid additional nail bed injury. Curved clamps or snaps should not be used as they can cause further nail matrix injury. Partial nail removal is rarely indicated for nail bed repair in children. Proximal exposure of the germinal matrix may require scalpel incisions along the eponychial folds and proximal retraction of the eponychial flap. The nail bed is repaired with interrupted 6-0 chromic or equivalent absorbable sutures under loupe magnification. Following repair, the nail bed is supported, and the dorsal nail fold is kept open using the previously removed nail plate or another substitute, such as the foil from the suture pack.[55,171,221]

TABLE 10-3 Fractures and Dislocations of the Hand and Carpal Bones

Nonoperative Treatment

Indications	Relative Contraindications
Stable	Unstable
Closed	Open
Low risk of infection, nail deformity, joint instability or growth plate arrest	High risk of infection, nail deformity, joint instability, or growth plate arrest

Operative Treatment of Distal Phalanx Fractures

Unstable extraphyseal fractures with wide displacement require stabilization. Open injuries with severe displacement or irreducible fractures require reduction and stabilization (Fig. 10-19).[4,26] The Seymour fracture represents an irreducible fracture that requires open reduction. The sterile matrix must be extricated from the fracture site and repaired beneath the eponychium. Epiphyseal dislocations also require operative intervention to both restore joint congruity and reestablish extensor tendon continuity. Physeal fractures with a dorsal fragment larger than 50% of the epiphysis or considerable DIP joint subluxation may require operative intervention.[38,82] An avulsion of the FDP is an indication for open tendon reinsertion. Surgery should be done as soon as possible to limit tendon ischemia and shortening. Delay in diagnosis may prohibit tendon reattachment.

Amputations of the fingertip are often open distal phalangeal fractures. The injury may involve skin, nail tissue, and bone. Support for nail growth is a primary consideration. Minimal loss of tissue can be treated with local wound care and healing through secondary intention. A small amount of exposed bone does not preclude spontaneous healing in children. The

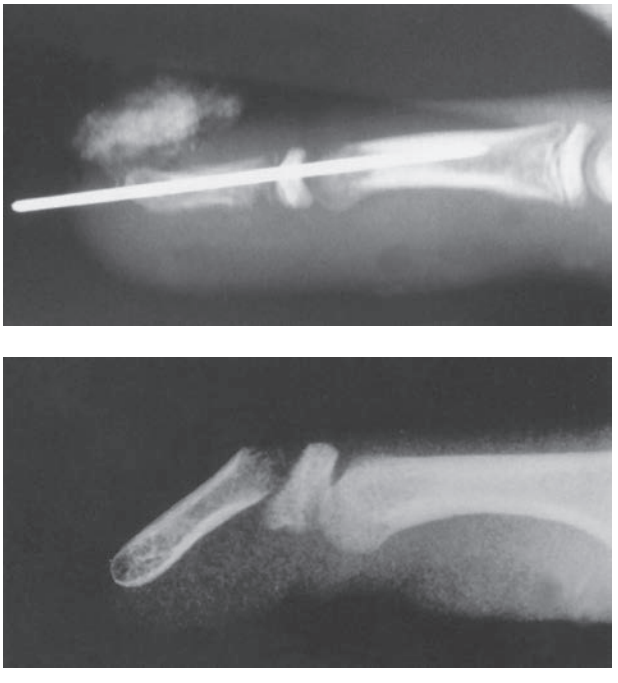

FIGURE 10-19 **A:** An irreducible distal phalangeal fracture that required extrication of the nail bed from within the fracture site. **B:** Stabilization of the fracture fragments with a longitudinal K-wire across the DIP joint.

FIGURE 10-20 A hook nail can become symptomatic and require revision nail ablation. Adequate primary management can prevent this sequelae.

likelihood of nail deformity (hook nail or "parrot's beak") is high for amputations that involve more than 50% of the distal phalanx. Primary nail ablation may be indicated in children with less than 50% remaining distal phalanx to avoid a sometimes painful, more often aesthetically disconcerting, hook nail deformity (Fig. 10-20).

Soft tissue coverage varies depending on the degree of tissue loss and direction of injury. Simple healing by primary closure is preferred for most volar oblique fingertip amputations. Dorsal oblique amputations are complicated by nail bed injury and are more difficult to cover. Composite grafts of skin and subcutaneous tissue from the amputated part have been used in young children <3 years of age with variable results. Local flaps are another option for coverage of large volar or dorsal oblique amputations. Options include a variety of flaps, such as a V–Y volar advancement, a thenar flap, a cross-finger flap, a pedicled flap, or a neurovascular island flap (Figs. 10-21 and 10-22).[7,100] Fortunately, coverage issues are rare in children. An amputation of the distal thumb can also be covered with a bipedicle (Moberg volar advancement flap) or a unipedicle neurovascular flap.[136] The choice of coverage depends on the degree and direction of soft tissue loss, age of the patient, and preference of the surgeon.

TABLE 10-4 Distal Phalanx Fractures

Preoperative Planning Checklist

- OR table: Hand table
- Position: Supine
- Fluoroscopy location: Minifluoro unit

Perpendicular or opposite the surgeon

- Equipment: Hand tray instruments, wire driver
- Tourniquet (sterile/nonsterile): Nonsterile or Esmark at approximately 200 mm Hg in small children
- Hardware: 0.027, 0.035, or 0.045 K-wires, limited role for other fixation devices
- Suture: 6-0 chromic for nail bed in all patients

5-0 chromic skin closure in young children; in older children, nonabsorbable monofilament (Prolene, Monocryl, or nylon suture) can be used for soft tissue laceration or incision closure

Surgical Treatment of Distal Phalanx Fractures

Preoperative Planning. Operating room and table setup for surgical treatment of hand fractures in children can be successfully accomplished using the checklist below (Table 10-4).

Surgical Approach and Technique. Closed manipulation and percutaneous K-wire fixation is usually effective treatment of displaced distal phalanx physeal fractures. One or two smooth 0.35 or 0.45 K-wires can be inserted retrograde through the tip of the finger and across the fracture for

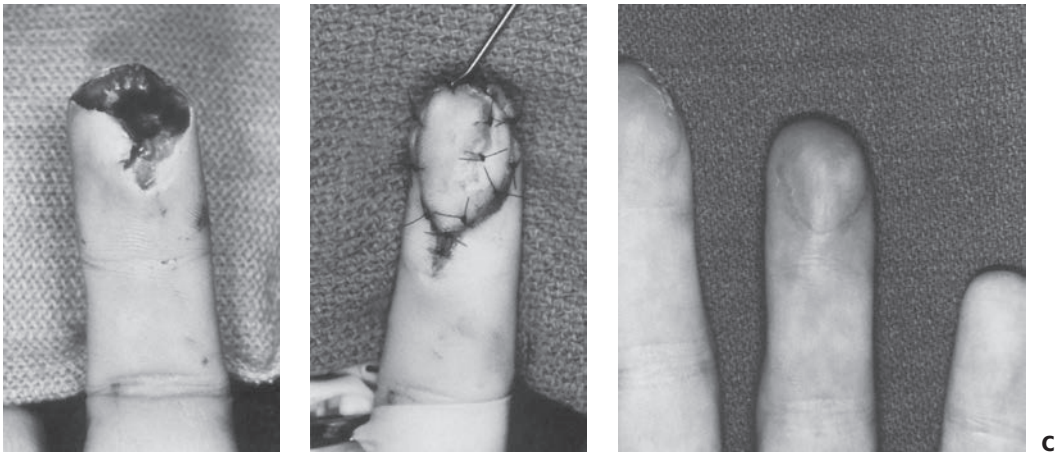

FIGURE 10-21 Volar V–Y advancement flap for coverage. **A:** A volar oblique tissue loss of the ring finger with intact nail bed. **B:** Flap designed with apex at the DIP joint and mobilized to cover the fingertip. The defect is closed proximal to the flap creating the Y. **C:** Satisfactory result with good durability and sensibility.

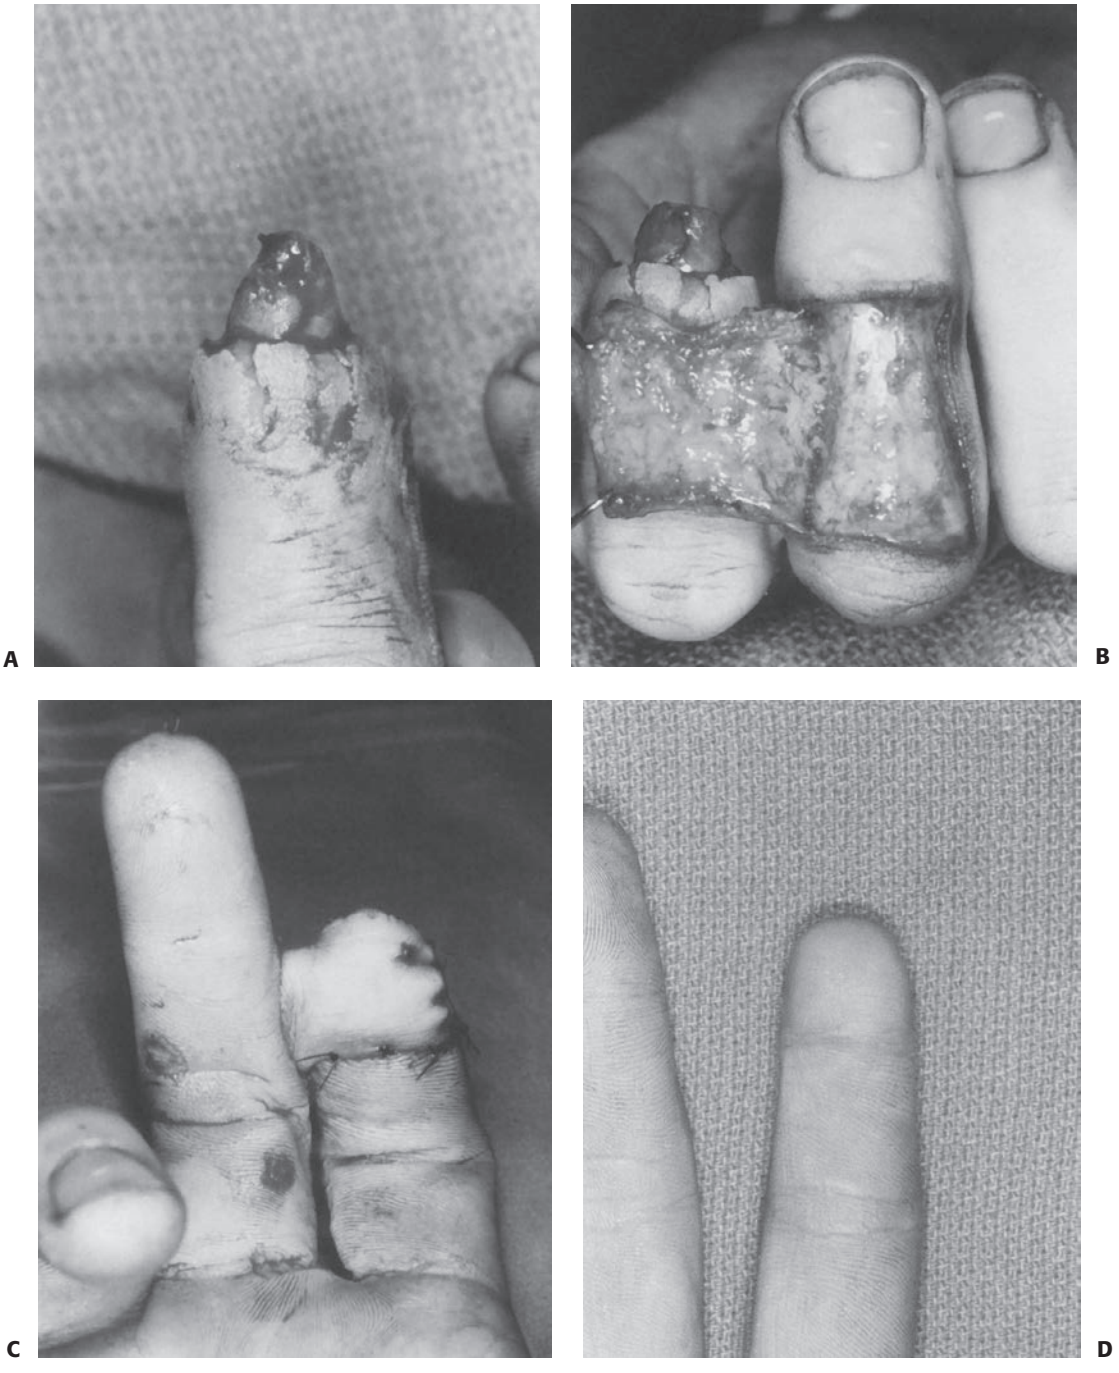

FIGURE 10-22 Cross-finger flap in a 17-year-old male with open distal phalangeal injury and tissue loss. **A:** Extensive volar and distal soft tissue loss with preservation of the bone and nail bed. **B:** A cross-finger flap of skin and subcutaneous tissue is elevated from the dorsal aspect of the adjacent donor digit based on the side of the index finger. **C:** The vascular epitenon is preserved on the donor digit to support a skin graft. The flap is transferred to the volar aspect of the index finger to recreate the tuft. **D:** Satisfactory coverage and functional result.

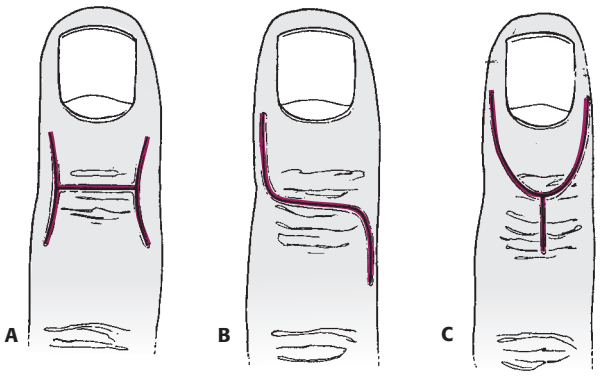

FIGURE 10-23 Exposures to the DIP joint. **A:** H-type flap with the transverse limb over the DIP joint. **B:** S-shaped exposure of the DIP joint. **C:** An extended exposure of the DIP joint. All exposures must avoid injury to the germinal matrix, which is located just proximal to the nail fold.

stabilization. A hypodermic needle can be used as an emergency substitute for smooth wires.[128] The assistance of joystick K-wires, tenaculums, or forceps can be applied as external temporary fixation while final fixation is placed. After the fracture is stabilized, the nail may be repaired in the technique described previously.

In open injuries or fractures that will not reduce with closed technique, a dorsal or midlateral approach is used for most extraphyseal and physeal fractures (Fig. 10-23). The dorsal fragment is isolated and reduced (Fig. 10-24). A small portion of the collateral ligaments may be recessed to enhance exposure; however, soft tissue dissection should be limited to prevent osteonecrosis of small bony fragments. Open fracture fixation can be accomplished with a smooth wire, pull-out wire, tension band, or heavy suture.[72,82,86,104,145] Fixation across the DIP joint with a small diameter, smooth wire is usually necessary to maintain joint and physeal congruity. A volar approach is only used for avulsion of the FDP tendon. In acute Jersey fingers, the FDP is identified at the level of retraction and repaired to the distal phalanx with transosseous sutures or wires (Fig. 10-25). The transosseous sutures or wires must avoid the growth plate in young children (Table 10-5).

TABLE 10-5 Distal Phalanx Fractures

Surgical Steps

- Attempt closed reduction of displaced or open fractures after irrigation and debridement of foreign bodies or contamination
- If alignment adequate, place one or two K-wires from fingertip, across physeal or extraphyseal fracture
- Use "joystick" smaller K-wires, towel clip, or small fragment reduction forceps to enhance the closed reduction
- If necessary, open skin in H-shape or transversely over physeal fracture
  - Preserve extensor and collateral soft tissue attachments
  - Avoid dissection of smaller bone fragments
- Reduce incarcerated, rotated, or extruded fragments and proceed with K-wire or rare screw fixation
- Remove nail plate and repair nail lacerations as indicated; replace plate or foil under dorsal nail fold

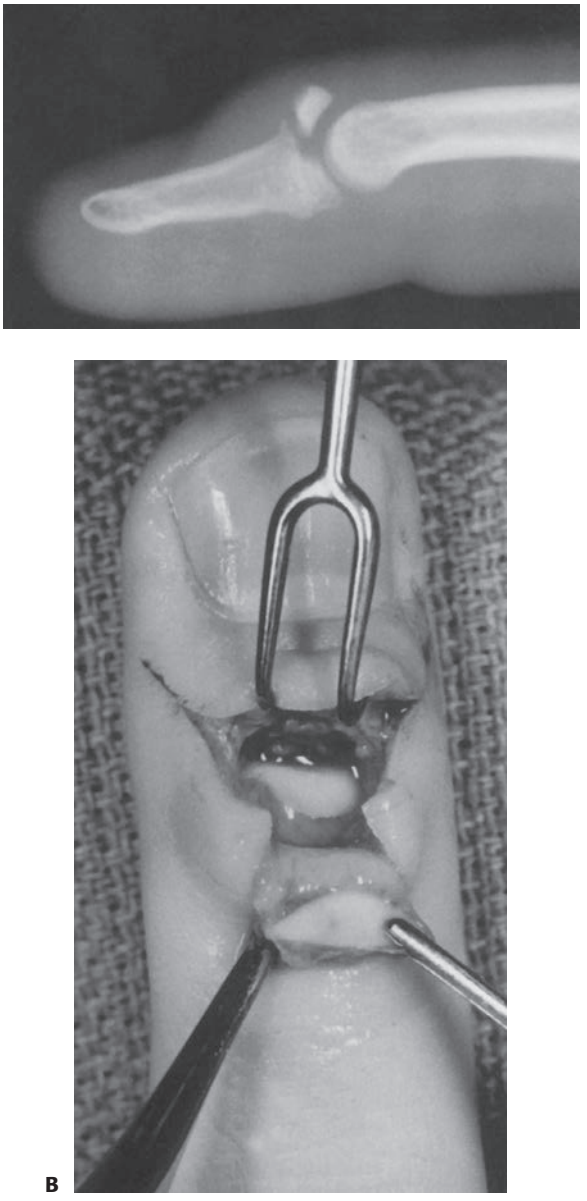

FIGURE 10-24 **A:** Displaced mallet fracture with considerable articular involvement and dorsal prominence. **B:** Open reduction through a dorsal approach reveals the articular fragment attached to the terminal tendon.

FIGURE 10-25 A 17-year-old athlete with an avulsion fracture from the FDP tendon. The fracture extends through the epiphysis and into the joint (*large arrow*). The FDP tendon with its attached bony fragment has retracted to the level of the A4 pulley (*small arrow*).

Author's Preferred Techniques

Extraphyseal Fractures

Simple closed stable fractures are treated with nonoperative immobilization for 3 to 4 weeks. Clinical union precedes complete radiographic healing by about 1 month. Protected range of motion should begin as soon as the patient has clinical union and painless range of motion to avoid stiffness. Uncommonly, in our practice, an unstable, displaced distal phalangeal fracture requires percutaneous pinning with a smooth K-wire. The DIP joint and physis are transfixed to provide additional stability. The pin is removed approximately 3 to 4 weeks after injury, followed by early protected range of motion.

Distal phalanx fractures with a nail bed laceration require adequate anesthesia, removal of the nail plate, and nail bed repair. The parents and patient are told that it takes several cycles of nail growth (3 to 6 months) before the final morphology of the nail is known. Fortunately, in properly treated nail bed injuries, chronic deformity is rare.

Physeal Fractures

Most closed pediatric S-H III physeal fractures, or bony mallet fingers, are treated in situ or by closed reduction and splinting. Placement of the DIP joint into neutral or mild hyperextension reduces most fractures. A splint is applied, and radiographs are taken to assess the degree of reduction. Adequate healing usually requires full-time splinting for 4 to 6 weeks depending on the age of the child, size of the fracture fragment, and amount of bony apposition. The DIP joint is positioned in neutral to 15 degrees of extension. Extreme hyperextension is contraindicated because dorsal skin hypoperfusion and necrosis may result.[161] Careful instructions regarding skin monitoring are given to parents and patients to avoid splint pressure necrosis. Radiographs are taken weekly for the first 2 weeks and then every 2 weeks thereafter to monitor for loss of reduction or volar joint subluxation. Adolescent mallet fingers with soft tissue terminal tendon disruption are treated similarly to adults with 4 to 6 weeks of dorsal DIP joint splint immobilization. Operative repair of soft tissue or bony mallet fingers is rarely indicated, even for a delay in presentation. Most acute and delayed presentation mallet injuries will heal with splint immobilization. The loss of digital flexion associated with surgery can be more disabling than a minor extension lag after an untreated injury.

Surgery is indicated for fractures that are open, grossly unstable, irreducible, or have unacceptable alignment (Fig. 10-24). Closed reduction and percutaneous fixation is preferred. Additional fixation of the dorsal fragment can be accomplished with a 0.028-in smooth K-wire placed parallel to the epiphysis. An irreducible fracture requires open reduction. Fixation techniques vary depending on the age of the child and the fracture configuration. Smooth wires, however, are the principal means of fixation. Entrapped soft tissue, osteochondral fragments, or epiphyseal dislocations require open reduction.

Physeal fractures with dorsal entrapment of the germinal matrix (Seymour fractures) require nail plate removal, extrication of the nail bed, and repair. Axial alignment after nail bed repair is maintained with a splint if stable or K-wire fixation if unstable for 3 to 4 weeks (Fig. 10-26).

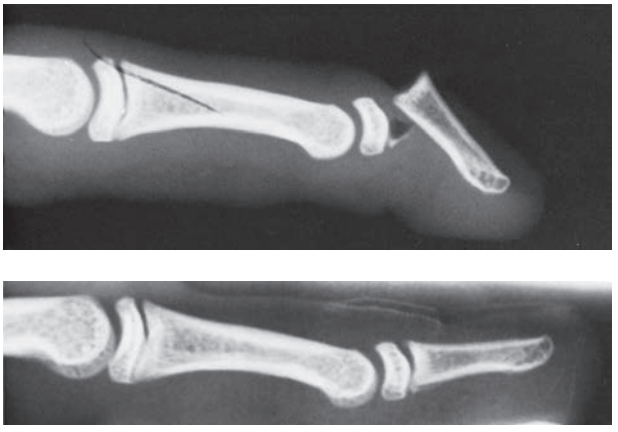

FIGURE 10-26 **A:** A 13-year-old boy sustained an open S-H type II fracture. **B:** The wound was cleansed, and acceptable alignment was obtained with closed reduction.

Jersey Finger

Avulsion injuries of the FDP require open repair (Fig. 10-25). Bone-to-bone fixation is preferred using pull-out wires or suture. Fragments that are too small for fixation require bone removal and repair of the tendon directly to the fracture bed. This usually requires transosseous sutures from volar to dorsal, avoiding injury to the germinal nail bed and growth plate. Repair of long-standing profundus avulsions is controversial and is usually not recommended with an intact and functioning FDS tendon.

Amputations

Mild to moderate loss of skin, subcutaneous tissue, and bone is best treated by wound cleansing, dressing changes, and healing by secondary intention. Acceptable functional and aesthetic results are uniform. Skin or composite grafts are rarely necessary for coverage in children and are associated with donor site morbidity, hyperpigmentation, and lack of sensibility. Extensive soft tissue loss with exposed bone requires more innovative coverage. A volar oblique injury can usually be treated with a variety of local flaps, including a V–Y advancement flap, cross-finger flap, or thenar flap (Figs. 10-21 and 10-22).

Dorsal tissue loss is more difficult to reconstruct. The nail bed injury adds additional complexity. Mild loss can be treated by local wound care. Moderate to severe loss may require a reverse cross-finger flap or a more distant flap. Unfortunately, nail bed replacement techniques often result in considerable nail deformity (Fig. 10-27).

Postoperative Care and Rehabilitation

Children younger than 4 or 5 years of age are immobilized with long-arm mitten strapping, soft casts (3M, St. Paul,

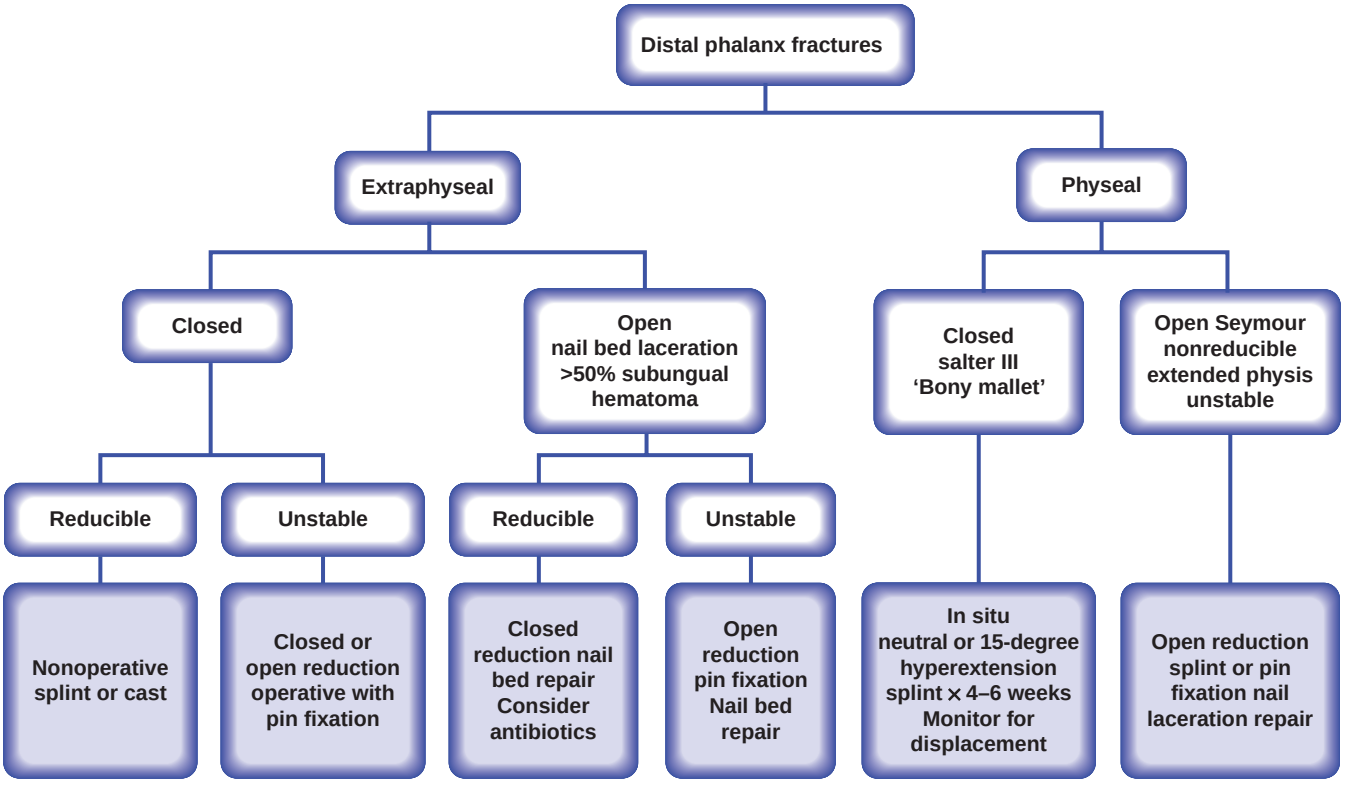

FIGURE 10-27 Author's preferred treatment algorithm for distal phalanx fractures.

Minnesota), or casts. As the child ages, the degree of immobilization is decreased. An adolescent with a simple distal phalangeal fracture or nail bed repair can usually be treated similar to an adult with only DIP joint immobilization. The use of adjunctive antibiotics and tetanus prophylaxis should be utilized in contaminated cases. Nonabsorbable suture should be removed after 2 weeks, but, whenever possible, chromic suture is used in a child to avoid the trauma of suture removal. Percutaneous fixation is removed in the office 3 to 4 weeks after surgery. The replaced dorsal nail plate or foil under the nail fold will loosen and fall off as the new nail grows in a distal direction. Formal hand therapy is usually not required, though a home instruction program with an emphasis on DIP joint motion is useful. To regain full joint movement, DIP blocking exercises are particularly helpful. Formal therapy is reserved for patients who fail to regain motion and strength after 3 to 4 weeks on a home program (Table 10-6).

Treatment-Specific Outcomes

Decision making in the treatment of distal phalanx fractures in children must be individualized to the exact injury and needs of the child. Crush mechanisms cause fractures and soft tissue injuries that range widely in severity. The number of studies that have sought to assess outcomes in distal phalanx fractures in children is limited. The cost-effectiveness of trephination and observation versus removal of the nail plate in nondisplaced nail lacerations over distal phalanx fractures has been studied in several case series.[43,166] These authors concluded that osteomyelitis and nail deformity were equivalent; however, trephination and observation were more cost-effective. All studies emphasize the need for a prospective randomized trial; however, a study of this kind is difficult to perform in the setting of emergent care of children.

TABLE 10-6 Distal Phalanx Fractures in Children

Potential Pitfalls and Preventions

Pitfalls	Preventions
Osteomyelitis	Irrigation, debridement Nail bed laceration repair Monitor and treat infection signs early with repeat irrigations and antibiotic coverage
Premature physeal closure	Smooth wires Minimize reduction attempts
Hook nail	Ablate nail plate when less than 50% distal phalanx amputated
Quadregia	Do not oversew extensors or flexors to tip of amputated finger
Extensor lag	Neutral or 15-degree extension splint Continue night, school, and sports splint use for additional 4 to 6 weeks after full-time day splint use discontinued

Management of Expected Adverse Outcomes and Unexpected Complications

Prognosis

The overall results following distal phalangeal fractures are favorable. A small loss of motion has little functional impact. A small extensor lag or minor longitudinal nail ridge is well tolerated by most patients. Considerable nail irregularity or deformity is a frequent source of dissatisfaction.

Complications

Bony complications from distal phalangeal fractures are uncommon. Potential problems include nonunion, malunion, and osteomyelitis. Nonunion and malunion are exceedingly rare, except in open injuries that result in avascular fracture fragments or untreated widely displaced fractures. Osteomyelitis can result from open fractures and requires application of the basic tenets for the treatment of infected bone. Debridement, removal of any sequestrum, and intravenous antibiotics are required to resolve the infection. Additional tissue coverage is necessary in digits with a marginal soft tissue envelope. These infections are rare because of the robust vascularity of a child's hand.

Soft tissue complications are more prevalent than bony problems. Difficulties may involve the skin, subcutaneous tissue, nail, and tendons. An inadequate soft tissue envelope can be reconstructed with replacement using a variety of local flaps.

Nail problems depend on the location and degree of nail bed injury. Damage to the germinal matrix produces deficient nail growth and nail ridging. Injury to the sterile matrix causes poor nail adherence or nail ridging. Treatment options are limited and usually involve resection of the damaged segment and replacement with a full-thickness or split-thickness skin or nail bed graft.[31,178,222] Adjacent digits or toes are potential sources of nail bed transfers. The results in children have been superior to those in adults.[105,178,179,222] The hook nail or "parrot's beak" nail is a nail plate complication related to the underlying bony and soft tissue deficit. The nail plate curves over the abbreviated end of the distal phalanx (Fig. 10-28). Treatment requires restoring length to the shortened distal phalanx and creation of an adequate soft tissue envelope to support the nail plate (Fig. 10-29).[7] In these situations, a thenar flap or composite graft is typically used to provide improved support for the nail bed.

A mild DIP joint or extensor tendon lag can occur after pediatric mallet fracture care. No further treatment is warranted. Severe DIP joint deformities are uncommon but may result in swan-neck positioning of the finger. Reconstruction options are similar to methods used in adults, such as a spiral oblique retinacular ligament reconstruction or central slip tenotomy.[200] In a young child, untreated lacerations proximal to the terminal tendon insertion may result in an extensor lag that can be repaired successfully with a tenodermodesis repair (Table 10-7).[44,101]

FIGURE 10-28 A hook-nail deformity of the small finger after a distal fingertip amputation.

Middle and Proximal Phalanx Fractures in Children

Middle and Proximal Phalanx Fracture Classification

Classification of middle and proximal phalanx fractures in children is based on anatomic location and mechanism of injury. There are four locations: The physis, shaft, neck, and condyles (Table 10-8). The fracture pattern varies with the direction and amount of force incurred. Most fractures of the proximal and middle phalanges result from a torsional or angular force combined with an axial load, such as catching a ball, falling on an outstretched hand, or colliding in sports. Crush injuries are less common in the proximal and middle phalanges than in the distal phalanx. The thumb proximal phalanx and MCP joint are subject to greater lateral bending forces.

Every fracture must be carefully examined for malrotation and rotational deformity regardless of classification, mechanism of injury, or radiographic appearance. Active finger flexion will produce deviation of the plane of the nails or overt digital scissoring (Fig. 10-30). Passive wrist extension will cause long finger flexor tenodesis, and malrotation is evident from an abnormal digital cascade.

Physeal Fractures

Physeal fractures of the proximal phalanx are reported in several series as the most common pediatric hand fracture.[10,73,86,110,202] Extra-articular S-H II fractures are more prevalent, and intra-articular S-H III and IV fractures are less common. A common fracture pattern is the S-H II fracture along the ulnar aspect of the proximal phalanx of the small digit. The small digit is angulated in an ulnar direction. This fracture has been termed the "extra-octave" fracture to denote its potential benefit to the span of a pianist's hand (Fig. 10-31).[159] Physeal fractures about the middle phalanx can involve the lateral, dorsal, or volar aspects of the physis. A lateral force across the PIP joint may cause an S-H III or IV fracture. Similarly, a flexion force may produce a dorsal S-H III fracture indicative of a central slip avulsion fracture (pediatric boutonniere injury). A

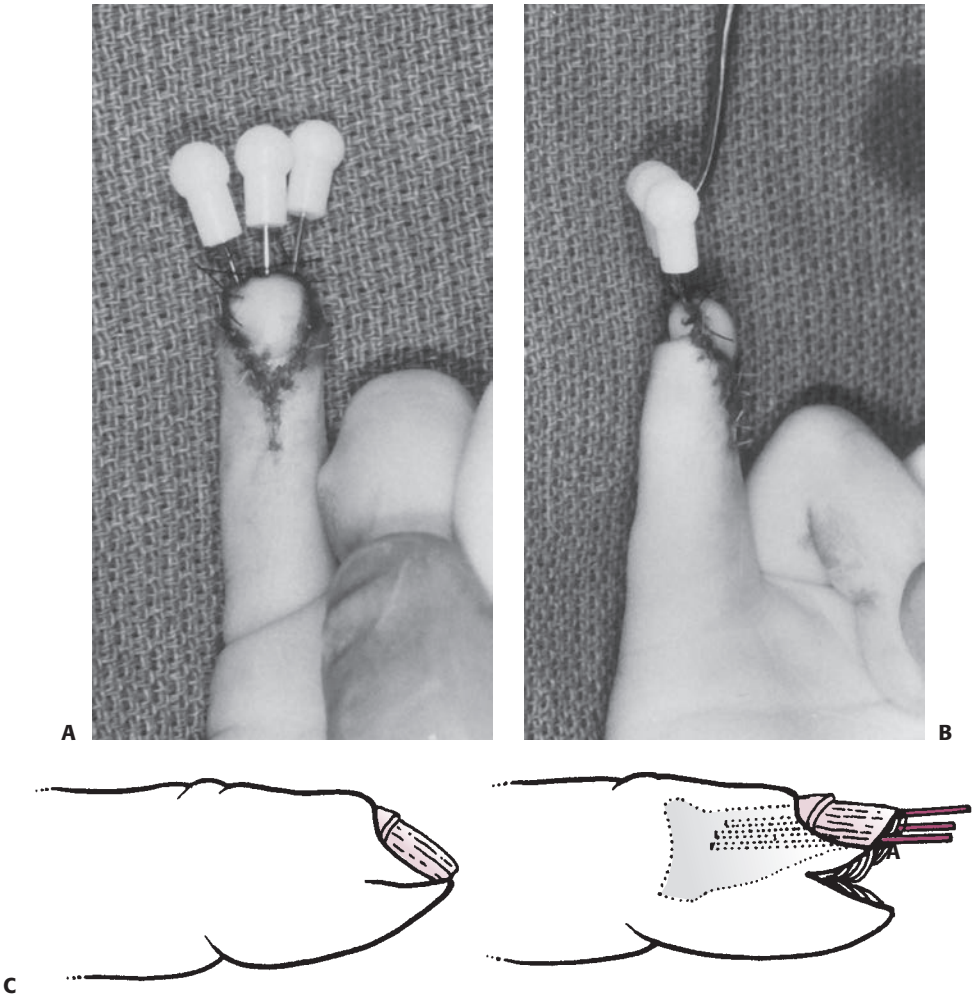

FIGURE 10-29 **A, B:** Postoperative photographs of the patient shown in Figure 10-21 after the antenna procedure. The procedure involved a volar V–Y advancement flap to cover the distal tip, elevation of the sterile matrix, and the nail supported using three K-wires. **C:** Line drawings demonstrating technique of elevation and support of the sterile matrix with wires. (**A, B:** Courtesy of William B. Kleinman, MD. **C:** Reprinted from Atasoy E, Godfrey A, Kalisman M. The "antenna" procedure for the "hook-nail" deformity. *J Hand Surg [Am].* 1983;8:55, with permission.)

hyperextension injury produces small avulsion fragments from the middle phalangeal epiphysis associated with damage to the volar plate.

The thumb proximal phalanx is particularly susceptible to injury. An ulnar collateral ligament (UCL) avulsion injury at the base of the thumb proximal phalanx is similar to the adult gamekeeper's or skier's thumb. The mechanisms of injury, clinical findings of UCL laxity at the MCP joint, and physical symptoms of instability with grip and pinch will be similar to the adult soft tissue UCL injury. However, the fracture pattern is usually an S-H III injury, as the ligament typically remains

TABLE 10-7 Distal Phalanx Fractures in Children

Common Adverse Outcomes and Complications
Osseous: Nonunion, malunion, osteomyelitis
Soft tissue: Scar, stiffness, extensor tendon insufficiency with extensor lag
Nail: Split or hook-nail deformity, rides, ingrown lateral or dorsal nail fold

attached to the epiphyseal fracture fragment (Fig. 10-32). Displaced injuries with articular incongruity or joint instability require open reduction and internal fixation (ORIF) to restore articular alignment and joint stability.[191]

Children rarely sustain comminuted intra-articular fractures of the PIP joint, the so-called "pilon" fractures or fracture–dislocations.[192] These injuries can occur in adolescent athletes and result from an axial load sustained while attempting to catch a ball or physically contacting an opponent. Fracture lines often propagate into the physis. The fracture fragment from the volar side may have the volar plate attached, whereas the dorsal fragment is likely to have the central slip attached. The central aspect of the joint may be depressed and comminuted. The joint can be unstable and incongruent, requiring careful treatment.

Shaft Fractures

Shaft fractures in children are less common. The fracture configuration may be transverse, spiral, or spiral oblique. The fracture may be comminuted. Proximal and middle phalangeal fractures are usually angulated in an apex volar pattern because the distal fragment is extended by the central slip and lateral band, and the proximal fragment is flexed by the FDS in the middle phalanx and by the intrinsic musculature in the proximal phalanx (Fig. 10-33). Oblique fractures often rotate and shorten. Careful clinical evaluation of rotational alignment is critical. Comminution is secondary to a high-energy injury or direct trauma to the phalanx (Fig. 10-34).

Neck Fractures

Neck fractures of the phalanx are problematic with regard to treatment and functional outcome. Displaced neck fractures are also referred to as subcondylar fractures and often occur in young children as a result of finger entrapment in a closing door (Fig. 10-35). The head fragment remains attached to the collateral ligaments and tends to rotate into extension.[47] This displacement disrupts the architecture of the subcondylar fossa, which normally accommodates the volar plate and base of the phalanx during interphalangeal joint flexion. Malunited neck fractures, therefore, result in a mechanical block to interphalangeal joint flexion. Frequently, these fractures are inadequately imaged, underappreciated, or misinterpreted as trivial and referred late for care.

Intra-Articular (Condylar) Fractures

Condylar fractures involve the joint and represent a constellation of fracture patterns, including small lateral avulsion fractures, unicondylar or intracondylar fractures, bicondylar or transcondylar fractures, and a rare shearing injury of the entire articular surface and its underlying subchondral bone from the distal aspect of the phalanx (Fig. 10-36). Condylar fractures can be associated with subluxations or dislocations of the joint. Many of these fractures are initially misdiagnosed as sprains.[86,110] Restoration of articular alignment and joint stability is critical to a successful outcome.

Treatment of the Middle and Proximal Phalanx Fractures

The treatment of middle and proximal phalangeal fractures varies greatly with the type of injury. Nonoperative treatment is predictable management for most physeal and shaft fractures. Operative treatment is common for neck and condylar fractures, especially fractures that are displaced or unstable (Table 10-9).

Nonoperative and Operative Techniques of Middle and Proximal Phalanx Fractures

Physeal Fractures

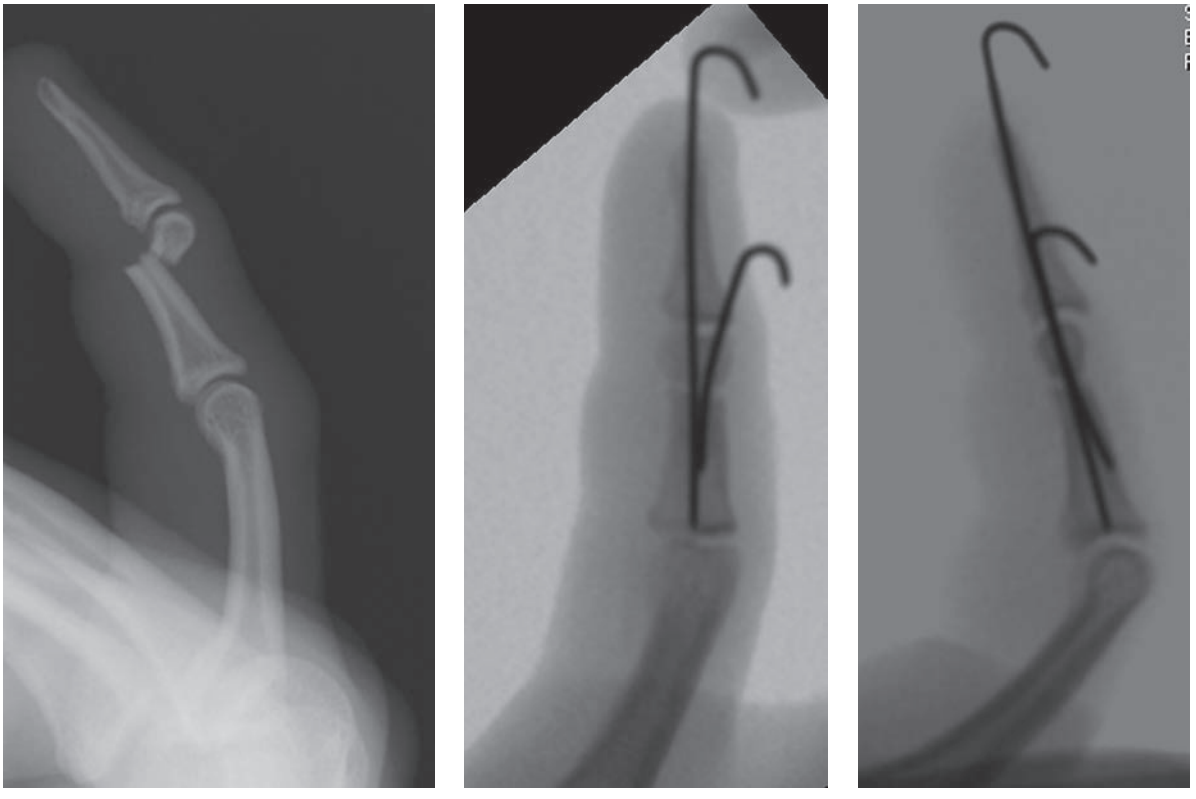
Most physeal fractures of the proximal and middle phalanges can be managed by simple immobilization. Displaced fractures often require closed reduction. Minimal displacement is treated with splinting in the safe position for 3 weeks. Moderate displacement requires closed reduction with local anesthesia or conscious sedation. Placing the MCP joint into flexion to tighten the collateral ligaments and angulating the digit into radial deviation for a fracture displaced in an ulnar direction reduces the fracture. In the "extra-octave" fifth proximal phalanx fracture, placing a pencil or digit in the fourth web

FIGURE 10-33 **A, B:** Radiographs of transverse middle and proximal phalangeal fractures which demonstrate the characteristic apex velar deformity.

FIGURE 10-34 Comminuted fractures secondary to a crush injury with longitudinal splitting into the physis.

space and using it as a fulcrum to assist reduction has been recommended.[215] Minimal force is necessary to restore alignment.[5,52] Buddy taping and cast immobilization will maintain alignment until healing (Fig. 10-31). The age and compliance of the patient determines if buddy tape or casting is indicated. Minimally displaced S-H III epiphyseal fractures at the base of the middle phalanx associated with volar plate avulsion can be treated with early buddy tape or extension block splint. "Pediatric boutonniere" fractures or dorsal S-H III epiphyseal fractures can be treated with a PIP extension splint and early DIP range of motion exercises just as in the adult.

Irreducible fractures of the physis have been reported.[10,37,85,110] Any surrounding soft tissue structures, including periosteum and tendons, may prevent reduction. Open treatment with removal of the impeding tissue and fracture reduction is required for these rare injuries (Fig. 10-37). In addition, some S-H II fractures may be reducible but unstable after reduction. These fractures tend to result from higher-energy mechanisms of injury that cause more disruption of the supporting soft tissues. Insertion of a smooth K-wire after reduction is required to maintain fracture alignment.[85,175] Another indication for operative management is a displaced S-H III fracture of the proximal phalangeal base with a sizable (more than 25%) epiphyseal fragment. Closed or open reduction may be required to restore articular congruity.[86,175] Small K-wires can be inserted parallel to the joint surface, avoiding the physis. Tension-band wiring[187] techniques can be used for S-H III and IV fractures in older children. Operative exposure and fixation



A, B C

FIGURE 10-35 **A:** Phalangeal neck fractures are often unstable and rotated. These fractures are difficult to reduce and control by closed means because of the forces imparted by the volar plate and ligaments. **B, C:** Fixed with a closed reduction and hyperextension maneuver across the DIP joint as well as a derotational wire.

A B

FIGURE 10-36 **A:** An AP radiograph reveals an intra-articular fracture of the small finger. **B:** Lateral view demonstrates the double density sign indicative of displacement (*arrows*).

TABLE 10-9 Treatment of Middle and Proximal Phalanx Fractures

Nonoperative Indications	Operative Indications
Stable initially or after closed reduction	Unstable
Closed, isolated	Open, polytrauma
Normal tenodesis	Malrotation
Joint congruity and stability	Joint incongruity (S-H III, neck, or condylar fractures)

techniques are challenging with nonborder digit proximal phalangeal S-H III fractures.

Classically in teenagers, a bony gamekeeper's or skier's thumb is an S-H III fracture of the proximal phalanx that requires closed reduction and percutaneous pinning (CRPP) or ORIF with K-wire or modular screw fixation if the fragment is large enough. Open visualization may be necessary for visualization of the articular reduction and reduction of the UCL. The approach is similar to the operative steps of an adult gamekeeper's thumb surgery with incision of the adductor fascia for exposure followed by later repair after fracture reduction (Fig. 10-38).

Beware of the "flipped physis" of the middle or proximal phalanx in younger children. The findings on x-ray may be subtle and only visible on the lateral view. Treatment most often requires open "flipping" of the physis, attempting to keep any collateral ligaments or capsule intact. Surprisingly, appropriate management rarely results in growth arrest (Fig. 10-39).

FIGURE 10-37 Displaced S-H II fracture of the proximal phalanx that was irreducible. The distal fragment was herniated through a rent in the periosteum and extensor mechanism that prohibited reduction.

Shaft Fractures

Shaft fractures that are nondisplaced and stable can be treated with simple immobilization. Safe position splinting for 3 to 4 weeks should be adequate for clinical union. Displaced or angulated fractures require closed reduction. The amount of acceptable angulation in the plane of motion is controversial.[180] In children less than 10 years of age, 20 to 30 degrees may be acceptable. In children older than 10 years, 10 to 20 degrees of angulation is acceptable. Less angulation is acceptable in the coronal plane. Malrotation is unacceptable.

Fractures that are unstable after reduction or irreducible by closed methods require operative intervention. A shaft fracture that is unstable after reduction is managed primarily by closed reduction and percutaneous K-wire fixation in either a longitudinal or horizontal direction, depending on the obliquity of the fracture (Fig. 10-40).[189] Open reduction is indicated for fractures that cannot be reduced. A dorsal approach is usually used for exposure. The extensor tendon is split for proximal phalangeal fractures and elevated for middle phalangeal fractures. The choice of implant depends on the age of the patient and the fracture configuration. Smooth wires, tension bands, or modular set screws are preferable to plates to avoid extensor mechanism adherence.[92] Bone grafting alone has been described to provide rigid fixation to proximal phalangeal base fractures.[194] All malrotated fractures require reduction and fixation.

Phalangeal Neck Fractures

Closed treatment of fractures of the phalangeal neck is difficult because these fractures are often unstable (Fig. 10-35A). Closed manipulation is done with digital distraction, a volar-directed pressure on the distal fragment, and hyperflexion of the DIP or PIP joint depending on the phalanx fractured. Percutaneous pinning is usually necessary to maintain the reduced position.[47] Under fluoroscopy, K-wires are inserted through the collateral recesses and across the fracture. These wires should engage the contralateral cortex proximal to the fracture site.

An alternative technique with a small distal fragment is to insert the pins through the articular surface of the phalanx in a longitudinal fashion, crossing the fracture to engage the proximal fragment. For example, in the middle phalanx neck fracture, a longitudinal wire can be placed distal to proximal, across the physis of the distal phalanx with the DIP in hyperextension to engage the distal fragment and condyles of the middle phalanx. Then the finger is flexed at the fracture site and the pin driven into the proximal middle phalanx with restoration of bony alignment (Fig. 10-35B, C).

Recent publications have drawn attention to the remodeling potential of shallow neck fractures in a child under the age of 2 years. Remarkable reforming of the anatomic condyles can occur, despite being so far from the epiphysis. If very young children present late, waiting out their remodeling potential may obviate the need for any management (Fig. 10-41).[157]

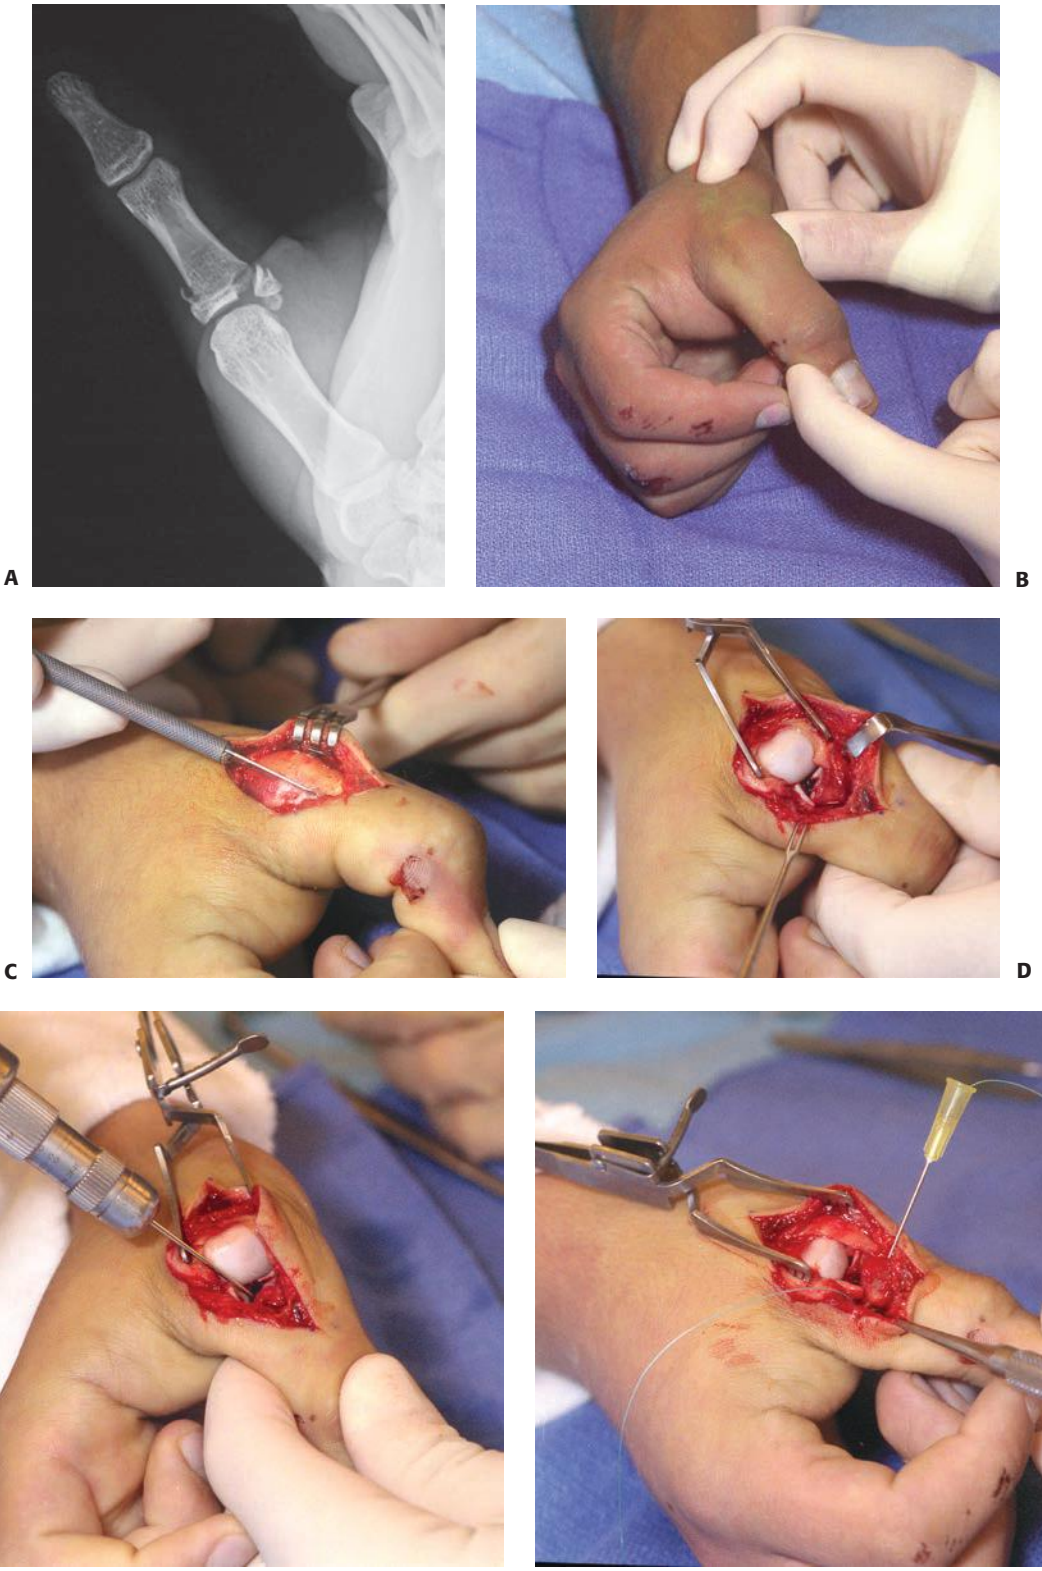


FIGURE 10-38 A–H: Open reduction and K-wire fixation of a bony gamekeeper's thumb. Taking care to repair the UCL, articular surface, and adductor aponeurosis.

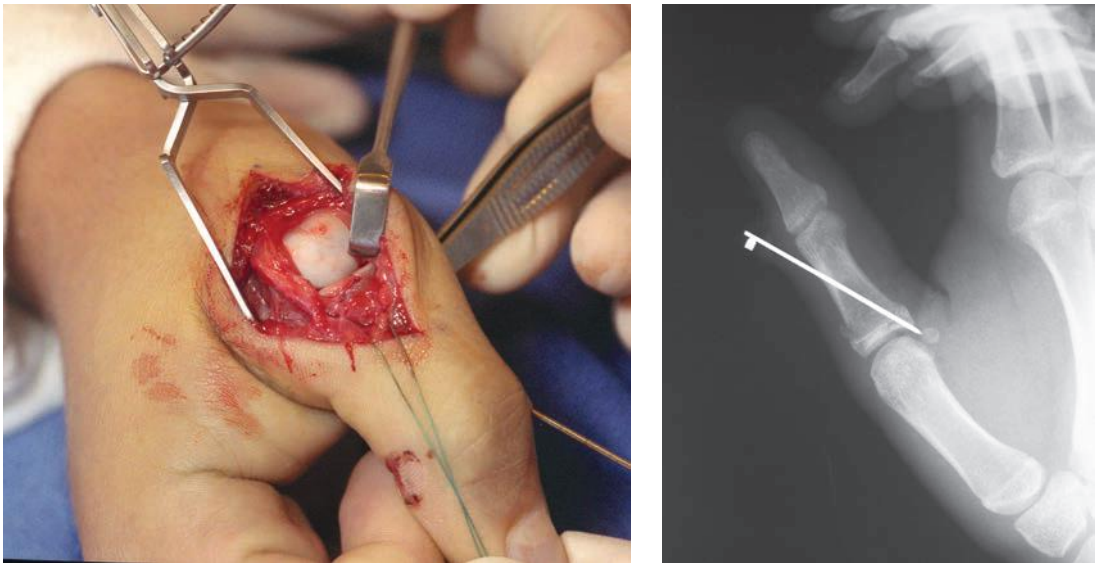

FIGURE 10-38 (*continued*)

Intra-Articular Fractures. Nondisplaced fractures can be treated by immobilization. Weekly radiographs are necessary to ensure maintenance of reduction. Displaced intra-articular fractures require closed or open reduction.[175] Closed or percutaneous reduction can be accomplished with traction and use of a percutaneous towel clip or reduction clamp to obtain provisional fracture reduction. Percutaneous fixation is used for definitive fracture fixation. Fractures not appropriate for closed manipulation require ORIF (Fig. 10-42). A dorsal, lateral, or rare volar incision is used for direct inspection of the fracture and articular surface. Care is taken to preserve the blood supply of the fracture fragments entering through the collateral ligaments. Fracture stabilization is either by K-wires or miniscrews.

Certain unusual intra-articular fractures are especially difficult to treat. Shear fractures and osteochondral slice fractures are difficult to recognize. Treatment is open reduction and smooth wire fixation. Osteonecrosis, especially of small fragments, is a concern. Some of these fractures require a volar surgical approach. Avoidance of extensive soft tissue dissection lessens the risk of osteonecrosis.

Comminuted pilon fracture–dislocations of the PIP joint are uncommon in children. Operative intervention is usually required to restore articular congruity. Anatomic reduction is

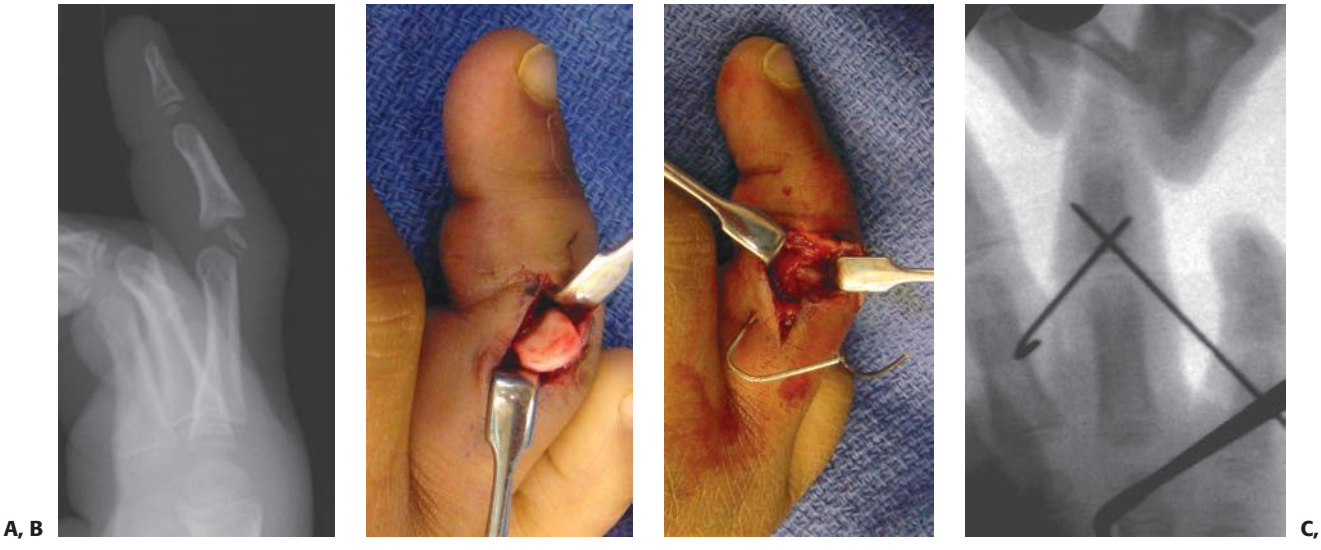

FIGURE 10-39 **A–D:** Beware of the "flipped" epiphysis. Requires open reduction and fixation, but in younger children may not even cause growth arrest. Higher risk of infection and growth arrest than other epiphyseal fractures. (Courtesy of Children's Hospital Los Angeles, CA.)

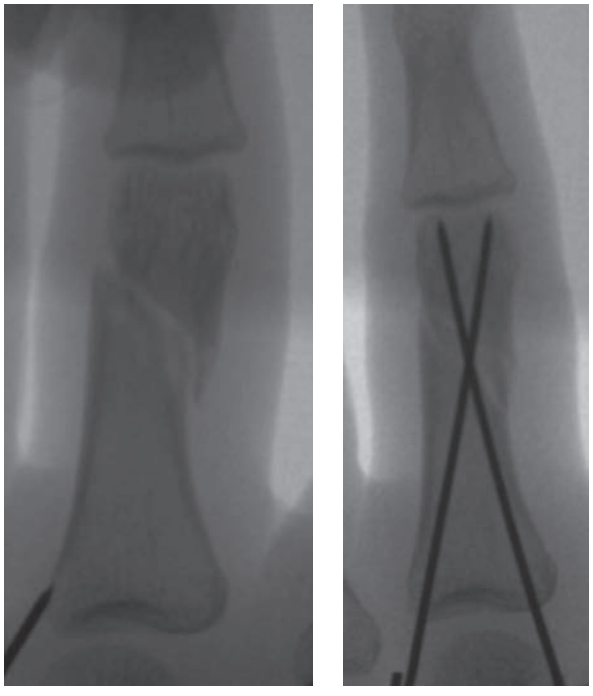

A B

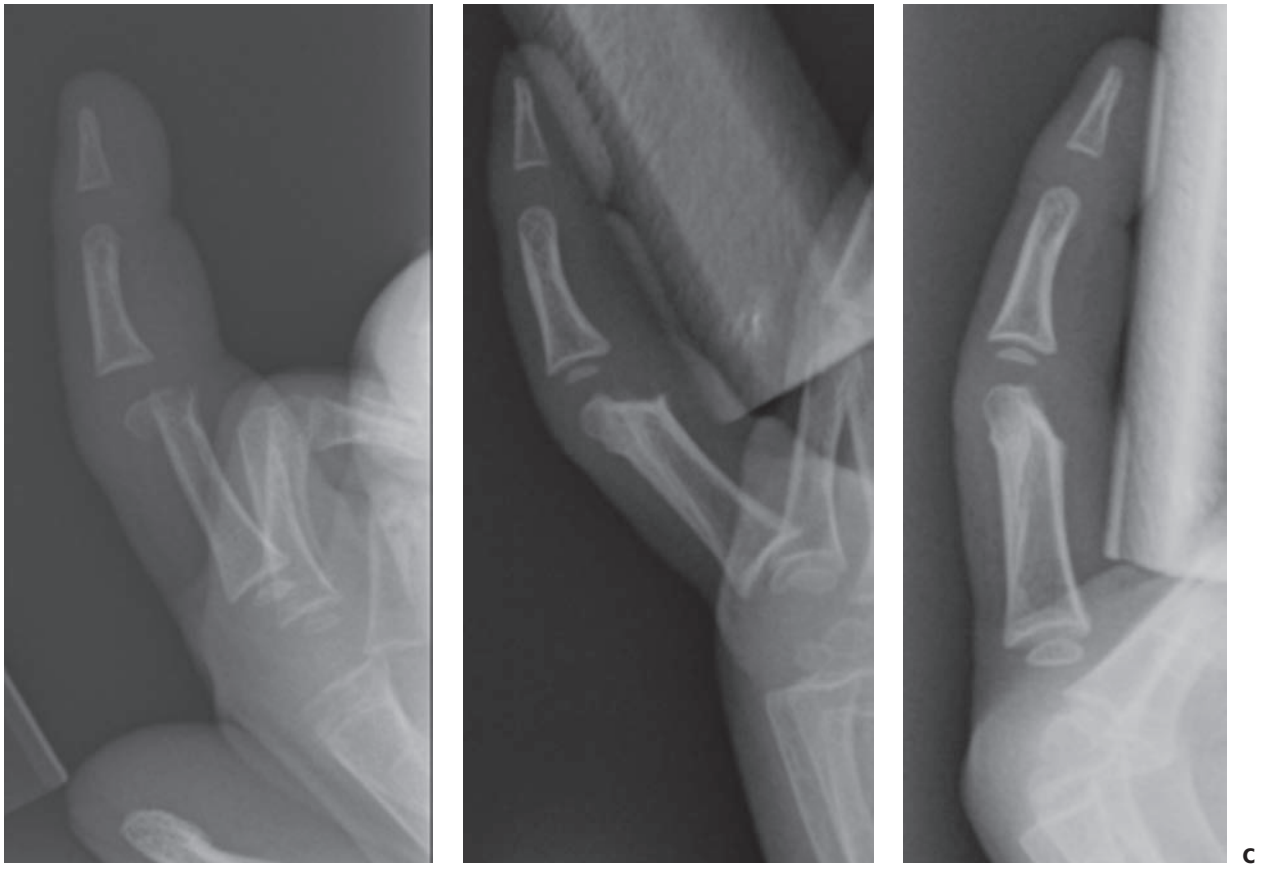
preferred whenever possible (Fig. 10-43).[193] Bone grafting may be necessary for stable reduction. Extreme joint comminution may preclude anatomic reduction, and alternative treatment options, such as dynamic traction, may be necessary.[2,174]

Complex Injuries. Combined injuries that affect several tissue systems are common in the digits. Skin, tendon, neurovascular structures, and bone may all be injured in the same digit (Fig. 10-44). Open fracture care is mandatory, followed by establishment of a stable bony foundation. Markedly comminuted fractures or injuries with bone loss may require external fixation followed by delayed bony reconstruction. Neurovascular and tendon reconstruction in children follows the same principles as for adults. Rehabilitation of complex injuries in children can be complicated by a lack of cooperation. Vascular injuries can affect subsequent growth (Tables 10-10 and 10-11).

Author's Preferred Treatment

Physeal Fractures

Nondisplaced fractures are treated with simple immobilization for 3 weeks. Most displaced S-H I and II fractures can be treated with closed reduction (Fig. 10-45). Alignment and rotation are verified clinically, and reduction is assessed with radiographs.



A, B C

FIGURE 10-41 A–C: Remodeling potential of the subcondylar fracture in a very young child.

The hand is immobilized in a safe-position splint, and a radiograph is obtained 5 to 7 days later to ensure maintenance of reduction. When there is doubt about anatomic alignment, the cast is removed for more thorough clinical and radiographic examinations. Immobilization is continued for 3 to 4 weeks. Physeal fractures that are unstable after closed reduction require percutaneous pin fixation. Small smooth wires are used to secure the reduction. Irreducible fractures require open reduction, removal of any interposed tissue, and fixation.

Displaced S-H III fractures of either the middle or proximal phalanges are difficult to reduce and maintain by closed methods. Dorsal S-H III or IV fractures of the middle phalangeal base often require open reduction and fixation to avoid the development of a boutonniere deformity (Fig. 10-46). A dorsal approach, with an incision between the central tendon and the lateral band, is preferred. The PIP joint may require supplemental pin fixation for 3 weeks to permit healing. Lateral S-H III fractures that are displaced more than 1.5 mm or involve more than 25% of the articular surface may also require ORIF. This fracture pattern is especially common in the proximal phalanx of the thumb.

Shaft Fractures

Nondisplaced fractures are treated with immobilization for 3 to 4 weeks. Displaced fractures are treated with CRPP fixation.[74] Reduction is accomplished with longitudinal traction

and rotation of the distal fragment to approximate the proximal fragment. For a proximal phalangeal fracture, the MCP joint is flexed to relax the intrinsic muscle pull and to stabilize the proximal fragment. The fracture orientation dictates the angle of pin insertion (Fig. 10-39). Optimal pin placement is perpendicular to the fracture line. Placement of the pins in the midaxial line prevents iatrogenic injury of the neurovascular structures or entrapment of the extensor mechanism by the pin. Open reduction is reserved for irreducible fractures.

Neck Fractures

Neck fractures usually require operative intervention. If closed reduction is obtainable, then percutaneous pin fixation is performed. The pin(s) are placed through the collateral recesses to engage the proximal fragment in a crossed fashion. If closed reduction is unsuccessful, open reduction with preservation of the collateral ligaments and similar percutaneous pinning are indicated. However, open reduction should be avoided whenever possible to decrease the chances of osteonecrosis.

Late presentation of a neck fracture requires consideration of the time from injury, age of the patient, and fracture displacement. Considerable displacement requires treatment to regain joint flexion (Fig. 10-47). If the fracture line is still visible, a percutaneous pin osteoclasis may be possible. Under fluoroscopy, one or two smooth K-wires are inserted into the fracture site to break up any callus. These K-wires are used to "joystick" the distal fragment into a reduced position.[209] The fracture is then stabilized with additional percutaneous pins. This approach may decrease the risk of osteonecrosis associated with late open reduction. A nascent or established malunion that cannot be reduced by osteoclasis can be treated by late open reduction (Fig. 10-48). The callus is gently removed and the fracture aligned. The risks of osteonecrosis must be weighed against acceptance of the malunion. Mild loss of the condylar recess can be treated with recession of the prominent volar bone rather than risk osteonecrosis associated with extensive fracture mobilization.[181,197] In addition, slow remodeling is feasible in very young children without rotational malalignment and with a family that is willing to wait up to 2 years for remodeling.[36,87]

Intra-Articular Fractures

Intra-articular fractures of the phalanges usually require percutaneous or open reduction. Unicondylar fractures that are mildly displaced can be treated with CRPP. Widely displaced unicondylar and bicondylar fractures require open reduction (Fig. 10-41). A dorsal approach is preferred. Fixation is usually obtained with smooth wires. Placement and direction of the wires are dictated by the fracture configuration. Rotational control of the fragment may require multiple wires. The fixation device must avoid tethering of the collateral ligament, which will limit PIP joint motion. Usually, a pin is placed parallel to the joint to maintain articular alignment, followed by oblique

Preoperative Planning Checklist

- OR table: Hand table
- Position: Supine
- Fluoroscopy location: Perpendicular or opposite the surgeon
- Equipment: Hand tray instruments, wire driver
- Tourniquet (sterile/nonsterile): Nonsterile or Esmark at approximately 200 mm Hg in small children
- Hardware: 0.027, 0.035, or 0.045 K-wires. Tension-band wires, modular screw set
- Suture: Nonabsorbable or absorbable suture for incision closure

TABLE 10-11 Orif of Middle and Proximal Phalanx Fractures

Surgical Steps

- Attempt closed reduction of displaced or open fractures after irrigation and debridement of foreign bodies or contamination
- If alignment adequate, place one or two K-wires parallel or crossed at fracture site, across physeal or extraphyseal fracture. Limit crossing of PIP joint
- Use "joystick" smaller K-wires, Freer elevator, dental pick, towel clip, or small fragment reduction forceps to enhance the closed reduction, osteoclasis
- If necessary, open skin through a direct lateral approach or expose the articular surface through the open fracture wound
  - Preserve extensor and collateral soft tissue attachments
  - Avoid dissection of smaller bone fragments
- Reduce incarcerated, rotated, or extruded fragments and proceed with K-wire or lag screw fixation

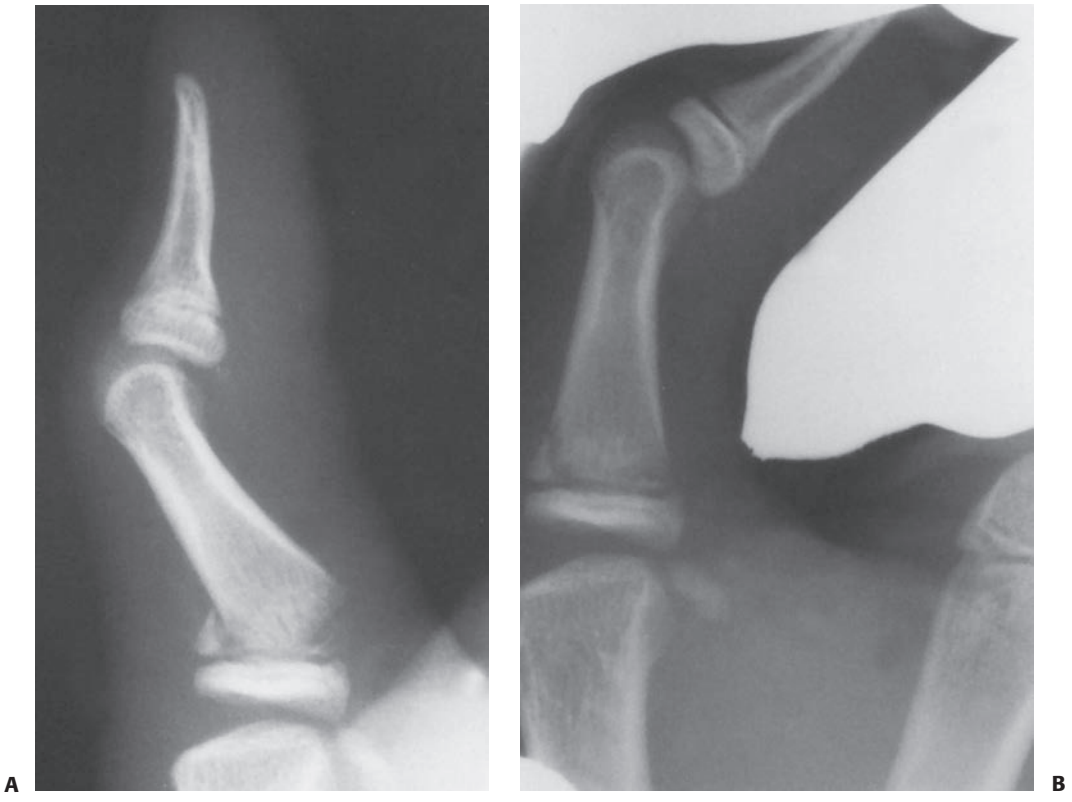

FIGURE 10-45 **A:** An S-H II fracture of the proximal phalanx of the thumb. **B:** Gentle closed reduction under fluoroscopic control obtained an anatomic reduction.

pins to stabilize the articular fragment(s) to the shaft. In adolescents, miniscrew fixation can be used, though these screws must avoid impingement of the collateral ligaments that will impede flexion.

Pilon fractures or intra-articular fracture–dislocations present a management dilemma.[193] Open reduction is worthwhile when the fragments are large and the joint surface can be reconstructed. Bone grafting may be necessary for stable reduction. Severe articular damage and comminution is best treated with dynamic traction (Fig. 10-49).

Postoperative Care

The duration of immobilization after surgical intervention for phalangeal fractures is usually 3 to 4 weeks. Percutaneous pins are removed at that time and motion instituted. Formal hand therapy usually is not required, though the child must be encouraged to reestablish a normal usage pattern to improve motion and flexibility. Periarticular fractures are monitored closely for persistent loss of motion that would benefit from formal hand therapy. Patients with complex fractures

FIGURE 10-47 Displaced phalangeal neck fracture of the proximal phalanx revealing loss of subchondral fossa at the PIP joint. If this is not corrected to anatomic alignment, there will be a mechanical block to flexion.

or replantations are more prone to develop stiffness. In these instances, therapy is routinely prescribed to regain motion. Therapy is directed at both flexion and extension of the injured digit. Static or dynamic splinting may be required after fracture healing. Persistent stiffness may require tenolysis and/or joint release to regain motion (Table 10-12; Fig. 10-50).

Prognosis

The overall results following proximal and middle phalangeal fractures are positive. Considering the frequency of these fractures, the occurrence of complications and functional impairment is low. Despite appropriate treatment, however, some children have permanent loss of motion, malunion, or growth disturbance. The major concern is to avoid rotational, articular, or periarticular malunion caused by the inappropriate diagnosis or treatment.

Management of Expected Adverse Outcomes and Unexpected Complications (Table 10-13)

Complications associated with proximal and middle phalangeal fractures begin with failure to recognize the injury (Fig. 10-51). Radiologic AP and lateral views of the injured digit must be made correctly and scrutinized for subtle abnormalities. Questionable findings warrant additional views or advanced imaging studies. A common misdiagnosis is failure to recognize a displaced phalangeal neck fracture because of inadequate lateral radiographs of the finger.

Another early complication is false interpretation of a "nondisplaced" fracture that is malrotated. All children with phalangeal fractures require careful examination for rotational alignment. The clinical examination is the mainstay for

A

B

FIGURE 10-48 **A:** A 14-year-old girl with incipient malunion of right thumb proximal phalanx neck fractures that impede flexion. **B:** Lateral radiograph reveals loss of the subchondral fossa.

determining fracture rotation. Digital scissoring is indicative of fracture malrotation and requires reduction. Regardless of radiographic appearance, rotational alignment should be evaluated by active finger flexion and passive tenodesis.

Most phalangeal fractures can be maintained in satisfactory alignment after closed reduction. Certain fractures, however, have a propensity for redisplacement (Fig. 10-52). Oblique shaft fractures, unicondylar articular fractures, and neck fractures are prime examples. Early follow-up to ensure maintenance of reduction is paramount if closed treatment is chosen. Displacement requires repeat manipulation and pin fixation. When in doubt, the digit should be examined out of cast carefully for malalignment and blocks to motion because of the fracture displacement. Most of these unstable fractures do best with pin fixation after acceptable reduction.

Late complications include rare nonunion, malunion, osteonecrosis, growth disturbance, and arthritis. Nonunion is rare except in combined injuries with devascularization of the fracture fragments. Bone grafting is usually successful for union. Malunion can result in angulation or limited motion. Extra-articular malunion can cause angulation or rotational abnormalities. The treatment depends on the child's age and ability to remodel according to fracture location, plane of malunion, and degree of deformity (Fig. 10-53). Considerable deformity may require osteotomy to realign the bone.[69] A subcondylar or intra-articular malunion is particularly difficult to treat. Early diagnosis within

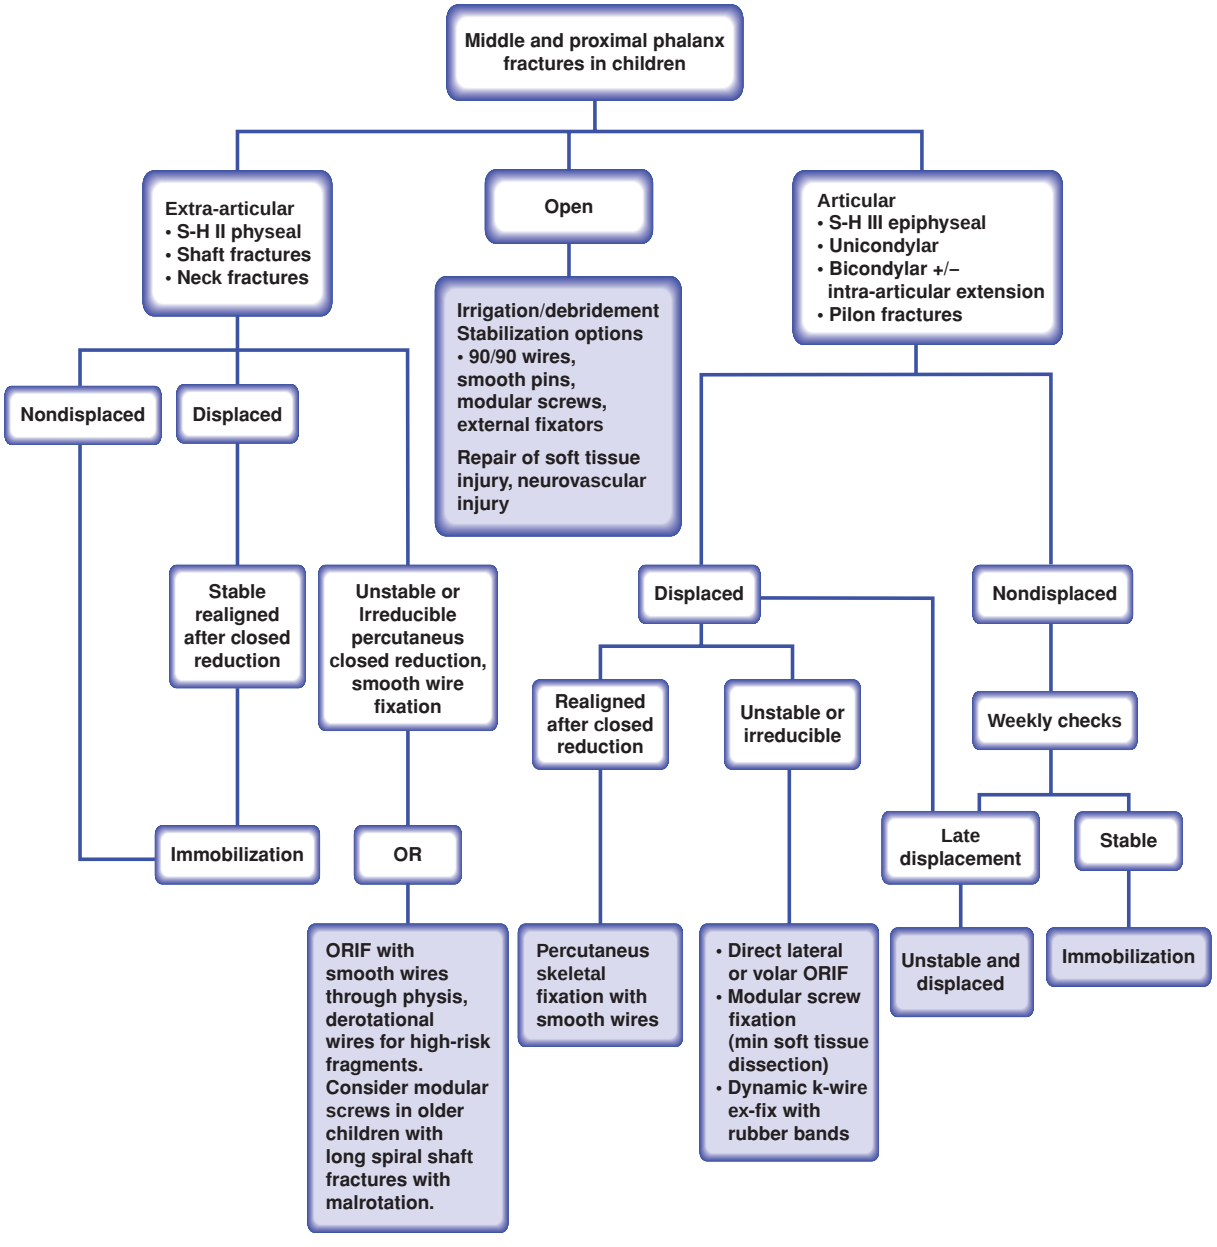

FIGURE 10-49 Author's preferred treatment algorithm for middle and proximal phalanx fractures in children.

TABLE 10-12 Middle and Proximal Phalanx Fractures

Potential Pitfalls and Preventions

Pitfalls	Preventions
Malrotation	• Check tenodesis intraoperatively • Use lateral view to establish if radial and ulnar condyles of middle or proximal phalanx are overlapping
Osteonecrosis	Minimize open procedures and soft tissue stripping of fragile blood supply to condyles
Pin tract infection	Bicortical fixation, relax tension on wire on skin
Stiffness	Allow early range of motion as soon as clinically stable; radiographic union will lag behind clinical union

the first month offers the possibility of fracture realignment through the site of deformity. Treatment of a late diagnosis must include consideration of the risks and benefits associated with extensive surgery. Successful late osteotomies can restore normal tenodesis and return to full function, but risk nonunion, stiffness, and painful functional recovery (Fig. 10-54).

Osteonecrosis is usually related to extensive fracture comminution, soft tissue injury, or surgical dissection of an intra-articular fracture. In severe cases, reconstruction is limited to some form of joint transfer. Growth disturbance can result from any injury that involves the physis. A shortened or angulated digit may result. It is fortunate that this complication is rare because

Pin tract infection, osteomyelitis

reconstruction options for children with remaining growth in the fingers are limited. Angulation must be addressed by corrective osteotomy.

Posttraumatic degenerative joint disease is rare in children, but intra-articular injury and sepsis may result in arthrosis. Treatment is directed toward the child's symptoms and not the radiographic findings. Minimal pain and excellent function often accompany considerable arthritic changes on radiographs and warrant no treatment. Pain and functional limitations require treatment; options include a vascularized joint transfer, interposition or distraction arthroplasty, hemi-hamate

osteochondral transfer, prosthetic joint replacement, and arthrodesis.[182] Arthrodesis in the most functional position is considered the most reliable procedure.

Metacarpal Fractures in Children

Metacarpal Fracture Classification

Metacarpal fractures are classified by location in the epiphysis, physis, neck, shaft, or base (Table 10-14). The metacarpals are surrounded by soft tissue and are relatively protected within the hand. Considerable variation exists in the relative mobility of the metacarpals through the CMC joints. The index and long rays have minimal CMC joint motion (10 to 20 degrees). In contrast, the ring and small rays possess more motion (30 to 40 degrees), and the thumb CMC joint has universal motion. Every metacarpal fracture must be examined for rotation. Malrotation will result in digital scissoring during active flexion or an abnormal digital cascade with passive tenodesis. Direct trauma, rotational forces, and axial loading may all cause fractures of the metacarpal. Contact sports and punching are the most common mechanisms of injury. Pediatric thumb metacarpal fractures have unique anatomy and characteristic patterns and are discussed in a separate section.

Epiphyseal and Physeal Fractures

Epiphyseal and physeal fractures of the metacarpal head are rare but occur most often in the small ray.[11,26,86,112] Physeal S-H II fractures of the small metacarpal occur among patients 12 to 16 years of age and are prone to partial closure of the physis.[112,126,145] Intra-articular, head-splitting fractures at the metacarpal epiphysis and physis consistent with S-H III and IV patterns seldom occur at the metacarpal level but are problematic when displaced (Fig. 10-55). There is an increased risk of head avascular necrosis after an epiphyseal fracture.

Metacarpal Neck Fractures

The metacarpal neck is the most frequent site of metacarpal fractures in children. The metacarpal geometry and composition

predispose the metacarpal neck to injury. The distal metacarpal neck angles as it approaches the MCP joint, and the cortical bone within the subcondylar fossa is relatively thin, making it vulnerable to injury. Neck fractures in children are analogous to boxer's fractures in adults (Fig. 10-56). Neck fractures are more common in the small and ring fingers. Fortunately, these injuries are juxtaphyseal and have considerable remodeling potential.

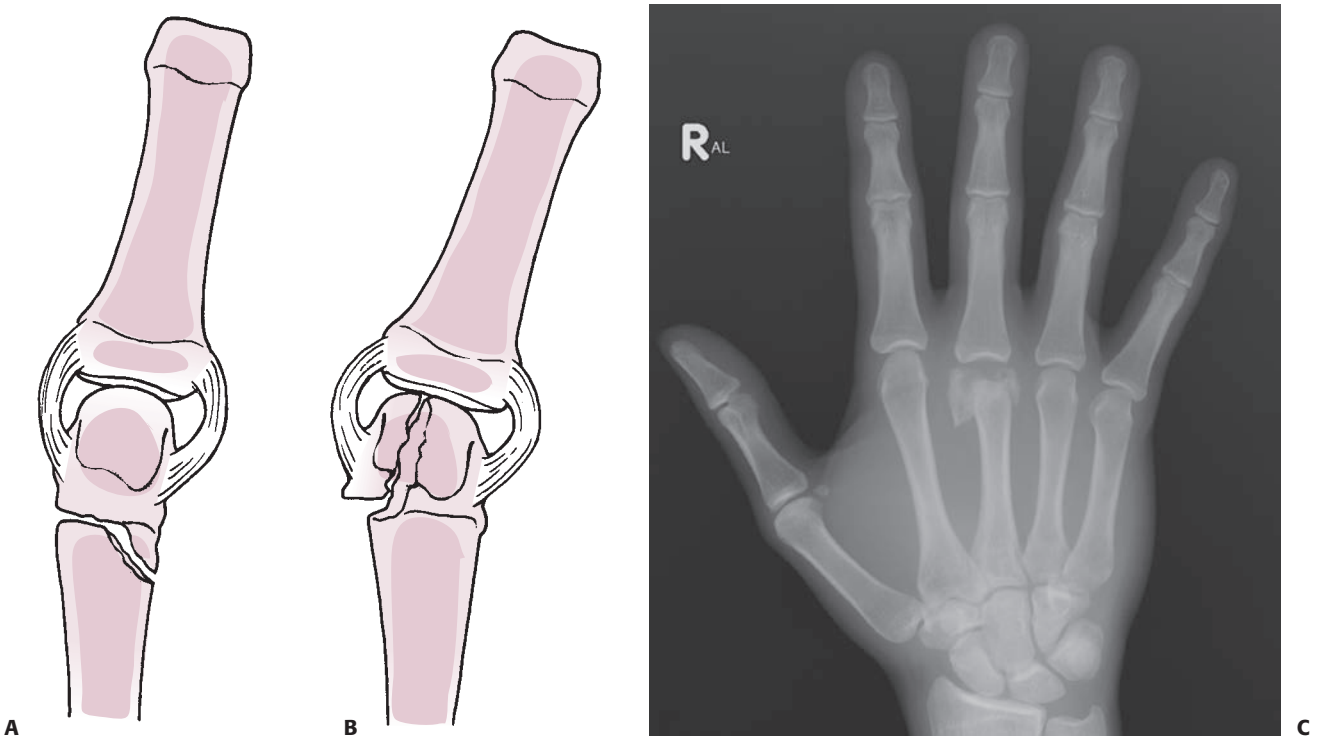

FIGURE 10-55 **A:** An S-H type II fracture of the metacarpal head. **B:** Head-splitting fracture of the metacarpal epiphysis. (Courtesy of Children's Hospital Los Angeles, CA.)

Metacarpal Shaft Fractures

Metacarpal shaft fractures are relatively common. Torsional forces combined with axial load cause long oblique and spiral fractures whereas direct trauma (being stepped on or a heavy object dropping onto the hand) produces short oblique or transverse fractures. An isolated shaft fracture of a central ray is suspended by the inter-metacarpal ligaments, which limit displacement and shortening. In contrast, the border digits (index and small) displace more readily.

Metacarpal Base Fractures

Metacarpal base fractures are uncommon in children. The base is protected from injury by its proximal location in the hand and the stability afforded by the bony congruence and soft tissue restraints. The small finger CMC joint is the most prone to injury. Fracture–dislocations of the small finger CMC joint are often unstable because of the proximal pull of the extensor carpi ulnaris (reverse Bennett fracture).

Metacarpal Fracture Treatment Options

Nonoperative and Operative Treatment of Metacarpal Fractures (Table 10-15)

The treatment of metacarpal fractures varies with the location, extent, and configuration of the fracture. Nonoperative or closed treatment is the primary mode of management for most fractures. Operative intervention is used for multiple metacarpal fractures, extensive soft tissue injury, intra-articular head-splitting fractures, malrotated fractures, and irreducible fractures.

Epiphyseal and Physeal Fractures

A metacarpal head-splitting fracture may be difficult to detect and requires special views. The Brewerton view is helpful and is performed with the dorsum of the hand against the cassette and the MCP joints flexed about 65 degrees. The central beam is angled 15 degrees to the ulnar side of the hand.[106] This projection focuses on the metacarpal heads and may highlight subtle bony abnormalities. An MRI scan to assess articular alignment is diagnostic in complex injuries.

Management is based on the amount of articular or fracture fragment displacement and stability detected on imaging studies, at times including MRI. Many of these fractures can be treated by closed methods. Gentle reduction under metacarpal or wrist block anesthesia is followed by application of a splint in the safe position. If the fracture is reducible but unstable, percutaneous pin fixation is recommended. If the Thurston Holland fragment is large enough, the wire can secure the metaphyseal piece and avoid the physis. Otherwise, the wire must cross the physis to obtain stability. A small-diameter smooth wire is advocated, and multiple passes should be avoided.

