FIGURE 27-17 A: This high-energy, midshaft femur fracture was treated with titanium nails. **B:** A large butterfly fragment was dislodged during nail insertion. Because the fracture is now length-unstable, the surgeon wisely chose to protect the child for a few weeks in a one-leg spica cast. **C:** The fracture healed and excellent alignment. Note how the nails have wound around each other. This can make nail removal more difficult.

flexible nailing, but the risk of shortening and angular malunion is greater,[187] and supplemental immobilization during early healing phase may be valuable.

Initial radiographs should be studied carefully for fracture lines that propagate proximally and distally, and might be otherwise unnoticed (Fig. 27-17). Although it is technically difficult to obtain satisfactory fixation with a retrograde technique when the fracture is near the distal metaphysis, a recent biomechanical study[138] demonstrated that retrograde insertion provides better stability than antegrade insertion for distal femoral shaft fractures. Nail size is determined by measuring the minimum diameter of the diaphysis, then multiplying by 0.4 to get nail diameter. For instance, if the minimum diameter of the diaphyseal canal is 1 cm, the 4-mm nails are used. Always choose the largest possible nail size that permits two nails to fit medullary canal.

Flexible nailing is most effectively performed on a fracture table, with a fracture reduced to near-anatomic position before incisions are made. Alternatively, a fluoroscopic table can be used, but the surgeon should assure that a reduction can be obtained prior to the start of the procedure, and extra assistance may be necessary.

The procedure described is with titanium elastic rods, but other devices are available and can be used with slight variations in procedure.

Rod Bending. The distance from the top of the inserted rod to the level of the fracture site is measured, and a gentle 30-degree bend is placed in the nail. The technique of elastic fixation of femoral fractures as described by Ligier et al.[120] requires that a bend be placed in the midportion of the rod at the level of the fracture site. This produces a spring effect (Fig. 27-18) that adds to the rigidity of the fracture fixation. The spread of the rods in opposite directions provides a "prestressed" fixation, which increases resistance to bending. The opposite bends of the two rods at the level of the fracture significantly increase resistance to varus and valgus stress, as well as torsion. A second bend is sometimes helpful near the entering tip of the nail to facilitate clearance of the opposite cortex during initial insertion. Based on the report by Sagan et al.,[178] sagittal plane configuration should be considered as well. An apex-posterior bend in one of the nails, with the nail shoe pointing anteriorly in the proximal femur, resists apex-anterior malunion.

Most pediatric femur fractures are fixed with 4-mm diameter nails; in smaller children, 3.5-mm nails may be necessary. Two nails of similar size should be used, and they should be as large as possible. Using nails that are too small, or mismatched in size, increases the rate of complications.[152] It is very unusual to use nails smaller than 3.5 mm, except in the very youngest, smallest children.

Retrograde Insertion. After the child is placed on the fracture table and the fracture reduced as much as possible, the leg is prepared and draped with the thigh (hip to knee) exposed. The image intensifier is used to localize the placement of skin incisions by viewing the distal femur in the AP and lateral planes.

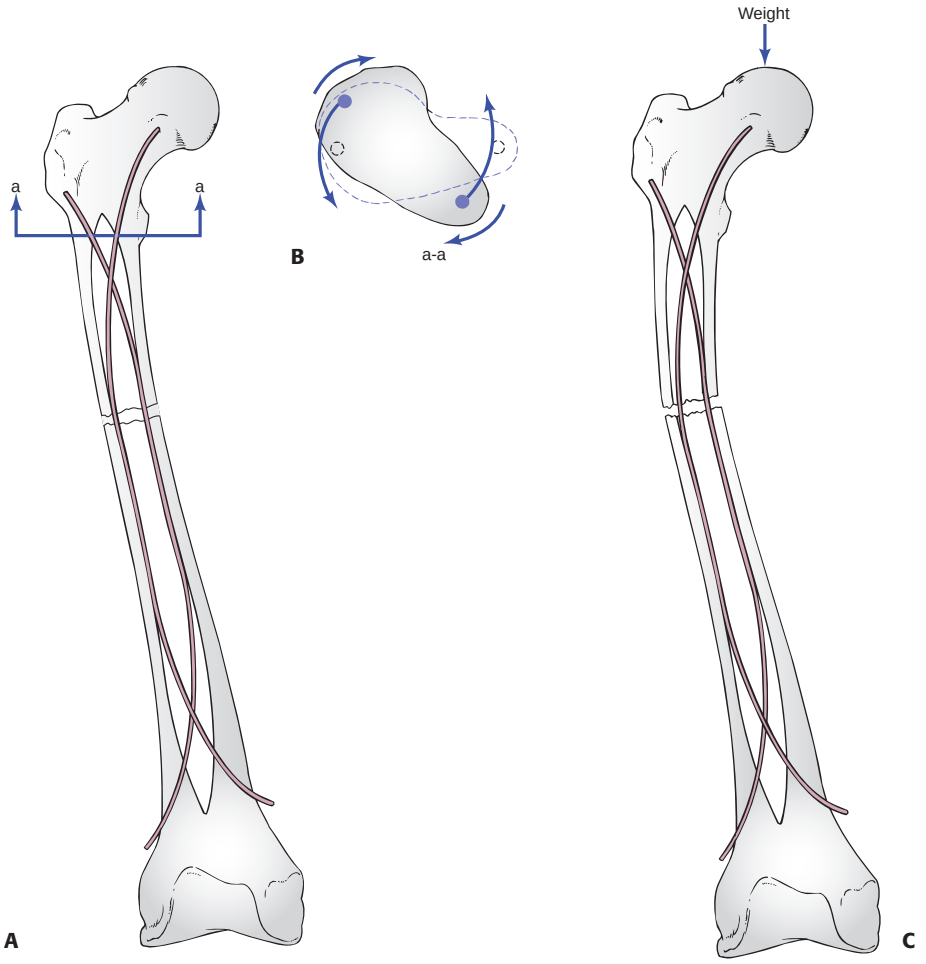

FIGURE 27-18 **A:** Stability from flexible rods comes from proper technique. **B:** Torsional stability results from divergence of the rods in the metaphysis. **C:** Resistance to sagittal and coronal bending results from spreading of the prebent rods through the diaphysis, as well as the size and material properties of the rods. Elastic rods return to their predetermined alignment when loaded unless plastic deformation occurs.

Incisions are made on the medial and lateral side distal to the insertion site in the bone. The proximal end of the 2- to 3-cm incision should be at or just distal to the level of the insertion site, which is about 2.5 to 3 cm proximal to the distal femoral physis (Fig. 27-19). A 4.5-mm drill bit or awl is used to make a hole in the cortex of the bone. The distal femoral metaphysis is opened 2.5 cm proximal to the distal femoral physis using a drill or awl. The drill is then steeply angled in the frontal plane to facilitate passage of the nail through the dense pediatric metaphyseal bone.

Upon insertion the rod glances off the cortex as it advances toward the fracture site. Both medial and lateral rods are

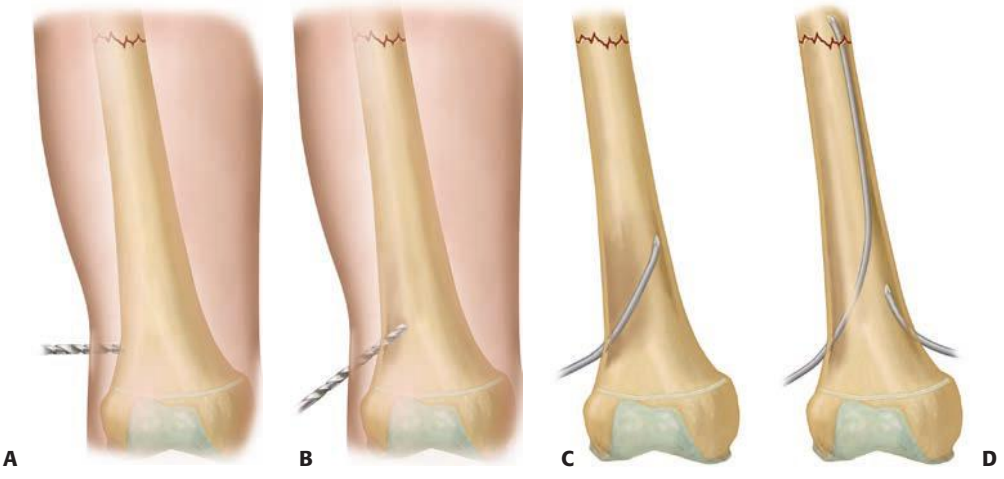

FIGURE 27-19 **A:** A drill bit slightly larger than the nail that will be implanted is used to broach the cortex. The drillbit can initially be placed in a perpendicular orientation. **B:** once the cortex is broached, the drill bit is dropped to a sharply oblique angle and the medullary canal is entered. **C:** The contoured nails inserted following the track of the drillbit. The angle insertion is sharply oblique so that the nail tip bounces off the opposite cortex and precedes up the canal. **D:** After the first nail is just across the fracture site, the second nail is inserted in a similar fashion.

inserted to the level of the fracture. At this point, the fracture reduction is optimized if necessary with a radiolucent fracture reduction tool which holds the unstable femoral fracture in the appropriate position to allow fixation. The surgeon judge which nail will be most difficult to get across the fracture site, and pass it first. If the easier nail is passed first, it may stabilize the two fragments such that the second, more difficult nail, cannot be passed easily. The two nails then are driven into the proximal end of the femur, with one driven toward the femoral neck and the other toward the greater trochanter. On the lateral, one nail should have its tip pointing anteriorly. When passing the second nail across the fracture site and rotating it, care must be taken not to wind one rod around the other. After the nails are driven across the fracture and before they are seated, fluoroscopy is used to confirm satisfactory reduction of the fracture and to ensure that the nails did not comminute the fracture as they were driven into the proximal fragment.

The nails are pulled back approximately 2 cm, the end of each nail is cut, then driven back securely into the femur. The end of the nail should lie adjacent to the bone of the distal femoral metaphysis, exposed just enough to allow easy removal once the fracture is healed. Do not bend the exposed to distal tip of the nail away from femoral metaphysis as this will irritate surrounding tissues.

A proximal insertion site can also be used. An insertion site through the lateral border of the trochanter avoids creating the stress riser that results from subtrochanteric entry.

Technique Tip. Mazda et al.[132] emphasized that for insertion of titanium elastic nails, the nails have to be bent into an even curve over the entire length, and the summit of the curve must be at the level of the fracture or very close to it in comminuted fractures. The depth of curvature should be about three times the diameter of the femoral canal. Flynn et al.[58] also stressed the importance of contouring both nails with similar gentle curvatures, choosing nails that are 40% of the narrowest diaphyseal diameter and using medial and lateral starting points that are at the same level in the metaphysis.

In length-unstable fractures, an endcap has been shown to confer increased stability that might lessen the risk of shortening[208] and nail backout.