Displaced intra-articular head-splitting fractures require ORIF to restore articular congruity. Many of these fractures have unrecognized comminution that complicates internal fixation. Wire or screw fixation is used, depending on the age of the patient and size of the fragments. Transosseous suture repair

FIGURE 10-56 **A:** A true boxer's fracture of the metacarpal neck of the fifth ray. **B:** This fracture is more in the diaphysis and should not be considered a boxer's fracture.

may be necessary. Bone grafting may be necessary for stable reduction. The primary goal of surgical treatment is anatomic reduction of the joint. A secondary goal is stable fixation to allow early motion.

Neck Fractures

Metacarpal neck fractures are usually treated by closed methods. The amount of acceptable apex dorsal angulation in children as in adults is controversial. Greater angulation is allowable in the mobile ring and small rays compared to the index and long. Another consideration is the effect of remodeling over time, which is dependent on the age of the child. In general, 10 to 30 degrees of angulation greater than the corresponding CMC joint motion is acceptable. Radiologic AP and lateral views may be supplemented by an oblique view to assess fracture configuration.

TABLE 10-15 Metacarpal Fractures

Nonoperative	Operative
Nondisplaced	Multiple metacarpals
Closed	Open or extensive soft tissue injury
Reducible	Displaced articular
Stable	Unstable
	Irreducible
	Malrotation
	Excessive shortening

Considerable angulation can be treated with closed reduction with local anesthesia or conscious sedation and splint or cast application. The Jahss maneuver is commonly recommended and involves initial flexion of the MCP joint to 90 degrees to relax the deforming force of the intrinsic muscles and tighten the collateral ligaments.[95] Subsequently, upward pressure is applied along the proximal phalanx to push the metacarpal head in a dorsal direction whereas counterpressure is applied along the dorsal aspect of the proximal metacarpal fracture. Jahss[95] suggested immobilization with the MCP and PIP joints flexed, but this type of immobilization is no longer advocated for fear of stiffness and skin breakdown. Immobilization in the intrinsic plus or safe position is the appropriate approach. A well-molded splint or ulnar gutter or outrigger cast is necessary. Three-point modeling over the volar metacarpal head and proximal dorsal shaft is recommended. The PIP joints may or may not be included in the immobilization depending on the status of the reduction and reliability of the patient.

Uncommonly, a neck fracture may be extremely unstable and require percutaneous pinning (Fig. 10-57). Pins can be inserted in a variety of configurations. Extramedullary techniques include crossed pinning or pinning to the adjacent stable metacarpal. Intramedullary techniques can also be used, similar to those used for metacarpal shaft and neck fractures in

FIGURE 10-57 A, B: A 14-year-old boy with a dorsally angulated fracture of the second metacarpal. **C:** Closed reduction was unstable, and percutaneous K-wire fixation was performed. (Reprinted from O'Brien ET. Fractures of the hand. In: Green DP, ed. *Operative Hand Surgery.* 2nd ed. New York, NY: Churchill Livingstone; 1988:715–716, with permission.)

adults.[58,70] Intramedullary techniques are reserved for patients near physeal closure. Prebent K-wires or commercially available implants are inserted through the metacarpal base in an antegrade fashion. The wires can be used to assist in fracture reduction. Stability is obtained by stacking several wires within the canal and across the fracture site.

Open reduction of metacarpal neck fractures is seldom required in children and is reserved for irreducible fractures, unstable fractures in skeletally mature children, multiple metacarpal fractures, and combination injuries that require a stable bony platform.

Shaft Fractures

An isolated long or ring metacarpal fracture is often minimally displaced because the metacarpals are suspended by the intermetacarpal ligaments. Immobilization for 4 weeks is usually all that is necessary. In contrast, the index and small digits may require additional treatment, such as closed reduction and immobilization. Percutaneous pinning is reserved for unstable shaft fractures (Fig. 10-58). Pins can be inserted with extramedullary or intramedullary techniques. Diaphyseal fractures are slower to heal and more prone to malunion than neck fractures.

An ORIF approach to a metacarpal shaft fracture is rarely indicated in children unless there are multiple fractures or extensive soft tissue damage or the child is skeletally mature. However, a long spiral-oblique fracture with substantial malrotation and shortening may require miniscrew fixation to reestablish alignment.

Metacarpal Base Fractures

Fractures of the metacarpal base or fracture–dislocations at the CMC joint are usually high-energy injuries with substantial tissue disruption. Assessment for signs of compartment

syndrome and careful neurovascular assessment are mandatory. Isolated fracture–dislocations of the small ray CMC joint are the most common metacarpal base fractures. Use of CT scan may better define articular congruity and comminution. A CRPP approach is usually sufficient to restore alignment and to resist the deforming force of the extensor carpi ulnaris.[170] The pins can be placed transversely between the small and ring metacarpals and/or across the CMC joint.

Open reduction may be necessary to achieve reduction and ensure stable fixation in high-energy injuries. A transverse or longitudinal incision can be used for exposure. Longitudinal incisions are recommended in patients with concomitant compartment syndrome to allow for simultaneous decompression. Fixation options are numerous, depending on the fracture configuration. Supplemental bone graft may be necessary for substantial comminution. Late presentation is especially difficult.

FIGURE 10-58 A 14-year-old boy with a reducible, but unstable, ring finger metacarpal shaft fracture. **A:** The injury on an AP radiograph appears reduced. **B:** Lateral radiograph shows persistent apex dorsal angulation. **C:** An AP radiograph after CRPP. **D:** Lateral radiograph reveals anatomic alignment.

Treatment often requires open reduction or CMC arthrodesis (Tables 10-16 and 10-17; Fig. 10-59).

Author's Preferred Treatment

Epiphyseal and Physeal Fractures

Nondisplaced epiphyseal and S-H II metacarpal neck fractures with up to 30 to 35 degrees of sagittal angulation in adolescents are treated with immobilization as long as there is no rotation and sufficient growth remaining. A widely displaced fracture that is reducible requires percutaneous pinning to maintain

TABLE 10-16 Orif of Metacarpal Fractures in Children

Preoperative Planning Checklist

- OR table: Hand table, radiolucent
- Position/positioning aids: Supine
- Fluoroscopy location: Parallel or perpendicular to the patient's hands
- Equipment: Hand instrument set, small tenaculums, bone clamps, or towel clips, rare pediatric use of modular screw and plate tray
- Tourniquet (sterile/nonsterile): Nonsterile, upper arm, not elevated unless converted to open procedure

TABLE 10-17 Orif of Metacarpal Fractures

Surgical Steps

- Expose longitudinally and dorsally with incision directly over metacarpal or in the case of multiple fractures, in interval between the two broken metacarpals
- Protect the extensor tendons and their juncturae. Handle with care, as increased manipulation may lead to postoperative adhesions
- Split the periosteum over the metacarpl shaft
- Use towel clips, bone clamps or tenaculums to reduce fracture and pin with longitudinal crossed pattern, proximal to distal or distal to proximal
- Transverse traction pinning of the distal fragment to the intact neighboring metacarpal may help with shortening in oblique fractures, but beware of overdistraction and malrotation
- Reduce joint component and provisionally stabilize with K-wires.
- In Bennett fractures, reduce displaced lateral metacarpal to intact ulnar fragment that is attached to the volar beak ligament
- Reduce metacarpal neck component, provisionally stabilize with wires
  - Rarely, pin placement through the base of the proximal phalanx and MCP joint may help capture very distal head fragments
- Restore rotation; check tenodesis after wire fixation

FIGURE 10-59 A 15-year-old boy with crush injury of the right hand requiring compartment release. He presented 6 weeks later with persistent pain and limited motion. **A:** An AP radiograph shows overlapping long, ring, and small CMC joints. **B:** Lateral radiographs reveal fracture–dislocations of long, ring, and small CMC joints. **C:** Postoperative AP radiograph after reduction and CMC fusion using miniplates. **D:** Lateral radiograph after reduction and CMC fusion. the reduction. Displaced epiphyseal fractures with considerable intra-articular displacement require ORIF through a dorsal approach and splitting of the extensor apparatus over the MCP joint. Anatomic reduction of the articular surface is the objective, and fixation devices vary according to the patient and fracture configuration. Even external fixation may be required for severely comminuted fractures (Fig. 10-60). Rarely, pinning across the base of the proximal phalanx with a smooth wire may be necessary to stabilize a small distal metacarpal fragment.

Metacarpal Neck Fractures

Nonoperative and closed methods are the mainstays of treatment. Considerable sagittal angulation is acceptable, especially in the ring and small digits. Small finger angulation up to 30 degrees does not usually necessitate closed reduction as long as there is no malrotation and there is sufficient growth remaining. Greater angulations are treated with closed reduction and cast application. Index and ring finger angulations of more than 20 degrees are treated by closed reduction. Pin fixation is used for unstable fractures that have a tendency to redisplace. Open reduction is rarely necessary.

Metacarpal Shaft Fractures

The number, configuration, and location of the metacarpal shaft fracture(s) dictate treatment. Isolated fractures that are minimally displaced require only immobilization. Isolated fractures that are displaced or malrotated require closed reduction and percutaneous fixation. Rotation is carefully assessed to ensure adequate reduction. An irreducible fracture or multiple fractures usually require open reduction (Fig. 10-58). The fixation technique varies according to the age of the child and fracture pattern. If open fixation is necessary, stable fixation is the goal. Miniplate and screw fixation is preferred to restore alignment and to allow early mobilization of tendons and soft tissue. The physis should be avoided during plate application to prevent growth disturbance. The operative approach and internal fixation principles are similar in children and adults. Long oblique fractures are managed with interfragmentary screw fixation. Short oblique and transverse fractures require a neutralization plate with purchase of four cortices proximal and distal to the fracture. Transverse wire fixation to the surrounding metacarpals is used sparingly because of the risk of metacarpal nonunion secondary to distraction. For transverse wiring, use large K-wires such as 0.062 in or 0.20 mm to avoid risk of breakage.

Metacarpal Base Fractures

Metacarpal base fractures are often displaced or unstable. Extra-articular fractures can be treated by closed reduction with or without percutaneous pinning. Intra-articular fracture–dislocations are more challenging. Percutaneous pinning is often required to stabilize the fracture and to reduce CMC joint subluxation. The wires are placed between the bases of the adjacent metacarpals or across the CMC joint in isolated injuries. Irreducible or multiple fracture–dislocations require open reduction. Late presentation with symptomatic degenerative changes requires CMC arthrodesis (Fig. 10-59).

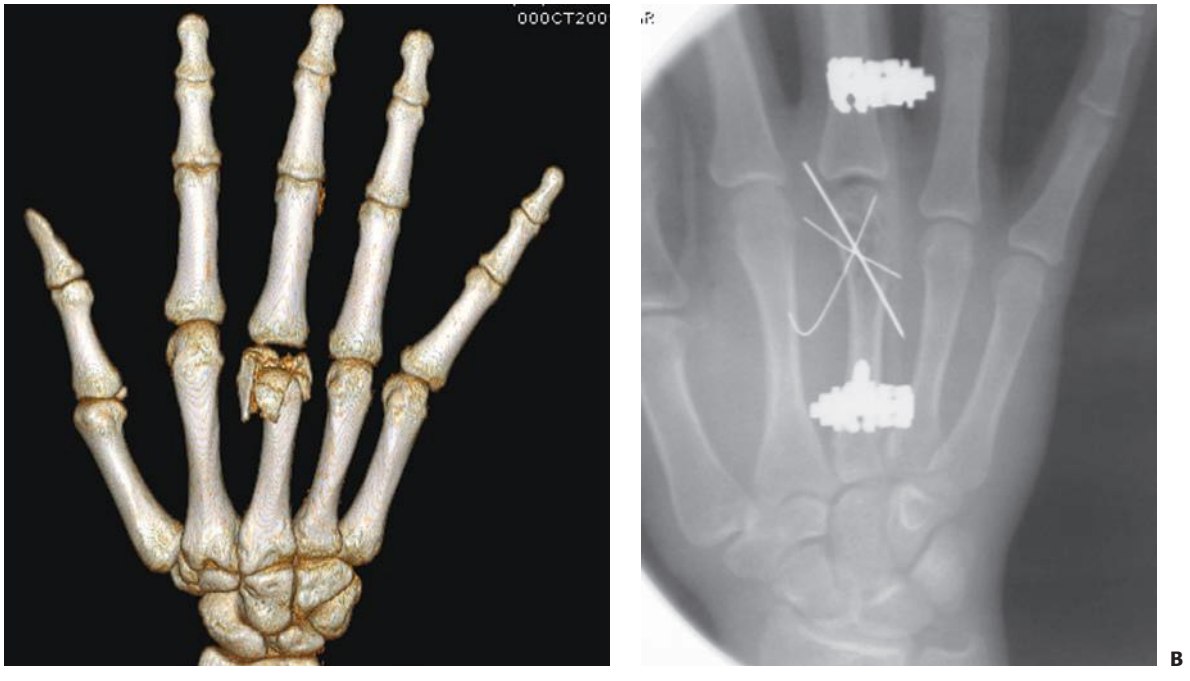

FIGURE 10-60 A 15-year-old boy with a punching injury causing **(A)** an articular, multifragmented metacarpal head fracture. **B:** Fragments were pinned together with 0.035 and 0.028 K-wires. A mini ex fix was utilized to provide distraction across the joint and alignment for collateral ligaments during healing.

Postoperative Care

Most metacarpal fractures managed by closed treatment are immobilized for 4 weeks. Subsequently, a home program of range of motion exercises is started and formal therapy is not needed. In active children and young athletes, a light splint can be worn for protection and as a peer warning signal for an additional few weeks. If percutaneous pin fixation is used, the wires are removed in the office 4 weeks after surgery.

Rehabilitation of open fracture reduction depends on the stability of the fixation and the reliability of the patient to postoperative recommendations. Older and reliable patients with stable internal fixation are mobilized earlier, usually 5 to 7 days after surgery. A removable splint for protection between exercise sessions is used for 4 to 6 weeks (Table 10-18).

Management of Expected Adverse Outcomes and Unexpected Complications

Most metacarpal fractures heal without substantial sequelae. Mild deformity in the plane of motion is tolerated and may correct with remodeling. Considerable angulation or rotation creates a functional impairment that requires treatment.

Bony complications include malunion and osteonecrosis (Table 10-19). Nonunion is rare.[94,145] Even a small amount (less than 10 degrees) of rotational malalignment may create overlap of the digits during flexion and a functional disturbance (Fig. 10-61). Corrective osteotomy to realign the digit is often necessary. The osteotomy for rotational correction can be made at the site of fracture or anywhere along the metacarpal. The proximal shaft or base has certain advantages. This area provides ample bone for healing and offers the opportunity for internal fixation using wires or a plate. Diaphyseal malunions with symptomatic flexion deformity into the palm require a dorsal wedge osteotomy and internal fixation.

Osteonecrosis of the metacarpal head may occur after an intra-articular fracture. Factors include the degree of injury and the intracapsular pressure caused by the hemarthrosis.[39,126,156] Theoretically, early joint aspiration may diminish the intra-articular pressure. Fortunately, partial osteonecrosis in a growing child incites remarkable remodeling of the adjacent articular surface and often results in a functional joint. Part-time splint protection during the remodeling phase is recommended. Considerable joint incongruity is rare, and reconstruction options are limited.[182]

TABLE 10-18 Metacarpal Fractures in Children

Potential Pitfalls and Preventions

Pitfalls	Preventions
Malrotation	Check tenodesis After each K-wire or reduction maneuver recheck tenodesis
Malunion	Stable fixation Allow shaft metacarpals an extended healing time, as the diaphysis may be slower to consolidate than the neck
Osteonecrosis of metacarpal head	Consider joint aspiration Avoid dissection of fragments during open repair

Fractures of the Thumb Metacarpal in Children

Thumb Metacarpal Fracture Classification

Fractures of the thumb metacarpal can occur at the epiphysis, physis, neck, shaft, or base. Fractures of the neck and shaft and their treatment principles are similar to those of the fingers

(Table 10-20). Thumb metacarpal base fractures that involve the physis or epiphysis require unique considerations (Fig. 10-62).

The adductor pollicis, abductor pollicis longus, and thenar muscles play a role in fracture mechanics and can displace metacarpal fractures. The muscles' directions of pull dictate the direction of fracture displacement and deformity. The adductor pollicis inserts onto the proximal phalanx and into the extensor apparatus through the adductor aponeurosis. Epiphyseal fractures of the proximal phalanx base with the attached UCL can displace outside the adductor aponeurosis.[191] This pediatric "Stener lesion" prohibits healing and requires open reduction. The abductor pollicis longus inserts onto the metacarpal base and is the primary deforming force in most fracture–dislocations about the thumb CMC joint (Bennett fractures or pediatric equivalents).

Direct trauma, rotational forces, and axial loading may all cause thumb metacarpal fractures. Sporting endeavors are the prime events causing fractures. A valgus force to the MCP joint usually produces an epiphyseal fracture. Skiing, biking, and playing baseball catcher are specific activities that place the thumb MCP joint and metacarpal shaft in a vulnerable position. Adduction forces, such as direct trauma to a soccer goalie

or basketball player during a fall or ball injury, place the thumb CMC joint and base of thumb metacarpal at risk.

Thumb Metacarpal Base Fractures

Fractures of the base of the thumb metacarpal are subdivided according to their location. Type A fractures occur between the physis and the junction of the proximal and middle thirds of the bone. The fractures are often transverse or slightly oblique. There is often an element of medial impaction, and the fracture is angulated in an apex lateral direction (Fig. 10-63).

Type B and C fractures are S-H II fractures at the thumb metacarpal base. Most patterns have the metaphyseal fragment on the medial side (type B) (Fig. 10-60). The shaft fragment is adducted by the pull of the adductor pollicis and shifted in a proximal direction by the pull of the abductor pollicis longus. Although this pattern resembles a Bennett fracture with respect to the deforming forces, there is no intra-articular extension.[13] Type C fractures are the least common and have the reverse pattern, with the metaphyseal fragment on the lateral side and the proximal shaft displacement in a medial direction. This pattern often results from more substantial trauma and does not lend itself to closed treatment.

A type D fracture is an S-H III or IV fracture that most closely resembles the adult Bennett fracture.[17,62,72,175] The deforming forces are similar to a type B injury with resultant adduction and proximal migration of the base-shaft fragment.

Biplanar x-rays including a hyperpronated view of the thumb accentuate the view of the CMC joint. Examination under live fluoroscopy or CT scan may also be necessary for preoperative planning and classification of fracture severity.

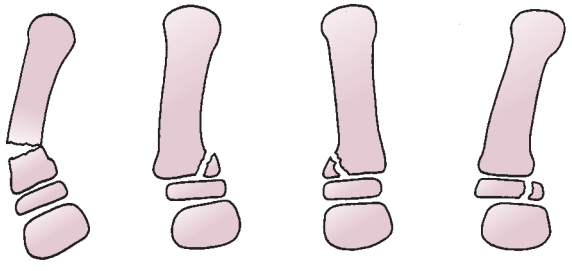

FIGURE 10-62 Classification of thumb metacarpal fractures. Type A: Metaphyseal fracture. Types B and C: S-H type II physeal fractures with lateral or medial angulation. Type D: an S-H type III fracture (pediatric Bennett fracture).

FIGURE 10-63 Metaphyseal thumb metacarpal fracture that does not involve the physis. Treatment consisted of closed reduction and cast immobilization.

Operative and Nonoperative Treatment Options of Thumb Metacarpal Fractures

Thumb Metacarpal Base Fractures

Type A. Type A fractures can usually be treated by closed methods. Although swelling about the thenar eminence limits manipulation of the fracture and diminishes the effectiveness of immobilization, most fractures can still be treated successfully by closed reduction and immobilization. Because the CMC joint has near universal motion and the physis is proximal in the metacarpal, remodeling is extensive in young patients. If reduction is attempted, pressure is applied to the apex of the fracture to effect reduction. Anatomic reduction is not required because remodeling is plentiful.[104,145] Unstable fractures with marked displacement require percutaneous pin fixation to maintain alignment (Fig. 10-64).

Types B and C. Closed reduction is more difficult for type B and C fractures. The mobility of the metacarpal base and the swelling make closed reduction difficult. Comminution, soft tissue interposition, or transperiosteal "buttonholing" in type C fractures may further complicate reduction.[215] If closed reduction is accomplished and stable, then short-arm thumb spica splint or cast

immobilization is possible. Repeat radiographic evaluation should be obtained 5 to 7 days later to ensure maintenance of reduction.[11]

If closed reduction is possible but the reduction is unstable, percutaneous pinning is recommended (Fig. 10-65). There are multiple options for pin configuration including direct fixation across the fracture, pinning across the reduced CMC joint, and pinning between the first and second metacarpals. Open reduction is indicated for irreducible fractures. Type C fractures may require open reduction to remove any interposed periosteum that blocks reduction (Fig. 10-66).[25,215]

Type D. Type D fractures are unstable and require closed or open reduction to restore physeal and articular alignment.[62,78] An acceptable closed reduction is maintained by percutaneous pin fixation. An unacceptable closed reduction is rare but requires open reduction and fixation.[175] A hyperpronated view of the thumb accentuates the view of the CMC joint. The choice of implant must be individualized, though smooth wires are favored to minimize potential injury to the physis and articular cartilage (Fig. 10-67).[72,175] Skeletal traction is an alternative treatment for complex injuries with severe bony or soft tissue damage.[23,186]

FIGURE 10-64 A 13-year-old boy fell down stairs and injured his right thumb. **A:** An AP radiograph shows displaced fracture base of the thumb metacarpal. **B:** Lateral radiograph shows considerable angulation. **C:** At time of reduction, fracture was very unstable. **D:** Closed reduction under fluoroscopy.

A B

FIGURE 10-65 **A:** An 8-year-old boy with reducible, but unstable, fracture. **B:** A single percutaneous pin was placed to maintain alignment.

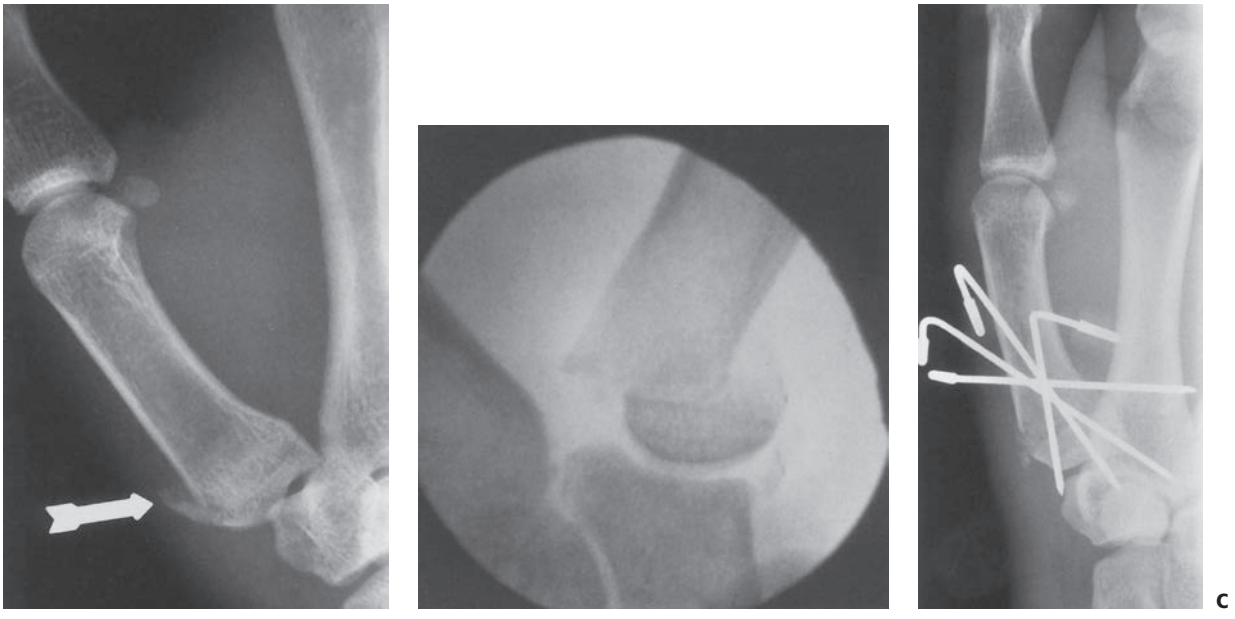
Author's Preferred Treatment

Type A

Type A fractures can usually be treated with closed reduction and cast application. Residual angulation between 20 and 30 degrees is acceptable depending on the age of the child and clinical appearance of the thumb. The multiplanar motion of the CMC joint combined with the potential for remodeling makes this degree of angulation inconsequential. Fractures that are reducible, but unstable, require percutaneous pinning (Fig. 10-64).

Types B and C

Treatment varies with the amount of displacement and degree of periosteal disruption. Mild angulation requires only cast application without reduction. Moderate angulation is treated with closed reduction and immobilization. Severe angulation is usually combined with displacement and requires reduction. A successful closed reduction is often augmented with percutaneous pin fixation because of the fracture instability. An unsuccessful closed reduction requires open reduction and fixation.



A, B C

FIGURE 10-66 **A:** Fracture of the thumb metacarpal base with small lateral metaphyseal flag that appears innocuous on radiograph (*arrow*). **B:** However, additional images revealed marked displacement of the distal fragment. **C:** Closed reduction was unsuccessful, because of interposed tissue. After open reduction, K-wires were used to stabilize the fracture.

FIGURE 10-67 **A:** A 14-year-old boy sustained an S-H type III fracture of the proximal thumb metacarpal with lateral subluxation of the carpometacarpal joint. **B:** Open reduction and K-wire fixation to restore joint alignment and congruity. (Reprinted from O'Brien ET. Fractures of the hand. In: Green DP, ed. *Operative Hand Surgery*. 2nd ed. New York, NY: Churchill Livingstone; 1988:769, with permission.)

Type D

Displaced S-H III and IV fractures are rare and require closed or open reduction and internal fixation. The goal is anatomic alignment of the joint and physis. If an open reduction is required, the preferred approach is through a gently curved incision overlying the CMC joint along the glabrous border of the skin. The cutaneous nerves are protected. The origins of the thenar eminence muscles are reflected. A CMC joint arthrotomy is made, and the articular surface is exposed. The fracture joint surface is reduced and fixed with pins or miniscrews. Additional percutaneous pin fixation of the first to the second metacarpal is used to protect the fracture fixation.

Postoperative Care

Closed treatment requires immobilization for 4 to 6 weeks, depending on the fracture severity and degree of soft tissue damage. A home program for range of motion is started thereafter. Formal therapy is not instituted unless considerable soft tissue injury occurred. In active children and young athletes, a light splint may be worn for protection for an additional few weeks.

Open fracture management depends on the stability of the fixation and the reliability of the patient. Young children or marginal fracture fixations require 4 to 6 weeks of immobilization. Fracture union with mild stiffness takes precedence over fracture nonunion with excessive motion. Adolescents with stable fixation can be mobilized earlier, usually 5 to 7 days after surgery, provided they are trustworthy in terms of activity restrictions. A removable splint is used for protection between exercise sessions until union.

Management of Expected Adverse Outcomes and Unexpected Complications

Thumb metacarpal fractures usually heal without altering hand function. The remodeling capabilities of fractures near or involving the physis are extensive. The basilar thumb joint also allows multiplanar motion and can accommodate moderate fracture malunion. Residual deformity along the thumb metacarpal can be concealed through CMC joint motion, and the thumb tolerates malrotation better than the fingers (Fig. 10-68).

Complications are uncommon. Nonunion, malunion, and articular incongruity are potential problems.[78] Intra-articular incongruity may occur after incomplete reduction of intra-articular fractures or inadequate fixation after satisfactory reduction. Sequelae include pain, diminished motion, and arthrosis. Fortunately, the occurrence of articular malunion and the development of symptoms are uncommon. Available treatment options are limited and include intra-articular osteotomy, fusion, or interposition arthroplasty.

Fractures of the Carpal Bones

Scaphoid Fractures in Children

The low incidence of scaphoid fracture in children is most likely related to the thick peripheral cartilage that covers and protects the ossification center. Therefore, fracture requires a considerable force to disrupt this cartilaginous shell and injure the underlying bone.[42] The pattern of pediatric scaphoid injury differs from that of adults because of the evolving ossification center.[53] During early stages of ossification, the scaphoid is more susceptible to avulsion fractures about the distal pole fracture.[188,203] As the ossification progresses from distal to proximal, the fracture pattern mirrors the adult forms by early adolescence (Fig. 10-69).

In children, fractures of the distal third of the scaphoid have traditionally been the most common injury pattern and often result from direct trauma.[16,42,203] However, scaphoid waist fractures are increasing in frequency in younger children as participation in contact athletics begins earlier.[65] Proximal pole fractures are rare in children and often represent an avulsion fracture of the scapholunate ligament. These fractures are at higher risk for nonunion and osteonecrosis. The scaphoid can also be fractured as a component of a greater arc perilunate injury.[53]

Scaphoid Fracture Patterns and Classification (Table 10-21)

Type A: Fractures of the Distal Pole

Distal pole fractures are often secondary to direct trauma or avulsion with a dorsoradial or dorsovolar fragment.[203] The

TABLE 10-21 Classification of Scaphoid Fractures

Fractures of the Distal Pole
Extra-articular distal pole fractures

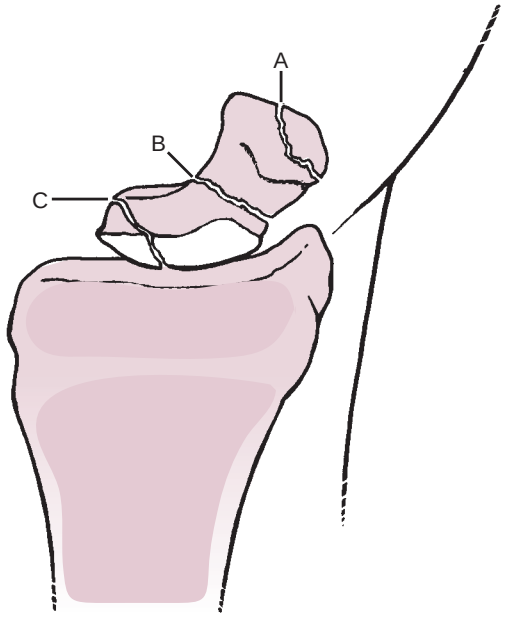

FIGURE 10-69 Three types of scaphoid fractures. **A:** Distal third. **B:** Middle third. **C:** Proximal pole.

strong scaphotrapezial ligaments and capsular attachments produce mechanical failure through the bone (Fig. 10-70).[33,203] The fracture line and size of the avulsion fragment vary from an isolated chondral injury that is barely visible on radiographs to a large osteochondral fragment.

Type A1: Extra-Articular Distal Pole Fractures. The most important prognostic factor is the presence or absence of joint involvement. Extra-articular fractures may be either volar or dorsal avulsions (Fig. 10-71). A volar pattern is more common and is attributed to the stout scaphotrapezial ligaments. A dorsal fracture configuration is less common and is attributed to the dorsal intercarpal ligament. The fragments vary in size, and the radiographic appearance is age dependent.

Type A2: Intra-Articular Distal Pole Fractures. This type of fracture may be a variation of a type A1 fracture with an intra-articular extension (Fig. 10-72). Similar types (i.e., volar and dorsal) and mechanisms of injury are possible.

Type B: Middle Third (Waist Fractures)

Middle third fractures do occur in skeletally immature patients. The mechanism of injury is usually a fall onto the outstretched hand and pronated forearm, which exerts tensile forces acting across the volar portion of the scaphoid as the wrist extends.[32,53,211] Bony comminution may be present (Fig. 10-73). A careful scrutiny for other injuries about the carpus is mandatory.[3,30]

Dividing the bone into thirds or delineating the area bounded by the radioscaphocapitate ligament defines the waist of the scaphoid. Waist fractures occur in many forms. Pediatric fractures are incomplete, minimally displaced, or complete with or without displacement. Comminuted fractures are rare and are associated with higher-energy injuries.

FIGURE 10-70 A 12-year-old boy fell on his right wrist and was tender over scaphoid tubercle. Radiograph reveals small avulsion fracture of distal scaphoid that might easily be overlooked. (Courtesy of Shriners Hospitals for Children, Philadelphia, PA.)

Type C: Proximal Third

Proximal pole fractures are rare in children but have been reported in competitive adolescent athletes. The mechanism is often unclear and can be atypical, such as punching game machines or fighting.[201] A proximal pole fracture may propagate through the interface between newly ossified tissue and the cartilaginous anlage, or the injury may be strictly through the cartilage. Proximal fractures may cause destabilization of the scapholunate joint, as the scapholunate interosseous ligament remains attached to the avulsed fragment (Fig. 10-74).

Proximal third fractures present diagnostic and therapeutic dilemmas. The proximal pole is the last to ossify, which further complicates diagnosis. The tenuous blood supply of this region presents the same problems in children as adults in terms of nonunion and risks of osteonecrosis.

Bipartite Scaphoid Controversy: Traumatic Versus Developmental

A bipartite scaphoid probably exists but is uncommon and may be associated with Down syndrome [48,116] Criteria that must

FIGURE 10-71 A 12-year-old boy fell playing ice hockey and complained of right wrist pain. Radiograph reveals an extra-articular distal pole scaphoid fracture with slight comminution. (Courtesy of Shriners Hospitals for Children, Philadelphia, PA.)

be met to diagnose a congenital bipartite scaphoid include the following: (a) Similar bilateral appearance, (b) absence of historical or clinical evidence of antecedent trauma, (c) equal size and uniform density of each component, (d) absence of degenerative change between the scaphoid components or elsewhere in the carpus, and (e) smooth, rounded architecture of each scaphoid component. A unilateral "bipartite scaphoid" should be viewed as a posttraumatic scaphoid nonunion (Fig. 10-75).

Capitate Fractures

Isolated fractures of the capitate are rare and usually result from high-energy trauma.[111] Capitate fractures may represent a form of greater arc perilunar injury (Fig. 10-76). The force can propagate completely around the lunate and cause a perilunate or lunate dislocation.[30,34,151] The injury can also halt within the capitate and produce a scaphocapitate syndrome.[6,205]

Excessive dorsiflexion of the wrist is the most common mechanism. The waist of the capitate abuts the lunate or dorsal aspect of the radius. The fracture occurs through the waist with variable displacement. The wrist is usually markedly swollen and painful to palpation. The clinical presentation varies with the associated carpal injuries. Median nerve paresthesias may be present secondary to swelling within the carpal tunnel.

Standard AP and lateral views are usually adequate (Fig. 10-77). Careful scrutiny of the radiographs is necessary. The capitate fracture can be subtle, or the proximal capitate fragment can rotate 180 degrees. Either scenario can create a confusing image that often results in misinterpretation. Incomplete ossification further complicates radiographic diagnosis

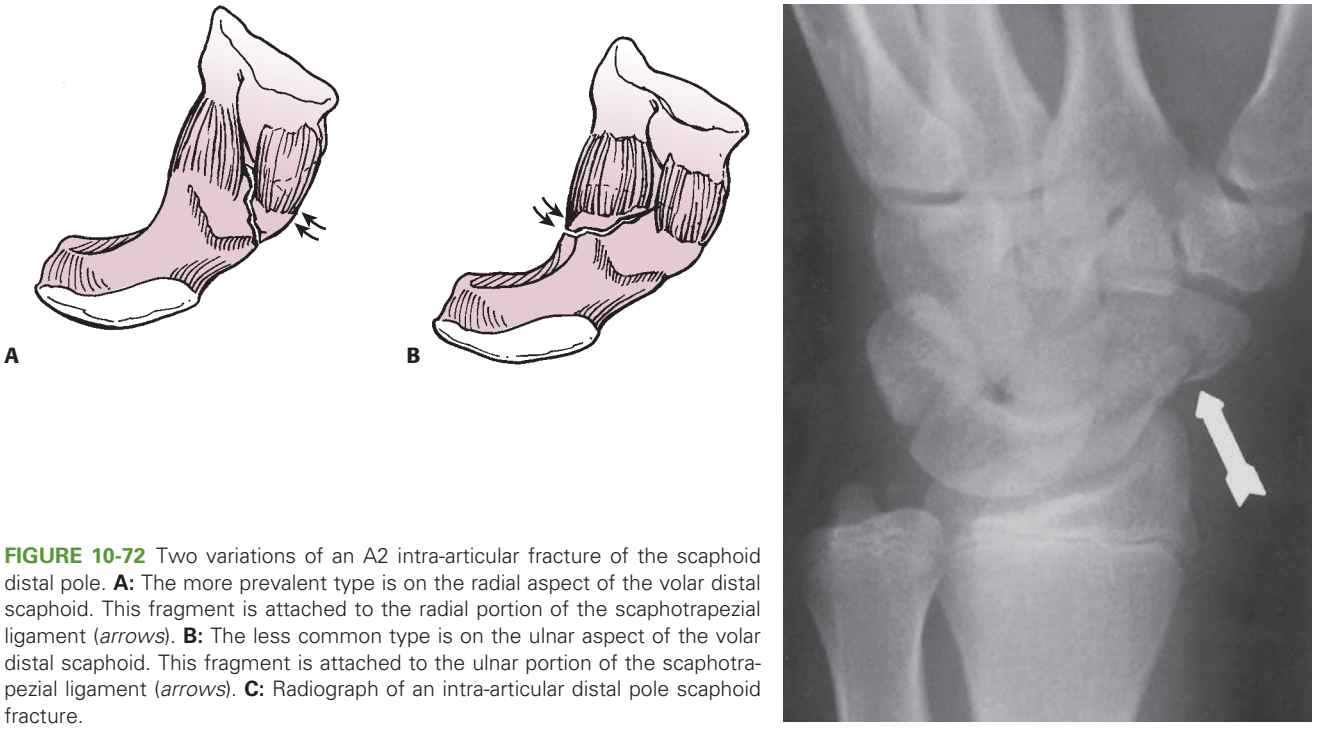

FIGURE 10-72 Two variations of an A2 intra-articular fracture of the scaphoid distal pole. **A:** The more prevalent type is on the radial aspect of the volar distal scaphoid. This fragment is attached to the radial portion of the scaphotrapezial ligament (*arrows*). **B:** The less common type is on the ulnar aspect of the volar distal scaphoid. This fragment is attached to the ulnar portion of the scaphotrapezial ligament (*arrows*). **C:** Radiograph of an intra-articular distal pole scaphoid fracture.

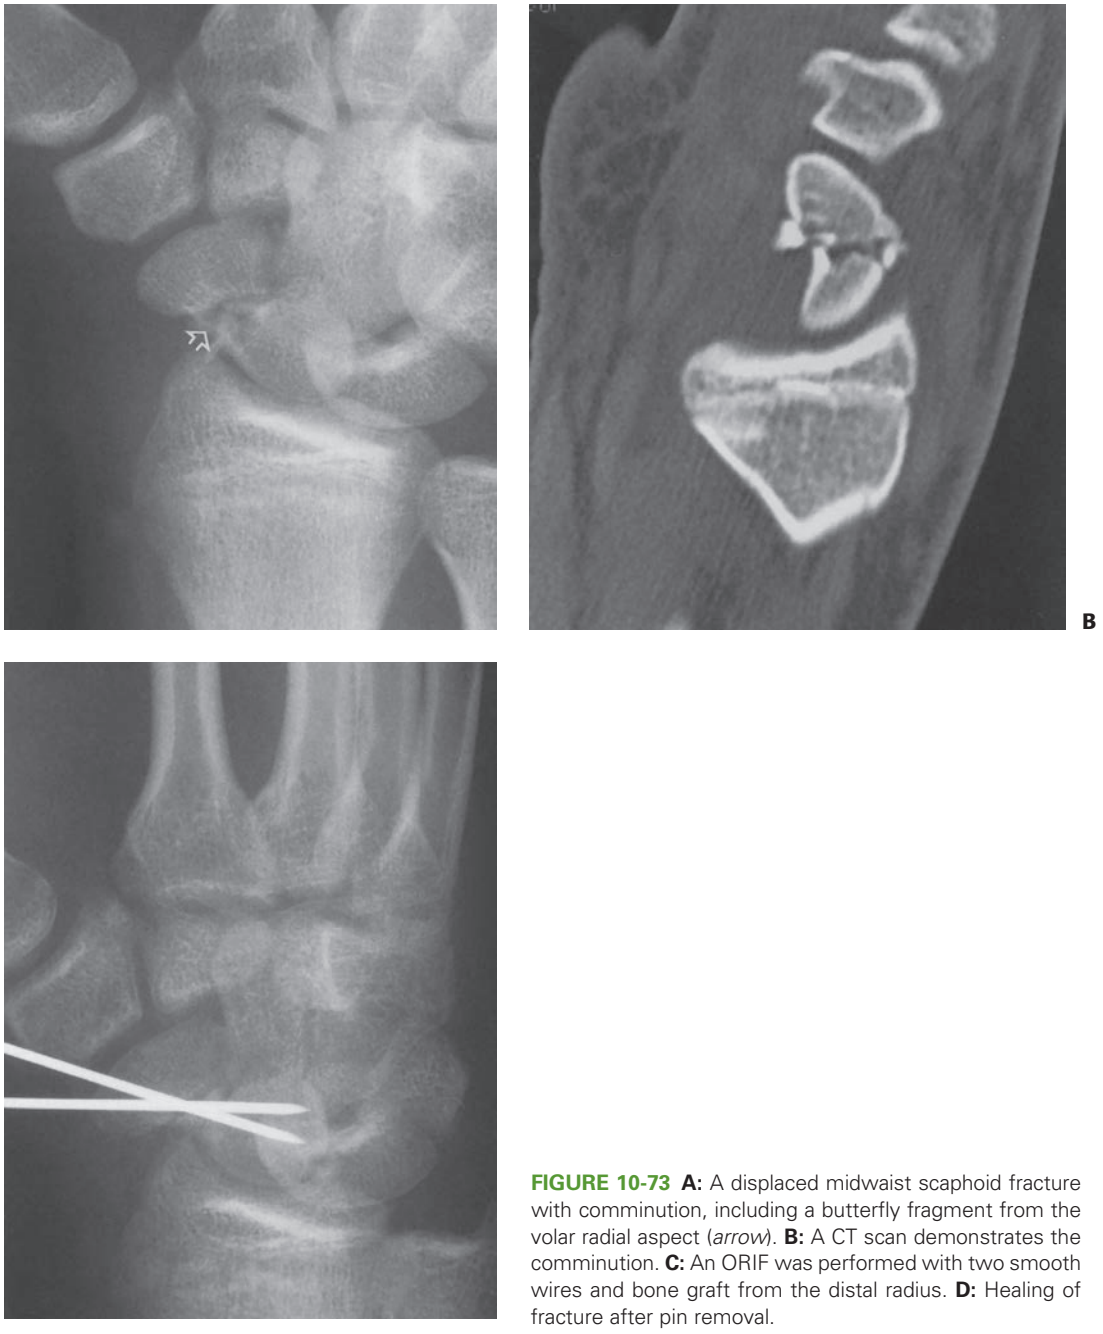

FIGURE 10-73 **A:** A displaced midwaist scaphoid fracture with comminution, including a butterfly fragment from the volar radial aspect (*arrow*). **B:** A CT scan demonstrates the comminution. **C:** An ORIF was performed with two smooth wires and bone graft from the distal radius. **D:** Healing of fracture after pin removal.

and degree of displacement. Small osteochondral fragments in the midcarpal region may indicate a greater arc injury or isolated capitate fracture. In these cases, advanced imaging studies, such as MRI or CT, may be useful (Fig. 10-78).

Triquetrum Fractures

Avulsion fractures of the triquetrum are more common in adults than in children. The injury may occur in adolescents as carpal ossification nears completion. A fracture through the body of the triquetrum is rare and may occur with a perilunar injury as the path of the greater arc injury passes through the triquetrum.[125] A fall on an outstretched wrist is the common event. The probable mechanism for a dorsal triquetrum fracture is a pulling force through the dorsal ligaments or abutment of the ulnar styloid.

The wrist is mildly swollen and painful to palpation directly over the dorsal triquetrum. The clinical presentation is more severe with associated carpal injuries.

Radiographic Findings

Radiologic AP and lateral views may not show the avulsion fracture. A pronated oblique view highlights the dorsum of the

FIGURE 10-74 An AP radiograph of a 16-year-old male hockey player with a proximal one-third scaphoid fracture. (Courtesy of Shriners Hospitals for Children, Philadelphia, PA.)

triquetrum and may reveal the avulsed fragment. At times, CT scans are necessary for accurate diagnosis (Fig. 10-79).

Hamate, Pisiform, Lunate, and Trapezium Fractures

Pediatric fractures of the hamate, pisiform, lunate, and trapezium are rare. Hamate fractures are classified by their location in the hook, type 1, or in the body, type 2. Hook of the hamate fractures usually occur in adults but may occur in adolescents who play baseball or golf or sustain traumatic falls. If the fracture involved the distal third of the hook, it may occur from an avulsion injury. A CT scan may be necessary for diagnosis if the fracture is not visible on the carpal tunnel view (Fig. 10-80). Dorsal or body hamate fractures can occur with axial load or punching injuries, as the bases of the fourth and fifth metacarpals act like pistons and shear off large or small pieces of the hamate.

Pisiform fractures are the result of direct trauma. Lunate fractures are associated with Kienbock disease,[160] which is relatively uncommon in children. Trapezium fractures can occur with CMC joint injuries about the thumb.

Soft Tissue Injuries about the Carpus

Ligamentous Injuries

Ligamentous injuries about the pediatric wrist are less common than osseous injuries.[64,66,151] The immature carpus and viscoelastic ligaments are relatively resistant to injury. Fracture–dislocations and isolated ligamentous injuries are usually caused by high-energy trauma (Fig. 10-81).[90] Motor vehicle

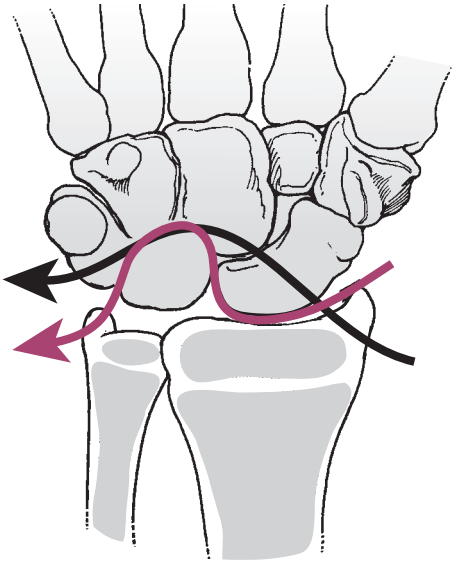

FIGURE 10-76 Progressive perilunar instability. The greater arc (*black arrow*) is associated with fractures of the carpal bones, which may include the scaphoid, lunate, capitate, hamate, and triquetrum. The *red arrow* depicts the lesser arc, in which forces are transmitted only through soft tissue structures. (Reprinted from Mayfield JK, Johnson RP, Kilcoyn RK. Carpal dislocations: Pathomechanics and progressive perilunar instability. *J Hand Surg Am.* 1980;5:226–241, with permission.)

FIGURE 10-77 A 12-year-old boy sustained multiple carpal fractures attributed to a crushing injury. An established nonunion of the capitate is present 16 months later, which required bone grafting to obtain union. (Courtesy of James H. Dobyns, MD.)

accidents and sports-related injuries are potential causes of the rare fracture–dislocation. However, recurrent or chronic wrist pain is not uncommon in adolescents. Most recurrent ligamentous pain results from hypermobility and overuse during the adolescent growth spurt. This mechanism may result in joint subluxation, chondral impingement, or ligamentous tears similar to patellofemoral injuries in adolescents.

A child with an acute traumatic injury avoids use of the wrist and hand. The wrist is swollen and painful to palpation, making

FIGURE 10-78 A 13-year-old boy with persistent midcarpal pain after a fall. An MRI scan shows a capitate fracture. (Courtesy of Shriners Hospitals for Children, Philadelphia, PA.)

FIGURE 10-79 A minimally displaced dorsal triquetral avulsion fracture (*arrow*) that was treated with short-term immobilization.

isolation of the injured segment difficult except in extremely cooperative children. Provocative maneuvers for carpal instability usually are not possible because of pain in the injured wrist.

Gross instability without pain on stress testing may indicate a hyperelasticity syndrome that is not related to trauma.[152] However, recurrent pain does occur in children with hypermobility, overuse, and relative muscular weakness. These children complain of diffuse pain, generalized tenderness, and limited strength on examination. Diagnosis is difficult particularly because of concerns regarding emotional overlay and somatization.

Radiologic AP and lateral views are routine. The incomplete ossification complicates radiographic interpretation, especially the assessment of carpal widening. Detection of slight widening or malalignment within the carpus is often difficult. Contralateral views are useful to compare ossification and carpal spacing.[98] Suspicion of a fracture warrants advanced imaging studies, such as arthrography, stress radiograph, fluoroscopy, and MRI. Ligamentous injuries are diagnosed with MRI scans.

Outcomes

As with the pediatric hand fractures, outcomes consist of union, alignment, and painless return to function and sports. Because of the vascular anatomy of the carpus, avascular necrosis is a rare but complicated outcome in proximal pole scaphoid fractures. Case series of children after carpal bone fractures and dislocations lack validated instrument scoring data.

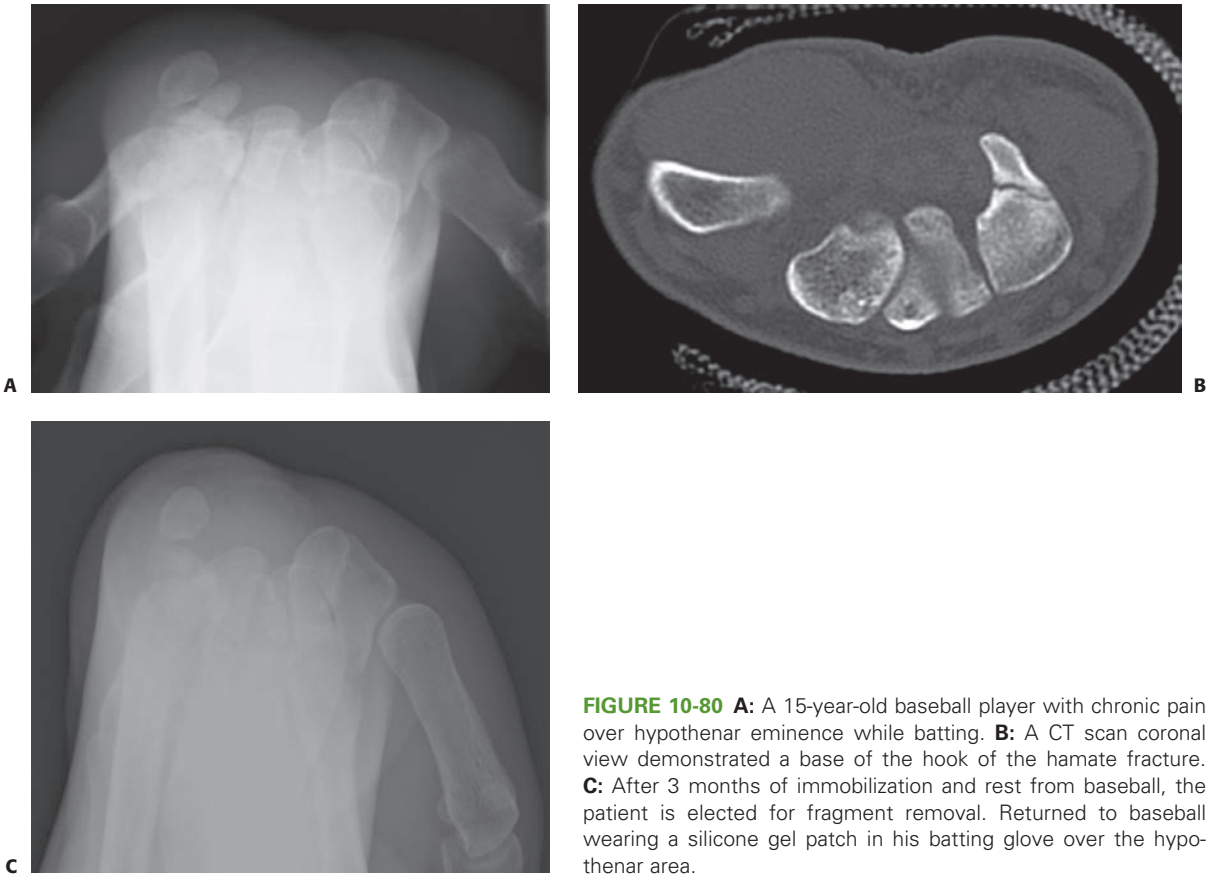

FIGURE 10-80 **A:** A 15-year-old baseball player with chronic pain over hypothenar eminence while batting. **B:** A CT scan coronal view demonstrated a base of the hook of the hamate fracture. **C:** After 3 months of immobilization and rest from baseball, the patient is elected for fragment removal. Fractures of the Carpal Bones Treatment Options (Table 10-22)

Scaphoid Fractures

Nondisplaced Scaphoid Fractures

Normal radiographs do not preclude the presence of a scaphoid fracture. Clinical suspicion in the presence of normal radiographs warrants immobilization and reevaluation in 2 weeks.[30] The cast is removed, the wrist is examined, and repeat radiographs are obtained. Pain resolution and negative radiographs warrant discontinuation of immobilization and return to normal activities. Persistent pain with normal radiographs requires continued immobilization and advanced imaging studies. In this clinical setting, MRI scans have been shown to be diagnostically useful to avoid both misdiagnosis and overtreatment (Fig. 10-82).[22,35,49,96,118] However, MRI may be overly sensitive in identifying bone edema that fails to develop into a fracture.

If radiographs reveal a fracture, immediate treatment is required. Most pediatric scaphoid fractures can be treated with cast immobilization because children possess a great ability to heal. In addition, most scaphoid fractures in children are either incomplete (disrupting only a single cortex) or nondisplaced. This principle is especially true for the distal pole, which is a frequent site of scaphoid fracture (Fig. 10-83).[53] Therefore, cast immobilization is the standard of treatment for most nondisplaced or minimally displaced pediatric scaphoid fractures. For avulsion and incomplete fractures, a short-arm thumb spica cast for 4 to 6 weeks is recommended. In the young child, a long-arm cast is appropriate to prevent the cast from sliding off the arm. For complete distal third and waist fractures, immobilization consisting of up to 6 to 8 weeks of casting is recommended until healing.

A longer period of immobilization (8 to 12 weeks) is recommended for proximal pole fractures, delayed diagnosis, or fractures with apparent bony resorption.[53] Immobilization usually begins with 4 to 6 weeks of a long-arm thumb spica cast, followed by up to 6 weeks of a short-arm thumb spica cast. The exact cast position and the joints immobilized are a matter of individual preference.[24,63,83] Most authors favor a long-arm thumb spica cast that permits thumb interphalangeal joint motion.[63]

TABLE 10-22 Fractures and Dislocations of the Hand and Carpal Bones

Nonoperative vs. Operative Treatment

Nonoperative	Operative
Nondisplaced	Displaced
Avulsion fractures	High risk of avascular necrosis or nonunion

Displaced Scaphoid Fractures

Closed Reduction and Casting. Historically, closed reduction of a displaced scaphoid fracture has been described.[24,83] Currently, ORIF is a more reliable method for restoring alignment and obtaining union.

Percutaneous Screw Fixation. In adults, percutaneous screw fixation for displaced fractures has been advocated.[1,219] However, the fracture must be reduced at the time of screw fixation. Fracture reduction can be accomplished with manipulation, joysticks, or arthroscopic assistance. This technique can be applied to adolescent patients with displaced scaphoid

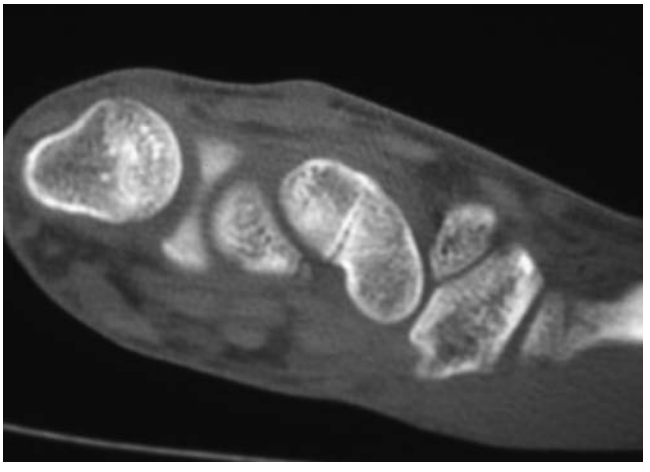

FIGURE 10-82 An MRI scan of a minimally displaced healing scaphoid fracture not seen on radiograph.

FIGURE 10-83 A 12-year-old boy depicted in Figure 10-69 after 8 weeks of casting. **A:** Scaphoid view demonstrates healing of the fracture. **B:** Pronated oblique radiograph further confirms fracture union. (Courtesy of Shriners Hospitals for Children, Philadelphia, PA.)

fractures. Screws can be placed under fluoroscopic control either volarly (distal to proximal) or dorsally (proximal to distal) depending on fracture patterns and surgeon preference (Fig. 10-84).[20,183] This procedure is challenging in displaced scaphoid fractures.

Open Reduction and Internal Fixation. Displacement of more than 1 mm or intrascaphoid angulation of more than 10 degrees on any image warrants ORIF. The implant choice is individualized according to the fracture and patient. Scaphoid screws are the primary fixation techniques, though K-wires can be used (Fig. 10-85).[131]

Smaller screws (mini and micro) may be necessary in the pediatric patient. Modern compression screws have been shown to speed healing.[65]

Capitate Fractures

Treatment depends on the capitate fracture pattern, degree of displacement, and associated injuries. Distraction radiographs, MRI, or CT scans may be necessary to determine the exact pattern of injury. Nondisplaced fractures of the capitate and/or scaphoid can be treated with a long-arm cast for 6 to 8 weeks. Closed reduction of displaced fractures is not

FIGURE 10-84 **A:** Nondisplaced proximal pole scaphoid fracture in a skeletally mature adolescent athlete. **B:** Treatment by percutaneous screw fixation led to healing.

feasible.[34] Displaced fractures require open reduction, especially the rotated proximal capitate pole. Associated perilunar injuries also require internal fixation and ligamentous repair. The anatomic relationships within the carpus must be restored. Wire or osseous screw fixation is appropriate stabilization after open reduction of fractures. Suture repair of ligamentous injuries is performed.

Triquetral Fractures

An avulsion fracture is treated with a short period of immobilization (3 to 6 weeks) followed by motion and return to activities. A fracture through the body of the triquetrum with a perilunar injury requires ORIF.

Hamate Fractures

Hook of the hamate, type 1, fractures are often missed in the acute setting unless a carpal tunnel view is ordered or a CT scan of the wrist obtained. Immobilization and avoidance of baseball batting, gymnastics, or golf may lead to complete union in children. After a period of casting, if imaging is consistent with a delayed union and the child is symptomatic, surgical ORIF or simple fragment excision may be pursued (Fig. 10-80). Careful protection of the ulnar nerve motor branch and ulnar artery anatomy is required, and subperiosteal dissection can minimize chances of injury. Postoperative return to sports that require direct pressure on the hypothenar eminence may be slow because of the hypersensitivity and require special silicone patches or glove padding.

Dorsal body hamate, type 2, fractures may be part of a CMC dislocation or isolated. Reduction of the dislocation may be assisted by fixation of the hamate fracture. If the fragment is large enough, ORIF with a headless screw may be indicated (Fig. 10-86).

Carpal Ligamentous Injury

General treatment recommendations for rare traumatic dislocation injuries are difficult. Decisive factors include the child's age, degree of clinical suspicion, and extent of injury. Minor injuries are treated with immobilization for 3 to 6 weeks and reexamination. Resolution of symptoms and signs allows return to normal activities. Persistent pain warrants

further clinical and radiographic evaluation. Overt ligamentous injuries with static instability and malalignment require accurate diagnosis and appropriate treatment. A complete ligament tear (e.g., an adolescent with a scapholunate injury) is treated according to principles similar to those for adults. Open reduction, anatomic reduction, and ligament repair are the basic tenets of treatment.

A child or adolescent with ligamentous laxity and persistent activity-related pain is especially difficult to treat. Discerning focal from nonfocal wrist pathology is imperative. Radiographs and MRI scans often are normal. Most of these children respond to therapeutic strengthening. Protective sports-specific wrist guards or taping may be appropriate (Fig. 10-87). A small subset of children have unresolved pain caused by chondral injuries or ligamentous tears that require arthroscopic treatment.[51]

Preoperative Planning (Table 10-23)

TABLE 10-23 Fractures of the Scaphoid

Preoperative Planning Checklist

- OR table: Hand table, radiolucent preferable
- Position/positioning aids: May consider wrist arthroscopy and completion of surgery on the tower with arthroscopic assistance
- Fluoroscopy location: Horizontal for dorsally placed screws, vertical for *volarly placed screws or screws placed on the distal pole*
- Equipment: Headless conical or compression screw, may require a miniversion if the child is smaller than adult size. Use x-ray of contralateral scaphoid to estimate length of screw
- Tourniquet (sterile/nonsterile): Nonsterile

Surgical Technique (Table 10-24)

TABLE 10-24 Orif of Fractures of the Scaphoid in Children

Surgical Steps

- Dorsal approach: Flex the wrist to identify screw starting point on the scaphoid, adjacent to scapholunate ligament. Aim guide wire down the thumb axis.

Small incision and spread soft tissue with a snap or tenotomy to avoid dorsal radial sensory nerve and extensor pollicis longus during pin or screw placement.

- Volar approach: Hockey stick incision over flexor carpi radialis and scaphoid tubercle. Open sheath of flexor carpi radialis, protect radial artery, incision between the long radial scaphoid ligament and ligament. Expose fracture and clear of fibrous debris or loose fragments. Place pins or screws volar to dorsal. Aim guide wire toward Lister's tubercle.

Joysticks: In fractures with substantial *dorsal intercalated segmental instability,* consider reducing the lunate and the transradius lunate pinning with K-wire to hold the lunate and the proximal pole in neutral during fixation. Remove after fixation completed.

Author's Preferred Treatment

Immobilization of nondisplaced carpal bone fractures or suspected injuries without x-ray findings is the most common preferred treatment. The type of immobilization varies from patient to patient. Options range from long- or short-arm casts, with or without thumb spicas or ulnar gutter extensions, to removable splints. Because children and adolescents are rarely compliant, we tend to err on the side of more immobilization. Early use of MRI to diagnose and follow outcomes in children with carpal bone injuries can be helpful in children with mostly cartilaginous carpal bones.[144]

Scaphoid Fractures

Almost all nondisplaced scaphoid fractures are treated with cast immobilization.

For nondisplaced fractures, the preferred immobilization is a long-arm thumb spica cast for the initial 4 to 6 weeks, followed by a short-arm cast until clinical and radiographic union. Radiographs are obtained in the first 7 to 10 days to ensure

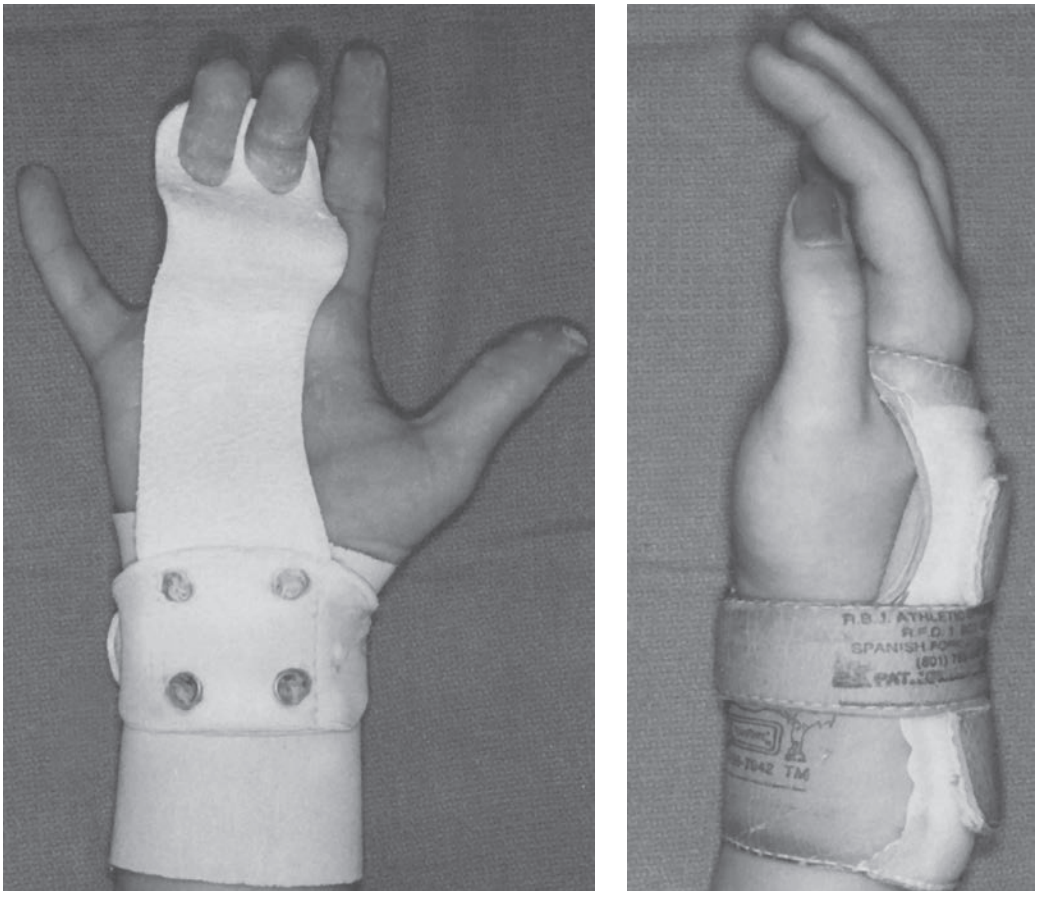

FIGURE 10-87 Wrist guards for gymnastics. **A:** The "lion's paw" protector used mainly for the vault. **B:** Hand and wrist protectors used primarily for the uneven parallel bars.

alignment and then monthly until union. If in doubt regarding anatomic alignment or union, a CT scan is obtained.

Proximal pole fractures are at high risk for osteonecrosis and nonunion. These injuries are unstable with motion because of the scapholunate ligament. Percutaneous or mini-open screw fixation stabilizes the fracture without further disruption of the precarious blood supply by operative exposure. Although technically challenging, percutaneous screw fixation of these fractures with protected immobilization until sufficient healing may lessen the risk of osteonecrosis, nonunion, and degenerative changes.

Indications for open reduction and fracture fixation are a waist fracture with more than 1 mm of displacement or an angular deformity of more than 10 degrees. Trans-scaphoid perilunate injuries also require operative management. Fractures of the middle and distal thirds are exposed through a volar approach. Proximal third fractures are exposed through a dorsal approach.[163] The implant depends on the fracture configuration and age of the child. Smooth wires may be necessary in young children. Wires are buried beneath the skin and removed after union. Scaphoid screw fixation is preferred in adolescents.[65,88,89,133,138] Comminution is treated with bone graft obtained from the ipsilateral metaphysis of the distal radius, olecranon, or iliac crest.

Postoperative Care and Rehabilitation

Nondisplaced fractures are treated with immobilization until union. After the cast is removed, a home therapy program is started. Formal therapy usually is not necessary. Displaced fractures treated with ORIF require variable periods of immobilization. Fixation with K-wires necessitates prolonged immobilization and may involve formal therapy for the recovery of motion. Stable screw fixation allows early motion 10 to 14 days after surgery with a short-arm thumb spica splint worn for protection during vigorous activity until union. However, many adolescents will not wear the splint dependably and require longer periods of nonremovable immobilization to prevent loss of screw fixation and nonunion.

Prognosis of Scaphoid Fractures

Prompt treatment of a nondisplaced scaphoid fracture allows healing in most patients.[30] Nondisplaced pediatric scaphoid fractures have a greater than 95% healing rate. A delay in treatment impedes healing and increases the possibility of displacement.[76,175,203] Displaced fractures require prompt recognition and open reduction because adequate reduction and fixation result in predictable union.[65]

Prognosis and Complications of Capitate Fractures

The rarity of this injury prevents broad generalizations. Early recognition and appropriate treatment lead to an acceptable outcome. Nonunion is rare and requires bone grafting (Fig. 10-76).[130] Despite the considerable rotation of the proximal pole in displaced fractures, osteonecrosis of the capitate is rare.

Prognosis and Complications of Triquetral Fractures

Avulsion fractures are relatively minor injuries. Treatment results in expedient and complete recovery. Body fractures associated with perilunate injuries have a guarded prognosis, depending on the extent of concomitant injuries and necessary treatment.

Potential Pitfalls and Preventive Measures (Table 10-25)

TABLE 10-25 Fractures of Carpal Bones in Children

Potential Pitfalls and Preventions

Pitfalls	Preventions
Nonunion	Early diagnosis and treatment Long-arm thumb spica nonremovable immobilization Identify displaced fractures
Malunion	Early recognition of lunate extension and dorsal intercalated segmental instability (DISI) deformity Three-dimensional advanced imaging, such as CT scan
Avascular necrosis	Early treatment of high-risk fractures, such as proximal pole of the scaphoid Knowledge of the vascular supply to each carpal bone to avoid injury during dissection
Intercarpal instability	Static and dynamic examination of entire wrist to identify greater or lesser arc injuries

Management of Expected Adverse Outcomes and Unexpected Complications

Complications of Scaphoid Fractures

The most prevalent complications are missed diagnosis and late presentation.[65] Scaphoid nonunions do occur in children, though the incidence is low.[30,45,56,115,124,146,185] Late presentation occurs for a number of reasons, including children's reluctance to tell their parents about a mechanism of injury, moderate symptoms seemingly not severe enough to warrant medical attention, and a child's fear of losing his or her position on a sporting team.[91] Open reduction, bone grafting, and internal fixation are the standard procedures for treatment of scaphoid nonunions (Fig. 10-88).[56,91,133,201] The approach varies according to the location of fracture and vascularity of the fracture fragments. The principles of operative scaphoid nonunion treatment in children are similar to those in adults. Persistent scaphoid nonunion results in altered kinematics within the wrist and produces degenerative changes over time.[117,210] The goal is to obtain union to prevent long-term arthrosis.

The long-term outcomes of treatment of nonunions of the scaphoid have been reported following treatment using both screws and K-wires. Masquijo and Willis reviewed 23 children, mean age 15.1 years old with scaphoid nonunions after bone grafting and fixation with a follow-up over 5 years. Scaphoid Outcome Scores were excellent in 66% and good in 33%.[122] Reigstad et al.[162] most recently reported 7-year outcomes in 11 adolescents with scaphoid waist nonunions treated with bone graft and K-wire fixation only. Range of motion, grip strength, key pinch strength, and subjective outcome scores were all excellent. No evidence of persistent nonunion or degenerative changes was evident on radiographs or from CT evaluation.

Osteonecrosis may result from a scaphoid fracture. The proximal fragment is more prone to avascular changes. Avascular changes within the proximal fragment do not preclude union after internal fixation. The size of the fragment and the extent of avascularity dictate management. The treatment principles are similar in adults and children. Options to obtain union include conventional or vascularized bone grafting.[208] With nonunion and osteonecrosis of the proximal pole, vascularized bone grafting from the distal radius has been successful.[190,208]

Triangular Fibrocartilage Complex Tears in Children

Triangular Fibrocartilage Complex Tear Classification

The TFCC consists of the triangular fibrocartilage (TFC) and the volar ulnocarpal ligaments. The TFC spans the sigmoid notch of the radius to the fovea at the base of the ulnar styloid and provides stability to the distal radioulnar and ulnocarpal joints. The location of the tear determines the classification of TFCC tears.[198] Peripheral tears (type B) are most common in adolescents. Tears from the radial insertion (type D) are next in frequency, whereas central (type A) and volar (type C) tears are rare.[147,149]

Triangular Fibrocartilage Complex Tear Treatment

The initial approach to adolescents with chronic wrist pain without instability incorporates rest until symptoms subside followed by a strengthening program. If pain persists after regaining symmetric pinch and grip strength, then further evaluation is appropriate. If clinical examination is consistent with a TFCC tear or ulnar–carpal impaction, MRI and/or arthroscopy is appropriate. A partial TFCC tear or carpal chondromalacia is treated with arthroscopic debridement. Full thickness tears from the fovea (type 1B) require peripheral repair, usually arthroscopically, to restore stability. Tears from the radial insertion (type 1D) with instability are rarer but require a transradial repair.

Dislocations of the Hand and Carpus

Dislocations of the Interphalangeal Joints

In children, the soft tissue stabilizers about the interphalangeal joints are stronger than the physis, which explains the propensity for fracture rather than dislocation. Occasionally, dislocations and fracture–dislocations occur about the interphalangeal and MCP joints, especially in adolescents (Fig. 10-89).

Distal Interphalangeal Joint

A hyperextension or lateral force may result in dorsal or lateral DIP joint dislocation. The collateral ligaments and volar plate typically detach from the middle phalanx. Most dislocations can be reduced by longitudinal traction, re-creation of the dislocation force, and reduction of the distal phalanx. The DIP joint reduction and congruity are confirmed by clinical motion and radiographs. Splinting of DIP joint for 2 to 3 weeks is sufficient, followed by a home program that focuses on DIP joint motion.

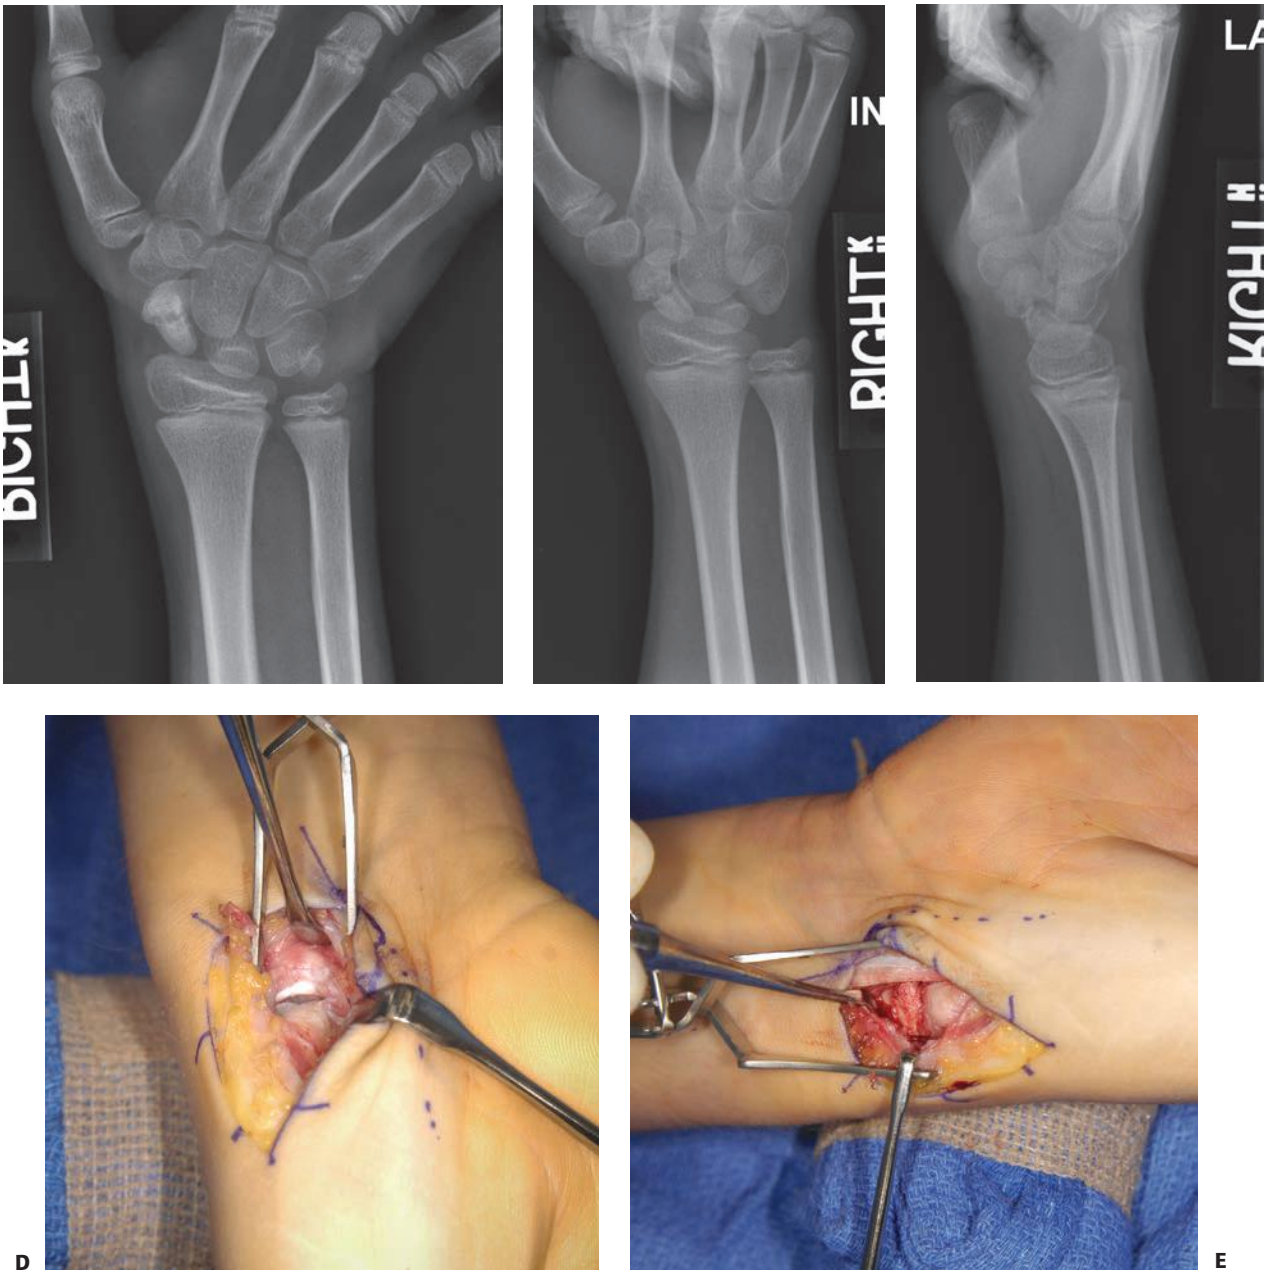

FIGURE 10-88 **A–C:** Radiographs of a 12-year-old boy with scaphoid nonunion and lunate extension through the fracture seen on the lateral view. **D:** Volar approach through the wrist to correct the mild humpback and flexion deformity. **E:** Iliac crest bone graft in place and headless screw fixation.

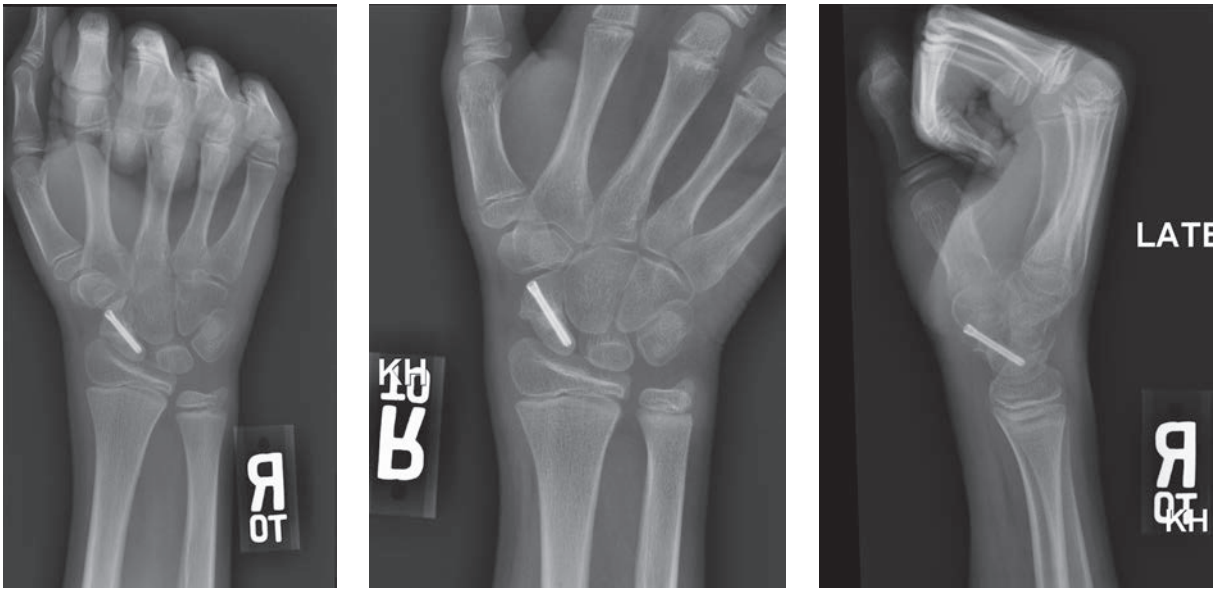

FIGURE 10-88 (*continued*) **F–H:** Final radiographs after integration of graft demonstrating correction of flexion deformity seen by lunate position on lateral. (Courtesy of Shriners Hospitals for Children, Philadelphia, PA.)

Irreducible or complex dislocations of the DIP occur primarily in adults but can occur in pediatric patients.[148,155,168,176,195] Open reduction through a dorsal approach is required for removal of the interposed tissue. The volar plate is often the offending agent, though the collateral ligaments and the FDP can block reduction.[148,155] A stable DIP joint is treated with DIP joint splinting for 3 to 4 weeks. An unstable DIP joint requires pin fixation for 3 to 4 weeks.

Proximal Interphalangeal Joint

Dislocation of the PIP joint may occur in a variety of directions. Dorsal dislocations are the most common, though lateral and volar dislocations also occur. The differential diagnosis includes adjacent bony and tendon injuries.[54] Radiographs are required to assess the physis and to confirm joint alignment. The post-reduction lateral radiograph must confirm concentric joint reduction. Persistent joint subluxation is detected by a slight offset between the proximal and middle phalanges along with a dorsal V-shaped space instead of smooth articular congruity.

Dorsal PIP Joint Dislocations

The middle phalanx is displaced dorsal to the proximal phalanx. The collateral ligaments and volar plate are disrupted. Many dorsal dislocations are probably joint subluxations that retain some of the collateral ligament or volar plate integrity. Some subluxations are reduced by the patient or trainer on the field and never receive medical evaluation.

Unreduced dorsal dislocations cause pain and obvious deformity. If necessary, anesthesia can usually be accomplished with a digital block. The dislocation is reduced with longitudinal traction, hyperextension, and palmar translation of the middle phalanx onto the proximal phalanx. The quality of the reduction and the stability of the joint must be assessed. Asking the patient to flex and extend the digit evaluates active motion. Most dislocations are stable throughout the normal range of motion, and radiographs confirm a concentric reduction. A stable joint requires a brief period (3 to 5 days) of splinting for comfort, followed by range of motion and buddy taping. Immediate motion may be started, though pain often prohibits movement

FIGURE 10-89 A dorsal dislocation of the PIP joint with an S-H type II fracture of the middle phalanx in a 15-year-old boy.

and exacerbates swelling. Prolonged immobilization leads to PIP joint stiffness.

An unstable reduction tends to subluxate or dislocate during PIP joint extension. The radiographs must be scrutinized for subtle dorsal subluxation and concomitant fracture of the middle phalangeal base. Unstable PIP joint dislocations, with or without small fractures of the middle phalangeal base, have a stable arc of motion that must be defined. This stable arc is typically from full flexion to about 30 degrees of flexion. This arc is used to determine the confines of extension block splinting.[126] A short-arm cast is applied with an aluminum outrigger that positions the MCP joint in flexion and the PIP joint in 10 degrees less than the maximal extension that leads to joint subluxation. Reduction is verified by lateral radiographs. The aluminum splint is modified every 7 to 10 days to increase PIP joint extension by 10 degrees. A lateral view or dynamic fluoroscopy is used to confirm concentric reduction. This process is continued over 4 to 5 weeks. The cast and splint are then discontinued and a home therapy program is instituted.

Extremely unstable injuries that dislocate in more than 30 degrees of flexion almost always involve considerable fracture of the middle phalanx. These injuries are regarded as pilon fractures or intra-articular fracture–dislocations. Treatment presents a management dilemma as discussed earlier.[193] Options range from open reduction to dynamic traction. Long-term subluxation, stiffness, and arthrosis are concerns.

Volar PIP Joint Dislocations

Volar PIP joint dislocations are uncommon in children,[97,150] and the diagnosis is often delayed.[150] Interposition of soft tissues or bony fragments can render the dislocation irreducible.[97] The proximal phalangeal head may herniate between the lateral band and the central tendon. In contrast to dorsal dislocations, long-term results are often suboptimal. This outcome may be related to a delay in treatment or the degree of soft tissue involvement, especially the central slip.

Volar dislocations require closed or open reduction. Reducible dislocations are treated with 4 weeks of full-time PIP joint extension splinting to promote healing of the central slip.[199] Radiographs are necessary to confirm concentric reduction. An unstable reduction may require temporary pin fixation across the PIP joint. Irreducible dislocations require open reduction through a dorsal approach to extricate any interposed tissue. The central slip can be repaired to the middle phalanx. Postoperative immobilization consists of 4 weeks of full-time PIP joint extension splinting.

Lateral PIP Joint Dislocations

Pure lateral dislocations are uncommon, though dorsal dislocations may have a lateral component.[61] An isolated lateral dislocation represents severe disruption of the collateral ligament complex. The injury represents a spectrum of damage, beginning with the proper and accessory collateral ligaments and culminating in volar plate disruption.[102] Bony avulsion fragments may accompany the ligamentous failure.[37] Closed reduction is uniformly successful. A brief period (5 to 7 days) of immobilization followed by buddy taping to protect the healing collateral ligament complex is the customary treatment.

Author's Preferred Treatment

Variables that affect treatment of PIP joint dislocations include the extent and anatomic location of soft tissue disruption, presence or absence of fracture, reducibility, and stability after reduction. The initial treatment of almost all PIP dislocations is an attempt at closed reduction followed by a stability assessment. A brief period of mobilization is important to prevent PIP joint stiffness.

Dorsal Dislocation

A stable reduction is treated with brief immobilization followed by early motion. Coban wrap (3M, St. Paul, MN) buddy taping is used until full stable motion is achieved. Sports are restricted until the patient gains joint stability and full motion. An unstable reduction that can be held reduced in more than 30 to 40 degrees of flexion is treated with extension block splinting. Extremely unstable fracture–dislocations require open treatment, external fixation, or dynamic traction depending on the size of the fracture fragments.

Volar Dislocation

A stable reduction is treated with immobilization for 4 weeks with the PIP joint in extension. Unstable reductions are treated with percutaneous pin fixation to maintain a concentric reduction. Irreducible dislocations require open reduction with repair of the central slip.

Lateral Dislocations

Pure lateral dislocations are rare. Closed reduction is usually obtainable, followed by a brief period of immobilization. Irreducible dislocations require open reduction with or without collateral ligament repair.

Metacarpophalangeal Joint Dislocations

The MCP joint is an uncommon site for dislocation in the child's hand.[67,113] The dislocation may involve a finger or thumb. The gamekeeper's or skier's thumb can be considered a subset of subluxation or dislocation.

Dorsal Metacarpophalangeal Dislocations of the Fingers

The most frequent dislocation of the MCP joint is dorsal dislocation of the index digit (Fig. 10-90), which results from a hyperextension force that ruptures the volar plate. The proximal phalanx is displaced dorsal to the metacarpal head. The diagnosis is readily apparent because the digit is shortened, supinated, and deviated in an ulnar direction. The interphalangeal joints are slightly flexed becuase of the digital flexor tendon tension. The volar skin is taut over the prominent metacarpal head.

A

B

FIGURE 10-90 **A:** A 3-year-old boy with a complete complex dislocation of the index finger metacarpal joint. **B:** Note the parallelism in this lateral view. Open reduction was done through a volar approach.

Dislocations of the MCP joint are classified as simple or complex. Complex dislocations are irreducible because of volar plate interposition in the joint. The injury can be open with the metacarpal head penetrating the palmar skin (Fig. 10-91). Simple dislocations are in a position of hyperextension on radiographs. Irreducible dislocations have bayonet apposition of the proximal phalanx dorsal to the metacarpal head. The sesamoid bone(s) of the index finger or thumb may be seen within the joint. The position of the sesamoid bones is indicative of the site of the volar plate.[26,164] The most common irreducible dislocation is at the index MCP joint. Additional structures may impede reduction.[99] The metacarpal head becomes "picture-framed" by the flexor tendon on the ulnar side and the lumbrical on the radial side. The superficial transverse metacarpal ligament and the natatory ligaments can also entrap the metacarpal neck. The collar of the restraining tissue is tightened by longitudinal traction, and this reduction maneuver may convert a dislocation from reducible to irreducible.

FIGURE 10-91 A 17-year-old male after fall from height with open index and middle finger dorsal dislocations. (Courtesy of Joshua Ratner, MD.)

Most simple dislocations can be reduced with distraction and volar manipulation of the proximal phalanx over the metacarpal head. Avoidance of hyperextension during reduction is important to prevent conversion of a simple to a complex dislocation. These reductions are usually stable. Reduction of a complex dislocation is problematic. The maneuver involves further hyperextension of the joint and palmar translation of the proximal phalanx. The goal is to extricate the volar plate with the proximal phalanx during palmar translation. Intra-articular infiltration of anesthetic fluid may assist reduction through joint distention and "floating" of the volar plate from its displaced position. The success rate for conversion of an irreducible dislocation to a reducible dislocation is low; open reduction is necessary in almost all patients.

Open Reduction

Open reduction can be accomplished through a volar or dorsal approach. The volar approach provides excellent exposure of the metacarpal head and the incarcerated structures.[9,12,67,75,99,113,127] However, the digital nerves are draped over the articular surface of the metacarpal head and precariously close to the skin. A deep skin incision can cut these nerves. The skin is gently incised and soft tissue is dissected. The first annular pulley is incised. The metacarpal head is extricated from between the flexor tendon and the lumbrical. The joint is evaluated for interposed structures, such as the volar plate, and then reduced under direct observation.

The dorsal approach offers a less extensive exposure but avoids the risk of digital nerve injury.[12] Through a dorsal incision, the extensor tendon is longitudinally split over the MCP joint. A transverse or longitudinal capsulotomy is made if the injury has not torn the capsule. A Freer elevator is placed within the joint to clear it of any interposed tissue. Often, the interposed volar plate needs to be split longitudinally to reduce the joint. If the flexor tendon is wrapped around the metacarpal, the Freer is used to extricate the metacarpal head.

Regardless of the approach used, early motion is necessary to optimize outcome.[99,127] The postoperative regimen is a 3- to 5-day immobilization period, followed by active motion. Rarely, a dorsal blocking splint is needed to prevent hyperextension that may foster repeat dislocation.

Dorsal dislocations of the other fingers are uncommon (Fig. 10-92).[8,143] Lateral fracture–dislocations are often S-H III fractures involving the base of the proximal phalanx (Fig. 10-93) and require ORIF of the displaced physeal fracture.

FIGURE 10-92 A rare dorsal dislocation of the long finger that was irreducible by closed means. A dorsal approach permitted inspection of the joint and extrication of the volar plate.

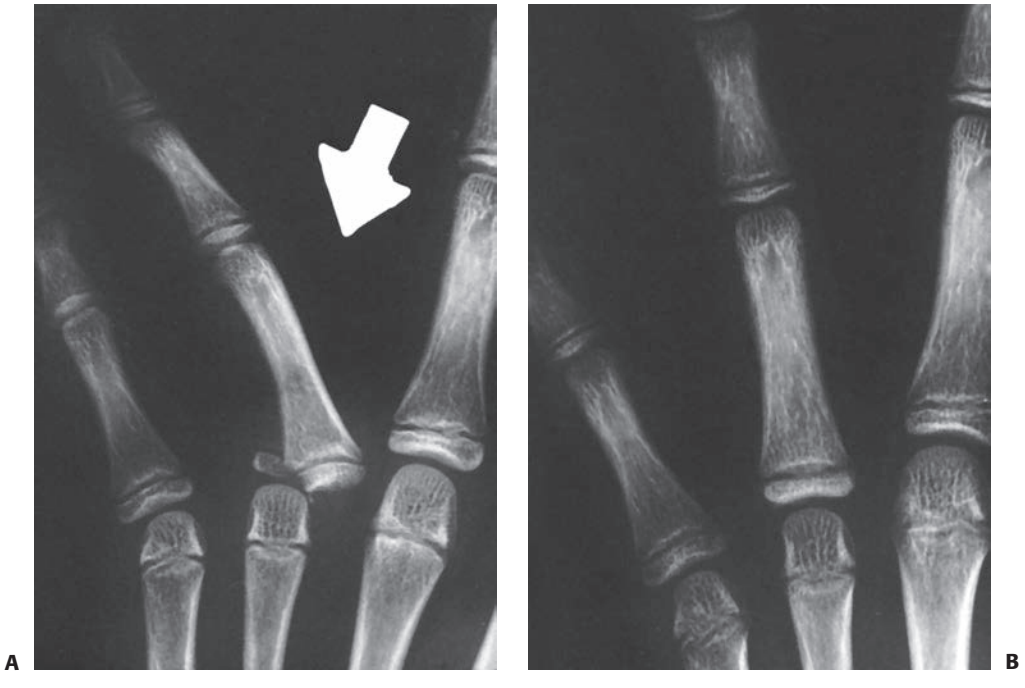

FIGURE 10-93 **A:** A 9-year-old girl sustained this radial fracture–dislocation of the middle fingers. **B:** Closed reduction restored joint and fracture alignment.