Postoperative Management. A knee immobilizer is beneficial in the early postoperative course to decrease knee pain and quadriceps spasm. When the flexible nailing technique is used for length-unstable fracture, walking (or one leg) spica is recommended, generally for about 4 to 6 weeks until callus is visible on radiographs. For length-stable fractures, touch-down weight bearing could begin as soon as the patient is comfortable. Gentle knee exercises and quadriceps strengthening can be begun, but there should be no aggressive passive motion of the knee, which increases the motion at the fracture site and increases quadriceps spasm. Postoperative knee motion does return to normal over time. Full weight bearing generally is tolerated by 6 weeks. Ozdemir et al.[160] recommended the use of postoperative functional bracing, demonstrating effectiveness in a group of patients treated with elastic rodding. Such postoperative support may occasionally be required, but in most cases it appears not to be needed.

The nails can be removed 6 to 12 months after injury when the fracture is fully healed, usually as an outpatient procedure.

Complications of Flexible Intramedullary Nailing

Complications are relatively infrequent after flexible intramedullary nailing. In 351 fractures reported in seven studies[10,31,53,80,120,123,132] one nonunion, one infection, and no occurrence of osteonecrosis were reported. Approximately 12% of patients had malunions, most often mild varus deformities, and approximately 3% had clinically significant leg length discrepancies from either overgrowth or shortening. A recent study noted overgrowth of more than 1 cm in 8.2% of preschool children treated with titanium elastic nailing.[149] This is a much higher rate of overgrowth than seen in older children, suggesting the technique should be used infrequently in preschool children. Mazda et al.[132] pointed out a technique-related complication that occurred in 10 of their 34 patients: Rods were left too long and caused painful bursae and limited knee flexion. All 10 patients had the nails removed 2 to 5 months after surgery. Flexible nails inserted in a retrograde fashion may also penetrate into the knee joint, causing an acute synovitis[174] In a multicenter study[58] that included 58 femoral fractures stabilized with titanium elastic nails, irritation of the soft tissue near the knee by the nail tip occurred in four patients (7%), leading to a deeper infection in two patients. This study also reported one refracture after premature nail removal, leading to a recommendation that nail removal be delayed until callus is solid around all cortices and the fracture line is no longer visible. Ozdemir et al.[160] measured overgrowth with a scanogram and found that the average increase in length was 1.8 mm, suggesting that significant femoral overgrowth is not seen with this method of treatment.

Flynn et al.[59] compared traction and spica cast with titanium elastic nails for treatment of femoral fractures in 83 consecutive school-aged children. The three unsatisfactory results were treated with traction followed by casting. The overall complication rate was 34% in the traction group and 21% in the elastic nail group.

An international multicenter study focused on factors that predict a higher rate of complications after flexible nailing of pediatric femoral shaft fractures.[20] Analyzing 234 fractures in 229 patients from six different Level 1 trauma centers, the authors found significantly more problems in older, heavier children. A poor outcome was five times more likely in patients who weigh more than 108.5 lb. A poor outcome was also almost four times more likely in patients older than 11 years old. The authors concluded that results were generally excellent for titanium elastic nailing, but poor results were more likely in children older than 11 years and heavier than 50 kg. Ho et al.[87] reported a 34% complication rate in patients 10 years and older, but only a 9% complication rate in patients younger than 10 years, emphasizing the concept that complications of flexible nailing are higher in older, heavier children.

Salem and Keppler[179] noted a 47% incidence of torsional malunion ≥15 degrees in the patients they treated at one center in Germany. These authors could not determine if the torsional malunion was due to instability after fixation, or faulty surgical

technique. In either case, the findings call attention to the need for rotational assessment after fixation.

External Fixation for Femoral Shaft Fractures

External fixation of femoral shaft fractures offers an efficient, convenient method to align and stabilize the fractured pediatric femur. It is the method of choice when severe soft tissue injury precludes nailing or submuscular plating, when a fracture shortens excessively in a spica cast, or as part of a "damage-control" strategy.[147] In head-injured or multiply injured patients and those with open fractures, external fixation offers an excellent method of rapid fracture stabilization. It is also valuable for very proximal or distal fractures, where options for flexible nailing, plating, or casting are limited. External fixation is particularly valuable for the benign pathologic fracture (e.g., through a nonossifying fibroma) at the distal metaphyseal–diaphyseal junction (Fig. 27-20), where the fracture will heal rapidly, but angular malunion must be avoided.

Aronson and Tursky[6] reported their early experience with 44 femoral fractures treated with primary external fixation and early weight bearing. Most patients returned to school by 4 weeks after fracture and had full knee motion by 6 weeks after the fixator was removed. In this early study, end-on alignment was the goal and overgrowth was minimal. Recently, Matzkin et al.[131] reported on a series of 40 pediatric femur fractures treated with external fixation. Seventy-two percent of their series were dynamized prior to external fixator removal, and their refracture rate was only 2.5%. They had no overgrowth, but one patient ended up 5 cm short.

Following early enthusiasm for the use of external devices, the last decade saw waning interest in their use because of complications with pin track infections, pin site scarring, delayed union, and refracture. These complications, coupled with the very low complication rate from flexible nailing, led to a decline of external fixation for pediatric femoral shaft fractures. Data from comparison studies also contributed to the change. Bar-On et al.[10] compared external fixation with flexible intramedullary rodding in a prospective randomized study. They found that the early postoperative course was similar but that the time to return to school and to resume full activity was less with intramedullary fixation. Muscle strength was better in the flexible intramedullary fixation group at 14 months after fracture. Parental satisfaction was also significantly better in the flexible intramedullary rodding group. Bar-On et al.[10] recommended that external fixation be reserved for open or severely comminuted fractures.

Frame Application: Technique

During preoperative planning, the fracture should be studied carefully for comminution, or fracture lines that propagate proximally or distally. The surgeon should assure that the fixator devices available are long enough to span the distance between the optimal proximal and distal pin insertion sites.

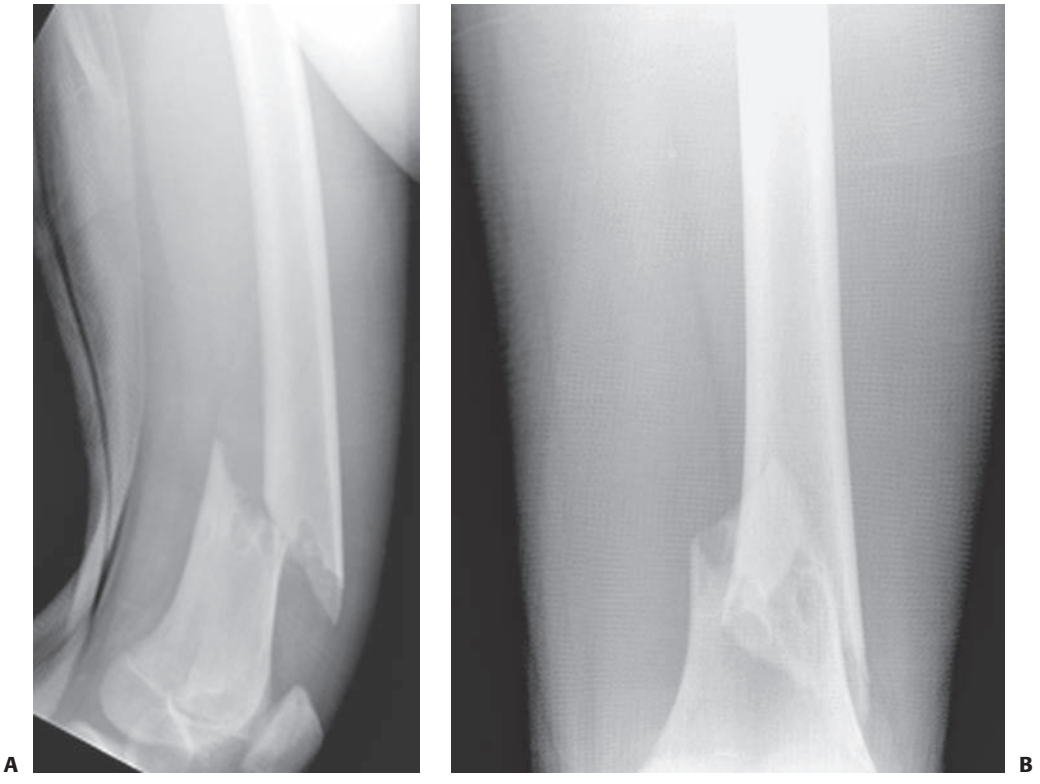

FIGURE 27-20 AP **(A)** and lateral **(B)** radiographs a low-energy short oblique fracture through a fibrous cortical defect in the distal femur; this type of fracture is not unusual. The surgeon judged that there was enough distance between the fracture site and the growth plate to allow external fixation.

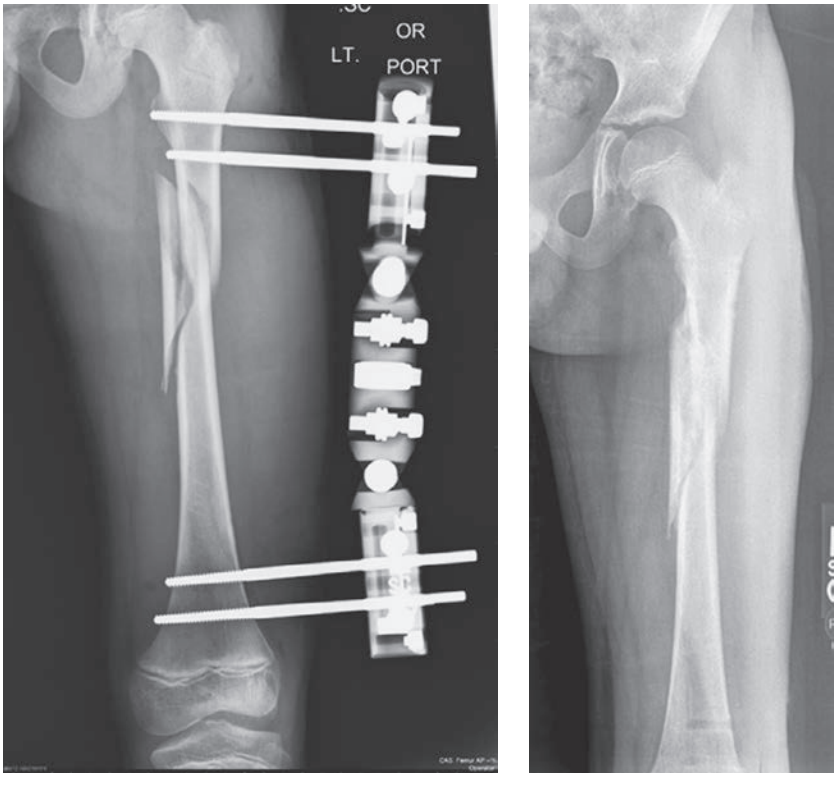
C D

FIGURE 27-20 (*continued*) AP **(C)** and lateral **(D)** X3 weeks after external fixation show early callus, slight varus on the AP, and good alignment on the lateral. The external fixation was removed shortly after this x-ray and the child was placed in a long leg cast, with weight bearing is tolerated.

As in the elastic nailing technique, either the fracture table or radiolucent table can be used, although the fracture table is much more efficient, as an anatomic reduction can be obtained before prepping and draping. First we try to reduce the fracture both in length and alignment. If the fracture is open, it should be irrigated and debrided before application of the external fixation device. With the fracture optimally aligned, fixation is begun. The minimal and maximal length constraints characteristic of all external fixation systems must be kept in mind, and the angular adjustment intrinsic to the fixation device should be determined. Rotation is constrained with all external fixation systems once the first pins are placed. That is, if parallel pins are placed with the fracture in 40 degrees of malrotation, a 40-degree malalignment will exist. Rotational correction must be obtained before placing the pins in the proximal and distal shafts of the femur (Fig. 27-21).

Application of the fixator is similar no matter what device is chosen. One pin is placed proximally in the shaft, and another pin is placed distally perpendicular to the long axis of the shaft. Alignment is based on the long axis of the shaft, rather than to the joint surface. Rotation should be checked before the second pin is placed because it constrains rotation but not angulation or length. After pins are correctly placed, all fixation nuts are secured and sterile dressings are applied to pins.

Technique Tips. Pin sizes vary with manufacturers, as do drill sizes. In general the pins are placed through predrilled holes to avoid thermal necrosis of bone. Sharp drills should be used. The manufacturer's recommendation for drill and screw sizes should be checked before starting the procedure. Some



A B

FIGURE 27-21 **A:** This proximal spiral femur fracture was deemed length unstable and a poor candidate for titanium elastic nails. The surgeon chose an external fixator, rather than a plate. **B:** Eight weeks after injury, the fracture is healing in excellent alignment and there is good early callous. Fixator removal is easier than plate removal.

self-drilling and self-tapping pins are available. At least two pins should be placed proximally and two distally. An intermediate or auxiliary pin may be beneficial.

Postoperative Care. The key to preventing pin site irritation is avoiding tension at the skin–pin interface. We recommend that our patients clean their pin sites daily with soap and water, perhaps as part of regular bath or shower. Showering is allowed once the wound is stable and there is no communication between the pin and the fracture hematoma. Antibiotics are commonly used at some point while the fixator is in place, because pin site infections are common and easily resolved with antibiotic treatment, usually cephalosporin.

There are two general strategies regarding fixator removal. The external fixation device can be used as "portable traction." With this strategy, the fixator is left in place until early callus stabilizes the fracture. At this point, usually 6 to 8 weeks after injury, the fixator device is removed and a walking spica cast is placed. This minimizes stress shielding from the fixator, and allows time for the pin holes to fill in while the cast is on. The alternative, classic strategy, involves using the fixator until the fracture is completely healed. Fixator dynamization, which is difficult in small, young children, is essential for this classic strategy. The surgeon should not remove the device until three or four cortices show bridging bone continuous on AP and lateral x-rays, typically 3 to 4 months after injury.

Complications of External Fixation

The most common complication of external fixation is pin track irritation/infection, which has been reported to occur in up to 72% of patients.[145] This problem generally is easily treated with oral antibiotics and local pin site care. Sola et al.[191] reported a decreased number of pin track infections after changing their pin care protocol from cleansing with peroxide to simply having the patient shower daily. Superficial infections should be treated aggressively with pin track releases and antibiotics. Deep infections are rare, but if present, surgical debridement and antibiotic therapy are usually effective. Any skin tenting over the pins should be released at the time of application or at follow-up.

In a study of complications of external fixators for femoral fractures, Gregory et al.[65] reported a 30% major complication rate and a high minor complication rate. Among the major complications were five refractures or fractures through pin sites. Another comprehensive study of external fixation complications[32] found an overall rate of refracture of 4.7%, with a pin track infection rate of 33.1%. Skaggs et al.[189] reviewed the use of external fixation devices for femoral fractures and found a 12% rate of secondary fractures in 66 patients. Fractures with fewer than three cortices with bridging callus at the time of fixator removal had a 33% risk of refracture, whereas those with three or four cortices showing bridging callus had only a 4% rate of refracture. Other reports in the literature with smaller numbers, but still substantial experience, document refracture rates as high as 21.6% with more significant complications.[45,49,66,91,145,166,185] Despite the complications, patients and treating physicians have found wound care and ability to lengthen through the fracture to be of great benefit of external fixation.

Although joint stiffness has been noted in older patients treated with external fixation, it is relatively uncommon in children with femoral fractures unless major soft tissue injury is present.[52]

Rigid Intramedullary Rod Fixation for Femoral Shaft Fractures

With reports by Beaty et al.[12] and others in the early 1990s alerting surgeons that antegrade intramedullary nailing can be complicated by osteonecrosis of the proximal femur, flexible nailing (either antegrade or retrograde) quickly became more popular than standard locked, antegrade rigid intramedullary nailing. Recently, however, locked antegrade femoral nailing for pediatric femur fractures has enjoyed a resurgence of interest with the introduction of newer generation implants that allow a very lateral trochanteric entry point. These newer implant systems avoid a piriformis entry site, reducing (but perhaps not completely eliminating) the risk of osteonecrosis.[88,107] Antegrade-locked intramedullary fixation is particularly valuable for adolescent femur fractures. Comparative studies by Reeves et al.[169] and Kirby et al.,[108] as well as retrospective reviews of traction and casting, suggest that femoral fractures in adolescents are better treated with intramedullary fixation[12,29,45,63,64,68,84,103,108,120,199,212,213] than with traditional traction and casting (Table 27-3). Keeler et al.[107] reported on 80 femur fractures in patients 8 to 18 years old treated with a lateral trochanteric entry starting point. There was no osteonecrosis, no malunion, and a 2.5% infection rate.

Length-unstable adolescent femur fractures benefit from interlocking proximally and distally to maintain length and rotational alignment.[13,24,73] Beaty et al.[12] reported the use of interlocking intramedullary nails for the treatment of 31 femoral shaft fractures in 30 patients 10 to 15 years of age. All fractures united, and the average leg length discrepancy was 0.51 cm. No angular or rotational malunions occurred. All nails were removed at an average of 14 months after injury; no refracture or femoral neck fracture occurred after nail removal. One case of osteonecrosis of the femoral head occurred, which was thought to be secondary to injury to the ascending cervical artery during nail insertion.

Reamed antegrade nailing in children with an open proximal femoral physis must absolutely avoid the piriformis fossa, because of the risk of proximal femoral growth abnormalities,[167] the risk of osteonecrosis of the femoral head,[12,141,165,196] the size of the proximal femur, and the relative success of other treatment methods. However, Maruenda-Paulino et al.[129] reported good results using 9-mm Kuntscher rods in children 7 to 12 years of age, and Beaty et al.[12] reported the use of pediatric "intermediate" interlocking nails for femoral canals with diameters as small as 8 mm. Townsend and Hoffinger[202] and Momberger et al.[146] published reviews of trochanteric nailing in adolescents with very good results. The combined series includes 82 patients of age 10 to 17+ 6 years with no reported cases of osteonecrosis and no significant alteration in proximal femoral anatomy.

TABLE 27-3 Results of Treatment of Femoral Shaft Fractures in Adolescents

Series	No. of Patients	Average Age (Range) in Years	Treatment	Results and Complications (*n*)
Kirby et al.[108]	13	12 + 7 (10 + 11–15 + 6)	Traction + cast	Short >2.5 cm (2) Significant residual angulation (4)
	12	12 + 0 (10 + 10–15 + 7)	Intramedullary nailing	No overgrowth No significant residual angulation
Ziv et al.[213]	17	8 + 3 (6–12)	Intramedullary nailing (9 Rush pins, 9 Kuntscher nails)	No leg length discrepancy >1 cm Change in AID 0.5–1 cm = 3 with Kuntscher nails
Reeves et al.[169]	41	12 + 4 (9 + 9–16 + 4)	Traction + cast	Delayed union (4) Malunion (5) Growth disturbance (4) Psychotic episodes (2)
	49	14 + 11 (11–16 + 10)	Intramedullary nailing	No infection, nonunion, or malunion
Beaty et al.[12]	30	12 + 3 (10–15)	Intramedullary nailing	Overgrowth >2.5 cm (2) AVN femoral head (1)
Aronson et al.[6]	42	9 + 7 (2 + 5–17 + 8)	External fixation	8.5% pin infection 10% cast or reapplication
Ligier et al.[120]	123	10 (5–16)	Flexible IM rods	1 infection 13 wound ulcerations 2 LLD >2 cm
Mazda et al.[132]	34	9.5 (6–17)	Flexible IM rods	1–1.5 cm overgrowth (3) 1–15-degree malalignment (2)

LLD, leg length discrepancy.

Open fractures in older adolescents can be effectively treated with intramedullary rodding, either as delayed or primary treatment, including those caused by gunshot wounds and high-velocity injuries.[16,200] Antegrade intramedullary rod insertion maintains length, prevents angular malunion and nonunion, and allows the patient to be rapidly mobilized and discharged from the hospital. However, other techniques with fewer potential risks should be considered.

Retrograde rodding of the femur has become an accepted procedure in adults.[159,171] In a large patient approaching skeletal maturity (bone age >16 years) but with an open proximal femoral physis and an unstable fracture pattern, one might consider this treatment as a way to avoid the risk of osteonecrosis yet stabilize the fracture. If growth from the distal femur is predicted to be less than 1 cm, leg length inequality should not be a problem. Ricci et al.[171] have shown that the complication rate with this technique compares favorably to that of antegrade nailing, with a higher rate of knee pain but a lower rate of hip pain. The malunion rate was slightly lower with retrograde rodding than with antegrade rodding of the femur.

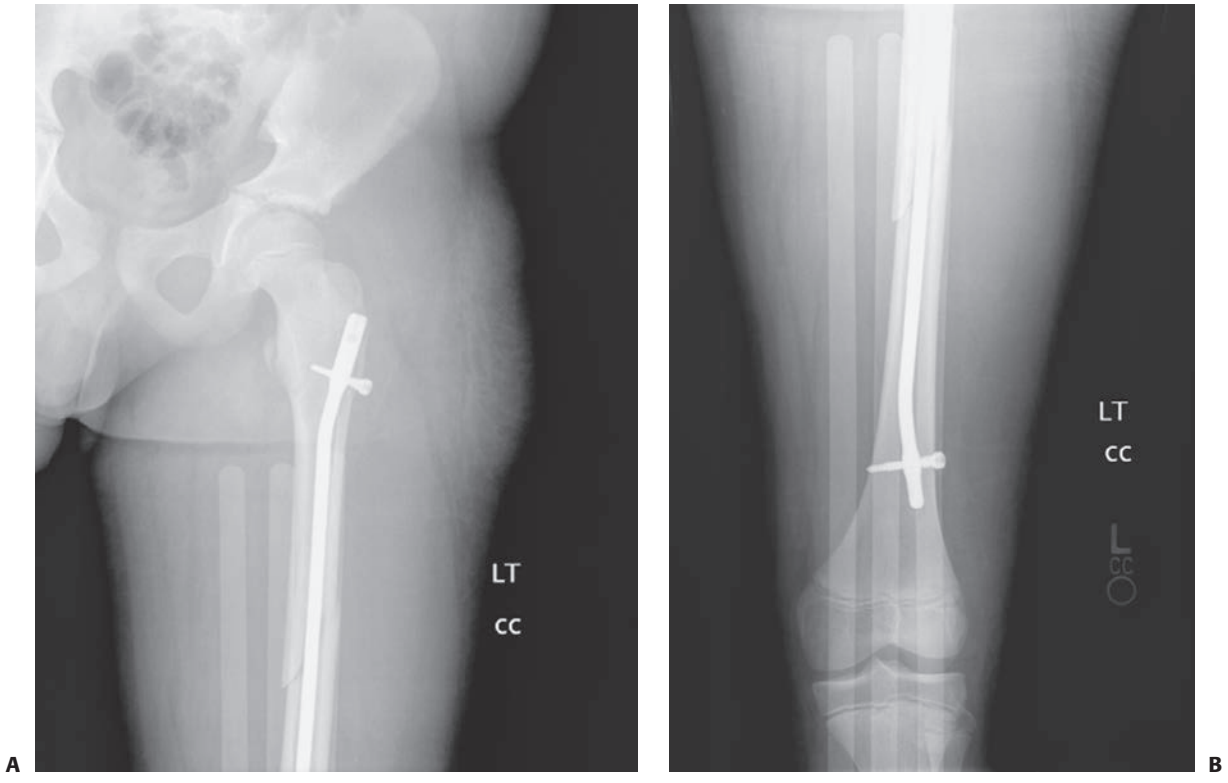
Antegrade Transtrochanteric Intramedullary Nailing: Technique

The patient is placed either supine or in the lateral decubitus position on a fracture table. The upper end of the femur is approached through a 3-cm longitudinal incision proximal that allows access to the lateral trochanteric entry point. The skin incision can be precisely placed after localization on both the AP and lateral views. Dissection should be limited to the lateral aspect of the greater trochanter, avoiding the piriformis fossa. This prevents dissection near the origin of the lateral ascending cervical artery medial to the piriformis fossa. The rod should be inserted through the lateral aspect of the greater trochanter. In children and adolescents, it's preferable to choose the smallest implant, with the smallest diameter reaming, to avoid damage to the proximal femoral insertion area.