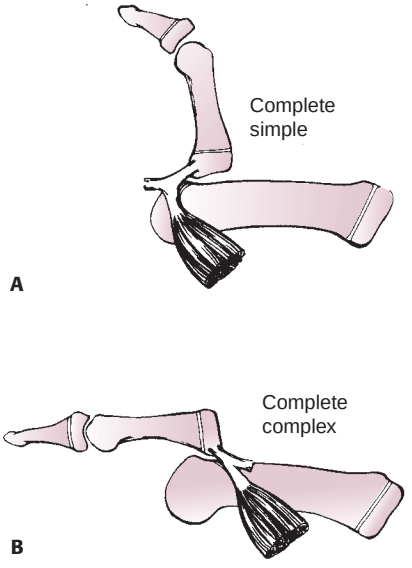

FIGURE 10-94 Simple and complex dorsal dislocations of the thumb MCP joint. Simple dislocations **(A)** are in extension and reducible. Complex dislocations **(B)** are in bayonet apposition and are irreducible because of the interposed volar plate.

Neglected Metacarpophalangeal Joint Dislocations

Early treatment is preferred for MCP joint dislocations,[93] but delay of a few months may still result in an acceptable outcome. A delay of more than 6 months is associated with joint degeneration and a less predictable result. Late reduction may require a combined dorsal and volar approach for adequate exposure.[9,114,139] Collateral ligament resection and temporary MCP joint pin fixation may be necessary.

Dorsal Dislocation of the Thumb Ray

Thumb MCP joint dislocations are similar to those of the fingers, and hyperextension is the common mechanism. Thumb dislocations are classified according to the integrity and position of the volar plate, the status of the collateral ligaments, and the relative position of the metacarpal and proximal phalanx. The components of the classification are incomplete dislocation, simple complete dislocation, and complex complete dislocation (Fig. 10-94).

Incomplete Thumb Metacarpophalangeal Joint Dislocation

An incomplete dislocation implies rupture of the volar plate with partial preservation of the collateral ligament integrity. The proximal phalanx perches on the dorsum of the metacarpal. Closed reduction is easily accomplished, and a 3-week course of immobilization is adequate. Return to sports requires protection for an additional 3 weeks.

Simple Complete Thumb Metacarpophalangeal Dislocation

A simple complete dislocation implies volar plate and collateral ligament disruption. The proximal phalanx is displaced in a dorsal direction and is angulated 90 degrees to the long axis of the thumb metacarpal. Many of these dislocations can be reduced by closed means, though unnecessary longitudinal traction may convert a reducible condition into an irreducible situation (Fig. 10-95).[75,127] A successful reduction requires thumb spica immobilization for 3 to 4 weeks to allow healing of the volar plate and collateral ligaments.

FIGURE 10-95 A 9-year-old boy with a complete simple dorsal dislocation of the thumb MCP joint.

Complex Complete Thumb Metacarpophalangeal Joint Dislocation

A complete or irreducible dislocation is the most severe form of this injury. The long axes of both the proximal phalanx and metacarpal are often parallel. Open reduction is usually required to extricate the volar plate from within the joint (Fig. 10-96).[19] A dorsal or volar approach is suitable and raises concerns similar to those for irreducible index MCP joint dislocations.[192]

Thumb Metacarpophalangeal Ulnar Collateral Ligament Injury (Gamekeeper's Thumb)

Injuries of the UCL are less prevalent in children than in adults. Forced abduction stress at a child's thumb MCP joint results in four types of injuries: (1) A simple sprain of the UCL, (2) a rupture or avulsion of the insertion or origin of the ligament, (3) a simple S-H I or II fracture of the proximal physis, or (4) an S-H III avulsion fracture that involves one-fourth to one-third of the epiphysis of the proximal phalanx (Figs. 10-97 and 10-98).[132,214]

The injury is most common in preadolescents and adolescents. A history of trauma is customary, especially involving sports. The thumb is swollen about the MCP joint with ecchymosis, and tenderness to palpation is well localized over the UCL. Pain is exacerbated by abduction stress. A complete rupture or displaced fracture lacks a discrete endpoint during stress testing. Radiographic AP and lateral views are used to diagnose and delineate fracture configuration. Stress views may be needed if the diagnosis is questionable. An MRI scan can be used to evaluate ligament disruption in complicated injuries.

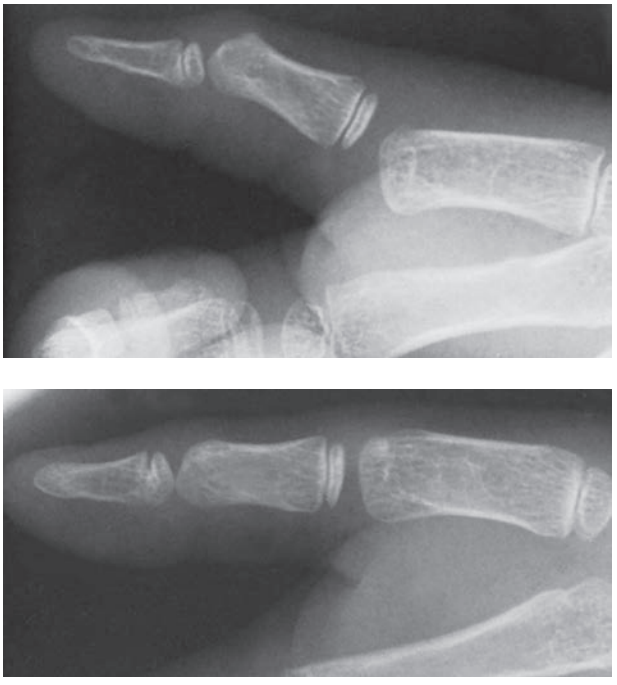

FIGURE 10-96 **A:** Irreducible dorsal MCP dislocation in a 7-year-old boy. **B:** After open reduction through a volar incision.

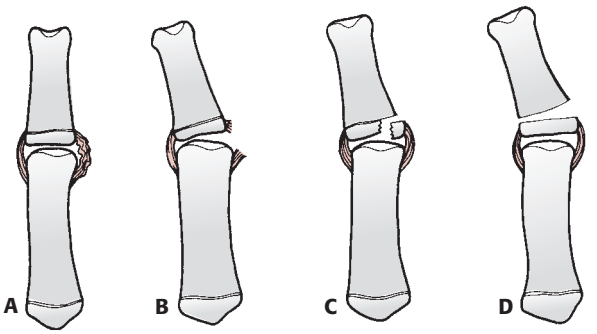

FIGURE 10-97 Ulnar instability of the thumb metacarpal joint. **A:** Simple sprain. **B:** Rupture of the ligament. **C:** Avulsion fracture (S-H type III). **D:** Pseudo-gamekeeper's injury resulting from an S-H type I or II fracture of the proximal phalanx.

Cast immobilization for 4 to 6 weeks is adequate for simple sprains, incomplete injuries, and nondisplaced fractures. A major concern is displacement of the ligament or fracture fragment behind the adductor aponeurosis known as a "Stener's lesion," which prohibits healing.[191,192] Complete ruptures, "Stener's lesion," or displaced fractures usually require operative intervention. Distal insertion avulsion without bony fracture will require anchor fixation for repair (Fig. 10-99).

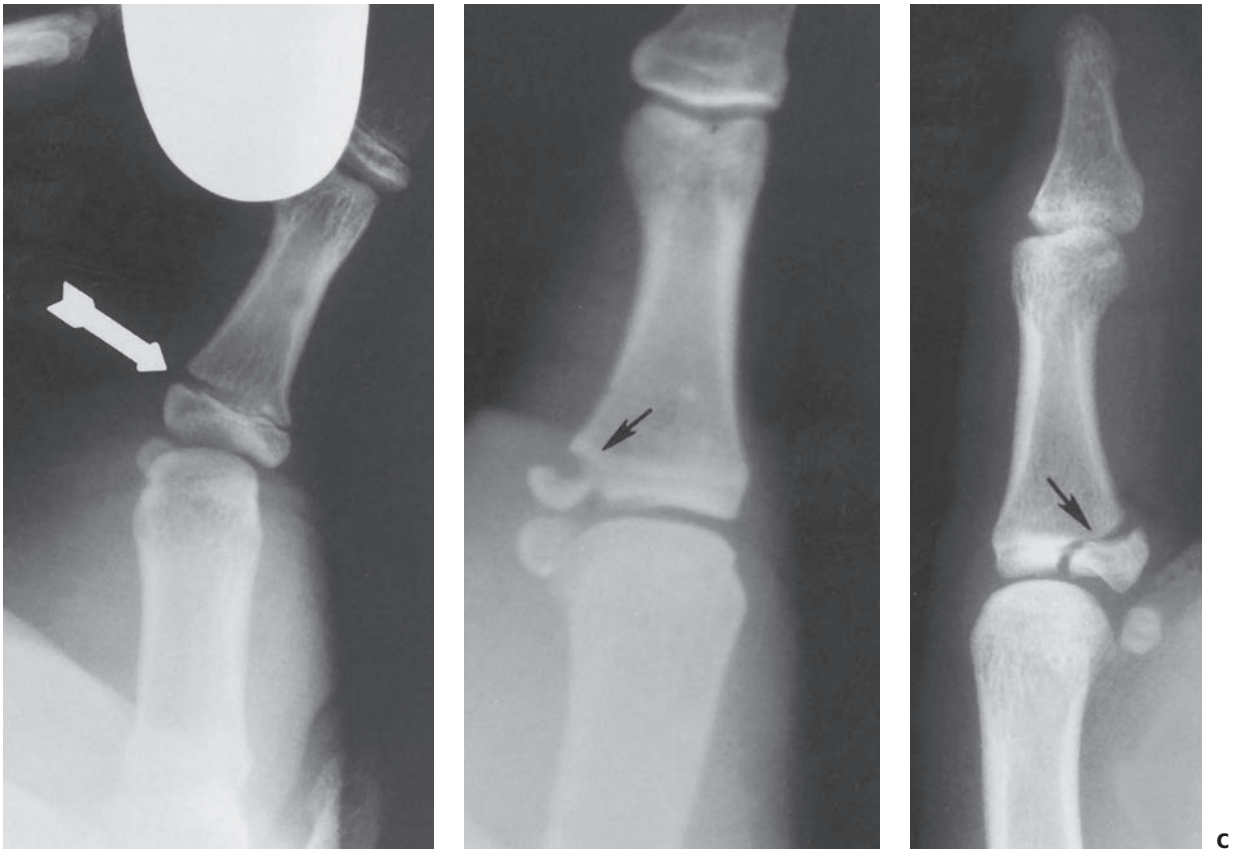

FIGURE 10-98 Spectrum of UCL injuries of the thumb. **A, B:** On stress examination, a widening of the physis is seen. Varying sizes of fragments **(B, C)** may be associated with UCL avulsion fractures (*arrows*). The size of the fragment is important with respect to the congruity of the MCP joint.

(Courtesy of Shriners Hospitals for Children, Philadelphia, PA.)

An S-H III fracture of the ulnar corner of the epiphysis of the proximal phalanx is the most common childhood gamekeeper's injury. A displaced fracture (fragment rotated or displaced more than 1.5 mm) requires ORIF to restore the integrity of the UCL and to obtain a congruous joint surface (Fig. 10-38).

Chronic UCL injuries are more difficult to manage. Treatment depends on the length of time since original injury, age of the patient, and current level of function. Options range from UCL reconstruction to MCP joint fusion.[182]

Author's Preferred Treatment

The treatment of dorsal MCP joint dislocations of the fingers and thumb should be stepwise and logical. The initial treatment for simple dislocations is usually closed reduction. This requires local anesthesia or conscious sedation to ensure comfort and eliminate resistance. Irreducible dislocations require open reduction. It is important to avoid multiple attempts at closed reduction of an irreducible dislocation. A dorsal or volar

approach is used with removal of any interposed structure(s). The volar approach must respect the taut digital nerves overlying the prominent metacarpal head. Postoperative immobilization is used for 7 to 10 days, followed by active motion with splint protection. Athletic activities are restricted until healing is complete.

Injuries of the UCL of the thumb are treated according to stability and displacement. Stable ligamentous injuries or minimally displaced fractures are treated with cast immobilization. Unstable complete ligamentous injuries or displaced fractures are treated with open reduction.

11 FRACTURES OF THE DISTAL RADIUS AND ULNA

Jonathan G. Schoenecker and Donald S. Bae

Introduction to Fractures of the Distal Radius and Ulna

Forearm fractures are the most common long bone fractures in children, occurring with an annual incidence of approximately 1.5 per 100 children per year[33] and comprising up to 40% of all pediatric fractures.[13,30,33,107,122] Among all forearm fractures, the distal radius and ulna are most commonly affec ted.[30,122,212] Peak incidence of distal radius and ulnar fractures occurs during the preadolescent growth spurt.[13,30,122,212] The nondominant arm in males is most commonly affected. Several recent studies suggest that the frequency of pediatric distal radius fractures is rising, likely due to epidemiologic trends toward diminished bone density, increased body mass indices, higher-risk activities, and younger age at the time of initial sports participation.[82,83,116,179]

In children younger than 15 years of age, the frequency with which these fractures occur demonstrates considerable seasonal variation.[200] In a prior longitudinal study of 5,013 children over 1 year in Wales, the incidence of wrist and forearm fractures was roughly half (5.9/1,000 per year) in the three winter months compared with the rest of the year (10.7/1,000 per year). In addition, the nonwinter fractures were more severe in terms of requiring reduction and hospitalization.

Due to the greater forces borne and imparted to the radius, as well as the increased porosity of the distal radial metaphysis, distal radial fractures are far more common than distal ulnar fractures and so, isolated distal radius fractures do occur regularly. However, fractures of the distal ulna most often occur in association with fractures of the distal radius.[122,155] The metaphysis of the distal radius is the most common site of forearm fracture in children and adolescents.[13,116,122] The pediatric Galeazzi injury usually involves a distal radial metaphyseal fracture and a distal ulnar physeal fracture that result in a displaced distal radioulnar joint (DRUJ). Galeazzi fracture-dislocations are relatively rare injuries in children with a cited occurrence of 3% of pediatric distal radial fractures.[198]

Given the frequency with which these injuries occur, the evaluation and management of distal radius and ulna fractures in children remains a fundamental element of pediatric orthopedics. Despite established treatment principles, however,

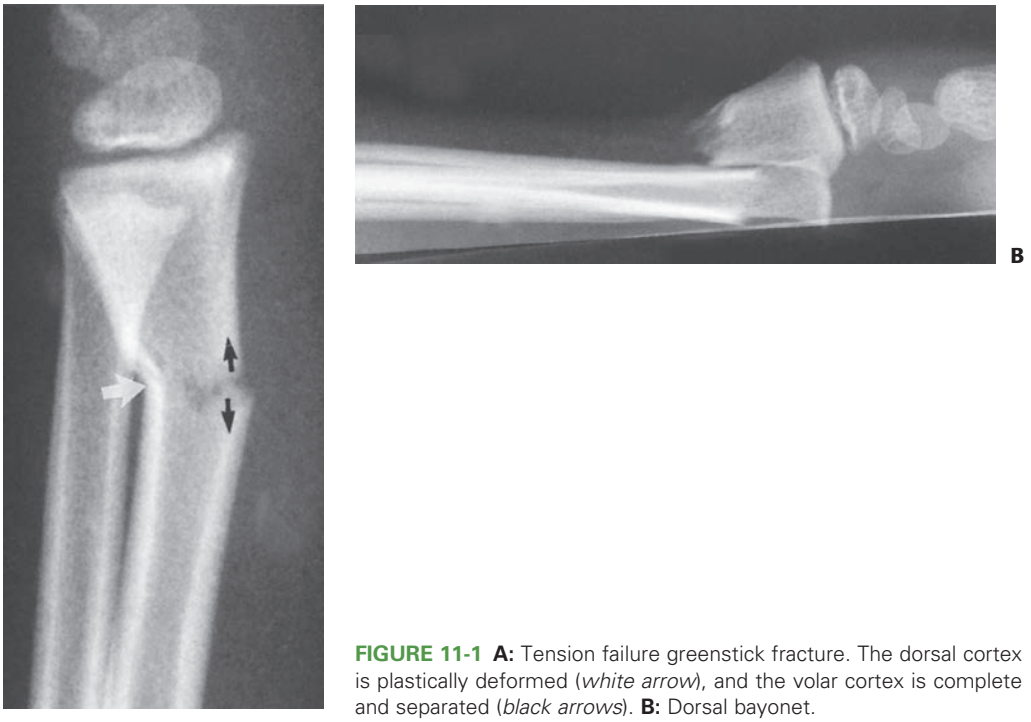

FIGURE 11-1 **A:** Tension failure greenstick fracture. The dorsal cortex is plastically deformed (*white arrow*), and the volar cortex is complete and separated (*black arrows*). **B:** Dorsal bayonet.

care of these injuries remain challenging due to the spectrum of injury patterns, issues of skeletal growth and remodeling, diversity of nonoperative and surgical techniques, evolving patient/family expectations, and increasing emphasis on cost-effective care.

Assessment of Fractures of the Distal Radius and Ulna

Fractures of the Distal Radius and Ulna Injury Mechanisms

Distal Radius and Ulna Fractures

The mechanism of injury is generally a fall on an outstretched hand. Typically, the extended position of the wrist at the time of loading leads to tensile failure on the volar side of the distal forearm. (Fig. 11-1). Conversely, axial loading on the flexed wrist will produce a volarly displaced fracture with apex dorsal angulation (Fig. 11-2). Occasionally, a direct blow sustained to the distal forearm may result in fracture and displacement. In addition to the angular deformity caused by axial and bending loads applied to the distal forearm, rotational displacement may also occur, based upon the position of the forearm and torsional forces sustained at the time of injury.

Fracture type and degree of displacement is also dependent on the height and velocity of the fall or injury mechanism.[212] Indeed, the spectrum of injury may range from nondisplaced torus (or "buckle") injuries (common in younger children with a minimal fall) or dorsally displaced fractures with apex volar angulation (more common in older children with higher-velocity injuries (Fig. 11-1). Displacement may be severe enough to cause foreshortening and bayonet apposition. Rarely, a mechanism such as a fall from a height can cause a distal radial fracture associated with a more proximal fracture of the forearm or elbow (Fig. 11-3).[12,171] These "floating elbow" situations connote higher-energy trauma and as a result are

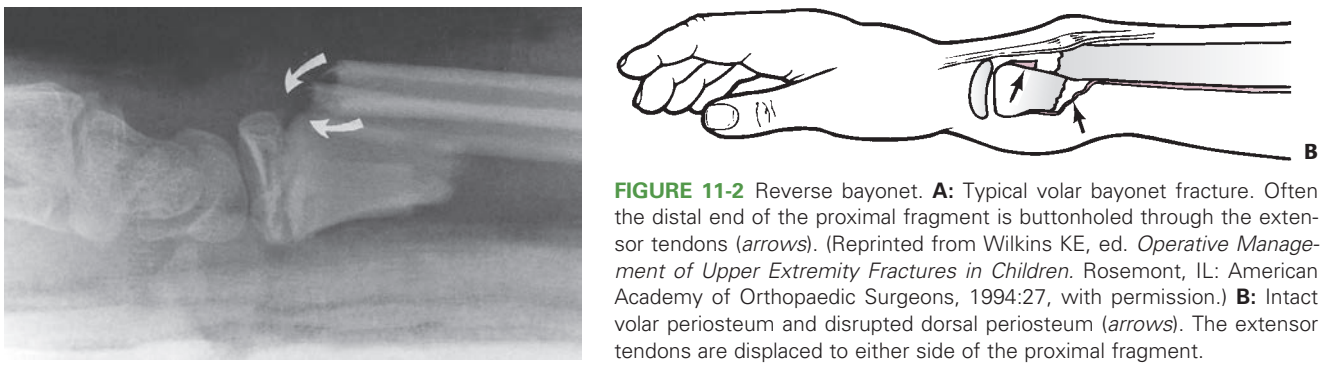

FIGURE 11-2 Reverse bayonet. **A:** Typical volar bayonet fracture. Often the distal end of the proximal fragment is buttonholed through the extensor tendons (*arrows*). (Reprinted from Wilkins KE, ed. *Operative Management of Upper Extremity Fractures in Children.* Rosemont, IL: American Academy of Orthopaedic Surgeons, 1994:27, with permission.) **B:** Intact volar periosteum and disrupted dorsal periosteum (*arrows*). The extensor tendons are displaced to either side of the proximal fragment.

FIGURE 11-3 A 10-year-old girl with an innocuous-appearing distal radial fracture associated with an ipsilateral angulated radial neck fracture (*arrows*.)

associated with risks of neurovascular compromise and compartment syndrome.[12,171]

Fractures of the distal forearm in children typically occur when the radius and/or ulna are more susceptible to fracture secondary to biomechanical changes during skeletal development. Recent work based upon load-to-strength ratio and other measures of bone quality have identified specific times during skeletal development where the biologic properties of the distal upper extremity produce relatively weaker bone, making a child more susceptible to fracture.[65,109,118,145] In these studies, prepubescent boys and girls were found to have lower estimates of bone strength compared to same sex postpubertal peers. From these studies, it can be concluded that children are uniquely susceptible for fracture when longitudinal growth outpaces mineral accrual during rapid growth.[13] As 90% of the radius growth is from the distal physis and accounts for 70% of the loading across the wrist, the radius is more prone to fracture than the ulna during rapid growth.[200] Fractures occur at the biomechanically weakest anatomic location of bone, which also varies over time. As the metaphyseal cortex of the radius is relatively thin and porous fractures in this region are most common, followed by physeal.[138,190]

Usually, fractures occur during sports-related activities. Indeed, the recent trend toward increased sports participation in children has led to a substantial increase in the incidence of distal radius and/or ulna fractures.[102,211] Certain sports, such as skiing/snowboarding, basketball, soccer, football, rollerblading/skating, and hockey have been associated with an increased risk of distal radial fracture, though a fall or injury of sufficient severity may occur in any recreational activity.[188] Protective wrist guards have been shown to decrease the injury rate in snowboarders, especially beginners and persons with rental equipment.[173]

As cited above, there is seasonal variation, with an increase in both incidence and severity of fractures in summer.[201] Children who are overweight, have poor postural balance, ligamentous laxity, or less bone mineralization are at increased risk for distal radial fractures.[83,117,123,165,180,212] Although bone quality measures predict that boys had lower risk of fracture than girls at every stage except during early puberty,[145] these fractures have been reported to be three times more common in boys. However, the increased participation in athletics by girls at a young age may be changing this ratio.

Radial Physeal Stress Fractures

Repetitive axial loading of the wrist may lead to physeal stress injuries, almost always involving the radius (Fig. 11-4). These physeal stress injuries are most commonly seen in competitive gymnasts.[29,47,52,191,192] Factors that predispose to this injury include excessive training, poor techniques, and attempts to advance too quickly in competitive level and have been also observed in other sports including wresting, break dancing, and cheerleading.[76]

Galeazzi Fracture

Axial loading of the wrist in combination with extremes of forearm rotation (Fig. 11-5) may result in distal radius fractures with associated disruption of the DRUJ, the so-called "pediatric Galeazzi fracture."[26,40,72,122,127,135,199] In adults, the mechanism of injury usually is an axially loading fall with hyperpronation. This results in a distal radial fracture with DRUJ ligament disruption and dorsal dislocation of the ulna. However, in children, both supination (apex volar) and pronation (apex dorsal) deforming forces have been described.[126,198] The mechanism of injury is most obvious when the radial fracture is incomplete. With an apex volar (supination) radial fracture, the distal ulna is displaced volarly, whereas with an apex dorsal (pronation) radial fracture, the distal ulna is displaced dorsally. This is evident both on clinical and radiographic examinations. In addition, the radius is foreshortened in a complete fracture, causing more radial deviation of the hand and wrist. In children, this injury may involve either disruption of the DRUJ ligaments or, more commonly, a distal ulnar physeal fracture (Fig. 11-6).[1,170]

Injuries Associated with Fractures of the Distal Radius and Ulna

The risk of associated injuries is significantly less in the skeletally immature as compared to skeletally mature patients.[58] The entire ipsilateral extremity should be carefully examined for fractures of the carpus, forearm, or elbow.[12,32,91,120,171,182,193] Indeed, 3% to 13% of distal radial fractures have associated ipsilateral extremity fractures.[182] Associated fractures of the hand and elbow regions need to be assessed because their presence

FIGURE 11-5 Supination-type Galeazzi fracture. **A:** View of the entire forearm of an 11-year-old boy with a Galeazzi fracture-dislocation. **B:** Close-up of the distal forearm shows that there has been disruption of the distal radioulnar joint (*arrows*). The distal radial fragment is dorsally displaced (apex volar), making this a supination type of mechanism. Note that the distal ulna is volar to the distal radius.

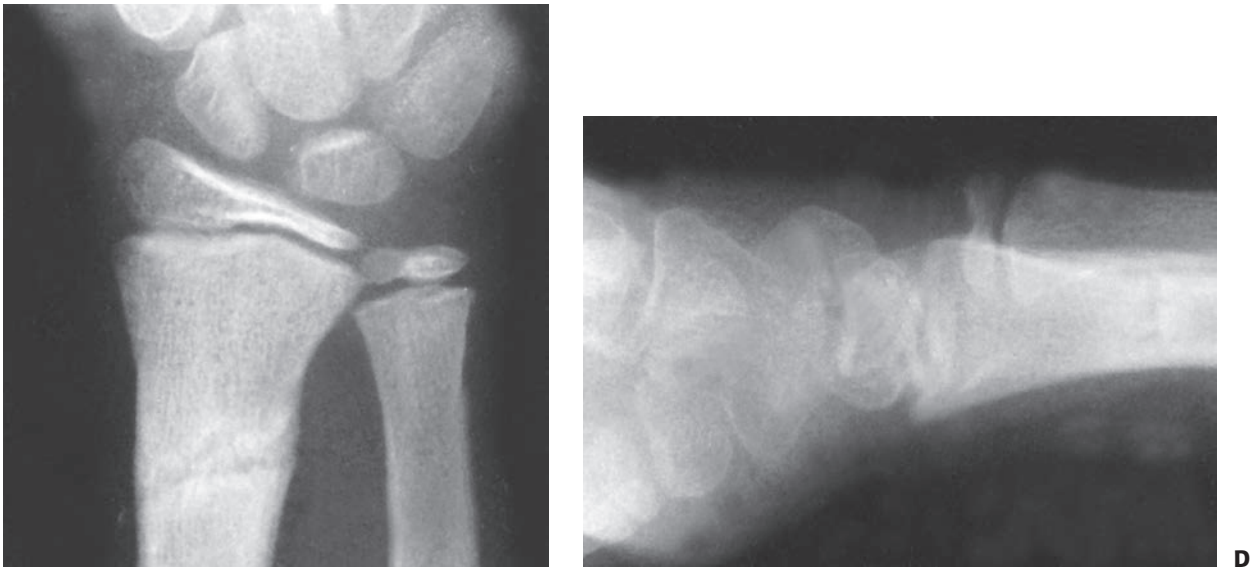

FIGURE 11-5 (*continued*) **C, D:** The fracture was reduced by pronating the distal fragment. Because the distal radius was partially intact by its greenstick nature, the length was easily maintained, reestablishing the congruity of the distal radioulnar joint. The patient was immobilized in supination for 6 weeks, after which full forearm rotation and function returned.

implies more severe trauma. For example, the incidence of a compartment syndrome is higher with a "floating elbow" combination of radial, ulnar, and elbow fractures.[171]

With marked radial or ulnar fracture displacement, neurovascular compromise can occur.[15,44,203] Median neuropathy may be seen in severely displaced distal radius fractures, due to direct nerve contusion sustained at the time of fracture displacement, persistent pressure or traction from an unreduced fracture, or an acute compartment syndrome (Fig. 11-7).[203] Ulnar neuropathy has been described with similar mechanisms, as well as entrapment or incarceration of the ulnar nerve within the fracture site.

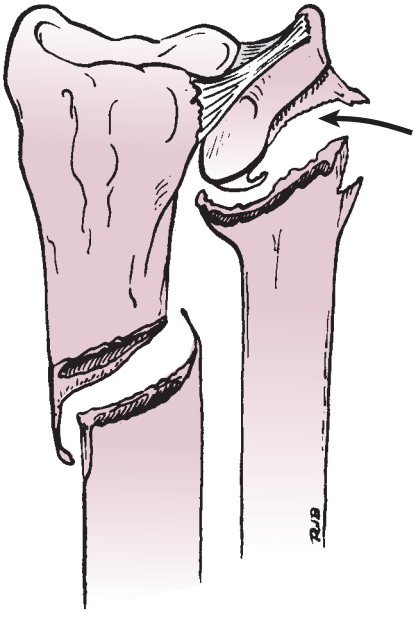

FIGURE 11-6 Galeazzi fracture-dislocation variant. Interposed periosteum can block reduction of the distal ulnar physis (*arrow*). This destabilizes the distal radial metaphyseal fracture. The taut volar transverse carpal ligament and fracture hematoma also are contributing factors. (Redrawn from Waters PM, Kolettis GJ, Schwend R. Acute median neuropathy following physeal fractures of the distal radius. *J Pediatr Orthop.* 1994;14:173–177, with permission.)

FIGURE 11-8 Coronal computed tomography (CT) image of an adolescent with ipsilateral distal radius and scaphoid fractures.

Wrist ligamentous and articular cartilage injuries have been described in association with distal radial and ulnar fractures in adults and less commonly in children.[12,55] Concomitant scaphoid fractures have occurred (Fig. 11-8).[32,41,194] Associated wrist injuries need to be treated both in the acute setting and in the patient with persistent pain after fracture healing. Some patients with distal radial and ulnar fractures are multitrauma victims. Care of the distal forearm fracture in these situations must be provided within the context of concomitant systemic injuries. More than 50% of distal radial physeal fractures have an associated ulnar fracture. This usually is an ulnar styloid fracture, but can be a distal ulnar plastic deformation, greenstick, or complete fracture.[33,107,123,190]

Isolated ulnar physeal fractures are rare injuries.[1,183] Most ulnar physeal fractures occur in association with radial metaphyseal or physeal fractures. Physeal separations are classified by the standard Salter–Harris criteria. The rare pediatric Galeazzi injury usually involves an ulnar physeal fracture rather than a soft tissue disruption of the DRUJ. Another ulnar physeal fracture is an avulsion fracture off the distal aspect of the ulnar styloid.[1] Although an ulnar styloid injury is an epiphyseal avulsion, it can be associated with soft tissue injuries of the TFCC and ulnocarpal joint, though does not typically cause growth-related complications.

Signs and Symptoms of Fractures of the Distal Radius and Ulna

Fractures of the Distal Radius and Ulna

Children with distal radial and/or ulnar fractures present with pain, swelling, and deformity of the distal forearm (Fig. 11-9). The clinical signs depend on the degree of fracture displacement. With a nondisplaced torus fracture in a young child, medical attention may not be sought until several days after injury; the intact periosteum and biomechanical stability is protective in these injuries, resulting in minimal pain and guarding. Similarly, many of the physeal injuries are nondisplaced and present only with pain and tenderness at the physis.[142,154] With displaced fractures, the typical dorsal displacement and apex volar angulation create an extension deformity that is usually clinically apparent. Careful inspection of the forearm is critical to evaluate for possible skin lacerations, wounds, and open fractures.

With greater displacement, physical examination is often limited by the patient's pain and anxiety, but it is imperative to obtain an accurate examination of the motor and sensory components of the radial, median, and ulnar nerves before treatment is initiated. Neurovascular compromise is uncommon but can occur.[203] A prior prospective study indicated an 8% incidence of nerve injury in children with distal radial fractures.[204] Median nerve irritability or dysfunction is most common, caused by direct trauma to the nerve at the time of injury or ongoing ischemic compression from the displaced fracture. Median nerve motor function is evaluated by testing the abductor pollicis brevis (intrinsic) and flexor pollicis longus (extrinsic) muscles. Ulnar nerve motor evaluation includes testing the first dorsal interosseous (intrinsic), abductor digit quinti (intrinsic), and flexor digitorum profundus to the small finger (extrinsic) muscles. Radial nerve evaluation involves testing the common digital extensors for metacarpophalangeal joint extension as well as extensor pollicis longus. Sensibility to light touch and two-point discrimination should be tested. Normal two-point discrimination is less than 5 mm but may not be reliably tested in children younger than 5 to 7 years of age. Pin-prick sensibility testing will only hurt and scare the already anxious child and should be avoided.

Radial Physeal Stress Fracture

In contrast to the child with an acute, traumatic distal radius fracture, patients with distal radial physeal stress injuries typically report recurring, activity-related wrist pain. Characteristically, this pain is described as diffuse "aching" and "soreness" in the region of the distal radial metaphysis and physis. Pain

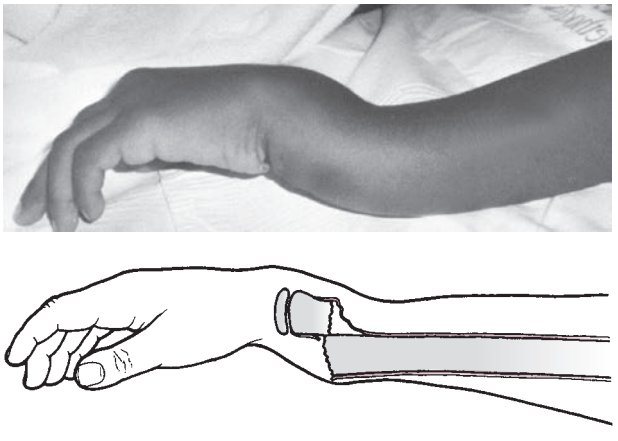

FIGURE 11-9 Dorsal bayonet deformity. **A:** Typical distal metaphyseal fracture with dorsal bayonet showing a dorsal angulation of the distal forearm. **B:** Usually, the periosteum is intact on the dorsal side and disrupted on the volar side.

may be reproduced in the extremes of wrist extension and flexion, and usually there is local tenderness over the dorsal, distal radial physis. Resistive strength testing of the wrist extensors will also reproduce the pain. There may be fusiform swelling about the wrist if there is reactive bone formation. The differential diagnosis includes physeal stress injury, ganglion, ligamentous or TFCC injury, tendinosis or musculotendinous strain, carpal fracture, and osteonecrosis of the scaphoid (Preiser disease) or lunate (Kienbock disease). Diagnosis is made radiographically in the context of the clinical presentation.

Galeazzi Fracture

Children with Galeazzi injuries present with pain, limited forearm rotation, and limited wrist flexion and extension. Neurovascular impairment is rare. The radial deformity usually is clinically evident. Prominence of the ulnar head is seen with DRUJ disruption. Ligamentous disruption is often subtle and may be evident only by local tenderness and instability to testing of the DRUJ.

Imaging and Other Diagnostic Studies Fractures of the Distal Radius and Ulna

Plain radiographs are diagnostic of the fracture type and degree of displacement. Standard anteroposterior (AP) and lateral radiographs usually are sufficient. Complete wrist, forearm, and elbow views are recommended in cases of high-energy injuries or when there is clinical suspicion for an ipsilateral fracture of the hand, wrist, or elbow. More extensive radiographic evaluation (e.g., computed tomography [CT], magnetic resonance imaging [MRI]) is typically reserved for evaluation of suspected or known intra-articular fractures or associated carpal injuries (e.g., scaphoid fractures, hook of hamate fractures, perilunate instability); these situations are most commonly encountered in older adolescents.

There has been increasing enthusiasm for the use of ultrasound in the diagnostic evaluation of distal radius and ulna fractures.[28,60,99,142,154,162] Two independent studies have demonstrated the feasibility and accuracy of bedside ultrasound for diagnosing nondisplaced fractures[28,162] Ultrasonography is most useful in cases of suspected fractures in the absence of plain radiographic abnormalities, or in very young children in whom the skeletal structures are incompletely ossified.

Radiographic evaluation should be performed not only to confirm the diagnosis but also to quantify the degree of displacement, angulation, malrotation, and comminution (Fig. 11-10). Understanding of the normal radiographic parameters is essential in quantifying displacement. In adults, the normal distal radial inclination averages 22 degrees on the AP view and 11 degrees of volar tilt on the lateral projection.[73,137,148,181,220] Radial inclination is a goniometric measurement of the angle between the distal radial articular surface and a line perpendicular to the radial shaft on the AP radiograph. Volar tilt is measured by a line across the distal articular surface and a line perpendicular to the radial shaft on the lateral view. Pediatric values for radial inclination and volar tilt may vary from adult normative values, depending on the degree of skeletal maturity and the ossification of the epiphysis. Indeed, radial inclination is often less than 22 degrees in younger children, though volar tilt tends to be more consistent regardless of patient age.

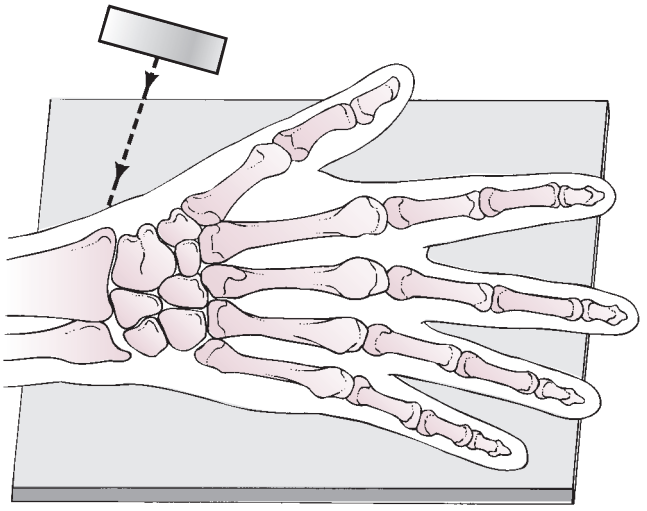

FIGURE 11-10 Angulation of the x-ray beam tangential to the articular surface, providing the optimal lateral view of the distal radius. The wrist is positioned as for the standard lateral radiograph, but the x-ray beam is directed 15 degrees cephalad. (Redrawn from Johnson PG, Szabo RM. Angle measurements of the distal radius: A cadaver study. *Skel Radiol.* 1993;22:243, with permission.)

As noted above, advanced imaging may be helpful in cases of intra-articular extension to characterize fracture pattern and joint congruity. This may be done by AP and lateral tomograms, CT scans, or MRI. Dynamic motion studies with fluoroscopy can provide important information on fracture stability and the success of various treatment options. Dynamic fluoroscopy requires adequate pain relief and has been used more often in adult patients with distal radial fractures.

Radiographs are also diagnostic in cases of suspected distal radial physeal stress injuries. Physeal widening, cystic and sclerotic changes in the metaphyseal aspect of the distal radial physis, beaking of the distal radial epiphysis, and reactive bone formation are highly suggestive of chronic physeal stress fracture. In advanced cases, premature physeal closure or physeal bar formation may be seen, indicating long-standing stress.[29,47,52,174,192,213] In these situations, continued ulnar growth leads to an ulnar positive variance with resulting pain from ulnocarpal impaction and/or TFCC tear.[12,174,213] Plain radiographs may not reveal early physeal stress fracture. If the diagnosis is suggested clinically, additional studies may be indicated. Technicium bone scanning is sensitive but nonspecific. MRI is usually diagnostic, demonstrating the characteristic "double line" on coronal T1 and gradient echo sequences.[128]

In Galeazzi fractures, the radial fracture is readily apparent on plain radiographs. Careful systematic evaluation of the radiographs will reveal concurrent injuries to the ulna and/or DRUJ (Fig. 11-11). A true lateral radiograph is essential to identify the direction of displacement and thus to determine the method of reduction. Rarely are advanced imaging studies, such as CT or MRI scan, are necessary.

Classification Fractures of the Distal Radius and Ulna

Distal Radius and Ulna Fractures

Distal radius and ulna fractures are classified according to fracture pattern, type of associated ulnar fracture, and direction of displacement, angulation, and rotation. Most distal radial metaphyseal fractures are displaced dorsally with apex volar angulation.[190] Volar displacement with apex dorsal angulation occurs less commonly with volar flexion mechanisms.

Distal radial and ulnar fractures are then defined by their anatomic relationship to the physis. Physeal fractures are classified by the widely accepted Salter–Harris system (see below).[27,175] Metaphyseal injuries are often different from their adult equivalents, due to the thick periosteum surrounding the relatively thin metaphyseal cortex. Metaphyseal fractures are generally classified according to fracture pattern and may be torus fractures, greenstick or incomplete fractures, or complete bicortical injuries. Pediatric equivalents of adult Galeazzi fracture-dislocations involve a distal radial fracture and either a soft tissue disruption of the DRUJ or a physeal fracture of the distal ulna (Table 11-1).

Physeal Injuries

The Salter–Harris system is the basis for classification of physeal fractures.[174] Most are Salter–Harris type II fractures.[27] In the more common apex volar injuries, dorsal displacement of the distal epiphysis and the dorsal Thurston–Holland metaphyseal fragment is evident on the lateral view (Fig. 11-12). Salter–Harris type I fractures also usually displace dorsally. Volar displacement of either a Salter–Harris type I or II fracture is less common (Fig. 11-13). Nondisplaced Salter–Harris type I fractures may be indicated only by a displaced pronator fat pad sign (Fig. 11-14),[175,218] ultrasound,[28,99,153] or tenderness over the involved physis.[141,153] A scaphoid fat pad sign may indicate a scaphoid fracture (Fig. 11-15).[94]

Salter–Harris type III fractures are rare and may be caused by a compression, shear, or avulsion of the radial origin of the volar radiocarpal ligaments (Fig. 11-16).[9,125] Triplane equivalent fractures,[157] a combination of Salter–Harris type II and III fractures in different planes, have similarly been reported but are rare. CT scans may be necessary to define the fracture pattern and degree of intra-articular displacement.

of classification has been shown to have good agreement between experienced observers.[167] Torus fractures are axial compression injuries. The site of cortical failure is the transition from metaphysis to diaphysis.[128] As the mode of failure is compression, these injuries are inherently stable and are further stabilized by the intact surrounding periosteum. Rarely, they may extend into the physis, putting them at risk for growth impairment.[155,156,158]

Incomplete or greenstick fractures occur with a combination of compressive, tensile, and rotatory forces, resulting in complete failure of one cortex and plastic deformation of the other cortex. Most commonly, the combined extension and supination forces lead to tensile failure of the volar cortex and dorsal compression injury. The degree of force determines the amount of plastic deformation, dorsal comminution, and fracture angulation and rotation.

With greater applied loads, complete fracture occurs with disruption of both the volar and dorsal cortices. Length may be maintained with apposition of the proximal and distal fragments. Frequently, the distal fragment lies proximal and dorsal to the proximal fragment in bayonet apposition (Table 11-2).

Ulnar fractures often associated with radial metaphyseal injuries may occur in the metaphysis, physis, or through the ulnar styloid. Similar to radial metaphyseal fractures, the ulnar fracture can be complete or incomplete. These injuries are also characterized according to fracture pattern and displacement.

Distal radial fractures also can occur in conjunction with more proximal forearm fractures,[19,203] Monteggia fracture-dislocations,[18] supracondylar distal humeral fractures,[170,181] or carpal fractures.[32,41,91,119] The combination of a displaced supracondylar distal humeral fracture and a displaced distal radial metaphyseal fracture has been called the pediatric floating elbow. This injury combination is unstable and has an increased risk for malunion and neurovascular compromise.

Distal Ulna Fractures

Isolated ulnar physeal fractures are rare, as most ulnar physeal injuries occur in association with radial metaphyseal or physeal fractures.[1,182] Physeal injuries are classified according to the Salter–Harris classification.[155] Ulnar physeal fractures may also be seen with the pediatric Galeazzi injuries,[169] which usually involve an ulnar physeal fracture rather than a soft tissue disruption of the DRUJ.

Avulsion fractures of the ulnar styloid also represent epiphyseal avulsion injuries. Most commonly associated with distal radial fractures,[1,182] these styloid fractures typically represent soft tissue avulsions of the ulnar insertion of the TFCC or ulnocarpal ligaments[12] and are rarely associated with growth-related complications.

Galeazzi Fracture

Galeazzi fracture-dislocations are most commonly described by direction of displacement of either the distal ulnar dislocation or the radial fracture.[126] Letts preferred to describe the direction of the ulna: volar or dorsal.[77,198] Others classified pediatric Galeazzi injuries by the direction of displacement of the distal radial fracture. Dorsally displaced (apex volar) fractures were more common than volarly displaced (apex dorsal) injuries in their series. Wilkins and O'Brien[209] modified the Walsh and McLaren method by classifying radial fractures as incomplete and complete fractures and ulnar injuries as true dislocations versus physeal fractures (Table 11-3). DRUJ dislocations are called true Galeazzi lesions and distal ulnar physeal fractures are called pediatric Galeazzi equivalents.[109,121,126]

Pathoanatomy and Applied Anatomy Relating to Fractures of the Distal Radius and Ulna

The distal radial epiphysis normally appears between 0.5 and 2.3 years in boys and 0.4 and 1.7 years in girls.[73,147,136] Initially transverse in appearance, it rapidly becomes more adultlike with its triangular shape. The contour of the radial styloid progressively elongates with advancing skeletal maturity. The secondary center of ossification for the distal ulna appears at about age.[147] Similar to the radius, the ulnar styloid appears with the adolescent growth spurt. It also becomes more elongated and adultlike until physeal closure. On average, the ulnar physis closes at age 16 in girls and age 17 in boys, whereas the radial physis closes on average 6 months later than the ulnar physis.[172,220] The distal radial and ulnar physes contribute approximately 75% to 80% of the growth of the forearm and 40% of the growth of the upper extremity (Fig. 11-18).[148]

The distal radius articulates with the distal ulna at the DRUJ.[177] Both the radius and ulna articulate with the carpus, serving as the platform for the carpus and hand. The radial joint surface has three concavities for its articulations: the scaphoid and lunate fossa for the carpus and the sigmoid notch for the ulnar head. These joints are stabilized by a complex series of volar and dorsal radiocarpal, ulnocarpal, and radioulnar ligaments. The volar ligaments are the major stabilizers. Starting radially at the radial styloid, the radial collateral, radioscaphocapitate, radiolunotriquetral (long radiolunate), and radioscapholunate (short radiolunate) ligaments volarly stabilize the radiocarpal joint. The dorsal radioscaphoid and radial triquetral ligaments are less important stabilizers. The complex structure of ligaments stabilize the radius, ulna, and carpus through the normal wrist motion of 120 degrees of flexion and extension, 50 degrees of radial and ulnar deviation, and 150 degrees of forearm rotation.[150]

The triangular fibrocartilage complex (TFCC) is the primary stabilizer of the ulnocarpal and radioulnar articulations.[150] It extends from the sigmoid notch of the radius across the DRUJ and inserts into the base of the ulnar styloid. It also extends distally as the ulnolunate, ulnotriquetral, and ulnar collateral ligaments and inserts into the ulnar carpus and

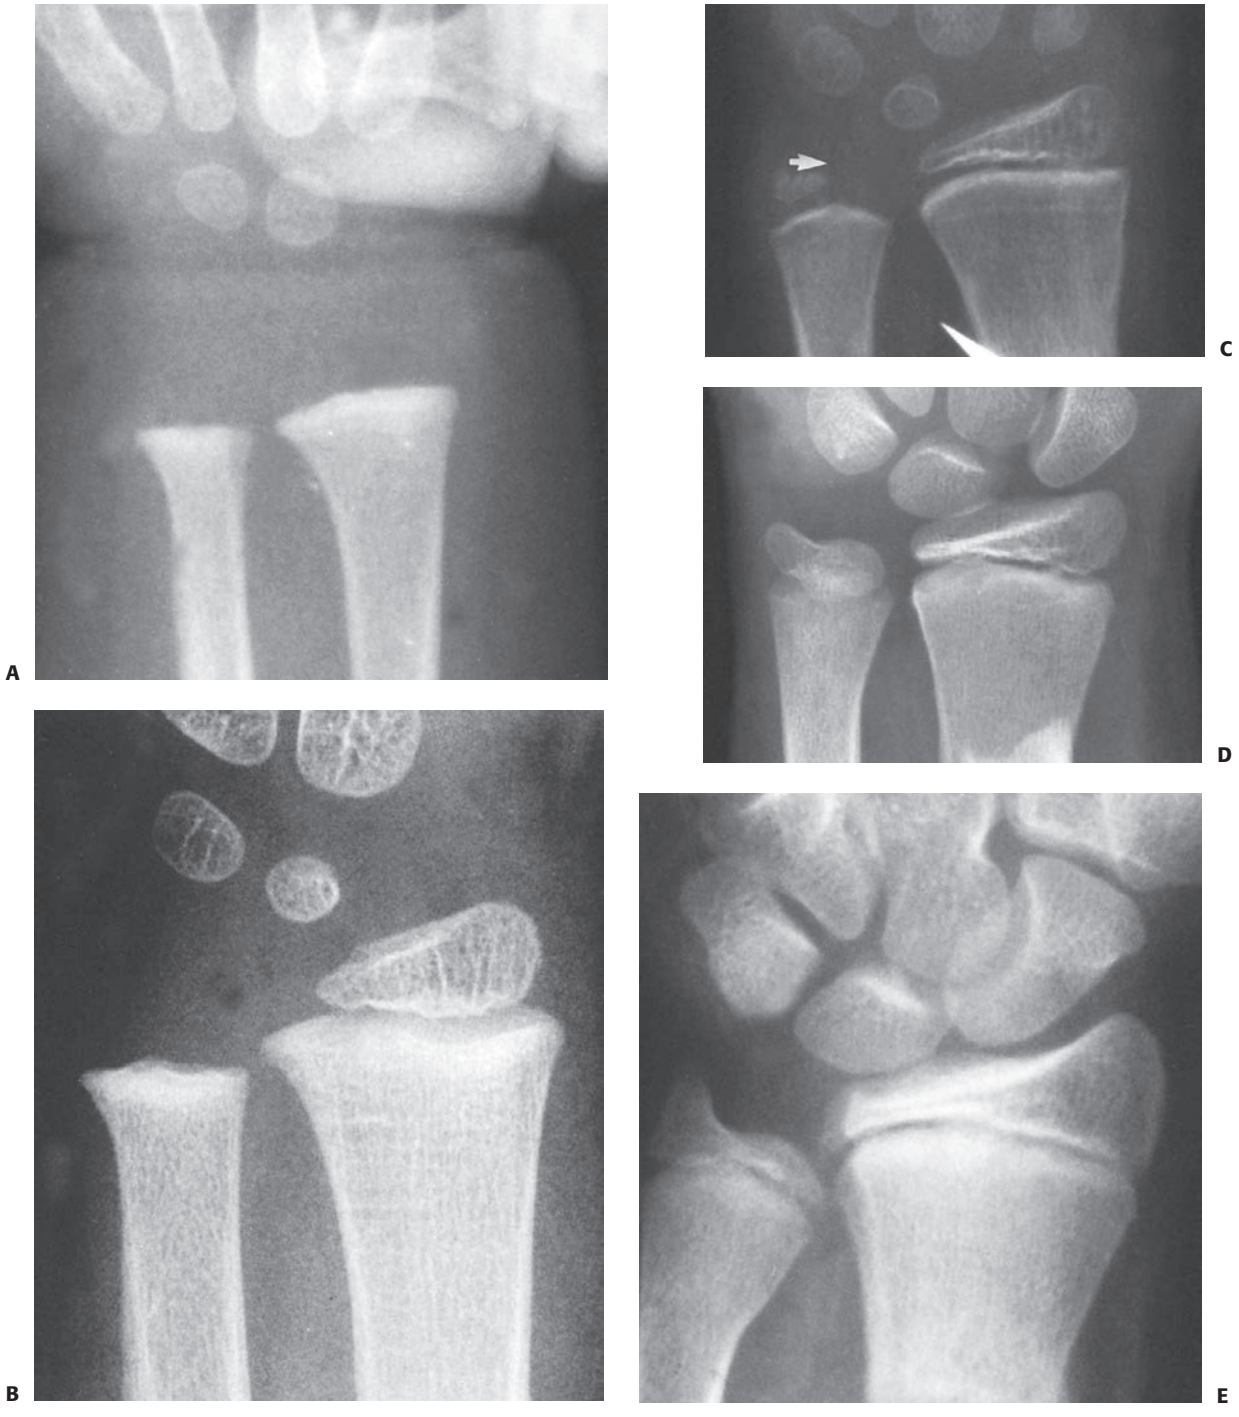

FIGURE 11-18 Ossification of the distal radius. **A:** Preossification distal radius with transverse ossification in a 15-month-year-old boy. **B:** The triangular secondary ossification center of the distal radius in a 2-year-old girl. **C:** The initial ossification center of the styloid in this 7-year-old girl progresses radially (*arrow*). **D:** Extension of the ulnar ossification center into the styloid process of an 11-year-old. **E:** The styloid is fully ossified and the epiphyses have capped their relative metaphyses in this 13-year-old boy.

base of the fifth metacarpal.[150] The volar ulnocarpal ligaments (V ligament) from the ulna to the lunate and triquetrum are important ulnocarpal stabilizers.[22,178] The central portion of the TFCC is the articular disk (Fig. 11-19). The interaction between the bony articulation and the soft tissue attachments accounts for stability of the DRUJ during pronation and supination.[151] At the extremes of rotation, the joint is most stable. The compression loads between the radius and ulna are aided by the tensile loads of the TFCC to maintain stability throughout rotation.

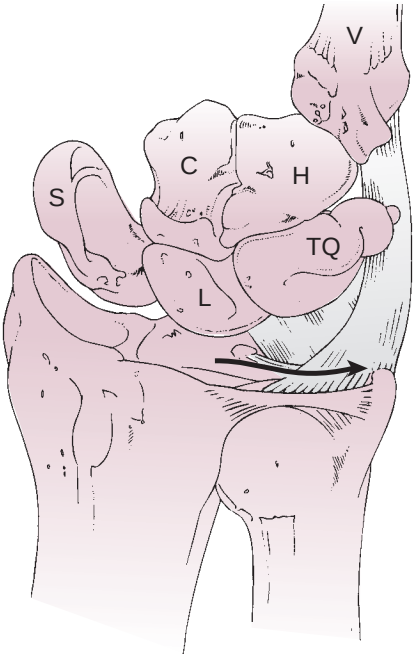

FIGURE 11-19 Diagrammatic drawing of the TFCC and the prestyloid recess. The meniscal reflection runs from the dorsoulnar radius to the ulnovolar carpus. The arrow denotes access under the reflection to the tip of the styloid the so-called prestyloid recess. (Redrawn from Bowers WH. *Green's Operative Hand Surgery*. New York, NY: Churchill-Livingstone, 1993.)

The interosseous ligament of the forearm (Fig. 11-20) helps stabilize the radius and ulna more proximally in the diaphysis of the forearm. The ulna remains relatively immobile as the radius rotates around it. Throughout the midforearm, the interosseous ligament connects the radius to the ulna. It passes obliquely from the proximal radius to the distal ulna. However, the interosseous ligament is not present in the distal radius. Moore et al.[140] found that injuries to the TFCC and interosseous ligament were responsible for progressive shortening of the radius with fracture in a cadaveric study. The soft tissue component to the injury is a major factor in the deformity and instability in a Galeazzi fracture-dislocation.

The length relationship between the distal radius and ulna at the wrist is defined as ulnar variance. In adults, this is measured by the relationship of the radial corner of the distal ulnar articular surface to the ulnar corner of the radial articular surface.[100] However, measurement of ulnar variance in children requires modifications of this technique. Hafner[89] described measuring from the ulnar metaphysis to the radial metaphysis to lessen the measurement inaccuracies related to epiphyseal size and shape, a technique recently validated by Goldfarb (Fig. 11-21).[80] If the ulna and radius are of equal lengths, there is a neutral variance. If the ulna is longer, there is a positive variance. If the ulna is shorter, there is a negative variance. Variance measurement is usually made in millimeters.

Although not dependent on the length of the ulnar styloid,[22] the measurement of ulnar variance is dependent on forearm position and radiographic technique.[61] Radiographs of the wrist to determine ulnar variance should be standardized with the hand and wrist placed on the cassette, with the shoulder abducted 90 degrees, elbow flexed 90 degrees, and forearm in neutral rotation (Fig. 11-22). The importance of ulnar variance relates to the force transmission across the wrist with axial loading. Normally, the radiocarpal joint bears approximately 80% of the axial load across the wrist, and the ulnocarpal joint bears 20%. Changes in the length relationship of the radius and ulna alter respective load bearing. Indeed, 2.5 mm of ulnar positive variance has been demonstrated to double the forces borne across the ulnocarpal articulation in adult biomechanical analyses.[105,151] Biomechanical and clinical studies have shown that this load distribution is important in fractures, TFCC tears (positive ulnar variance), and Kienbock disease (negative ulnar variance).[4,75]

The distal radius normally rotates around the relatively stationary ulna. The two bones of the forearm articulate at the proximal radioulnar joints and DRUJs. In addition, proximally the radius and ulna articulate with the distal humerus and distally with the carpus. These articulations are necessary for forearm pronation and supination. At the DRUJ, the concave sigmoid notch of the radius incompletely matches the convex, asymmetric, semicylindrical shape of the distal ulnar head.[22,151] This allows some translation at the DRUJ with rotatory movements. The ligamentous structures are critical in stabilizing the radius as it rotates about the ulna (Fig. 11-23).

Treatment Options for Fractures of the Distal Radius and Ulna

Nonoperative Treatment of Fractures of the Distal Radius and Ulna

The goal of pediatric distal radius fracture care is to achieve bony union within acceptable radiographic parameters to optimize long-term function and avoid late complications.

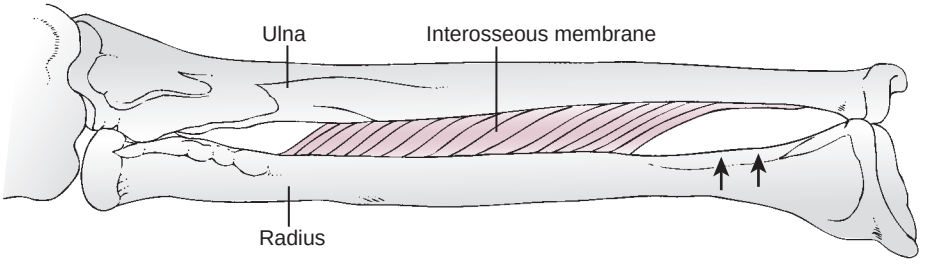

FIGURE 11-20 The attachment and the fibers of the interosseous membrane are such that there is no attachment to the distal radius. (Redrawn from Kraus B, Horne G. Galeazzi fractures. *J Trauma*. 1985; 25:1094, with permission.)

(Adapted from Hafner R, Poznanski AK, Donovan JM. Ulnar variance in children. Standard measurements for evaluation of ulnar shortening in juvenile rheumatoid arthritis, hereditary multiple exostosis and other bone or joint disorders in childhood. *Skel Radiol*. 1989;18:514, with permission.)

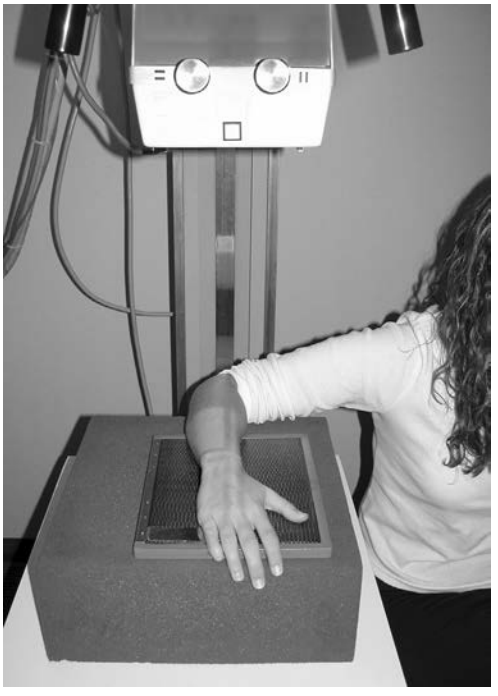

FIGURE 11-22 Technique for neutral rotation radiograph with wrist neutral, forearm pronated, elbow flexed 90 degrees, and shoulder abducted 90 degrees.

Management is influenced tremendously by the remodeling potential of the distal radius in growing children (Fig. 11-24). In general, remodeling potential is dependent upon the amount of skeletal growth remaining, proximity of the injury to the physis, and relationship of the deformity to plane of adjacent joint motion. Fractures in very young children, close to the distal radial physis, with predominantly sagittal plane angulation have the greatest remodeling capacity. Acceptable sagittal plane angulation of acute distal radial metaphyseal fractures has been reported to be from 10 to 35 degrees in patients under

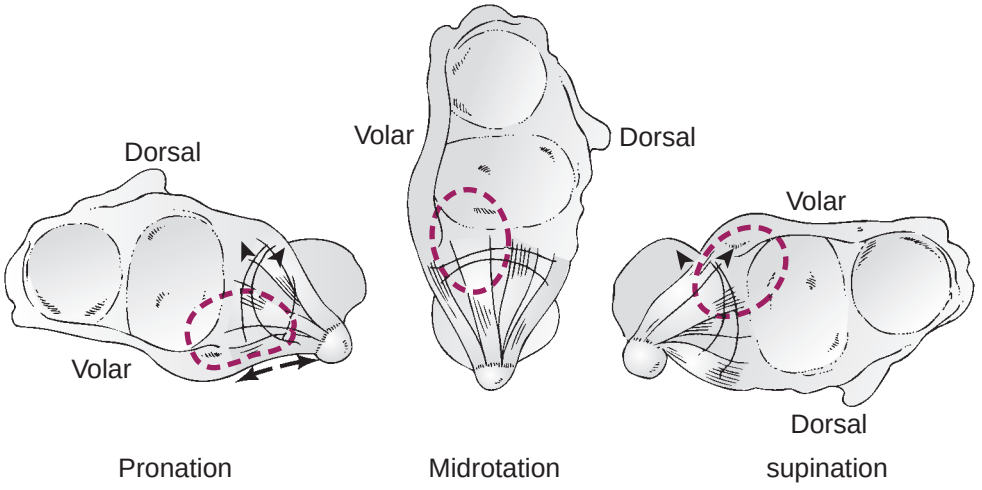

FIGURE 11-23 Distal radioulnar joint stability in pronation (*left*) is dependent on **(A)** tension developed in the volar margin of the triangular fibrocartilage (TFCC, *small arrows*) and **(B)** compression between the contact areas of the radius and ulna (volar surface of ulnar articular head and dorsal margin of the sigmoid notch, *large arrows*). Disruption of the volar TFCC would therefore allow dorsal displacement of the ulna in pronation. The reverse is true in supination, where disruption of the dorsal margin of the TFCC would allow volar displacement of the ulna relative to the radius as this rotational extreme is reached. The dark area of the TFCC emphasizes the portion of the TFCC that is not supported by the ulnar dome. The dotted circle is the arc of load transmission (lunate to TFCC) in that position. (Redrawn from Bowers WH. *Green's Operative Hand Surgery*. New York, NY: Churchill-Livingstone, 1993.)

5 years of age.[63,108,114,147,161,169,209] Similarly, in patients under 10 years of age, the degree of acceptable angulation has ranged from 10 to 25 degrees.[63,108,114,147,161,169,209] For children over 10 years of age, acceptable alignment has ranged from 5 to 20 degrees depending on the skeletal maturity of the patient (Table 11-4).

Criteria for what constitutes acceptable frontal plane deformity have been more uniform. The fracture tends to displace radially with an apex ulnar angulation. This deformity also has remodeling potential,[152,221] but less so than sagittal plane deformity. Most authorities agree that 10 degrees or less of acute malalignment in the frontal plane should be accepted. Greater magnitudes of coronal plane malalignment may not remodel and may result in limitations of forearm rotation (Table 11-4).[42,44,54,62,208]

In general, 20 to 30 degrees of sagittal plane angulation, 10 to 15 degrees of radioulnar deviation, and complete bayonet apposition with reliably remodel in younger children with growth remaining.[50,70,97,221]

Indications/Contraindications

For the reasons cited above, the vast majority of pediatric distal radius fractures may be successfully treated with nonoperative means. General indications for nonoperative treatment include

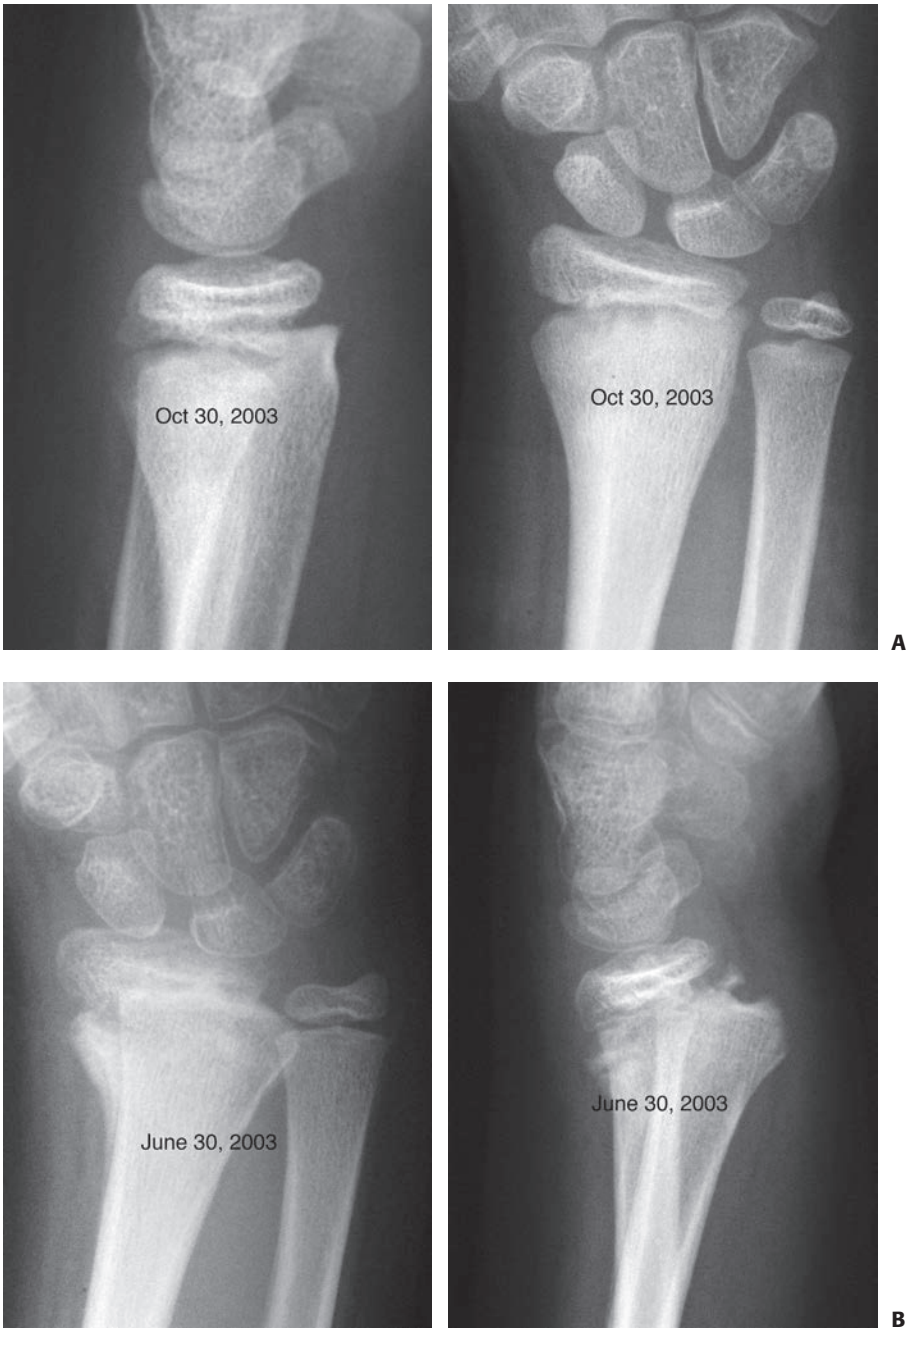

FIGURE 11-24 **A:** AP and lateral views of displaced radial physeal fracture. **B:** Healed malunion 1 month after radial physeal fracture.

D

FIGURE 11-24 (*continued*) **C:** Significant remodeling at 5 months after fracture. **D:** Anatomic remodeling with no physeal arrest.

torus fractures, displaced physeal or metaphyseal fractures within acceptable parameters of expected skeletal remodeling, displaced fractures with unacceptable alignment amenable to closed reduction and immobilization, and late presenting displaced physeal injuries.

Contraindications to nonoperative care include open fractures, fractures with excessive soft tissue injury or neurovascular compromise precluding circumferential cast immobilization, irreducible fractures in unacceptable alignment, unstable fractures failing initial nonoperative care, and fractures with displacement that will not remodel (Table 11-5).

Techniques: Splint Immobilization of Torus Fractures

By definition, torus fractures are compression fractures of the distal radial metaphysis and are therefore inherently stable (Fig. 11-25). There is typically minimal cortical disruption or displacement. As a result, treatment should consist of protected immobilization to prevent further injury and relieve pain. Multiple studies have compared the effectiveness and cost of casting, splinting, and simple soft bandage application in the treatment of torus fractures. As expected, there is little difference in outcome of the various immobilization techniques.[2,21,102,145,161,171,180,205]

TABLE 11-5 Distal Radius Fractures

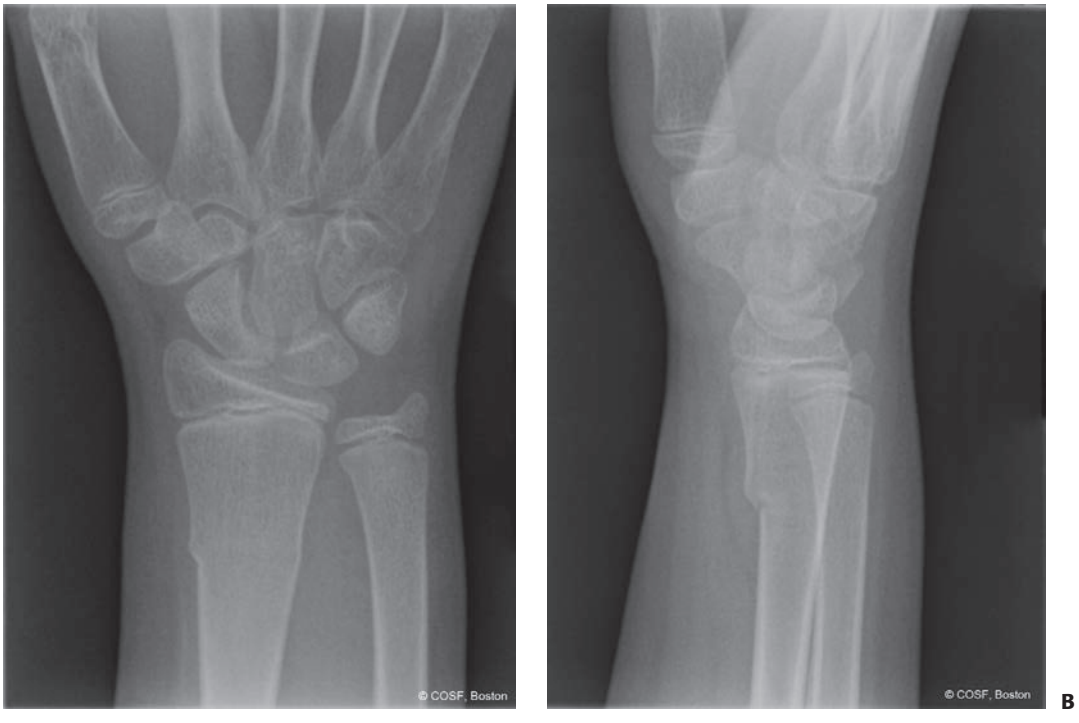
Nonoperative Treatment

Indications	Relative Contraindications
Torus fractures	Open fractures
Nondisplaced fractures	Neurovascular compromise or excessive swelling precluding circumferential cast immobilization
Displaced fractures within acceptable radiographic alignment	Irreducible fracture in unacceptable alignment
Displaced fractures amenable to closed reduction and immobilization	Unstable fractures failing initial reduction and cast immobilization
Late presenting physeal fractures	
Distal radial physeal stress fractures	

Davidson et al.[43] randomized 201 children with torus fractures to plaster cast or removable wrist splint immobilization for 3 weeks. All patients went on to successful healing without complications or need for follow-up clinical visits or radiographs. Similarly, Plint et al.[159] reported the results of a prospective randomized clinical trial in which 87 children were treated with either short-arm casts or removable splints for 3 weeks. Not only were there no differences in healing or pain, but also early wrist function was considerably better in the splinted patients. West et al.[207] even challenged the need for splinting in their clinical study randomizing 39 patients to either plaster casts or soft bandages. Again, fracture healing was universal and uneventful, and patients treated with soft bandages had better early wrist motion.

Given the reliable healing seen with torus fracture healing, Symons et al.[184] performed a randomized trial of 87 patients treated with plaster splints to either hospital follow-up or home removal. No difference was seen in clinical results, and patient/families preferred home splint removal. A similar study by Khan et al.[115] confirmed these findings. No differences in outcomes were seen in 117 patients treated with either rigid cast removal in fracture clinic versus soft cast removal at home, and families preferred home removal of their immobilization.

A recent meta-analysis of torus and minimally displaced fractures treated by removable splints instead of circumferential



A B

casts was found to have improved secondary outcomes for the patient and family and with equal position at healing.[11] Therefore, simple splinting is sufficient, and once the patient is comfortable, range-of-motion exercises and nontraumatic activities may begin. Fracture healing usually occurs in 3 to 4 weeks.[2,10] Simple torus fractures heal without long-term sequelae or complications.

Techniques: Cast Immobilization of Nondisplaced or Minimally Displaced Distal Radial Metaphyseal and Physeal Fractures

Nondisplaced fractures are treated with cast immobilization until appropriate bony healing and pain resolution have been achieved.[47,52,173] Although these fractures are radiographically well aligned at the time of presentation, fracture stability is difficult to assess and a risk of late displacement exists (Fig. 11-26). Serial radiographs are obtained in the first 2 to 3 weeks to confirm maintenance of acceptable radiographic alignment. In general, most fractures will heal within 4 to 6 weeks.

Simple immobilization without reduction may also be considered in minimally displaced fractures within acceptable alignment, based upon patient age and remodeling potential. Hove and Brudvik[98] evaluated a cohort of 88 patients treated nonoperatively for distal radius fractures. Though eight patients had early loss of reduction with greater than 15 to 20 degrees angulation, all demonstrated complete remodeling and restoration of normal function. Al-Ansari et al. similarly evaluated 124 patients with "minimally angulated" distal radius fractures. Even patients who healed with 30 to 35 degrees angulation

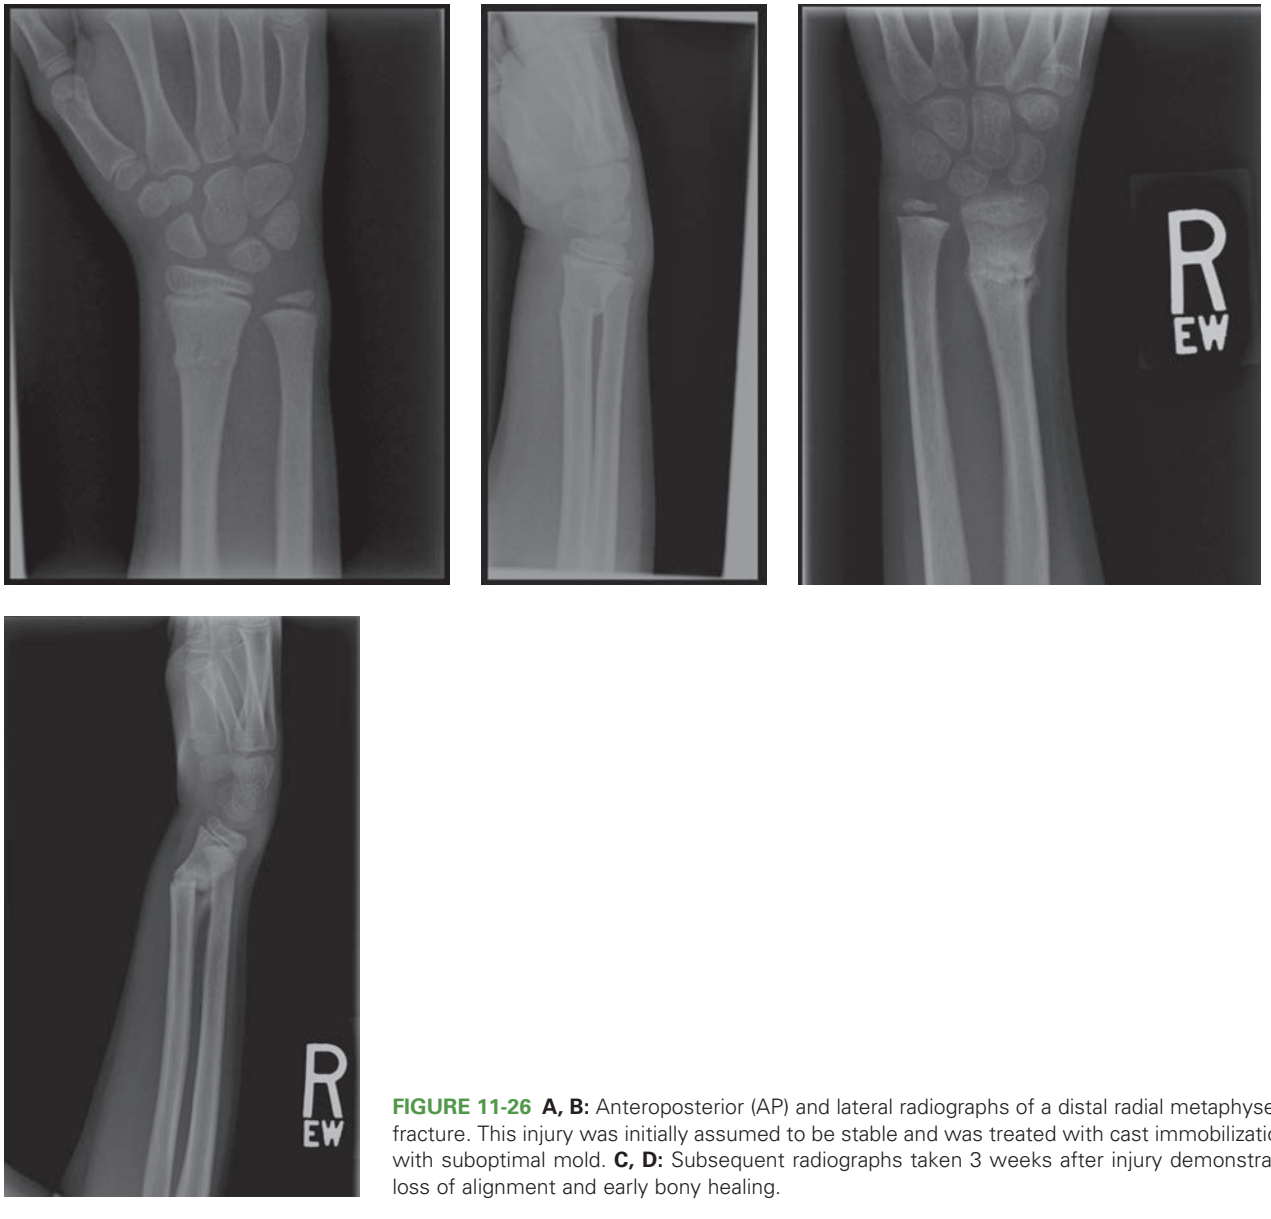

FIGURE 11-26 **A, B:** Anteroposterior (AP) and lateral radiographs of a distal radial metaphyseal fracture. This injury was initially assumed to be stable and was treated with cast immobilization with suboptimal mold. **C, D:** Subsequent radiographs taken 3 weeks after injury demonstrate loss of alignment and early bony healing.

went on to complete fracture remodeling and normal function.[5] Finally, in a prior randomized clinical trial, 96 patients between 5 and 12 years of age with distal radius fractures with less than 15 degrees of sagittal plane angulation were treated with either cast or splint immobilization.[21] No difference were seen in fracture alignment at 6 weeks in the two treatment groups, and functional outcomes did not differ, as measured by the Activity Scale for Kids. Though the risk of late displacement and issues of compliance and comfort exist, this investigation supports the concept that splint immobilization may be considered in younger patients with minimal displacement.

Furthermore, cast immobilization alone without fracture manipulation may be effective in young patients with complete dorsal displacement and bayonet apposition with acceptable sagittal and coronal plane alignments. Recently, Crawford et al. prospectively evaluated 51 children under the age of 10 years treated with cast immobilization for shortened and bayonetted fractures of the distal radial metaphysis.[38,50] All patients went on to complete radiographic remodeling and full return of wrist motion.

Techniques: Reduction and Immobilization of Incomplete Fractures of the Distal Radius and Ulna

Treatment of incomplete distal radial and ulnar fractures is similarly dependent upon patient age and remodeling potential, magnitude, and direction of fracture displacement and angulation, and the biases of the care provider and patient/family regarding fracture remodeling and deformity. In cases of incomplete or greenstick distal radius fractures—with or without ulnar involvement—with unacceptable deformity, closed reduction and cast immobilization are recommended.

The method of reduction for greenstick fractures depends on the pattern of displacement. With apex volar angulated fractures of the radius, the rotatory deformity is supination. Pronating the radius and applying a dorsal-to-volar reduction force is utilized to restore bony alignment. Conversely, fractures with apex dorsal angulation result from pronation mechanisms of injury. Supinating the distal forearm and applying a volar-to-dorsal force should reduce the incomplete fracture of the radius.[135] Though these fractures are incomplete and patients often present with minimal pain, adequate analgesia will facilitate bony reduction and quality of cast application. Typically this is done with the assistance of conscious sedation.[64,79,114]

Following reduction, portable fluoroscopy may be used to evaluate fracture alignment. Once acceptable alignment is achieved, a long-arm cast is applied with appropriate rotation and three-point molds, based upon the initial pattern of injury. Long-arm casting is typically used for the first 4 weeks, and bony healing is achieved in 6 weeks in the majority of patients.

The high potential for remodeling of a distal radial metaphyseal malunion has led some clinicians to recommend immobilization alone.[50] As in the case of torus fractures,[195] a recent study suggests that soft bandages can be applied to treat incomplete green stick forearm fractures;[120] however, as the greenstick fracture is substantially more unstable than the torus fracture[166] the authors do not advocate soft bandage treatment of greenstick fractures.

Techniques: Closed Reduction and Cast Immobilization of Displaced Distal Radial Metaphyseal Fractures

Closed reduction and cast immobilization remains the standard of care for children with displaced distal radial metaphyseal fractures presenting with unacceptable alignment. Again, fracture reduction maneuvers are dependent upon injury mechanism and fracture pattern. In patients with typical dorsal displacement of the distal epiphyseal fracture fragment with apex volar angulation, closed reduction is performed with appropriate analgesia, typically conscious sedation or general anesthesia. Finger traps applied to the ipsilateral digits may facilitate limb positioning and stabilization during fracture reduction but application of weights may hinder reduction by increasing dorsal periosteal tension. Recently, the lower extremity-aided fracture reduction maneuver (LEAFR) has been proposed as a simple, effective, reproducible, and mechanically advantageous technique of effectuating closed reductions in children with bayoneted distal radius fractures.[59] Given the stout, intact dorsal periosteum in these injuries, pure longitudinal traction is often insufficient to restore bony alignment, particularly in cases of bayonet apposition. Fracture reduction is performed first by hyperextension and exaggeration of the deformity, which relaxes the dorsal periosteal sleeve (Fig. 11-27). Longitudinal traction is then applied to restore adequate length. Finally, the distal fracture fragment is flexed to correct the translational and angular displacement, with rotational correction imparted as well. If available, fluoroscopy may be utilized to confirm adequacy of reduction, and a well-molded cast is applied.

The optimal type of cast immobilization remains controversial. Both long- and short-arm casts have been proposed following distal radial fracture reduction.[31,88,93,205] Long-arm casts have the advantage of restricting forearm rotation and theoretically reducing the deforming forces imparted to the distal radius. However, above elbow immobilization is more inconvenient and has been associated with greater need for assistance with activities of daily living, as well as more days of school missed.[205] Prior randomized controlled trials have demonstrated that short-arm casts are as effective at maintaining reduction as long-arm casts, provided that acceptable alignment is achieved and an appropriate cast mold is applied.[20,205] A recent meta-analysis pooling the results of over 300 study subjects have further supported these findings.[93]

Perhaps more important than the length of the cast applied is the cast mold applied at the level of the fracture (Fig. 11-28). Appropriate use of three-point molds will assist in maintenance of alignment in bending injuries. Similarly, application of interosseous mold will help to maintain interosseous space between the radius and ulna as well as coronal plane alignment. A host of radiographic indices have been proposed to quantify and characterize the quality of the cast mold, including the cast index, three-point index, gap index, padding index, Canterbury index, and second metacarpal/distal radius angle

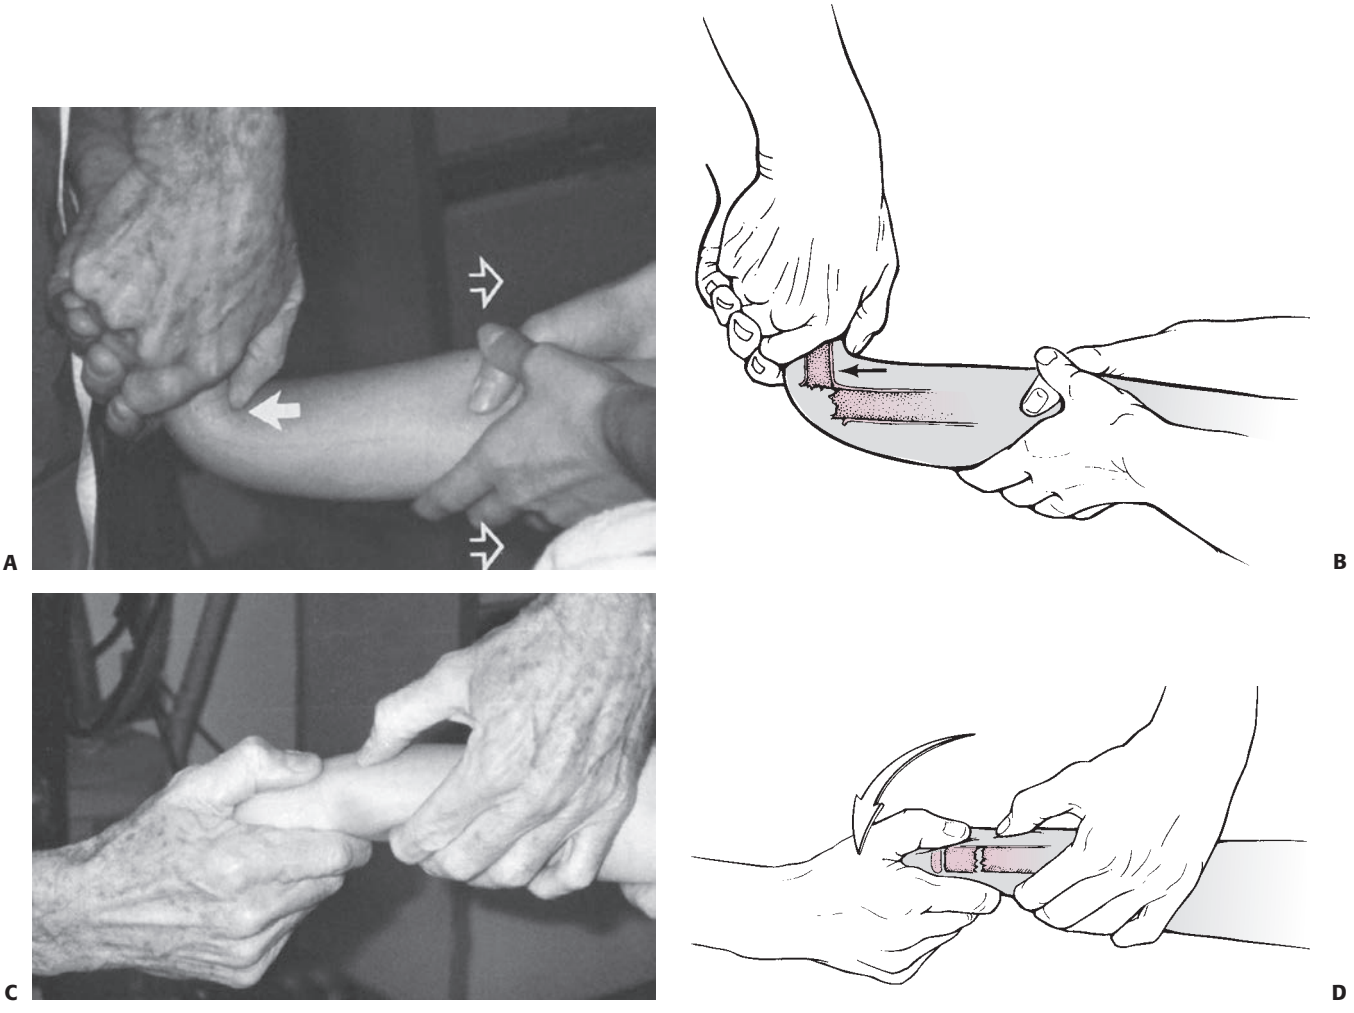

FIGURE 11-27 **A, B:** Use of the thumb to push the distal fragment hyperdorsiflexed 90 degrees (*solid arrow*) until length is reestablished. Countertraction is applied in the opposite direction (*open arrows*). **C, D:** Once length has been reestablished, the distal fragment is flexed into the correct position. Alignment is checked by determining the position of the fragments with the thumb and forefingers of each hand.

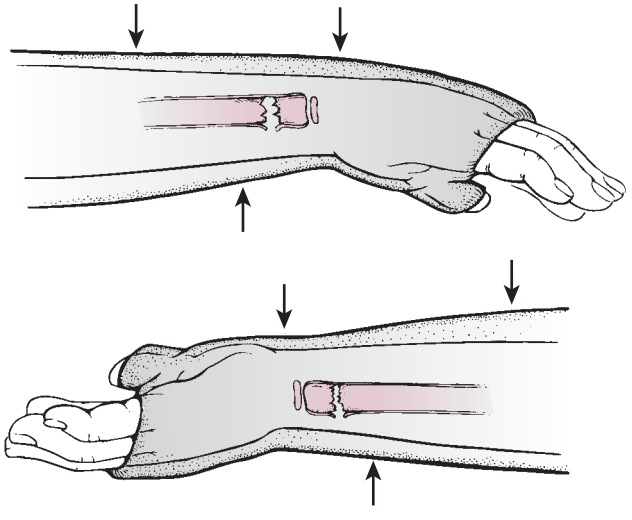

FIGURE 11-28 Three-point molding. **Top:** Three-point molding for dorsally angulated (apex volar) fractures, with the proximal and distal points on the dorsal aspect of the cast and the middle point on the volar aspect just proximal to the fracture site. **Bottom:** For volar angulated fractures, where the periosteum is intact volarly and disrupted on the dorsal surface, three-point molding is performed with the proximal and distal points on the volar surface of the cast and the middle point just proximal to the fracture site on the dorsal aspect of the cast.

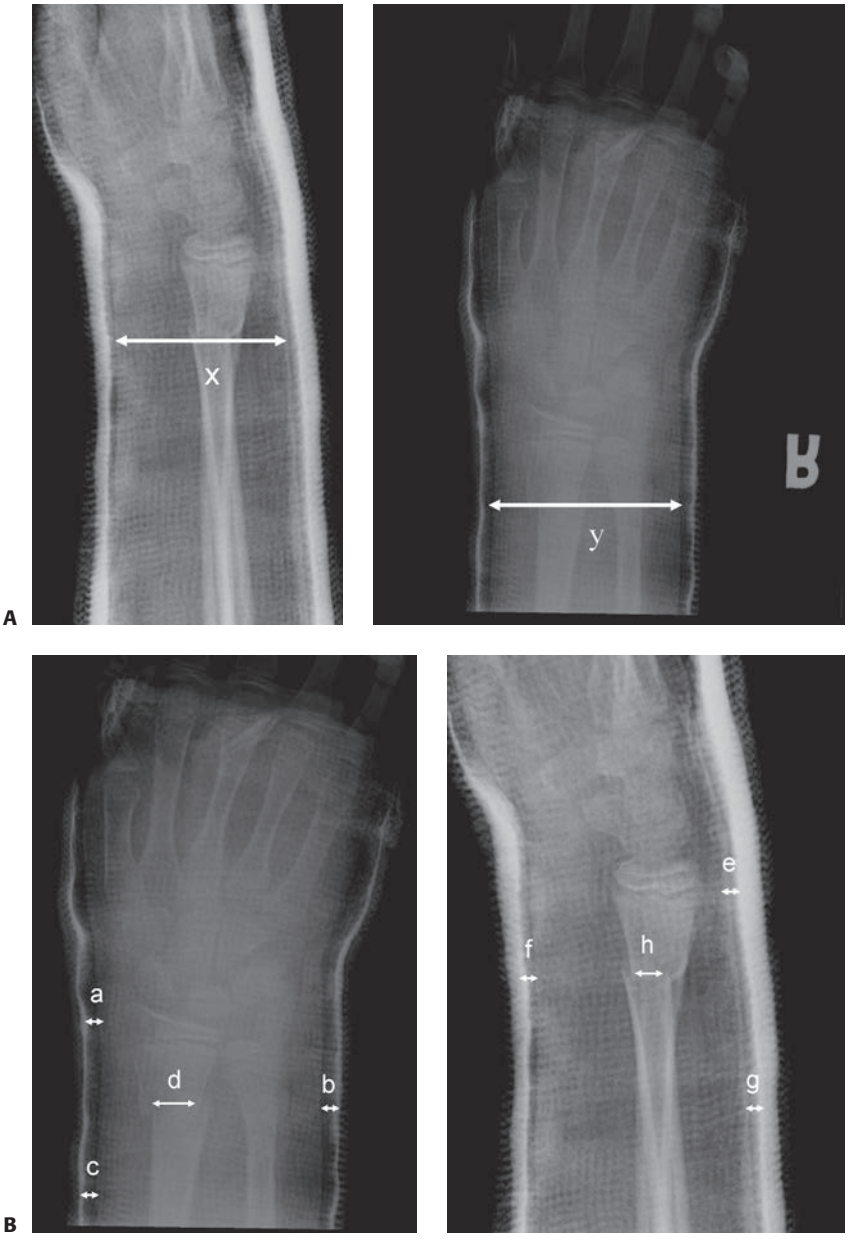

FIGURE 11-29 Radiographic evaluation of cast mold. **A:** Cast index (x/y) is the ratio of the inner cast diameter at the level of the fracture on the lateral projection (x) to the inner cast diameter at the level of the fracture as seen on the anteroposterior (AP) view (y). **B:** The three point index ([(a + b + c)/x] + [(d + e + f)/y]) is the sum of the three critical gaps divided by the contact area of the fracture fragments as assess on both the AP and lateral views.

(Fig. 11-29).[10,57,90,162] Although the cast index is easily calculated and perhaps most widely utilized, some authorities tout the three-point index as the preferred index for this assessment and prediction of redisplacement.[48]

Complete fractures of the distal radius have a higher rate of loss of reduction after closed treatment than do incomplete fractures (Fig. 11-30).[246] Indeed, prior investigations have demonstrated that 20% to 30% of patients will have radiographic loss of reduction following closed reduction and casting of displaced distal radius fractures. Risk factors for loss of reduction include greater initial fracture displacement and/or comminution, suboptimal reduction, suboptimal cast mold, associated distal ulnar fractures.[7,10,48,57,90,139,162]

Given the risk of radiographic loss of reduction, serial radiographs are recommended in the early postinjury period. Weekly radiographs are obtained in the first 2 to 3 weeks following reduction to confirm adequacy of alignment. Failure to identify and correct malalignment in the early postinjury period may lead to malunion and subsequent clinical loss of motion and upper limb function.

FIGURE 11-30 **(A)** Serial radiographs at 3 days and 10 days **(B)** revealing slow loss of reduction that is common after closed reduction of distal radial metaphyseal fractures.

Malalignment of fractures during the development of soft tissue callus before bridging ossification (injury to 2 to 3 weeks after reduction) often can be realigned using cast wedging (Fig. 11-31).[14,17,36,85,101,190,206] Recently, this technique has been utilized less frequently given the advances in surgical management of fractures. Authors have advocated opening wedges, closing wedges, as well as a combination of each of these approaches. Most commonly we use open wedge techniques as closing wedges have the potential for pinching of the skin and causing accumulation of cast padding at the wedge site which may cause skin breakdown.[85,101] In addition, closing wedges also may shorten and reduce the volume of the cast thus decreasing fracture stability. There have been multiple techniques proposed for predicting the size of a wedge. Bebbington et al.[14] suggested a technique that involves tracing the angle of displacement onto the cast itself thus representing the fracture fragments. Wedges are then inserted until the malalignment is reduced as the traced line becomes straight. Wells et al. recently

FIGURE 11-31 Lateral fluoroscopic projection of a distal radius fracture treated with dorsal cast wedging to correct loss of reduction.

described a technique in which the wedge position and opening angle are determined from the radiographic displacement and center of rotational alignment. Utilizing these methods on saw bones, they were able to reduce malalignment within 5 degrees with 90% success.[206] Regardless of the method, if utilized appropriately, cast wedging reduces the risk of additional anesthesia and potential surgery.

Techniques: Displaced Distal Radial Physeal Fractures

Most displaced Salter–Harris I and II fractures are treated with closed reduction and cast stabilization. Closed manipulation of the displaced fracture is similarly performed with appropriate conscious sedation, analgesia, or, rarely, anesthesia to achieve pain relief and an atraumatic reduction.[64,79,114] Most of these fractures involve dorsal and proximal displacement of the epiphysis with an apex volar extension deformity. Manipulative reduction is by gentle distraction and flexion of the distal epiphysis, carpus, and hand over the proximal metaphysis (Fig. 11-32). The intact dorsal periosteum is used as a tension band to aid in reduction and stabilization of the fracture. Unlike similar fractures in adults, finger trap distraction with pulley weights is often counterproductive. However, finger traps can help stabilize the hand, wrist, and arm for manipulative reduction and casting by applying a few pounds of weight for balance. Otherwise, an assistant is helpful to support the extremity in the proper position for casting.

If portable fluoroscopy is available, immediate radiographic assessment of the reduction is obtained. Otherwise, a well-molded cast is applied and AP and lateral radiographs are obtained to assess the reduction. The cast should provide three-point molding over the distal radius to lessen the risk of fracture displacement and should follow the contour of the normal forearm. The distal dorsal mold should not impair venous outflow from the hand, which can occur if the mold is placed too distal and too deep so as to obstruct the dorsal veins. Advocates of short-arm casting indicate at least equivalent results with proper casting techniques and more comfort during immobilization due to free elbow mobility. Instructions for elevation and close monitoring of swelling and the neurovascular status of the extremity are critical.

The fracture also should be monitored closely with serial radiographs to be certain that there is no loss of anatomic alignment (Fig. 11-33). Generally, these fractures are stable after closed reduction and cast immobilization. If there is loss of reduction after 7 days, the surgeon should be wary of repeat reduction, as forceful remanipulation may increase the risk of

A, B **C**

FIGURE 11-32 **A:** Lateral radiograph of dorsally displaced Salter–Harris type II fracture. **B:** Lateral radiograph after closed reduction and cast application. **C:** Reduction of the volar displaced fracture. The forearm was in supination with three-point molding anterior over the distal epiphysis and proximal shaft (*white arrows*). The third point is placed dorsally over the distal metaphysis (*open arrow*). (The dorsal surface of the cast is oriented toward the bottom of this figure.) FIGURE 11-33 A: AP and lateral radiographs of severely displaced Salter–Harris type II fracture of the distal radius. **B:** Closed reduction shows marked improvement but not anatomic reduction. The case had to be bivalved due to excess swelling.

iatrogenic physeal arrest.[27,125,174] Fortunately, remodeling of an extension deformity with growth is common if the patient has more than 2 years of growth remaining and the deformity is less than 20 degrees. Even marked deformity can remodel if there is sufficient growth remaining and the deformity is in the plane of motion of the wrist.

Techniques: Galeazzi Fractures

Nonoperative management remains the first-line treatment for pediatric Galeazzi fractures, distinguishing these injuries from their adult counterparts.[56,169,198] Indeed, the adult Galeazzi fracture has been often called a "fracture of necessity," given the near universal need for surgical reduction and internal fixation to restore anatomic radial alignment and DRUJ congruity. In pediatric patients, however, the distal radial fracture often is a greenstick type that is stable after reduction; therefore, nonoperative treatment with closed reduction and cast immobilization is sufficient.[109,169] Surgical treatment may be considered for adolescents with complete fractures and displacement, as their injury pattern, skeletal maturity, and remodeling potential is more similar to the adult Galeazzi.

Incomplete fractures of the distal radius with either a true dislocation of the DRUJ or an ulnar physeal fracture are treated with closed reduction and long-arm cast immobilization. This can be done in the emergency room with conscious sedation or in the operating room with general anesthesia. Portable fluoroscopy is useful in these situations. If the radius fracture has apex volar angulation and dorsal displacement of the radius—and associated volar dislocation of the ulnar head in relationship to the radius, pronation and volar-to-dorsal force on the radial fracture is used for reduction. Conversely, if the radius fracture is apex dorsal with volar displacement and dorsal dislocation of

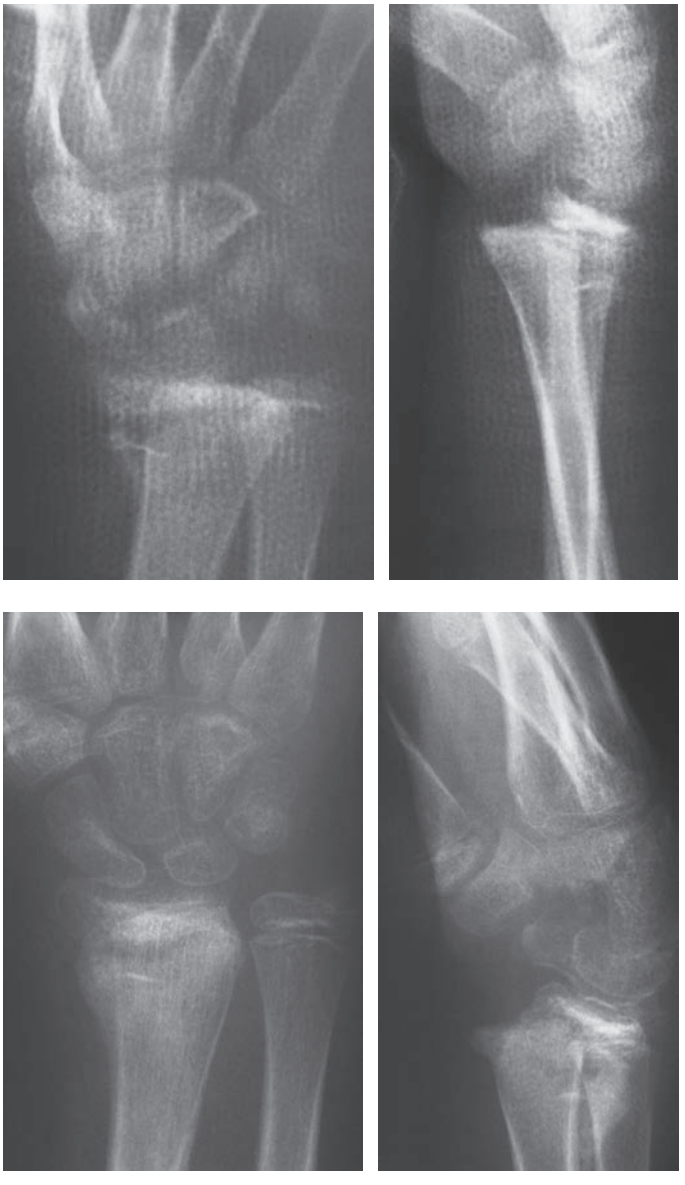

FIGURE 11-33 (*continued*) **C:** Unfortunately the patient lost reduction after a new fiberglass cast was applied. **D:** Out-of-cast radiographs show a healed malunion in a similar position to the prereduction radiographs.

the distal ulna, supination and dorsal-to-volar force is utilized during reduction. The reduction and stability of the fracture and DRUJ dislocation may then be checked on dynamic fluoroscopy; if both are anatomically reduced and stable, a long-arm cast with the forearm in the appropriate rotatory position (i.e., pronation or supination) is applied. Six weeks of long-arm casting is recommended to allow for sufficient bony and soft tissue healing.

In patients with Galeazzi equivalent injuries characterized by complete distal radius fractures associated with ulnar physeal fractures, both bones should be reduced. Usually, this can be accomplished with the same methods of reduction as when the radial fracture is incomplete. If there is sufficient growth remaining and the distal ulnar physis remains open, remodeling of a nonanatomic distal ulnar physeal reduction may occur. As long as the DRUJ is reduced, malalignment of less than 10 degrees can remodel in a young child. DRUJ congruity and stability, however, are dependent upon distal ulnar alignment, and great care should be taken in assessment of the DRUJ when accepting a nonanatomic distal ulnar reduction. Furthermore, the risk of ulnar growth arrest after a Galeazzi equivalent has been reported to be as high as 55%.[81] If the fracture is severely malaligned, the DRUJ cannot be reduced, or the patient is older and remodeling is unlikely, open reduction and smooth pin fixation are indicated.[209]

Techniques: Distal Radial Physeal Stress Fractures

Treatment of distal physeal stress injuries first and foremost involves rest. This activity restriction may be challenging in the pediatric athlete, depending on the level of the sports participation and the desires of the child, parents, and other stakeholders to continue athletic participation. Education regarding the long-term consequences of a growth arrest is important in these emotionally charged situations. Short-arm cast immobilization for several weeks may be the only way to restrict stress to the distal radial physis in some patients. Splint protection is

appropriate in cooperative patients. Protection should continue until there is resolution of tenderness and pain with activity. The young athlete can maintain cardiovascular fitness, strength, and flexibility while protecting the injured wrist. Once the acute physeal injury has healed, return to weight-bearing and open-chain activities should be gradual. The process of return to sports should be gradual, often 3 to 6 months, and adjustment of techniques and training methods is necessary to prevent recurrence. The major concern is development of a radial growth arrest in a skeletally immature patient, and consideration should be given to serial clinical and radiographic follow-up in high-risk patients to confirm maintenance of growth.

Techniques: Distal Ulna Physeal Fractures

Treatment options are similar to those for radial physeal fractures: immobilization alone, closed reduction and cast immobilization, closed reduction and percutaneous pinning, and open reduction. Often, these fractures are minimally displaced or nondisplaced. Immobilization until fracture healing at 3 to 6 weeks is standard treatment. Closed reduction is indicated for displaced fractures with more than 50% translation or 20 degrees of angulation. Most ulnar physeal fractures reduce to a near anatomic alignment with reduction of the concomitant radius fracture due to the attachments of the DRUJ ligaments and TFCC. Failure to obtain a reduction of the ulnar fracture may indicate that there is soft tissue interposed in the fracture site, necessitating open reduction and fixation.

Outcomes

Most of the published literature provide information on the short-term clinical and radiographic results of treatment for pediatric distal radius fractures indicates a positive outcome. With adherence to the principles and techniques described above, radiographic realignment, successful bony healing, and avoidance of complications are achieved in the majority of cases. Given the high healing capacity and remodeling potential of these injuries, there is less concern regarding long-term outcomes of nonoperative treatment compared with adult patients. In general, concerns regarding long-term outcomes have focused on patients who sustain distal radial physeal fractures and thus are at risk for subsequent growth disturbance and skeletal imbalance of the distal forearm.

The risk of growth disturbance following distal radial physeal fractures is approximately 4%. Cannata et al.[27] previously reported the long-term outcomes of 163 distal radial physeal fractures in 157 patients. Displaced fractures were treated with closed reduction and cast immobilization for 6 weeks. Mean follow-up was 25.5 years. Posttraumatic growth disturbance resulting in 1cm or greater of length discrepancy was seen in 4.4% of distal radial and 50% of distal ulnar physeal fractures. In a similar prospective analysis of 290 children with distal radial physeal fractures, Bae and Waters[12] noted that 4% of patients went on to demonstrate clinical or radiographic distal radial growth disturbance. Consideration should be given for follow-up radiographic evaluation following distal radial physeal fractures to assess for possible physeal arrest. In symptomatic patients with posttraumatic growth disturbance and growth remaining, surgical interventions including distal ulnar epiphysiodeses, corrective osteotomies of the radius, ulnar shortening osteotomies, and associated soft tissue reconstructions have been demonstrated to improve clinical function and radiographic alignment.[201]

Operative Treatment of Fractures of the Distal Radius and Ulna

Indications/Contraindications

Although surgical indications and techniques continue to evolve, in general surgical indications for pediatric distal radius and ulna fractures include open fractures, irreducible fractures, unstable fractures, floating elbow injuries, and fractures with soft tissue or neurovascular compromise precluding circumferential cast immobilization. Surgical reduction and fixation is also indicated in cases of joint incongruity associated with intra-articular Salter–Harris III, IV, or "triplane" fractures.

Distal radial fracture stability has been more clearly defined in adults[204] than in children. At present, an unstable fracture in a child is often defined as one in which closed reduction cannot be maintained. Pediatric classification systems have yet to more precisely define fracture stability, but this issue is critical in determining proper treatment management. As noted above, distal radial metaphyseal fractures have been shown to have a high degree of recurrent displacement and, therefore, inherent instability[7,10,48,57,90,138,162,204] For these reasons, pediatric distal radial metaphyseal fractures are not classified in the same manner as adults in regard to stability. Instead, unstable fractures have been predominately defined by the failure to maintain a successful closed reduction. Irreducible fractures usually are due to an entrapped periosteum or pronator quadratus.

Surgical treatment is similarly recommended in patients with neurovascular compromised and severely displaced injuries. Operative stabilization serves both to maintain adequate bony alignment and more importantly, minimize the risk of compartment syndrome due to excessive swelling and circumferential immobilization. Perhaps the best indication is a displaced radial physeal fracture with median neuropathy and significant volar soft tissue swelling (Fig. 11-34).[202] These patients are at risk for development of an acute carpal tunnel syndrome or forearm compartment syndrome with closed reduction and well-molded cast immobilization.[15,44,202] The torn periosteum volarly allows the fracture bleeding to dissect into the volar forearm compartments and carpal tunnel. If a tight cast is applied with a volar mold over that area, compartment pressures can increase dangerously. Percutaneous pin fixation allows the application of a loose dressing, splint, or cast without the risk of loss of fracture reduction.

Internal fixation usually is with smooth, small-diameter pins to lessen the risk of growth arrest. Plates and screws rarely are used unless the patient is near skeletal maturity because of concerns about further physeal injury. In the rare displaced intra-articular Salter–Harris type III or IV fracture, internal fixation can be intraepiphyseal without violating the physis. If it is necessary to cross the physis, then smooth, small-diameter pins should be used to lessen the risk of iatrogenic physeal injury. Extra-articular external fixation also can be used to stabilize and align the fracture.

FIGURE 11-34 **A:** Clinical photograph of patient with a displaced Salter–Harris type II fracture of the distal radius. The patient has marked swelling volarly with hematoma and fracture displacement. The patient had a median neuropathy upon presentation. **B:** Lateral radiograph of the displaced fracture. **C:** Lateral radiograph following closed reduction and cast application. Excessive flexion has been utilized to maintain fracture reduction, resulting in persistent median neuropathy and increasing pain. **D:** Radiographs following urgent closed reduction and percutaneous pinning. **E:** Follow-up radiograph depicting distal radial physeal arrest and increased ulnar variance.

Surgical Procedure: Closed Reduction and Pin Fixation of Displaced Distal Radial Fractures

Preoperative Planning. Preoperative planning begins with careful clinical and radiographic evaluation. Thorough neurovascular examination is performed to assess for signs and symptoms of nerve injury or impending compartment syndrome. Radiographs—both from the time of injury, after initial attempts at closed reduction, and any subsequent follow-up radiographs—are carefully evaluated to assess pattern of injury and direction of instability.

TABLE 11-6 Closed Reduction and Pin Fixation of Distal Radius Fractures

Preoperative Planning Checklist

- OR Table: Standard
- Position/positioning aids: Supine position with affected limb supported by radiolucent hand table or image intensifier of fluoroscopy unit
- Fluoroscopy location: Variable, dependent upon surgeon position
- Equipment: Smooth Kirschner (K)-wires, typically 0.045″ or 0.062″ in diameter
- Tourniquet (sterile/nonsterile): nonsterile tourniquet

Given the relative simplicity of closed reduction and percutaneous fixation techniques, minimal equipment is required. Intraoperative fluoroscopy and surgical instrumentation for pin placement are typically sufficient (Table 11-6).

Positioning. After adequate induction of general anesthesia, patients are positioned supine on a standard operating table, with the affected limb abducted and supported on a radiolucent hand table. While a nonsterile tourniquet may be applied to the proximal brachium, this is typically not utilized. Fluoroscopy may be brought in from the head, foot, or side of the patient, depending on surgeon position and preference. For example, as most pinning is performed from distal to proximal, the right-hand dominant surgeon may wish to sit in the axilla and have the fluoroscopy unit come in from the head of the patients when pinning a left distal radius.

Surgical Approach(es). While percutaneous pinning may be performed without need for skin incision, placement of K-wires into the region of the radial styloid carries the risk of iatrogenic radial sensory nerve or extensor tendon injury.[135] For this reason, a small longitudinal incision over the radial styloid at the site of pin insertion may be utilized to identify and retract adjacent soft tissues, facilitating safe pin passage. Alternatively, smooth pins may be inserted using an oscillating technique.

FIGURE 11-35 Small incision noted with pins left out of skin for removal at 4 weeks.

Pin Fixation. After appropriate anesthesia, closed reduction of the distal radius fracture into anatomic alignment is performed, using the principles and techniques previously described. While maintaining fracture reduction, a skin incision is made over the radial styloid, long enough to ascertain there is no iatrogenic injury to the radial sensory nerve or extensor tendons (Fig. 11-35). Careful longitudinal spreading is performed in the subcutaneous tissues, and the radial sensory nerve and extensor tendons may be identified and carefully retracted. Pin fixation can be either single or double, though often a single pin will suffice (Fig. 11-36). A smooth pin is then inserted into the distal fracture fragment and passed obliquely in a proximal

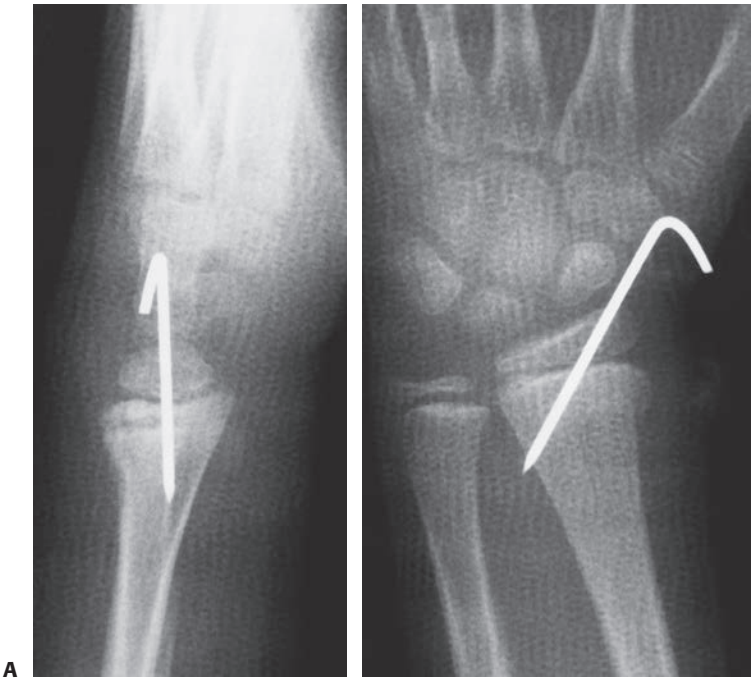

FIGURE 11-36 A: AP and lateral radiographs of displaced Salter–Harris type II fracture pinned with a single pin.

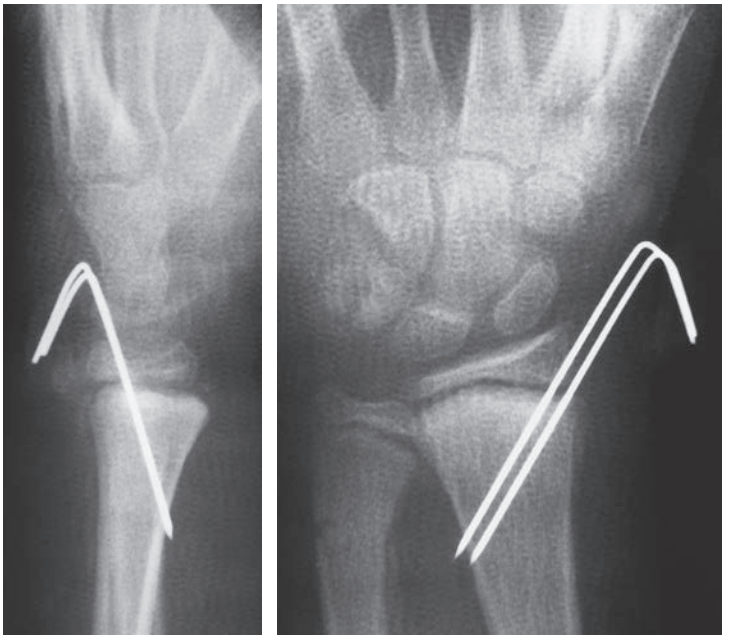

FIGURE 11-36 (*continued*) **B:** After reduction and pinning with parallel pins.

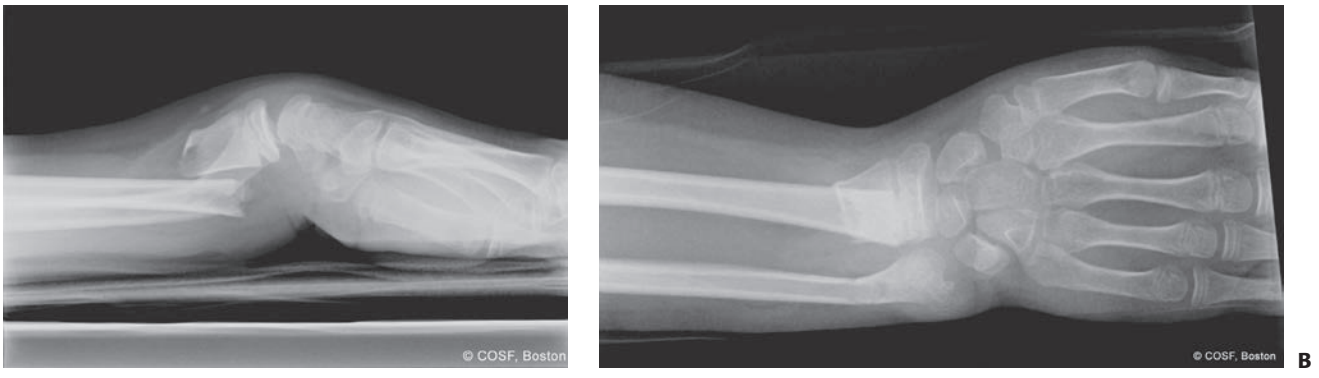

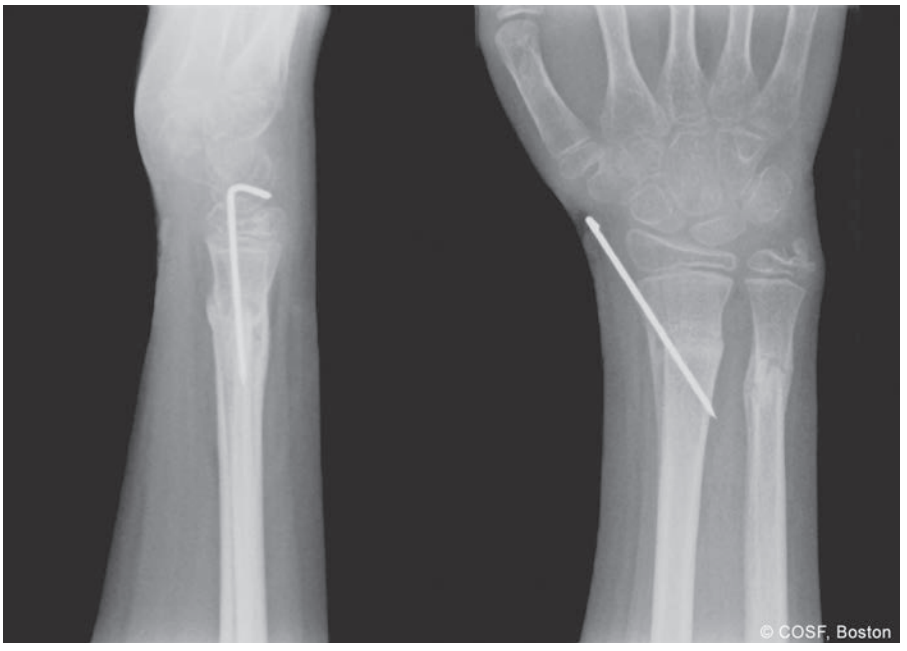

FIGURE 11-37 Severe swelling. **A, B:** Complete displacement and bayonet apposition of a distal radial fracture associated severe swelling from a high-energy injury. **C:** Once reduced, the fragment was secured with an oblique percutaneous pin across the fracture site, sparing the distal radial physis.

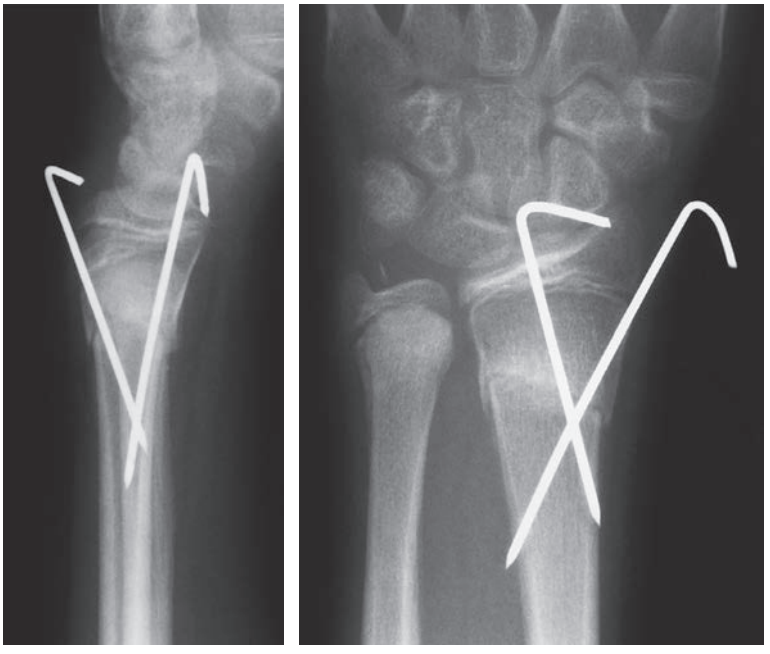

FIGURE 11-38 Crossed-pin technique for stabilization of distal radial metaphyseal fracture in a skeletally immature patient.

and ulnar fashion, crossing the fracture site and engaging the far ulnar cortex proximal to the fracture line. Fluoroscopy is used to guide proper fracture reduction and pin placement.

Pin(s) may be placed within the distal radial epiphysis and passed across the physis before engaging the more proximal metaphyseal fracture fragment. Alternatively, smooth pins may be placed just proximal to the distal radial physis; while theoretically decreasing the risk of physeal disturbance, this has not been well demonstrated in the published literature.[252]

Stability of the fracture should be evaluated with flexion and extension and rotatory stress under fluoroscopy. Often in children and adolescents, a single pin and the reduced periosteum provide sufficient stability to prevent redisplacement of the fracture (Fig. 11-37). If fracture stability is questionable with a single pin, a second pin should be placed. The second pin can either parallel the first pin or, to create cross-pin stability, can be placed distally from the dorsal ulnar corner of the radial epiphysis between the fourth and fifth dorsal compartments and passed obliquely to the proximal radial portion of the metaphysis (Fig. 11-38). Again, the skin incisions for pin placement should be sufficient to avoid iatrogenic injury to the extensor tendons.

The pins are bent, left out of the skin, and covered with petroleum guaze and sterile dressing. Splint or cast immobilization is used but does not need to be tight, as fracture stability is conferred by the pins. The pins are left in until there is adequate fracture healing (usually 4 weeks). The pins can be removed in the office without sedation or anesthesia.

One of the arguments against pin fixation is the risk of additional injury to the physis by a pin.[23] The risk of physeal arrest is more from the displaced fracture than from a short-term, smooth pin. As a precaution, smooth, small-diameter pins should be used, insertion should be as atraumatic as possible, and removal should be done as soon as there is sufficient fracture healing for fracture stability in a cast or splint alone.

Another pinning technique involves intrafocal placement of multiple pins into the fracture site to lever the distal fragment into anatomic reduction (Fig. 11-39). The pins are then passed through the opposing cortex for stability.[129,192] A supplemental, loose-fitting cast is applied (Table 11-7).

Surgical Procedure: Open Reduction and Fixation

Preoperative Planning. Open reduction is indicated for open or irreducible fractures. Open fractures constitute approximately 1% of all distal radial metaphyseal fractures. Although treatment approaches to open fractures continue to evolve, at

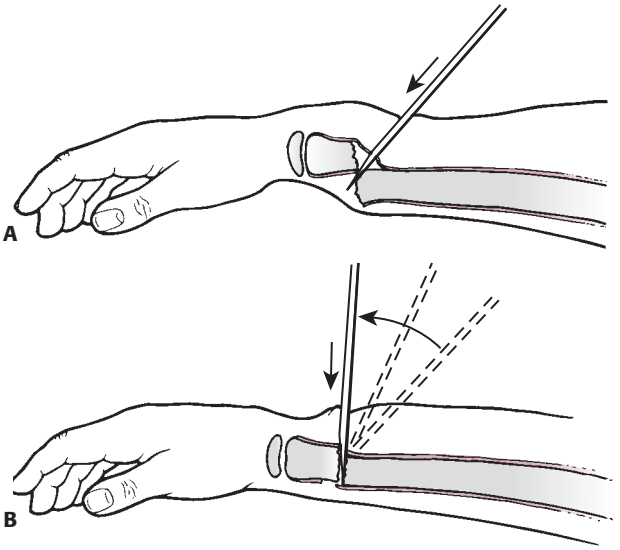

FIGURE 11-39 Pin leverage. **A:** If a bayonet is irreducible, after sterile preparation, a chisel-point Steinmann pin can be inserted between the fracture fragments from a dorsal approach. Care must be taken not to penetrate too deeply past the dorsal cortex of the proximal fragment. **B:** Once the chisel is across the fracture site, it is levered into position and supplementary pressure is placed on the dorsum of the distal fragment (*arrow*) to slide it down the skid into place. This procedure is usually performed with an image intensifier.

TABLE 11-7 Closed Reduction and Pin Fixation of Distal Radius Fractures

Surgical Steps

- Closed reduction of distal radius fracture
- Confirm bony alignment with intraoperative fluoroscopy
- Small incision over radial styloid
  - Longitudinal spreading in subcutaneous tissues
  - Retraction/protection of radial sensory nerve and extensor tendons
- Place smooth K-wire from distal fracture fragment, across fracture site, engaging the ulnar cortex of the proximal fracture fragment
  - Fluoroscopic confirmation of pin trajectory and placement
- Assess fracture stability
- Place second K-wire if needed
  - Cross-pinning may be performed from dorsoulnar corner of distal radial epiphysis proximally and radially into proximal fracture fragment
- Assess stability
- Bend and cut pins outside of skin
- Sterile dressing and cast application
- Pin removal after adequate bony healing, typically in 4 wks

present the standard of care remains surgical irrigation and debridement, followed by appropriate fracture care (also see controversies regarding nonoperative management of open fractures).

Irreducible metaphyseal or physeal fractures are rare and generally are secondary to interposed soft tissues. With dorsally displaced fractures, the interposed structure usually is the volar periosteum or pronator quadratus[95] and rarely the flexor tendons or neurovascular structures.[95,112,214] In volarly displaced fractures, the periosteum or extensor tendons may be interposed.

Closed reduction rarely fails if there is no interposed soft tissue. Occasionally, however, multiple attempts at reduction of a bayonet apposition fracture can lead to significant swelling that makes closed reduction impossible. If the patient is too old to remodel bayonet apposition, open reduction is appropriate.

Plate fixation can be used in more skeletally mature adolescents. Low-profile, fragment-specific fixation methods and locking plates also are now commonly used for internal fixation of distal radial fractures in adults. The utility of these anatomically contoured locking plates in children and skeletally immature adolescents is unknown, as is the deleterious effect, if any, on growth potential. Furthermore, the advantage of these more rigid constructs in younger patients in whom adequate stability may be achieved with pins is unclear, particularly given the reports of late tendon rupture and other soft tissue complications associated with fixed-angle volar plates,[165] Indications for skeletally mature adolescents are the same as for adults. Articular malalignment and comminution are assessed by CT preoperatively, and fracture-specific fixation is used as appropriate.

Preoperative planning for open reduction and fixation is similar to the approach cited above, with a few additional considerations. Assessment of skeletal maturity and physeal status is important, particularly when considering use of implants which rigidly engage the distal radial epiphysis and when open reduction may potentially increase the risk of physeal disturbance. Secondly, children are not small adults, and care should

TABLE 11-8 Open Reduction and Fixation of Distal Radius Fractures

Preoperative Planning Checklist

- OR Table: Standard
- Position/positioning aids: Radiolucent hand table
- Fluoroscopy location: Variable depending upon surgeon preference
- Equipment: Smooth K-wires (0.0625" diameter), small fragment 3.5-mm plates and screws, precontoured volar locking plates in older patients or intra-articular fractures
- Tourniquet (sterile/nonsterile): Nonsterile tourniquet placed on ipsilateral proximal brachium

be made to evaluate the width of the distal radial metaphysis and epiphysis. Use of precontoured volar locking plates typical of adult distal radius fractures may not be feasible, given size mismatch and/or presence of an open distal radial physis. Finally, care should be made to assess for articular extension of the fracture. Anatomic realignment of the distal radial joint surface is critical, even in the young child (Table 11-8).

Positioning. Patients are positioned supine with the affected limb supported by a radiolucent hand table. Positioning of the fluoroscopic unit is similar to that in closed reduction and pinning techniques.

Surgical Approach(es). All open fractures, regardless of grade of soft tissue injury, should be irrigated and debrided in the operating room (Fig. 11-40). The open wound should be enlarged adequately to debride the contaminated and nonviable tissues and protect the adjacent neurovascular structures.

A **B**

FIGURE 11-40 Open fractures. Radiograph **(A)** and clinical photo **(B)** of an open fracture of the distal radius. This patient needs formal irrigation and debridement in the operating room.

Judicious extension of the traumatic wound will allow for extensile exposure, facilitate fracture reduction, and allow for implant placement.

Open reduction for closed unstable or irreducible fractures is typically performed through a volar approach to the distal radius. A longitudinal incision overlying the flexor carpi radialis (FCR) tendon is created, centered on the fracture site with awareness of the location of the distal radial physis. Classically, superficial dissection is carried out in the interval between the radial artery and the FCR. In distal radius fractures, dissection may also be performed directly through the FCR sheath by incising the roof of the FCR sheath and retracting the tendon ulnarly; the intact radial FCR sheath, when retracted, will serve to protect the adjacent radial artery. Deep to the FCR, a fat plane will be encountered overlying the pronator quadratus. The pronator quadratus is incised along its radial border, leaving a small cuff of tissue for subsequent repair, and elevated in a subperiosteal fashion from radial to ulnar. Although this muscle can be interposed in the fracture site, the volar periosteum is more commonly interposed. This is evident only after elevation of the pronator quadratus. The periosteum is extracted from the physis with care to minimize further injury to the physis. Upon completion of pronator quadratus elevation, the fracture may be easily visualized.

Technique. After adequate fracture exposure is obtained, bony reduction is performed easily using similar maneuvers as during closed manipulations. Once anatomic fracture alignment is achieved, percutaneous smooth K-wires may be used for stabilization of the reduction. The method of pin insertion is the same as after closed reduction; use of a small incision during K-wire insertion will minimize risk to the radial sensory nerve and extensor tendons.

Similarly for open fracture care, fracture reduction and fixation is performed, usually with two smooth K-wires, after thorough irrigation and debridement. In the uncommon open physeal fractures, care is taken with mechanical debridement to avoid injury to the physeal cartilage. If the soft tissue injury is severe, supplemental external fixation allows observation and treatment of the wound without jeopardizing the fracture

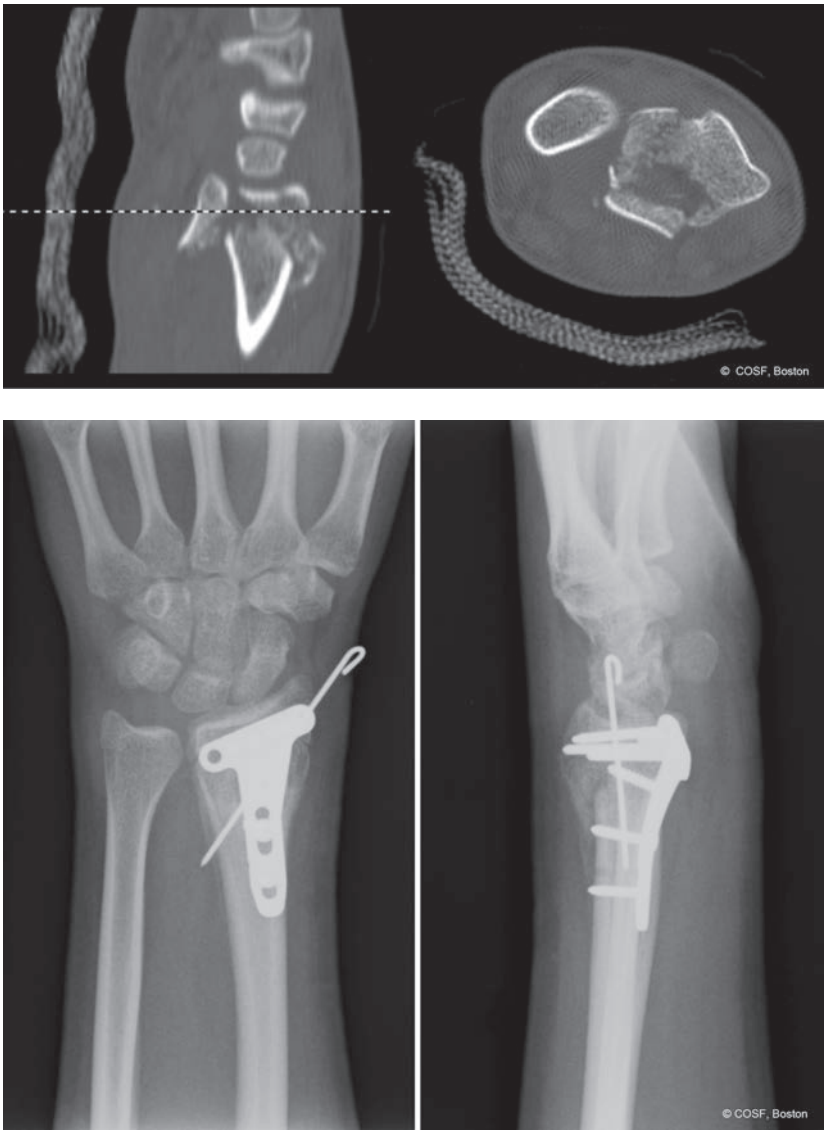

FIGURE 11-41 ORIF of distal radius with T plate and supplemental pin fixation. **A:** Injury CT scan revealing intra-articular displacement. **B:** ORIF with T buttress plate and supplemental styloid pin 1-month postoperative.

reduction. The original open wound should not be closed primarily. Appropriate prophylactic antibiotics should be used depending on the severity of the open fracture.

Plate fixation may also be used for stabilization following open reduction. While the indications for plate fixation evolve and remain patient- and surgeon-dependent, plate fixation is more strongly considered in multitrauma patients, comminuted fractures, older patients nearing or at skeletal maturity, refractures, and fractures at the metaphyseal–diaphyseal junction in whom percutaneous pinning techniques are more challenging.

Following standard surgical exposure and fracture reduction, neutralization or dynamic compression plates are applied to radius using techniques similar to adult fracture care, with a few caveats. Standard 3.5-mm implants may be too bulky for younger or smaller pediatric patients. In these situations, double-stacked one-third tubular plates, 2.7-mm plates, or 2.4-mm plates may be used. In addition, given the rapid bony healing, stout periosteum, and postoperative cast immobilization characteristic of pediatric fracture care, two cortices of fixation may be sufficient distal to the fracture site. Finally, in patients with skeletal growth remaining, implants should be placed sparing the distal physis.

In older adolescents at skeletal maturity or those with intra-articular injuries, volar locking plates may be used for internal fixation. Although a host of commercially available plates are available, the principles are constant: meticulous exposure, anatomic fracture reduction, and stable fixation proximal and distal to the fracture site. Care should be made in anatomically contoured volar locking plates to avoid penetration of obliquely angled distal locking screws into the radiocarpal joint, as well as excessive dorsal prominence of screws, which may lead to late extensor tendon irritation or rupture (Fig. 11-41).

Following fixation, the pronator quadratus, FCR sheath, and subcutaneous tissues are closed in layers, followed by skin closure. In cases of plate fixation, short-arm cast immobilization is sufficient postoperatively (Table 11-9).

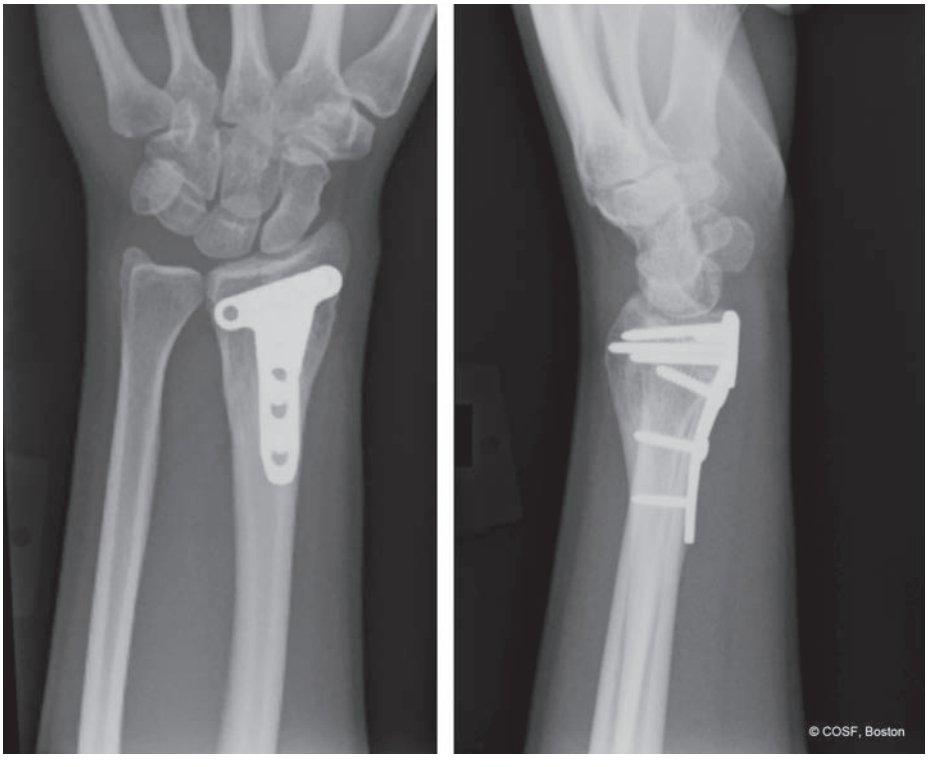
TABLE 11-9 Open Reduction and Fixation of Distal Radius Fractures

Surgical Steps

- Expose distal radius
  - Volar approach most common
- Superficial dissection through FCR sheath or in FCR-radial artery interval
- Incise radial margin of pronator quadratus with radial-to-ulnar subperiosteal elevation
- Fracture exposure and reduction
  - Careful extraction of interposed periosteum or soft tissue
- Stable fixation with either K-wires or plate-and-screw constructs
- Meticulous layered wound closure
- Postoperative cast immobilization

Surgical Procedure: Fixation of Intra-Articular fractures

Preoperative Planning. The rare Salter–Harris type III or IV fracture or "triplane" fracture[158] may require open reduction if the joint or physis cannot be anatomically reduced via



C

FIGURE 11-41 (*continued*) **C:** One year after ORIF with anatomic alignment and asymptomatic hardware.

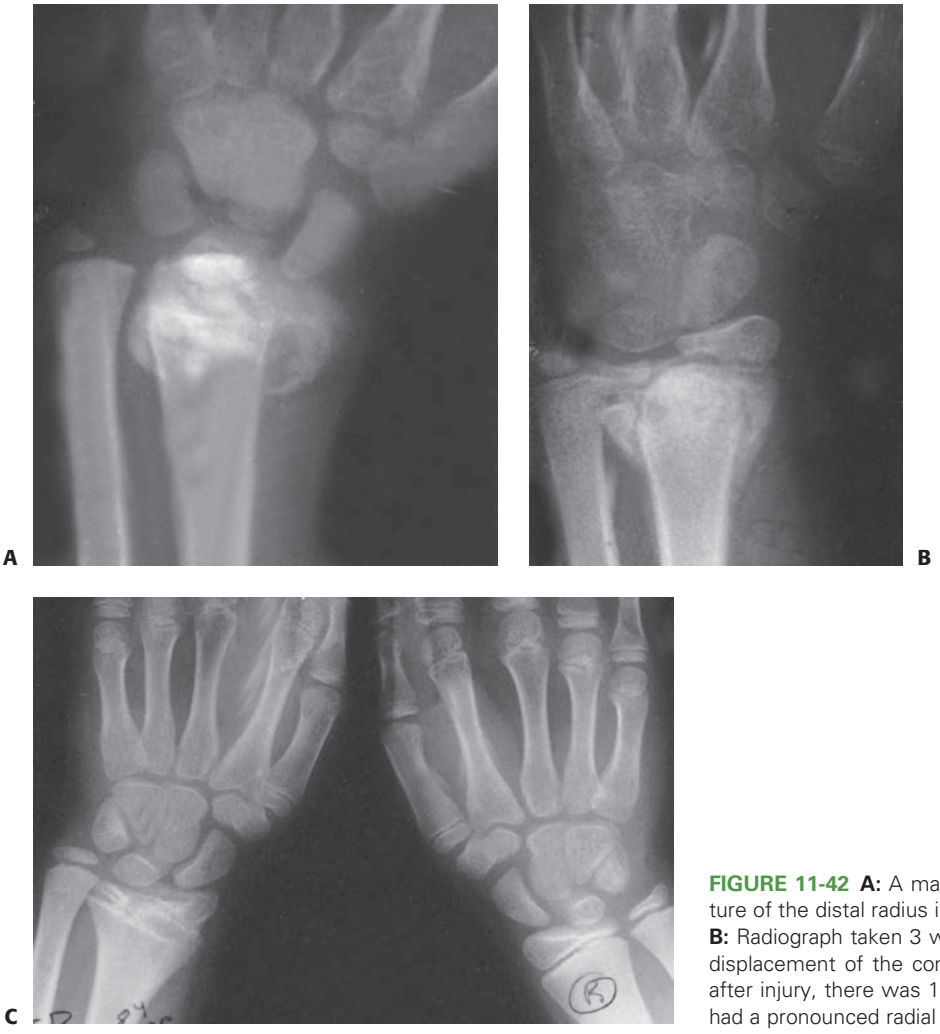


FIGURE 11-42 **A:** A markedly displaced Salter–Harris type IV fracture of the distal radius in an 11-year-old boy who fell from a horse. **B:** Radiograph taken 3 weeks after closed reduction demonstrates displacement of the comminuted fragments. **C:** Eighteen months after injury, there was 15 mm of radial shortening, and the patient had a pronounced radial deviation deformity of the wrist.

closed means. If anatomic alignment of the physis and articular surface is not present, the risk of growth arrest, long-term deformity, or limited function is great (Fig. 11-42). Even minimal displacement (more than 1 mm) should not be accepted in this situation.

Preoperatively, CT or MRI scans are invaluable in defining fracture pattern, assessing articular congruity, and planning definitive treatment (Fig. 11-43). Based upon these images, appropriate preoperative planning may be performed. There is great variation in fracture patterns, and treatment and fixation must be individualized to restore bony alignment and stability. In addition to traditional percutaneous and open techniques, arthroscopically assisted reduction may be helpful to align and stabilize these uncommon intra-articular fractures.[53] Although it is an equipment intensive operation with arthroscopy, external fixation, transphyseal and transepiphyseal pin or screw fixation, and fluoroscopy, anatomic reduction, and stabilization of the physis and articular surface can be achieved (Fig. 11-44, Table 11-10).

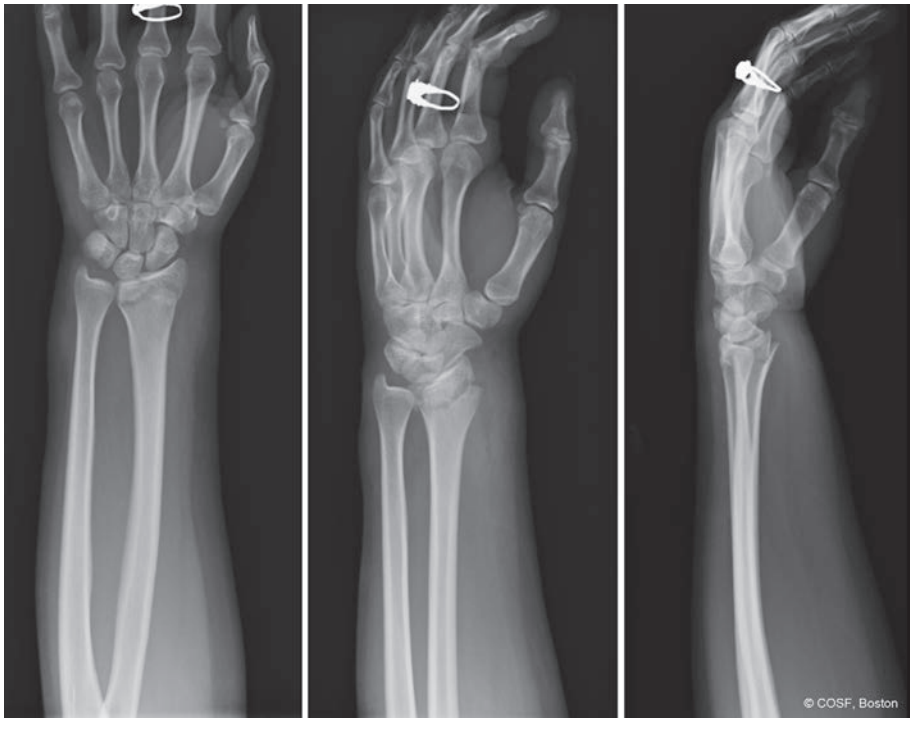
Positioning. Standard positioning is utilized, as described above. In cases where wrist arthroscopy is to be performed, use of a wrist traction tower with finger trap suspension applied to the index and long fingers will stabilize the wrist and provide appropriate traction for arthroscopic visualization.

Surgical Approach(es). The volar surgical approach remains the standard workhorse exposure for distal radius fractures requiring open reduction. Often, more distal subperiosteal elevation is needed to visualize intra-articular fracture lines. This is more common in older, skeletally mature adolescents.

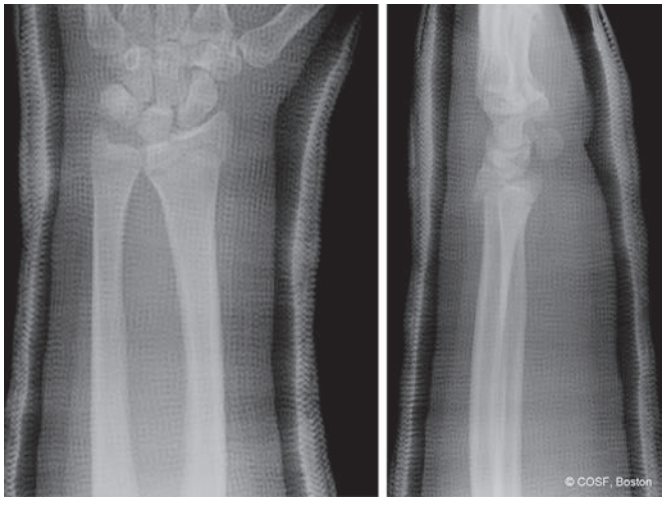
TABLE 11-10 Fixation of Intra-Articular Fractures

Preoperative Planning Checklist

- OR Table: Standard
- Position/positioning aids: Radiolucent hand table
- Fluoroscopy location: Variable according to surgeon preference
- Equipment: K-wires, small fragment plating systems, anatomically precontoured volar locking plates, small joint arthroscope
- Tourniquet (sterile/nonsterile): nonsterile tourniquet on proximal brachium
- Adequate preoperative imaging, including CT or MRI



A



B

FIGURE 11-43 **A:** Displaced distal radius metaphyseal and intra-articular fracture. **B:** Emergency department postreduction radiographs in cast.

(*continues*)

In many intra-articular fracture patterns, there are radial styloid and/or dorsal lunate facet fragments that necessitate exposure, reduction, and fixation. In these cases, supplemental dorsal approaches may need to be utilized. A longitudinal incision based over or ulnar to Lister's tubercle is most commonly utilized and provides a utilitarian approach. Superficial dissection is performed to the extensor retinaculum, with preservation of the dorsal veins if possible. In dorsal lunate facet fractures, incision of the retinaculum over the third or fourth extensor compartment and subsequent retraction of the extensor pollicis longus or extensor digitorum communis tendons, respectively, will provide access to the distal dorsal radius. Care is made to preserve the origins of the radiocarpal ligaments whenever possible.

Technique. Given the spectrum of intra-articular distal radius fracture patterns, a sequential description of surgical steps is difficult; each patient must be treated in an individualized fashion according to fracture pattern, size of bony fragments, severity of displacement, and skeletal maturity. Universal surgical principles of adequate fracture reduction, anatomic realignment, and stable fixation will provide for optimal results. A few additional considerations are important.

Attempts should be made to achieve closed or minimally invasive reduction whenever possible. With adequate anesthesia, muscle relaxation, and traction, displaced articular fragments may often be anatomically realigned, facilitating percutaneous fixation or implant placement without violating the radiocarpal joint or physis. Furthermore, K-wires may be used to joystick displaced fracture fragments or in an intrafocal fashion[192] to further assist in fracture reduction. Intraoperative fluoroscopy is invaluable in these cases.

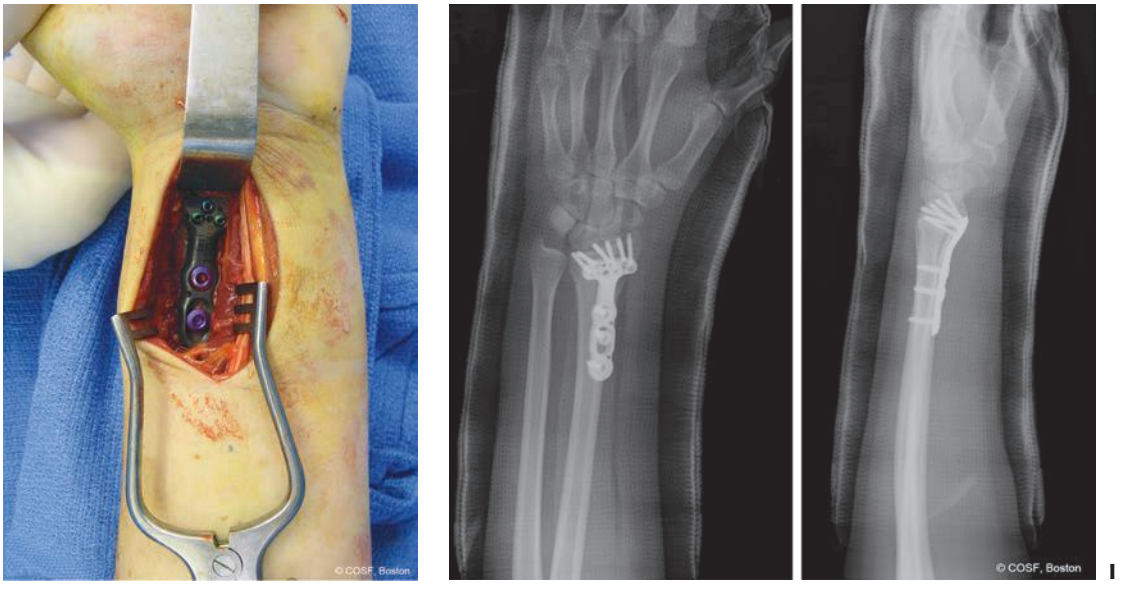

FIGURE 11-43 (*continued*) **H:** Plate fixation of fracture anatomically. **I:** Radiographs of ORIF with volar plating system.

Wrist arthroscopy may be a helpful adjunct for articular visualization.[35,53] With approximately 10 to 12 pounds of distraction placed via finger traps to the index and long fingers, a small joint arthroscope (2.4 to 2.9 mm in diameter) may be inserted into the standard 3 to 4 wrist arthroscopy portal; this portal lies between the third and fourth extensor compartments and is typically 1 to 2 cm distal to Lister's tubercle. Care should be taken to avoid excessive extravasation of arthroscopy fluid into the zone of injury during arthroscopy; expeditious arthroscopy and use of low-pressure and flow rates are helpful in these situations.

Finally, a wide spectrum of internal fixation options are available. Percutaneous K-wires are effective when properly positioned, particularly in younger patients with open physes in whom efforts are made to minimize the risk of iatrogenic growth disturbance. Wires passed obliquely from distal to proximal are effective for radial styloid and dorsal lunate

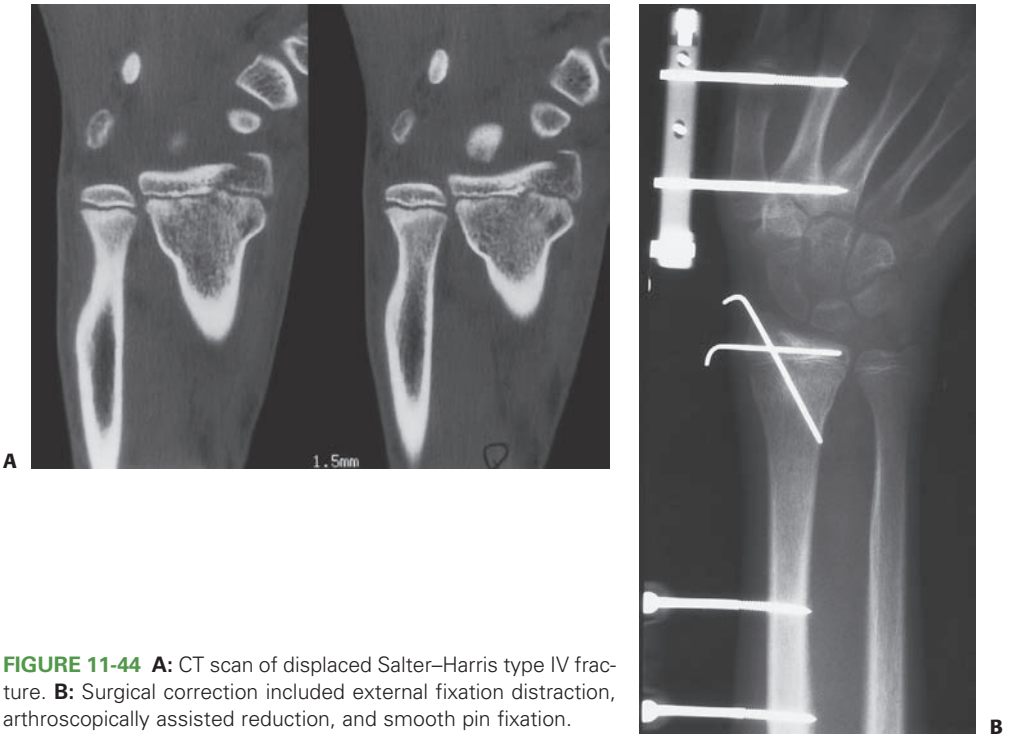

FIGURE 11-44 **A:** CT scan of displaced Salter–Harris type IV fracture. **B:** Surgical correction included external fixation distraction, arthroscopically assisted reduction, and smooth pin fixation.

TABLE 11-11 Fixation of Intra-Articular Fractures

Surgical Principles

- Careful preoperative evaluation of fracture pattern, comminution, and displacement
- Fracture-specific surgical approaches
- Articular realignment
  - Use of traction, wrist arthroscopy, fluoroscopy, or arthrotomy to aid in visualization
- Stabilization of the articular surface to the proximal radius
- Fixation using K-wires, interfragmentary screws, or plate-and-screw constructs for maintenance of alignment

facet fracture fragments; similarly, transverse epiphyseal pins may impart stability to articular fracture fragments. In older patients nearing or at skeletal maturity, adultlike locking plate constructs may be utilized (Table 11-11).

Surgical Procedure: Reduction and Fixation of Distal Ulnar Fractures

Open reduction is performed in cases where acceptable alignment is not achieved following radial reduction and attempted closed manipulation. This is an indication for open reduction.

Preoperative Planning. Preoperative planning and patient positioning are similar to that of displaced distal radius fractures.

Surgical Approach(es). Incisions for surgical exposure of the ulna are typically ulnar or dorsoulnar, though ideally surgical exposure approaches the ulna from the side of periosteal disruption. In physeal fractures, the periosteum is typically torn opposite the Thurston–Holland fragment; in metaphyseal injuries, periosteal injury is opposite the direction of displacement. Deep dissection is most commonly made in the extensor carpi ulnaris—flexor carpi ulnaris interval ulnarly or the extensor digiti quinti—extensor carpi ulnaris intervals dorsally. Careful subperiosteal elevation may be performed in the zone of injury, which is typically already traumatized from the fracture. Interposed soft tissue (periosteum, extensor tendons, abductor digiti quinti, or flexor tendons) may then be identified and must be extracted from the fracture site.[1,81,182]

Technique. Following exposure, soft tissue extraction, and bony reduction, if fracture instability persists, internal fixation is performed. Often, a single small-diameter smooth K-wire can be used to maintain alignment. This K-wire may be passed obliquely from distal to proximal, crossing the fracture site. In older patients with larger bones and greater instability, two parallel K-wires may be used, and this may be further supplemented by tension band fixation (Fig. 11-45). A small drill hole made proximal to the fracture site is created, and a nonabsorbable braided suture or small caliber stainless steel wire is passed through the drill hole and around the previously placed K-wires in a figure-of-eight fashion. Pins are typically removed after 4 weeks following radiographic confirmation of bony healing. Plate and screw fixation may also be performed in distal metaphyseal fractures and/or older, skeletally mature patients. Use of smaller implants, distal locking screws, or mini-fragment blade plates will assist in obtaining adequate

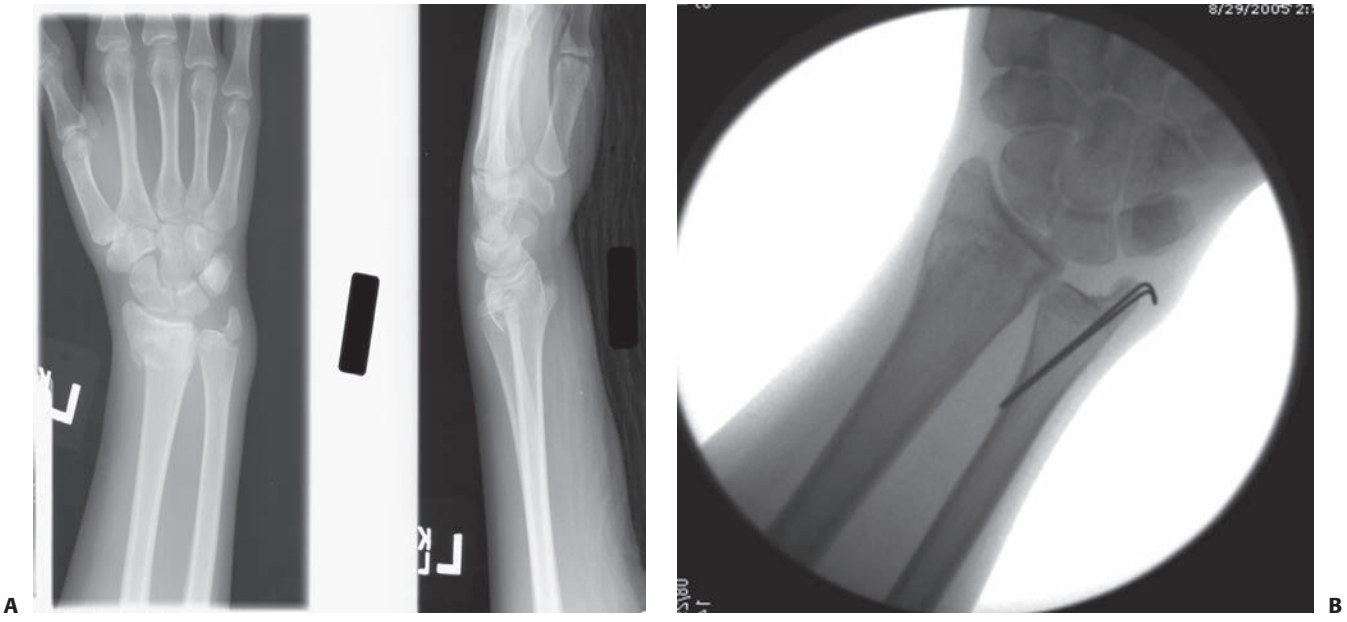

FIGURE 11-45 **A:** Plain radiographs depicting displaced distal radial metaphyseal and ulnar styloid fractures. Given the fracture and distal radioulnar joint instability, the injury was treated with closed reduction and percutaneous pinning of the distal radius as well as open reduction and tension band fixation of the ulnar styloid. **B:** Follow-up radiograph following reduction and fixation demonstrate anatomic alignment. The prior radial pins have been removed, and the parallel smooth wires used for tension band fixation of the ulnar styloid are seen.

TABLE 11-12 Fixation of Displaced Distal Ulnar Fractures

Surgical Steps

- Expose distal ulna
  - Preserve distal ulnar physis, capsular attachments of DRUJ and ulnocarpal joint, and ulnar wrist ligaments whenever possible
- Anatomic reduction of ulnar fracture
- Stable fixation based upon fracture pattern and patient age
  - K-wire fixation
  - K-wire with tension band construct
  - Plate-and-screw fixation
- Assess DRUJ alignment and stability intraoperatively
- Postoperative cast immobilization

fixation in the often small distal ulnar fracture fragment. Further injury to the physis should be avoided during operative exposure and reduction because of the high risk of growth arrest (Table 11-12).[81]

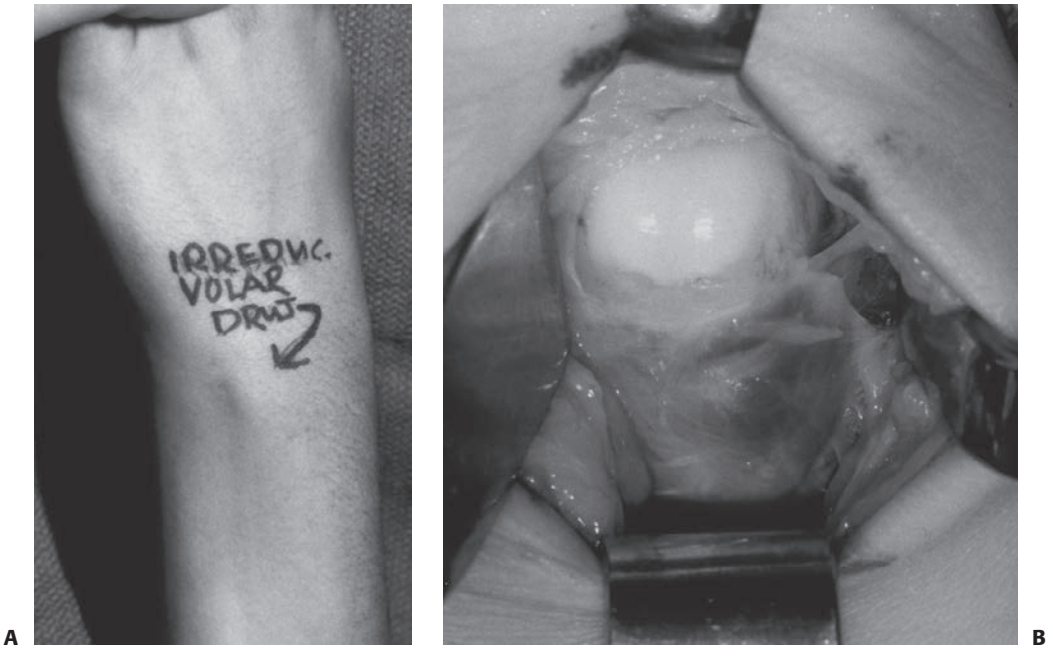
Surgical Procedure: Galeazzi Fractures

Open reduction of the radius is indicated in Galeazzi fractures or fracture equivalents in cases of failure to obtain or maintain fracture and DRUJ reduction. This most often occurs with unstable complete fractures in older adolescents.

Preoperative Planning. Preoperative planning and patient positioning are similar as described above. Unlike adult Galeazzi fracture dislocations, advanced imaging (e.g., CT or MRI) is rarely needed in pediatric patients.

Surgical Approach(es). Open reduction and internal fixation of complete radius fractures is performed through a standard volar approach, as described above. In the majority of acute injuries, with anatomic reduction of the radius, restoration of radial length and alignment will allow for spontaneous reduction of the DRUJ. Occasionally, however, the DRUJ dislocation cannot be reduced via closed means (Fig. 11-46). In these situations, the first intra-operative step is to reassess the quality of radial fracture reduction and fixation. Following this, open reduction of the DRUJ may be performed to remove any interposed soft tissues blocking reduction (periosteum, extensor carpi ulnaris tendon, extensor digiti quinti tendon, other ligamentous structures).[56,86,110,126,149,170,199]

The easiest approach for open reduction of the DRUJ is an extended ulnar approach. Care should be taken to avoid injury to the ulnar sensory nerve branches, which typically pass obliquely from proximal volar to distal dorsal in the region of the ulnar styloid. This approach allows exposure both volarly and dorsally to extract the interposed soft tissues and repair the torn structures. Alternatively, a Bowers approach to the DRUJ may be used (Fig. 11-47). A curvilinear incision is made over the DRUJ. The fifth dorsal extensor compartment is incised and the extensor digiti quinti is retracted. The DRUJ lies immediately deep to this interval, and the joint may be opened and inspected, facilitating reduction.



A B

FIGURE 11-46 An adolescent girl presented 4 weeks after injury with a painful, stiff wrist. **A:** By examination, she was noted to have a volar distal radioulnar dislocation that was irreducible even under general anesthesia. **B:** At the time of surgery, the distal ulna was found to have buttonholed out of the capsule, and there was entrapped triangular fibrocartilage and periosteum in the join.

FIGURE 11-47 **A:** Clinical photograph depicting the dorsoulnar curvilinear incision used to approach the distal radioulnar joint in a patient with an irreducible Galleazi fracture. **B:** Intraoperative photograph depicting the sigmoid notch of the distal radius. The ECU and EDQ tendons are seen retracted volarly and radially. The volarly displaced distal ulna remains dislocated.

Technique. Open reduction and internal fixation of the radius are done through an anterior approach. Standard compression plating is preferred to intramedullary or cross-pinning techniques (Fig. 11-48). Stable, anatomic reduction of the radius almost always leads to stable reduction of the DRUJ dislocation. A long-arm cast is used for 6 weeks to allow fracture and soft tissue healing.

If the DRUJ dislocation cannot be reduced, it is exposed as described above. Typically after anatomic alignment of the radius and extraction of any soft tissues blocking DRUJ reduction, the joint is stable and no additional fixation is required. In cases of extreme instability and/or soft tissue compromise, smooth K-wire fixation of the DRUJ can be used to maintain reduction and allow application of a loose-fitting cast. The K-wire(s) are placed with the forearm in supination and passed transversely across from the reduced DRUJ from the ulna to the radius, and the pin(s) left exposed out of the skin. Pin removal is in the office at 4 weeks with continuation of the cast for 6 weeks.

Ulnar physeal fractures may also be irreducible in Galeazzi equivalent injuries. This also has been reported to be secondary to interposed periosteum, extensor tendons, or joint capsule.[56,86,122,127,149,170,199] Open reduction must be executed with care to avoid further violating the physis (Table 11-13).

Surgical Procedure: External Fixation

External fixation rarely is indicated for fractures in skeletally immature patients. Though a viable treatment option,[178] the success rates of both closed reduction and percutaneous pinning techniques make external fixation unnecessary for uncomplicated distal radial fractures in children. Presently, indications for external fixation include distal radius fractures with severe associated soft tissue injuries. Severe crush injuries, open fractures, or replantations after amputation requiring additional soft tissue coverage are all indications for external fixation. Supplemental external fixation also may be necessary for severely comminuted fractures to maintain length and provide additional stability to pin or plate constructs. Standard application of the specific fixator chosen is done with care to avoid injury to the adjacent sensory nerves and extensor tendons.

Preoperative Planning. Preoperative planning and patient positioning are similar to as described above. A host of commercially available external fixators may be utilized, with selection of pin diameter based upon fracture location and patient size.

Surgical Approach(es). In general, external fixation for distal radius fractures in children spans the radiocarpal articulation. Although nonbridging (or wrist joint sparing) constructs

TABLE 11-13 Galeazzi Fractures

Surgical Steps

- Expose distal radius fracture
- Anatomic reduction and stabilization of radius
  - Plate fixation preferred
- Careful intraoperative assessment of forearm rotation and DRUJ stability
  - Intraoperative fluoroscopy to confirm DRUJ alignment
- If DRUJ not reducible, open reduction via ulnar or Bowers approach
- If DRUJ not reducible in setting of distal ulnar physeal fracture, open reduction and stabilization of ulnar fracture performed
- Radioulnar pinning in cases of reducible but unstable DRUJ reduction
- Long-arm cast immobilization for 6 wks
  - If utilized, radioulnar pin removal 4–6 wks postoperatively

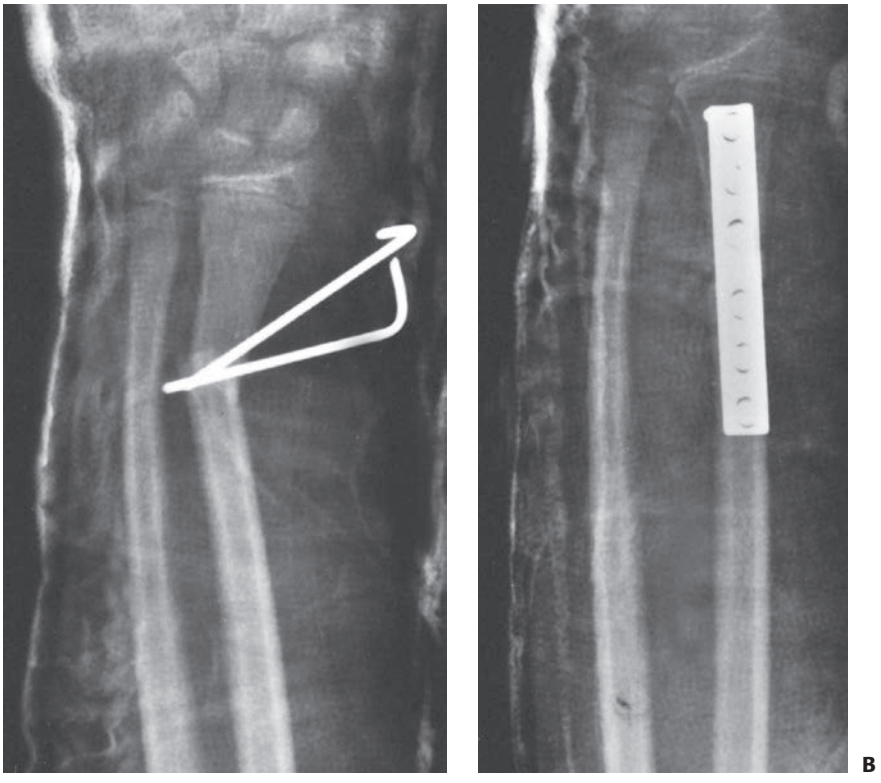


FIGURE 11-48 **A:** The patient with a pronation injury had a closed reduction and attempted fixation with pins placed percutaneously across the fracture site. However, this was inadequate in maintaining the alignment and length of the fracture of the distal radius. **B:** The length of the radius and the distal radioulnar relationship were best reestablished after internal fixation of the distal radius with a plate placed on the volar surface. The true amount of shortening present on the original injury film is not really appreciated until the fracture of the distal radius is fully reduced. (Reprinted from Wilkins KE, ed. *Operative Management of Upper Extremity Fractures in Children.* Rosemont, IL: American Academy of Orthopaedic Surgeons, 1994:34, with permission.)

may be utilized, the small size of the distal radial epiphysis in young children often precludes the ability to obtain adequate purchase with external fixator pins. For this reason, typical constructs involve fixator pin placement through the index metacarpal and more proximal radial diaphysis.

Distally, a dorsoradial incision is made over the mid-diaphyseal region of the index metacarpal. Dissection is performed through the subcutaneous tissues. The periosteum may be incised via an open approach, and careful limited subperiosteal elevation will allow for the first dorsal interosseous and adductor pollicis muscles to retract safely. Percutaneous techniques may also be utilized, with care taken to avoid inadvertent injury to the radial sensory nerve, extensor tendons, or intrinsic muscles.

Proximally, a dorsoradial approach in the region of the distal radial metadiaphysis is made. Again identification and retraction of the radial sensory nerve is performed. Deep dissection will allow visualization of the characteristic "bare area" between the musculotendinous units of the first and second extensor compartments. A longitudinal periosteal incision is created, facilitating safe and direct placement of external fixator pins.

Technique. Exposure and pin placement are described as above. Following placement of two terminally threaded pins distal and proximal to the fracture, appropriate traction and reduction may be performed. Use of double-stacked radiolucent bars will increase construct rigidity and facilitate radiographic evaluation.

After fluoroscopic confirmation of pin placement and acceptable fracture alignment, prior surgical incisions may be closed primarily and sterile bandages and/or petroleum gauze may be applied to the pin sites.

Authors' Preferred Method of Treatment for Fractures of the Distal Radius and Ulna

Torus Fractures

Torus fractures may be safely and effectively treated with removable splint immobilization for 3 weeks. Immobilization provides comfort from pain during healing and protects against displacement with secondary injury. After 3 weeks, splints may be removed at home without need for formal clinical evaluation. Gradual resumption of activities is allowed once wrist motion and strength return.

Incomplete Greenstick Fractures

Displaced greenstick fractures are at risk for progressive malalignment and subsequent loss of forearm rotation. For this reason, closed reduction and long-arm cast immobilization is performed for displaced greenstick fractures with greater than 10 degrees of angulation. Generally, these fractures have apex volar angulation and dorsal displacement. Conscious sedation is used with portable fluoroscopy in the emergency care setting. The distal fragment and hand are distracted and then reduced

volarly. With isolated distal radial fractures, it is imperative to reduce the DRUJ with appropriate forearm rotation. For apex volar fractures, this usually is with pronation. If the fracture is apex dorsal with volar displacement, the reduction forces are the opposite. A long-arm cast with three-point molding is used for 3 to 4 weeks. Radiographs are obtained every 7 to 10 days until there is sufficient callus formation. A short-arm cast or volar wrist splint is used until full healing, generally at 4 to 6 weeks after fracture reduction. The patient is then restricted from contact sports until full motion and strength are regained, which may take up to several weeks after cast removal. Formal therapy rarely is required. The patient and parents are counseled regarding the risk of redisplacement of the fracture during cast immobilization, as well as the risk of refracture following cast removal.

Bicortical Complete Radial Metaphyseal Injuries

Nondisplaced bicortical metaphyseal fractures are treated with cast immobilization. Our preference at present is to begin with short-arm cast immobilization, with achieving appropriate fracture mold. Given the risk of late displacement, serial radiographs are obtained for the first 2 to 3 weeks. By 3 to 4 weeks after injury, there is sufficient healing to transition to short-arm cast immobilization. Casts are discontinued at 6 weeks, with gradual resumption of activities with return of wrist motion and strength.

Displaced fractures with unacceptable alignment are treated with closed reduction and long-arm cast immobilization. At our institutions, we reduce this fracture in the emergency room with conscious sedation and supplemental local hematoma block or in the operating room with general anesthesia. In either situation, portable fluoroscopy is used. The fracture usually is reduced in the emergency room in young patients with minimal swelling and no neurovascular compromise and in whom cast treatment will be sufficient. Reduction with general anesthesia is preferred for older patients and for those with marked displacement, swelling, or associated neurovascular compromise in whom percutaneous pin treatment is considered.

The reduction maneuver is the same regardless of anesthesia type or stabilization method. As opposed to a Colles fracture in an adult, traction alone will not reduce the fracture because the dorsal periosteum acts as a tension band that does not respond to increasing linear traction with weights. Finger traps with minimal weight (less than 10 lb) can be used to balance the hand and help with rotational alignment (Fig. 11-49). However, applying progressive weight will only distract the carpus and will not alter the fracture alignment.

After applying preliminary traction with either lightweight finger traps or hand traction, a hyperdorsiflexion maneuver is performed. The initial deformity is accentuated and the distal fragment is brought into marked dorsiflexion. The dorsum of the hand should be brought more than 90 degrees and at times parallel to the dorsum of the forearm to lessen the tension on the dorsal periosteum. Thumb pressure is used on the distal fragment while still in this deformed position to restore length

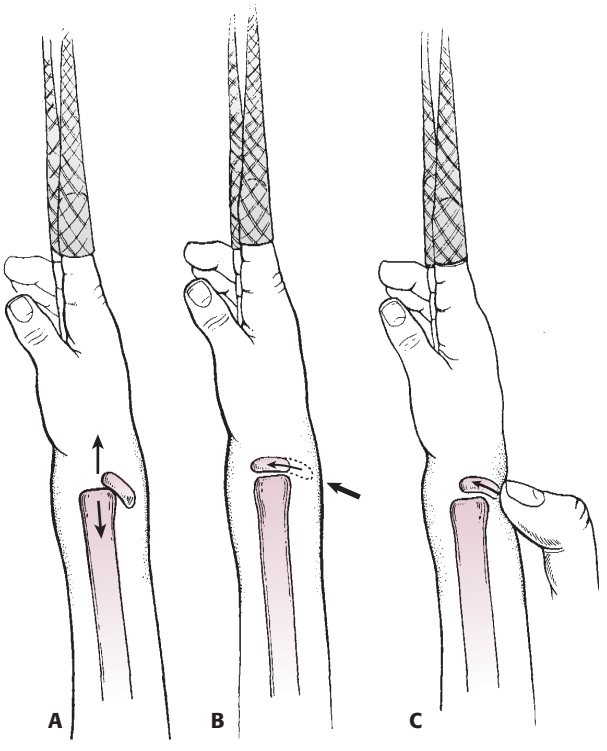

FIGURE 11-49 Acceptable method of closed reduction of distal physeal fractures of the radius. **A:** Position of the fracture fragments as finger trap traction with countertraction is applied (*arrows*). **B:** With traction alone, the fracture will often reduce without external pressure (*arrows*). **C:** If the reduction is incomplete, simply applying direct pressure over the fracture site in a distal and volar direction with the thumb often completes the reduction while maintaining traction. This technique theoretically decreases the shear forces across the physis during the reduction process.

by bringing the distal fragment beyond the proximal fragment. Reduction is then obtained by flexing the distal fragment while maintaining length. Often, this initial reduction maneuver restores length and alignment, but translational reduction is incomplete. The fracture should be completely reduced by toggling the distal fragment volarly by repetitive slight dorsiflexion positioning of the distal fragment followed by volar pressure with the thumbs. It is important to anatomically reduce the fracture. Loss of reduction with cast immobilization is more likely if the fracture remains translated or malaligned.

A long-arm cast is applied with the elbow flexed 90 degrees, the wrist in slight palmar flexion, and the forearm in the desired rotation for stability and alignment. Rotational positioning and short- versus long-arm casting varies with each fracture and each surgeon. Our preference is neutral forearm rotation unless the fracture dictates differently. This allows excellent molding against the volar aspect of the distal radius at the fracture site.

One of the most important elements in a successful casting for a forearm fracture is the application of the cast padding (Webril, Kendall, Mansfield, MA). Cast padding should be applied in a continuous roll with overlap of one-third to

one-half its width. Extra padding is applied over the olecranon when a long-arm cast is used, along the volar and dorsal forearm where the cast may have to be split, and at the ends of the cast to prevent irritation from fraying.

A three-point mold is applied at the fracture site as the cast hardens. In addition, molds are applied to maintain a straight ulnar border, the interosseous space, and straight posterior humeral line. This creates the classic "box" long-arm cast rather than the all too frequent "banana" cast that allows displacement. Final radiographs are obtained, and if the reduction is anatomic, the cast is overwrapped.

Patients are either discharged or admitted to the hospital depending on the degree of concern regarding risk of excessive swelling, neurovascular compromise, and patient and parental reliability. If there is any doubt, the patient is admitted for observation. The cast is split anytime there are signs of neurovascular compromise or excessive swelling. The patient is instructed to maintain elevation for at least 48 to 72 hours after discharge and return immediately if excessive swelling or neurovascular compromise occurs. The patient and family are warned of the risk of loss of reduction and the need for close follow-up. We inform our patients and parents that the risk of return to the day surgery unit for repeat reduction or pinning is approximately 20% to 30% during the first 3 weeks.

Follow-up examinations and radiographs are obtained weekly for 2 to 3 weeks. If there is loss of reduction, we individualize treatment depending on the patient's age, degree of deformity, time since fracture, and remodeling potential. If restoration of alignment with growth occurs, we reassure the family that the child should achieve anatomic alignment over time with growth. If the child is older, there is risk of further displacement, or the deformity is marked, repeat reduction is done in the day surgery unit with fluoroscopy. Most often, a percutaneous pin is used for the second reduction (Fig. 11-50). Occasionally, in pure bending injuries, loss of reduction can be corrected with cast wedging.

Cast immobilization usually is for 4 to 6 weeks. Patients are typically transitioned from a long-arm cast to a short-arm cast at 4 weeks postinjury. With clinical and radiograph healing, a protective volar splint is used and activities are restricted until the patient regains full motion and strength, usually in 1 to 3 weeks after cast removal. As with other distal radial fractures, formal physical therapy rarely is required.

In cases of loss of reduction exceeding the limits of fracture remodeling, repeat closed reduction and pin fixation is consid-

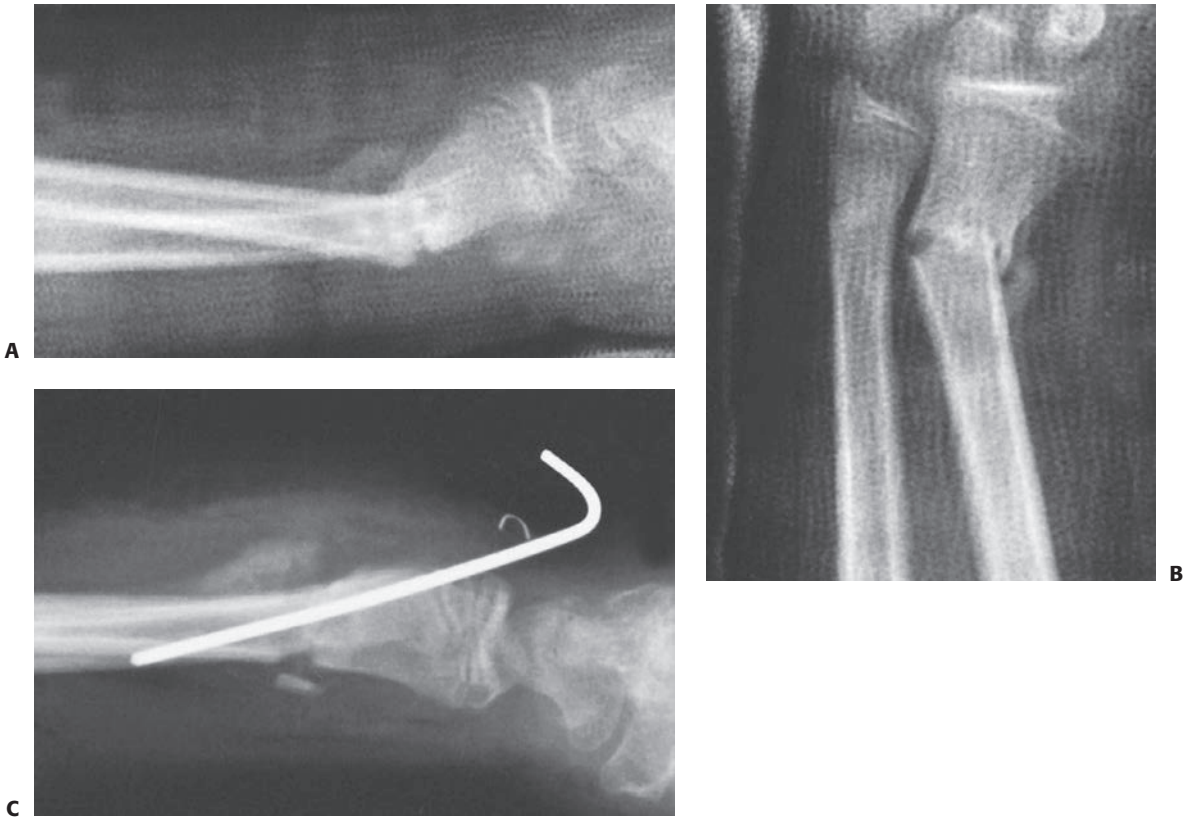

FIGURE 11-50 Remanipulation. **A, B:** Two weeks after what initially appeared to be an nondisplaced greenstick fracture, a 14-year-old boy was found to have developed late angulation of 30 degrees in both the coronal and sagittal planes. **C:** Because this was beyond the limits of remodeling, a remanipulation was performed. To prevent reangulation, the fracture was secured with a pin placed percutaneously obliquely through the dorsal cortex.

ered. Percutaneous pinning is also performed in cases of excessive swelling or signs of neurologic injury. In these situations, the patient is at risk for development of a forearm or carpal tunnel compartment syndrome with a well-molded, tight-fitting cast. Similarly, concurrent displaced supracondylar and distal radial fractures are treated with percutaneous fixation of both fractures to lessen the risk of neurovascular compromise. Older patients near the end of growth with bayonet apposition fractures also are treated with percutaneous pin fixation because they have less ability to remodel and their fractures are very unstable with a high risk of displacement. Finally, open fractures usually are treated with pin fixation.