The technique for reaming and nail insertion varies according to the specifics of the implant chosen. In general, the smallest rod that maintains contact with the femoral cortices is used (generally 9 mm or less) and is locked proximally and distally (Fig. 27-22). Only one distal locking screw is necessary, but two can be used.[106] Rods that have an expanded proximal cross section should be avoided, as they require excessive removal of bone from the child's proximal femur. The proximal end of the nail should be left slightly long (up to 1 cm) to make later removal easier. The rod chosen should be angled proximally and specifically designed for transtrochanteric insertion (Fig. 27-23).

Technique Tips. Dissection should be limited to the lateral aspect of the greater trochanter (Fig. 27-24), without extending to the capsule or midportion of the femoral neck. Some systems provide a small diameter, semiflexible tube that can be inserted up to the fracture site after initial entry-site reaming. This tube is extremely valuable in manipulating the flexed, abducted proximal fragment in proximal-third femur fractures.

Postoperative Management. Nails can be removed 9 to 18 months after radiographic union to prevent bony overgrowth



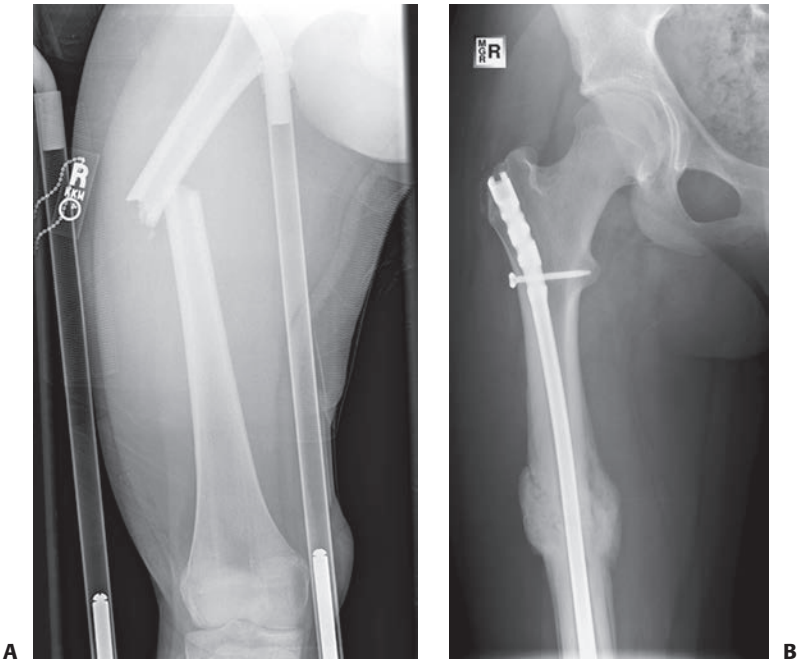
A B

FIGURE 27-22 AP **(A)** and lateral **(B)** radiographs immediately after internal fixation of the midshaft femur fracture in a 13-year old with a pediatric locking nail that permits easy lateral entry, and requires minimal reaming of the child's proximal femur.

over the proximal tip of the nail. We do not routinely remove locked antegrade nails from our teenage patients unless they are symptomatic or request removal for another reason. Dynamization with removal of the proximal or distal screw generally is not necessary.

Complications of Locked Intramedullary Nailing

Although good results have been reported with locked intramedullary nails and patient satisfaction is high, problems with proximal femoral growth, osteonecrosis, and leg length



A B

FIGURE 27-23 Preoperative **(A)** and postoperative **(B)** images showing the use of a newer generation lateral entry nail to treat a proximal third femur fracture in a 14-year-old girl.

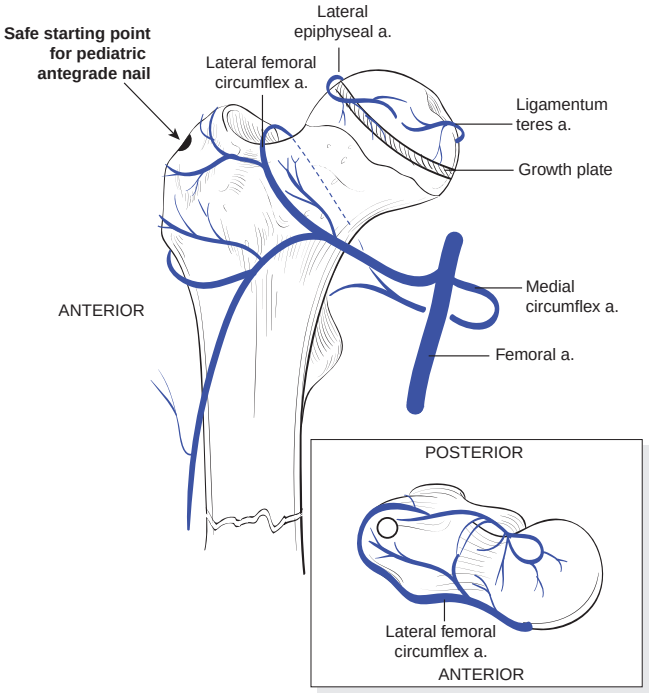


FIGURE 27-24 Trochanteric entry point for intramedullary nail indicated with *arrow*. Entry here with smaller diameter nails limits the risk of AVN and ensures no awl in the piriformis fossa. (Reprinted from Skaggs D, Flynn J. Trauma about the pelvis/hip/femur. *Staying Out of Trouble in Pediatric Orthopaedics*. Philadelphia, PA: Lippincott Williams & Wilkins; 2006:109.)

discrepancy cannot be ignored. Fortunately, the osteonecrosis rate with newer lateral trochanteric entry nails is lower.

In a series of intramedullary nailing of 31 fractures, Beaty et al.[12] reported one patient with segmental osteonecrosis of the femoral head (Fig. 27-25), which was not seen on x-ray until 15 months after injury. Kaweblum et al.[106] reported a patient with osteonecrosis of the proximal femoral epiphysis after a greater trochanteric fracture, suggesting that the blood supply to the proximal femur may have been compromised by vascular disruption at the level of the greater trochanter during rod insertion. Other researchers have reported single patients with osteonecrosis of the femoral head after intramedullary nailing.[141,158,196] A poll of the members of the Pediatric Orthopaedic Society disclosed 14 patients with osteonecrosis in approximately 1,600 femoral fractures. Despite the use of a "safe" transtrochanteric insertion site for antegrade femoral rodding, a case of osteonecrosis has been reported. Buford et al.[27] showed in their MRI study of hips after antegrade rodding that subclinical osteonecrosis may be present. Antegrade rodding through the trochanter or the upper end of the femur appears to be associated with a risk of osteonecrosis in children with open physes, regardless of chronologic age. Chung[34] noted the absence of transphyseal vessels to the proximal femoral epiphysis and demonstrated that the singular lateral ascending cervical artery predominantly supplies blood to the capital femoral epiphysis (Fig. 27-26). He stated that all of the epiphyseal and metaphyseal branches of the lateral ascending cervical artery originate from a single stem that crosses the capsule at the trochanteric notch. Because the space between the trochanter and

(*continues*)

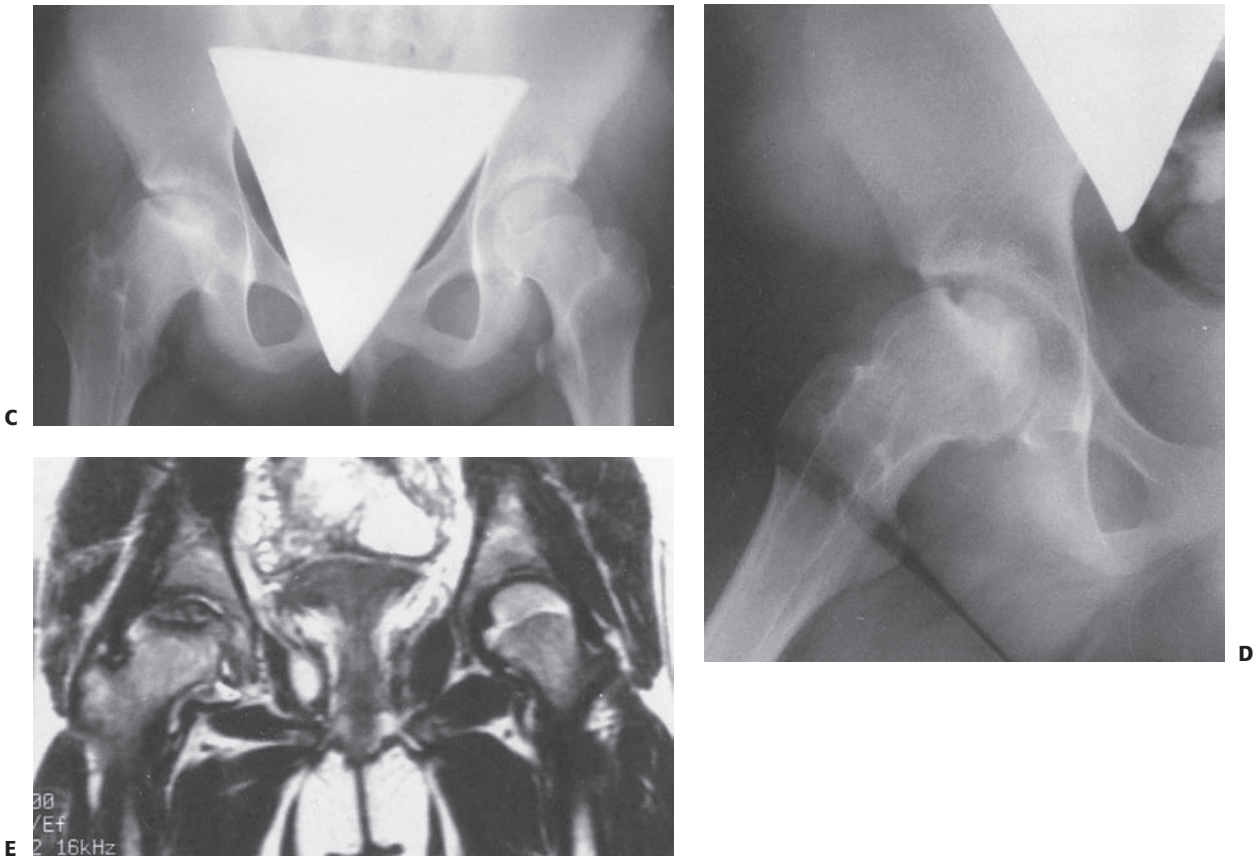

FIGURE 27-25 (*continued*) **C:** Eight months after injury, fracture is healed; note early signs of osteonecrosis of right femoral head. **D:** Fifteen months after injury, segmental osteonecrosis of the femoral head is evident on x-rays. **E:** Magnetic resonance image shows extent of osteonecrosis of right femoral head. (**D** reprinted from Beaty JH, Austin SM, Warner WC, et al. Interlocking intramedullary nailing of femoral-shaft fractures in adolescents: Preliminary results and complications. *J Pediatr Orthop.* 1994;14:178–183, with permission.)

the femoral head is extremely narrow, this single artery is vulnerable to injury and appears to be so until skeletal maturity, regardless of chronologic age.