FIGURE 11-51 **A:** Radiograph of an open humeral diaphyseal fracture in the setting of a "floating elbow injury." **B:** Radiograph depicting a displaced distal radial metaphyseal fracture. **C:** Plate fixation following irrigation and debridement of the humerus fracture. **D, E:** Radiographs following open reduction and plate fixation of the radius fracture, sparing the distal radial physis.

The pinning technique for the radius is either a single radial-sided pin or crossed radial- and ulnar-sided pins. Fixation of the ulna rarely is necessary. Stability with a single pin is checked with fluoroscopy, and if further fixation is needed, a second pin is added. The physis is avoided if possible. Intrafocal pins are used if reduction is not possible without levering the distal fragment into a reduced position. A small incision is made for the insertion of each pin to protect the radial sensory nerve and adjacent extensor tendons. Smooth pins are used and are removed in the office as soon as there is sufficient healing to make the fracture stable in a cast or splint (usually at 4 weeks). Rehabilitation is similar to that for cast-treated fractures.

Open reduction is typically reserved for open or irreducible fractures in which an adequate closed reduction cannot be achieved. All open fractures are irrigated and debrided in the operating room. The initial open wound is extended adequately to inspect and cleanse the open fracture site. After thorough irrigation and debridement, the fracture is reduced and stabilized. A cast rarely is applied in this situation because of concern about fracture stability, soft tissue care, and excessive swelling. Crossed-pin fixation often is used with Gustilo grade 1 or 2 open fractures. More severe soft tissue injuries usually require external fixation with a unilateral frame, with care taken to avoid soft tissue impingement during pin placement. If flap coverage is necessary for the soft tissue wounds, the fixator pins should be placed in consultation with the microvascular surgeon planning the soft tissue coverage. In addition, open reduction internal fixation with volar plating is performed for unstable fractures in the skeletally mature adolescent.

Irreducible fractures usually are secondary to soft tissue entrapment. With dorsal displacement, this is most often either the volar periosteum or pronator quadratus, and open reduction through a volar approach is necessary to extract the interposed soft tissues and reduce the fracture. Percutaneous pin fixation usually is used to stabilize the fracture in patients with open physes. If plate fixation is used, it should avoid violation of the physis (Fig. 11-51). Displaced intra-articular injuries in skeletally immature adolescents are adultlike and require standard treatment, such as open reduction and internal fixation (Fig. 11-52). Lower-profile and locking plates have been used more recently (Fig. 11-53).

Physeal Injuries

Most Salter–Harris type I and II fractures are reduced closed under conscious sedation with the assistance of portable fluoroscopy. A long-arm cast with appropriate three-point molding is applied. This is changed to a short-arm cast when there

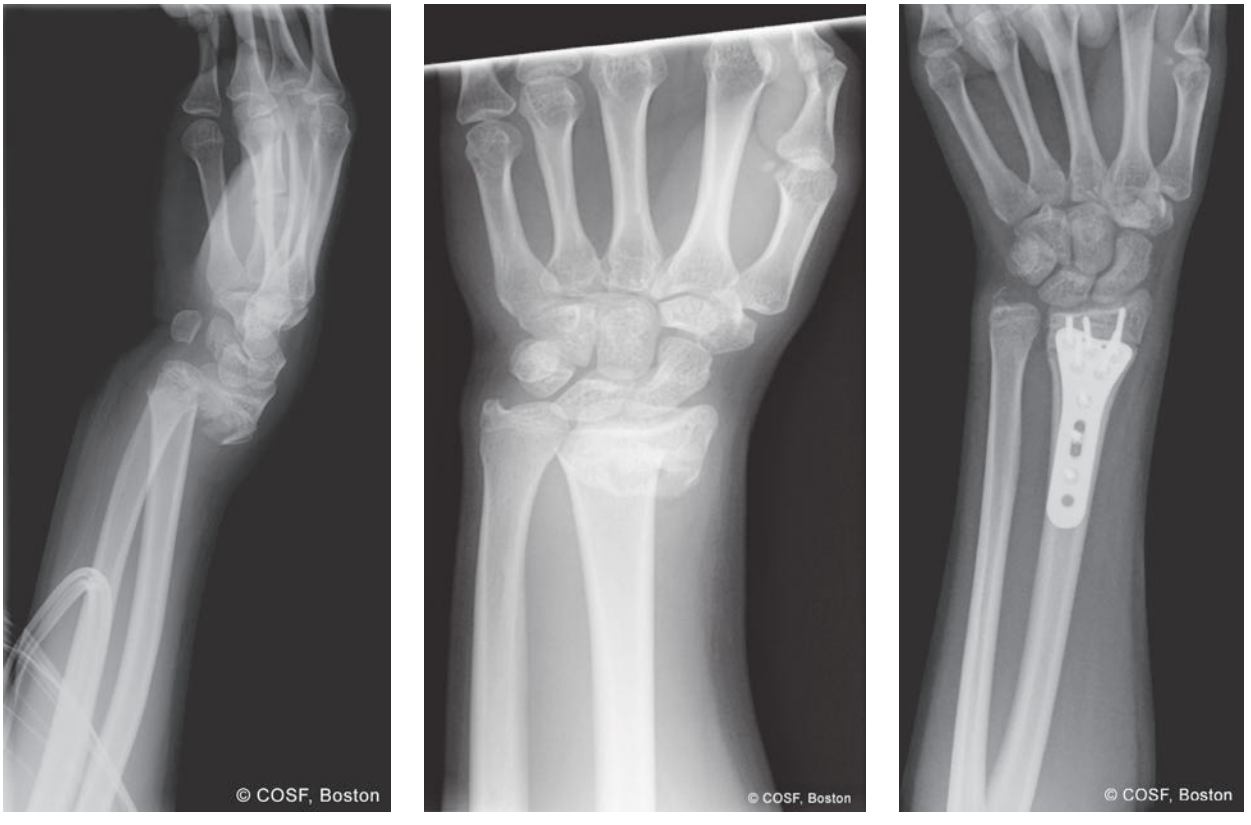

FIGURE 11-52 **A, B:** AP and lateral radiographs of a 14-year-old skeletally mature female with a displaced extra-articular fracture. **C, D:** This fracture was treated with a fixed-angle volar locking plate, with distal screws crossing the physis. FIGURE 11-52 (*continued*)

is sufficient healing for fracture stability, usually after 3 to 4 weeks. Cast immobilization is discontinued when there is clinical and radiographic evidence of fracture healing, generally 4 to 6 weeks after fracture. Range-of-motion and strengthening exercises are begun with a home program. When the child achieves full motion and strength, he or she can return to full activity, including competitive sports. As the risk of posttraumatic physeal disturbance is approximately 4% to 5%, follow-up radiographs are obtained at 6 to 12 months after fracture to be certain there is no growth arrest.[12,27]

Patients with distal radial physeal fractures with late displacement present treatment challenges. In younger patients with more than 2 years of growth remaining, remanipulation of physeal fractures is not performed after 7 to 10 postinjury, given concerns of iatrogenic growth arrest. In these situations, patients and families are counseled about remodeling potential and potential need for future interventions in the event that incomplete remodeling occurs (e.g., late corrective osteotomy). Serial radiographs are obtained 6 to 12 months after fracture healing to confirm appropriate skeletal remodeling and rule out growth disturbance.

A patient with a displaced Salter–Harris type I or II physeal fracture associated with significant volar soft tissue swelling, median neuropathy, or ipsilateral elbow and radial fractures (floating elbow') is treated with closed reduction and percutaneous pinning (Fig. 11-54). This avoids the increased risk of compartment syndrome in the carpal canal or volar forearm that is present if a well-molded, tight cast is applied. In addition, acute percutaneous pinning of the fracture prevents increased swelling, cast splitting, loss of reduction, and concerns about malunion or growth arrest with repeat reduction. The risk of growth arrest from a narrow-diameter, smooth pin left in place for 3 to 4 weeks is exceedingly small.[217]

Open reduction is reserved for irreducible Salter–Harris type I and II fractures, open fractures, fractures with associated acute carpal tunnel or forearm compartment syndrome, displaced (more than 1 mm) Salter–Harris type III or IV fractures, or triplane equivalent fractures. For an irreducible Salter–Harris type I or II fracture, exposure is from the side of the torn periosteum. Because these fractures usually are displaced dorsally, a volar exposure is used. Smooth pins are used for stabilization and are left in for 3 to 4 weeks. Open fractures are exposed through the open wound with proximal and distal extension for adequate debridement. All open debridements are performed in the operating room under general anesthesia. Acute compartment syndromes are treated with immediate release of the transverse carpal ligament or forearm fascia. The transverse

carpal ligament is released in a Z-plasty fashion to lengthen the ligament and prevent volar bow-stringing and scarring of the median nerve against the palmar skin.

Intra-Articular Fractures

Displaced intra-articular fractures in the skeletally immature are best treated with arthroscopically assisted reduction and fixation. Distraction across the joint can be achieved with application of an external fixator or wrist arthroscopy traction devices and finger traps. Standard dorsal portals (3/4 and 4/5) are used for viewing the intra-articular aspect of the fracture and alignment of the reduction. [66,76] In addition, direct observation through the arthroscope can aid in safe placement of the intraepiphyseal pins.[53,87,92] Fluoroscopy is used to evaluate the extra-articular aspects of the fracture (triplane equivalent and type IV fractures), the reduction, and placement of fixation pins.

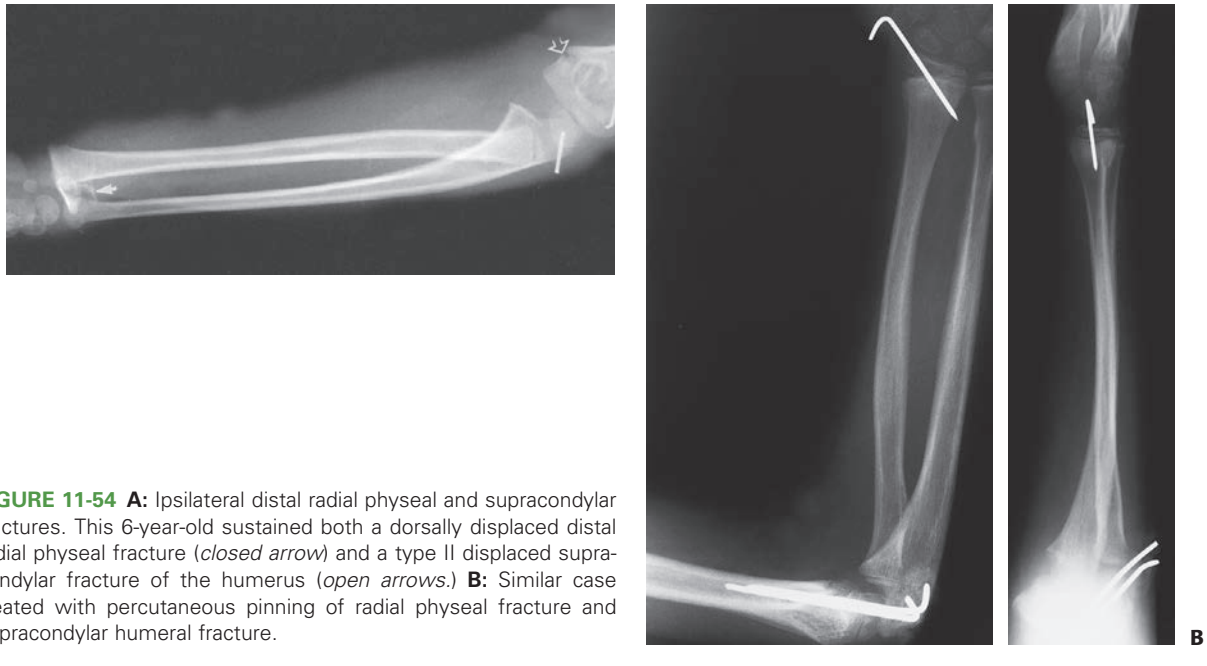

FIGURE 11-54 **A:** Ipsilateral distal radial physeal and supracondylar fractures. This 6-year-old sustained both a dorsally displaced distal radial physeal fracture (*closed arrow*) and a type II displaced supracondylar fracture of the humerus (*open arrows*.) **B:** Similar case treated with percutaneous pinning of radial physeal fracture and supracondylar humeral fracture.

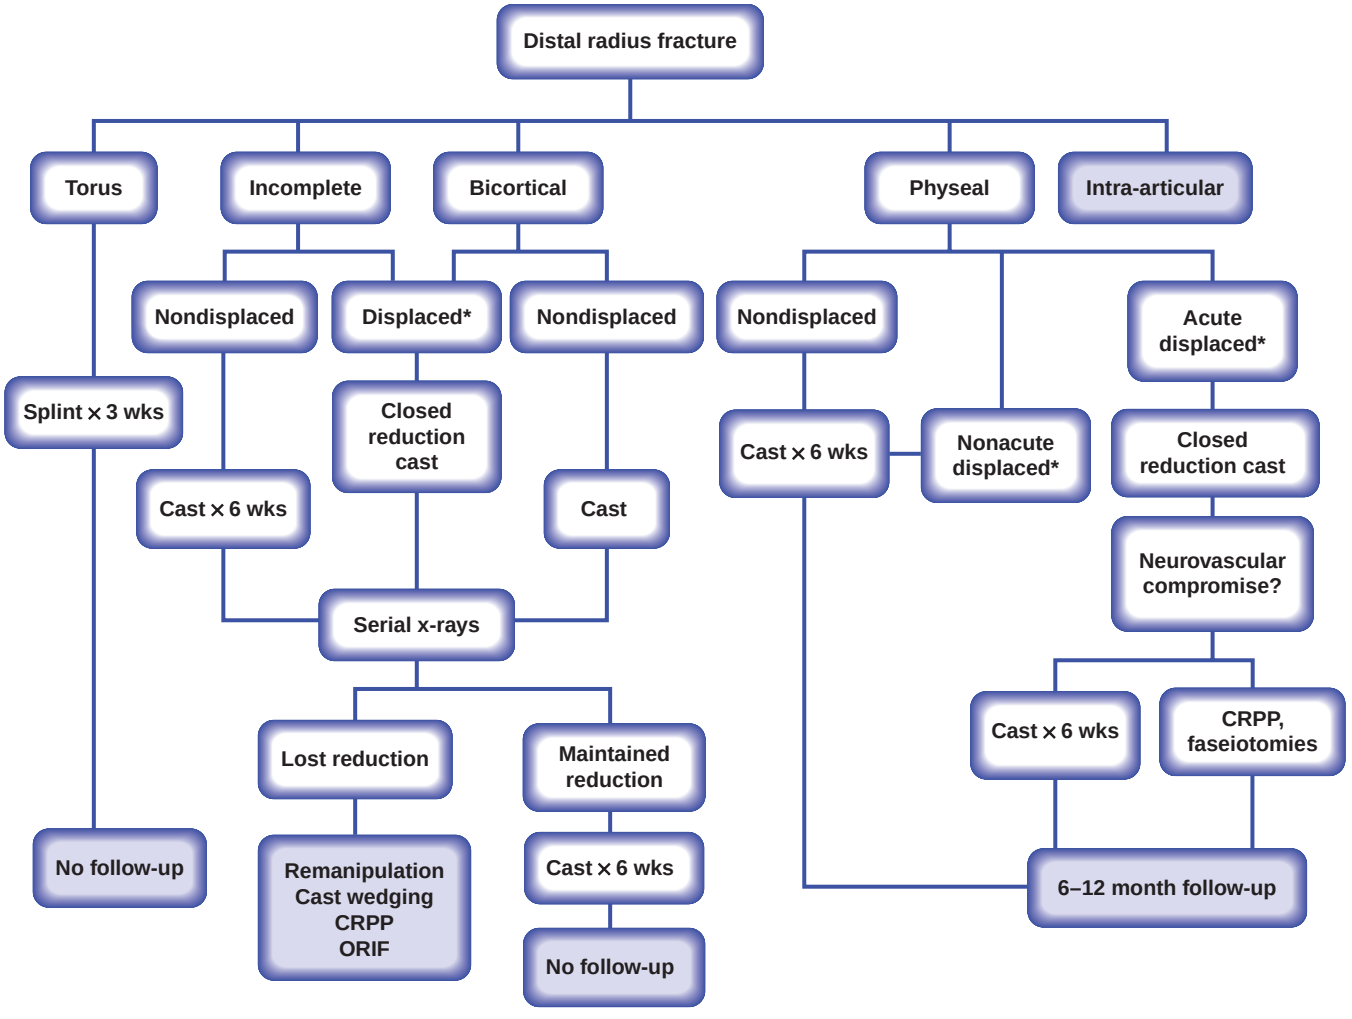

FIGURE 11-55 Algorithm

In older patients near or at skeletal maturity with intra-articular comminution, volar locking plate fixation is performed, similar to adults (Figs. 11-55, 11-56).

Potential Pitfalls and Preventative Measures

Potential pitfalls and preventative measures are described in the preceding sections and summarized in Table 11-14.

Management of Expected Adverse Outcomes and Unexpected Complications in Fractures of the Distal Radius and Ulna

Loss of Reduction

Loss of reduction is a common occurrence after closed reduction and cast immobilization of displaced distal radius fractures (Fig. 11-57). Multiple studies demonstrate an incidence of loss of reduction of 20% to 30%.[6,7,10,48,57,90,103,131,134,139,163,164,198,205,216,219] From these studies, factors that have been identified as increasing the risk of loss of reduction with closed manipulation and casting include poor casting, bayonet apposition, age greater than 10, translation of more than 50% the diameter of the radius, apex volar angulation of more than 30 degrees, isolated radial fractures, and radial and ulnar metaphyseal fractures at the same level. More specifically, Mani et al.[131] concluded that initial displacement of the radial shaft of over 50% was the single most reliable predictor of failure of reduction. Proctor et al.[164] found that complete initial displacement resulted in a 52% incidence of redisplacement of distal radial fractures in children and described remanipulation rates of 23%. Pretell et. al.[163] found that post reduction translation of the radius greater than 10% in the sagittal plane resulted 2.7 times more likely loss of reduction. Alemdarólu et al.[6,7] suggest that radial fractures with greater than 30 degrees of obliquity have 11.7 times more likelihood to redisplace than a straight transverse fracture.

In addition to the initial and postreduction angulation, a poor casting technique is often implicated as a cause of loss of reduction. Recently, it has become evident that casting alone is likely not sufficient to prevent loss of reduction for fractures at high risk of loss of reduction. Miller et al.[136] reported that despite these optimal conditions, 30% of high-risk patients

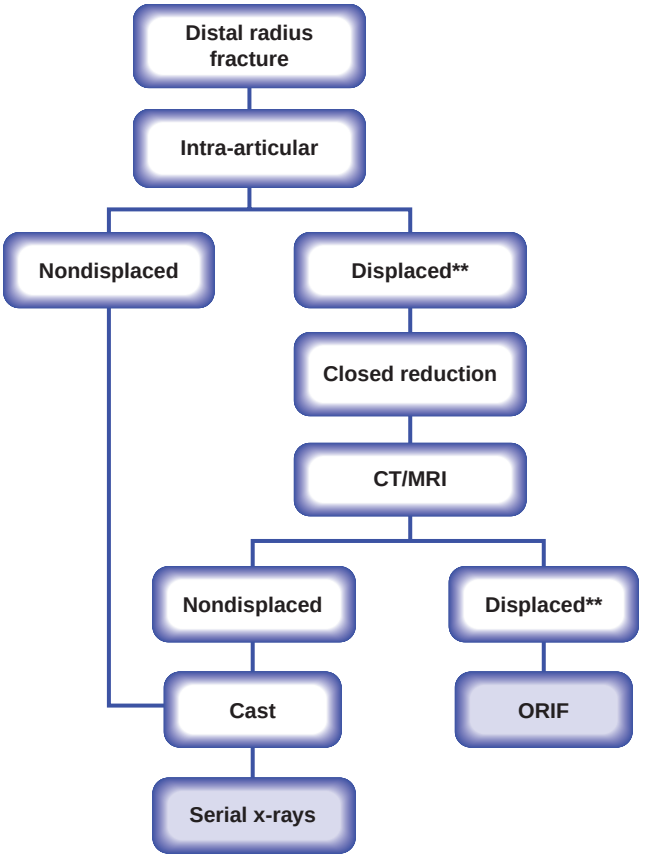

FIGURE 11-56 **Algorithm**

TABLE 11-14 Distal Radius Fractures

Potential Pitfalls and Preventions

Pitfall	Preventions
Loss of reduction	Correct diagnosis of bicortical disruption Optimal fracture reduction Well-molded cast application Serial radiographic evaluation
Posttraumatic growth arrest	Avoidance of repeated forceful reduction maneuvers acutely Avoidance of late manipulation for loss of reduction in children with considerable remaining growth
Compartment syndrome	Thorough neurovascular evaluation at time of initial presentation Avoidance of excessive forceful manipulation during reduction maneuvers Immediate pin fixation in patients with excessive soft tissue swelling or neurovascular compromise Bivalve circumferential casts to avoid excessive external compression Timely surgical stabilization with fasciotomies or carpal tunnel release in patients with impending compartment syndrome
Radial sensory nerve injury	Use of small incisions for nerve identification and retraction during pinning procedures Pin placement using oscillating technique

treated with cast immobilization alone sustained a loss of reduction that required remanipulation. These findings have generated enthusiasm for percutaneous pinning and casting for as a preferable method to avoid loss of reduction.[78,217] Although the authors of these studies, and others,[217] conclude that pinning is a safe, effective means of treating distal radial metaphyseal fractures (see Controversies); the results of casting and pinning were equivalent after 2 years postfracture.[38,133]

In general loss of reduction has been tolerated because of the remodeling potential of the distal radius.[70,153,221] However, given that remodeling can be incomplete leading to malunion (see Malunion section) with functional deficits, high rates of loss of reduction has led to considerable controversies regarding acceptable displacement, casting techniques, remanipulation, and need for initial percutaneous pinning. We prefer to reduce forearm fractures as near to perfect alignment as possible. No element of malrotation is accepted in the reduction. As indicated in the treatment sections, fractures at high risk of loss of reduction and malunion are treated with anatomic reduction and pin or, rarely, plate fixation. Fractures treated in a cast are followed closely and rereduced for any loss of alignment of more than 10 degrees. Although loss of forearm rotation can occur with anatomic healing,[144,190] it is less likely than with a malunion.

Malunion

While complications from metaphyseal and physeal fractures of the radius are relatively rare, malunions do occur.[11,31,39,37,38,44,50,198] De Courtivron[45] reported that of 602 distal radial fractures, 14% had an initial malunion of more than 5 degrees. In addition, as noted above, the rate of loss of reduction for distal radius fractures ranges from 20% to 30%, and although many of these fractures will be rereduced, inevitably surgeons will encounter malunion of the distal radius most often to avoid injury to the physis from remanipulation beyond 7 days of injury or a patient may miss a follow-up appointment. Fortunately, with significant growth remaining, many angular malunions of the distal radius will remodel,[45,50,70,108,153,221] probably because of asymmetric physeal growth (Fig. 11-24).[112,125] The younger the patient, the less the deformity, and the closer the fracture is to the physis, the greater the potential for remodeling. Distal radial fractures are most often juxtaphyseal, the malunion typically is in the plane of motion of the wrist joint (dorsal displacement with apex volar angulation), and the distal radius accounts for 60% to 80% of the growth of the radius. All these factors favor remodeling of a malunion.

The malunited fracture should be monitored over the next 6 to 12 months for remodeling. If the fracture does not remodel, persistent extension deformity of the distal radial articular surface puts the patient at risk for developing midcarpal instability[185,186] or degenerative arthritis of the wrist, though a recent report has raised the question of whether imperfect final radiographic alignment necessarily leads to symptomatic arthrosis.[69] For malunion correction, an opening-wedge (dorsal or volar) osteotomy is made, iliac crest bone of appropriate trapezoidal shape to correct the deformity is inserted, and either a plate or external fixator is used to maintain correction until healing.[68]

As there are controversies as to what degree of deformity is either less likely to remodel, or cause a functional loss (see Controversies) the degree and plane of loss of motion, as well as the individual affected, determine if this is functionally significant.[215] In cadaver studies, malangulation of more than 20 degrees of the radius or ulna caused loss of forearm rotation,[132,187] whereas less than 10 degrees of malangulation did not alter forearm rotation significantly. Distal third malunion affected rotation less than middle or proximal third malunion. Radioulnar malunion affected forearm rotation more than volar–dorsal malunion. Excessive angulation may lead to a loss of rotation at a 1:2 degree ratio, whereas malrotation may lead to rotational loss at only a 1:1 degree loss.[169] The functional loss associated with rotational motion loss is difficult to predict. This has led some clinicians to recommend no treatment,[42,44] arguing that most of these fractures will remodel, and those that do not remodel will not cause a functional problem.[106] However, a significant functional problem is present if shoulder motion cannot compensate for loss of supination.

Intra-articular malunion is potentially devastating complication, due to the risk of degenerative arthritis if the articular stepoff is more than 2 mm.[119] MRI or CT scans can be useful in preoperative evaluations. Arthroscopy allows direct examination of the deformity and areas of impingement or potential degeneration. Intra-articular osteotomy with bone grafting in the metaphysis to support the reconstructed articular surface is controversial and risky; however, it has the potential to restore anatomic alignment to the joint and prevent serious long-term complications. This problem fortunately is uncommon in children because of the rarity of the injury and this type of malunion.

In Galeazzi fractures, malunion of the radius can lead to subluxation of the DRUJ, limited forearm rotation, and pain, usually secondary to persistent shortening and malrotation of the radial fracture. Most often, this occurs when complete fractures are treated with closed reduction and there is failure to either obtain or maintain reduction of the radial fracture. The ulna remains subluxed and heals with an incongruent joint. Treatment of this requires proper recognition and corrective osteotomy. If physical examination is not definitive for diagnosis, then a CT scan in pronation, neutral rotation, or supination may be helpful. MRI or wrist arthroscopy will aid in the diagnosis and management of associated ligamentous, chondral, or TFCC injuries that will benefit from debridement or repair. It is important to understand that if the DRUJ subluxation is caused by a radial malunion, a soft tissue reconstruction of the DRUJ alone will fail. In the true soft tissue disruption, repair of the TFCC will often stabilize the DRUJ. If there is no TFCC tear, soft tissue reconstruction of the DRUJ ligaments with extensor retinaculum or local tendon is appropriate.

Nonunion

Nonunion of a closed radial or ulnar fracture is rare. In children, nonunion has been universally related to a pathologic condition of the bone or vascularity.[27,84] Congenital pseudarthrosis or neurofibromatosis (Fig. 11-58) should be suspected in a patient with a nonunion after a benign fracture.[111] This occurs

FIGURE 11-58 This 3-year-old presented to the emergency room with pain after an acute fall on his arm. The ulna is clearly pathologic with thinning and deformity before this injury. This represents neurofibromatosis.

most often after an isolated ulnar fracture.[81,183] The distal bone is often narrowed, sclerotic, and plastically deformed. These fractures rarely heal with immobilization. Vascularized fibular bone grafting usually is necessary for healing of a nonunion associated with neurofibromatosis or congenital pseudarthrosis. If the patient is very young, this may include a vascularized epiphyseal transfer to restore distal growth.

Vascular impairment also can lead to nonunion. Distal radial nonunion has been reported in a child with an ipsilateral supracondylar fracture with brachial artery occlusion. Revascularization of the limb led to eventual union of the fracture. Nonunion also can occur with osteomyelitis and bone loss.[25] Debridement of the necrotic bone and either traditional bone grafting, osteoclasis lengthening, vascularized bone grafting, or creation of a single-bone forearm are surgical options. The choice depends on the individual patient.

Cross-Union

Cross-union, or posttraumatic radioulnar synostosis, is a rare complication of pediatric distal radial and ulnar fractures. It has been described after high-energy trauma and internal fixation.[196,197] A single-pin crossing both bones increases the risk of cross-union.[197] Synostosis take-down can be performed, but the results usually are less than full restoration of motion. It is important to determine if there is an element of rotational malunion with the cross-union because this will affect the surgical outcome.

Soft tissue contraction across both bones also has been described.[66] Contracture release resulted in restoration of forearm motion.

Refracture

Fortunately, refractures after distal radial fractures are rare and much less common than after diaphyseal level radial and ulnar fractures and fractures in adults. This is likely due to the unique biology in children where, as opposed to adults, remineralization after forearm fractures in children occurs rapidly with a transient elevation in bone mineral density.[71] Most commonly, refracture occurs with premature discontinuation of immobilization or early return to potentially traumatic activities. It is advisable to protectively immobilize the wrist until full radiograph and clinical healing (usually 6 weeks) and to restrict activities until full motion and strength are regained (usually an additional 1 to 6 weeks). Individuals involved in high-risk activities, such as downhill ski racing, snowboarding, or skateboarding, should be protected with a splint during those activities for much longer.

Physeal Arrest of the Distal Radius

Distal radial physeal arrest can occur from either the trauma of the original injury (Fig. 11-59)[3,8,96] or late reduction of a displaced fracture. The incidence of radial growth arrest has been shown to be 4% to 5% of all displaced radial physeal fractures.[12,27,126] The trauma to the physeal cartilage from displacement and compression is a significant risk factor for growth arrest. However, a correlation between the risk of growth arrest and the degree of displacement, type of fracture, or type of reduction has yet to be defined. Similarly, the risk of further compromising the physis with late reduction at various time intervals is still unclear. The current recommendation is for an atraumatic reduction of a displaced physeal fracture less than 7 days after injury.

When a growth arrest develops, the consequences depend on the severity of the arrest and the amount of growth remaining. A complete arrest of the distal radial physis in a skeletally immature patient can be a serious problem. The continued growth of the ulna with cessation of radial growth can lead to incongruity of the DRUJ, ulnocarpal impaction, and development of a TFCC tear (Fig. 11-60).[12,202] The radial deviation deformity at the wrist can be severe enough to cause limitation of wrist and forearm motion. Pain and clicking can develop at the ulnocarpal or radioulnar joints, indicative of ulnocarpal impaction or a TFCC tear. The deformity will progress until the end of growth. Pain and limited motion and function will be present until forearm length is rebalanced, until the radiocarpal, ulnocarpal, and radioulnar joints are restored, and until the TFCC tear and areas of chondromalacia are repaired or debrided.[12,150,189]

Ideally, physeal arrest of the distal radius will be discovered early before the consequences of unbalanced growth develop. Radiographic screening 6 to 12 months after injury can identify the early arrest. A small area of growth arrest in a patient near skeletal maturity may be clinically inconsequential. However, a large area of arrest in a patient with marked growth remaining

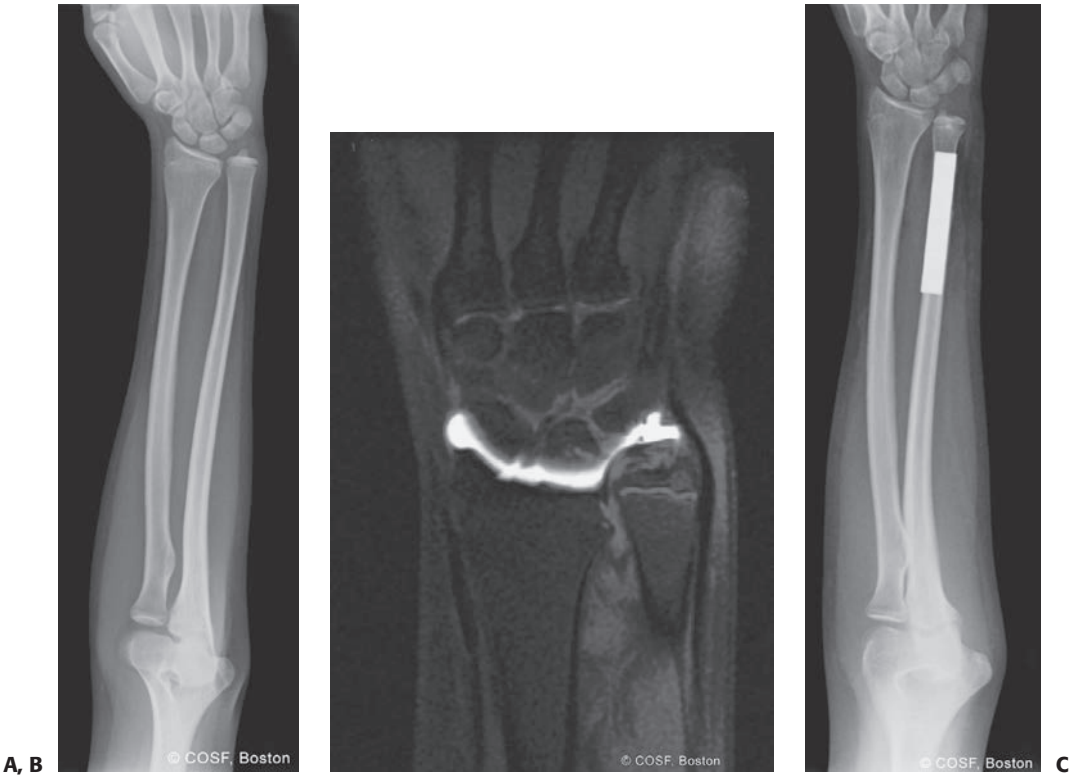

FIGURE 11-59 **A:** AP radiograph of growth arrest with open ulnar physis. **B:** MRI scan of large area of growth arrest that was not deemed respectable by mapping. Note is made of impaction of the distal ulna against the triquetrum and a secondary peripheral TFCC tear. **C:** Radiograph after ulnar shortening osteotomy, restoring neutral ulnar variance.

can lead to ulnocarpal impaction and forearm deformity if intervention is delayed. MRI can map the area of arrest.[155] If it is less than 45% of the physis, a bar resection with fat interposition can be attempted.[124] This may restore radial growth and prevent future problems (Fig. 11-61). If the bar is larger than 45% of the physis, bar resection is unlikely to be successful. An early ulnar epiphysiodesis will prevent growth imbalance of the forearm.[202] The growth discrepancy between forearms in most patients is minor and does not require treatment. However, this is not the case for a patient with an arrest at a very young age, for whom complicated decisions regarding forearm lengthening need to occur.

FIGURE 11-60 **A:** AP radiograph of radial growth arrest and ulnar overgrowth after physeal fracture. Patient complained of ulnar-sided wrist pain and clicking. **B:** Clinical photograph of ulnar overgrowth and radial deviation deformity.

FIGURE 11-61 Osseous bridge resection. **A:** This 10-year-old had sustained a distal radial physeal injury 3 years previously and now complained of prominence of the distal ulna with decreased supination and pronation. **B:** Polytomes revealed a well-defined central osseous bridge involving about 25% of the total diameter of the physis. **C:** The bridge was resected, and autogenous fat was inserted into the defect. Growth resumed with resumption of the normal ulnar variance. Epiphysiodesis of the distal ulna was postponed for 6 months. **D:** Unfortunately, the radius slowed its growth, and a symptomatic positive ulnar variance developed. **E:** This was treated with an epiphysiodesis (*open arrow*). and surgical shortening of the ulna. The clinical appearance and range of motion of the forearm returned to essentially normal.

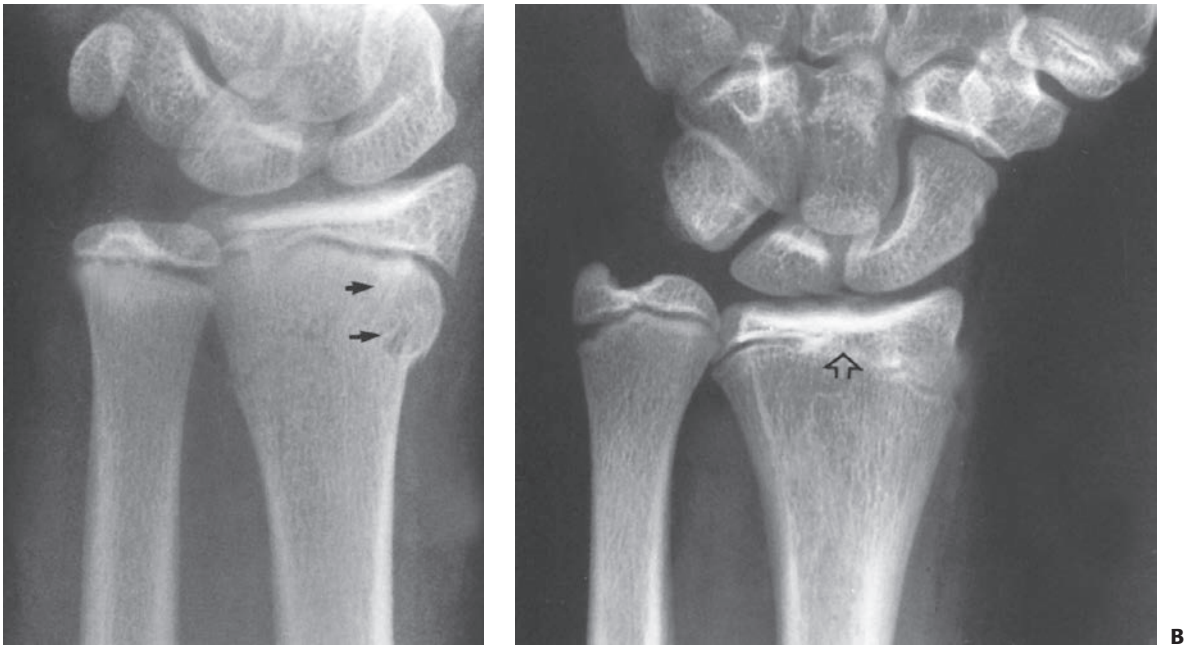

FIGURE 11-62 Physeal arrest in a Peterson type I fracture. **A:** Injury film showing what appears to be a benign metaphyseal fracture. Fracture line extends into the physis (*arrows*). **B:** Two years postinjury, a central arrest (*open arrow*) has developed, with resultant shortening of the radius. (Reprinted from Wilkins KE, ed. *Operative Management of Upper Extremity Fractures in Children*. Rosemont, IL: American Academy of Orthopaedic Surgeons, 1994:21, with permission.)

If a radial growth arrest occurs associated with a radial physeal stress fracture, treatment depends on the degree of deformity and the patient's symptoms. Physeal bar resection often is not possible because the arrest is usually too diffuse in stress injuries. If there is no significant ulnar overgrowth, a distal ulnar epiphysiodesis will prevent the development of an ulnocarpal impaction syndrome. For ulnar overgrowth and ulnocarpal pain, an ulnar shortening osteotomy is indicated. Techniques include transverse, oblique, and Z-shortening osteotomies. Transverse osteotomy has a higher risk of nonunion than either oblique or Z-shortening and should be avoided. Even when oblique or Z-shortenings are used, making the osteotomy more distally in the metaphyseal region will lessen the risk of nonunion, owing to the more robust vascularity of the distal ulna. The status of the TFCC also should be evaluated by MRI or wrist arthroscopy. If there is an associated TFCC tear, it should be repaired as appropriate.

Growth arrest of the distal radius after metaphyseal fracture is extremely rare with only five cases reported in the literature. Wilkins and O'Brien[209] proposed that these arrests may be in fractures that extend from the metaphysis to the physis. This coincides with a Peterson type I fracture (Fig. 11-62)[156] and in essence is a physeal fracture. These fractures should be monitored for growth arrest.

Both undergrowth and overgrowth of the distal radius after fracture were described by de Pablos.[46] The average difference in growth was 3 mm, with a range of −5 to +10 mm of growth disturbance compared with the contralateral radius. Maximal overgrowth occurred in the 9- to 12-year-old age group. As long as the patient is asymptomatic, under- or overgrowth is not a problem. If ulnocarpal impaction or DRUJ disruption occurs, then surgical rebalancing of the radius and ulna may be necessary

Physeal Arrest Distal Ulna

Physeal growth arrest is frequent with distal ulnar physeal fractures (Fig. 11-63), occurring in 10% to 55% of patients.[81] It is unclear why the distal ulna has a higher incidence of growth arrest after fracture than does the radius. Ulnar growth arrest in a young child leads to relative radial overgrowth and bowing. The most common complication of distal ulnar physeal fractures is growth arrest. Golz[81] described 18 such fractures, with growth arrest in 10%. If the patient is young enough, continued growth of the radius will lead to deformity and dysfunction. The distal ulnar aspect of the radial physis and epiphysis appears to be tethered by the foreshortened ulna (Fig. 11-64). The radial articular surface develops increased inclination toward the foreshortened ulna. This is similar to the deformity Peinado[152] created experimentally with arrest of the distal ulna in rabbits' forelimbs. The distal ulna loses its normal articulation in the sigmoid notch of the distal radius. The metaphyseal–diaphyseal region of the radius often becomes notched from its articulation with the distal ulna during forearm rotation. Frequently, these patients have pain and limitation of motion with pronation and supination.[16]

Ideally, this problem is identified before the development of marked ulnar foreshortening and subsequent radial deformity. Because it is well known that distal ulnar physeal fractures have

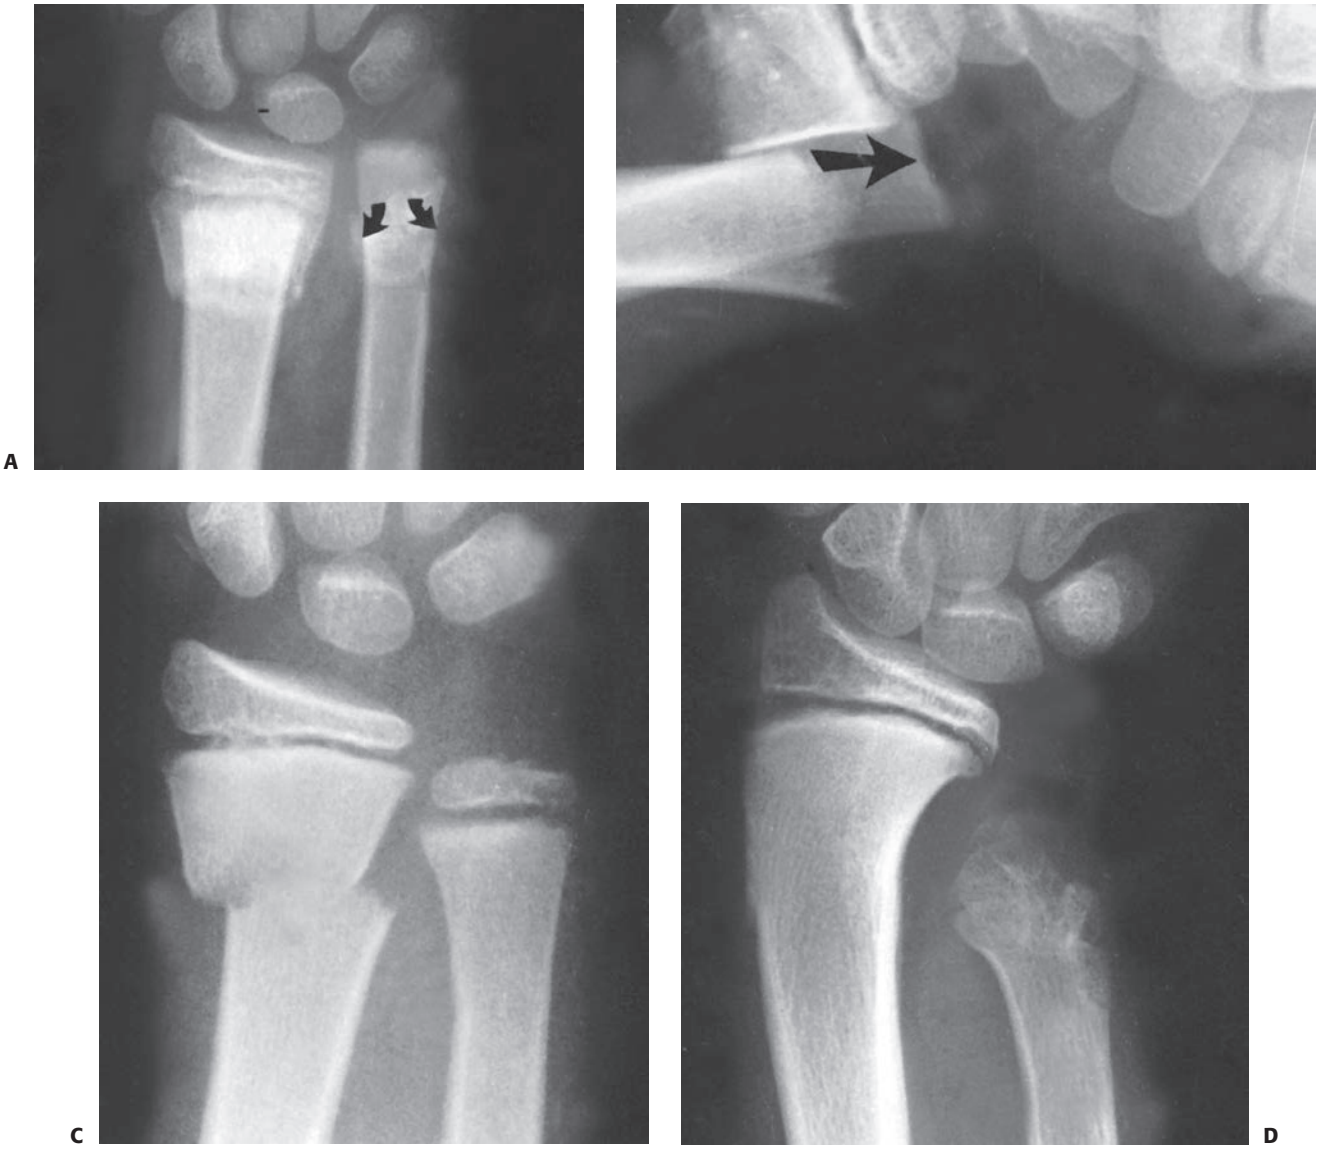

FIGURE 11-63 **A, B:** A 10-year-old boy sustained a closed Salter–Harris type I separation of the distal ulnar physis (*arrows*) combined with a fracture of the distal radial metaphysis. **C:** An excellent closed reduction was achieved atraumatically. **D:** Long-term growth arrest of the distal ulna occurred.

a high incidence of growth arrest, these patients should have serial radiographs at 6 to 12 months after fracture for early identification. Unfortunately, in the distal ulnar physis, physeal bar resection generally is unsuccessful. Surgical arrest of the radial physis can prevent radial deformity. Usually, this occurs toward the end of growth so that the forearm length discrepancy is not a problem.

Rarely, patients present late with established deformity. Treatment involves rebalancing the length of the radius and ulna. The options include hemiphyseal arrest of the radius, corrective radial closing wedge osteotomy, and ulnar lengthening,[16,81,143] or a combination of these procedures. The painful impingement of the radius and ulna with forearm rotation can be corrected with reconstitution of the DRUJ. If the radial physis has significant growth remaining, a radial physeal arrest should be done at the same time as the surgical rebalancing of the radius and ulna. Treatment is individualized depending on the age of the patient, degree of deformity, and level of pain and dysfunction.

Golz et al.[81] cited ulnar physeal arrest in 55% of Galeazzi equivalent fractures. If the patient is young enough, this ulnar growth arrest in the presence of ongoing radial growth will lead to deformity. Initially, there will be ulnar shortening. Over time, the foreshortened ulna can act as a tether, causing asymmetric growth of the radius. There will be increased radial articular inclination on the AP radiograph and subluxation of the

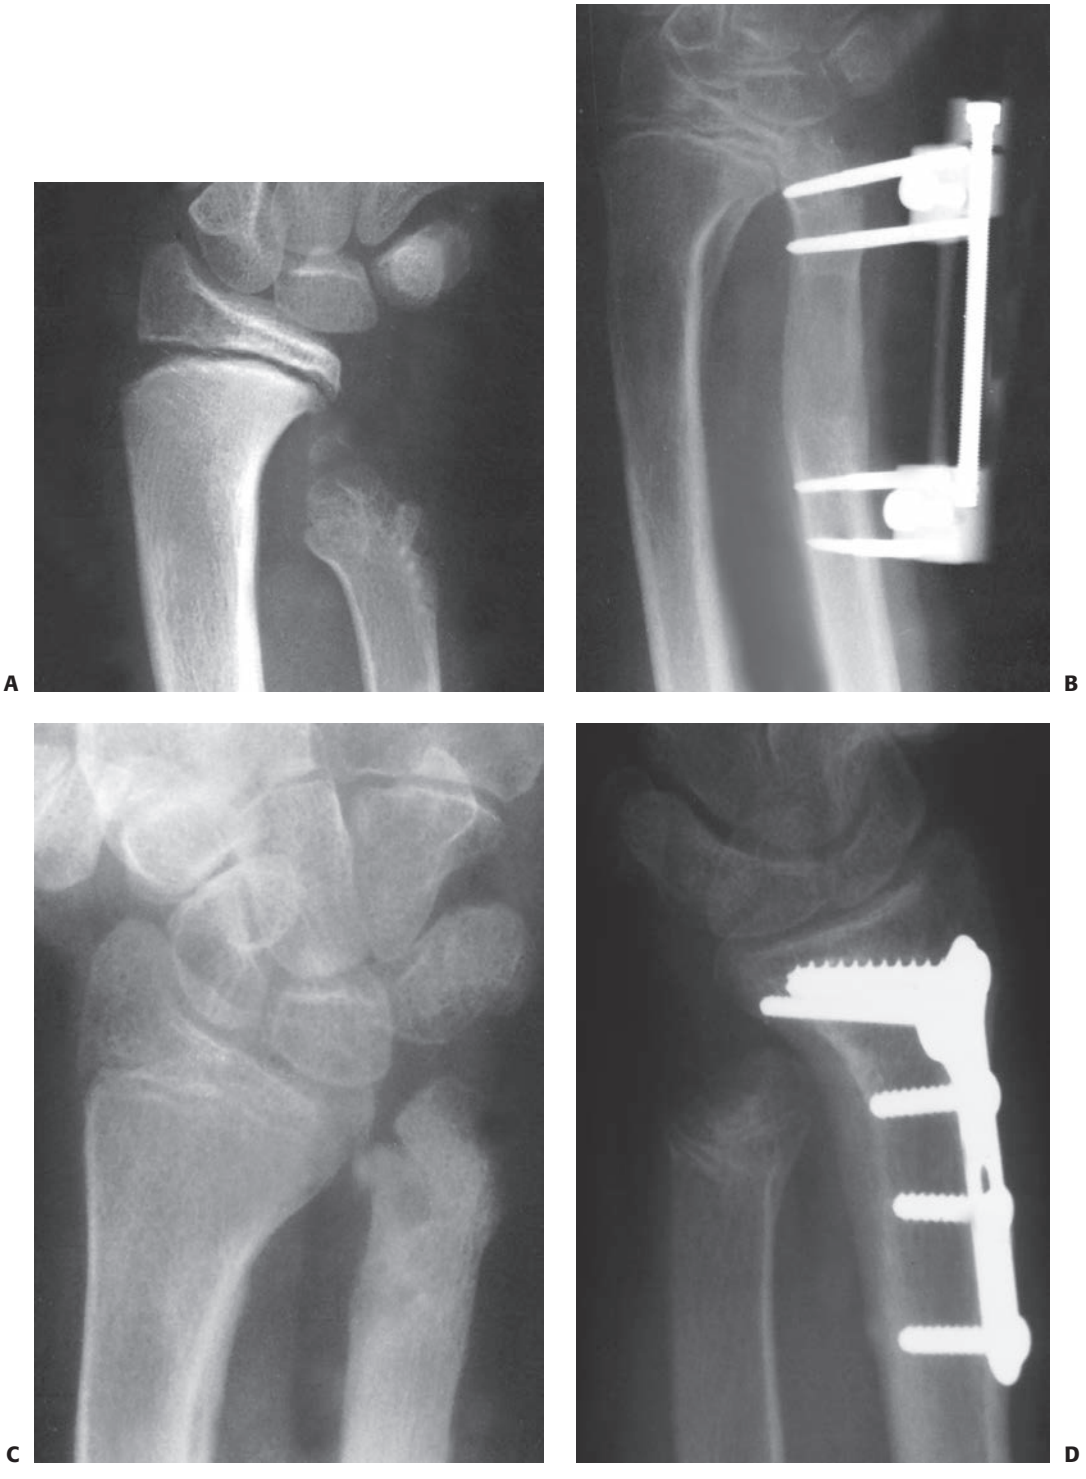

FIGURE 11-64 **A:** The appearance of the distal ulna in the patient seen in Figure 11-44, 3 years after injury, demonstrating premature fusion of the distal ulnar physis with 3.2 cm of shortening. The distal radius is secondarily deformed, with tilting and translocation toward the ulna. **B:** In the patient in Figure 11-44 with distal ulnar physeal arrest, a lengthening of the distal ulna was performed using a small unipolar distracting device. The ulna was slightly overlengthened to compensate for some subsequent growth of the distal radius. **C:** Six months after the lengthening osteotomy, there is some deformity of the distal ulna, but good restoration of length has been achieved. The distal radial epiphyseal tilt has corrected somewhat, and the patient has asymptomatic supination and pronation to 75 degrees. **D:** Similar case to Figure 11-66A–C, but with more progressive distal radial deformity treated with corrective osteotomy and epiphysiodesis of the distal radius.

DRUJ. Operative choices include ulnar lengthening, radial closing wedge osteotomy, radial epiphysiodesis, and a combination of the above procedures that is appropriate for the individual patient's age, deformity, and disability.

Ulnocarpal Impaction Syndrome

The growth discrepancy between the radius and ulna can lead to relative radial shortening and ulnar overgrowth. The distal ulna can impinge on the lunate and triquetrum and cause pain with ulnar deviation, extension, and compression activities.[16] This is particularly true in repetitive wrist loading sports such as field hockey, lacrosse, and gymnastics.[49] Physical examination loading the ulnocarpal joint in ulnar deviation and compression will recreate the pain. Radiographs show the radial arrest, ulnar overgrowth, and distal ulnocarpal impingement. The ulnocarpal impaction also may be caused by a hypertrophic ulnar styloid fracture union or an ulnar styloid nonunion.[25] MRI may reveal chondromalacia of the lunate or triquetrum, a tear of the TFCC, and the extent of the distal radial physeal arrest.

Treatment should correct all components of the problem. The ulnar overgrowth is corrected by either an ulnar shortening or radial lengthening osteotomy. Most often, a marked degree of positive ulnar variance requires ulnar shortening to neutral or negative variance (Fig. 11-65). If the ulnar physis is still open, a simultaneous arrest should be done to prevent recurrent deformity. If the degree of radial deformity is marked, this should be corrected by a realignment or lengthening osteotomy. Criteria for radial correction is debatable, but we have used radial inclination of less than 11 degrees on the AP radiograph as an indication for correction.[202] In the rare case of complete arrest in a very young patient, radial lengthening is preferable to ulnar shortening to rebalance the forearm.

Triangular Fibrocartilage Complex Tears

Peripheral traumatic TFCC tears should be repaired. The presence of an ulnar styloid nonunion at the base often is indicative of an associated peripheral tear of the TFCC.[1,12,150,189] The symptomatic ulnar styloid nonunion is excised[25] and any TFCC tear is repaired. If physical examination or preoperative MRI indicates a TFCC tear in the absence of an ulnar styloid nonunion, an initial arthroscopic examination can define the lesion and appropriate treatment. Peripheral tears are the most common TFCC tears in children and adolescents and can be repaired arthroscopically by an outside-in suture technique. Tears off the sigmoid notch are the next most common in adolescents and can be repaired with arthroscopic-assisted, transradial sutures. Central tears are rare in children and, as opposed to adults with degenerative central tears, arthroscopic debridement usually does not result in pain relief in children. Distal volar tears also are rare and are repaired open, at times with ligament reconstruction.[189]

Some ulnar styloid fractures result in nonunion or hypertrophic union.[1,12,25,150,189] Nonunion may be associated with TFCC tears or ulnocarpal impaction. The hypertrophic healing represents a pseudoulnar positive variance with resultant ulnocarpal impaction. Both cause ulnar-sided wrist pain. Compression of the lunate or triquetrum on the distal ulna reproduces the pain. Clicking with ulnocarpal compression or forearm rotation

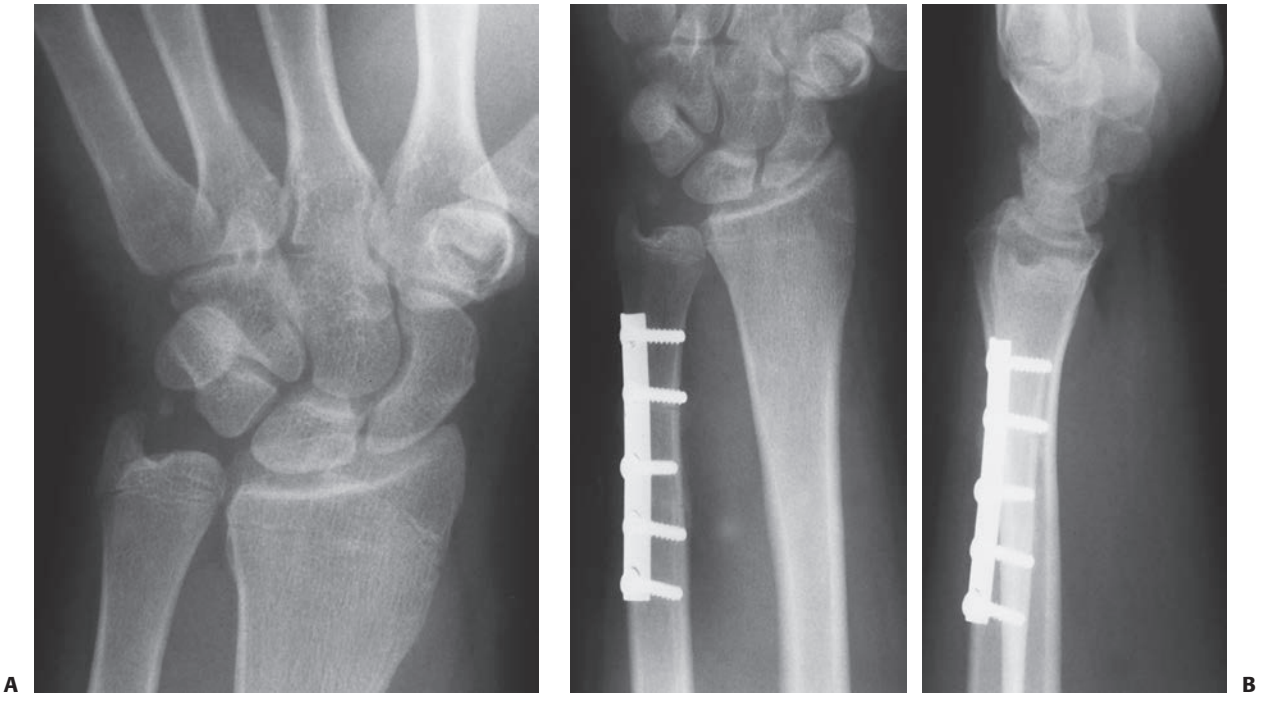

FIGURE 11-65 **A:** AP radiograph of distal radial growth arrest, ulnar overgrowth, and an ulnar styloid nonunion. Wrist arthroscopy revealed an intact triangular fibrocartilage complex. **B:** AP and lateral radiographs after ulnar shortening osteotomy.

represents either a TFCC tear or chondromalacia of the lunate or triquetrum. Surgical excision of the nonunion or hypertrophic union with repair of the TFCC to the base of the styloid is the treatment of choice. Postoperative immobilization for 4 weeks in a long-arm cast followed by 2 weeks in a short-arm cast protects the TFCC repair.

Neuropathy

Median neuropathy can occur from direct trauma from the initial displacement of the fracture, traction ischemia from a persistently displaced fracture, or the development of a compartment syndrome in the carpal canal or volar forearm (Fig. 11-7).[15,203] Median neuropathy and marked volar soft tissue swelling are indications for percutaneous pin stabilization of the fracture to lessen the risk of compartment syndrome in a cast. Median neuropathy caused by direct trauma or traction ischemia generally resolves after fracture reduction. The degree of neural injury determines the length of time to recovery. Recovery can be monitored with an advancing Tinel sign along the median nerve. Motor-sensory testing can define progressive return of neural function.

Median neuropathy caused by a carpal tunnel syndrome will not recover until the carpal tunnel is decompressed. After anatomic fracture reduction and pin stabilization, volar forearm and carpal tunnel pressures are measured. Gelberman[74] recommended waiting 20 minutes or more to allow for pressure–volume equilibration before measuring pressures. If the pressures are elevated beyond 40 mm Hg or the difference between the diastolic pressure and the compartment pressure is less than 30 mm Hg,[107] an immediate release of the affected compartments should be performed. The carpal tunnel is released through a palmar incision in line with the fourth ray, with care to avoid injuring the palmar vascular arch and the ulnar nerves exiting the Guyon canal. The transverse carpal ligament is released with a Z-plasty closure of the ligament to prevent late bow-stringing of the nerve against the palmar skin. The volar forearm fascia is released in the standard fashion.

Both the median and ulnar[34,195] nerves are less commonly injured in metaphyseal fractures than in physeal fractures. The mechanisms of neural injury in a metaphyseal fracture include direct contusion from the displaced fragment, traction ischemia from tenting of the nerve over the proximal fragment,[153] entrapment of the nerve in the fracture site,[210] rare laceration of the nerve, and the development of an acute compartment syndrome. If signs or symptoms of neuropathy are present, a prompt closed reduction should be performed. Extreme positions of immobilization should be avoided because this can lead to persistent traction or compression ischemia and increase the risk of compartment syndrome. If there is marked swelling, it is better to percutaneously pin the fracture than to apply a constrictive cast. If there is concern about compartment syndrome, the forearm, and carpal canal pressures should be measured immediately. If pressures are markedly elevated, appropriate fasciotomies and compartment releases should be performed immediately. Finally, if the nerve was intact before reduction and is out after reduction, neural entrapment should be considered, and surgical exploration and decompression may be required. Fortunately, most median and ulnar nerve injuries recover after anatomic reduction of the fracture.

Injuries to the ulnar nerve and anterior interosseous nerve have been described with Galeazzi fracture-dislocations.[56,135,170,199] These reported injuries have had spontaneous recovery. Moore et al.[141] described an 8% rate of injury to the radial nerve with operative exposure of the radius for internal fixation in their series. Careful surgical exposure, dissection, and retraction can decrease this risk.

TABLE 11-15 Distal Radial and Ulnar Fractures

Common Adverse Outcomes and Complications

Loss of reduction
Malunion
Nonunion
Growth disturbance (radius or ulna)
Ulnocarpal impaction
TFCC tears
Synostosis
Neuropathy
Infection

Infection

Infection after distal radial fractures is rare and is associated with open fractures or surgical intervention (also see Controversies). Fee et al.[67] described the development of gas gangrene in four children after minor puncture wounds or lacerations associated with distal radial fractures. Treatment involved only local cleansing of the wound in all four and wound closure in one. All four developed life-threatening clostridial infections. Three of the four required upper limb amputations, and the fourth underwent multiple soft tissue and bony procedures for coverage and treatment of osteomyelitis.

Infections related to surgical intervention also are rare. Superficial pin-site infections can occur and should be treated with pin removal and antibiotics. Deep-space infection from percutaneous pinning of the radius has not been described (Table 11-15).

Summary, Controversies, and Future Directions in Fractures of the Distal Radius and Ulna

Controversies

Acceptable Deformity

There is considerable controversy about what constitutes an acceptable reduction.[11,37,38,39,42,45,50,69] This is clearly age dependent; the younger the patient, the greater the potential for remodeling. Volar–dorsal malalignment has the greatest potential for remodeling because this is in the plane of predominant motion of the joint. A recent prospective study found excellent

long-term clinical and radiographic results with reduced cost with nonsedated cast molding in patients with displaced fractures in preteen children.[38] Marked radioulnar malalignment is less likely to remodel. Malrotation will not remodel. The ranges for acceptable reduction according to age are given in the immobilization section on incomplete fractures and apply to complete fractures as well.

Greenstick Fractures

Controversy exists regarding completion of greenstick fractures.[44,168,176] Although some researchers advocate completion of the fracture to reduce the risk of subsequent loss of reduction from the intact periosteum and concave deformity acting as a tension band to redisplace the fracture, completing the fracture increases the risk of instability and malunion.[168,203,209]

Immobilization

The position and type of immobilization after reduction also have been controversial. Recommendations for the position of postreduction immobilization include supination, neutral, and pronation. The rationale for immobilization in pronation is that reduction of the more common apex volar fractures requires correction of the supination deformity.[63] Following this rationale, apex dorsal fractures should be reduced and immobilized in supination. Pollen[160] believed that the brachioradialis was a deforming force in pronation and was relaxed in supination (Fig. 11-66) and advocated immobilization in supination for all displaced distal radial fractures. Kasser[113] recommended immobilization in slight supination to allow better molding of the volar distal radius. Some researchers advocate immobilization in a neutral position, believing this is best at maintaining the interosseous space and has the least risk of disabling loss of forearm rotation in the long term. Davis and Green[44] and Ogden[146] advocated that each fracture seek its own preferred position of stability. Gupta and Danielsson[88] randomized immobilization of distal radial metaphyseal greenstick fractures in neutral, supination, or pronation to try to determine the best position of immobilization. Their study showed a statistical improvement in final healing with immobilization in supination. More recently, Boyer et al.[24] prospectively randomized 109 distal third forearm fractures into long-arm casts with the forearm in neutral rotation, supination, or pronation following closed reduction. No significant differences in final radiographic position were noted among the differing positions of forearm rotation.

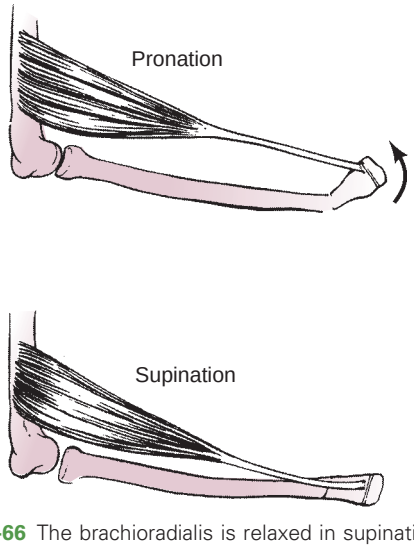

FIGURE 11-66 The brachioradialis is relaxed in supination but may become a deforming force in pronation. (Reprint from Pollen AG. *Fractures and Dislocations in Children.* Churchill Livingstone, MD: Williams & Wilkins, 1973, with permission.)

Another area of controversy is whether long- or short-arm cast immobilization is better. Historically, most publications on pediatric distal radial fracture treatment advocated long-arm cast treatment for the first 3 to 4 weeks of healing.[20,93,146,160] The rationale is that elbow flexion reduces the muscle forces acting to displace the fracture. In addition, a long-arm cast may further restrict the child's activity and therefore decrease the risk of displacement. However, Chess et al.[31] reported redisplacement and reduction rates with well-molded short-arm casts similar to those with long-arm casts. They used a cast index (sagittal diameter divided by coronal diameter at the fracture site) of 0.7 or less to indicate a well-molded cast. In addition, two prospective studies have recapitulated these findings. The short-arm cast offers the advantage of elbow mobility and better patient acceptance of casting. Two recent randomized prospective clinical trials and a meta-analysis review compared the efficacy of short- and long-arm cast immobilization following closed reduction for pediatric distal radial fractures.[20,93] Bohm et al.[20] randomized 102 patients over the age of 4 years to either short- or long-arm casts following closed reduction of displaced distal radial metaphyseal fractures. No statistically significant difference was seen in loss of reduction rate between the two treatment groups. Webb et al.[205] similarly randomized 103 patients to short- or long-arm casts after reduction of distal radial fractures. No significant difference in rate of lost reduction was seen between the two cohorts. Patients in short-arm casts, however, missed fewer days of school and required less assistance with activities of daily living than those with long-arm casts. In both of these studies, quality of fracture reduction and cast mold were influential factors in loss of reduction rates. These studies have challenged the traditional teaching regarding the need for elbow immobilization to control distal radial fracture alignment.

Immediate Pinning of Displaced Distal Radius Fractures

In the past decade or two, closed reduction and percutaneous pinning have become more common as the primary treatment of distal radial metaphyseal fractures in children and adolescents.[95,78,129,183,192,217] Despite this practice change, a meta-analysis review of the data comparing cast immobilization versus immediate pinning reveals equivalent long-term outcomes, despite more loss of reduction in the cast groups and more pin complications in the pin groups[11] The indications cited include fracture instability and high risk of loss of

reduction increasing the likelihood of the need for remanipulation,[6,48,57,90,103,130,133,138,162,163,219] excessive local swelling that increases the risk of neurovascular compromise,[15,44,202] and ipsilateral fractures of the distal radius and elbow region (floating elbow) that increase the risk of compartment syndrome.[19,170,181] In addition, surgeon's preference for pinning in a busy office practice has been considered an acceptable indication because of similar complication rates and long-term outcomes with pinning and casting[132,135] and the avoidance of remanipulation because alignment is secure.

Open Fractures

There have been multiple studies[51,104] demonstrating that the infection rate (2.5% to 4%) following nonoperative treatment of Gustillo grade 1 open fractures results in infection rates comparable to reported rates for operative[84] treatment (2.5%). However, these were retrospective studies and likely will not change the standard of care of these fractures until an appropriate prospective randomized study has been conducted.

Conclusions

Fractures of the distal forearm are common in the pediatric population. Given their proximity to the distal physes of the radius and ulna, these fractures have tremendous remodeling capacity and as a result, the majority may be effectively treated with appropriate nonoperative means. The future direction for management of these fractures is primarily focused upon prognosticating which fractures would be better served through surgical reduction and fixation, considering the relatively high rate of loss of reduction of these fractures.

12 DIAPHYSEAL RADIUS AND ULNA FRACTURES

Charles T. Mehlman and Eric J. Wall

Introduction to Diaphyseal Radius and Ulna Fractures

Injuries to the shafts of the radius and ulna are the most common reasons for children to receive orthopedic care[60,62,203] and are among the most challenging to the orthopedist because of their treatment complexity and risk of complications.[79,233,257] Because of numerous differences in both treatment and prognosis, shaft fractures are considered to be clinically distinct from fractures of the distal (metaphyseal fractures and physeal fractures) and proximal (radial neck fractures and physeal fractures) ends of the same bones.[71,145,282,323,328,329] Many shaft injuries in children are effectively treated with skillful closed fracture care,[162,256,354] but failures continue to occur despite good orthopedic intentions.[40] Care by reduction, splint/cast molding, remanipulation, and recasting, as well as treatment of delayed union, malunion, and refracture must be mastered.

Over the past 10 years there has been a dramatic increase in surgical fixation of forearm shaft fractures,[139,301] primarily with elastic nails.[103] Shaft fractures of the forearm are also the most common reason for operative care of the forearm in children.[60,128] The evolving indications for surgical treatment of forearm shaft fractures and the resulting outcomes will be covered in detail in this chapter. Thus, it is very important for orthopedic surgeons who treat children to skillfully manage the cognitive and technical aspects of both nonoperative and operative treatment for injuries to the shafts of the radius and ulna.

Risk is a central concept in clinical epidemiology.[215] Landin[185] has shown that the overall risk of fracture in children slowly increases for both males and females until they are 11 or 12 years old and then drops for females and increases further for males (Fig. 12-1). This risk difference is starkly illustrated by the fact that males who are 13 or older have

approximately double the fracture rate of their female peers.[185] Forearm fractures have been reported to be the most common pediatric fracture associated with backyard trampoline use[27] and the second most common one (supracondylar humeral fractures were first) associated with monkey bars.[342] Using a national database, Chung and Spilson[62] looked at the frequency of upper extremity fractures in the United States and found that the single largest demographic group was fractures of the radius and ulna in children aged 14 years or less, with a rate approaching 1 in 100. Two groups of researchers have recently evaluated the relationship between bone mineral density and forearm fractures in children. Using DXA scans Andre Kaelin and his co-authors in Geneva, Switzerland prospectively studied 50 teenagers presenting with their first forearm fracture and 50 healthy controls and found no significant differences between the groups.[54] These same authors suggested that forearm fractures in such teenagers do not appear to be related to osteopenia.[54] However, Laura Tosi and her fellow researchers studied African American children (5 to 9 years of age) in Washington, DC. and found that those who sustained forearm fractures did demonstrate lower bone mineral density and lower vitamin D levels.[276] Therefore taking a calcium intake history on forearm fracture patients remains a prudent practice.

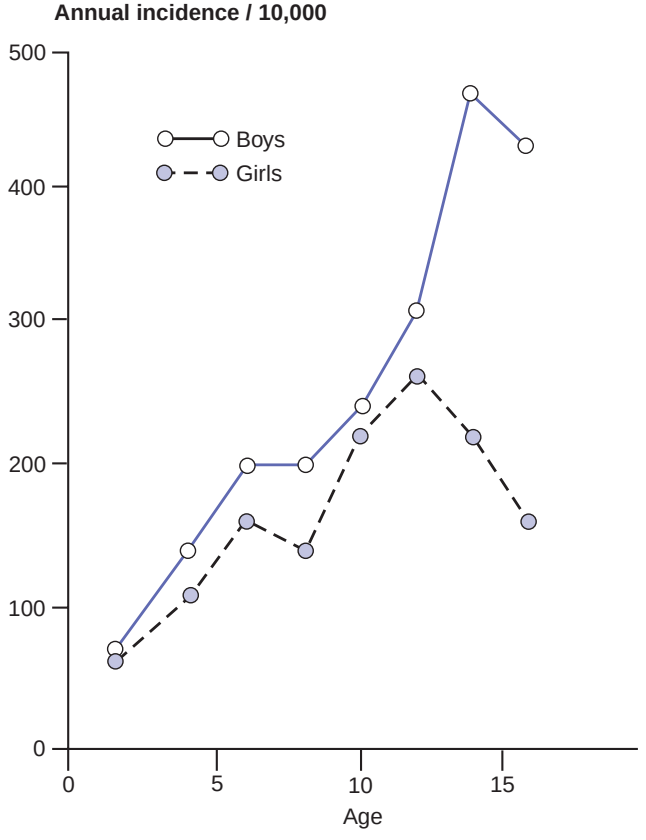

FIGURE 12-1 Annual incidence of all fractures in children. (From Landin LA. Epidemiology of children's fractures. *J Pediatr Orthop B*. 1997;6:79–83.)

Large studies that distinguish distal radial fractures from forearm shaft fractures indicate that overall, radial shaft injuries rank as the third most common fracture of childhood (behind distal radial and supracondylar humeral fractures).[60] Open fractures in children are most often fractures of the shaft of the radius and ulna or tibial shaft fractures.[60] Among pediatric fractures, forearm shaft injuries are the most common site of refracture.[185] Forearm shaft fractures have been shown to occur most commonly in the 12- to 16-year-old age group, a challenging age group to treat.[60] The impact of increasing age on fracture incidence is further illustrated by Worlock and Stower,[353] who showed that the rate of forearm shaft fractures in school-age children (more than 5 years old) is more than double than that in toddlers (1.5 to 5 years old). Age also may have an effect on injury severity. Many experienced clinicians have pointed out the increasing level of treatment difficulty as the level of forearm fracture moves proximally,[71,145,243,328,329] and more proximal fractures tend to occur in older patients.[71]

Assessment of Diaphyseal Radius and Ulna Fractures

Mechanisms of Injury for Diaphyseal Radius and Ulna Fractures

The primary mechanism of injury associated with radial and ulnar shaft fractures is a fall on an outstretched hand that transmits indirect force to the bones of the forearm.[3,66,167] Biomechanical studies have suggested that the junction of the middle and distal thirds of the radius and a substantial portion of the shaft of the ulna have an increased vulnerability to fracture.[151] Often, a significant rotational component is associated with the fall, causing the radius and ulna to fracture at different levels (Fig. 12-2).[93,210] If the radial and ulnar fractures are near the same level, a minimal torsional component can be inferred (Fig. 12-3). If comminution is present, higher-energy trauma should be suspected.[84] Significant hyperpronation forces are associated with isolated shaft fractures of either the radius or the ulna and concomitant dislocation of either the distal or the proximal radioulnar joint (PRUJ). Thus, in any single-bone forearm shaft fracture, these important joints need to be closely scrutinized. Galeazzi and Monteggia fracture dislocations are discussed in Chapters 11 and 14, respectively.

A direct force to the arm (such as being hit by a baseball bat) can fracture a single bone (usually the ulna) without injury to the adjacent distal or PRUJs.[31] Isolated ulnar shaft fractures have been referred to as "nightstick fractures." Alignment of the radial head should be confirmed in any child with such a fracture to avoid a "missed Monteggia" injury.[149] Isolated radial shaft fractures are rare but notoriously difficult to reduce with closed methods.[70,92]

The mechanisms of injury of two particular forearm fracture patterns, traumatic bowing (also known as bow fractures or plastic deformation)[264] and greenstick fracture, also bear mentioning. The bone behaves differently based on the direction of the forces applied to it. This is the so-called anisotropic property of bone, and it can be simply explained as follows:

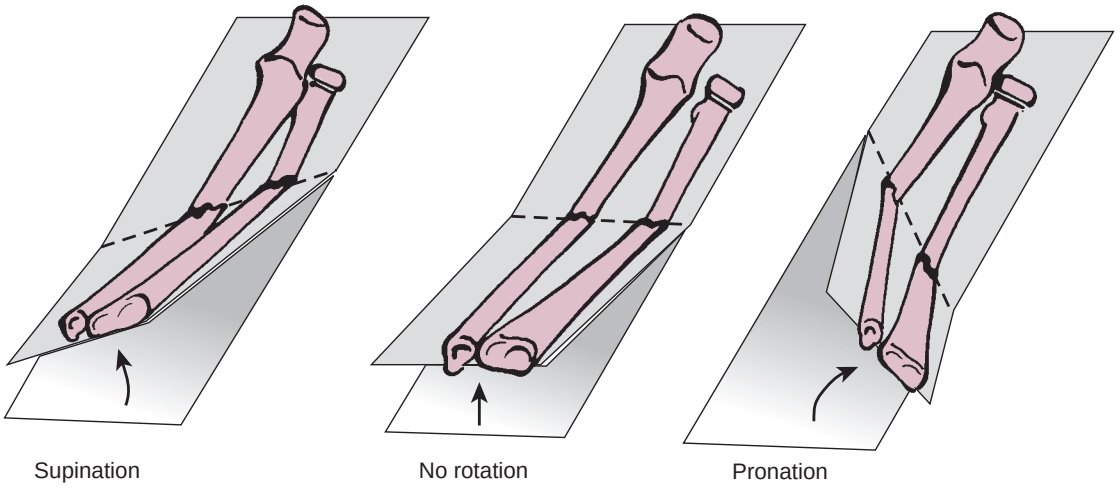

FIGURE 12-2 Radius and ulna shaft fractures occurring at different levels, implying rotational mechanism.

Bone is more resistant to axial forces than to bending and rotational forces.[51] Pediatric bone also is much more porous than its adult counterpart and behaves somewhat differently from a **biomechanical** standpoint.[55,236] Because of its porosity, pediatric bone absorbs significantly more energy prior to failure than the adult bone does.[74] When relatively slowly applied, longitudinal forces bend the immature bone beyond its elastic limits and into its plastic zone, resulting in traumatic bowing.[36,201] Thus, when a bending force is applied relatively slowly, many microfractures occur along the length of the bone, leading to macroscopic deformity without discernible radiographic fracture. This bending can usually be seen radiographically if suspected.

Greenstick fractures represent an intermediate step between plastic deformation and complete fractures.[52] On anteroposterior (AP) and lateral radiographs, greenstick fractures show cortical violation of one, two, or three of their radiographic cortices, and thus some bony continuity is preserved. Rotational

FIGURE 12-3 Radial and ulnar shaft fractures occurring at same level, implying no significant rotation.

deformity is considered to be intimately related to the clinical deformity seen with greenstick fractures of the forearm, and the analogy of a cardboard tube that tends to bend as it is twisted has been offered by Holdsworth.[145] Specifically, hyperpronation injuries usually are associated with apex-dorsal greenstick fractures of the forearm, and hypersupination injuries usually are associated with the opposite, apex-volar injuries.[92,223] The treatment of these greenstick fractures requires a derotation maneuver in addition to correction of any angulation.[52,133]

Associated Injuries with Diaphyseal Radius and Ulna Fractures

Most fractures of the shafts of the radius and ulna occur as isolated injuries, but wrist and elbow fractures may occur in conjunction with forearm fractures, and the elbow and wrist region needs to be included on standard forearm radiographs.[26,75,167,314,351,358] If clinical suspicion is high, then dedicated wrist and elbow films are necessary. The so-called floating elbow injury (fracture of the bones of the forearm along with ipsilateral supracondylar humeral fracture) is a well-described entity that must not be missed.[26,272,314,351] Surgical stabilization of both the supracondylar fracture and the forearm fractures has been recommended by multiple authors in recent years[30,138,271,272,319,322] to avoid the risk of a compartment syndrome. Galeazzi and Monteggia fracture dislocations also must be ruled out. Compartment syndrome can also occur in conjunction with any forearm shaft fracture.[73,362] This rare but potentially devastating complication can lead to a Volkmann ischemic contracture, which has been shown to occur after forearm shaft fractures almost as often as it does after supracondylar humeral fractures in children.[224] Patients with severe pain unrelieved by immobilization and mild narcotic medication should be reassessed for excessive swelling and tight forearm compartments. If loosening of the splint, cast, and underlying cast materials fails to relieve pain, then measurement of compartment pressures and subsequent fasciotomy may be necessary.

Abrasions or seemingly small unimportant lacerations that occur in conjunction with forearm fractures must be carefully evaluated because they may be an indication of an open fracture. Clues to the presence of an open fracture include persistent slow bloody ooze from a small laceration near the fracture site and subcutaneous emphysema on injury films. Careful evaluation and, in some situations, sterile probing of suspicious wounds will be necessary. Open forearm fractures are discussed later in this chapter.

Vascular or neurologic injuries are rarely associated with forearm shaft fractures, but the consequences of such injuries are far-reaching. Serial neurovascular examinations should be performed and documented. Radial and ulnar pulses along with distal digital capillary refill should be routinely evaluated. Davis and Green[79] reported nerve injuries in 1% (5/547) of their pediatric forearm fracture patients, with the most commonly injured nerve being the median nerve. Combined data from three large series of pediatric open forearm fractures reveal an overall nerve injury rate at presentation of 10% (17/173), with the median nerve once again being the one most commonly injured.[128,135,198] To screen for these rare but significant injuries, every child with a forearm fracture should routinely have evaluation of the radial, ulnar, and median nerves for both motor and sensory function.[70] Nerve injuries occurring at the time of injury must be differentiated from treatment-related or iatrogenic neurologic deficits.

Davidson[78] suggested using the game of "rock-paper-scissors" for testing the median, radial, and ulnar nerves (Fig. 12-4). The pronated fist is the rock and tests median nerve function. The extended fingers and wrist depict paper and test radial nerve function. Fully flexed small and ring fingers, an adducted thumb, and spreading the index and ring fingers mimic scissors and test ulnar nerve function. Further focused testing should also be done on two important nerve branches: The anterior interosseous nerve (branch of median nerve) and the posterior interosseous nerve (branch of radial nerve). The anterior interosseous nerve provides motor function to the index flexor digitorum profundus, the flexor pollicis longus, and pronator quadratus and is best tested by having the patient make an "OK" sign. The posterior interosseous nerve typically innervates the extensor carpi ulnaris, extensor digitorum communis, extensor digiti minimi, extensor indicis, and the three outcropping muscles of the thumb (abductor pollicis longus, extensor pollicis brevis, and extensor pollicis longus).[42] Its function is best documented by full extension of the phalangeal and metacarpophalangeal joints. This is especially difficult to test in a patient in a cast or splint that partially covers the fingers. Most injuries that occur in association with forearm fractures are true neurapraxias and typically resolve over the course of days to weeks.[73,79]

Signs and Symptoms of Diaphyseal Radius and Ulna Fractures

The signs and symptoms indicating fracture of the shafts of the radius and ulna usually are not subtle. Deformity and pain are the classic findings. Patients typically experience exquisite pain emanating from the involved area. Decreased pronation and supination motion are also usually noted.[309] Neither practitioners nor parents are always reliable assessors of children's pain, and ideally patients should rate their own pain.[172,299] Significant anxiety and muscle spasm almost always amplify a child's painful experience.[46,117] It has been suggested that muscle spasm is a protective effort by the body to splint or otherwise protect the injured body part.[117] When such muscle spasm occurs in association with certain fracture patterns (e.g., a radial shaft fracture proximal to the pronator teres insertion), it produces predictable fracture displacement (e.g., a pronated distal radial fragment and a supinated proximal fragment).

More subtle fractures present special diagnostic challenges. Certain pathologic fractures of the forearm may occur in the absence of overt trauma.[157,181] Many minimally displaced fractures of the shafts of the radius and ulna can be mistaken for a "sprain" or "just a bruise" for several days to several weeks. This usually occurs in young children who continue to use the fractured arm during low-level play activities. As a general rule, a fracture should be suspected if the child has not resumed all normal arm function within 1 or 2 days of injury.

Imaging and Other Diagnostic Studies for Diaphyseal Radius and Ulna Fractures

Because important forearm fracture treatment decisions frequently are based on radiographic measurement of angular deformities, it must be remembered that these angles are projected shadows that are affected by rotation.[102] If angulation is present on both AP and lateral views (commonly called two orthogonal views), the true deformity is out of the plane of the radiographs, and its true magnitude is greater than that measured on each individual view. Certain forearm shaft fracture deformities are clearly "two-plane deformities" whose maximal angular magnitude is in some plane other than the standard AP or lateral plane (Fig. 12-5).[16] Bar and Breitfuss[16] produced a table (based on the Pythagorean theorem) that predicts the true maximal angulation. Accurate deformity measurement can be made when angulation is seen on only one view and there is no angulation on the other orthogonal view.

Evans pointed out the importance of tracking the rotational alignment of the free-moving radial fragment by ascertaining the relative location of the bicipital tuberosity. This was a major step forward in refining the orthopedic care of these forearm injuries. On a fully supinated AP radiograph of an unfractured forearm, the bicipital tuberosity points predominantly in a medial direction (nearly 180 degrees opposite of the radial tuberosity).[94] The radius and ulna are also nearly parallel to each other on such a view. On a fully pronated AP radiograph of an unfractured forearm, the bicipital tuberosity points in a lateral direction and the radial tuberosity is situated medially.[94] The radius also crosses over the ulna in a pronated AP view. Rang[265] noted that in an unfractured limb, the bicipital tuberosity tended to align with a point near the thenar eminence (Fig. 12-6), more nearly a 165-degree relationship than a true 180-degree one. These relationships are best assessed on standard radiographs that include the entire forearm on one film[75,257,329] rather than the specialized bicipital tuberosity view originally suggested by Evans.[94] A CT scan of both forearms with cuts through the bicipital tuberosity and the radial styloid is probably the best way to accurately identify a rotational malunion after a fracture that could be causing a loss of forearm rotation. The ulna can be similarly assessed by comparing the distal ulnar styloid to the proximal coronoid process on orthogonal views (similar to bicipital tuberosity and radial styloid, the coronoid process, and ulnar styloid should be 180 degrees apart). CT scan cuts of the coronoid process and the ulna styloid on the fractured

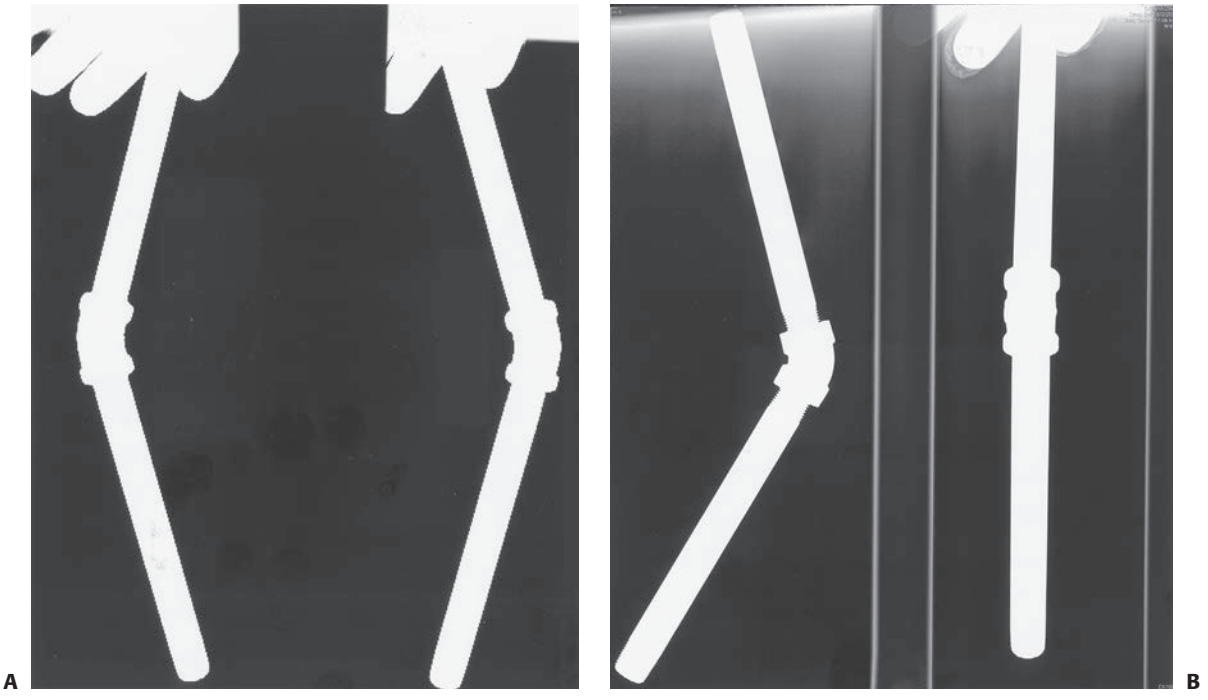

FIGURE 12-5 Underestimation of true angulation. **A:** "Out of the AP and lateral plane" underestimates angulation at 30 degrees. **B:** True AP and lateral demonstrates that true maximal angulation is 40 degrees.

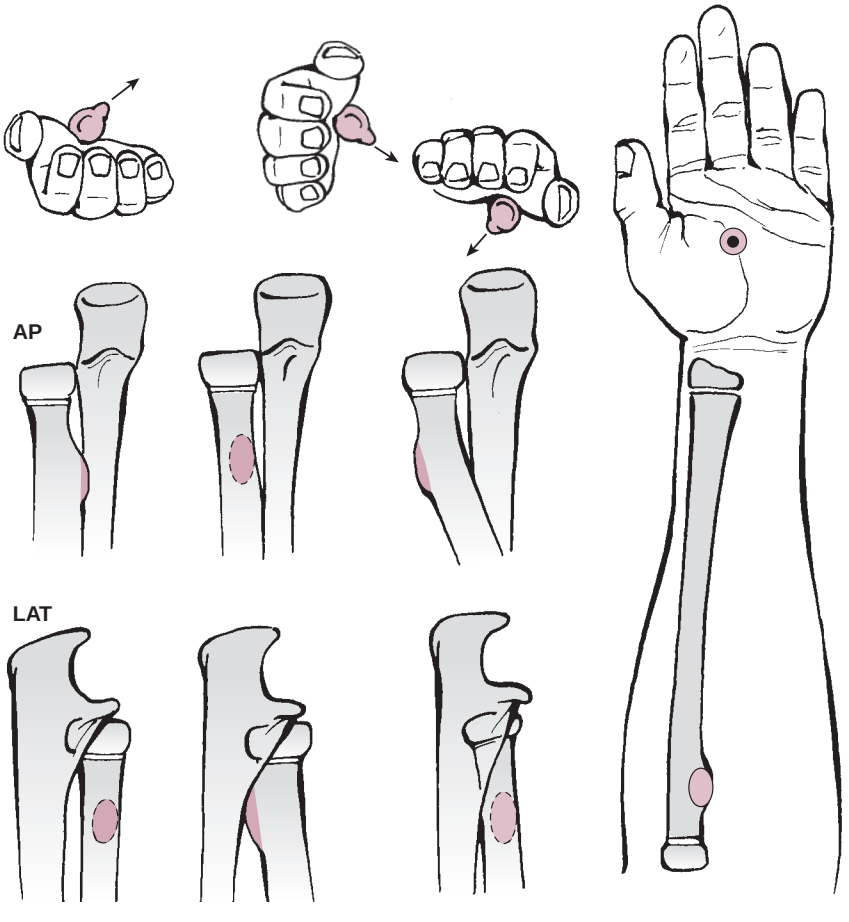

FIGURE 12-6 Rang's illustration depicting the position of the bicipital tuberosity on AP and lateral views with the forearm in pronation, supination, and neutral position. (From Rang M. *Children's Fractures*. Philadelphia, PA: JB Lippincott, 1974:126.)

and nonfractured sides are most reliable for measuring the rotational alignment of the ulna.

Classification of Diaphyseal Radius and Ulna Fractures

Fractures of the shafts of the radius and ulna often are described in rather imprecise terms such as "both-bone forearm fracture" and "greenstick fracture." Radiographs confirm the diagnosis of forearm shaft fracture and are the basis for most classification systems. The most comprehensive classification of forearm fractures is the one adopted by the Orthopaedic Trauma Association (OTA).[10] Although this system is sound in concept, its 36 discrete subtypes[10] make it impractical for everyday clinical use, and it has not been widely used by clinical researchers.[269] Despite its complexity, the OTA classification does not account for one of the most important prognostic factors in pediatric forearm shaft fracture: Location of the fracture in the distal, middle, or proximal third of the shaft.

Clinicians and clinical researchers have favored simpler descriptions of forearm shaft fractures. An orderly and practical approach to forearm shaft fracture classification should provide information about the bone (single bone, both bones), the level (distal, middle, or proximal third), and the pattern (plastic deformation, greenstick, complete, comminuted). Bone involvement is important because it not only indicates the severity of injury but also influences suspicion regarding additional soft tissue injury (e.g., single-bone injury increases the likelihood of a Monteggia or Galeazzi injury)[333] and affects reduction tactics (unique single-bone fracture reduction strategies can be used) (Fig. 12-7). Single-bone shaft fractures occur, but both-bone fractures are far more common. Level is important for anatomic reasons relative to muscle and interosseous ligament attachments, as well as differences in prognosis for distal-, middle-, and proximal-third shaft fractures. The pattern is important because it significantly alters the treatment approach. For example, the primary reduction strategy is very different for greenstick fractures (rotation) compared to that for complete fractures (vertical traction). Certain comminuted fractures (e.g., comminution of both bones) may preclude reduction and casting and require surgical fixation.[104,106] Fortunately, comminuted fracture patterns are rare in children. For all practical purposes, the buckle fracture pattern that is common in the distal radial metaphysis never occurs in isolation in the shaft region. The typical buckle fracture "speed bump" may accompany either plastic deformation or greenstick fractures. Thus, there are two bones, three levels, and four common fracture patterns (Fig. 12-8). We believe this is a practical and clinically relevant way to describe forearm shaft fractures.[216]

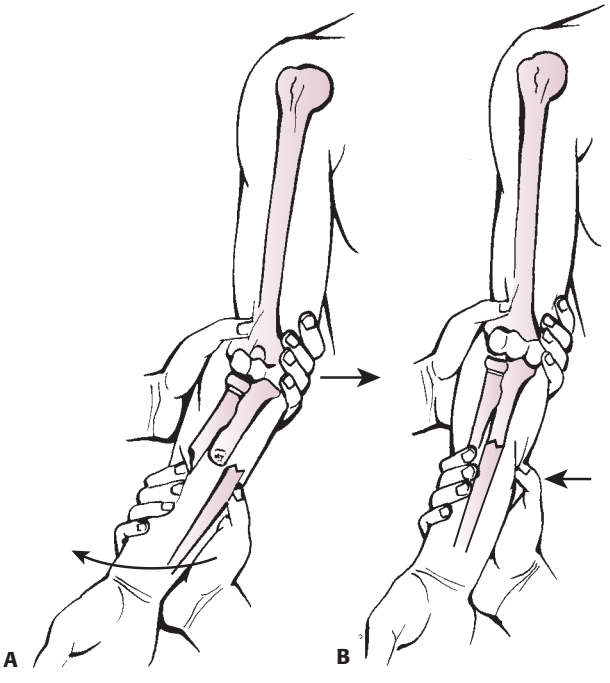

FIGURE 12-7 Isolated ulnar shaft reduction technique (Blount). Valgus force applied to fracture site and direct thumb pressure over distal ligament.

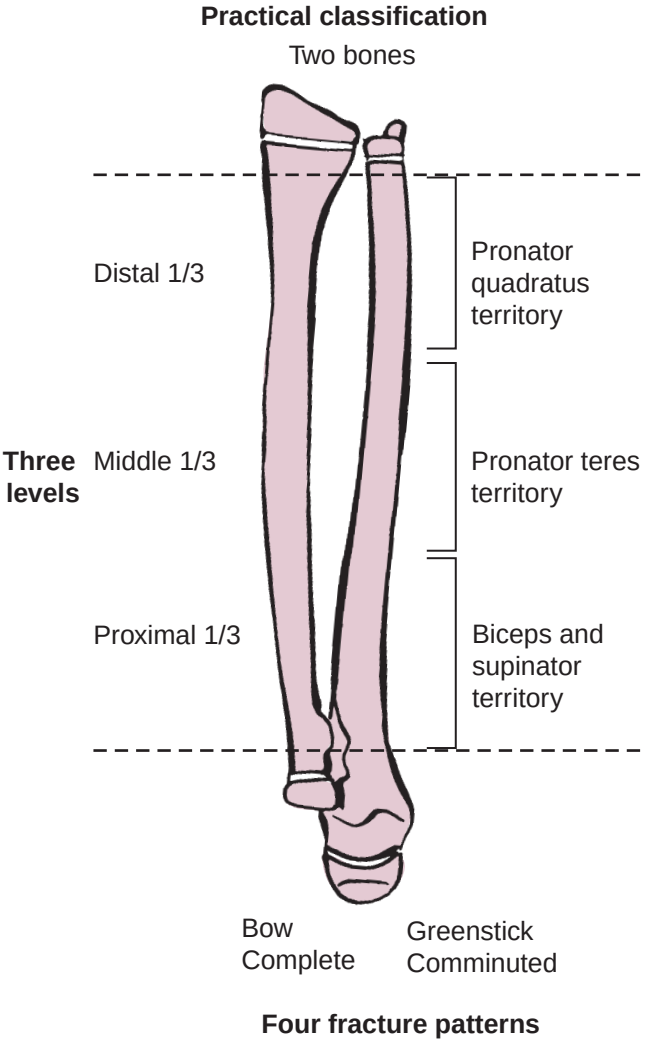

FIGURE 12-8 Practical classification of forearm shaft fractures. (Distal dotted line defined by proximal extent of the Lister tubercle and proximal dotted line defined by proximal extent of bicipital tuberosity.)

Once the forearm fracture has been described in the terms of this practical classification, fracture displacement must be evaluated. Fracture displacement can occur as angulation, rotation, shortening, or translation. Angulation is important in treatment decision-making and can be measured with reasonable reliability.[189,320] Rotation is a simple concept, but it is difficult to assess clinically.[93,257] The best that usually can be done is to roughly estimate rotation within a 45-degree margin of error.[71,257] Based on available clinical studies, it appears that less than 1 cm of shortening should be accepted in either single-bone or both-bone fracture patterns.[50,80,85,214,274] It has also been suggested that the shortening that accompanies displaced fractures may help preserve future motion through interosseous membrane relaxation.[257] Completely (100%) translated fractures of the middle third[71,257] and distal third[85,214,274] of the forearm have been shown to reliably remodel. Certain situations may raise concern regarding complete translation, such as isolated middle-third radial fractures with medial (ulnar) displacement that significantly narrows the interosseous space and translation in children who have less than two full years of growth remaining, because remodeling of the translated fracture site is less predictable than in younger children.[233,236]

Outcome Measures for Diaphyseal Radius and Ulna Fractures

The fundamental reason for treating fractures of the shafts of the radius and ulna relates to the likelihood of bad results in the absence of adequate care. Data from certain developing countries may be as close as we come to natural history studies of untreated fractures. Archibong and Onuba[12] reported on 102 pediatric fracture patients treated in Southeastern Nigeria. Their patients most commonly had upper extremity fractures, and they frequently experienced significant delays in seeking medical treatment, which led to high rates of malunion requiring surgical treatment.[12] Other Nigerian authors have found that young age was not protective against fracture malunion (more than 50%) and nonunion (25%) following traditional bonesetter treatment.[239] It is unclear whether children treated in this fashion are better or worse off than if they had received no treatment at all. The rationale for treating pediatric forearm shaft fractures is thus based on the premise that the results of modern orthopedic treatment will exceed "pseudo-natural histories" such as these.

The consequences of excessively crooked (and malrotated) forearm bones are both aesthetic and functional (Fig. 12-9).[28,33,145,209,232,329] Limited forearm supination following a forearm shaft malunion is illustrated in Figure 12-10. Despite their great concern to parents, aesthetic issues have not been formally studied, and as a result the practitioner must interpret forearm appearance issues on a case-by-case basis. Clinical experience has shown that the ulna appears to be less forgiving from an aesthetic standpoint because of its long subcutaneous border. Early and repeated involvement of the parents (or other legal guardians) in an informed and shared decision-making process is essential.

Bony malunion and soft tissue fibrosis have both been implicated as causes of limited forearm motion after forearm shaft fractures.[144,232] Limited forearm pronation and supination can have significant effects on upper extremity function.[26,245,257] Inability to properly pronate often can be compensated for with shoulder abduction, but no easy compensatory mechanism exists for supination deficits.[70,145,245,257] Daruwalla[75] identified a nearly 53% rate of limited forearm rotation (subtle in some, dramatic in others) in his series of 53 children with forearm fractures and attributed it to angular deformity and rotational malalignment. Several patients in Price's[257] classic series of pediatric forearm malunions had severe forearm range-of-motion losses that significantly limited vocational and recreational activities. Trousdale and Linscheid[329] reported range-of-motion losses severe enough to prompt corrective osteotomies in many of their predominantly pediatric (less than 14 years old at time of injury) patients with forearm malunions. Meier[217] also reported significant range-of-motion deficits in association with pediatric forearm malunion.

Range-of-motion losses caused by deformity have been studied by numerous authors using adult cadaveric forearm specimens. Matthews et al.[209] studied 10- and 20-degree midshaft angular deformities of the radius and ulna in 10 forearm specimens. They found that 10-degree deformities of either bone individually resulted in little or no measurable motion loss (in the range of 3 degrees or less). When both bones were angulated 10 degrees dorsal, volar, or toward the interosseous membrane, larger motion losses were documented (approximately 10-degree pronation and 20-degree supination). Significantly greater losses of motion occurred when one or both bones were angulated 20 degrees (approximately 40 degrees for both pronation and supination). Some of the 10-degree angulated specimens demonstrated "cosmetically unacceptable deformity."[209] These findings indicate that relatively small angular deformities can be clinically significant.

Additional important information about the influence of fracture level on forearm motion was provided by a series of adult cadaver experiments conducted by Sarmiento et al.[281,321] They found that fracture angulation of 15 to 30 degrees led to greater supination losses when the deformity was in the middle third of the forearm (40 to 90 degrees) and greater pronation losses when in the distal third (30 to 80 degrees).[321] Fracture angulation of 10 degrees or less in the proximal or middle forearm rarely resulted in more than 15 degrees of motion loss,[281,321] but the same angulation in the distal third of the forearm was at times (usually with isolated radius fracture) associated with pronation losses of 20 degrees.[281,321] These findings challenge commonly held beliefs that the distal third of the forearm is the most forgiving. These same authors asserted that rotational malalignment led to rotational motion losses that usually were equal in magnitude and opposite in direction to the deformity (e.g., a 10-degree pronation deformity led to a 10-degree loss of supination).[321]

Rotational malalignment of the forearm has been studied in greater detail in recent years, mostly in adults and in the laboratory.[88,169,330] In isolated midshaft radial fractures, more than 30 degrees of malrotation was a threshold for significant losses in motion (approximately 15 degrees).[169] Isolated midshaft ulnar fracture malrotation did not alter the total arc of forearm motion but did change the set point (e.g., a 30-degree pronation deformity took away 30 degrees of pronation and added 30 degrees of supination).[330] Larger ulnar axial malalignment of 45 degrees decreased overall forearm rotation by no more than 20 degrees.[330] Large residual ulnar shaft translation has similarly been found to have little impact on forearm rotation.[212] Simulated combined radial and ulnar midshaft rotational malunions resulted in the worst motion (more than 50% losses of pronation and supination when 60-degree rotational malunions were in opposite directions).[88] Rotational malunions that approximated recommended limits in the literature (45 degrees)[257] produced less extreme but real limitations of motion (Table 12-1).[88] From these studies and our clinical experience, it appears that the radius is more sensitive to rotational problems and less sensitive regarding aesthetic issues, whereas the ulna is exactly the opposite.

Several generations of orthopedic surgeons have been taught that 50 degrees of pronation and 50 degrees of supination represent adequate forearm motion.[222] It must be remembered that this classic study performed by Morrey and his Mayo Clinic colleagues involving 33 normal subjects (18 female, 15 male) from 21 to 75 years of age is not the only study that addresses forearm motion. The average arc of normal forearm motion for the Mayo group (68-degree pronation to 74-degree supination)[222] was approximately 20 degrees less than that measured in 53 healthy male subjects who were not older than 19 years old (77-degree pronation to 83-degree supination) reported by Boone and Azen[35] and 35 degrees less than that reported by Rickert et al.[270] (75-degree pronation to 100-degree supination) in 141 subjects of both sexes between 20 and 30 years of age. Contemporary three-dimensional motion analysis has revealed that maximal pronation occurs when pouring liquid from a pitcher and maximal supination commonly occurs during personal hygiene activities.[262] Thus, it seems clear that the forearm motion "goals" reported by Morrey et al.[222] are not necessarily ideal or even optimal, but rather they may be considered as the minimal limits of forearm function. Stated another way, losing 20 degrees or 30 degrees of either pronation or supination carries the potential for significant functional impact upon important activities of daily living. At the present time, loss of pronation can affect keyboarding and computer usage.

The goal of treatment is to achieve satisfactory healing of the forearm injury within the established anatomic and functional guidelines while also taking into account the reasonable degree of remodeling that can be expected in growing children.[156] Most of the time, these goals can be achieved with closed fracture care, and little or no radiographic or clinical abnormality can be detected following healing. A paradox exists in pediatric forearm fractures whereby anatomic radiographic alignment is not always associated with normal motion, and normal motion often is associated with nonanatomic radiographic healing.[144,228,232,321] Herein lies the inherent controversy between

TABLE 12-2 Pros and Cons of Cast Versus Surgical Treatment

Pros and Cons
Cast Treatment
Long track record
Anatomic reduction rare
Negligible infection risk
Stiffness may still occur
Fine-tuning possible
Frequent follow-up visits
Surgical Treatment
Anatomic reduction
Risk of infection
Minimize immobilization
Need for implant removal
Fewer follow-up visits
Stiffness from surgery

operative and nonoperative treatment approaches (Table 12-2). In patients with anatomic radiographs, range-of-motion problems usually have been attributed to scarring of the interosseous membrane.[170,245,257] With nonanatomic radiographs (incomplete remodeling), range-of-motion deficits usually are attributed to the radiographic abnormalities. Thus, treatment of forearm shaft fracture must balance the risk of allowing stiffness to occur secondary to malunion against the risk of creating stiffness secondary to surgical procedures.

The rationalization for the remodeling of pediatric forearm fractures has strong historical support,[22,31,48,241] but knowledge of the limits of remodeling must be taken into consideration. Established reduction criteria state that complete (100%) translation is acceptable,[214,257] as well as up to 15 degrees of angulation and up to 45 degrees of malrotation.[257] The fundamental reason for treating fractures of the shafts of the radius and ulna relates to the likelihood of bad results in the absence of adequate care or acceptable remodeling. As noted earlier, data from certain developing countries may be as close as we come to natural history studies of untreated fractures. Nigerian[12,239] studies indicate high rates of malunion with untreated or bonesetter treatment of diaphyseal fractures.

Published clinical studies have shown that pediatric forearm shaft fractures have great remodeling potential that occurs through several mechanisms.[288] The distal radial epiphysis will redirect itself toward normal at about 10 degrees per year. As long as the physis is open, this rate is independent of age. Although the epiphysis will return to normal direction, it will have much less effect on correcting an angular deformity at the midshaft compared to fractures at the subphyseal level. Remodeling also occurs with lengthening of the bone through growth, which produces an apparent decrease in angulation, especially if measured as the difference between the proximal and distal ends of the bone. The bone also remodels by intramembranous apposition on the concave side and resorption on the convex side.[74,156,288] This occurs throughout life, but more rapidly when driven by the thick periosteum found in children. Larsen[186] found that although the epiphyseal angle realigns quickly, children older than 11 years correct bone angulation less than the younger children. Thomas stated the following regarding pediatric forearm remodeling potential: "We should not fail to recall that the remodeling capabilities of the bones of children have not changed in the last million years and that open reduction and internal fixation must be undertaken only after due deliberation."[323] Others such as Johari[158] would state that if one critically evaluates the limits of forearm shaft remodeling capacity you will find a much higher rate (approximately 50%) of incomplete remodeling in children over 10 years of age.

The perfect (or nearly perfect) pediatric diaphyseal forearm fracture outcome study has not yet been performed, therefore scientific answers regarding optimal treatment are lacking.[107] However, there is a growing consensus among pediatric orthopedic trauma surgeons that there are patient subsets (usually older patients with more proximal fractures) whose outcomes are clearly improved by flexible intramedullary nail surgical intervention.[347] A large retrospective cohort study focusing on radiographic outcomes has indicated that among pediatric forearm shaft fracture patients who underwent reduction, most (51%) exceed established radiographic criteria over the course of 2 to 4 weeks.[40] This is greatly concerning as a very clear relationship exists between radiographic and clinical outcomes for forearm shaft injuries in both adults and children.[37,87,166] For those patients deemed at higher risk, the risk–benefit ratio also appears to be favorable as flexible nail surgical complications are mainly minor and in some respects measurably lower than nonoperative forearm shaft fracture care.[279,300]

Pathoanatomy and Applied Anatomy Relating to Diaphyseal Radius and Ulna Fractures

The forearm is a large nonsynovial joint with nearly a 180-degree arc of motion. Its bones, the radius and ulna, are not simple straight bony tubes. The shaft of the radius is a three-sided structure with two prominent curvatures. One major gradual convexity (approximately 10 degrees with its apex lateral-radial) is present along its midportion; a second, more acute curve of approximately 15 degrees with its apex medial occurs proximally near the bicipital tuberosity.[100,127,278] The deviation along the midportion is commonly referred to as the radial bow, and maintenance of this normal contour is a goal of forearm shaft fracture care.[260,284,285] The most important bony landmarks of the radius are the radial styloid (lateral prominence) and the bicipital tuberosity (anteromedial prominence), which are oriented about 135 degrees away from each other (Fig. 12-11).[220] Maintenance of the styloid-tuberosity rotational relationship is another forearm shaft fracture principle. The nutrient artery of the radius enters the bone in its proximal half and courses anterior to ulnar (medial).[120] Such nutrient vessels typically are seen on only one orthogonal view and should not be confused with fracture lines. In cross section, most of the shaft of the ulna is also shaped like a classic three-sided prism, although its more distal and proximal portions are much more circular. The most important bony

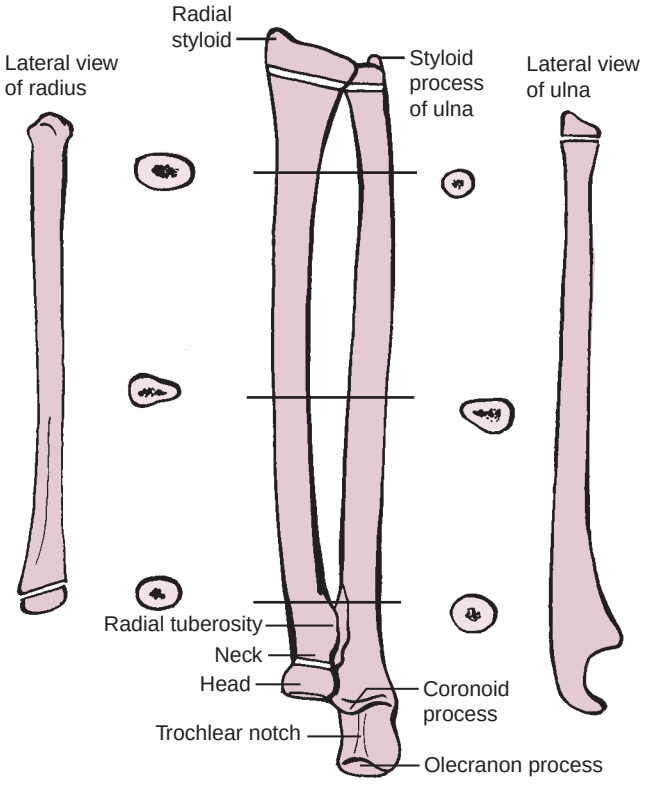

FIGURE 12-11 Radial and ulnar anatomy.

landmarks of the ulna are its styloid process (distally) and its coronoid process (proximally). These two landmarks are oriented nearly 180 degrees from one another, with the styloid aimed in a posterior (dorsal) direction and the coronoid in an anterior (volar) direction.[220] Tracking styloid–coronoid rotational alignment of the ulna is another part of forearm shaft fracture care. The ulnar shaft has mild curvatures in both its proximal (apex lateral/radial) and distal (apex medial/ulnar) portions but is otherwise relatively straight.[127,278] The nutrient artery to the ulna enters the bone in its proximal half and courses anterior to radial (lateral).[120]

The classic works of Evans helped focus attention on rotational deformity associated with fractures of both bones of the forearm.[94,210,264] Evans stated, "The orthodox position in which to immobilize these fractures is that of full supination for the upper third, and the midposition for fractures of the middle and lower thirds, these positions being based on the anatomical arrangement of the pronators and supinators of the forearm. However, it is unreasonable to suppose that all fractures at a given level will present the same degree of rotational deformity."[94] The radius and ulna are joined by three major passive restraints: The PRUJ, the distal radioulnar joint (DRUJ), and the interosseous membrane complex, all of which have important stabilizing and load-transferring functions. These structures allow rotation of the radius about the ulna along an axis that runs approximately from the center of the radial head to the center of the distal ulna.[146,245] The PRUJ and DRUJ are discussed elsewhere in this book (Chapters 9 and 11). The structure and biomechanic function of the interosseous membrane have been studied extensively in recent years. Hotchkiss et al.[150] showed that the central band of the interosseous membrane (the interosseous ligament) courses from a point near the junction of the proximal and middle thirds of the radius to a point near the junction of the middle and distal thirds of the ulna. It is an important longitudinal stabilizer of the forearm in that 71% of forearm longitudinal stiffness is provided by the interosseous ligament after radial head excision.[150] Transverse vectors have also been identified[248] and reflect the stabilizing effect of the interosseous ligament during pronation and supination movements. The interosseous ligament demonstrates tensile properties comparable to the patellar tendon and the anterior cruciate ligament,[249] indicative of the magnitude of the arm forces to which this structure is subjected.

Although some difference of opinion still exists,[81,110,304] multiple studies have shown that the most strain in the central band of the interosseous membrane is generated when the forearm is in the neutral position.[206,207,304] These findings of maximal strain in neutral in cadaver studies also are consistent with radiographic measurement studies[71] and dynamic magnetic resonance imaging studies of the forearm showing that the interosseous space is maximal near a neutral position.[229] This may help explain certain pathologic situations such as the fixed supination deformity of neonatal brachial plexus palsy[211] as well as limitations of pronation and supination because of encroachment on the interosseous space from malangulated fractures (Fig. 12-12).[359] The interosseous membrane also serves as an important anchoring point for several forearm muscles: The flexor digitorum profundus, flexor pollicis longus, extensor indicis, and the outcropping muscles (extensor digitorum brevis, abductor pollicus longus).

The paired and seemingly balanced radial and ulnar bones have an unbalanced number of muscular connections. The ulna typically has 14 attached muscles and the radius only 10 (Tables 12-3 and 12-4).[86,127] Powerful supinators attach to the proximal third of the forearm, whereas important pronators attach to its middle and distal thirds (Fig. 12-13). The accompanying vasculature of the forearm is complex: These muscles are supplied by more than 248 vascular pedicles arising from the brachial artery, its branches, or other collateral vessels.[268] The radial, ulnar, and median nerves (or their branches) along with the musculocutaneous nerve provide all of the key innervations to the motors that attach to the forearm bones. As mentioned earlier, the median nerve is the most commonly injured nerve with forearm fractures.[78,79,128,135]

The radial nerve proceeds from a posterior to anterior direction and enters the forearm after passing the lateral epicondyle between the brachialis and brachioradialis muscles. Near this same level, it divides into superficial and deep terminal branches. The deep motor branch of the radial nerve is also known as the posterior interosseous nerve. In addition to its routine innervation of the brachioradialis and extensor carpi radialis longus, most commonly (55% of the time) a motor branch arises from the radial nerve proper or its superficial terminal branch to innervate the extensor carpi radialis

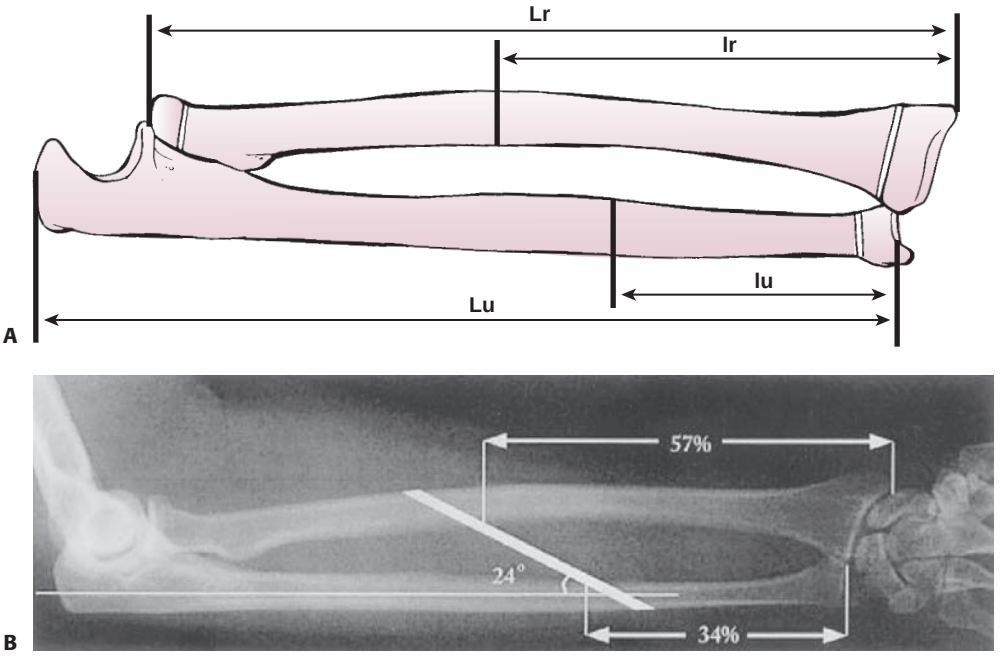

FIGURE 12-12 Anatomy of interosseous ligament. **A:** Central oblique orientation of interosseous ligament. **B:** Interosseous ligament attachment in terms of percentage forearm length. brevis, whereas the rest of the time (45%) this motor branch comes from the posterior interosseous nerve.[2] The superficial branch travels along with and beneath the brachioradialis. The posterior interosseous nerve enters the supinator muscle, passing the fibrous thickening called the arcade of Frohse shortly after branching from the radial nerve proper. It courses within the supinator past the proximal radius, later exiting this muscle dorsally (posteriorly) near the junction of the proximal and middle thirds of the radius. Following its emergence from the supinator, the posterior interosseous nerve branches repetitively to the superficial extensors and the deeper outcropping muscles. The ulnar nerve enters the forearm between the two heads of the flexor carpi ulnaris.[122] It traverses the forearm between the flexor carpi ulnaris and the flexor digitorum profundus. In the distal forearm, it lays just beneath the flexor carpi ulnaris. The median nerve enters the forearm as it passes between the two heads of the pronator teres.[57] It next passes beneath the archway created by the two heads of the flexor digitorum superficialis. The median nerve then continues down the course of the forearm nestled between the flexor digitorum superficialis and the flexor digitorum profundus. It becomes much more superficial as it nears the level of the carpal tunnel. The anterior interosseous branch arises from the median nerve at the level of the pronator and travels deep with the anterior interosseous vessels. Abundant muscles shield the radial, ulnar, and median nerves from the shafts of the radius and ulna through most of the forearm except for the posterior interosseous nerve near the proximal radius.

Common Surgical Approaches of Diaphyseal Radius and Ulna Fractures

The large exposure required for plate fixation of pediatric forearm fractures can be achieved with: The Henry (anterior) or Thompson (posterior) approaches to the radial shaft and the direct (medial) approach to the ulnar shaft.[72,226] Compartment syndrome release usually requires the serpentine incision of McConnell's combined approach.[142] These approaches and their variations are well described and illustrated in detail elsewhere.[4,18,90,148,296] For open reduction of both the radius and the ulna, most authors favor separate incisions to minimize the possibility of communicating hematoma and the development of a radioulnar synostosis.[184,260,332] The Thompson approach to the radius is generally used for fractures of its proximal third[357] but requires special care to protect the posterior interosseous nerve.[83,218,318] Other authors have emphasized the utility of the Henry approach for plating of the entire radius including the proximal aspect.[218] When open reduction is done in conjunction with other internal fixation techniques (e.g., intramedullary fixation), limited versions of the same surgical approaches are used.

Indirect reduction and internal fixation of forearm fractures require knowledge of appropriate physeal-sparing entry portals about the distal and proximal forearm. Because of the relative inaccessibility of its proximal end, the radius usually is approached only distally through either a dorsal or radial entry point. The dorsal entry point is near the proximal base of the Lister tubercle or just lateral to it in a small bare area between the second and third dorsal compartments. This location is a short distance proximal to the physis of the distal radius. Another dorsal alternative is pin entry just medial to the Lister tubercle, between the third and fourth dorsal compartments,[273] but this may entail greater risk to the extensor tendons, especially the extensor pollicus longus. The most commonly used radial entry point is located in line with the styloid process just proximal to the physis.[354] Entry in this area passes adjacent to the first dorsal compartment, and thus the tendons of abductor pollicis longus and extensor pollicis brevis (as well as branches of the superficial radial nerve) must be protected (Fig. 12-14). Because of its extensive branching pattern, portions of the superficial branch of the radial nerve may be at risk when dorsal or radial intramedullary entry points are used.[1,14]

Both distal and proximal intramedullary entry sites for the ulna have been described.[192,197,256,297,335] In the distal portion of the ulna, an entry site can be made proximal to the physis and in the interval between the extensor carpi ulnaris and flexor carpi ulnaris tendons. Care must be taken to avoid branches of the dorsal cutaneous sensory nerve. Ulnar entry is most easily accomplished in the proximal portion of the bone along its lateral metaphyseal border (just distal to the olecranon apophysis), piercing peripheral fibers of the anconeus (Fig. 12-15).[45,188,194] This anconeus entry site

described by the Nancy group avoids the physis and avoids the painful bursa that tends to form over "tip of the olecranon" pins.

Transphyseal approaches to both the distal radius[363–365] and the proximal ulna[8,197,318] have been suggested by some authors. Significant growth potential exists at the distal radius (approximately 10 mm per year), whereas there is proportionately less from the olecranon apophysis (approximately 2 mm per year). There is an unnecessary risk to the radial physis and few if any technical advantages to transphyseal entry of the radius in diaphyseal level fracture fixation. The ulna apophyseal entry site is used in many centers.

Treatment Options for Diaphyseal Radius and Ulna Fractures

Nonoperative Treatment of Diaphyseal Radius and Ulna Fractures

Indications/Contraindications (Table 12-5)

TABLE 12-5 Diaphyseal Radius and Ulna Fractures

Nonoperative Treatment

Indications	Relative Contraindications
Closed fractures	Open fractures
Skeletally immature, displaced and nondisplaced	Displaced and skeletally mature
Irreducible by closed means	

Most pediatric radial and ulnar shaft fractures can be treated by nonoperative methods.[365] Low-energy, undisplaced, and minimally displaced forearm fractures can be immediately immobilized in a properly molded (three-point mold concept of Charnley) above-elbow cast.[8] If post-traumatic tissue swelling is a concern, noncircumferential splint immobilization (e.g., sugar-tong splint) can be used initially.[70,325,361] For fractures in the distal third of the forearm, below-elbow casting has been shown to be as effective as above-elbow casting in maintenance of satisfactory fracture alignment.[61,113] Appropriate follow-up is important for these undisplaced fractures (an initial follow-up radiograph usually is taken 7 to 14 days after injury) because displacement may still occur for a variety of reasons: New trauma to the extremity, male gender, and poor casting technique.[70,114,289,361]

Good casting technique is infrequently discussed in contemporary orthopedic textbooks and sometimes is underemphasized during orthopedic residency training. The principles of good forearm casting technique include: (a) interosseous molding, (b) supracondylar molding, (c) appropriate padding, (d) evenly distributed cast material, (e) straight ulnar border, and (f) three-point molding (Fig. 12-16). The risk of excessive cast tightness can be minimized through the use of the stretch-relax fiberglass casting technique described by Davids et al.[76] Chess et al.[61] described a cast index for distal radial fractures defined as the sagittal cast width divided by the coronal cast width at the level of the fracture site; a normal ratio is considered to be 0.70. The cast index has not been validated for forearm shaft fractures, but it embodies the sound concept of good interosseous molding. Techniques such as pins and plaster and cast wedging also have had a role in fracture care.[17,89] Cast wedging is almost always done with an opening wedge technique because this entails less risk of soft tissue impingement.[171]

Displaced fractures usually require reduction following appropriate analgesia.[85,334] Options include hematoma block,[108,141,160] regional intravenous (IV) anesthesia[43,77,164] and inhalational methods,[95,129,141] and IV sedation with propophol. After informed consent for sedation and reduction is obtained,

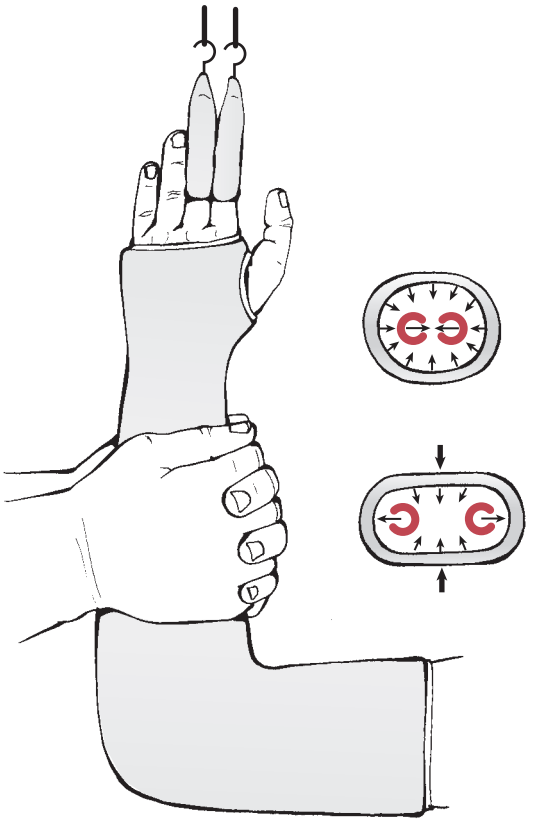

FIGURE 12-16 Interosseous mold technique.

monitored sedation can be used in the emergency department with a combination of narcotics and anxiolytics.[175] This typically requires a dedicated nurse to administer oxygen and perform appropriate monitoring functions (vital signs, continuous electrocardiogram, and pulse oximetry).[7,64,143] Ketamine protocols are also being used with increased frequency.[121,175] Young children with less than 5 or 10 degrees of angulation in the plane of wrist and elbow motion probably do not require the additional trauma, time, expense, and sedation risk involved in a formal reduction because of the predictable remodeling in this age group as long as immobilization brings stability to the fracture and prevents late displacement.[12] It has been shown that the more displaced the fracture, the more likely that formal monitored sedation techniques will be used for pediatric forearm fracture reduction as opposed to other techniques.[334]

More specific closed treatment options are discussed for pediatric forearm injuries in terms of their common fracture patterns: Bow (plastic deformation), greenstick, complete, and comminuted.

Traumatic Bowing/Plastic Deformation

Although traumatic bowing was described by Rauber in 1876,[298] it was not widely recognized until Spencer Borden's classic paper was published in 1974.[36] This injury occurs almost exclusively with children's forearm fractures.[178] Bow fractures (Fig. 12-17) show no obvious macroscopic fracture

FIGURE 12-17 Bow fracture: Approximately 15 degrees of apex-dorsal bowing of radius and ulna shaft.

line or cortical discontinuity, but they do demonstrate multiple microfractures (slip lines) along the length of the bow.[280] At times, a nearly classic buckle fracture (torus fracture) coexists with a bow fracture. The most common clinical scenario is a plastically deformed ulna along with a more typical fracture of the radius.[201]

Borden[36] and subsequent authors stressed the importance of natural remodeling potential in these injuries but voiced concern about this approach in older children (especially those over 10 years of age).[36,201,280] Vorlat and De Boeck[337] reported incomplete remodeling in 3 of 11 children at long-term follow-up (average 6.7 years) after traumatic bowing of the forearm. Because these three children were between the ages of 7 and 10 at the time of injury, the authors recommended more aggressive efforts at reduction in all patients with clinically significant deformity (more than 10 degrees) older than 6 years of age.[337] Traumatic bowing that causes aesthetically and/or functionally unacceptable angular deformity[277] should be manipulated under general anesthesia or deep sedation because strong (20 to 30 kg) gradual force applied over 2 to 3 minutes is required to obtain acceptable alignment (Fig. 12-18).[280] Application of this reductive pressure over a rolled towel, block, or surgeon's knee fulcrum followed by a three-point molded cast can substantially (although at times still incompletely) correct the deformity. Care must be taken to avoid direct pressure over adjacent epiphyses for fear of creating a physeal fracture.

Greenstick Fractures

Greenstick fractures present special issues in terms of diagnosis and treatment. Angulated greenstick fractures of the shafts of the radius and ulna at different levels indicate a significant rotational component to the injury (Fig. 12-2). Evans, Rang, and others have stated that the apex-volar angulation pattern usually is associated with a supination-type injury mechanism, whereas most apex-dorsal greenstick fractures involve a pronation-type injury mechanism (Fig. 12-19),[92,94,233,265] although exceptions certainly occur.[92,132] Often, the apparent angular deformity can be corrected by simply reversing the forearm rotational forces (e.g., reducing an apex-dorsal pronation-type injury with supination). Noonan and Price[233] observed that it is difficult to remember whether to use pronation or supination reductive forces and suggested that most fractures can be reduced by rotating the palm toward the deformity. They also noted that most greenstick fractures are supination injuries with apex-volar angulation and thus can be reduced by a pronation movement.[233] Pediatric orthopedic researchers from the Arnold Palmer Hospital for Children have recently proposed the "radius crossover sign" as an indicator of significant angular and torsional deformity in greenstick fractures of the radial shaft.[355] Proper interpretation

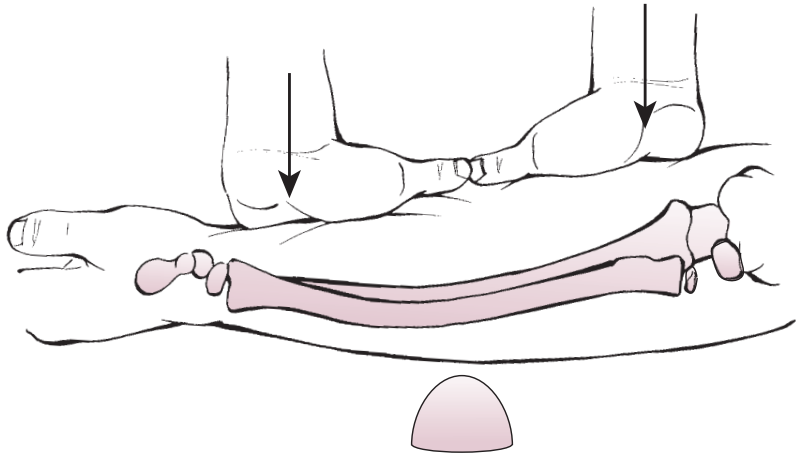

FIGURE 12-18 Reduction technique of bow fracture over fulcrum. (From Sanders WE, Heckman JD. Traumatic plastic deformation of the radius and ulna: A closed method of correction of deformity. *Clin Orthop Relat Res.* 1984;188:58–67.)

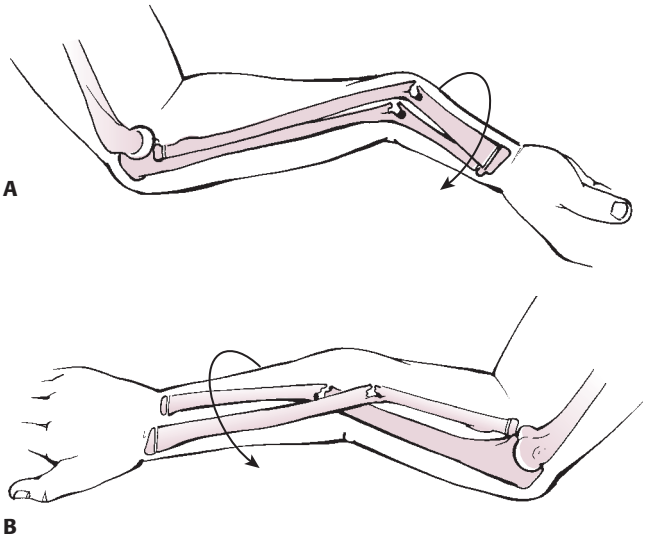

FIGURE 12-19 Shaft fractures at different levels implies rotational mechanism. **A:** Apex-volar angulation with supination deformity of the forearm. **B:** Apex-dorsal angulation with pronation deformity of forearm.

of this sign relies on full length forearm films that include a good AP view of the distal humerus.

Greenstick fractures that occur near the same level probably have little to no rotational component and are best corrected by manipulative reduction and three-point molding techniques (Fig. 12-3). Charnley believed that greenstick fractures of the forearm in children perfectly illustrated his dictum that "A curved plaster is necessary to make a straight limb."[59] He also stated that "The unsuspected recurrence of angular deformity in greenstick fractures of the forearm, while concealed in plaster, is an annoying event if it takes the surgeon by surprise and is not discovered until the plaster is removed. Parents, quite understandably, may be more annoyed about this happening to their children than if it had happened to themselves, and do not easily forgive the surgeon."[59] Despite these concerns, it is clear from large published reports that greenstick fractures can almost always be successfully treated with nonoperative methods.[363]

Two philosophies are reflected in the literature regarding greenstick fracture reduction: One in which the greenstick fracture is purposely completed and another in which it is not. Those who favor completing the fracture (dating back at least to the 1859 work of Malgaigne) cite concerns about lost reduction and recurrent deformity that can be prevented only by converting the greenstick into a complete fracture.[23,31,106,153] Others prefer to maintain and perhaps exploit some of the inherent stability of the greenstick fracture.[5,61,79,92,323] In addition to the traditional view that loss of reduction is less likely if a greenstick fracture is completed, there also is the theoretical advantage of a lower refracture rate because of more exuberant callus formation.[61,233] To the best of our knowledge, these theories have not been validated in any controlled clinical studies. Davis and Green[79] advocated a derotational approach to greenstick fracture reduction and reported a 10% (16/151) reangulation rate in their series of patients with greenstick fracture. They compared this to the 25% (12/47) reangulation rate in patients with complete fractures and questioned the wisdom of routinely completing greenstick fractures.[79] In a prospective study, Boyer et al.[41] showed statistically that greenstick fractures maintain their reduction better than complete forearm fractures.

Complete Fractures

Complete fractures in different regions of the shaft of the forearm behave differently from a clinical perspective and have classically been divided into distal-, middle-, and proximal-third fractures. Single-bone complete fractures usually are caused by direct trauma (nightstick fracture) and are difficult to reduce. Blount described a reduction technique that may be effective for reduction of a displaced single-bone shaft fracture. The intact bone is used as a lever to re-establish the length of the fractured bone, and then transverse forces are applied to realign the bone ends (Fig. 12-7). Both-bone complete fractures (often with bayonet shortening) are common and are best treated with finger-trap or arm traction applied over 5 to 10 minutes. This stretches out the soft tissue envelope and aids in both reduction and cast or splint application. Traction allows complete fractures to "seek their own level of rotation" and allows correction of rotational malalignment.[79]

The position of immobilization for forearm fractures has been an area of debate since the days of Hippocrates.[31] Theoretically, the position of forearm rotation in an above-elbow cast or splint affects rotational alignment of complete fractures at all levels; however, a study of distal-third forearm fractures found no significant effect of forearm rotation position on ultimate alignment.[41] We are aware of no similar studies analyzing the effects of forearm position on middle- or proximal-third shaft fractures, and treatment is influenced by certain anatomic considerations. Because of the strong supination pull of the biceps, aided by the supinator, complete proximal radial fractures may be best immobilized in supination so that the distal forearm rotation matches that of the proximal forearm (Fig. 12-13). The position of immobilization of fractures in the middle third of the forearm commonly is dictated by whether the radial fracture occurs distal or proximal to the insertion of the pronator teres. Fractures proximal to its insertion are best treated by fully supinating the distal fragment, whereas those distal to its insertion are probably best treated in a neutral position. Fractures at different levels in the midshaft that require pronation or supination as part of the reduction maneuver should be immobilized in the position of reduction.

Manipulated fractures should be evaluated weekly for the first 2 to 3 weeks because most position loss can be recognized and corrected during this time.[182,338] Any significant shift in position between visits necessitates cast wedging or a cast change, with remolding and possible fracture remanipulation if unacceptable displacement is present. Voto et al.[338] found that, in general, 7% of forearm fractures redisplace; this can occur up to 24 days after the initial manipulation. Davis[79] reported a 25% reangulation rate in complete fractures. Remanipulation can be done in the office following administration of oral

analgesics. Judicious use of benzodiazepines may also be valuable because of their anxiolytic effects.

Although in adults the above-elbow cast generally is changed to a below-elbow cast after 3 to 4 weeks, this is unnecessary in most children because they heal more quickly and permanent elbow stiffness is rare.[173] A cast change at week 3 or 4 also can be traumatic to a young child and carries the additional small risk of cast saw injury. Once the fracture shows good callus formation, the cast can be removed. Because shaft fractures of the radius and ulna in children have a significant rate of refracture,[13,185,328] they should be splinted for an additional period of time.[69] Parents should be warned that forearm shaft fractures have the highest risk of the risk of refracture, which can occur even 6 to 12 months after the original injury.

Above-elbow casting with the elbow in extension has been suggested for some complete fractures of the middle and proximal thirds.[292,341,345] The supination moment exerted by the biceps has been shown to be diminished when the elbow is extended.[227] Walker and Rang[341] reported successful treatment of 13 middle- or proximal-third forearm shaft fractures with this method (some following failed flexed-elbow casting). They suggested that the "short fat forearms" of some young children prevented successful flexed-elbow casting.[341] Shaer et al.[292] also reported 20 children treated with this method and emphasized full supination of the forearm. Three of their patients required cast wedging, but at final follow-up 19 of the 20 patients had excellent results.[292] One patient who was lost to follow-up for 6 months (presumably removing his own cast) did suffer "mild residual deformity."[292] Walker and Rang[341] recommended that benzoin be applied to the skin, in addition to creation of an adequate supracondylar mold, to further secure the cast. Casting the thumb in abduction with extra padding may prevent the cast from sliding. Turco[293] suggested that reduction should be obtained with horizontal traction applied to the extended upper extremity, followed by additional steps outlined in Table 12-6. Based on published clinical results, concerns related to cast slippage and elbow stiffness appear to have been overstated.[292,341] The main drawback of this technique is its awkwardness as compared to flexed-elbow casting[341] (Fig. 12-20).

Because radius and ulna shaft fractures have the highest rate of childhood refracture, casting is generally recommended for 6 to 8 weeks. This is followed with a forearm splint until all four cortices are healed and there is no transverse lucency at the site of the original fracture (complete healing).

TABLE 12-6 Technique for Extended Elbow Cast Treatment

   b. 3 weeks at 135 degrees
   c. 3 weeks at 90 degrees

FIGURE 12-20 A forearm fracture lost of position while treated in an above-elbow cast with elbow at standard 90-degree elbow flexion. At 3 weeks post injury the arm was remanipulated and placed in an above-elbow cast with elbow extended down to only 45 degrees of flexion, with three- point mold placed. The fracture healed anatomically.

Comminuted Fractures

Although comminuted forearm fractures are less common in children than in adults,[323] they do occur.[24,104,106,153,184,357] Comminuted fractures tend to occur in conjunction with high-energy injuries, such as open fractures.[153,208] Comminuted forearm fractures deserve special attention because they often require specially tailored treatment approaches. If satisfactory reduction cannot be achieved or maintained by closed methods, then other treatment alternatives should be considered.

One option is to accept some shortening; according to Price,[257] this may help maintain motion through interosseous membrane slackening. Shortening of more than 1 cm is unacceptable in either single-bone or both-bone comminuted patterns. Standard closed fracture treatment generally is unsuccessful when both bones are comminuted, and surgical stabilization may be necessary.[106] Bellemans and Lamoureux[24] reported intramedullary nailing of all comminuted forearm fractures in their pediatric series. Other reported fixation methods for comminuted forearm fractures in children include plate-and-screw devices,[104,106] flexible intramedullary nailing for single-bone comminution,[269] and pins-and-plaster techniques.[339] Bone grafting is rarely if ever indicated in acute comminuted forearm features in children.

Operative Treatment of Diaphyseal Radius and Ulna Fractures

Indications/Contraindications

Duncan and Weiner[89] cited an "aggressive surgical mentality" as the reason for frequent operative treatment of pediatric forearm fractures, and Wilkins[350] expressed concern about "impetuous" surgeons who are too eager to operate. Cheng et al.[60] and Flynn et al.[103] documented a 10-fold and sevenfold increase in the rate of operative treatment of forearm shaft fractures in children, but it is unclear as to whether this increase in operative treatment has led to a commensurate improvement in clinical outcomes.

Operative treatment of radial and ulnar shaft fractures usually is reserved for open fractures, those associated with compartment syndrome, floating elbow injuries, and fractures that develop unacceptable displacement during nonoperative management. Residual angulation after closed treatment is much better tolerated by younger children than older adolescents and adults because of the increased remodeling potential in the younger age group.[113] As a consequence, adolescents are more likely to benefit from surgical treatment of their forearm fractures than are younger children. Although internal fixation is the standard of care for displaced forearm fractures in adults, the success of nonoperative methods and the complications associated with internal fixation have tempered enthusiasm for its application to pediatric forearm fractures. Compared to closed treatment methods, healing is slower after open reduction and internal fixation,[24] no matter what type of implant is used.[106] Crossed Kirschner wire (K-wire) fixation techniques that often are used successfully in the distal radius are technically difficult in the shaft region of the radius and ulna. In rare situations, external fixation has been used for pediatric forearm fixation.[290]

Preoperative planning is essential regardless of which surgical technique is chosen. Assessment of the fracture, including rotation and the presence or absence of comminution, is important. Bone–plate mismatch (because of narrow bones and wide plates) and extensive soft tissue dissection are risks when adult-sized plates are applied to pediatric bones.[354] Before intramedullary nailing of fractures, the forearm intramedullary canal diameter should be measured, especially at the narrowest canal dimension; typically this is the central portion of the radius[305] and the distal portion of the ulna near the junction of its middle and distal thirds. Precise canal measurement can be difficult,[278,306] and the consequences of a nail or pin that is too large are probably worse than those of a nail or pin that is too small.[237,287] Modern digital radiography systems have made these measurements easier.[244]

Plate Fixation

Open reduction and internal fixation of pediatric forearm shaft fractures with plates and screws is a well-documented procedure in both pediatric series[242,310,324,332] and adult series that include patients as young as 13[58] and even 7[58] years of age. In one of the early series of pediatric forearm fractures fixed with plates,[82] dynamic compression plates and one-third tubular plates applied with standard atlas orthogonal technique (six cortices above and below the fracture site) obtained good results.[230] Four-cortex fixation on either side of the fracture site has been shown to be equally effective in pediatric forearm fractures.[357]

Plate fixation uses the standard adult approach and technique except that smaller plates (2.7-mm compression and stacked one-third tubular), fewer screws, and single-bone fixation often are acceptable.[357] Plate fixation may allow more anatomic and stable correction of rotational and angular abnormalities and restoration of the radial bow than with noncontoured intramedullary rods; however, the larger incisions and extensive surgical exposures required for plate fixation have raised concerns regarding unsightly scars[273,332,354] and muscle fibrosis with consequent motion loss.[357] Although the aesthetic concerns seem valid, ultimate forearm motion is similar with the two techniques, with only minor losses reported in the literature after both plating and intramedullary nailing.[73,170,297,331] Fernandez et al.[97] recently documented these precise issues very nicely in that they found no significant differences in functional outcome in their plate fixation versus intramedullary nailing patients, but they noted the longer operating room time and inferior appearance of the plated patients' scars.

Open reduction and internal fixation with plates and screws may be appropriate in the management of fractures with delayed presentation or fractures that angulate late in the course of cast care,[135,357] when significant fracture callus makes closed reduction and percutaneous passage of intramedullary nails difficult or impossible.[11] Other indications for plate fixation include shaft fractures with significant comminution[106] and impending or established malunion[329] or nonunion.[136,193,237] Several authors have reported good results with plate fixation of the radius only[47,105,242,265] or the ulna only (Fig. 12-21).[25] Bhaskar and Roberts[25] compared 20 children with both-bone plate fixation to 12 with ulna-only fixation and found significantly more complications in the dual plating group, although motion was equal at 1-year follow-up. Single-bone fixation requires satisfactory reduction of both bones. Flynn and Waters[105] stated that they would preferentially plate the radius only when the fracture could not be reduced by closed means. Two patients in Bhaskar and Roberts'[25] study required open reduction and internal fixation of the radius when it was not adequately reduced after plate fixation of the ulna.

Kirschner Wire, Rush Rod, and Steinmann Pin Intramedullary Fixation

Currently, intramedullary fixation is the preferred method for internal fixation of forearm fractures in children.[8,45,184,192,197,260,261,335] Intramedullary fixation of children's forearm fractures dates back at least to Fleischer's 1975 report in the German literature in which he called it "marrow wiring."[101] Closed intramedullary nailing (also known as indirect reduction and internal fixation) of diaphyseal forearm fractures in adolescents was later reported in the English literature by Ligier et al.,[194] Amit et al.,[8] and others.[29,188,354] A variety of implants have been used for forearm intramedullary nailing, including K-wires, Rush rods, and Steinmann pins. Continued favorable reports from around the world (e.g., England, Germany, New Zealand, Turkey, and the United States) have

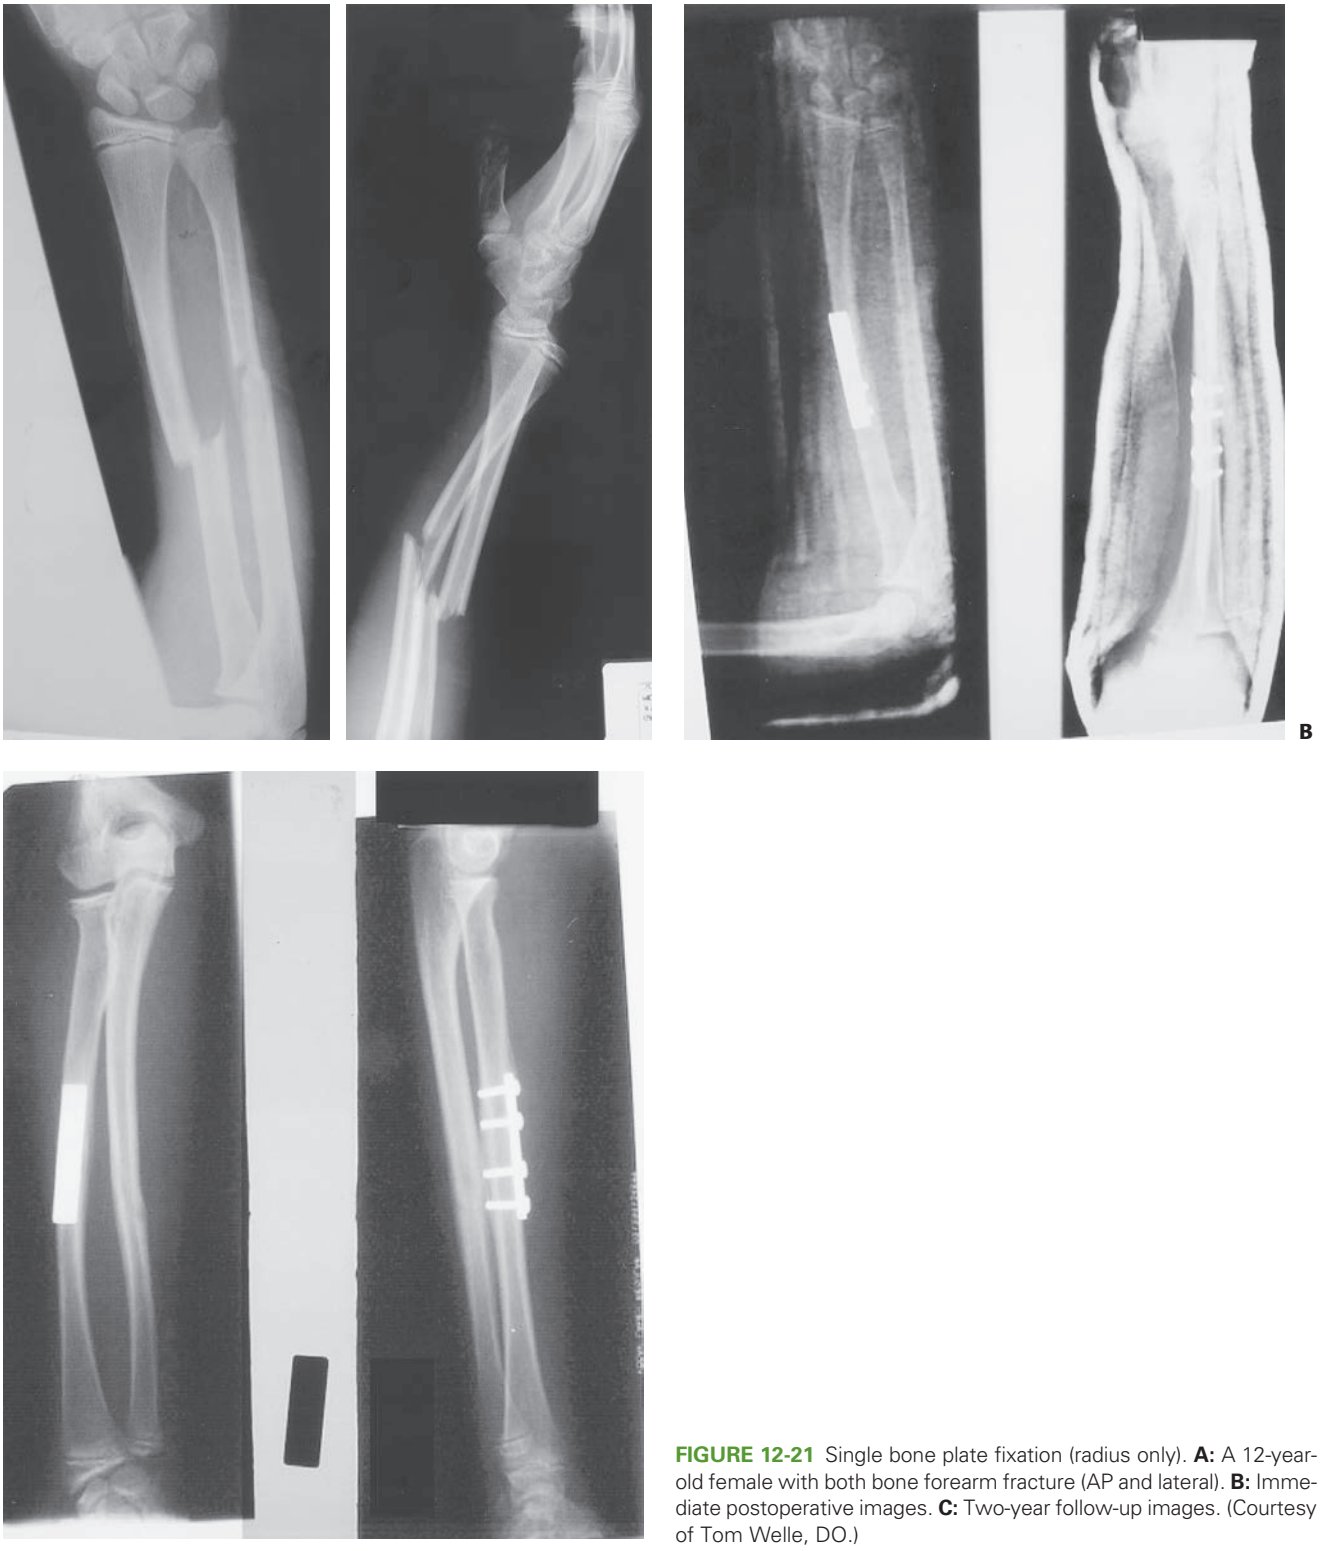

FIGURE 12-21 Single bone plate fixation (radius only). **A:** A 12-year-old female with both bone forearm fracture (AP and lateral). **B:** Immediate postoperative images. **C:** Two-year follow-up images. (Courtesy of Tom Welle, DO.)

established intramedullary fixation as the surgical treatment of choice.[53,116,163,192,267]

Intramedullary fixation has several advantages over plate fixation, including improved aesthetics because of smaller incisions and less deep tissue dissection, potentially leading to a lower risk of stiffness.[73,184,297,354] Contoured pins are used in the radius to preserve its natural anatomic bow;[8,73,260,267,343] contoured pins are not necessary for the ulna.[8] Although the rotational stability of pediatric forearm fractures treated with intramedullary fixation has been questioned, Blasier and Salamon[29] suggested

that the strong periosteum in children resists torsional stresses. In a cadaver study of the rotational stability of fractures of the ulna and radius treated with Rush rods, Ono et al.[240] found that intramedullary fixation of both bones reduced fracture rotation to one-eighth of that in unfixed fractures.

Elastic Stable Intramedullary Nailing

In the early 1980s, Metaizeau et al.[219] described elastic stable intramedullary nailing (ESIN) of pediatric forearm fractures with small-diameter (1.5 to 2.5 mm) contoured implants.[194] No effort was made to fill the medullary canal as with other intramedullary nailing techniques,[269] and the "summit of the curve must be calculated preoperatively to lie at the level of the fracture."[188] The prebent flexible rods (known as Nancy nails) were reported to maintain satisfactory fracture alignment while encouraging development of normal physiologic fracture callus.[194,219,253] Biomechanically, these implants have been shown to act as internal splints provided the nails extend three or more diameters beyond the fracture site.[159] Good results with this technique have been reported by numerous authors (Figs. 12-22 and 12-23).[131,228,269,286,294,326,327,356]

FIGURE 12-23 (*continued*) **J:** Thirty-nine month follow-up AP wrist radiograph and lateral **(K)** wrist radiograph (taken because of new trauma) demonstrating normal bony anatomy. Nails were removed 6 months postoperatively.

Because the ESIN technique emphasizes the interdependence of the radius and ulna, if both bones are fractured, both bones are internally fixed.[188] It is also dependent on anchorage of the nails in the upper and lower metaphyseal portions of the bone to produce an internal three-point fixation construct.[188] Technique principles include fixing first the bone that is easiest to reduce, using physeal-sparing entry points, and using small nails varying in diameter from 1.5 to 2.5 mm.[188] A nail that is too large may lead to nail incarceration and distraction at the fracture site, especially in the ulna.[237] Large nails may also increase the fixation rigidity which may decrease the amount of callus formation, leading to delayed union and nonunion. Contouring of both nails is recommended, with particular attention to restoration of the appropriate radial bow (Fig. 12-24). Initially, nails were removed by about the fourth postoperative month, but several refractures led the originators of the technique to delay nail removal until one full year after surgery.[188] Pin ends should be cut short and buried to maintain prolonged fixation.

Immediate motion has been recommended by some authors after ESIN of pediatric forearm fractures,[24,131,188,335] whereas others have recommended immobilization for variable periods of time.[45] Early refracture with nails in place has been reported. Bellemans and Lamoureux[24] considered displaced oblique or comminuted midshaft forearm fractures in children older than 7 years of age to be an indication for ESIN. They considered bayonet apposition (overriding) to be unacceptable at any age because of concerns about rotational malalignment and frequent narrowing of the interosseous space.[24] Their fixation technique involved passage of the intramedullary nails followed by rotation of each nail until the greatest distance between the two bones was achieved in full supination.[24]

Management of Open Fractures of Diaphyseal Radius and Ulna Fractures

In one large epidemiologic study, open fractures of the shafts of the radius and ulna and open tibial shaft fractures occurred with equal frequency, making them the most common open fractures in children.[60] Although the infection rate is extremely low for open fractures, even grade I open forearm fractures in children have been associated with serious complications such as gas gangrene.[96] Early irrigation and debridement[213,302] are indicated for open forearm fractures, and care should be taken to inspect and properly clean the bone ends.[167] Roy and Crawford[273] recommended routinely inspecting both of the bone ends for the presence of intramedullary foreign material (Fig. 12-25). Once debrided, open forearm fractures can be stabilized by any of the

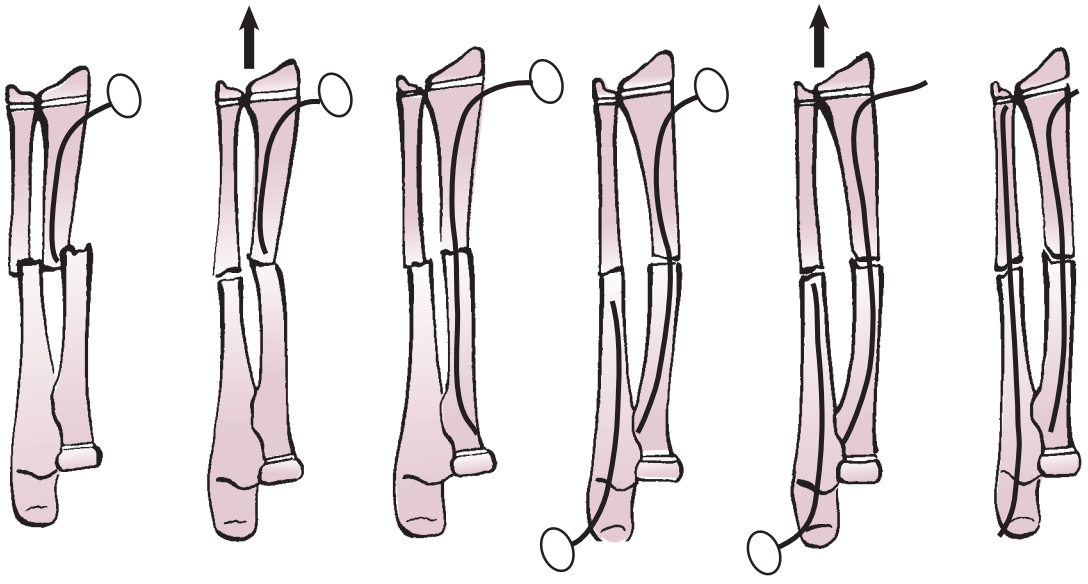

FIGURE 12-24 Metaizeau ESIN technique. The radial rod is twisted 180 degrees in step 4 to re-establish the radial bow.

available internal fixation methods without undue risk of infection (Fig. 12-26).[128,135,198] Open fractures tend to be more unstable than closed fractures (because of soft tissue stripping and comminution) and more commonly require internal fixation. Internal fixation also may facilitate soft tissue management and healing.[357] Professor Lim[195] and his colleagues from the KK Children's Hospital in Singapore recently reminded us that internal fixation is not an absolute prerequisite and many children with such open fractures may still be successfully managed with casting alone.

The amount of periosteal stripping and possible foreign body reaction associated with open forearm fractures may produce an unusual radiographic appearance: The "ruffled border sign" (Fig. 12-27). Usually, this seems to represent a normal healing response in growing children, but occasionally it is an early sign of osteomyelitis. The infection rate ranges from 0% to 33% for open fractures in children.[73,128,135,182,198,233,242,257,357] Even grade I open forearm fractures in children can be complicated by gas gangrene or osteomyelitis, and therapeutic amputation has been reported.[79,96,153] Open fracture grade does not appear to correlate with the infection rate in childhood forearm fractures, with most of the serious forearm infections reported in the literature occurring after grade I fractures.

Fracture Reduction/Conscious Sedation Protocol

Significantly displaced forearm shaft fractures are usually manipulated in the emergency department using a conscious sedation protocol. After obtaining informed consent for conscious sedation and fracture manipulation, an IV line is started, and the child's blood pressure, pulse, respirations, electrocardiogram, and peripheral oxygen level are monitored during the procedure and for about 30 minutes after the procedure. We use ketamine/atropine or fentanyl/midazolam administered intravenously in divided doses. Although many children moan or cry briefly during the manipulation, very few recall pain. Two recent reports have drawn attention to ketamine-related concerns. Perez-Garcia et al. reported the disturbing complication of severe hypertension in a 12-year old who had undiagnosed coarctation of the aorta and Kinder et al. found that children with a high body mass index were at greater risk for nausea and vomiting.[179,246] Reductions are done under mini-C-arm (fluoroscopy) control. The initial position

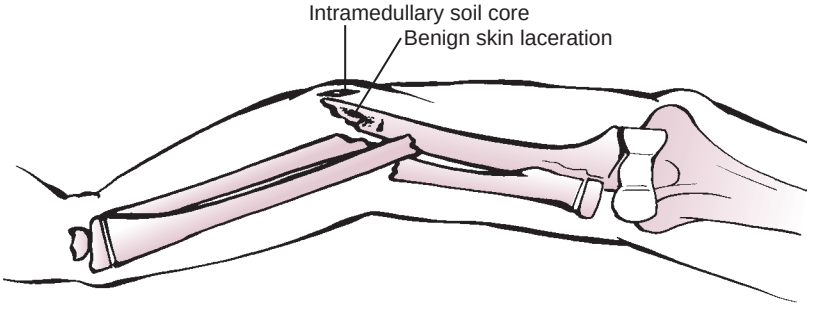

FIGURE 12-25 Intramedullary organic soil contamination from open forearm fracture with benign appearing skin laceration.

FIGURE 12-26 A 13-year-old female with open forearm fracture. **A:** AP and lateral radiographs; note extrusion of ulna on lateral view. **B:** After irrigation and debridement and flexible nail internal fixation. Note the Penrose drain in the ulnar wound.

FIGURE 12-27 Ruffled border sign at the site of previous open fracture of ulna; same patient from Figure 12-23 at 1-month follow-up.

of forearm rotation is based on the level of the fracture, and the final position is based on the best reduction under fluoroscopy. Small portable fluoroscopy units improve the quality of the reduction, decrease the radiation exposure to the patient, and decrease the need for repeat fracture reduction and save time.[10] Finger-trap traction with 10 to 15 lbs of counterweight frequently is used for completely displaced both-bone forearm fractures (especially those with shortening). We do not complete greenstick fractures because the partial bone continuity adds stability.

Because of concerns about soft tissue swelling, we place nonmanipulated and manipulated fractures into a plaster sugar-tong splint (incorporating the elbow). We avoid the circumferential wrapping of the arm with cast padding by using a "sandwich splint" technique. Before manipulation, the sugar-tong splint is prepared by laying out 7 to 10 layers of appropriate-length 3-in plaster casting material on top of a work surface. A four-layer matched length of cotton cast padding also is laid out and will form the inner padding (skin side) of the splint. A final single layer of cast padding is laid out and will form the outer layer of the splint to prevent elastic wrap adherence to the plaster. Once manipulation is completed, the plaster is dipped, wrung out, smoothed, and then sandwiched between the dry four-ply and one-ply cotton padding. This splint is then placed with the four-ply cotton side against the skin and secured with an elastic bandage (ace wrap). We prefer to avoid the circumferential application of cotton padding because it may limit splint expansion during follow-up swelling. If necessary, parents also

can unwrap and loosen the elastic bandage at home to relieve pressure if swelling makes the splint too tight. Patients are given a prescription for mild narcotic analgesics, and discharge instructions to call back or return to the emergency room for pain not relieved by the pain medicine.

Patients usually return to the office within a week for repeat radiographs and clinical assessment. Provided that satisfactory alignment has been maintained, we remove the elastic wrap but leave the plaster sugar-tong splint in place. Nonmanipulated fractures can be converted to a conventional or waterproof cast on the first visit if it is >48 hours after the injury, but manipulated fractures that maintain good position are overwrapped with fiberglass for at least a week before converting to the definitive cast. The splint is "boxed in" by applying cotton cast padding over the splint and the exposed upper arm, and by wrapping with fiberglass to convert the splint into an above-elbow cast. Follow-up radiographs are taken of manipulated fractures at about 1-week intervals for the next 2 weeks. Fractures that are losing position but are still in acceptable alignment usually require removal and remolding of a new cast to prevent further position deterioration in the upcoming week. Fractures that show increasing displacement at the initial follow-up visits, can continue to angulate up until 4 to 5 weeks post injury. Minor remanipulations can be done in the office after appropriate administration of oral analgesics and anxiolytics. Major remanipulations are best done with general anesthesia. The decision regarding the need for remanipulation may be tipped by viewing the arm position by the parents and physician after all splint and cast materials are removed.

We rarely convert an above-elbow cast to a below-elbow cast at 3 to 4 weeks post injury as is common in adults. This step may be omitted in younger children because of their faster healing and their minimal inconvenience from temporary elbow immobilization.[173] Patients can return to sports after conversion to a below-elbow cast as long as the cast is padded during play and league rules allow casts. Patients usually are required to have a physician's note allowing sports participation with a cast. This decision is made with the patient's and parents' understanding of potential increase in refracture risk. Adequate fracture healing (4/4 cortices completely healed and no transverse shaft lucency) usually has occurred after several more weeks of cast treatment but should be confirmed by radiographic and physical examination before unlimited athletic participation. Older children are given home elastic band strengthening exercises and allowed to participate in normal activities while they continue to be protected in either a removable Velcro fracture brace or a customized thermoplastic forearm gauntlet brace. Formal physical therapy rarely is required. This fracture protocol is aimed at minimizing refracture risk.

Acceptable Limits of Angulation

Based on available evidence in the literature, we accept approximately 20 degrees of angulation in distal-third shaft fractures of the radius and ulna, 15 degrees at the midshaft level, and 10 degrees in the proximal third (provided the child has at least 2 years of growth remaining).[360] We accept 100% translation if shortening is less than 1 cm. Although other authors recommend accepting up to 45 degrees of rotation, we find this is extremely difficult to measure accurately using the bicipital tuberosity and radial styloid as landmarks because of the lack of anatomic distinction in younger children. Plastic deformation fractures seem to have less remodeling potential than other fractures, and radiographically or aesthetically unacceptable angulation may require gradual, forceful manipulation under sedation or general anesthesia. Children approaching skeletal maturity (less than 2 years of remaining growth) should be treated using adult criteria because of their reduced remodeling potential. Parents should be cautioned that even mild angulation of the ulna, especially posterior sag, will produce an obvious deformity after cast removal because of the subcutaneous location of the bone (Fig. 12-28). This aesthetic deformity is exacerbated by abundant callus formation, but it will ultimately remodel if it falls within acceptable angulation criteria. Ulnar sag may be countered by placing the child in an extended elbow cast. Mild-to-moderate angulation of the radius usually produces much less aesthetic deformity but may limit motion more (Fig. 12-29).

FIGURE 12-28 Ulnar sag on serial radiographs. Note the prominent ulnar fracture callus.

Surgical Procedure of Diaphyseal Radius and Ulna Fractures

Most forearm shaft fractures continue to be successfully treated with closed methods at our institution. Our top two indications for surgical treatment of these injuries are open shaft fractures and shaft fractures that exceed our stated reduction limits. If surgical treatment is deemed necessary, intramedullary fixation

is preferred over plate fixation because of reduced soft tissue disruption. We occasionally fix one bone when both bones are fractured if overall forearm alignment is acceptable and stable after single-bone fixation.

If single-bone fixation is done, the ulna usually is treated first because of its more benign entry site, subcutaneous location, and relatively straight canal compared to the radius. Our preferred intramedullary ulnar entry site is just distal to the olecranon apophysis (anconeus starting point), just anterior to the subcutaneous border of the proximal ulna on its lateral side. Care is taken not to enter the ulna more than 5 mm anterior to its subcutaneous crest to avoid encroachment into the region of the PRUJ. Pins placed directly through the tip of the olecranon apophysis have a strong tendency to cause bursitis and pain until removal. We prefer to open the cortex with an awl because it tends to wander less than motorized drills and it allows ulnar entry with little or no formal incision. The awl technique also simplifies operating room setup in that no pneumatic hose hookups or battery packs are necessary (Table 12-7).

The patient is positioned supine with the arm abducted 90 degrees on a hand table. A wide sturdy strap is placed in the axilla to allow traction without pulling the patient off the table. Traction helps to gain length of overriding fracture ends

TABLE 12-7 Elastical Nailing of Diaphyseal Radius and Ulna Fractures

Preoperative Planning Checklist

- ***OR table:*** Standard table with radiolucent hand table. Rotate table 90 degrees to position arm opposite anesthesiologist.
- ***Position/positioning aids:*** Supine with restraint strap across chest placed high in axilla. Traction on arm must not pull patients head off of the table.
- ***Fluoroscopy location:*** Bring in parallel to the OR table on the foot (axilla) side. One fluoro monitor should be on the opposite side of the table where anesthesiologist sits, and the other should be caudal to the arm.
- ***Equipment:*** Elastic nail set, small bone wrench (small femoral wrench), vice grips, awl, nail grip device, mallet, ragnell retractors, small fragment set bone reduction clamps, K-wire set.
- ***Tourniquet (nonsterile):*** Placed high in axilla.
- ***Etc:*** Need a Kerlix gauze around distal humerus or a blunt mallet to apply counter traction against the hand with elbow flexed 90 degrees (see video).

To improve the torque needed to rotate the rod, a locking plier or extra heavy duty needle driver can be clamped to the rod near its insertion into the T-handle. The handle alone will frequently slip during rotation in the diaphysis.

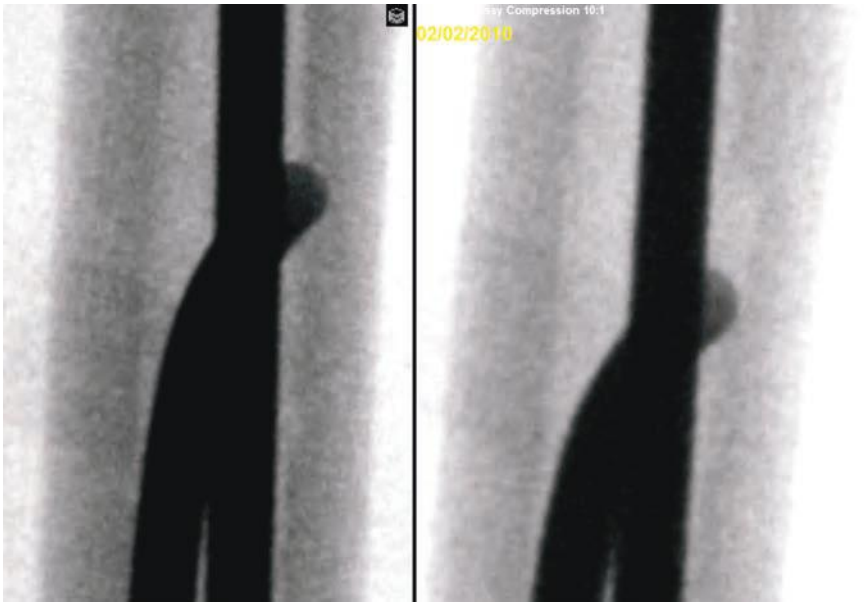

FIGURE 12-30 This illustrates the "rod rut" incurred during a femur Nancy nail insertion. In left figure the tip of the rod has dug a rut in the cortex and is stuck. It was backed up 5 mm, leaving behind a visible rut. The rod was twisted 90 degrees and then passed up the shaft freely.

and allows the bones to seek their normal rotation. If dual-bone fixation is elected, then the radius is fixed first as it is usually more difficult to rod, and it is always more difficult to approach with an open reduction than the ulna. If the ulna is fixed first it will limit forearm mobility and make it very difficult to manipulate the radius and pass the nail which forces a risky and complex open reduction on the radius. Optimizing the closed rodding of the radius by fixing it first makes the ulna reduction a little more difficult, but open reduction of the ulna is vastly simpler than an open reduction of the radius fracture at any fracture level. The distal radial entry site can be either through a physeal-sparing direct lateral approach through the floor of the first dorsal compartment or dorsally near the proximal extent of the Lister tubercle between the second and third dorsal compartments. Both of these entry points are approximately 1 cm proximal to the physis of the distal radius. We insert the radial nail through a 1- to 2-cm incision, protecting the superficial radial nerve and the dorsal tendons with small blunt retractors. An awl is used to gain intramedullary access to the radius. We typically use small intramedullary nails (2 to 2.5 mm in diameter) to maintain some flexibility at the fracture site and stimulate appropriate callus formation. Larger nails may become incarcerated in either the narrow central canal of the radius or that of the distal third of the ulna. Care must be taken not to overbend the tip of the nail as this effectively increases the diameter of the implant and may impede its intramedullary passage. If the rod gets stuck, the tip has often been pounded into a rut (Fig. 12-30).

Backing the rod up 5 mm and rotating it away from the rut will ease passage down the shaft isthmus. If the nail fails to engage the shaft on the other side of the fracture, tap it back to the fracture, rotate it 90° to 180° and then retry. A "shoehorn" technique can be used to percutaneously align the fracture. A 2 mm K-wire is placed into the fracture between the two ends of the translated bone. It is then levered to allow the bone ends to translate into alignment. With the K-wire lever in place, then pass the nail across the fracture (Fig. 12-31).

Failure to pass the intramedullary nail across the fracture site after several attempts may necessitate a limited open reduction with at least a 2-cm incision to directly pass the rod across the fracture site (Fig. 12-32). Because of the thick soft tissue envelope, an open approach to the radius needs to be twice this long. Placing a bone clamp on either side of the fracture allows bone alignment control. Persistence in attempting to achieve closed reduction and rodding has been associated with compartment syndrome.[362] We are sensitive to both time and attempts during ESIN of forearm shaft fractures in our pediatric patients and recommend surgeons not to do prolonged attempts at reduction and fixation closed and recommend relatively rapid conversion to a small open reduction if needed.

If single-bone fixation is done, the ulna usually is treated first because of its more benign entry site, subcutaneous location, and relatively straight canal compared to the radius. Our preferred intramedullary ulnar entry site is just distal to the olecranon apophysis (anconeus starting point), just anterior to the subcutaneous border of the proximal ulna on its lateral side. Care is taken not to enter the ulna more than 5 mm anterior to its subcutaneous crest to avoid encroachment into the region of the PRUJ. Pins placed directly through the tip of the olecranon apophysis have a strong tendency to cause bursitis and pain until removal. We prefer to open the cortex with an awl because it tends to wander less than motorized drills and it allows ulnar entry with little or no formal incision. The awl technique also simplifies operating room setup in that no pneumatic hose hookups or battery packs are necessary (Table 12-8).

We prefer to leave the nails buried beneath the skin because complete fracture healing takes at least 2 months, and often much longer. Because refracture can even occur with nails in

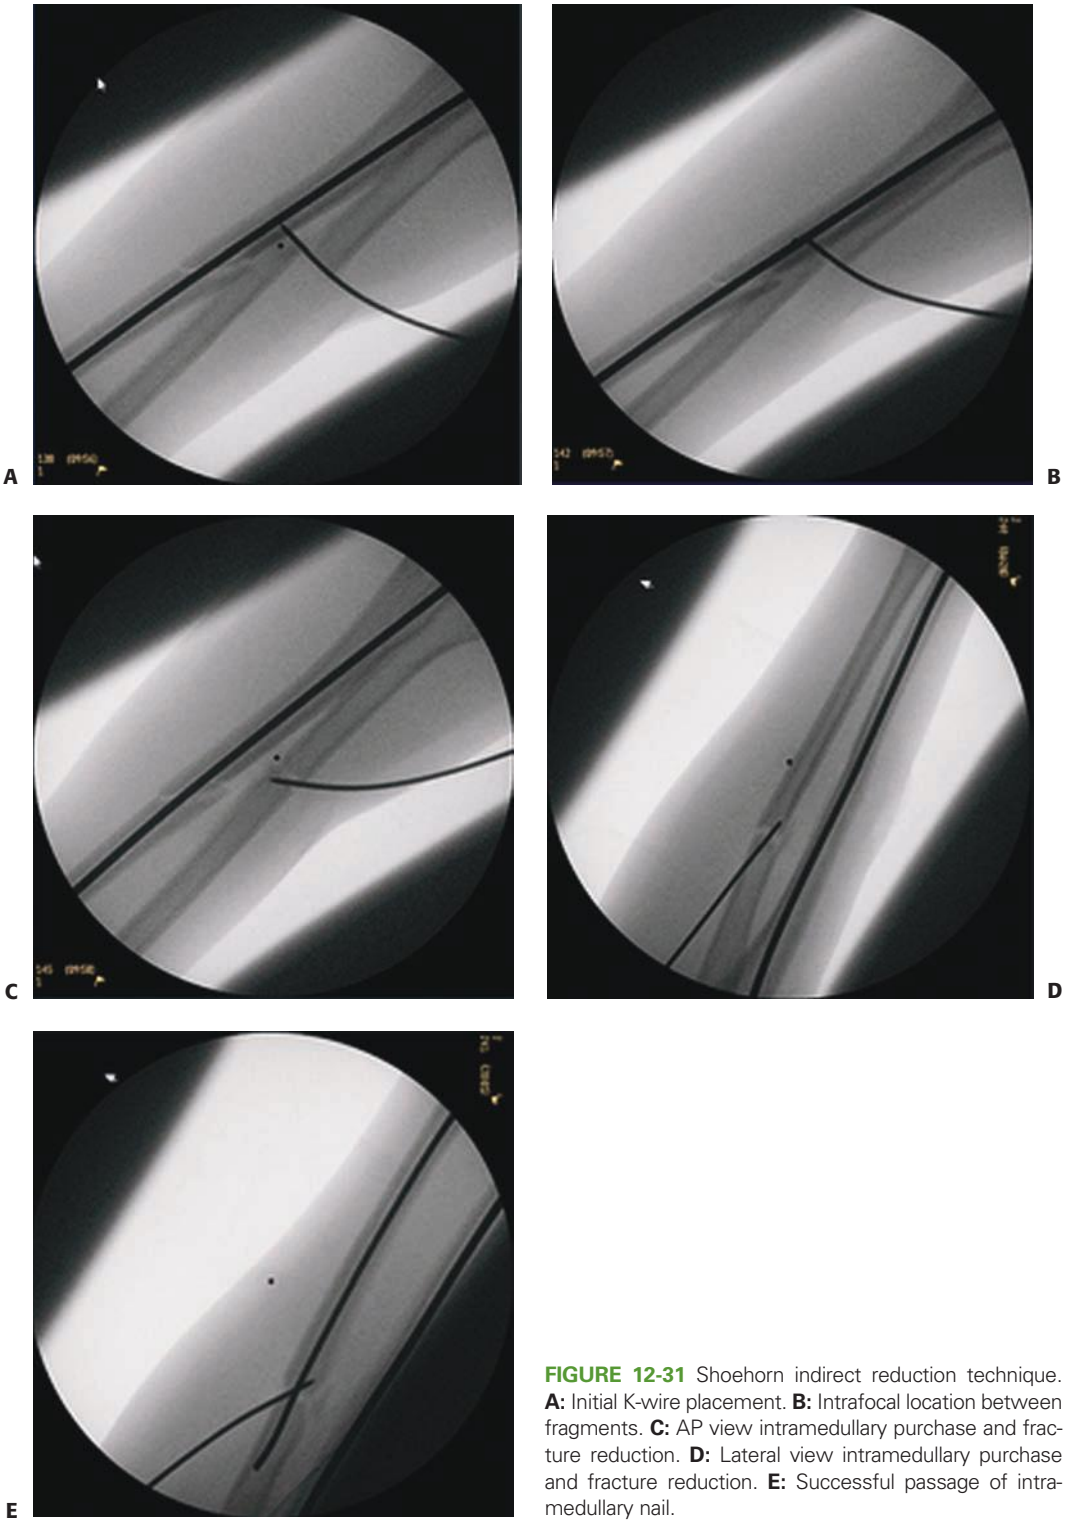

FIGURE 12-31 Shoehorn indirect reduction technique. **A:** Initial K-wire placement. **B:** Intrafocal location between fragments. **C:** AP view intramedullary purchase and fracture reduction. **D:** Lateral view intramedullary purchase and fracture reduction. **E:** Successful passage of intramedullary nail.

place, we protect children for at least the first month with a removable fracture brace. If a single bone of a both-bone fracture is fixed, above-elbow cast immobilization usually is necessary instead of a below-elbow cast or brace, as is used after dual-bone fixation. After the appearance of satisfactory callus, splint and activity restrictions are progressively relaxed. We recommend nail removal after complete four-cortex healing of each bone (6 to 12 months in most patients).

Plating is preferred to intramedullary nailing when early malunion is present and callus formation is noted radiographically.

FIGURE 12-32 A 12-year-old female with midshaft both bone complete forearm fracture. **A:** AP and lateral injury radiographs. **B:** Two-month follow-up radiographs. **C:** Six-month follow-up radiographs (ulnar nail removed).

D, E F

FIGURE 12-32 (*continued*) **D:** Pronation. **E:** Supination. **F:** Axial alignment.

Plating allows open osteoclasis and reduction. The plating technique is similar to that used in adults, except that smaller plates can be used and fewer cortices (often only four cortices above and below the fracture) are required for adequate fixation.

In children with both-bone forearm fractures, plating of a single bone may be adequate and reduce the morbidity associated with dual-bone plating.[25] Significant comminution of both bones also may be an indication for plate fixation (Table 12-9).

TABLE 12-8 Elastic Nailing of Diaphyseal Radius and Ulna Fractures

Surgical Steps

- Always expose the radius first with a 1–2 cm incision, just proximal to the Lister tubercle between the second and third tendon compartments. Alternatively, perform a styloid approach through the first dorsal compartment just proximal to the physis.
- Avoid major branches of the superficial radial nerve and clearly identify the tendons to avoid damage.
- With the Lister approach there is a "bare area" of bone between the EPL and ECRB tendons that is elevated clear of its periosteum.
- Use an awl to create a start window in the "bare area" for the Lister approach, or between the APL and EPB tendons for styloid approach.
- Forcibly tighten the T-handle on the rod and insert the rod by hand with an oscillating twist motion.
- Pull traction on arm against the axillary strap
- Use mallet to advance to fracture if impossible by hand. If rod fails to advance, the tip could be stuck in a rut. Tap the rod 5 mm backward; rotate the tip, then advance down the shaft again to the fracture.
- Pull heavy traction on the hand, manipulate the fracture, and use the small femoral wrench align the bone ends. If you miss, pull the nail back, rotate the rod 90 degrees, reattempt to pass, and repeat until it passes.
- If the fracture ends remain 100% translated despite manipulation, try the "shoehorn" K-wire technique before opening.
- If you have to open, make a 3–4 cm incision, grip the bone ends with small reduction clamps and hold reduced while assistant passes nail. Use the volar (Henry's approach to open, carefully avoiding the posterior interosseous nerve as it.
- Only advance the nail 1 cm past the fracture so it is just "perched." Full insertion will make it nearly impossible to manipulate the ulna next.
- Start the ulna about 3 cm distal to the olecranon tip about 4 mm lateral to the posterior crest. Palpate the radial head and stay clear of it. The starting incision can be 3–4 mm long and made percutaneously.
- Advance the nail with an oscillating twist technique to the fracture, past the rod similar to radial rod. With the radius rod just perched across the fracture by 1 cm, the ulna can be freely manipulated to ease nail passage across the ulna fracture.
- Insert nail about 1 cm short of the distal ulna physis to leave room for final impaction.
- Remove the T-handle, put about a 45 degree bend in the rod just as it enters the bone. Do not lever the rod against the bone because it will plough or fracture through the metaphyseal bone.
- Cut the nail as close to the bone as possible, then final impact the nail so only 3 mm stick outside the bone for purchase during removal.
- Rotate the radial rod so that the bow in the nail follows the natural bow of the radius. Leave 1 cm short of the end of the bone to allow for final impaction after cutting the rod similar to the ulna.
- If using the Lister approach, make sure that the EPL tendon is not rubbing on the protruding nail end to avoid rupture.