The proximal femoral physis is a continuous cartilaginous plate between the greater trochanter and the proximal femur in young children. Interference with the physis may result in abnormal growth of the femoral neck, placing the child at a small risk for subsequent femoral neck fracture.[185] Antegrade nailing with reaming of a large defect also may result in growth disturbance in the proximal femur as well as femoral neck fracture (Fig. 27-27). Beaty et al.[12] reported no "thinning" of the femoral neck in their patients, which they attributed to an older patient group (10 to 15 years of age) and design changes in the femoral nail that allowed a decrease in the cross-sectional diameter of the proximal portion of the femoral rods.

Plate Fixation for Femoral Shaft Fractures

Submuscular Bridge Plating

Submuscular bridge plating (Fig. 27-28)[75,102] allows for stable internal fixation with maintenance of vascularity to small fragments of bone, facilitating early healing.[119]

Modern techniques of femoral plating,[176] limiting incisions, maintaining the periosteum, and using long plates and filling only a few select screw holes, have been adopted by many pediatric orthopedic trauma surgeons as a valuable tool to manage length-unstable femur fractures. Pathologic fractures, especially in the distal femoral metaphysis, create larger areas of bone loss that can be treated with open biopsy, plate fixation, and immediate bone grafting.

Kanlic et al.[103] reported a series of 51 patients using submuscular bridge plating with up to 10-year follow-up. Fifty-five percent had unstable fracture patterns. There were two significant complications: One plate breakage (3.5 mm) and one fracture after plate removal. Functional outcome was excellent with 8% significant leg length discrepancy. Hedequist et al.[74] reported on 32 patients aged 6 to 15 years old. Most fractures in their series were comminuted, pathologic, osteopenic, or in a difficult location. Rozbruch et al.[176] described modern techniques of plate fixation popularized by the AO Association for the Study of Internal Fixation that include indirect reduction, biologic approaches to internal fixation, and greater use of blade plates and locked plates (Fig. 27-29).

FIGURE 27-29 **A:** This child with an unstable femoral fracture in osteopenic bone was managed with a submuscular locking plate providing alignment and stability. **B:** The lateral bow of the femur may be partially preserved despite a straight plate.

Sink et al.[186] reported on their center's transition to treating unstable femur fractures with submuscular plating and trochanteric entry nails, and reserving elastic nailing for stable fractures. Their complication rate declined sharply with this change in treatment philosophy.

In very rare situations, such as when there is limited bone for fixation between the fracture and the physes, locked plating techniques may be valuable. This technique provides greater stability by securing the plate with a fixed-angle screw in which the threads lock to the plate as well as in the bone. This effectively converts the screw-plate to a fixed-angle blade plate device. In using this type of device, one should lock first, then compress, and finally lock the plate on the opposite side of the fracture. The locked plate can be used with an extensile exposure or with submuscular plating, but the latter is more difficult and should only be attempted when the technique is mastered.

We do not routinely use locking plates unless pathologic lesions, severe osteopenia, or severe comminution is present. Locking screws can "cold weld" to the plate, later turning a simple implant removal into a very difficult exercise involving large exposures, cutting of the implant, and possibly locally destructive maneuvers to remove the screws.

Technique: Submuscular Bridge Plating. The technique for submuscular bridge plating of pediatric femur fractures has been well described in recent publications.[103,187,188] The patient is positioned on a fracture table, and a provisional reduction is obtained with gentle traction. In most cases, a 4.5-mm narrow, low-contact DCP plate is used. In osteopenic patients, or when there is proximal or distal fracture, locking plates may be used. A very long plate, with 10 to 16 holes, is preferred; the plate selection is finalized by obtaining an image with the plate over the anterior thigh, assuring that there are six screw holes proximal and distal to the fracture (although in some more proximal and distal fractures, only three holes will be available). Depending on the fracture location and thus the position of the plate, the plate will need to be contoured to accommodate the proximal or distal femur. The table-top plate bender is used to create a small flare proximally for the plate to accommodate the contour of the greater trochanter, or a larger flare to accommodate the distal femoral metaphysis. The plate must be contoured anatomically, because the fixed femur will come to assume the shape of the plate after screw fixation. A 2- to 3-cm incision is made over the distal femur, just above the level of the physis. Exposure of the periosteum just below the vastus lateralis facilitates the submuscular passage of the plate. A Cobb elevator is used to dissect the plane between the periosteum and the vastus lateralis. The fracture site is not exposed, and, in general, a proximal incision is not required. The plate is inserted underneath the vastus lateralis, and the femoral shaft is held to length by traction. The plate is advanced slowly, allowing the surgeon to feel the bone against the tip of the plate. Fluoroscopy is helpful in determining proper positioning of the plate. A bolster is placed under the thigh to help maintain sagittal alignment. Once the plate is in position and the femur is out to length, a Kirschner wire is placed in the most proximal and most distal hole of the plate to maintain length (Fig. 27-30). Fluoroscopy is used to check the AP and lateral views and be

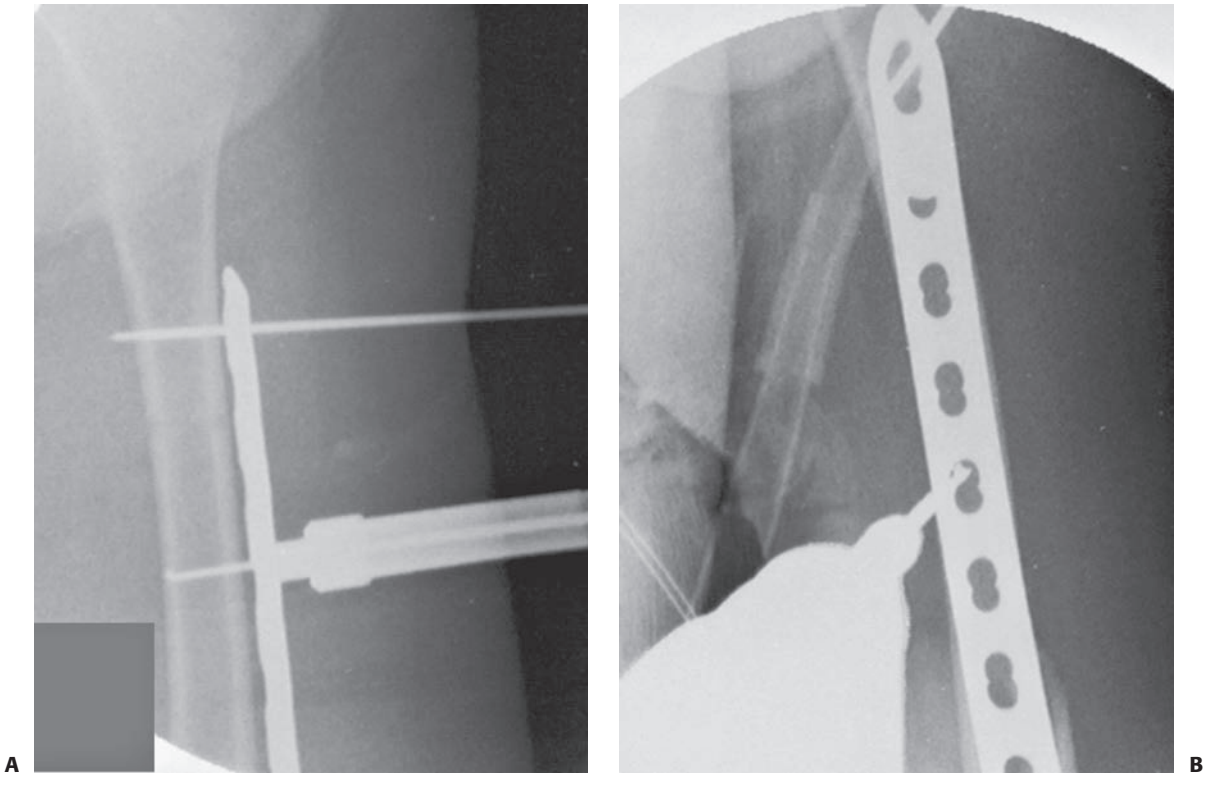

FIGURE 27-30 **A:** A Kirschner wire is inserted in the end holes of the plate to maintain length. **B:** Drill holes and screws are placed with fluoroscope imaging.

sure the bone is at appropriate length at this point. A third Kirschner wire may be used to provide a more stable reduction of the femoral shaft. Although screws can be used to facilitate angular reduction to the plate, length must be achieved before the initiation of fixation.

The principles of external fixation are used in choosing sites for screw fixation. Greater spread of screws increases the stability of fracture fixation. We generally place one screw through the distal incision under direct visualization. At the opposite end of the femur, the next most proximal screw is placed to fix length and provisionally improve alignment. Central screws are then placed, using a free-hand technique with the "perfect circle" alignment of the plate over the fracture fragments. Stab holes are made centrally for drill and screw insertion. Rather than using a depth gauge directly, because the bone will be pulled to the plate, the depth gauge is placed over the thigh itself to measure appropriate length of the screw. When screws are inserted, a Vicryl tie is placed around the shank to avoid losing the screw during percutaneous placement. Self-tapping screws are required for this procedure. Six cortices are sought on either side of the fracture.

The postoperative management includes protected weight bearing on crutches with no need for cast immobilization, as long as stable fixation is achieved. At times, there is benefit to a knee immobilizer; however, in general, this is not required. Early weight bearing in some series of plate fixation has resulted in a low but significant incidence of plate breakage and nonunion. These complications should be decreased by a cautious period of postoperative management.

There are occasional cases with sufficient osteopenia or comminution to require a locked plate to provide secure fixation. In using a locked plate submuscularly, a large enough incision must be used to be sure the bone is against the plate when it is locked. The articular fragment is fixed first to ensure that the angular relationship between the joint surface and the shaft is perfect.