TABLE 12-9 Keep Elastic Nails in Place for at Least Six Months

Refracture	Keep elastic nails in place for nearly a year. Splint or cast for at least 6–8 weeks after elastic nailing
Delayed union	Use the smallest nail that will pass to allow callus formation (1.75–2.5 mm) Use a plate instead of a nail after skeletal maturity
Infection	Wash out all open fractures, especially if they occur on organic surface (soccer field, fall from tree, dirt bike). Beware of the lawn biopsy in which a dirt clod gets stuck in the intramedullary canal
Nail incarceration in canal	Back up out of rut, rotate nail, then advance down canal
Difficult nail passage across fracture	Use a percutaneous K-wire to lever the ends of the fracture into alignment
Muscle/tendon entrapment or rupture	Make sure that elastic nail does not rub on or impale EPL tendon
Neurapraxia	Most will resolve spontaneously if noted prereduction. Fix radius first to minimize need to open which could injury PIN. Identify or avoid PIN during open reduction
Compartment syndrome	During elastic nailing, perform an open reduction if nail does not pass after multiple attempts (20–30 min). Perform fasciotomy in any patient who has increasing anxiety, analgesia requirements, and apprehension.
Complex regional pain syndrome	Early recognition and referral to physical therapy or pain service for treatment

Management of Expected Adverse Outcomes and Unexpected Complications in Diaphyseal Radius and Ulna Fractures (Table 12-10)

Redisplacement/Malalignment in Diaphyseal Radius and Ulna Fractures

The most common short-term complication of forearm shaft fracture treatment is loss of satisfactory reduction in a previously well-reduced and well-aligned fracture, a complication that occurs in 10%[56,63,79,162,339] to 25% of patients.[56,79] Initial follow-up radiographs are a screening test aimed at identifying redisplacement. Kramhoft and Solgaard[182] recommended that children with displaced diaphyseal forearm fractures have screening radiography at 1 and 2 weeks after reduction. Voto338 also pointed out that most fractures that redisplace do so within the first 2 weeks after injury. Inability to properly control fracture alignment with closed methods is the most commonly reported indication for operative intervention.[192,260,273,297,363]

The most common explanations for loss of fracture reduction are cast related (poor casting technique, no evidence of three-point molding).[61,339] The more experienced the surgeon, the greater the likelihood of successful reduction.[56] Other factors that have been found to be associated with forearm fracture redisplacement are quality of initial reduction,[361] missed follow-up appointments,[70] proximal-third fractures,[71] and failure of the doctor to respond to early warning signs such as slight loss of reduction at 1-week follow-up.[114] Strategies for dealing with redisplacement include allowing the deformity to remodel,[144] cast wedging,[17,153,171] rereduction and recasting,[79,339] pins and plaster,[32,89,339] indirect reduction and internal fixation,[8] and open reduction and internal fixation.[357] Reports in the literature suggest that most forearm shaft fractures that redisplace can be successfully managed with repeat closed reduction and casting.[79,339]

Forearm Stiffness in Diaphyseal Radius and Ulna Fractures

The forearm is a predominantly nonsynovial joint with high-amplitude motion as its main function. The most common long-term complication of forearm shaft fracture treatment is significant forearm stiffness,[144] with pronation loss occurring almost twice as frequently as supination loss.[145] Loss of pronation or supination motion sometimes occurs despite perfectly normal-appearing radiographs.[170,232,257] Abnormal bony alignment of the forearm bones can lead to motion deficits.[168] However, stiffness can exceed that expected from bony malalignment alone[168] and stiffness can occur with normal radiographs and both situations may be indicative of fibrosis of the interosseous membrane and/or contracture of the interosseous ligament.[170,257]

With focused testing of forearm motion, between 18%[49] and 72%[145] of patients show at least some minor deficits after nonsurgical treatment. Most minor deficits are not even noticed by patients and rarely are associated with functional limitations.[49,75,232] More severe losses of forearm rotation have far greater impact.[222] In their series of malunited forearm fractures (thus strongly weighted to demonstrate forearm stiffness), Price et al.[257] reported a 15% (6/39) rate of mild stiffness (up to 25-degree loss) and an 8% (3/39) rate of severe forearm stiffness (loss of 45 degrees or more of either pronation or supination). Holdsworth's[145] series of malunited pediatric forearm fractures had a similar rate (6%) of severe forearm stiffness. Holdsworth[145]

told the classic story of a female whose inability to properly pronate caused her to elbow her neighbors when eating at the table. Patrick[245] pointed out that it is possible to compensate for pronation losses with shoulder abduction, but no similar compensation mechanism exists for supination losses. Such severe motion loss is a very undesirable outcome. For surgical treatment of these injuries to be a rational choice, the rates of stiffness after surgery must be lower than those after cast treatment.[130]

Bhaskar and Roberts[25] published one of the only studies of plated pediatric forearm fractures to report goniometric pronation and supination data. Both their single-bone (ulna) and both-bone plated patients showed mild forearm motion losses (maximal 18% loss of pronation).[25] Variable rates of mild forearm range-of-motion losses have been reported after intramedullary fixation. Amit et al.[8] reported a 40% rate of mild stiffness (5 to 10 degrees) in 20 pediatric patients after Rush rod fixation of forearm fractures. Combined data from five series of the flexible intramedullary nailing (K- wires, Steinmann pins, Nancy nails) reveal a 1.6% rate (2/128) of mild forearm stiffness (up to a 20-degree loss) and a 0% (0/128) rate of severe motion loss (40 degrees or more loss of either pronation or supination).[8,24,98,184,297,363] No published series of nonoperatively treated forearm shaft fracture patients has exceeded these results relative to preservation of forearm motion.

Refracture in Diaphyseal Radius and Ulna Fractures

Refracture occurs more often after forearm shaft fractures in children than after any other fracture.[185] Tredwell[328] found that forearm refractures occurred at an average of 6 months after original injury and were more common in males (3:1) and in older children (approximately 12 years old). Baitner and his San Diego colleagues suggested that middle- and proximal-third forearm shaft fractures created a higher risk of refracture for pediatric patients.[15] Refracture rates of 4%[98] to 8%[196] have been reported in pediatric diaphyseal forearm fractures. Bould and Bannister[39] reported that diaphyseal forearm fractures were eight times more likely to refracture than metaphyseal fractures. Schwarz et al.[291] found that 84% (21/28) of the forearm refractures in their series had initially presented as greenstick fractures. Based on the stage of bony healing, refractures may occur through the original fracture site, through both the original site and partially through intact bone or completely through intact bone,[348] but most seem to occur through the original fracture site.

Several authors have suggested that internal fixation is necessary after refracture,[13,254,269] but Schwarz et al.[291] reported good results with repeat closed reduction and casting in 14 of 17 patients with refractures. Closed reduction of the fracture and the bent rods has been shown to be effective for forearm refractures that occur with flexible nails in place (Fig. 12-33).[225] The best treatment of refracture is prevention, and patients should be splint protected (removable forearm splint or thermoplastic gauntlet) for a period of 2 months depending on the activity after initial bone healing.[233,257] Refracture is rare during splint wear. Parents must be cautioned about the risk of refracture despite apparently adequate bone healing on radiographs.

Refracture after plate removal has been discussed frequently in the literature[106,230,256,331] and appears to be associated with decreased bone density beneath the plate.[176] This has led many authors to question the routine use of plate fixation for pediatric forearm fractures.[29,70,256,332] Refractures also have been reported after removal of intramedullary forearm fixation in children.[73,135,170,188,297,327,364] The main strategies aimed at decreasing the risk of refractures after implant removal are documentation of adequate bony healing before implant removal, and an additional period of splint protection after implant removal until the holes have filled in.

Malunion in Diaphyseal Radius and Ulna Fractures

Evaluation of pediatric forearm fracture malunion must take into account established malreduction limits and expected pediatric remodeling potential. Thus, a malunion of 30 degrees may become less than 10 degrees during the course of follow-up. The level of the malunited fracture also must be considered, because the consequences of malreduction vary according to level.[281,360] More deformity in the predominant plane of motion is acceptable in fractures near physes of long bones than in diaphyseal fractures. Normal motion can be preserved despite persistent radiographic abnormality (Fig. 12-34).

Malunion of radial and ulnar shaft fractures can lead to an aesthetic deformity and loss of motion; however, significant loss of function occurs in only a small percentage of patients.[49,75,232] Some authors have recommended more aggressive efforts at

correction of forearm fracture malunions.[217,255] Early malunions (up to 4 or 5 weeks after injury) can be treated with closed osteoclasis under anesthesia. If closed osteoclasis fails to adequately mobilize the fracture, a minimally invasive drill osteoclasis can be done.[28] A small-diameter drill (or K- wire) is used to make multiple holes in the region of the malunion before forcefully manipulating the bone back into alignment.[28] Internal fixation is rarely, if ever, needed.

Once significant callus is present, indirect reduction and internal fixation with flexible intramedullary nails can be difficult or impossible because the fracture site is now blocked with callus. Thus, established or impending malunions that cannot be adequately controlled with a cast may require formal open reduction and plate fixation (Figs. 12-35 and 12-36). Many fractures that heal with angulation or rotation of more than the established criteria regain full motion and have an excellent cosmetic outcome. Fractures may require corrective osteotomy if they fail to remodel after an adequate period of observation or if adequate motion fails to return.[217,329] Such corrective osteotomies have been done long after injury (up to 27 years) and additional motion has still been regained.[329] There is a minor subset of malunions that do not remodel, that have functional limits (especially when there is limited supination deformity), and therefore, are candidates for osteotomy.

Delayed Union/Nonunion in Diaphyseal Radius and Ulna Fractures

The diagnosis of delayed union is based on documentation of slower-than-normal progression toward union.[193] Daruwalla[75] stated that normal healing of closed pediatric forearm shaft fractures occurs at an average of 5.5 weeks (range 2 to 8 weeks). Delayed union can be practically defined as a failure to demonstrate complete healing (four cortices) on sequential radiographs by 12 weeks after injury, which exceeds the upper limit of normal healing by about 1 month. Nonunion can be

defined as the absence of complete bony union by 6 months after injury, which exceeds the upper limit of normal healing by about 4 months.

Delayed unions and nonunions are rare after closed forearm shaft fractures in children.[99,193,308] In six large series of pediatric diaphyseal forearm fractures treated by closed methods, a less than 0.5% rate (1/263) of delayed union and no nonunions were reported.[49,75,145,170,182,257] Delayed unions and nonunions are more common after open reduction and internal fixation and open fractures. Particular concern has been raised about the potential of antegrade ulnar nailing (olecranon starting point) to distract the fracture site.[237] Combined data from four series of plated pediatric forearm fractures indicated a 3% (3/89) nonunion rate;[25,230,332,357] 24% (21/89) of these were open fractures and at least one[357] of the three nonunions occurred after a grade III open fracture.[230,332] Large series of open pediatric forearm fractures (treated by a variety of internal fixation methods) reported comparable numbers: 5% (8/173) delayed union rate and 1% (2/173) nonunion rate.[78,128,135] In a series of 30 nonunions in children, only 6 were in the forearm, and half of these were after open fractures.[193]

Because of the overall rarity of nonunions in children, the possibility of unusual diagnoses such as neurofibromatosis must be considered.[65,67,155,205] After open injury or surgical intervention for other reasons, the possibility of septic nonunion must be ruled out. In the absence of such extraneous factors, nonunion of pediatric forearm fractures seems to be related to surgical treatment.[65,67,155,205,308] Weber and Cech[346] divided nonunions into atrophic and hypertrophic types. Atrophic nonunions probably are best treated with bone grafting and compression plating. Compression plating or other stable internal fixation without grafting usually is sufficient for hypertrophic nonunions.[190]

Cross-Union/Synostosis in Diaphyseal Radius and Ulna Fractures

Posttraumatic radioulnar synostosis results in complete loss of forearm rotation. Most cross-unions that form after pediatric forearm shaft fractures are type II lesions (diaphyseal cross-unions), as described by Vince and Miller (Fig. 12-37).[336] Although some series of adult forearm fractures reported synostosis rates of 6% to 9%,[21,317] posttraumatic radioulnar synostosis is a rare complication of pediatric forearm shaft fractures.[336] In children, it is usually associated with high-energy injuries,[336] radial neck fractures,[275] and surgically treated forearm fractures.[73,238] Some have suggested a familial predisposition to this complication.[202] Postoperative synostosis after forearm fractures in children is almost exclusively associated with plate fixation.[352,357] The risk of cross-union is increased when open reduction and internal fixation of both-bone fractures are done through one incision.[21,70]

Both osseous and nonosseous cross-unions may form in the forearm,[9,63,340] but the more common type is osseous. After a synostosis matures (6 to 12 months), it can be excised along with any soft tissue interposition.[235,336] The results of synostosis resection may be better in adults than children,[336] perhaps because of the more biologically active periosteum in children.[84,336] Interposition of inert material (such as Gore-tex [W. L. Gore & Associates, Inc., Elkton, MD] or bone wax) has been used to decrease the chances of recurrent synostosis.[9,19,238,336] Nonsteroidal anti-inflammatory drugs and radiation treatment have been reported after synostosis excision in adults, but their use in children remains undefined. An alternative treatment is corrective osteotomy if the patient is synostosed in a position of either extreme pronation or supination. If the patient is stuck in a neutral position after

posttraumatic synostosis, surgical intervention is usually not recommended.

Infection in Diaphyseal Radius and Ulna Fractures

Infection occurs only in surgically treated forearm shaft fractures and open fractures. Appropriately timed preoperative antibiotic prophylaxis is believed to diminish the risk of infection. Children with open forearm fractures are considered to be at high risk for infection, and early (usually less than 24 hours)[302] irrigation and debridement in the operating room is indicated.[273] Whether in the backyard, the barnyard, the football field, or the hay field, open forearm fractures that occur in organic settings are best treated with early irrigation and debridement with inspection of the intramedullary canal of both bone ends, where soil contamination tends to occur during injury (Fig. 12-25). Soil contamination has been reported to lead to gas gangrene and subsequent upper extremity amputation in children with grade I open forearm fractures.[96] Emergency room irrigation and debridement is not recommended and is considered inadequate with increased risk of serious infection.

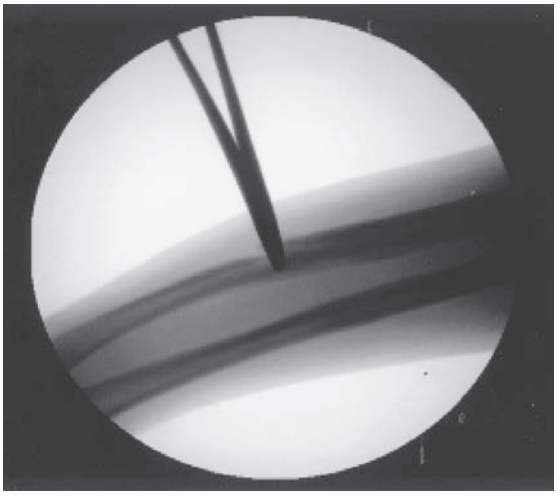
In four published series of plated pediatric forearm fractures (25% open fractures), deep infection (osteomyelitis) occurred in 5% (4/83).[222,230,332,357] Such deep infections usually require extensive additional surgical treatment to eradicate them. Combined data from 12 series of similar pediatric forearm fractures (15% open fractures) treated with intramedullary K-wires, Steinmann pins, or Rush rods revealed a deep infection rate of 0.46% (2/437)[8,45,73,184,197,260,261,297,343,363] and a superficial infection rate of 2.5% (11/437). Six studies of ESIN fixation reported a 0.2% (1/370) deep infection rate and a 3% (12/370) superficial infection rate.[45,131,188,204,269,335] Superficial infections may require oral antibiotics, pin removal, or both.

Open forearm fractures clearly are at increased risk for infection. Most (96%) open forearm fractures in children are Gustilo and Anderson[134] grade I or II.[128,135,198] Two studies specifically investigated the relationship between the time from injury until irrigation and debridement and the risk of later infection. Luhmann et al.[198] reported on 65 fractures (52 type I, 12 type II, 1 type III) that were irrigated and debrided an average of 5.6 hours (range 1.5 to 24 hours) after injury, and Greenbaum et al.[128] reported 62 fractures (58 type I, 4 type II) that were irrigated and debrided an average of 14.6 hours (range 1.7 to 37.8 hours) after injury. No statistically significant association was found in either of these studies; however, most (87%) of these fractures were grade I injuries. Pooled data revealed an overall 1.2% rate (2/173) of deep infection and a 0.6% rate (1/173) of superficial infection after current open fracture treatment protocols.[128,135,198]

Neurapraxia in Diaphyseal Radius and Ulna Fractures

The median nerve is the most commonly injured nerve with forearm shaft fractures (whether closed or open injuries),[79,128,135,198] but any peripheral nerve and at times multiple nerves may be involved.[73] Most of these injuries are simple neurapraxias that occur at the time of injury and resolve spontaneously over weeks to months.[79,134,231] Actual nerve entrapment within or perforation by the bony fragments has been reported,[6,112,118,119,152,258,259,313] most often with greenstick fractures.[119,152,258,259] Constricting

A



B

fracture callus and fibrous tissue also have been known to cause nerve palsies.[259,313] In patients who fail to recover normal nerve function within a satisfactory time period,[6] nerve exploration, decompression, and possible nerve repair should be considered. If signs of progressive nerve recovery (e.g., advancing Tinel sign, return of function) are not present by the end of the third month after injury, further diagnostic work-up (electromyography with nerve conduction studies) is indicated. Prolonged waiting can be harmful to long-term outcome.

Nerve injury after internal fixation is always a concern. Operative treatment of pediatric forearm fractures by either indirect reduction and internal fixation techniques or classic open reduction and internal fixation techniques requires fracture manipulation and soft tissue retraction, which have the potential to worsen existing subclinical nerve injury or to create a new injury. Such injuries are rare and may be underreported. Nerve injury after pediatric forearm plate fixation has been alluded to but not discussed extensively.[184] Luhmann et al.[197] reported an 8% (2/25) iatrogenic nerve injury rate after fixation with intramedullary K-wires or Rush rods: Both were ulnar nerve injuries that resolved in 2 to 3 weeks. Cullen et al.[73] reported one ulnar nerve injury that took 3 months to resolve in a group of 20 patients treated with K-wires or Rush rods.

Certain sensory nerves also are at risk for iatrogenic damage during surgical forearm fracture treatment, especially the superficial branch of the radial nerve.[45,197,315] Pooled data from six series that included 370 ESIN procedures revealed a 2% (7/370) rate of injury to the superficial branch of the radial nerve.[45,131,188,204,269,335] The branching pattern of this sensory nerve is complex, and efforts must be taken to protect it during insertion of intramedullary nails through distal radial entry points.[1,14]

Muscle or Tendon Entrapment/Tendon Rupture in Diaphyseal Radius and Ulna Fractures

Severely displaced forearm fractures may trap portions of muscle between the fracture fragments.[147,260] Often, interposed tissue can be effectively removed during standard fracture reduction, but the muscle may become an obstacle to successful closed reduction. Much of the volar aspects of the shafts of the radius and ulna are covered by the flexor pollicis longus and flexor digitorum profundus, respectively. Many displaced forearm shaft fractures also have apex-volar angulation.[233] As a result, portions of these muscles (or their tendons) are particularly prone to fracture site incarceration (Fig. 12-38). The pronator quadratus also is vulnerable to fracture site entrapment in the distal third of the radius and ulna, and it can block reduction of distal-third forearm fractures.[147]

Flexor digitorum profundus entrapment within ulnar[140,180,266,295] and radial[344] shaft fractures has been reported. Entrapment of the flexor digitorum profundus typically causes an inability to fully extend the involved finger (usually index, long, or ring fingers alone or in combination)[140,295] Isolated ring finger flexor digitorum profundus entrapment has also recently been reported.[307] Even if identified early, this complication rarely responds to occupational or physical therapy. Surgical intervention is the preferred treatment and requires only a small incision (usually over the ulna) through which the adherent tissue is elevated with a blunt instrument from the bone at the site of the fracture. Excellent restoration of finger motion can be achieved, even when the release is done up to 2 years after the fracture.[266]

Extensor tendon injury has been reported after intramedullary nailing of pediatric forearm shaft fractures.[131,188,250,260] The extensor pollicis longus appears to be at particular risk

for this injury if a dorsal entry point is utilized near the second and third dorsal compartments.[183,312] Primary tendon disruption may be caused by direct trauma during either nail insertion or extraction. Delayed tendon disruption may be caused by slow erosion of the tendon as it glides past a sharp nail edge. The possibility of this complication can be minimized by using surgical incisions large enough to allow insertion of small blunt retractors to protect adjacent tendons during nail insertion and extraction. Avoidance of tendon erosion requires pin lengths that extend beyond the tendon level into either the subcutaneous tissues[73,297] or through the skin (external pins).[260] Conceivably, the pins could be buried completely within the bone, but this would require either accepting them as permanent implants (something not commonly practiced at this time) or significantly increasing the level of difficulty of nail removal. The extensor pollicis longus is more at risk near the Lister tubercle and may require a late tendon reconstruction with extensor indicis proprius transfer if ruptured.

Compartment Syndrome in Diaphyseal Radius and Ulna Fractures

Compartment syndrome is rare after closed forearm fractures in children, but its consequences can be devastating. Yuan et al.[362] found no compartment syndromes in 205 closed forearm injuries, and Jones and Weiner[162] reported no compartment syndromes in their series of 730 closed forearm injuries. A single compartment syndrome that developed during cast treatment of a 12-year-old female with a closed both-bone forearm fracture was reported by Cullen et al.[73] Because the diagnosis of compartment syndrome can be difficult in children,[263] the index of suspicion must be high.

Compartment syndrome should be suspected in any child who is not reasonably comfortable 3 to 4 hours after adequate reduction and immobilization of a forearm fracture.[68] The risk of compartment syndrome is higher with open fractures[135,362] and fractures that are difficult to reduce and require extended operative efforts.[362] Yuan et al.[362] voiced concern that the 10% (3/30) rate of compartment syndrome in their patients with closed fractures might be caused by multiple passes or "misses" with intramedullary devices during efforts at indirect reduction and internal fixation. Compartment syndrome was reported by Haasbeek and Cole[135] in 5 (11%) of 46 open forearm fractures in their series. The so-called floating elbow injury has been associated with a rate of compartment syndrome as high as 33%.[362] In children, the three A's of increasing analgesia, anxiety, and agitation are the most reliable clinical signs of a pending compartment syndrome. Forearm compartment syndrome is best treated with fasciotomy, releasing both the superficial and deep volar compartments and the mobile wad. Both the lacertus fibrosis and the carpal tunnel should be released as part of the procedure.

Complex Regional Pain Syndromes in Diaphyseal Radius and Ulna Fractures

Complex regional pain syndromes such as reflex sympathetic dystrophy are uncommon complications after pediatric forearm shaft fractures.[332] Paradoxically, relatively minor injuries seem to place patients at greatest risk.[316,349] The most reliable sign in children is true allodynia: Significant reproducible pain with light touch on the skin. Swelling and other vasomotor changes often are accompanying signs.[191] The diagnosis in children is made based almost exclusively on the history and physical examination, with little reliance on studies such as bone scans.[316] These pain syndromes are best treated initially with physical therapy aimed at range of motion and desensitization.[316,349] Failure to respond to physical therapy may warrant a referral to a qualified pediatric pain specialist.[174,191]

Author's Preferred Treatment for Diaphyseal Radius and Ulna Fractures

Closed Fracture Care for Diaphyseal Radius and Ulna Fractures

We agree with Jones and Weiner that "closed reduction still remains the gold standard for closed isolated pediatric forearm fractures" (Fig. 12-39).[162] Most nondisplaced and minimally displaced radial and ulnar shaft fractures can be splinted in the emergency department and referred for orthopedic follow-up within 1 week. Radiographs are repeated at the first orthopedic visit, and a cast is applied. During warmer weather, when fracture incidence peaks, we tend to use waterproof cast liners. We avoid flexing the elbow past 80 to 90 degrees in waterproof casts because the soft tissue crease that forms in the antecubital fossa tends to trap moisture. Because waterproof cast lining alone does not shield the skin from cast saw cuts and burns as well as traditional padding does, specialized material may be added along the anticipated course of the cast saw to protect the skin during cast removal.

We prefer an above-elbow cast for all forearm fractures in children under the age of 4 years, because young children tend to lose or remove a below-elbow cast because of soft tissue differences (baby fat) common to the age group.[85] Most older children with forearm shaft fractures also are treated with above-elbow casting, except for those with distal-third fractures. Good forearm casting technique should focus on the principles outlined earlier in this chapter. Patients with nondisplaced fractures usually are reevaluated radiographically in 1 to 2 weeks after initial immobilization to check for fracture displacement. Forearm shaft fractures heal more slowly than metaphyseal and physeal fractures of the distal radius and ulna.[13,79] The cast is removed in 6 to 8 weeks if adequate healing is present on radiographs. Because of the significant refracture rate after forearm shaft fractures, we splint these fractures for several weeks or even a few months until all transverse lucency of the original fracture disappears and all four cortices are healed. It is extremely helpful to warn patients and their parents about the high rate of refracture with forearm shaft fracture throughout their treatment. Fractures that heal in bayonet apposition (complete translation and some shortening) can take longer to heal than those with end-to-end apposition and may require prolonged splinting to prevent refracture.[85,274]

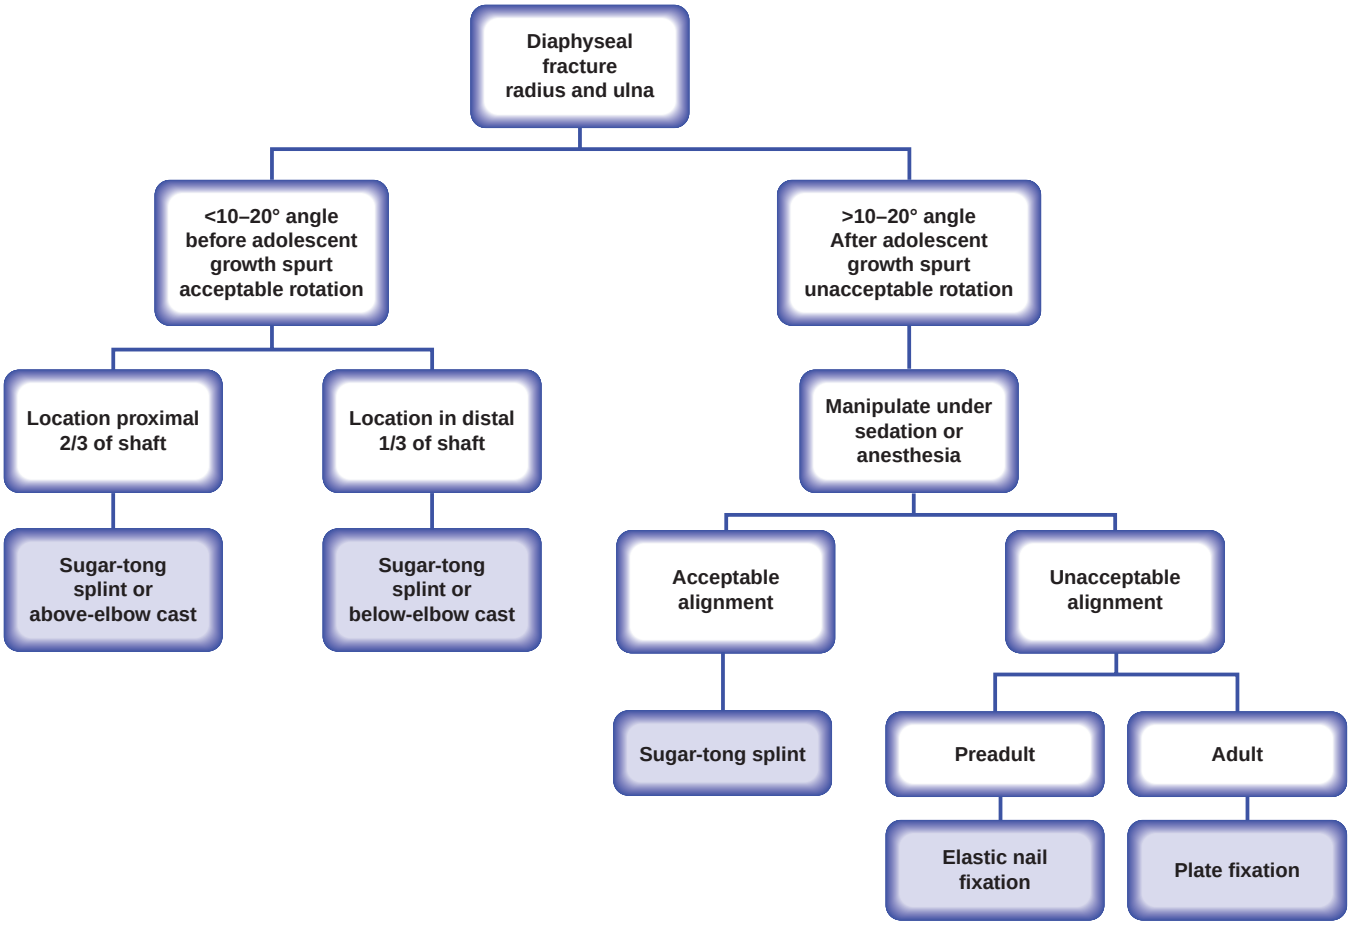

FIGURE 12-39 Author recommended treatment.

Summary, Controversies, and Future Directions Related to Diaphyseal Radius and Ulna Fractures

Fracture Risk/Fracture Prevention

Over the past three decades, the rate of forearm fractures has increased dramatically in the United States: 33% higher for males and 56% higher for females.[177] Certain risk-taking behaviors demonstrated by children, as well as increased use of roller blades, skateboards, scooters, trampolines, Heelys skate shoes, bicycle ramping, snowboarding, and motorized vehicles like all-terrain vehicles, may be at least partly to blame.[44,200] Increased general physical activity patterns and decreased calcium intake also have been suggested as explanations,[177] but gaps persist in our epidemiologic understanding. Preventing these injuries remains an admirable but elusive goal. Two main avenues of research have been explored: Optimizing safety during activities known to be associated with forearm fractures and investigating biologic mechanisms related to fracture risk.

The relationship between in-line skating (rollerblading) and pediatric forearm fractures has been shown,[21,251] with 1 in 8 children sustaining a fracture on his or her first skating attempt.[221] Prevention efforts have focused largely on protective gear. Wrist guards have been shown to decrease distal forearm bone strain[311] and injury rates.[283] Similar protective effects of wrist guards in snowboarders have been shown.[234] Trampolines are another target of injury prevention efforts aimed at a specific play activity.[91] Dramatic increases in trampoline-related injuries were reported during the 1990s, with rates doubling[305] or even tripling.[109] Safety recommendations have ranged from constant adult supervision and one-child-at-a-time use[187] to outright bans on public trampoline use.[109,305]

A variety of biologic risk factors have been studied relative to forearm fractures. Children who avoid drinking milk have been shown to have increased fracture risk,[126] as well as those who prefer to drink fruit juice and soda.[247] Several studies have shown an increased risk of fractures in females aged 3 to 15 years with low bone density.[123,125] Diet, nutrition, and exercise are being explored as causative factors, but the precise reason for the low bone density has not been confirmed. Too little physical activity (as measured by television, computer, and video viewing) has been associated with increased fracture risk, presumably because of decreased bone mineral density.[199] Caution also must be exercised when obtaining dual-energy x-ray absorptiometry data in children, as up to 88% of scans

may be misinterpreted.[111] Childhood obesity is a growing problem in our society.[115,154] Increased body weight and decreased cross-sectional dimensions of the forearm bones also have been found in females who fracture their forearms.[303] Other researchers have found an increased risk of forearm fracture in obese children.[124,161]

Parental Presence During Fracture Reduction in Diaphyseal Radius and Ulna Fractures

Parental presence is becoming increasingly popular for pediatric emergency department procedures. Several studies on chest tubes, IV cannulation, lumbar puncture, and urethral catheterization have shown increased parental satisfaction when parents are allowed to stay for these procedures.[20,137,252] Parental presence during induction of anesthesia also has been shown to have favorable effects on children older than 4 years of age.[165] To the best of our knowledge, there are no published studies on parental presence during orthopedic procedures performed in the emergency department setting. There are also no parental presence studies on any emergency department procedures performed on children who are under sedation, when the child is probably not aware of the parent's presence.

Certain relationships between perceived procedural invasiveness and parental presence have been borne out in the literature. Four hundred parents from the Indiana area were surveyed, and with increasing invasiveness, the parents' desire to be present decreased.[34] A survey of academic emergency medicine attendings, residents, and nurses from across the country also showed that there is an inverse relationship between increasing invasiveness and support for parental presence.[22] Boudreaux et al. published their critical review of the parental presence literature and concluded that "randomized controlled trials are mixed regarding whether family presence actually helps the patient."[38]

Extrapolation of information from the previously mentioned studies to pediatric orthopedic settings should be done with caution. We typically allow parents to be present for the induction of sedation, and once the patient is sedated the parents are asked to wait in a designated area. If parents are allowed to be present, we strongly recommend a dedicated employee to attend to the parent or parents (a "spotter"). Several parents (typically fathers) have fainted during such orthopedic procedures and injured themselves. Parents who stay for a reduction also should be counseled that the patient may moan or cry during reduction but will not remember it. Parents who are not present during reduction should be asked to wait far enough away from the procedure room so they cannot hear the child.

13 RADIAL NECK AND OLECRANON FRACTURES

Mark Erickson and Sumeet Garg

Introduction to Fractures of the Proximal Radius and Ulna

Fractures of the proximal radius in skeletally immature patients usually involve the metaphysis or physis. True isolated radial head fractures are rare. In the proximal ulna, the olecranon, which biomechanically is a metaphysis, often fails with a greenstick pattern. Fractures in this area also may involve the physis. Fractures of the olecranon associated with proximal radioulnar joint disruption are considered part of the Monteggia fracture pattern and are discussed in Chapter 14.

Fractures of the radial neck account for slightly more than 1% of all children's fractures.[49] Radial neck fractures make up approximately 5% of elbow fractures in children.[8,28,40,43,52,69] Radial head fractures are uncommon, and when they occur usually are Salter–Harris type IV injuries. The median age at injury is 9 to 10 years in the pediatric population.[22,40,50,68,86,102,108,113] There is little difference in the occurrence rates between males and females[22,40,68]; however, this injury seems to occur on an average approximately 2 years earlier in girls than in boys.[102]

Fractures of the proximal ulna in skeletally immature children present in three different patterns: Fractures involving the proximal apophysis, metaphyseal fractures of the olecranon, and fractures of the coronoid process.

"Separation of the olecranon epiphysis is the rarest form of epiphyseal detachment."[77] This quote from Poland's 1898 textbook on epiphyseal fractures is still true. Few fractures of the ulnar apophysis are described in the English literature, most recently by Carney[13,35,77,92,98] In addition to acute injuries in children, some have been described in young adults with open physes.[48,75,96,109] In the French literature, Bracq[9] described 10 patients in whom the fracture extended distal and parallel to the apophyseal line and then crossed it at the articular surface. Most reports of apophyseal olecranon fractures describe patients with osteogenesis imperfecta, who seem predisposed to this injury.

Isolated metaphyseal fractures of the olecranon are relatively rare (Table 13-1). They are often associated with other fractures about the elbow. In the combined series of 4,684 elbow fractures reviewed, 230 were olecranon fractures, for an incidence of 4.9%. This agrees with the incidence of 4% to 6% in the major series reported.[27,57,71] Only 10% to 20% of the total fractures reported in these series required an operation. Six reports totaling 302 patients with fractures of the olecranon in children are in the English literature.[31,35,57,68] Considering all age groups, 25% of olecranon fractures in these reports occurred in the first decade and another 25% in the second decade.[50] During the first decade, the peak age for olecranon fracture was between age 5 and 10 years.[36,69] Approximately 20% of patients had an associated fracture or dislocation of the elbow, most involving the proximal radius. Only 10% to 20% required an operation.

TABLE 13-1 Incidence of Metaphyseal Fractures of the Olecranon

Age distribution: First decade, 25%; second decade, 25%; third decade, 50%
Peak age: 5–10 y
Extremity predominance: Left (55%)
Sex predominance: Male (65%)
Associated elbow injuries: 20%
Requiring surgical intervention: 19%

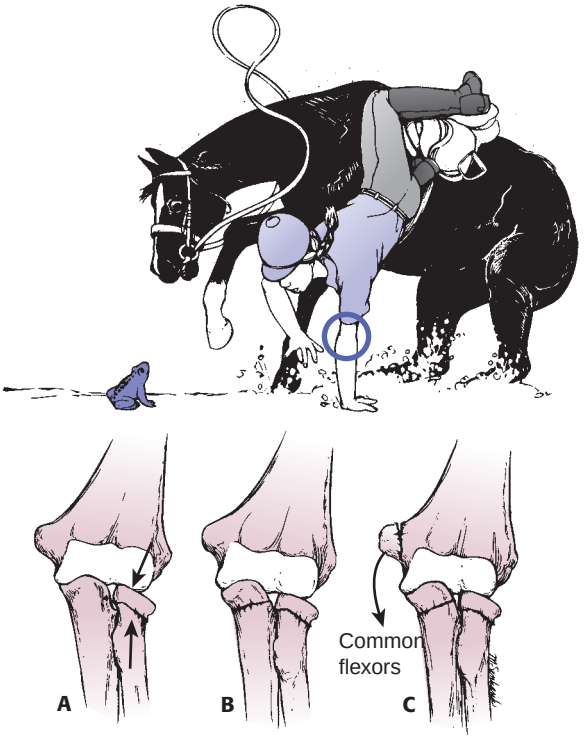

FIGURE 13-1 The most common mechanism of radial neck fractures involves a fall on the outstretched arm. This produces an angular deformity of the neck **(A).** Further valgus forces can produce a greenstick fracture of the olecranon **(B)** or an avulsion of the medial epicondylar apophysis **(C).** (Redrawn with permission from Jeffery CC. Fractures of the head of the radius in children. *J Bone Joint Surg Br.* 1950;32:314–324.)

The incidence of fracture of the coronoid varies from less than 1% to 2% of elbow fractures.[57] Because most fractures of the coronoid process occur with dislocations of the elbow, it seems logic that they would happen in older children. However, in a review of 23 coronoid fractures in children, Bracq[9] found that the injuries occurred in two peak age groups: One was between 8 and 9 years of age and the other between 12 and 14 years.

Assessment of Fractures of the Proximal Radius

Mechanisms of Injury for Fractures of the Proximal Radius

Most fractures of the proximal radius occur at the neck. Fractures of the proximal radius most commonly occur after a fall on an outstretched arm with elbow extended and valgus stress at the elbow.[33,40,43,68,69,117] The immature radial head is primarily cartilaginous and intra-articular radial head fractures in children and adolescents are rare. The cartilaginous head absorbs the force and transmits it to the weaker physis or metaphysis of the neck.[117] These fractures characteristically produce an

angular deformity of the head with the neck (Fig. 13-1A). The direction of angulation depends on whether the forearm is in a supinated, neutral, or pronated position at the time of the fall. Vostal showed that in neutral, the pressure is concentrated on the lateral portion of the head and neck. In supination, the pressure is concentrated anteriorly, and in pronation it is concentrated posteriorly.[117]

Proximal radial fractures also may occur in association with elbow dislocation. The fracture will occur either during the dislocation event, typically displaced anterior. Alternatively, the fracture may occur during spontaneous reduction of the distal humerus, driving the displacement of the proximal radius posterior (Fig. 13-2).

Associated Injuries with Fractures of the Proximal Radius

Proximal radius fractures can occur concomitantly with distal humerus, ulna, radial shaft, or distal radius fractures.[33,43,44,69,102] Fractures in combination with ulnar fractures often are part of the Monteggia fracture pattern detailed in Chapter 14. Presence

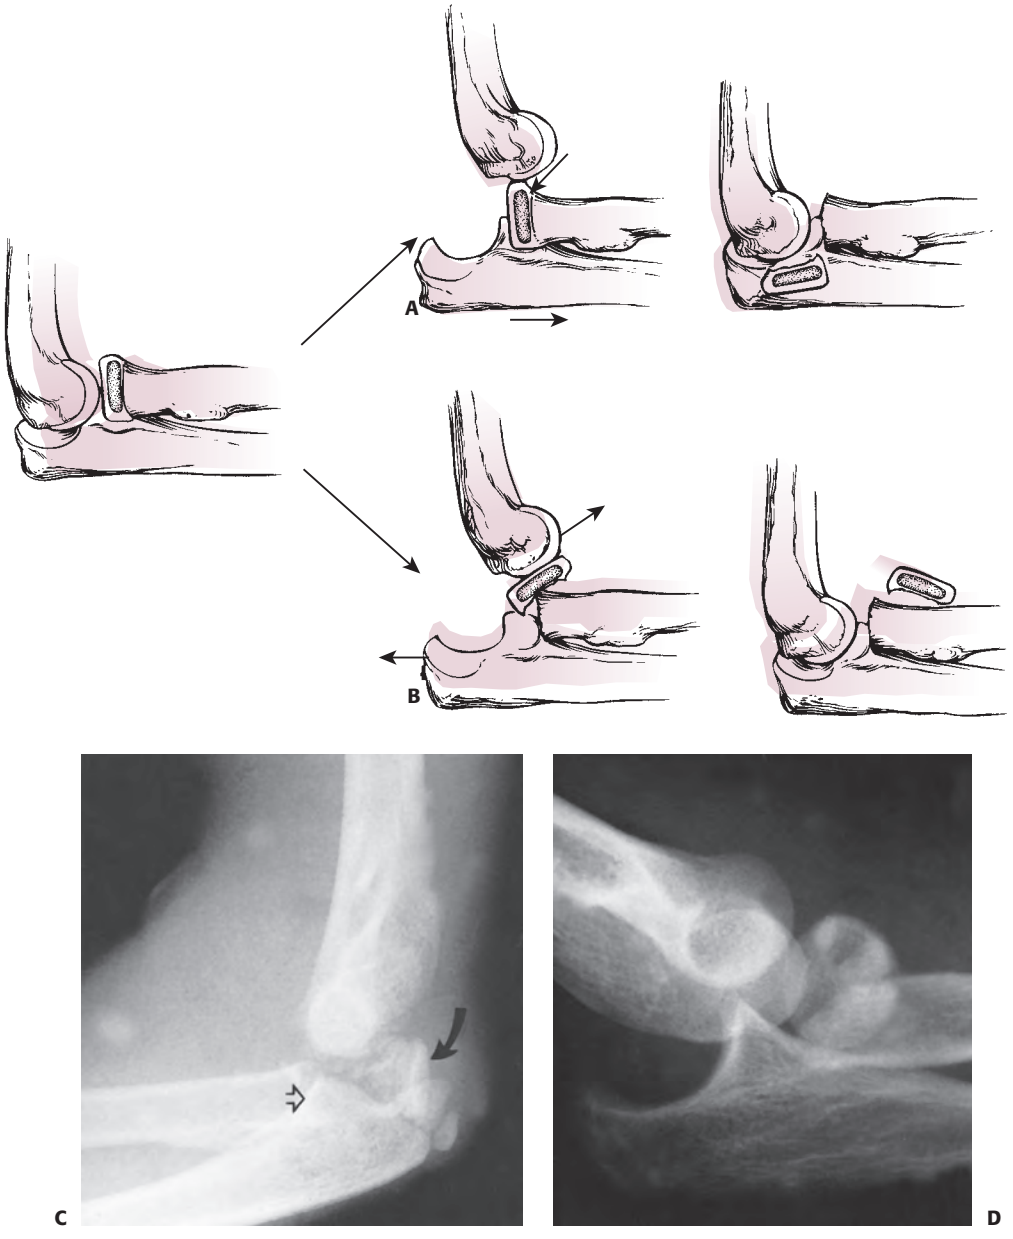

FIGURE 13-2 Dislocation fracture patterns. **A:** Type D: The radial neck is fractured during the process of reduction by the capitellum pressing against the distal lip of the radial head.[124] **B:** Type E: The radial neck is fractured during the process of dislocation by the capitellum pressing against the proximal lip of the radial head.[94] **C:** Radiographs of a radial head that was fractured during the reduction of the dislocation (type D). The radial head (*solid arrow*) lies posterior to the distal humerus, and the distal portion of the neck (*open arrow*) is anterior. (Courtesy of Richard E. King, MD.) **D:** Radiograph of the dislocated elbow in which the fracture of the radial neck occurred during the process of dislocation (type E).

of associated fractures portends a poor prognosis for patients with proximal radius fractures with higher rates of persistent stiffness and pain compared to those with isolated proximal radius fractures.[104] As detailed further in Chapter 18, proximal radius fractures can also occur during traumatic elbow dislocations. The posterior interosseous nerve (PIN) wraps around the proximal radius and occasionally can be injured in association with proximal radius fractures. More typically, however, the nerve is at risk during percutaneous manipulation or open reduction of proximal radius fractures.

Signs and Symptoms of Fractures of the Proximal Radius

Following a fracture, palpation over the radial head or neck is painful. The pain is usually increased with forearm supination and pronation more so than with elbow flexion and extension. Displaced fractures frequently result in visible bruising or ecchymosis on the lateral aspect of the elbow with significant soft tissue swelling. Neurologic examination should in particular evaluate the PIN, which can be affected by fractures of the proximal radius.

In a young child, the primary complaint may be wrist pain, and pressure over the proximal radius may accentuate this referred wrist pain.[2] The wrist pain may be secondary to radial shortening and subsequent distal radioulnar joint dysfunction. The misdirection of such a presentation reinforces the principle of obtaining radiographs of both ends of a fractured long bone and complete examination of the entire affected extremity.

Imaging and Other Diagnostic Studies for Fractures of the Proximal Radius

Displaced proximal radius fractures are usually easy to identify on standard anteroposterior (AP) and lateral radiographs. Some variants in the ossification process can resemble a fracture. Most of these involve the radial head, although a step-off also can develop as a normal variant of the metaphysis. There may be a persistence of the secondary ossification centers of the epiphysis. Comparison views of the contralateral elbow are useful for evaluation of unusual ossification centers after an acute elbow injury.

If the elbow cannot be extended because of pain, special views are necessary to see the AP alignment of the proximal forearm and distal humerus. A regular AP view with the elbow flexed may not show the fracture because of obliquity of the beam. One view is taken with the beam perpendicular to the distal humerus, and the other with the beam perpendicular to the proximal radius. The perpendicular views show the proximal radial physis in clear profile.

With a minimally displaced fracture, the fracture line may be difficult to see because it is superimposed on the proximal ulna, and oblique views of the proximal radius may be helpful.[10,117] One oblique view that is especially helpful is the radiocapitellar view suggested by Greenspan et al.[37,38] and Hall-Craggs et al.[39] This view projects the radial head anterior to the coronoid process (Fig. 13-3) and is especially helpful if full supination and pronation views are difficult to obtain because of acute injury (Fig. 13-4).

There is evidence of some disruption of the normal growth of the anterior portion of the physis (*black arrow*). The capitellum also shows radiographic signs of osteochondritis dissecans (*white arrow*). (Courtesy of Kenneth P. Butters, MD.)

The diagnosis of a partially or completely displaced fracture of the radial neck may be difficult in children whose radial head remains unossified.[88] The only clue may be a little irregularity in the smoothness of the proximal metaphyseal margin (Fig. 13-5). The full extent of the injury was appreciated only by magnetic resonance imaging (MRI). Displacement of the supinator fat pad may also indicate fracture of the proximal radius[90]; however, this fat pad and the distal humeral anterior and posterior fat pads are not always displaced with occult fractures of the radial neck or physis.[41,93,95] Arthrogram, ultrasound, or MRI are helpful to assess the extent of the displacement and the accuracy of reduction in children with an unossified radial epiphysis (Fig. 13-6).[17,42,51]

In the preossification stage, on the AP radiograph, the edge of the metaphysis of the proximal radius slopes distally on its lateral border. This angulation is normal and not a fracture. In the AP view, the lateral angulation varies from 0 to 15 degrees, with the average being 12.5 degrees.[113] In the lateral view, the angulation can vary from 10 degrees anterior to 5 degrees posterior, with the average being 3.5 degrees anterior.[10]

Recently described posterior radiocapitellar subluxation following what appeared to be fairly innocuous radial head fractures have been attributed to undiagnosed ligamentous injury associated with the fracture. Kasser includes this in lesions he describes as "The radiographic appearance seemed harmless (TRASH)."[119] MRI provides excellent anatomic detail of the elbow joint and should be considered when evaluating displaced radial head fractures, particularly if change in position is noted on serial radiographs.

Classification of Fractures of the Proximal Radius

Chambers Classification of Proximal Radial Fractures

In a prior edition of this textbook, Chambers[15] classified proximal radial fractures into three major groups based on the mechanism of injury and displacement of the radial head (Table 13-2):

- Group I: The radial head is primarily displaced (most common type)
- Group II: The radial neck is primarily displaced
- Group III: Stress injuries

Head-Displaced Fractures (Group I). With valgus elbow injuries, the fracture pattern can be one of three types (A, B, or C) (Fig. 13-7). In the first two types, the fracture line

TABLE 13-2 Classification of Fractures Involving the Proximal Radius

Group I: Primary Displacement of the Radial Head

A. Valgus fractures
   1. Type A—Salter–Harris type I and II injuries of the proximal radial physis
   2. Type B—Salter–Harris type IV injuries of the proximal radial physis
   3. Type C—Fractures involving only the proximal radial metaphysis

B. Fractures associated with elbow dislocation
   1. Type D—Reduction injuries
   2. Type E—Dislocation injuries

Group II: Primary Displacement of the Radial Neck

A. Angular injuries (Monteggia type III variant)
B. Torsional injuries

Group III: Stress Injuries

A. Osteochondritis dissecans or osteochondrosis of the radial head
B. Physeal injuries with neck angulation

involves the physis. Type A represents either a Salter–Harris type I or II physeal injury. In a Salter–Harris type II injury, the metaphyseal fragment is triangular and lies on the compression side. In type B fractures, the fracture line courses vertically through the metaphysis, physis, and epiphysis to produce a Salter–Harris type IV fracture pattern (Fig. 13-7). This is the only fracture type that involves the articular surface of the radial head. In type C fractures, the fracture line lies completely within the metaphysis (Fig. 13-8), and the fracture can be transverse or oblique. Type B fractures, intra-articular radial head fractures, are rare. These can have poor long-term results if posterior radiocapitellar subluxation develops (Fig. 13-9).[114,119] The incidences of types A and C fractures are approximately equal.[102]

In two rare types of fractures of the radial neck associated with elbow dislocation, the head fragment is totally displaced from the neck.[5,12,29,43,68,118] Fractures occurring during spontaneous reduction of elbow dislocation generally drive the radial head dorsal as the capitellum applies a dorsally directed force to the radial neck during reduction (type D) (Fig. 13-2A).[43,118] Fractures occurring during the dislocation event generally drive the radial head volar as the capitellum applies a volarly direct force during the process of dislocating (type E) (Fig. 13-2B).[5,68,113] Even with spontaneous or manipulative elbow reduction the radial head fragment will usually remain volar to the radial shaft with the fractured radial neck articulating with the capitellum.

Regardless of the type of fracture pattern, displacement can vary from minimal angulation to complete separation of the radial head from the neck (Fig. 13-10). With minimal angulation, the congruity of the proximal radioulnar joint is usually retained. If the radial head is displaced in relation to the radial neck, the congruity of the proximal radioulnar joint is lost.

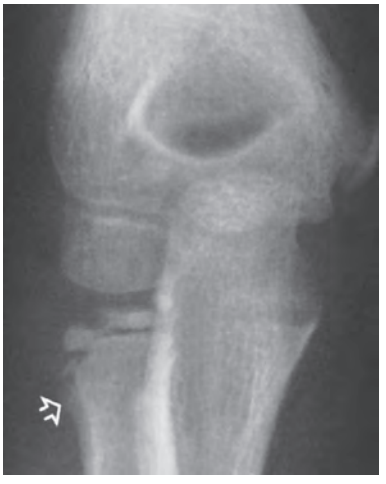

FIGURE 13-7 Valgus (type B) injury. **A:** Three weeks after the initial injury, there was evidence of distal migration of this Salter–Harris type IV fracture fragment. Periosteal new bone formation has already developed along the distal metaphyseal fragment (*arrow*). **B:** Six months after the initial injury, there is evidence of an osseous bridge formation between the metaphysis and the epiphysis. Subsequently, the patient had secondary degenerative arthritis with loss of elbow motion and forearm rotation.

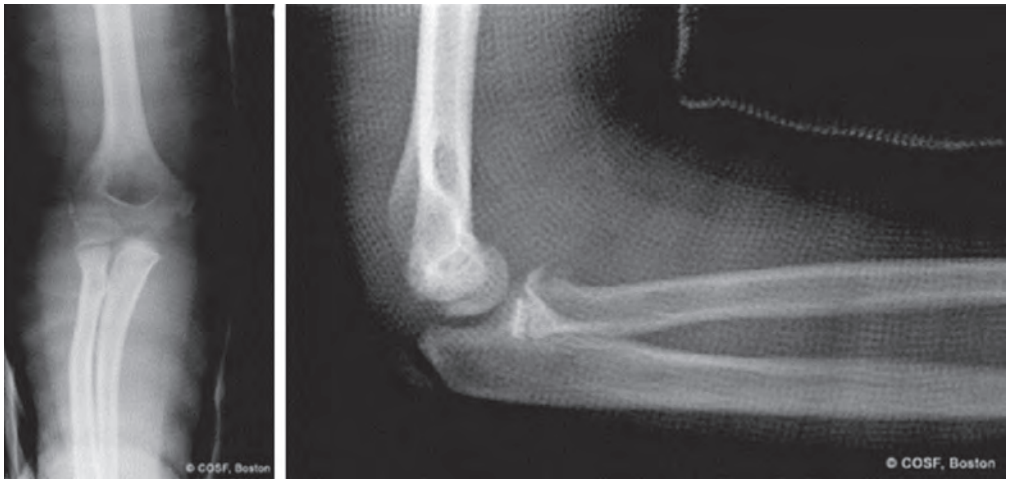
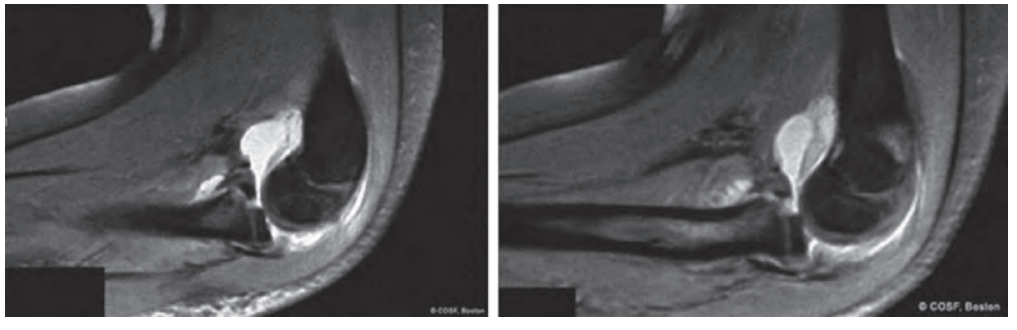
FIGURE 13-8 Valgus type C injury. The fracture line is totally metaphyseal and oblique (*arrows*).





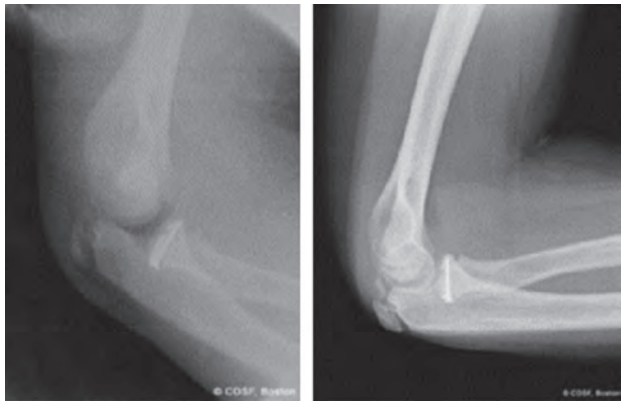


FIGURE 13-9 **A:** Acute injury films revealing small displacement of radial head fracture on the flexed elbow anteroposterior (AP) view and subtle posterior subluxation not originally appreciated on the lateral view. **B:** Follow-up radiographs at 1 week noted more difficulty interpreting the AP view in cast, and more radiocapitellar posterior displacement on the lateral view. An MRI scan **(C)** was ordered urgently and revealed a marked effusion and intra-articular displacement of radial head fracture and posterior radiocapitellar subluxation. **D:** Open reduction internal fixation was performed to anatomically align the radial head fracture and reduce the joint. (From Waters PM, Beaty J, Kasser J. Elbow "TRASH" (The Radiographic Appearance Seemed Harmless) Lesions. *J Pediatr Orthop.* 2010;30:S77–S81, with permission.)

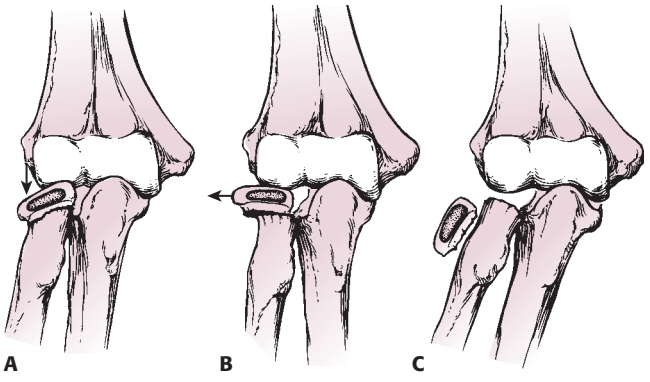

FIGURE 13-10 Displacement patterns. The radial head can be angulated **(A),** translated **(B),** or completely displaced **(C)**.

Completely displaced fractures are often associated with more severe injuries.

Neck-Displaced Fractures (Group II). Rarely, angular or torsional forces cause a primary disruption or deformity of the neck while the head remains congruous within the proximal radioulnar joint. Treatment of these fractures is manipulation of the distal neck fragment to align it with the head. For the neck-displaced fractures, there are two subgroups: Angular and torsional.

An angular fracture of the radial neck may be associated with a proximal ulnar fracture. This association is recognized as a Monteggia variant. A Monteggia type III fracture pattern is created when a varus force is applied across the extended elbow, resulting in a greenstick fracture of the olecranon or proximal ulna and a lateral dislocation of the radial head.[124] Occasionally, however, the failure occurs at the radial neck (Monteggia III equivalent) and the radial neck displaces laterally, leaving the radial head and proximal neck fragment in anatomic position under the annular ligament (Fig. 13-11).[70]

Rotational forces may fracture the radial neck in young children before ossification of the proximal radial epiphysis. This has been described only in case reports with a supination force.[33,40] Reduction was achieved by pronation of the forearm. Diagnosis of these injuries is difficult and may require arthrography or an examination under general anesthesia. This injury should be differentiated from the more common subluxation of the radial head ("nursemaids elbow"), in which the forearm usually is held in pronation with resistance to supination.

Stress Injuries (Group III). A final mechanism of injury is chronic repetitive stress, both longitudinal and rotational, on either the head or the proximal radial physis. These injuries are usually the result of athletic activity in which the upper extremity is required to perform repetitive motions. Repetitive stresses disrupt growth of either the neck or the head with eventual deformity. A true stress fracture is not present.

In the United States, the popularity of organized sports has produced a number of unique injuries in children related to repetitive stress applied to growth centers. Most elbow stress injuries are related to throwing sports such as baseball. Most of this "Little League" pathology involves tension injuries on the medial epicondyle. In some athletes, however, the lateral side is involved as well because of the repetitive compressive forces applied to the capitellum and radial head and neck. Athletes involved in sports requiring upper extremity weight bearing, such as gymnastics or wrestling, are also at risk. In the radial head, lytic lesions similar to osteochondritis dissecans may occur (Figs. 13-12 and 13-13).[24,110,123] Chronic compressive loading may cause an osteochondrosis of the proximal radial

FIGURE 13-11 Angular forces. This 8-year-old sustained a type III Monteggia equivalent in which the radial neck fractured (*arrow*), leaving the radial head reduced proximally. (Courtesy of Ruben D. Pechero, MD.)

FIGURE 13-12 Osteochondritis dissecans. Radiograph of this 11-year-old Little League pitcher's elbow shows fragmentation of the subchondral surfaces of the radial head. These changes and the accelerated bone age are evidence of overuse.

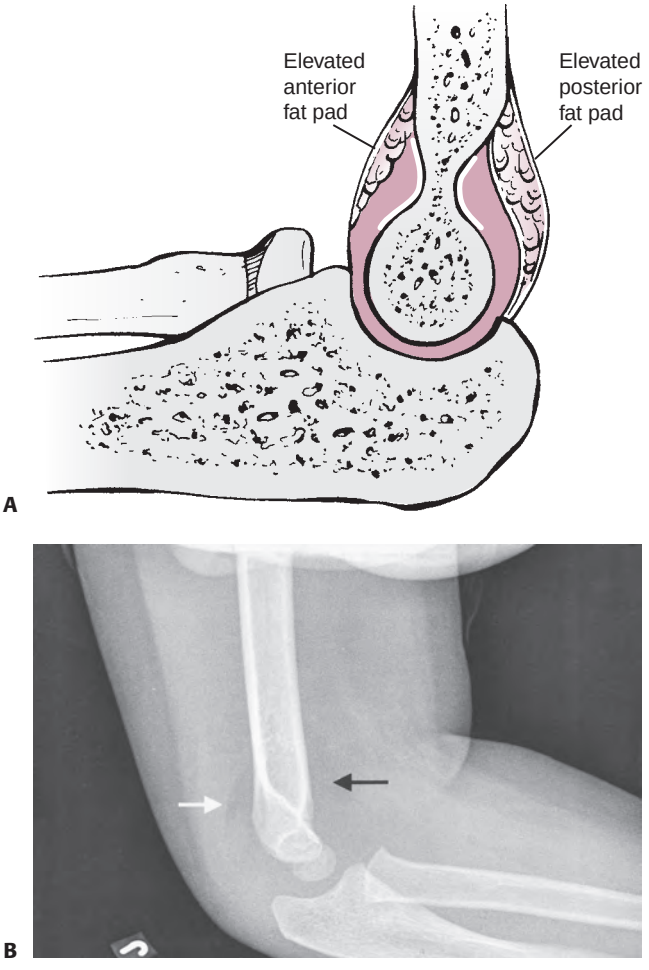

FIGURE 13-13 Elevated anterior and posterior fat pads. **A:** Illustration (adapted with permission from Skaggs DL, Mirzayan R. epiphysis, with radiographic signs of decreased size of the ossified epiphysis, increased radiographic opacity, and later fragmentation. If the stress forces are transmitted to the radial neck, the anterior portion of the physis may be injured, producing an angular deformity of the radial neck (Fig. 13-3).[25]

Judet Classification of Radial Neck Fractures

Radial neck fractures, the most common type of proximal radius fracture, (Group IA and IC) have also been classified based on angulation by Judet (Table 13-3).[59] Increasing grade has generally been associated with poorer outcomes with both nonoperative and operative care as discussed in the section on treatment outcomes.

Outcome Measures for Fractures of the Proximal Radius

Most previously published literature on the outcomes of pediatric proximal radius fractures have used nonvalidated functional outcome measures. Various iterations of "excellent," "good," "fair," and "poor" with individualized descriptions have been utilized. The growing emphasis in orthopedics on critical functional assessments following injury or surgery should improve the quality of future evidence on this topic. It is hoped that validated functional measures for upper extremity function and global pediatric and adolescent function be utilized in future research efforts in this area.

Range of motion following treatment of proximal radius fractures is a critical component of outcome. Usually assessments have been done manually using a goniometer. The wider availability of digital motion capture technology will hopefully provide more accurate measures of range of motion following extremity trauma in future studies.

TABLE 13-3 Judet Classification of Radial Neck Fractures

Type I	Nondisplaced
Type II	<30-degree angulation
Type III	30–60-degree angulation
Type IVa	60–80-degree angulation
Type IVb	>80-degree angulation

Pathoanatomy and Applied Anatomy Relating to Fractures of the Proximal Radius

In the embryo, the proximal radius is well defined by 9 weeks of gestation. By 4 years of age, the radial head and neck have the same contours as in an adult.[69] Ossification of the proximal radius epiphysis begins at approximately 5 years of age as a small, flat nucleus (Fig. 13-14). This ossific nucleus can originate as a small sphere or it can be bipartite, which is a normal variation and should not be misinterpreted as a fracture.[10,58,95]

No ligaments attach directly to the radial neck or head. The radial collateral ligaments attach to the annular ligament, which originates from the radial side of the ulna. The articular capsule attaches to the proximal third of the neck. Distally, the capsule protrudes from under the annular ligament to form a pouch (recessus sacciformis). Thus, only a small portion of the neck lies within the articular capsule.[117] Because much of the neck is extracapsular, fractures involving only the neck may not produce an intra-articular effusion, and the fat pad sign may be negative with fracture of the radial neck.[10,41,95]

The proximal radioulnar joint has a precise congruence. The axis of rotation of the proximal radius is a line through the center of the radial head and neck. When a displaced fracture disrupts the alignment of the radial head on the center of the radial neck, the arc of rotation changes. Instead of rotating smoothly in a pure circle, the radial head rotates with a "cam" effect. This disruption of the congruity of the proximal

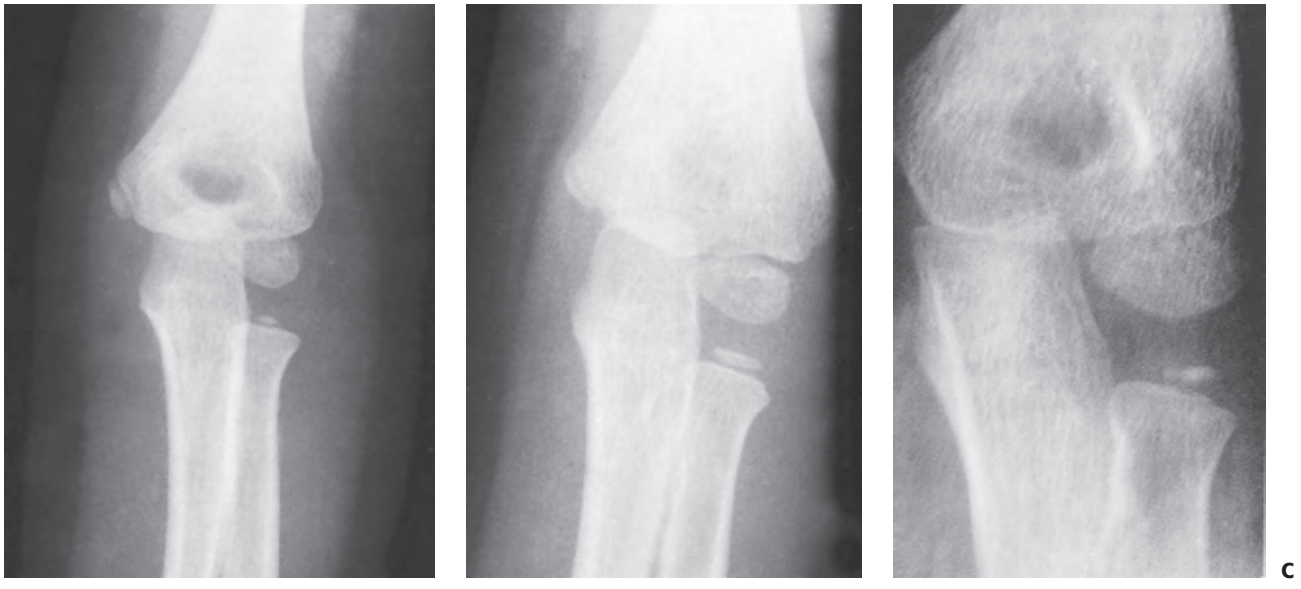

FIGURE 13-14 Ossification pattern. **A:** At 5 years, ossification begins as a small oval nucleus. **B:** As the head matures, the center widens but remains flat. **C:** Double ossification centers in developing proximal radial epiphysis. radioulnar joint (as occurs with displaced fractures of the proximal radius) may result in a loss of the range of motion in supination and pronation (Fig. 13-15).[121]

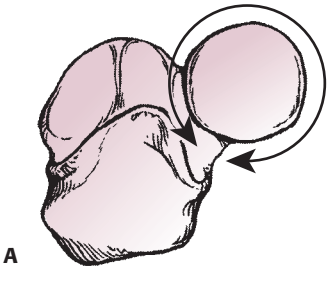
Table 13-4 lists the proposed mechanisms for fractures of the radial head and neck in children.



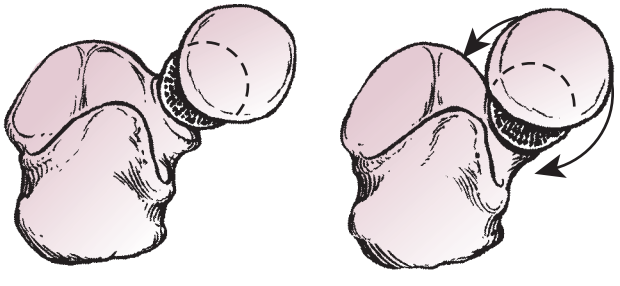


FIGURE 13-15 **A:** Normal rotation of the forearm causes the radial head to circumscribe an exact circle within the proximal radioulnar joint. **B:** Any translocation of the radial head limits rotation because of the "cam" effect described by Wedge and Robertson.[121]

Treatment Options for Fractures of the Proximal Radius

Nonoperative Treatment of Fractures of the Proximal Radius

Indications/Contraindications

Nonoperative treatment is indicated for the majority of proximal radius fractures. A great deal of remodeling of the proximal radius can be expected in skeletally immature children. Based on multiple retrospective case series, radial neck angulation of 30 to 45 degrees generally remodels and conservative treatment will lead to good results.[22,66,68,102,113] It is critical to assess forearm rotation, and if a block to full rotation is appreciated operative treatment should be considered. Intra-articular aspiration of hematoma and injection of local anesthetic can assist with pain relief and assessment of range of motion.

TABLE 13-4 Fractures of the Radial Head and Neck. Proposed Mechanisms in Children

I. Primary displacement of the head (incongruous)
  A. Valgus injuries
  B. Associated with dislocation of the elbow
    1. During reduction
    2. During dislocation
II. Primary displacement of the neck
  A. Angular forces
  B. Rotational forces
  C. Chronic stress forces

In the case of nondisplaced radial head fractures (Salter–Harris IV, Group 1B in the Chambers classification) close follow-up with serial radiographs is warranted to monitor radiocapitellar alignment. If subluxation is suspected, advanced imaging with ultrasound or MRI along with consideration of operative treatment should be considered.

Closed reduction techniques should be attempted if there is displacement or unacceptable angulation at the fracture site. The goal should be to restore the alignment to accepted indications below with full forearm rotation. Internal fixation is usually not necessary if successful closed reduction can be accomplished.

Patients not requiring closed reduction should be immobilized for comfort for a short period of time to allow for comfort and soft tissue healing. This is generally 1 to 3 weeks based on extent of injury and age. After fracture pain has subsided patients should work on progressively increasing range of motion and resumption of activities as symptoms allow. Immobilization can be accomplished with a sling, posterior arm splint, or long-arm cast based on surgeon and patient preference (Table 13-5).

Closed Reduction Techniques

Several closed reduction techniques for proximal radius fractures have been described in the literature. All have generally good reported results and the surgeon should be familiar with multiple techniques and apply them as needed because closed treatment of proximal radius fractures generally has been shown to have improved results compared to open treatment. No technique has been demonstrated to have superiority over another. Techniques are variations on either manipulating the proximal fragment to the fixed radial shaft or manipulating the radial shaft to the fixed proximal fragment.

Patterson[74] described a reduction technique for the radial neck in 1934. Conscious sedation or general anesthesia is recommended in children to allow for adequate relaxation for the procedure. The annular ligament should be intact to stabilize the proximal radial head fragment.[58] An assistant grasps the arm proximal to the elbow joint with one hand (Fig. 13-16) and places the other hand medially over the distal humerus to provide a medial fulcrum for the varus stress applied across the elbow. The surgeon applies distal traction with the forearm supinated to relax the supinators and biceps. A varus force is then placed on the elbow with added direct lateral pressure on the radial head in an attempt to reduce the fracture. Kaufman et al.[45] proposed another technique in which the elbow is manipulated in the flexed position. The surgeon presses his or her thumb against the anterior surface of the radial head with the forearm in pronation.

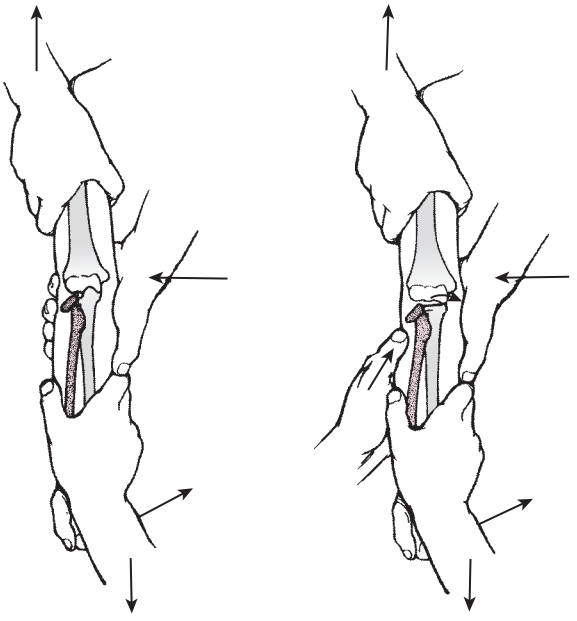

FIGURE 13-16 Patterson's manipulative technique. **Left:** An assistant grabs the arm proximally with one hand placed medially against the distal humerus. The surgeon applies distal traction with the forearm supinated and pulls the forearm into varus. **Right:** Digital pressure applied directly over the tilted radial head completes the reduction. (Redrawn with permission from Patterson RF. Treatment of displaced transverse fractures of the neck of the radius in children. *J Bone Joint Surg.* 1934;16:695–698.)

Although forearm supination relaxes the supinator muscle, supination may not be the best position for manipulation of the head fragment. Jeffrey[43] pointed out that the tilt of the radial head depends on the position of the forearm at the time of injury. The direction of maximal tilt can be confirmed by radiograph and is also when fracture deformity will be most palpable clinically. The best position for reduction is the degree of rotation that places the radial head most prominent laterally. If the x-ray beam is perpendicular to the head in maximal tilt, it casts an oblong or rectangular shadow; if not, the shadow is oval or almost circular.[43] With a varus force applied across the extended elbow, the maximal tilt directed laterally, and the elbow in varus, the radial head can be reduced with the pressure of a finger (Fig. 13-16, right). An alternative technique with the elbow in extension was described by Neher and Torch. An assistant uses both thumbs to place a laterally directed force on the proximal radial shaft while the surgeon applies a varus stress to the elbow. Simultaneously, the surgeon uses his other thumb to apply a reduction force directly to the radial head (Fig. 13-17).[65]

The Israeli technique involves stabilization of the proximal fragment with the thumb anteriorly while rotating the forearm into full pronation to reduce the shaft to the proximal fragment.[45] The elbow should be flexed to 90 degrees for the manipulation (Figs. 13-18 and 13-19). Another technique

TABLE 13-5 Proximal Radius Fractures: Nonoperative Treatment

Indications	Relative Contraindications
<2 mm displacement of the radial head or neck	Open fracture
<30–45-degree angulation of the radial neck (<30 degrees age greater than 10, <45 degrees age less than 10)	Incongruent elbow joint
Full forearm pronation and supination	

FIGURE 13-17 Neher and Torch reduction technique. (From Neher CG, Torch MA. New reduction technique for severely displaced pediatric radial neck fractures. *J Pediatr Orthop.* 2003;23:626–628, with permission.)

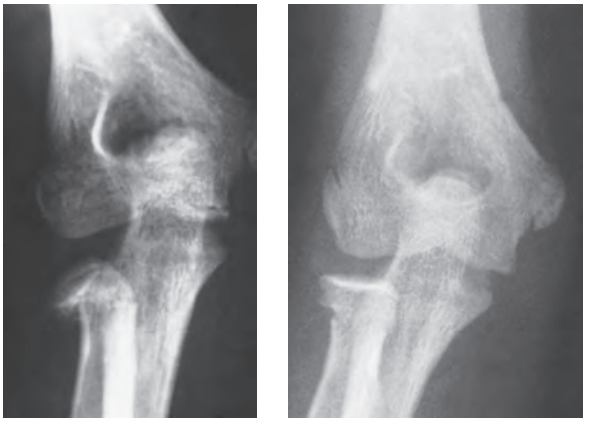

FIGURE 13-18 Flexion-pronation (Israeli) reduction technique.[47] **A:** Radiograph of the best reduction obtained by the Patterson[74] method. **B:** Position of the radial head after the flexion-pronation method. (Courtesy of Gerald R. Williams, MD.)

emphasizing reduction of the shaft to the proximal fragment was recently described by Monson. After adequate sedation or anesthesia the elbow is flexed to 90 degrees and forearm fully supinated. The proximal radial fragment should be stabilized in place by the annular ligament. A directly applied force to the radial shaft is applied to reduce the shaft to the head (Figs. 13-20 and 13-21). Initial experience with this technique in six children has been reported with excellent results and no need for additional procedures.[61]

Lastly, use of an Esmarch bandage wrap as is done for limb exsanguination prior to tourniquet use in extremity surgery has been described to serendipitously promote fracture reduction (Fig. 13-22).[15] This can be utilized as an easy adjunct in nearly all of the described closed reduction techniques.

Regardless of the technique chosen alignment should be assessed by fluoroscopy. Radial neck angulation should be reduced to less than 45 degrees in children under 10 years of age and less than 30 degrees in children greater than 10 years of age. The radiocapitellar joint should be congruent. The elbow joint must be stable to stress. Immobilization for a short duration is recommended for pain control and soft tissue healing.

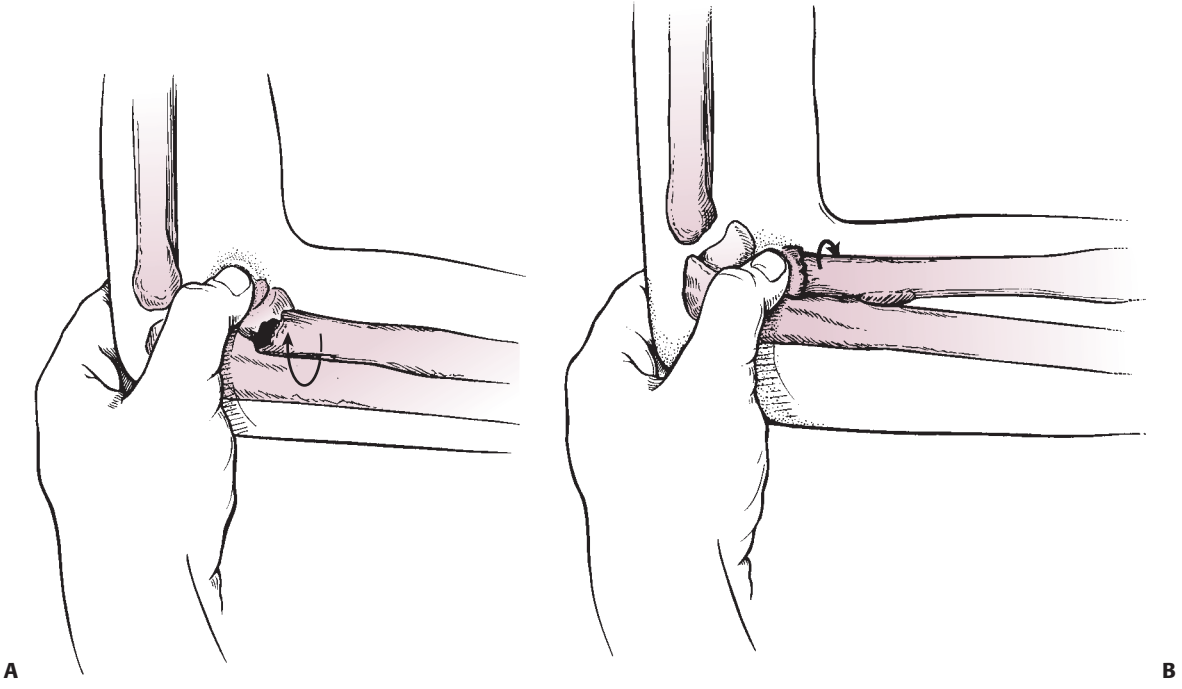

FIGURE 13-19 Flexion-pronation (Israeli) reduction technique.[45] **A:** With the elbow in 90 degrees of flexion, the thumb stabilizes the displaced radial head. Usually the distal radius is in a position of supination. The forearm is pronated to swing the shaft up into alignment with the neck (*arrow*). **B:** Movement is continued to full pronation for reduction (*arrow*).

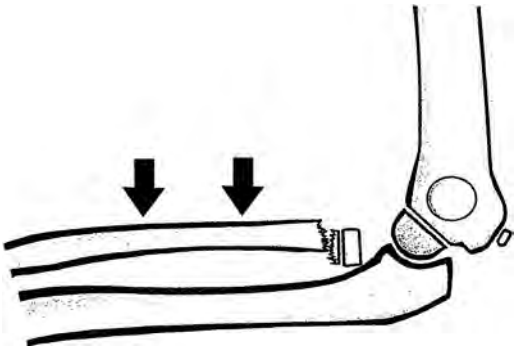

FIGURE 13-20 As the fracture is usually displaced laterally, placing the forearm in supination results in the apex being anterior. The radial head is relatively stable and locked by the annular ligament. Pressure on the proximal radial shaft with the arm in supination reduces the shaft to the radial head. (From Monson R, Black B, Reed M. A new closed reduction technique for the treatment of radial neck fractures in children. *J Pediatr Orthop.* 2009;29(3); 243–247.)

Early range of motion should be encouraged once the acute pain has resolved, generally within 1 to 3 weeks.

Operative Treatment of Fractures of the Proximal Radius

Indications/Contraindications

Surgical treatment is indicated in situations where acceptable alignment cannot be achieved with closed means, or if there is persistent elbow instability or restricted range of motion after closed treatment. Most fractures of the proximal radius present to the surgeon with minimal deformity and do not require treatment other than a short period of immobilization. Operative treatment should be considered when displacement remains over 2 mm, angulation is greater than 45 degrees (age < 10) or greater than 30 degrees (age < 10), and for open injuries. Nerve palsy is generally not an indication for surgery because most will recover function over time.

Instrument-Assisted Closed Reduction

Preoperative Planning (Table 13-6)

TABLE 13-6 Instrument-Assisted Closed Reduction of Proximal Radius Fractures

Preoperative Planning Checklist

- OR table: Standard with radiolucent hand table
- Position/positioning aids: Turn table 90 degrees, bring patient to edge of table toward hand table. Secure head with blanket/towel and tape. Safety strap over torso
- Fluoroscopy location: In line with affected extremity, perpendicular to OR table
- Equipment: Smooth Kirschner wires
- Tourniquet (sterile/nonsterile): Nonsterile tourniquet
- Esmarch bandage

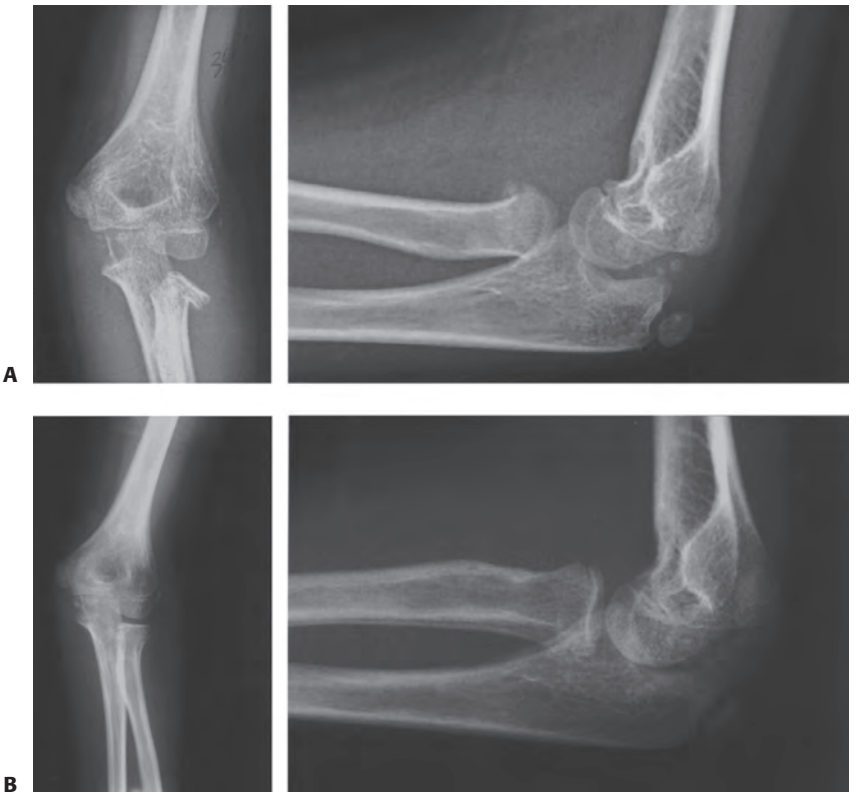

FIGURE 13-21 **A:** Preoperative anteroposterior and lateral radiographs of left elbow of a 9-year-old girl showing 34 degrees of angulation and 50% displacement. **B:** Anteroposterior and lateral radiographs of the fracture 5 months postreduction showing maintenance of reduction with good callus formation. (From Monson R, Black B, Reed M. A new closed reduction technique for the treatment of radial neck fractures in children. *J Pediatr Orthop.* 2009;29(3);243–247.)

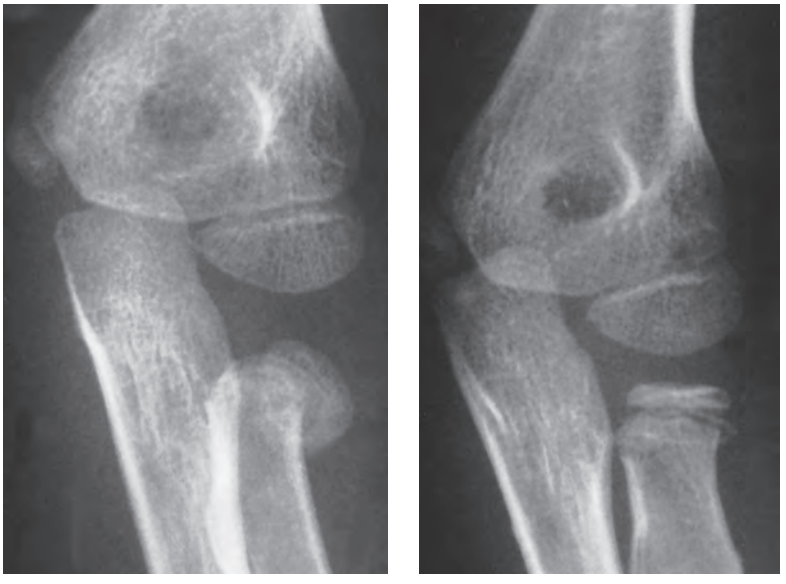

FIGURE 13-22 Elastic bandage wrap reduction. **A:** The final position achieved after manipulation by the Patterson[74] method. **B:** Position of the radial head after applying an elastic bandage to exsanguinate the extremity.

Positioning. The patient should be positioned supine on the operating table with a radiolucent hand table attached to the operating bed. The affected extremity should be placed directly in the middle of the hand table. The entire operating table should be rotated 90 degrees from standard position to place the injure extremity opposite the anesthesiologist. Fluoroscopy will be brought in directly in line with the injured extremity with surgeon and assistant on either side of the hand table (Fig. 13-23). The patient should be brought to the lateral edge of the bed and head secured to the operating room table. We suggest a towel or blanket draped over the head surrounded by strong tape from one edge of the table to the other (Fig. 13-24). This is especially important for small patients to allow for the fluoroscopy unit to be able to image the area of interest and not be blocked by the table. Torso should be secured to the table with a safety strap. A nonsterile tourniquet should be applied to the humerus. Surgeons may be standing or seated per their preference.

Surgical Approach. Percutaneous direct lateral approach is utilized as described in the technique below to minimize risk of injury to the PIN.

Technique. Simple steel K-wires generally are appropriate to assist with closed reduction. Size will range from 2 to 2.7 mm based on the size of the child. Other instruments utilized include Steinmann pins, periosteal elevators, or a double-pointed

FIGURE 13-23 Preferred positioning and operative room setup for operative treatment of proximal radius and ulna fractures.

FIGURE 13-24 Detailed view of showing recommended method of securing head safely to the operative table while allowing for appropriate elbow positioning on the hand table for intraoperative fluoroscopy.

bident.[3,30,87] Fluoroscopy is used to localize the fracture site and intended entry site of the wire. This should be along the direct lateral cortex of the radial shaft to decrease risk of injury to the PIN. Pronating the forearm further moves the PIN away from the surgical field. Skin is incised with a small stab wound and a small curved clamp is utilized to bluntly dissect through the muscle to the radial cortex. The sharp end of the wire is cut for surgeon safety and the blunt end is inserted down to the radial cortex. Fluoroscopic guidance is used to localize the fracture site and the blunt end of the wire can be used to push the distal fracture fragment back into an appropriate position (Fig. 13-25). Arthrography can be helpful to assess congruency of the elbow joint. (Dormans 1994)[19] Once the fracture is reduced to within appropriate guidelines the pin is removed and stability and range of motion are assessed. If the fracture remains stable through a normal arc of motion no internal fixation is needed.[7,68,121] If instability is noted then internal fixation can be placed. Small antegrade K-wires can be placed percutaneously to transfix the fracture.[20,28,44] (Fig. 13-26). Pins should stay lateral to minimize injury to the PIN. Pins traversing the capitellum into the proximal radius should be avoided because they have a high rate of migration and/or pin breakage.[28,68,93,121] Various iterations of this technique have been described in the literature.[3,6,20,76,101]

Alternatively, the sharp end of the wire can be retained and introduced to the fracture site and the wire used as a lever to correct angulation.[14] Once corrected, the pin can be driven from proximal to distal across the radial cortex and serve as a buttress against recurrent angulation of the distal fragment. In this instance, the wire is introduced through the skin closer to the fracture site than in the prior described technique to prevent soft tissue from blocking appropriate

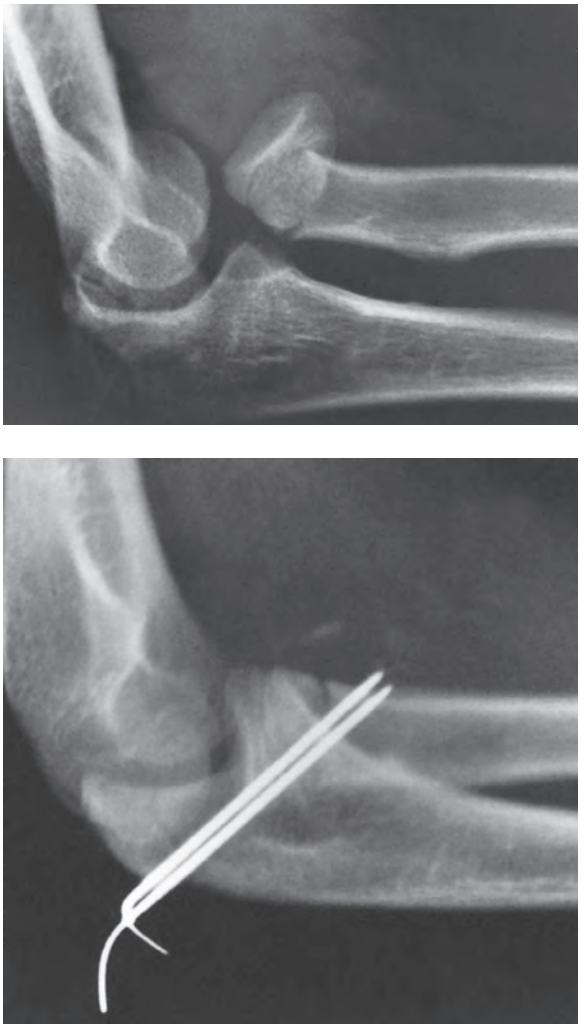
leverage of the distal fracture fragment. The pin is cut short but left out of the skin and underneath postoperative immobilization. It may be removed in 1 to 3 weeks when the surgeon is comfortable allowing range of motion at the elbow (Fig. 13-27).

A modification described by Wallace utilizes an instrument to provide counterforce on the radial shaft. Fluoroscopy in an AP projection is used to determine the forearm rotation that exposes the maximum amount of deformity of the fracture, and the level of the bicipital tuberosity of the proximal radius is marked. A 1-cm dorsal skin incision is made at that level just lateral to the subcutaneous border of the ulna. A periosteal elevator is gently inserted between the ulna and the radius, with care not to disrupt the periosteum of the radius or the ulna. The radial shaft is usually much more ulnarly displaced than expected, and the radial nerve is lateral to the radius at this level. While counterpressure is applied against the radial head, the distal fragment of the radius is levered away from the ulna. An assistant can aid in this maneuver by gently applying traction and rotating the forearm back and forth to disengage the fracture fragments. The proximal radial fragment can be reduced either manually with thumb pressure or assisted by a percutaneous instrument as described (Table 13-7, Figs. 13-28 and 13-29).