Complications of Plate Fixation

Refracture is rare at the end of the plate or through screw holes, and whether bone atrophy under a plate is caused by stress shielding or by avascularity of the cortex is unknown. Although still somewhat controversial, the plate and screws may be removed at 1 year after fracture to avoid fracture at the end of the plate.

Plate removal can be difficult after submuscular plating; in fact, the problems with plate removal keep some surgeons from using the technique routinely. Pate et al.[161] reviewed a series of 22 cases of plate removal after submuscular plating for femoral shaft fracture. In 7 of the 22 cases, the incision and surgical dissection was more extensive in the plate removal than in the initial insertion. The authors alert the reader that bone can form on the leading edge of the plate, complicating plate removal.

Quadriceps strength after plate fixation appears not to be compromised,[56] relative to intramedullary fixation or cast immobilization.

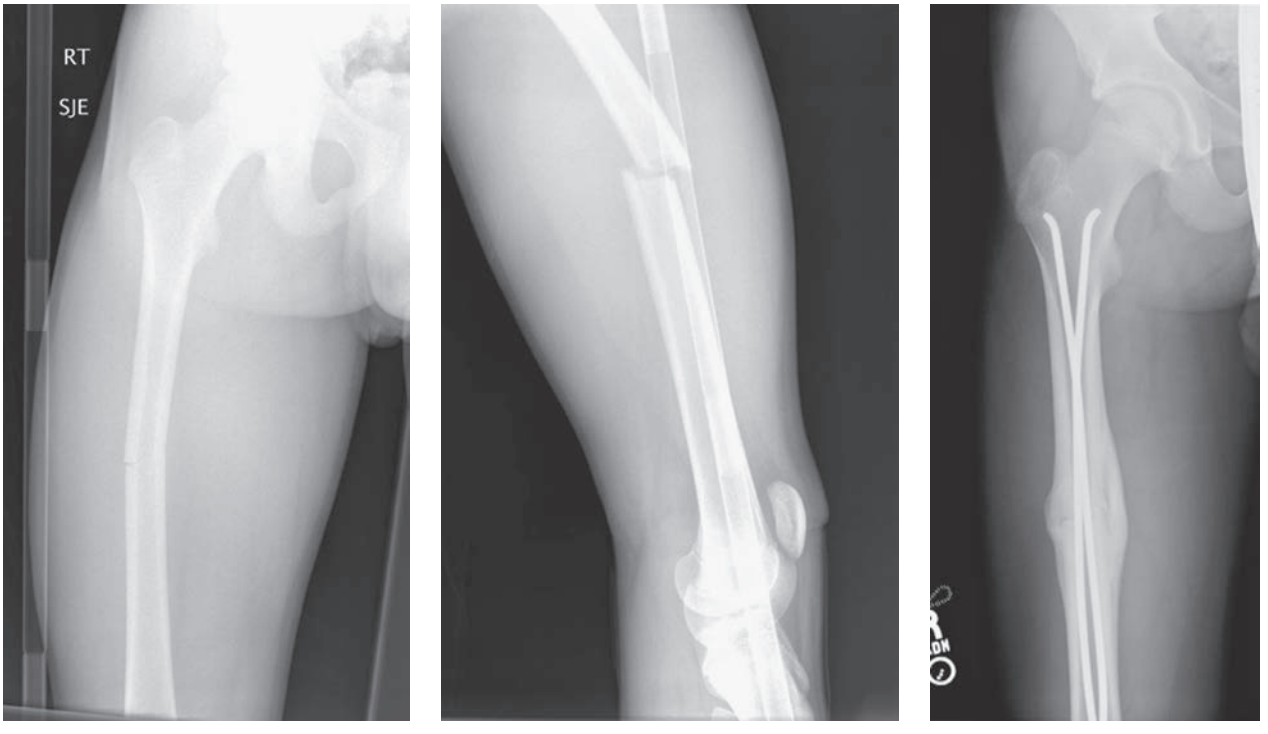
Author's Preferred Treatment for Femoral Shaft Fractures

For stable femur fractures in children under 6 months of age, we use a Pavlik harness. Webril is gently wraped around the thigh before placing the Pavlik. Abuse and metabolic bone disease must be considered in an infant with a femoral fracture. If the fracture is unstable, usually the proximal fragment is flexed and a Pavlik harness is the ideal device for reducing and holding the fracture. The use of a Pavlik harness requires an attentive and compliant caregiver. A Gore-Tex-lined spica is an alternative, especially for the bigger, older baby. Traction with a spica cast is rarely used if ever needed in this group.

For children 6 months to 5 years of age with an isolated femoral fracture, an early spica cast is usually the treatment of choice. In the typical low-energy toddler femur fracture, we have noted similar clinical results, but much happier families and children, when we use a one-leg "walking spica," so this has become our choice for this age group. Some children with a walking spica benefit from cast wedging 1 to 2 weeks after injury, so we prepare families for this possibility as we consent for the procedure. A Gore-Tex liner, if available, markedly improves skin care. If length or alignment cannot be maintained in an early spica cast (this is rare in low-energy fractures), traction followed by casting can be used. We typically use a distal femoral traction pin and place the child in a 90/90 or oblique position in the bed for traction. We must emphasize that over 95% of infants and toddlers can be managed without traction with a low complication rate and low cost. In children with multiple-system trauma, either flexible intramedullary nailing or external fixation is often a better choice, based on the fracture anatomy and the soft tissue injury. Traction is very rarely used in the setting of multiple-system trauma.

In children 5 to 11 years of age, retrograde flexible intramedullary nailing is generally the safest and best option for length-stable fractures (and many length-unstable fractures). Submuscular bridge plating or external fixation is used for unstable fracture patterns, comminuted fractures, and fractures with severe soft tissue injury. Early spica casting may be used for nondisplaced or minimally displaced fractures in this age group. In very large or obese children (greater than 50 kg) who are 9 to 11 years of age, we may use a small diameter locked trochanteric entry nail. In certain situations, the family and surgeon prefer a "nonsurgical" option; in such cases, spica casting, usually with traction, may be used in these school-aged children.

In children 11 years to maturity, we generally prefer a trochanteric entry locked IM nail or submuscular bridge plating. Flexible intramedullary rods can be effective in this age group (Fig. 27-31), especially for midshaft transverse fractures in petite teens. The surgeon should be aware that the complication rate rises with flexible nailing in this older group.[148] External fixation is occasionally valuable in the 11- to



A, B C

FIGURE 27-31 Successful use of titanium elastic nails in older teenager. This 15-year old sustained a minimally displaced midshaft femur fracture **A:** AP and **(B)** lateral views at presentation. **C:** This radiograph, taken 3 months after injury, shows that the fracture healed in perfect alignment with abundant callous.

16-year-old group, particularly in complex proximal or distal fracture. Healing is slow, however, and the full treatment course may take 4 months or more. Submuscular plating is also valuable for subtrochanteric and supracondylar fractures of the femur, whereas intramedullary nails are ideal for midshaft fractures. If antegrade rodding is chosen, a transtrochanteric approach is used. There is a limited role for retrograde-locked intramedullary nailing in adolescents approaching skeletal maturity.

Complications of Femoral Shaft Fractures

Leg Length Discrepancy

The most common sequela after femoral shaft fractures in children is leg length discrepancy. The fractured femur may be initially short from overriding of the fragments at union; growth acceleration occurs to "make up" the difference, but often this acceleration continues and the injured leg ends up being longer. The potential for growth stimulation from femoral fractures has long been recognized, but the exact cause of this phenomenon is still unknown. Growth acceleration has been attributed to age, sex, fracture type, fracture level, handedness, and the amount of overriding of the fracture fragments. Age seems to be the most constant factor, but fractures in the proximal third of the femur and oblique comminuted fractures also have been associated with relatively greater growth acceleration.

Overgrowth and Shortening

Overgrowth after femoral fracture is most common in children 2 to 10 years of age. The average overgrowth is 0.9 cm, with a range of 0.4 to 2.5 cm.[183] Overgrowth occurs when the fracture is short, at length, or overpulled in traction at the time of healing. In general, overgrowth occurs most rapidly during the first 2 years after fracture and to a much lesser degree for the next year or so.[67] Because the average overgrowth after femoral fracture is approximately 1 cm, shortening of 2 to 3 cm in the cast is the maximal acceptable amount.

Truesdell[203] first reported the phenomenon of overgrowth in 1921, and many researchers since have verified the existence of growth stimulation after fracture.[1,2,4,9,36,39,50,126,136,167] The relationship of the location of the fracture to growth is somewhat controversial. Staheli[192] and Malkawi et al.[126] reported that overgrowth was greatest if the fracture occurred in the proximal third of the femur, whereas Henry[83] stated that the most overgrowth occurred in fractures in the distal third of the femur. Other investigators have found no relationship between fracture location and growth stimulation.[50,83,170,183] The relationship between fracture type and overgrowth also is controversial. In general, most researchers believe that no specific relationship exists between fracture type and overgrowth, but some have reported overgrowth to be more frequent after spiral, oblique, and comminuted fractures associated with greater trauma.

Angular Deformity

Some degree of angular deformity is frequent after femoral shaft fractures in children, but this usually remodels with growth. Angular remodeling occurs at the site of fracture, with appositional new bone formation in the concavity of the long bone. Differential physeal growth also occurs in response to diaphyseal angular deformity. Wallace and Hoffman[210] stated that 74% of the remodeling that occurs is physeal, and appositional remodeling at the fracture site occurs to a much lesser degree. However, this appears to be somewhat age dependent. It is clear that angular remodeling occurs best in the direction of motion at the adjacent joint.[210] That is, anterior and posterior remodeling in the femur occurs rapidly and with little residual deformity. In contrast, remodeling of a varus or valgus deformity occurs more slowly. The differential physeal growth in a varus or valgus direction in the distal femur causes compensatory deformity, which is usually insignificant. In severe varus bowing, however, a hypoplastic lateral condyle results, which may cause a distal femoral valgus deformity if the varus bow is corrected.

Guidelines for acceptable alignment vary widely. The range of acceptable anterior and posterior angulation varies from 30 to 40 degrees in children up to 2 years of age (Fig. 27-32), decreasing to 10 degrees in older children and adolescents.[125] The range of acceptable varus and valgus angulation also becomes smaller with age. Varus angulation in infants and children should be limited to 10 to 15 degrees, although greater degrees of angulation may have a satisfactory outcome. Acceptable valgus angulation is 20 to 30 degrees in infants, 15 to 20 degrees in children up to 5 years of age, and 10 degrees in older children and adolescents. Compensation for deformity around the knee is limited, so guidelines for the distal femoral fractures should be stricter than proximal femoral fractures.

Late development of genu recurvatum deformity of the proximal tibia after femoral shaft fracture has been most often reported as a complication of traction pin or wire placement through or near the anterior aspect of the proximal tibial physis, excessive traction, pin track infection, or prolonged cast immobilization.[205] However, proximal tibial growth arrest may complicate femoral shaft fracture, presumably as a result of occult injury.[89] Femoral pins are preferred for traction, but if tibial pins are required, the proximal anterior tibial physis must be avoided.[144] Femoral traction pins should be placed 1 or 2 fingerbreadths proximal to the superior pole of the patella to avoid the distal femoral physis.

If significant angular deformity is present after fracture union, corrective osteotomy should be delayed for at least a year unless the deformity is severe enough to markedly impair function. This will allow determination of remodeling potential before deciding that surgical correction is necessary. The ideal osteotomy corrects the deformity at the site of fracture. In juvenile patients, however, metaphyseal osteotomy of the proximal or distal femur may be necessary. In adolescents with midshaft deformities, diaphyseal osteotomy and fixation with an interlocking intramedullary nail are often preferable.

Distal femoral angular malunion is being recognized after submuscular plating. Care in plate contouring and postoperative monitoring are recommended.

Rotational Deformity

According to Verbeek,[206] rotational deformities of 10 degrees to more than 30 degrees occur in one-third of children after

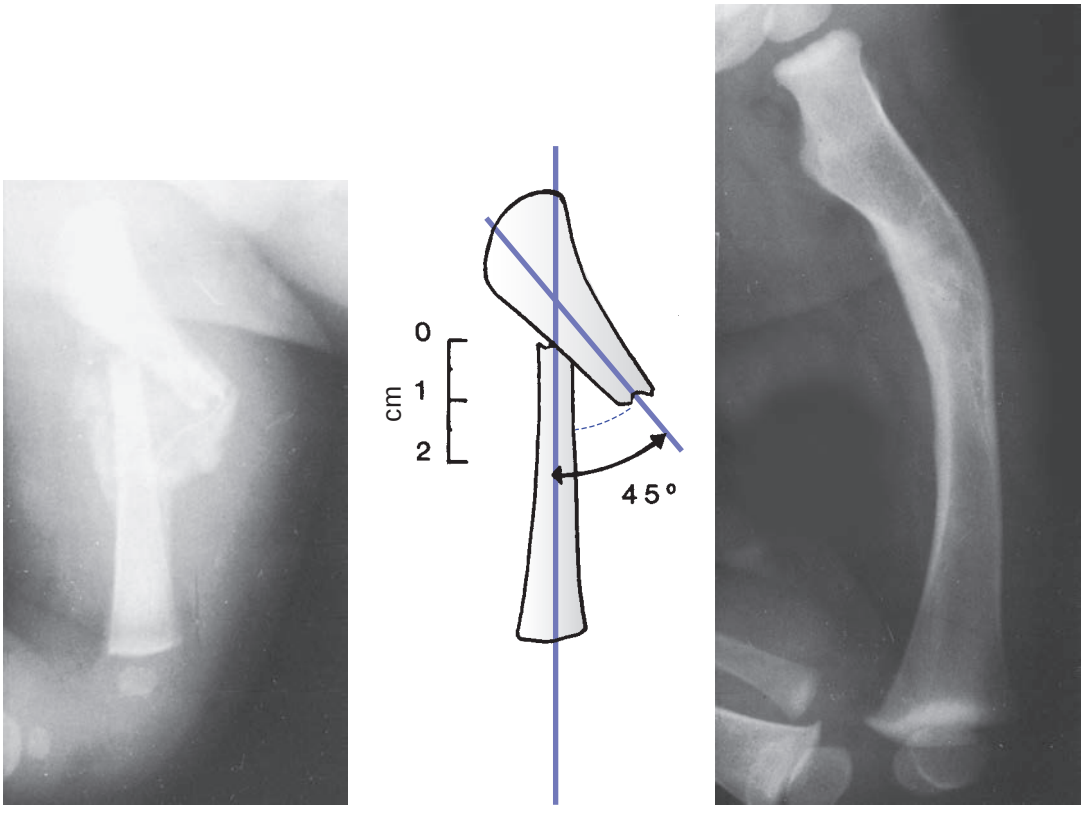


FIGURE 27-32 Remodeling potential of the femur during infancy. This infant sustained a femoral fracture during a breech delivery and was placed in a spica cast but with insufficient flexion of the hip. **Left:** At 3 weeks, union is evident with about 45 degrees of angulation in the sagittal plane and 1.5 cm of overriding. **Center:** Line drawing demonstrating true angulation. **Right:** Twelve months later the anterior angulation has reduced to a level such that it was not apparent to the family, and the shortening has reduced to less than 1 cm.

conservative treatment of femoral shaft fractures. Malkawi et al.[126] found asymptomatic rotational deformities of less than 10 degrees in two-thirds of their 31 patients. Salem and Keppler[179] noted a 47% incidence of torsional malunion ≥15 degrees in the patients they treated with elastic nails at one center in Germany. Torsional deformity usually is expressed as increased femoral anteversion on the fractured side compared with the opposite side, as demonstrated by physical examination; a difference of more than 10 degrees has been the criterion of significant deformity. However, Brouwer et al.[23] challenged this criterion, citing differences of 0 to 15 degrees in a control group of 100 normal volunteers. The accuracy of measurements from plain x-rays also has been disputed, and Norbeck et al.[155] suggested the use of computed tomographic (CT) scanning for greater accuracy.

Rotational remodeling in childhood femoral fractures is another controversy in the search for criteria on which to base therapeutic judgments. According to Davids[44] and Braten et al.[22] up to 25 degrees of rotational malalignment at the time of healing of femoral fractures appears to be well tolerated in children. In their patients with more than 25 degrees of rotational malalignment, however, deformity caused clinical complaints. Davids[44] found no spontaneous correction in his study of malunions based on CT measurements, but the length of follow-up is insufficient to state that no rotational remodeling occurs. Brouwer et al.[23] and others[15,72,157,206] reported slow rotational correction over time. Buchholz et al.[26] documented five children with increased femoral anteversion of 10 degrees or more after fracture healing in children between 3 and 6 years old. In three of five children there was full correction of the rotational deformity but the oldest of the children failed to correct spontaneously.

Certainly, in older adolescents, no significant rotational remodeling will occur. In infants and juveniles, some rotational deformity can be accepted[55] because either true rotational remodeling or functional adaptation allows resumption of normal gait. Up to 30 degrees of malrotation in the femur should result in no functional impairment unless there is preexisting rotational malalignment. The goal, however, should be to reduce a rotational deformity to 10 degrees, based on alignment of the proximal and distal femur radiographically, interpretation of skin and soft tissue envelope alignment, and correct positioning within a cast, based on the muscle pull on the proximal fragment. The distal fragment should be lined up with the position of the proximal fragment determined by the muscles inserted upon it (Fig. 27-3).

Delayed Union

Delayed union of femoral shaft fractures is uncommon in children. The rate of healing also is related to soft tissue injury and type of treatment. The time to fracture union in most children is rapid and age dependent. In infants, fracture can be healed in a 2 to 3 weeks. In children under 5 years of age, healing usually occurs in 4 to 6 weeks. In children 5 to 10 years of age, fracture healing is somewhat slower, requiring 8 to 10 weeks. Throughout adolescence, the time to healing continues to lengthen. By the age of 15 years, the mean time to healing is about 13 weeks, with a range from 10 to 15 weeks (Fig. 27-33). Application of an external fixation device appears to delay callus formation and slow the rate of healing. Flexible nailing allows some motion at the fracture site, promoting extensive callus formation. Bone grafting and internal fixation with either a compression plate or locked intramedullary nail is the usual treatment for delayed union in older children and adolescents. Delayed union of a femoral fracture treated with casting in a child 1 to 6 years of age is probably best treated by continuing cast immobilization until bridging callus forms or (rarely) by additional bone grafting.

Nonunion

Nonunions of pediatric femoral fractures are rare.[118] They tend to occur in adolescents, in infected fractures, or in fractures with segmental bone loss or severe soft tissue loss. Tibial fractures are the most common source of pediatric nonunions; femoral fractures account for only 15% of nonunions in children. Even in segmental fractures with bone loss, young children may have sufficient osteogenic potential to fill in a significant fracture gap (Fig. 27-34).[140] For the rare femoral shaft nonunion in a child 5 to 10 years of age, bone grafting and plate-and-screw fixation have been traditional treatment methods, but more recently insertion of an interlocking intramedullary nail and bone grafting have been preferred, especially in children over 10 to 12 years of age. Aksoy et al.[3] reported a small series of nonunions in malunions salvaged with titanium elastic nails. Union was achieved in 6 to 9 months in most cases.

Robertson et al.[173] reported the use of external fixators in 11 open femoral fractures. The time to union was delayed, but a satisfactory outcome occurred without subsequent procedures. This supports the belief that the rates of delayed union and nonunion are low in pediatric femoral fractures, because open fractures would have the highest rates of delayed union.

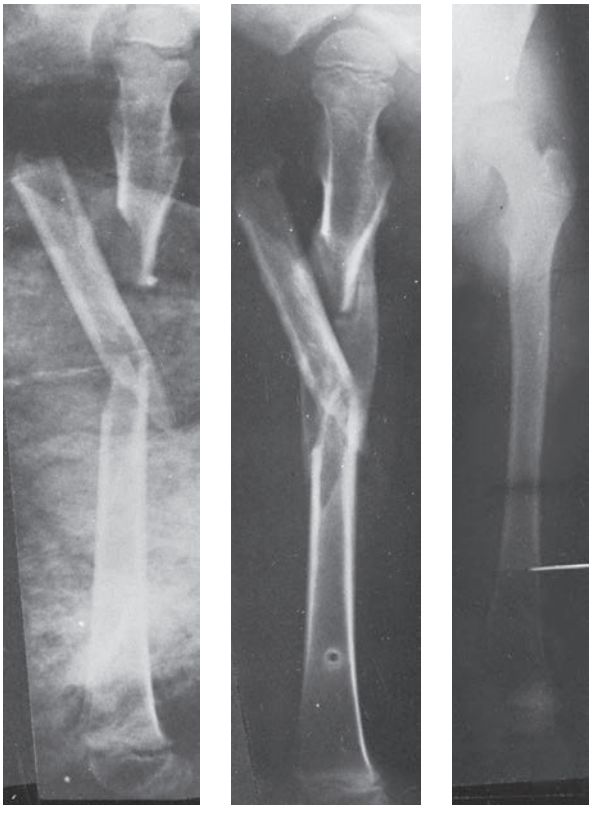

FIGURE 27-34 The effectiveness of remodeling of the femur in a child. **Left:** Comminuted fracture in an 8-year-old child managed with a femoral pin incorporated in a spica cast. The midfragment is markedly angulated. **Center:** Fracture after union 12 weeks later with filling in of the defect and early absorption of the protruding fragment. **Right:** Appearance at age 12 with only a minimal degree of irregularity of the upper femur remaining.

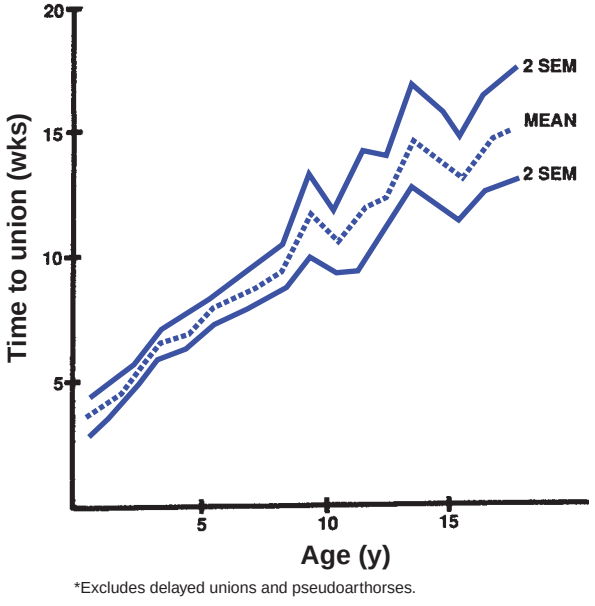

FIGURE 27-33 Time required for union of femoral shaft fractures in childhood and adolescence. (Redrawn from Skak SV, Jensen TT. Femoral shaft fracture in 265 children. *Acta Orthop Scand.* 1988;59:704–707, with permission.)