Intramedullary Nail Reduction/Fixation

Preoperative Planning. Implant size should be estimated prior to surgery. The technique was initially described using K-wires which are readily available and inexpensive. Some prefer using titanium flexible nails that also work well but are more costly. The isthmus of the radius should be measured on both



A

B

FIGURE 13-26 Oblique pin. **A:** Displaced fracture of the radial neck in a 10-year-old. **B:** A closed reduction was performed, and to stabilize the head fragment, two pins were placed percutaneously and obliquely across the fracture site from proximal to distal. If open reduction and pinning are done, the preferred alignment is obliquely across the fracture site from distal to proximal. TABLE 13-7 Instrument-Assisted Closed Reduction of Proximal Radius Fractures

Surgical Steps

- Attempt closed reduction
- Percutaneous insertion of blunt end K-wire lateral forearm
- Reduce fracture by pushing on proximal fragment
- Assess stability and range of motion
  - If stable: Immobilize in long-arm cast
  - If unstable: Antegrade K-wire fixation
- Alternatively—use leverage technique described in text

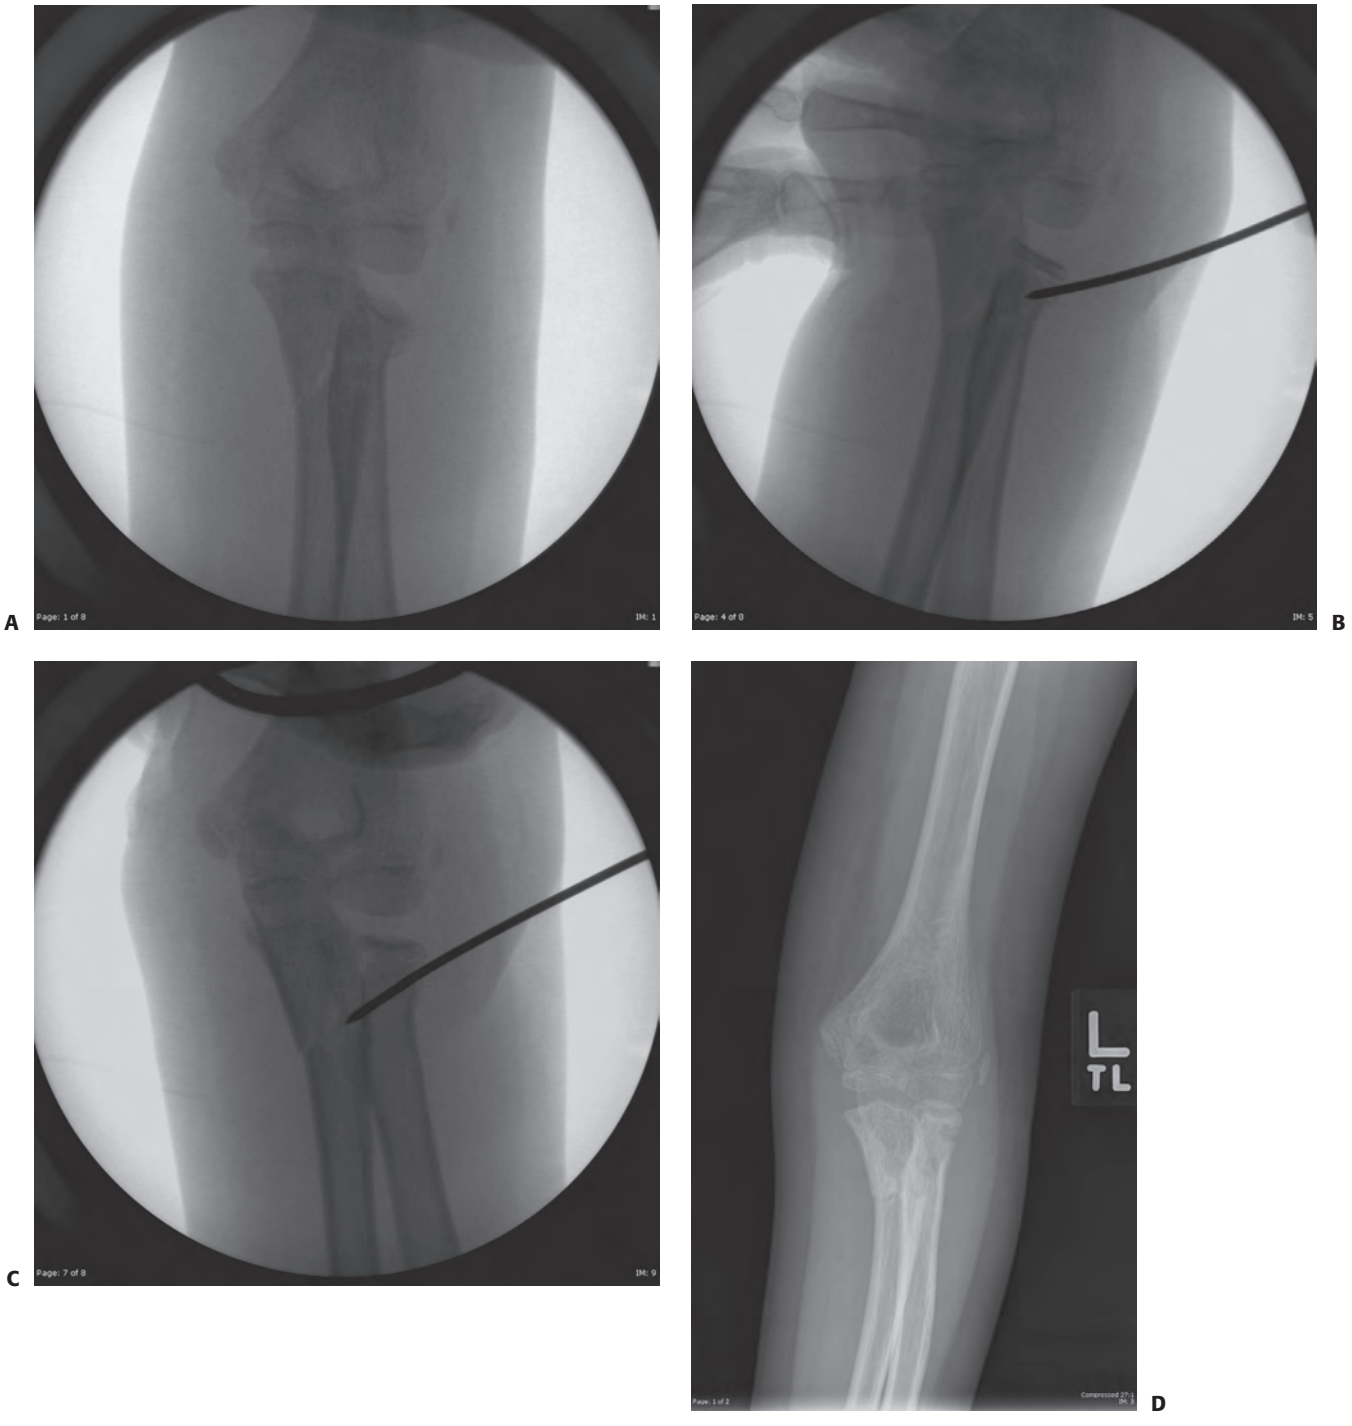

FIGURE 13-27 Leverage technique of instrument-assisted closed reduction of the proximal radius **(A).** Intraoperative AP fluoroscopy image demonstrating angulated radial neck fracture **(B).** K-wire inserted at fracture site and levering proximal fragment into a reduced position **(C).** AP view of elbow following pin removal in clinic showing anatomic alignment of proximal radius fracture **(D)**. Same wire driven through the opposite cortex to hold reduced position of the proximal fragment.

AP and lateral views and implant size should be chosen to easily pass. Generally an implant 60% to 70% of the width of the isthmus will pass without too much difficulty. In adolescents this will usually be a 2- or 2.4-mm K-wires. It is advised to have one size larger and smaller than planned available if needed (Table 13-8).

Positioning. Same as for instrument-assisted closed reduction.

Surgical Approach(es). The implant is inserted at the distal radius via a radial entry. The distal radial physis should be localized with fluoroscopy. A direct lateral incision of 1 to 2 cm

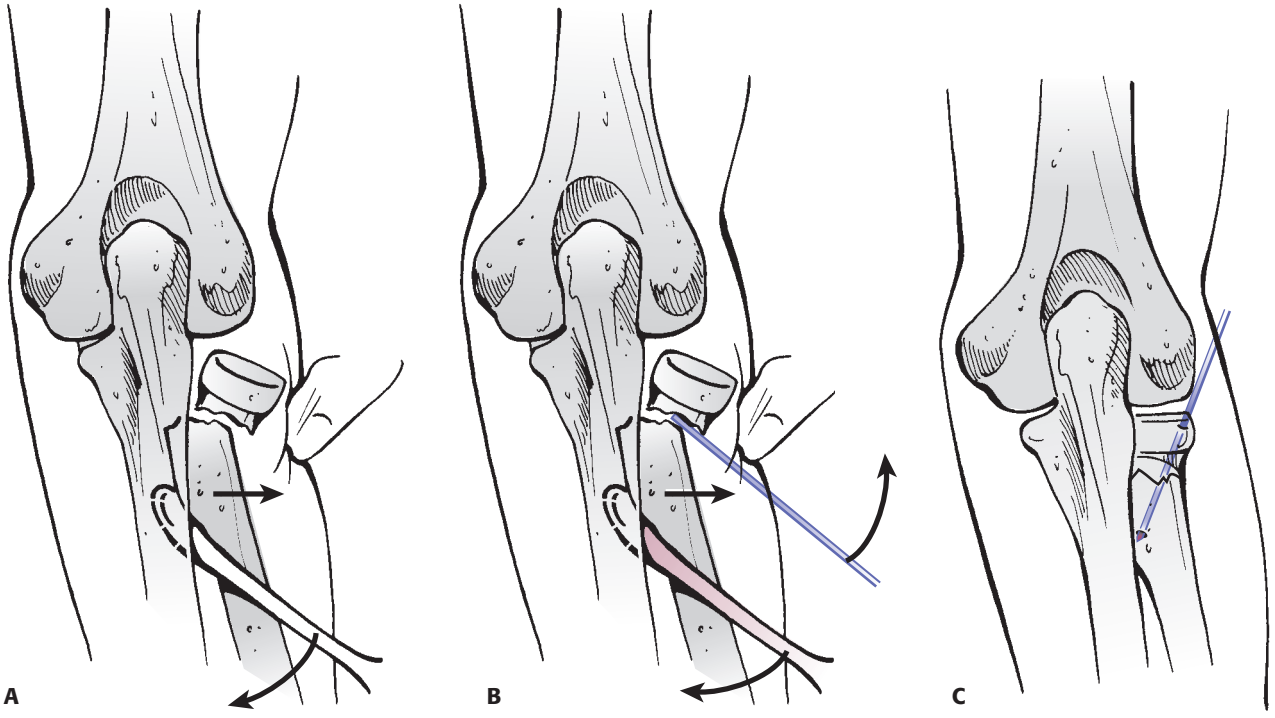

FIGURE 13-28 Wallace radial head reduction technique. **A:** A periosteal elevator is used to lever the distal fragment laterally while the thumb pushes the proximal fragment medially. **B:** Kirschner wires are used to assist the reduction if necessary. **C:** The position of the reduction can be fixed with an oblique Kirschner wire.

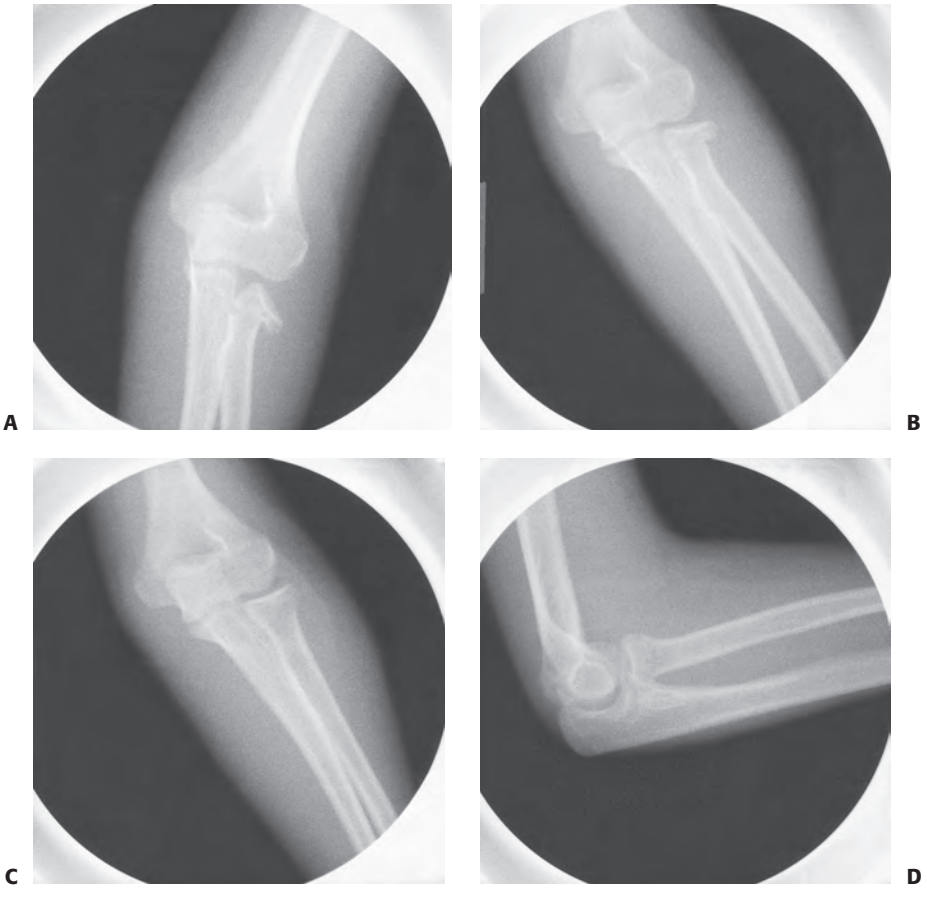

FIGURE 13-29 **A:** Radial neck fracture angulated 45 degrees in a 14-year-old female. **B:** Radiograph after closed reduction using thumb pressure on the radial head. **C:** Final reduction after manipulation of the distal fragment with an elevator using the Wallace technique. **D:** Lateral view of the elbow after reduction.

TABLE 13-8 Intramedullary Nail Reduction/ Fixation of Proximal Radius Fractures

Preoperative Planning Checklist

- OR table: Standard with radiolucent hand table
- Position/positioning aids: Turn table 90 degrees, bring patient to edge of table toward hand table. Secure head with blanket/towel and tape. Safety strap over torso
- Fluoroscopy location: In line with affected extremity, perpendicular to OR table
- Equipment: Smooth Kirschner wires
- Tourniquet (sterile/nonsterile): Nonsterile
- Esmarch bandage

is made just proximal to the physis of the distal radius. Careful scissor dissection to the lateral radial cortex is made with care taken not to injure the superficial radial nerve. It is not required to search for the nerve, however, if encountered it should be gently retracted. Extensor tendons from the first dorsal compartment may also be encountered and should be retracted.

Alternatively, the implant may be inserted via a direct dorsal approach over the dorsal tubercle of the radius. Either longitudinal or transverse incisions may be utilized. Extensor tendons will be encountered and should be protected during opening of the radial cortex at the dorsal tubercle.

Technique. Intramedullary reduction and fixation of proximal radius fractures was described by Metaizeau in 1980.[60] After selection of an appropriate-sized implant (K-wire or titanium flexible nail) the distal 3 to 4 mm of the implant should be bent sharply about 40 degrees. Either a dorsal or radial approach can be utilized at the entry site of the distal radius. The wire is advanced through the radial canal to the fracture site. If necessary, closed maneuvers should be used to improve alignment at the fracture site to allow for successful passage of the distal tip of the implant into the proximal fragment. The implant should be impacted into the epiphysis to achieve maximal fixation prior to reduction attempts with the implant. Once advanced appropriately, the nail should be rotated 90 to 180 degrees as needed to reduce the proximal fragment. The forearm should be held by the assistant to prevent the radial shaft from rotating with the implant (Fig. 13-30). Stability at the elbow joint and range of motion are assessed. The implant should be cut distally balancing need for ease of recovery during implant removal with soft tissue irritation from implant prominence at the distal radius. Rigid immobilization is not necessary with use of an intramedullary implant; however, most surgeons will immobilize the extremity in a long-arm splint or cast for 7 to 10 days for pain relief and to allow for soft tissue healing. Early range of motion is encouraged to minimize postoperative stiffness (Table 13-9).

Open Reduction Internal Fixation

Preoperative Planning. Appropriate implants should be available if rigid internal fixation is planned. These may include mini fragment screws, mini-fragment plates, or specialty proximal radius plates. Small fragment screws and plates are too large for fixation of the proximal radius. Specialty plates are produced by numerous manufacturers, but are designed for adult patients. Many will be too large for children and young

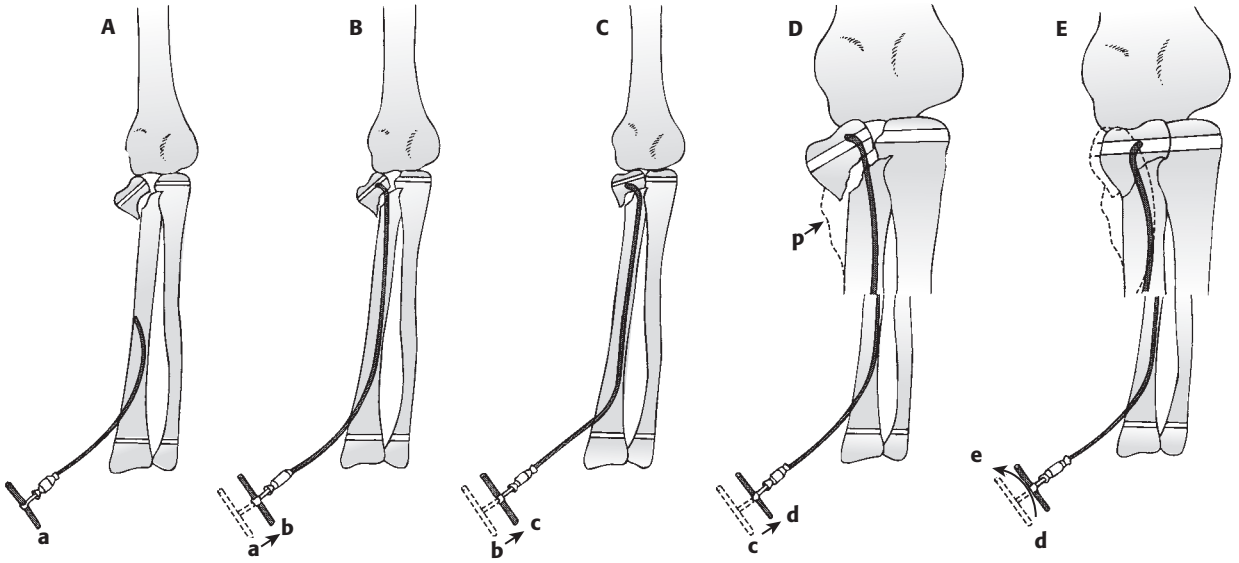

FIGURE 13-30 Intramedullary pin reduction. **A:** The insertion point for the curved flexible pin is in the metaphysis. **B:** The curved end of the rod passes in the shaft and engages the proximal fragment. **C:** Manipulation of the rod disimpacts the fracture. **D, E:** Once disimpacted, the head fragment is rotated into position with the intramedullary rod. (From Metaizeau JP, Lascombes P, Lemelle JL, et al. Reduction and fixation of displaced radial neck fractures by closed intramedullary pinning. *J Pediatr Orthop.* 1993;13:355–360, with permission.)

TABLE 13-9 Intramedullary Nail Reduction/ Fixation of Proximal Radius Fractures

Surgical Steps

- Prebend implant at distal end
- Open distal radial cortex via radial or dorsal approach
- Advance implant to the fracture site
- Closed manipulation of fracture to allow implant to enter distal fragment
- Advance implant into distal fragment
- Rotate implant as needed to reduce fracture
- Assess stability and range of motion
- Cut implant distally under the skin
- Close surgical wound
- Immobilize to allow for soft tissue healing

TABLE 13-10 Open Reduction Internal Fixation of Proximal Radius Fractures

Preoperative Planning Checklist

- OR table: Standard with radiolucent hand table
- Position/positioning aids: Turn table 90 degrees, bring patient to edge of table toward hand table. Secure head with blanket/towel and tape. Safety strap over torso
- Fluoroscopy location: In line with affected extremity, perpendicular to OR table
- Equipment: 2–2.7-mm screws; minifragment plates versus fracture specific plates (radial neck, radial head)
- Tourniquet (sterile/nonsterile): Nonsterile
- Esmarch bandage

adolescents, however, they may fit appropriately in the older adolescent (Table 13-10).

Positioning. Same as for instrument-assisted closed reduction.

Surgical Approach(es). A lateral approach to the proximal radius should be utilized for open reduction of proximal radius fractures. The lateral Kocher approach provides appropriate exposure. Dissection should occur between the anconeus and extensor carpi ulnaris. Usually the interval is easier to identify distally and can be traced back proximally. The muscle fibers will be seen to run in divergent directions distally which assist with location of the interval. Often the annular ligament will be traumatically disrupted and also the joint capsule will be disrupted. Care should be taken to stay superior to the lateral collateral ligament of the elbow to prevent adding iatrogenic instability. Distally the supinator may be released if needed for plate application.

When exposing the proximal radius the forearm should be kept in a pronated position to move the PIN further away from the surgical field. Vigorous retraction should be avoided anteriorly to limit traction on the PIN.

Technique. After adequate exposure of the fracture site the anatomy of the fracture should be evaluated. Radial neck fractures are more common and can be reduced using manual pressure or instrumented manipulation. Often a dental pick is useful to hold a reduced position after manual reduction. The fracture can be either definitively or provisionally fixed at this point with small K-wires. Radial head fractures are usually more complex and may have multiple fragments. Attempts should be made to reduce the radial head in children and adolescents with use of small pins or bone clamps to hold provisional reduction. Radial head excision is generally a salvage operation but can be considered as a primary treatment if there is extensive comminution prohibiting reconstruction. Results have been uniformly poor after excision with high incidence of cubitus valgus and radial deviation at the wrist.[21,40,44] Radial head replacement has not been described for children or adolescents but is increasingly utilized for adults.

When proceeding with open reduction, most surgeons elect to place more rigid fixation to allow for early range of motion. Screw fixation with minifragment screws or small headless screws provides stable fixation of radial head and neck fractures (Figs. 13-31 and 13-32).[97] Plates have been utilized for fixation of radial neck fractures requiring open reduction (Fig. 13-33). They should be placed in the "safe zone" of the proximal radius. This is an area of about 100 to 110 degrees of the circumference of the proximal radius that does not articulate with the proximal ulna during forearm rotation. With the forearm in 10 degrees of supination the "safe zone" is directly lateral.[99] (JOT 1998 12:291-293)[100] Screws should be kept unicortical to prevent perforation into the proximal radioulnar joint. Plate application requires more extensive dissection than isolated screw fixation and has led some authors to strongly advocate for multiple screw fixation alone for radial head and neck fractures. There is no good quality evidence supporting one form of internal fixation over another in the treatment of fractures of the proximal radius.

During closure the annular ligament and joint capsule should be repaired if it was injured during the trauma or surgical dissection. The arm should be immobilized in a posterior splint for 1 to 2 weeks to allow for soft tissue healing before initiating range of motion. A regional anesthetic block prior to surgery or after surgery can provide improved patient comfort postoperatively. A detailed neurologic examination should be conducted preoperatively prior to regional nerve block (Table 13-11).

Outcomes

Severity of initial displacement and angulation are the best predictors of results after treatment. A higher incidence of good outcomes is found in patients who do not require fracture manipulation (closed or open) and present with fractures with minimal angulation and displacement.[68,108] For patients having operative treatment, closed methods generally lead to improved results compared to open treatments. This is again largely because of increased severity of fractures requiring open reduction. In certain cases, however, open treatment is preferred and small case series demonstrates improved results with open treatment in appropriately selected patients.[64,102]

FIGURE 13-31 Miniscrew fixation. **A, B:** Anteroposterior and lateral views of the elbow of a 6-year-old male in whom the head fragment lies posterior to the capitellum (*arrows*). **C:** At the time of open reduction a Salter–Harris type III fracture through the epiphysis and proximal physis was apparent. The fragment involved 60% of the head diameter and had soft tissue attached. **D:** A screw placed through the epiphysis fixed the reduction. **E:** Six months after surgery, an arthrogram showed maintenance of the architectural structure of the medial head after screw removal. The patient had 60 degrees of supination and pronation. (From Wilkins KE, ed. *Operative Management of Upper Extremity Fractures in Children*. Rosemont, IL: American Academy of Orthopaedic Surgeons; 1994:58, with permission.)

FIGURE 13-32 Patient underwent operative intervention using low-profile fixation with 3-mm cannulated screws and repair of a torn lateral ulnar collateral ligament complex. Gentle range of motion was started on postoperative day 1 and progressed as tolerated. Anteroposterior **(A)** and lateral **(B)** radiographs of the elbow at 3-month follow-up demonstrated healing of the fracture, and clinical assessment demonstrated full function and range of motion. (From Smith AM, Morrey BF, Steinmann SP. Low profile fixation of radial head and neck fractures: Surgical technique and clinical experience. *J Orthop Trauma*. 2007;21(10):718–724.)

Examination under anesthesia demonstrated very unstable elbow joint and therefore decision made to proceed with open reduction internal fixation **(D).** Lateral radiograph after open reduction internal fixation with a fracture-specific plate.

TABLE 13-11 Open Reduction Internal Fixation Proximal Radius Fractures

Surgical Steps

- Kocher lateral approach to proximal radius
  - Keep forearm pronated during exposure
  - Protect lateral collateral ligament
- Provisional reduction of proximal radius fracture
  - Stabilize with small K-wires or clamps
- Internal fixation with minifragment screws
- If plate fixation utilized identify "safe zone" and apply plate
- Wound closure—repair annular ligament
- Posterior arm splint

The overall incidence of poor results in large series varies from 15% to 33%.[28,40,44,102,113] Considering only severely displaced fractures, the incidence of poor results was as high as 50%.[102] Thus, at least one in five or six children can be expected to have a poor result despite adequate treatment. It is wise to counsel the parents before beginning treatment if poor prognostic factors are present. These include injuries associated with high-energy mechanism such as elbow dislocation, olecranon fracture, or other fractures of the elbow.[28,52,90,102]

Early reviews reported poor results with significant loss of range of motion in patients treated operatively,[8,10,15,25] but more recently Steinberg et al.[102] combined their results of open reduction of severely displaced fractures with those of five other series[43,44,76,108] and reported 49% good results after operative

treatment compared to 25% after nonoperative treatment. None of these authors used percutaneous pin reduction. The results of moderately displaced fractures treated operatively were equal to the results of those treated nonoperatively. If the head of the radius is completely displaced, results are usually better with surgical intervention. A completely separated radial head may remain viable if surgically replaced as late as 48 hours after injury.[32,46]

Various tolerance for residual angulation has been described, and most authors believe that good results and remodeling can be achieved when there is less than 30 to 45 degrees of angulation.[7,22,52,58,68,69,81,113,116] D'Souza evaluated the results in 100 children from 1972 to 1990 and described better results with closed compared to open treatment. Overall 86 had results described as "good" or "excellent." More recently Tan and Mahadev[104] reported on 108 children with radial neck fractures. The majority were treated nonsurgically with only eight requiring a closed reduction, seven requiring instrument-assisted closed reduction, and seven requiring open reduction. Results were "excellent" in 93 children. Adverse outcomes were more likely in older patients and those with associated fractures about the elbow. Most believe that ability to achieve less than 30 to 45 degrees angulation with closed treatment provides superior outcomes compared to patients having open reduction even with anatomic alignment.

As opposed to substantial angulation, displacement is not well tolerated because of the "cam effect" described. More recently there has been increased attention paid to intra-articular radial head fractures in children. These are problematic injuries and must be monitored closely. Progressive posterior radiocapitellar subluxation has been described leading to severe cartilage deterioration (Fig. 11-34). Most patients with progressive

FIGURE 13-34 A 13-year-old male patient after fall on pronated outstretched hand. **A, B:** Anteroposterior and lateral radiographs of the injured elbow. subluxation presenting in a delayed manner end up requiring radial head excision.[114] Functional outcomes are very poor when this is identified and treated in a delayed manner. Kasser has described this injury as one of his "The Radiographic Appearance Seemed Harmless (TRASH)" lesions (Fig. 13-9).[114]

An increasing number of reports with good results after intramedullary wire technique for angulated and displaced proximal radius fractures have been published recently.[76] (Ugutmen 2010, Prathapkumar 2006, Eberl 2010, Klitscher 2009)[23,36,47,112] Self-determined "excellent" results are described in 80% to 90% patients in these reported series. Metaizeau's initial results of treatment using intramedullary K-wires reported excellent results in 30/31 children treated with his technique.[59]

Author's Preferred Treatment for Fractures of the Proximal Radius

Nonoperative management is our preferred treatment for most proximal radius fractures. Operative treatment should aim to reduce displacement of the radial head/neck to less than 2 mm and restore angulation of radial neck fractures to less than 30 degrees while also confirming normal arc of forearm rotation. Open approaches are avoided if these goals can be achieved. Necessity for internal fixation should be evaluated on an individual basis and is avoided if possible. We have become more aggressive with operative treatment of radial head fractures because of the increased reports of adverse outcomes with progressive posterior radiocapitellar subluxation. Low-profile internal fixation with minifragment screws and if needed, a minifragment plate, is utilized for stable fixation to allow for early range of motion. MRI is utilized more frequently in the evaluation of radial head fractures because of its improved ability to assess for associated soft tissue injuries and evaluation of the radiocapitellar joint in skeletally immature patients (Fig. 13-35).

Postoperative Care

Immobilization should only be for symptomatic relief from surgical trauma and soft tissue healing. Generally 1 to 2 weeks is sufficient in patients with open reduction internal fixation or intramedullary fixation. Longer immobilization of 2 to 3 weeks may be required for some patients treated with no reduction or closed reduction to achieve enough symptom relief to allow for mobilization. Collar and cuff, posterior splint, and long-arm cast are all appropriate methods of immobilization. Range of

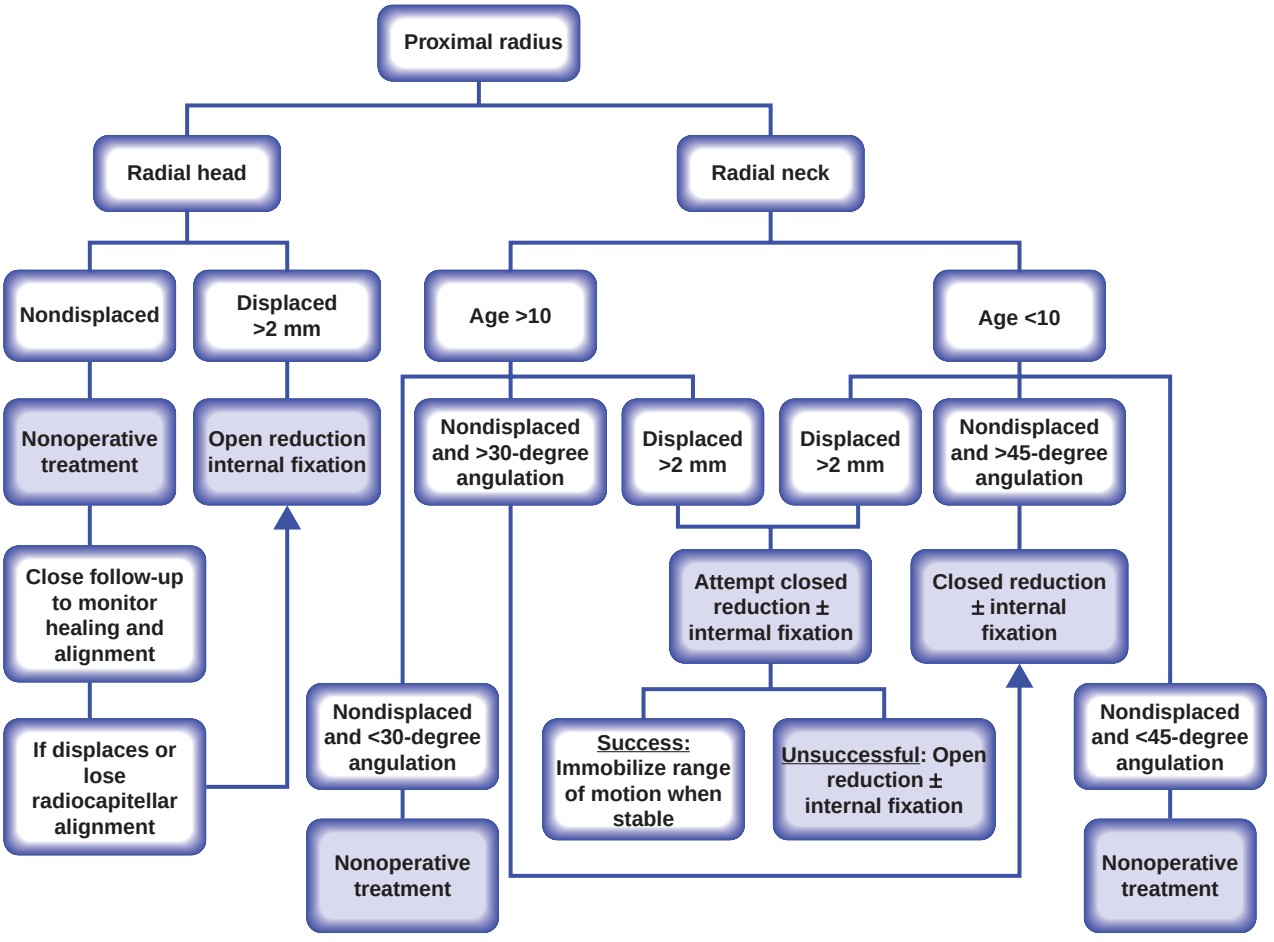

FIGURE 13-35 Author's preferred treatment algorithm.

motion should be allowed and encouraged when acute fracture pain has resolved and surgical scar has healed.

Potential Pitfalls and Preventative Measures

Iatrogenic PIN injury can occur during both percutaneous and open approaches to the proximal radius. Pronation of the forearm during open exposure or during percutaneous pin insertion helps move the PIN away from the surgical field and reduces the risk of nerve injury. Vigorous anterior retraction during open exposure should also be avoided. Knowledge of the anatomy of the PIN is required to safely place instrumentation and expose the proximal radius.

Radiocapitellar subluxation posteriorly is an extremely poor prognostic factor for outcomes of proximal radius fractures. Close vigilance is warranted in fracture patterns predisposed to this complication, especially intra-articular radial head fractures. In children with intra-articular fractures or those with unossified proximal radial epiphysis strong consideration should be made for ultrasound or MR imaging to determine the anatomic extent of injury. Surgical treatment can prevent this dangerous pitfall in appropriate cases.

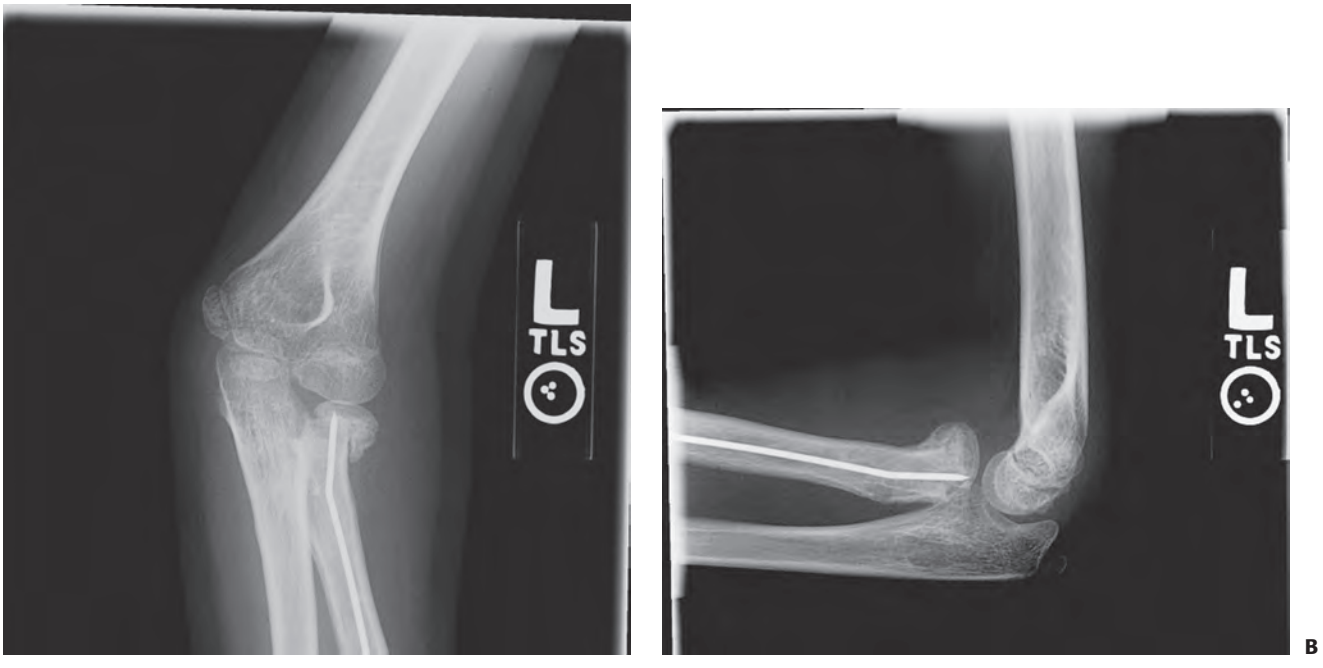
The intramedullary technique has demonstrated good results in experienced hands. Surgeons with less experience may struggle with adequate engagement of the proximal fragment and loss of fixation with attempted rotation of the implant (Fig. 13-36). To decrease this adverse event the implant should be bent sharply to 30 to 40 degrees at its distal end to promote engagement of the proximal fragment. The fragment should also be fixed all the way to the epiphysis, crossing the growth plate, to maximize purchase, and decrease risk of implant failure with the corrective force during rotation of the implant.

Restricted range of motion after open reduction and internal fixation of proximal radius fractures is common. To minimize additional restriction because of implant placement the surgeon should take care to apply plate fixation only to the "safe zone" of the proximal radius and screws aiming toward the proximal radioulnar articulation should be unicortical (Table 13-12).

Management of Expected Adverse Outcomes and Unexpected Complications in Fractures of the Proximal Radius

Loss of Motion in Fractures of the Proximal Radius

Loss of motion is secondary to a combination of loss of joint congruity and posttraumatic or postoperative soft tissue scarring. Loss of pronation is more common than loss of supination. Flexion and extension are rarely significantly limited. Very little improvement in motion occurs after 6 months. Steinberg et al.[102] found that range of motion in their patients at 6 months was almost equal to that when the patients were examined years later. Patients should be encouraged to start range of motion early with both nonoperative and operative treatment to minimize loss of motion from posttraumatic stiffness. Both static and dynamic splinting can be useful along with aggressive therapy in the treatment of posttraumatic or postoperative elbow sand forearm stiffness.



A B

FIGURE 13-36 Failure of fixation with intramedullary technique for proximal radius fracture. **A:** AP view showing loss of fixation of the proximal fragment. **B:** Lateral view showing loss of fixation of the proximal fragment.

TABLE 13-12 Proximal Radius Fractures: Potential Pitfalls and Preventions

Pitfall	Preventions
PIN injury	Pronate forearm when approaching proximal radius in open approaches Avoid vigorous retraction during open reduction Insert percutaneous implants for reduction assistance directly lateral
Radiocapitellar subluxation	Consider ultrasound or MRI for intra-articular radial head fractures Close radiographic surveillance out of cast/splint for patients with radial head fracture
Failure to engage proximal fragment with intramedullary implant	Choose appropriate-sized implant based on preoperative templating Ensure distal end of implant has an appropriate bend to capture proximal fragment
Mechanical block to forearm rotation	Ensure any plate fixation of the proximal radius is in the "safe zone" Screws aiming toward the proximal radioulnar joint should be unicortical

Radial Head Overgrowth in Fractures of the Proximal Radius

Next to loss of range of motion of the elbow and forearm, radial head overgrowth is probably the most common sequela (20% to 40%).[22,113] The increased vascularity following the injury may stimulate epiphyseal growth, but the mechanisms of overgrowth following fractures are poorly understood. Radial head overgrowth usually does not compromise functional results,[20,44] but it may produce some crepitus or clicking with forearm rotation.[22]

Premature Physeal Closure in Fractures of the Proximal Radius

Many series report premature physeal closure[28,32,68,69,102,121] after fractures of the radial head and neck. This complication did not appear to affect the overall results significantly, except in one patient described by Fowles and Kassab,[28] who had a severe cubitus valgus. Newman[68] found that shortening of the radius was never more than 5 mm compared with the opposite uninjured side.

Osteonecrosis in Fractures of the Proximal Radius

The incidence of osteonecrosis is probably higher than recognized. D'Souza et al.[22] reported the frequency to be 10% to 20% in their patients, 70% of whom had open reductions. In patients with open reduction, the overall rate of osteonecrosis was 25%. Jones and Esah[44] and Newman[68] found that patients with osteonecrosis had poor functional results. It has been our experience, however, that revascularization can occur without any significant functional loss. Only in those in whom a residual functional deficit occurs is osteonecrosis considered a problem (Fig. 13-37).

Malunion in Fractures of the Proximal Radius

Failure to reduce a displaced and angulated proximal radial fracture in a young child often results in an angulated radial neck with subsequent incongruity of both the proximal radioulnar joint and the radiocapitellar joint (Fig. 13-38). Partial physeal arrest also can create this angulation (Fig. 13-3).

In our experience, this malunion, because of the incongruity of the radiocapitellar joint, often results in erosion of the articular surface of the capitellum, with subsequent degenerative joint disease. In the English literature, there is little information about using osteotomies of the radial neck to correct this deformity.

Nonunion of the Radial Neck in Fractures of the Proximal Radius

Nonunion of the radial neck is rare; union may occur[93] even after prolonged treatment (Fig. 13-39). Waters and Stewart[120] reported nine patients with radial neck nonunions, all of whom were treated with open reduction after failed attempts at closed reduction. These authors recommended observation of patients with radial neck nonunions who have limited symptoms and a functional range of motion. They suggested open reduction for displaced

FIGURE 13-37 Osteonecrosis with nonunion in a radial head 1 year after open reduction. Both nonunion and osteonecrosis of the radial neck and head are present. Severe degenerative arthritis developed subsequently. (Courtesy of Richard E. King, MD.)

FIGURE 13-38 Angulation. **A:** Injury film showing 30 degrees of angulation and 30% lateral translocation of a radial neck fracture in a 10-year-old. **B:** Radiograph appearance of the proximal radius taken about 5 months later, showing lateral angulation of the neck. **C:** Lateral view showing the anterior relationship of the radial neck with proximal migration. At this point the patient had full supination and pronation but a clicking sensation with forearm rotation in the area of the radial head. **D:** Three-dimensional reconstruction showing the incongruity of the proximal radiocapitellar joint. (Courtesy of Vince Mosca, MD.)

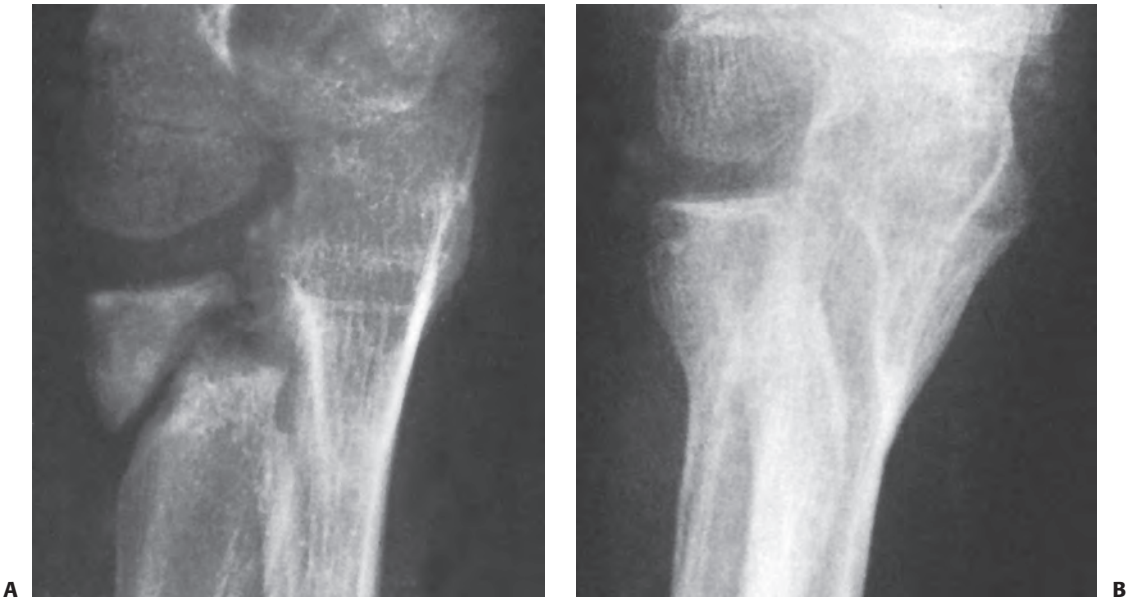


FIGURE 13-39 Nonunion. **A:** Eight months after radial neck fracture in an 8.5-year-old female. Patient had mild aching pain, but no loss of motion. There was some suggestion of proximal subluxation of the distal radioulnar joint. **B:** Three months later, the fracture is united after long-arm cast immobilization and external electromagnetic stimulation. (Courtesy of Charles T. Price, MD.)

nonunions, patients with limited range of motion, and patients with restricting pain. Nonunion of intra-articular radial head fractures can also occur and should be treated with open reduction internal fixation if symptomatic and radiocapitellar joint has remained congruent (Fig. 13-40). In many cases nonunion of these fractures leads to progressive radiocapitellar subluxation and cartilage destruction as previously described.

Changes in Carrying Angle (Cubitus Valgus) in Fractures of the Proximal Radius

In patients who have fractures of the radial neck, the carrying angle often is 10 degrees more (increased cubitus valgus) than on the uninjured side.[22,44] The increase in carrying angle appears to produce no functional deficit and no significant deformity.

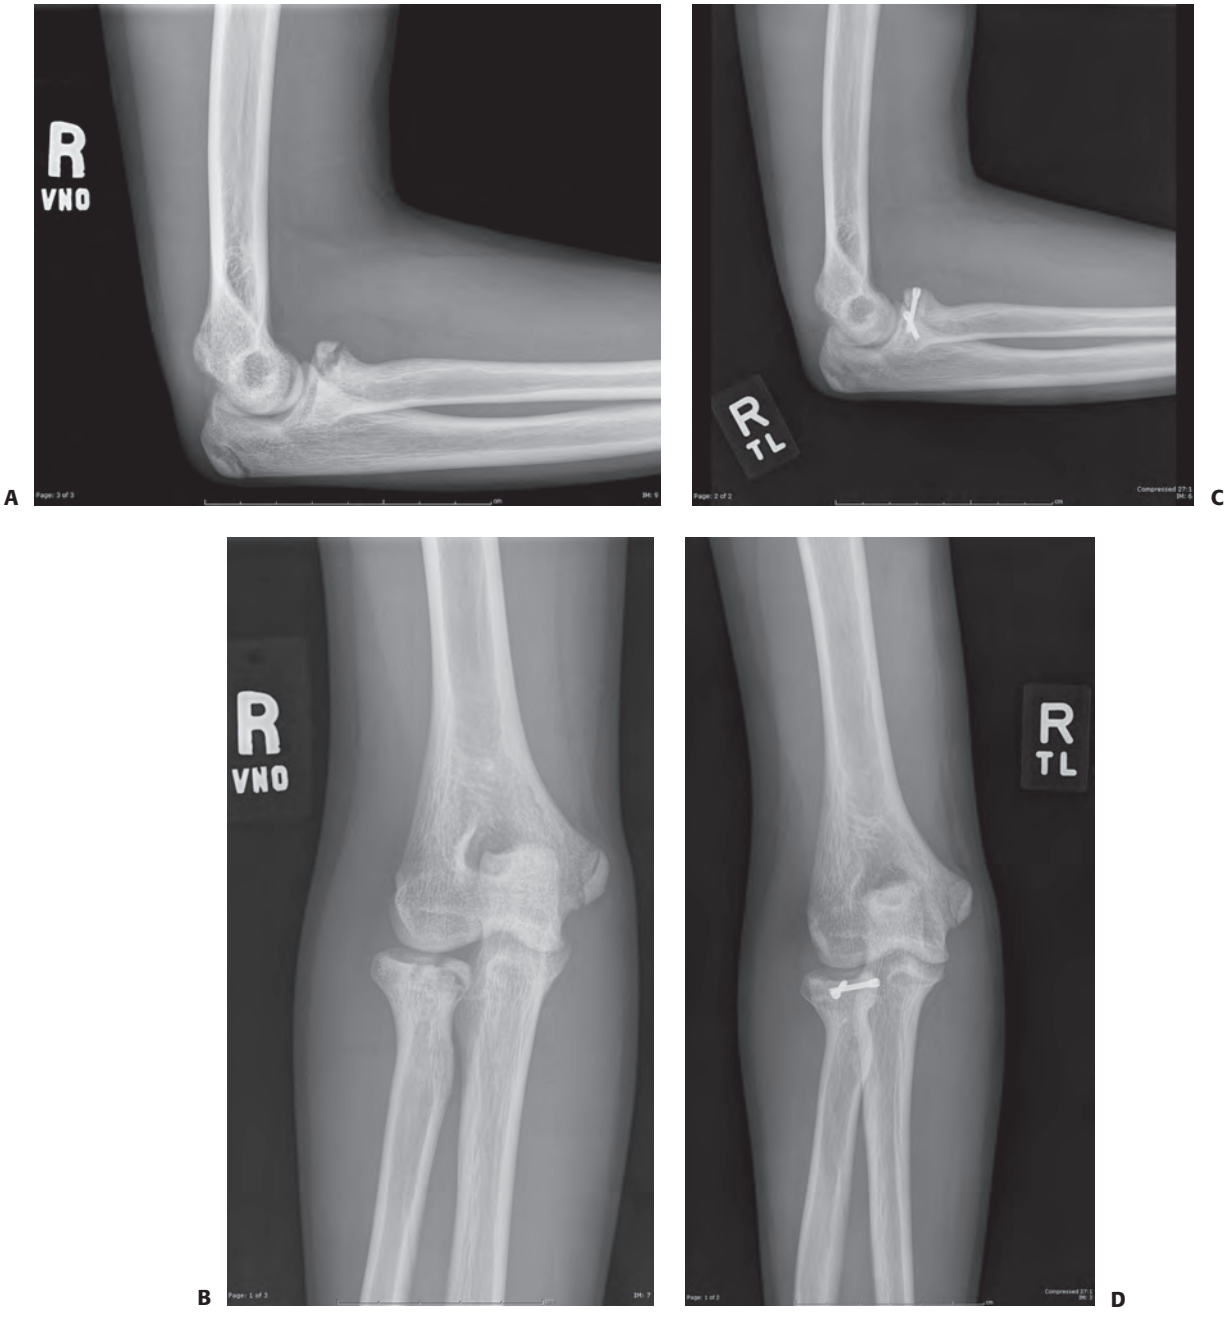

FIGURE 13-40 Nonunion of intra-articular radial head fracture. (Courtesy of R. E. King, MD.)

Nerve Injuries in Fractures of the Proximal Radius

Partial ulnar nerve injury[40] and PIN injury may occur as a direct result of the fracture, but most injuries to the PINs are caused by surgical exploration[22] or percutaneous pin reduction.[5] These PIN injuries usually are transient and exploration is not generally warranted.

Radioulnar Synostosis in Fractures of the Proximal Radius

Proximal radioulnar synostosis can occur following treatment of proximal radius fractures (Fig. 13-41). It occurs most often after open reduction of severely displaced fractures,[32,40,68,101] but has been reported to occur after closed reduction. Case reports argue that delayed treatment increases the likelihood of this complication. Treatment is based on functional limitation and disability.

Myositis Ossificans in Fractures of the Proximal Radius

Myositis ossificans is relatively common but usually does not impair function. Vahvanen[113] noted that some myositis ossificans occurred in 32% of his patients. In most, it was limited to the supinator muscle. If ossification was more extensive and was associated with a synostosis, the results were poor (Table 13-13).

Assessment of Fractures of the Proximal Ulna

Mechanisms of Injury for Fractures of the Proximal Ulna

Fractures Involving the Proximal Apophysis

The location of the triceps expansive insertion on the metaphysis distal to the physis probably accounts for the rarity of fracture along the physeal line. Only a few reports mention the mechanism of these physeal injuries. In most of the fractures reported by Poland,[77] three of which were confirmed by amputation specimens, the force of the injury was applied directly to the elbow. The force may be applied indirectly, producing an avulsion type of fracture. In our experience, this fracture is usually caused by avulsion forces across the apophysis with the elbow flexed, similar to the more common flexion metaphyseal injuries. Children with osteogenesis imperfecta (usually the tarda form) seem especially predisposed to this injury.[18,62]

Stress fractures of the olecranon apophysis can occur in athletes (especially throwing athletes) who place considerable recurrent tension forces on the olecranon.[72] Stress injuries also have been reported in surfers, elite gymnasts,[54] and tennis players.[85] If the recurring activity persists, a symptomatic nonunion can develop.[75,85,109,111,122]

TABLE 13-13 Proximal Radius Fractures: Common Adverse Outcomes and Complications

Loss of range of motion
Radial head overgrowth
Avascular necrosis of the radial head
Nonunion
Malunion
Proximal radioulnar synostosis
Cubitus valgus
Posterior interosseous nerve injury

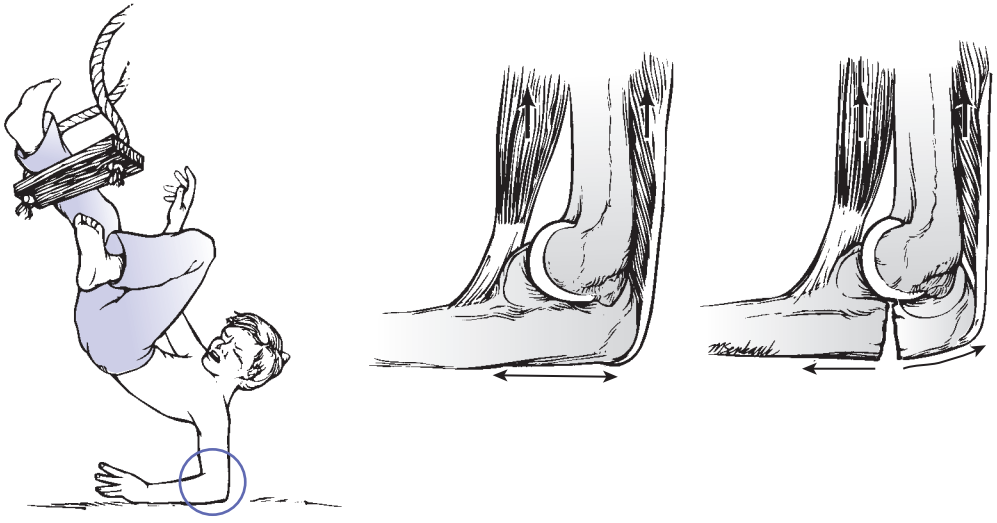

FIGURE 13-42 Mechanism of flexion injuries. **Center:** In the flexed elbow, a tension force develops on the posterior aspect of the olecranon (*small double arrow*). **Right:** Failure occurs on the tension side, which is posterior as a result of the muscle pull or a direct blow to the prestressed posterior olecranon. Arrows represent pull of brachialis (*left arrow*) and triceps (*right arrow*).

Metaphyseal Fractures of the Olecranon

Three main mechanisms produce metaphyseal olecranon fractures. First, in injuries occurring with the elbow flexed, posterior tension forces play an important role. Second, in injuries in which the fracture occurs with the elbow extended, the varus or valgus bending stress across the olecranon is responsible for the typical fracture pattern. Third, a less common mechanism involves a direct blow to the elbow that produces an anterior bending or shear force across the olecranon. In this type, the tension forces are concentrated on the anterior portion of the olecranon.

Flexion Injuries

A fall with the elbow in flexion places considerable tension forces across the posterior aspect of the olecranon process. Proximally, the triceps applies a force to the tip of the olecranon process. Distally, there is some proximal pull by the insertion of the brachialis muscle. Thus, the posterior cortex is placed in tension. This tension force alone, if applied rapidly enough and with sufficient force, may cause the olecranon to fail at its midportion (Fig. 13-42). A direct blow applied to the posterior aspect of the stressed olecranon makes it more vulnerable to failure. With this type of mechanism, the fracture line is usually transverse and perpendicular to the long axis of the olecranon (Fig. 13-43). Because the fracture extends into the articular surface of the semilunar notch, it is classified as intra-articular.

The degree of separation of the fracture fragments depends on the magnitude of the forces applied versus the integrity of the soft tissues. The low incidence of displaced olecranon fractures indicates that the soft tissues are quite resistant to these avulsion forces. In flexion injuries, there are relatively few associated soft tissue injuries or other fractures.[67]

Extension Injuries

Because the ligaments are more flexible in children, the elbow tends to hyperextend when a child breaks a fall with the outstretched upper extremity. In this situation, the olecranon may be locked into the olecranon fossa. If the elbow goes into extreme hyperextension, usually the supracondylar area fails. If, however, the major direction of the force across the elbow is varus or valgus, a bending moment stresses the olecranon. Most of this force concentrates in the distal portion of the olecranon. Because the olecranon is metaphyseal bone, the force produces greenstick-type longitudinal fracture lines (Fig. 13-44). Most of these fracture lines are linear and remain extra-articular. In addition, because the fulcrum of the bending force is more distal, many of the fracture lines may extend distal to the coronoid process and into the proximal ulnar shaft regions. The major deformity of the olecranon with this type of fracture is usually an angulated greenstick type of pattern.

FIGURE 13-43 Radiograph of flexion injury showing greater displacement on the posterior surface.

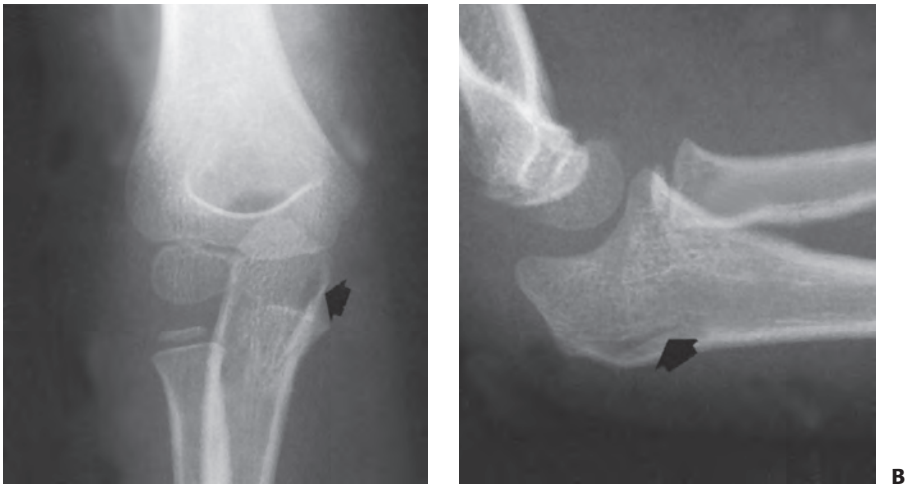

FIGURE 13-44 **A:** Anteroposterior view of a linear greenstick fracture line (*arrow*) in the medial aspect of the olecranon. **B:** Lateral view showing the posterior location of the fracture line (*arrow*).

Many of these fractures are associated with other injuries in the elbow region, which depend on whether the bending force is directed toward varus or valgus. If a child falls with the forearm in supination, the carrying angle tends to place a valgus stress across the elbow. The result may be a greenstick fracture of the ulna with an associated fracture of the radial neck or avulsion of the medial epicondylar apophysis (Fig. 13-45). If the fracture involves the radial neck, Bado[4] classified it as an equivalent of the type I Monteggia lesion.

Shear Injuries

Anterior tension failure is a rare injury that can occur when a direct blow to the proximal ulna causes it to fail with an anterior tension force; the proximal radioulnar joint maintains its integrity. The most common type of shear injury is caused by a force applied directly to the posterior aspect of the olecranon, with the distal fragment displacing anteriorly (Figs. 13-46 and 13-47). The intact proximal radioulnar joint displaces with the

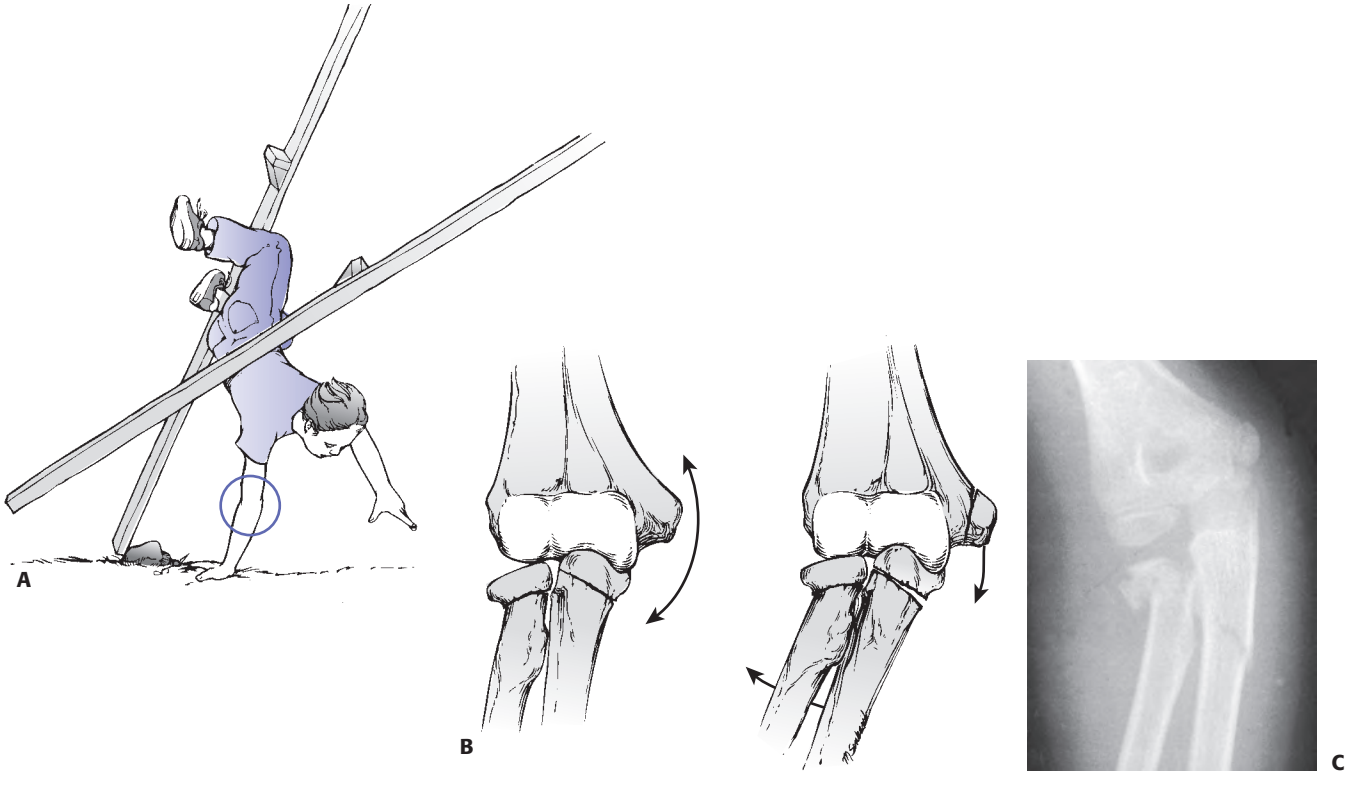

FIGURE 13-45 Valgus pattern of an extension fracture. **A:** A fall with the elbow extended places a valgus stress on the forearm. **B:** With increased valgus, a greenstick fracture of the olecranon can occur with or without a fracture of the radial neck or avulsion of the medial epicondylar apophysis. **C:** Radiograph of a valgus extension fracture of the olecranon with an associated fracture of the radial neck.

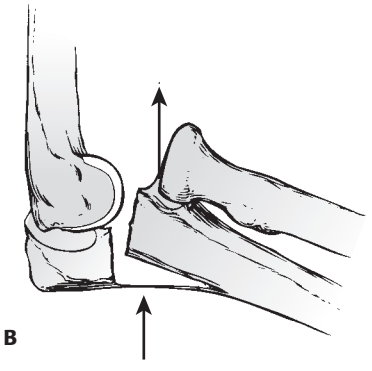

FIGURE 13-46 Flexion shear injuries. **A, B:** Fracture with the elbow flexed. The direct blow to the distal portion of the posterior olecranon causes the fracture to fail in tension of the anterior surface. The intact proximal radioulnar joint displaces anteriorly. **C:** Radiograph of a flexion shear injury showing the distal fragments displaced anteriorly as a unit.

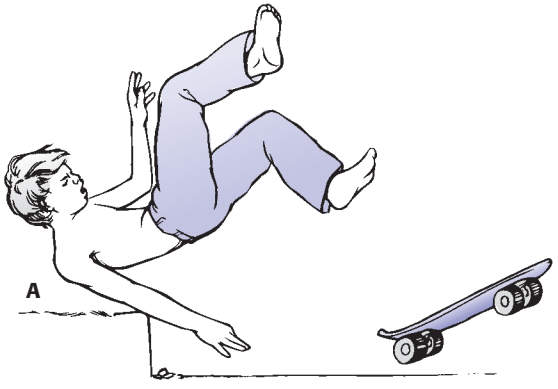

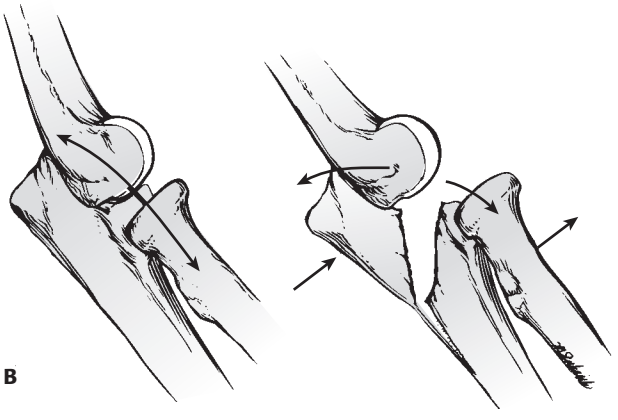

FIGURE 13-47 Extension shear injuries. **A, B:** Fracture with the elbow extended. If the elbow is extended when the direct blow to the posterior aspect of the elbow occurs, the olecranon fails in tension but with an oblique or transverse fracture line (*arrows*). **C:** With the elbow extended, the initial failure is in the anterior articular surface (*arrows*).

distal fragment. In this type of injury, the elbow may be either flexed or extended when the direct shear force impacts the posterior aspect of the olecranon. These fractures are caused by a failure in tension, with the force concentrated along the anterior cortex. This is opposite to the tension failure occurring on the posterior aspect of the cortex in the more common flexion injuries. In the shear-type injury, the fracture line may be transverse or oblique. The differentiating feature from the more common flexion injury is that the thick posterior periosteum usually remains intact. The distal fragment is displaced anteriorly by the pull of the brachialis and biceps muscles. Newman[68] described one patient in whom a shear force was directed medially; the radial neck was fractured, and the radial head remained with the proximal fragment.

Fractures of the Coronoid Process

Isolated coronoid fractures are theoretically caused by avulsion by the brachialis or secondary to an elbow dislocation that reduced spontaneously, which is usually associated with hemarthrosis and a small avulsion of the tip of the olecranon process (Fig. 13-48).

FIGURE 13-48 Lateral radiograph of an 11-year-old male who injured his left elbow. Displaced anterior and posterior fat pads, plus a small fracture of the coronoid (*arrow*), indicate a probable partially dislocated elbow as the primary injury.

Associated Injuries with Fractures of the Proximal Ulna

Metaphyseal Fractures of the Olecranon and the Proximal Apophysis

Associated injuries occur in 48% to 77% of patients with olecranon fractures,[11,36,71,106] especially varus and valgus greenstick extension fractures, in which the radial head and neck most commonly fracture (Fig. 13-44). Other associated injuries include fractures of the ipsilateral radial shaft,[103] Monteggia type I lesions with fractures of both the ulnar shaft and olecranon,[70] and fractures of the lateral condyle (Fig. 13-49).[9]

Fractures of the Coronoid Process

Although most coronoid fractures are associated with elbow dislocations, fractures of the olecranon, medial epicondyle, and lateral condyle also can occur.[68] The fracture of the coronoid may be part of a greenstick olecranon fracture (i.e., the extension-type metaphyseal fracture; Fig. 13-50).

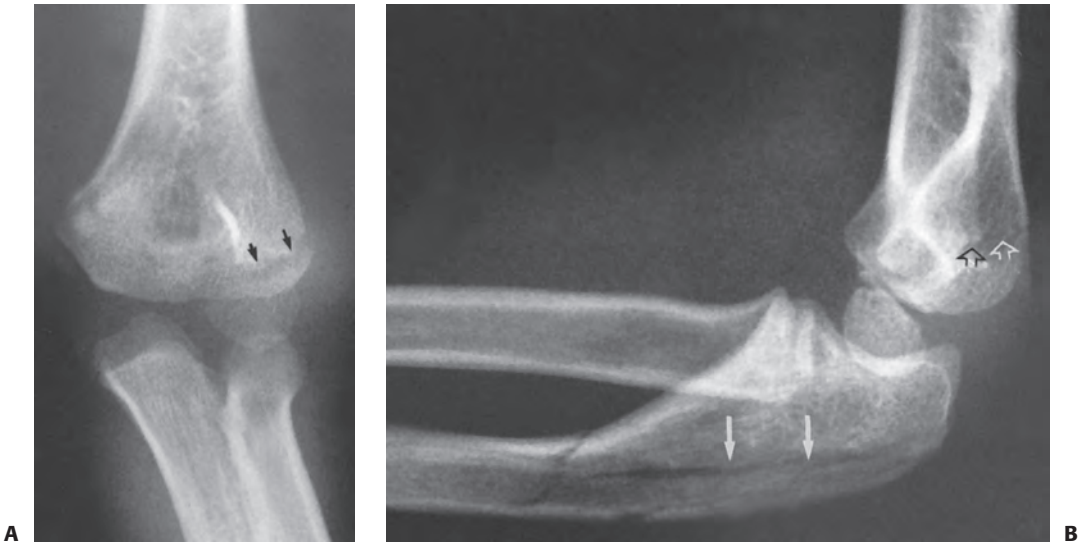

FIGURE 13-49 **A:** Undisplaced fracture of the lateral condyle (*arrows*) associated with a varus greenstick fracture of the olecranon. **B:** Lateral view showing greenstick fractures in the olecranon (*solid arrows*) and a nondisplaced fracture of the lateral condyle (*open arrows*).

FIGURE 13-50 Fracture of the coronoid (*arrow*) as part of an extension valgus olecranon fracture pattern. There was an associated fracture of the radial neck. Both the neck fracture and the distal portion of the coronoid process show periosteal new bone formation (*open arrows*).

Signs and Symptoms of Fractures of the Proximal Ulna

Metaphyseal Fractures of the Olecranon and the Proximal Apophysis

Flexion injuries cause soft tissue swelling and tenderness over the olecranon fracture. The abrasion or contusion associated with a direct blow to the posterior aspect of the elbow provides a clue as to the mechanism of injury. If there is wide separation, a defect can be palpated between the fragments. In addition, there may be weakness or even lack of active extension of the elbow, which is difficult to evaluate in an anxious young child with a swollen elbow. Associated proximal radius fractures may be noted clinically by swelling and tenderness laterally with palpation in this region.

Fractures of the Coronoid Process

Because of the common association of these fractures with elbow dislocations, a high index of suspicion is necessary when evaluating these injuries. Significant soft tissue swelling about the elbow is a consistent finding. The patient may also recall the "clunking" sensation of dislocation and spontaneous relocation with specific inquiry.

Imaging and Other Diagnostic Studies for Fractures of the Proximal Ulna

Metaphyseal Fractures of the Olecranon and the Proximal Apophysis

The radiographic diagnosis may be difficult before ossification of the olecranon apophysis. The only clue may be a displacement of the small ossified metaphyseal fragment (Fig. 13-51), and the diagnosis may be based only on the clinical sign of tenderness over the epiphyseal fragment. If there is any doubt about the degree of displacement, injection of radiopaque material into the joint may delineate the true nature of the fracture. Alternatively, an MRI may be useful if uncertainty remains.

Fractures of the Coronoid Process

The radiographic diagnosis of this fracture is often difficult because on the lateral view the radial head is superimposed over

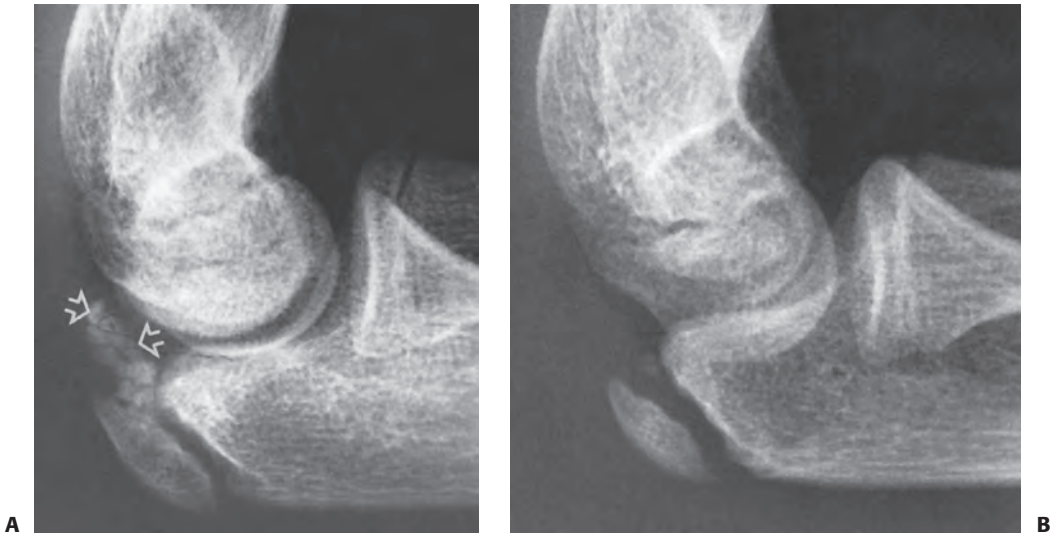

FIGURE 13-51 Apophysitis. **A:** Chronic stimulation with irregular ossification of the articular apophyseal center (*arrows*) in a basketball player who practiced dribbling 3 hours per day. **B:** Normal side for comparison.

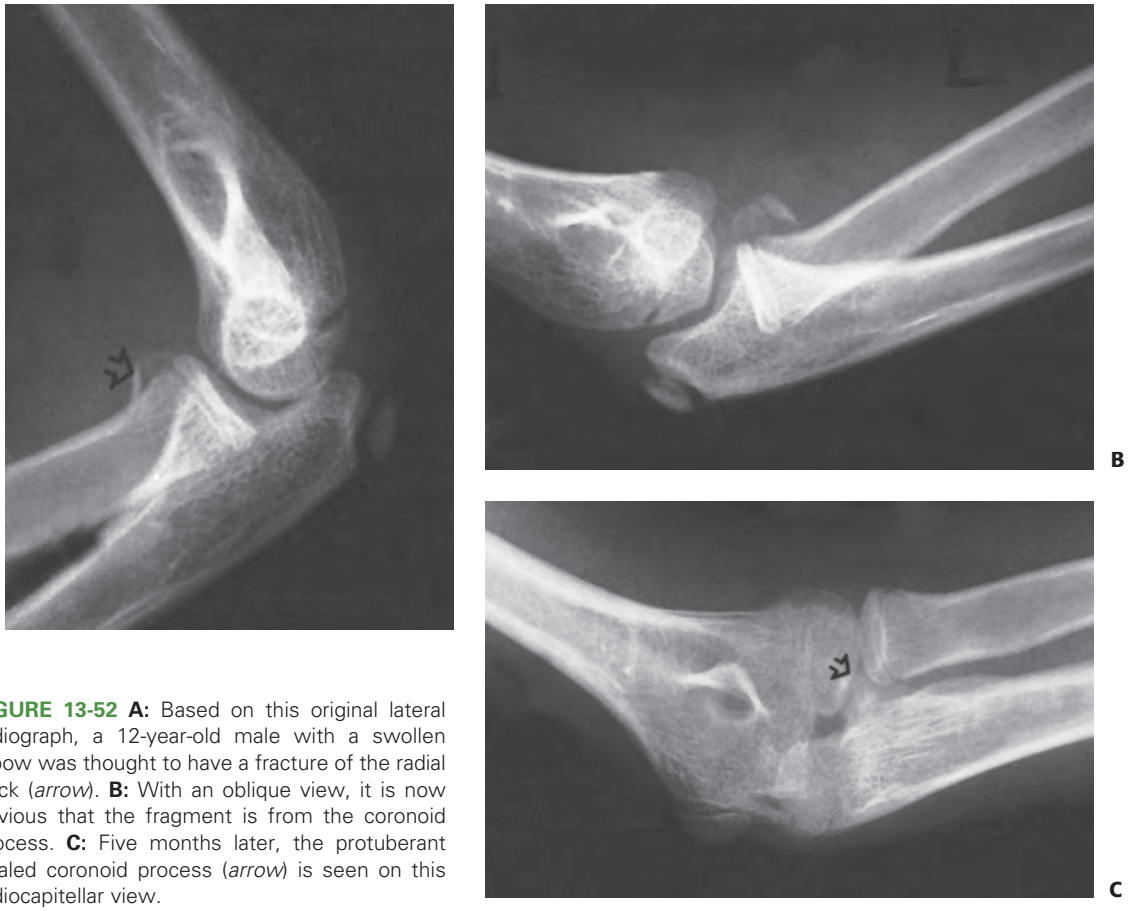

FIGURE 13-52 **A:** Based on this original lateral radiograph, a 12-year-old male with a swollen elbow was thought to have a fracture of the radial neck (*arrow*). **B:** With an oblique view, it is now obvious that the fragment is from the coronoid process. **C:** Five months later, the protuberant healed coronoid process (*arrow*) is seen on this radiocapitellar view.

the coronoid process. Evaluation of a minimally displaced fracture may require oblique views (Fig. 13-52).[102] The radiocapitellar view (Fig. 13-4) shows the profile of the coronoid process.

Classification of Fractures of the Proximal Ulna

Fractures Involving the Proximal Apophysis

Injuries to the apophysis of the olecranon can be classified as one of three types (Table 13-14). Type I is a simple apophysitis in which there is irregularity in the secondary ossification center (Fig. 13-53A).[16,54] The apophyseal line may widen. Type II is an incomplete stress fracture that involves primarily the apophyseal line, with widening and irregularity (Fig. 13-53B). A small adjacent cyst may form, but usually the architecture of the secondary ossification center is normal. These injuries occur primarily in sports requiring repetitive extension of the elbow, such as baseball pitching,[72] tennis,[85] or gymnastics.[54] Type III injuries involve complete avulsion of the apophysis. True apophyseal avulsions (type IIIA) occur in younger children as a fracture through the apophyseal plate (Fig. 13-53A,B). In some of his amputation specimens, Poland[77] found that the proximal apophyseal fragment included the distal tongue, which extended up to the coronoid process. Apophyseal–metaphyseal combination fractures (type IIIB), in which metaphyseal fragments are attached to the apophysis (Fig. 13-53C,D), usually occur in older children. Grantham and Kiernan[35] likened it to a Salter–Harris type II physeal injury. Proximal displacement of the fragment is the only clue seen on a radiograph that a type IIIB fracture has occurred.

Metaphyseal Fractures of the Olecranon

The classification is based on the mechanism of injury, flexion/extension/shear (Table 13-15). This classification system is useful in guiding treatment options.

TABLE 13-14 Classification of Apophyseal Injuries of the Olecranon

Type I: Apophysitis
Type II: Incomplete stress fracture
Type III: Complete fractures
A. Pure apophyseal avulsions
B. Apophyseal–metaphyseal combinations

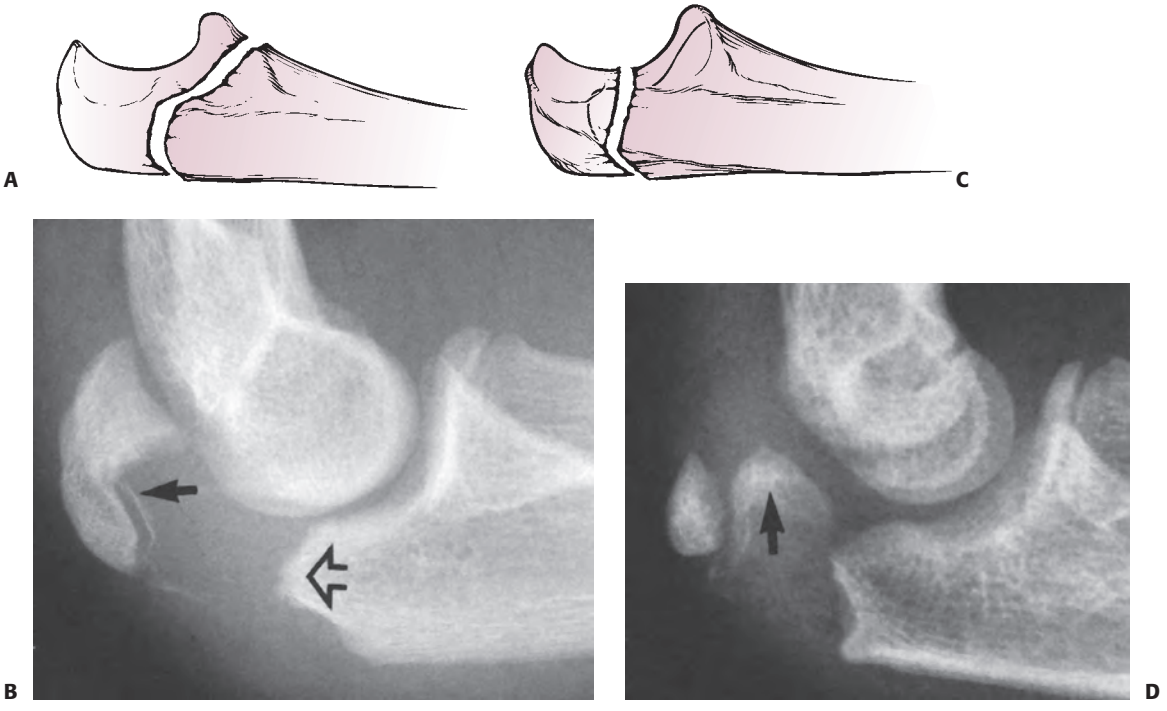

FIGURE 13-53 Apophyseal avulsions. Pure apophyseal avulsions. **A:** The fracture follows the contour of the apophyseal line. **B:** The distal fracture line is in the shape of the apophyseal line (*open arrow*) with a small metaphyseal flake attached to the apophysis (*solid arrow*). Apophyseal–metaphyseal combination. **C:** The fracture line follows the line of tension stress. **D:** A large portion of the metaphysis (*arrow*) is often with the proximal metaphyseal fragment.

Fractures of the Coronoid Process

Regan and Morrey[84] classified coronoid fractures into three types based on the amount of the coronoid process involved (Table 13-16). This classification is useful in predicting the outcome and in determining the treatment. Type I fractures involve only the tip of the process (Fig. 13-48), type II fractures involve more than just the tip but less than 50% of the process (Fig. 13-52), and type III fractures involve more than 50% of the process.

Outcome Measures for Fractures of the Proximal Ulna

The current literature is deficient in the area of functional outcome instruments for fractures of the proximal ulna. The previously published studies on the outcomes of these fractures have used descriptive assessments that are currently nonvalidated techniques. Elbow range of motion after these injuries continues to be a driver of functional outcomes. As such, there is a definite need for both accurate methods of measuring range of motion as well as validated techniques for reporting the results.

Pathoanatomy and Applied Anatomy Relating to Fractures of the Proximal Ulna

Fractures Involving the Proximal Apophysis in Fractures of the Proximal Ulna

At birth, the ossification of the metaphysis of the proximal ulna extends only to the midportion of the semilunar notch. At this age, the leading edge of the metaphysis is usually perpendicular to the long axis of the olecranon (Fig. 13-54A,B). As ossification progresses, the proximal border of the metaphysis becomes

The proximal margin is perpendicular to the long axis of the ulna. **C:** Lateral view of the olecranon at 6 years of age. The proximal margin is oblique. **D:** Secondary ossification center developing in the olecranon in a 10-year-old. A sclerotic border has developed on the proximal metaphyseal margin. **E:** Bipartite secondary ossification center. The larger center is the traction center (*open arrow*). The smaller, more proximal center is the articular center (*white arrow*). **F:** Before complete fusion, a partial line remains (*arrow*), bordered by a sclerotic margin.

more oblique. The anterior margin extends proximally and to three-fourths of the width of the semilunar notch by 6 years of age. At this age, the physis extends distally to include the coronoid process (Fig. 13-53C). A secondary center of ossification occurs in the coronoid process. Just before the development of the secondary center of ossification in the olecranon, the leading edge of the metaphysis develops a well-defined sclerotic margin.[92] Ossification of the olecranon occurs in the area of the triceps insertion at approximately 9 years of age (Fig. 13-54D).[92] Ossification of the coronoid process is completed about the time that the olecranon ossification center appears.[77]

The secondary ossification center of the olecranon may be bipartite (Fig. 13-54E).[79] The major center within the tip of the olecranon is enveloped by the triceps insertion. This was referred to by Porteous[79] as a traction center. The second and smaller center, an articular center, lies under the proximal fourth of the articular surface of the semilunar notch.

Fusion of the olecranon epiphysis with the metaphysis, which progresses from anterior to posterior, occurs at approximately 14 years of age. The sclerotic margin that defines the edge of the metaphysis may be mistaken for a fracture (Fig. 13-54F).[92] Rarely, the physeal line persists into adulthood.[48,75,109] If this does occur, it is usually in athletes who have used the extremity in repetitive throwing activities.[16,85,96,111,122] The chronic tension forces applied across the apophysis theoretically prevent its normal closure.

Occasionally, a separate ossification center called a patella cubiti develops in the triceps tendon at its insertion on the tip of the olecranon.[107] This ossicle is completely separate and can articulate with the trochlea. It is usually unilateral, unlike other persistent secondary ossification centers, which are more likely to be bilateral and familial. Zeitlin[125] believed that the patella cubiti was a traumatic ossicle rather than a developmental variation.

Metaphyseal Fractures of the Olecranon

Because the olecranon is a metaphyseal area, the cortex is relatively thin, allowing for the development of greenstick-type fracture deformities. The periosteum in children is immature and thick, which may prevent the degree of separation seen in adults. Likewise, the larger amount of epiphyseal cartilage in children may serve as a cushion to lessen the effects of a direct blow to the olecranon. In the production of supracondylar fractures, ligamentous laxity in this age group tends to force the elbow into hyperextension when the child falls on the outstretched upper extremity. This puts a compressive force across the olecranon and locks it into the fossa in the distal humerus, where it is protected. An older person, whose elbow does not go into hyperextension, is more likely to fall with the elbow semiflexed. This unique biomechanical characteristic of the child's olecranon predisposes it to different fracture patterns than those in adults.

Fractures of the Coronoid Process

Up to age 6 years, the coronoid process consists of epiphyseal cartilage and physeal cartilage at the distal end of a tongue extending from the apophysis of the olecranon. The coronoid process does not develop a secondary center of ossification, but instead ossifies along with the advancing edge of the metaphysis (Fig. 13-54).

Treatment Options for Fractures of the Proximal Ulna

Nonoperative Treatment of Fractures Involving the Proximal Apophysis in Fractures of the Proximal Ulna

Indications/Contraindications

For apophysitis and undisplaced stress fractures, we ask the patient to cease the offending activity. During this period of rest, the patient should maintain upper extremity strength with a selective muscle exercise program as well as maintain cardiovascular conditioning.

In a recently published series by Rath[82], isolated epiphyseal fractures of the olecranon were met with good long-term outcomes after nonoperative management with up to 2 mm of intrafragmentary displacement (Table 13-17).

Techniques

With minimal displacement of the fracture, satisfactory closed reduction can be obtained with the elbow extended. The elbow can then be immobilized in extension with a long-arm cast.

Outcomes

In general, these injuries recover well and the patients return to full activities quickly. The highest risk group for failure of nonoperative management is the stress injuries.

Nonoperative Treatment of Metaphyseal Fractures of the Olecranon in Fractures of the Proximal Ulna

Indications/Contraindications

Flexion Injuries. Flexion injuries are the most common type of olecranon fractures. In those with minimal displacement, nonoperative treatment is the preferred option. Nonoperative management is contraindicated in displaced olecranon fractures.

Extension Injuries. Treatment of extension injuries requires both adequate realignment of the angulation of the olecranon and treatment of the secondary injuries. Indications for nonoperative treatment in these injuries include the ability to restore anatomic alignment.

Zimmerman[126] reported that the original angulation tends to redevelop in some fractures. If a varus force produced the fracture, the proximal ulna or olecranon may drift back into

TABLE 13-17 Fractures Involving the Proximal Apophysis: Nonoperative Treatment

Indications	Relative Contraindications
Nondisplaced fractures	Displaced fractures
Apophysitis	Open fractures

TABLE 13-18 Metaphyseal Fractures of the Olecranon: Nonoperative Treatment

Indications	Relative Contraindications
Nondisplaced fractures	Nonreducible fractures
Fractures reducible to anatomic alignment by closed methods	Open fractures

varus, which can cause a painful subluxation of the radial head. A secondary osteotomy of the proximal ulna or olecranon may be necessary if the angulation is significant.

Shear Injuries. For anterior shear fractures, the key to management is recognition that the distal fragment is displaced anteriorly and the posterior periosteum remains intact. The intact posterior periosteum can serve as an internal tension band to facilitate reduction (Table 13-18).

Techniques

Flexion Injuries. Most displace minimally and require immobilization with the elbow in no more than 75 to 80 degrees of flexion (Fig. 13-55). Even if the fracture displaces severely, immobilization in full or partial extension usually allows the olecranon to heal satisfactorily.[27,98,126]

Extension Injuries. Often in varus injuries, correction of the alignment of the olecranon also reduces the radial head. The olecranon angulation corrects with the elbow in extension. This locks the proximal olecranon into the olecranon fossa of the humerus so that the distal angulation can be corrected at the fracture site with a valgus force applied to the forearm. Occasionally, in extension fractures, complete separation of the fragments requires open reduction and internal fixation (Fig. 13-56).

Shear Injuries. Some of these fractures are reduced better in flexion, and the posterior periosteum serves as a compressive force to maintain the reduction. Smith[98] reported treatment of this fracture using an overhead sling placed to apply a posteriorly directed force against the proximal portion of the distal fragment. The weight of the arm and forearm helps supplement the tension-band effect of the posterior periosteum.

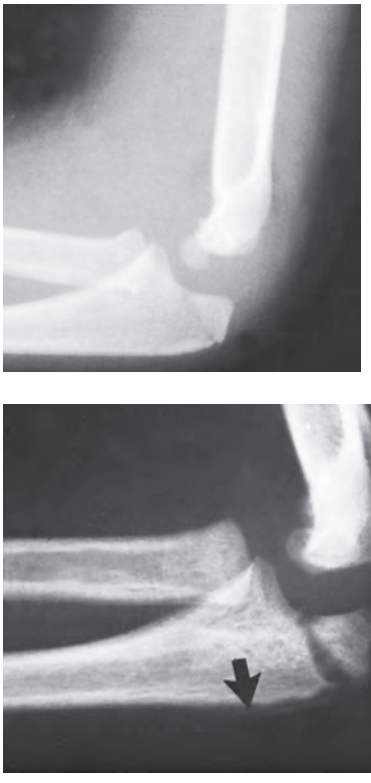

FIGURE 13-55 Simple immobilization of a flexion injury. **A:** Injury film, lateral view, showing minimal displacement. **B:** Three weeks later, the fracture has displaced further. Periosteal new bone is along the posterior border of the olecranon (*arrow*). Healing was complete with a normal range of motion. (Courtesy of Jesse C. DeLee, MD.)

Outcomes

The majority of nondisplaced proximal ulna fractures can be treated successfully with nonoperative methods. However, these injuries need to be followed closely to ensure maintenance of alignment. Any loss of reduction/alignment should be recognized and lead to surgical management.

FIGURE 13-56 Open reduction of a valgus extension injury. **A:** Anteroposterior injury film shows complete displacement of the radial head. **B:** Lateral view also shows the degree of displacement of the olecranon fracture. This patient required surgical intervention with internal fixation to achieve a satisfactory reduction.

Nonoperative Treatment of Fractures of the Coronoid Process in Fractures of the Proximal Ulna

Indications/Contraindications

The degree of displacement or the presence of elbow instability guides the treatment. The associated injuries also are a factor in treatment. Regan and Morrey[83,84] treated types I and II fractures with early motion if there were no contradicting associated injuries (Table 13-19).

TABLE 13-19 Fractures of the Coronoid Process: Nonoperative Treatment

Indications	Relative Contraindications
Elbow stability	Elbow instability
Mild displacement (Types 1 and 2)	Type 3 fractures

Techniques

For initial immobilization, if the fracture is associated with an elbow dislocation, the elbow is placed in approximately 100 degrees of flexion, with the forearm in full supination.[68] Occasionally, in partial avulsion fractures, the fracture reduces more easily with the elbow in extension. In these rare cases, the brachialis muscle may be an aid in reducing the fragment in extension.[67]

Outcomes

Regan and Morrey[84] found that the elbow often was unstable in type III fractures, and they secured these fractures with internal fixation. They had satisfactory results with type I and II fractures, but in only 20% of type III fractures were the results satisfactory.

Operative Treatment of Fractures Involving the Proximal Apophysis and Olecranon Metaphysis in Fractures of the Proximal Ulna

Indications/Contraindications