Muscle Weakness

Weakness after femoral fracture has been described in the hip abductor musculature, quadriceps, and hamstrings, but persistent weakness in some or all of these muscle groups seldom causes a long-term functional problem. Hennrikus et al.[82] found that quadriceps strength was decreased in 30% of his patients and 18% had a significant decrease demonstrated by a one-leg hop test. Thigh atrophy of 1 cm was present in 42%

of patients. These deficits appeared to be primarily related to the degree of initial displacement of the fracture. Finsen et al.[56] found hamstring and quadriceps deficits in patients with femoral shaft fractures treated with either rods or plates.

Damholt and Zdravkovic[43] documented quadriceps weakness in approximately one-third of patients with femoral fractures, and Viljanto et al.[207] reported that this weakness was present when patients were treated operatively or nonoperatively. Biyani et al.[17] found that hip abductor weakness was related to ipsilateral fracture magnitude, long intramedullary rods, and, to a lesser degree, heterotopic ossification from intramedullary rodding. Hedin and Larsson[76] found no significant weakness in any of 31 patients treated with external fixation for femoral fractures based on either Cybex testing or a one-leg hop test. He felt that the weakness seen in other studies may be related to prolonged immobilization.

Injury to the quadriceps muscle probably occurs at the time of femoral fracture, and long-term muscle deficits may persist in some patients regardless of treatment. Severe scarring and contracture of the quadriceps occasionally require quadricepsplasty.[94]

Infection

Infection may rarely complicate a closed femoral shaft fracture, with hematogenous seeding of the hematoma and subsequent osteomyelitis. Fever is commonly associated with femoral fractures during the first week after injury,[193] but persistent fever or fever that spikes exceedingly high may be an indication of infection. One should have a high index of suspicion for infection in type III open femur fractures. A series of 44 open femur fractures[93] reported no infection in type I and II fractures, but a 50% (5 of 10) of type III fractures developed osteomyelitis. Presumably this occurs because of the massive soft tissue damage accompanying this injury.

Pin track infections occasionally occur with the use of skeletal traction, but most are superficial infections that resolve with local wound care and antibiotic therapy. Occasionally, however, the infections may lead to osteomyelitis of the femoral metaphysis or a ring sequestrum that requires surgical debridement.

Neurovascular Injury

Nerve and vascular injuries are uncommonly associated with femoral fractures in children.[46,99,175,193] An estimated 1.3% of femoral fractures in children are accompanied by vascular injury[46,99,175,193] such as intimal tears, total disruptions, or injuries resulting in the formation of pseudoaneurysms.[181] Vascular injury occurs most frequently with displaced Salter–Harris physeal fractures of the distal femur or distal femoral metaphyseal fractures. If arteriography indicates that vascular repair is necessary after femoral shaft fracture, open reduction with internal fixation or external fixation of the fracture is usually recommended first to stabilize the fracture and prevent injury of the repair. Secondary limb ischemia also has been reported after the use of both skin and skeletal traction. Documentation of peripheral pulses at the time of presentation, as well as throughout treatment, is necessary.

Nerve abnormalities reported with femoral fractures in children include those caused by direct trauma to the sciatic or femoral nerve at the time of fracture and injuries to the peroneal nerve during treatment. Weiss et al.[211] reported peroneal nerve palsies in 4 of 110 children with femoral fractures treated with early 90/90 hip spica casting. They recommended extending the initial short leg portion of the cast above the knee to decrease tension on the peroneal nerve.

Riew et al.[172] reported eight nerve palsies in 35 consecutive patients treated with locked intramedullary rodding. The nerve injuries were associated with delay in treatment, preoperative shortening, and boot traction. Resolution occurred in less than 1 week in six of eight patients.

Many peroneal nerve deficits after pediatric femoral shaft fractures will resolve with time. In infants, however, the development of an early contracture of the Achilles tendon is more likely. Because of the rapid growth in younger children, this contracture can develop quite early; if peroneal nerve injury is suspected, an ankle-foot orthosis should be used until the peroneal nerve recovers. If peroneal, femoral, or sciatic nerve deficit is present at initial evaluation of a closed fracture, no exploration is indicated. If a nerve deficit occurs during reduction or treatment, the nerve should be explored. Persistent nerve loss without recovery over a 4- to 6-month period is an indication for exploration.

Compartment Syndrome

Compartment syndromes of the thigh musculature are rare, but have been reported in patients with massive thigh swelling after femoral fracture and in patients treated with intramedullary rod fixation.[142] If massive swelling of thigh musculature occurs and pain is out of proportion to that expected from a femoral fracture, compartment pressure measurements should be obtained and decompression by fasciotomy should be considered. It is probable that some patients with quadriceps fibrosis[170] and quadriceps weakness[41,198] after femoral fracture had intracompartmental pressure phenomenon. Mathews et al.[130] reported two cases of compartment syndrome in the "well leg" occurring when the patient was positioned for femoral nailing in the hemilithotomy position. Vascular insufficiency related to Bryant traction may produce signs of compartment syndrome with muscle ischemia.[36] Janzing et al.[100] reported the occurrence of compartment syndrome using skin traction for treatment of femoral fractures. Skin traction has been associated with compartment syndrome in the lower leg in both the fractured and nonfractured sides. It is important to realize that in a traumatized limb, circumferential traction needs to be monitored closely and is contraindicated in the multiply injured or head-injured child. As noted in the spica cast section, several cases of leg compartment syndrome have been reported after spica cast treatment in younger children with femur fractures.

Special Fractures of the Femoral Shaft

Subtrochanteric Fractures

Subtrochanteric fractures generally heal slowly, angulate into varus, and are more prone to overgrowth. These fractures offer a challenge, as the bone available between the fracture site and the femoral neck limits internal fixation options. In younger

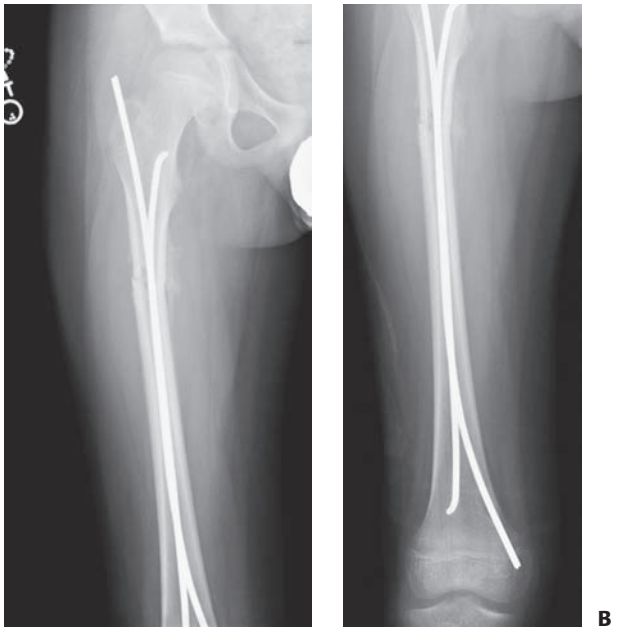

FIGURE 27-35 A, B: The combination of anterograde and retrograde titanium elastic nail insertion is a good solution for the proximal femur fracture.

children, traction and casting can be successful.[47] Three weeks of traction is usually necessary, and the surgeon should place a good valgus mold at the fracture site, and monitor the fracture closely in the first 2 weeks after casting. When the patient returns for follow-up and the subtrochanteric fracture has slipped into varus malangulation, the cast can be wedged in clinic or casting can be abandoned for another method. Parents should be warned that loss of reduction in the cast is quite common, and wedging in clinic is a routine step in management. An external fixation strategy can be quite successful if there is satisfactory room proximally to place pins. Once there is satisfactory callus (about 6 weeks), the fixator can be removed and the weight bearing allowed in a walking spica (long leg cast with a pelvic band—place a valgus mold to stabilize fracture in the first few weeks after external fixator removal). Flexible nailing can be used, with a proximal and distal entry strategy (Fig. 27-35). A pitfall in this fracture is thinking the proximal fragment is too short to use flexible IM nails on the AP radiograph because the proximal fragment is pulled into flexion by the unopposed psoas muscle. Pombo and Shilt[163] reported a series of 13 children, averaging of 8 years old with subtrochanteric fractures, treated with flexible nailing. Results were excellent or satisfactory in all cases. Submuscular plating can also produce satisfactory results.[98] In adolescents, there is insufficient experience with this fracture to determine at what age intramedullary fixation with a reconstruction-type nail and an angled transfixion screw into the femoral neck is indicated. Antegrade intramedullary nail systems place significant holes in the upper femoral neck and should be avoided. Unlike subtrochanteric fractures in adults, nonunions are rare in children with any treatment method.

Supracondylar Fractures

Supracondylar fractures represent as many as 12% of femoral shaft fractures[190] and are difficult to treat because the gastrocnemius muscle inserts just above the femoral condyles and pulls the distal fragment into a position of extension (Fig. 27-36),[70] making alignment difficult (Fig. 27-3). The traditional methods of casting and single-pin traction may be satisfactory in young children (Fig. 27-37). As mentioned in the external fixation section above, supracondylar fractures through a benign lesion are safely and efficiently treated with a brief period (4 to 6 weeks) of external fixation (Fig. 27-38), followed by a walking cast until the callus is solid and the pin sites are healed. In other cases, internal fixation is preferable, either with submuscular plating (Figs. 27-28 and 27-39) and fully threaded cancellous screws (if there is sufficient metaphyseal length) or with crossed smooth K-wires transfixing the fracture from the epiphysis to the metaphysis, as described for distal femoral physeal separations.[182] If there is sufficient metaphyseal length, flexible nailing can be used, so long as fixation is satisfactory. The flexible nails can be either placed antegrade as originally described, or a retrograde if there is satisfactory distal bone for fixation near the nail entry site. Biomechanically, retrograde insertion is superior.[138] Pathologic fractures in this area are common, and an underlying lesion should always be sought.

Open Femoral Fractures

Open femoral fractures are uncommon in children because of the large soft tissue compartment around the femur. Proper wound care, debridement, stabilization, and antibiotic therapy are required to reduce the chance of infection.[70] In a study by Hutchins et al.,[93] 70% of children with open femoral fractures had associated injuries and 90% were automobile related. The average time to healing was 17 weeks, and 50% of the Gustilo type III injuries developed osteomyelitis.

External fixation of open femoral shaft fractures simplifies wound care and allows early mobilization. The configuration of the external fixator is determined by the child's size and the fracture pattern. Generally, monolateral half-pin frames are satisfactory, but thin-wire circular frames may be necessary if

(*text continues on page 1022*)

FIGURE 27-36 It is difficult to treat distal femoral shaft fractures in traction. The muscle forces around the knee often result in significant flexion at the fracture site.

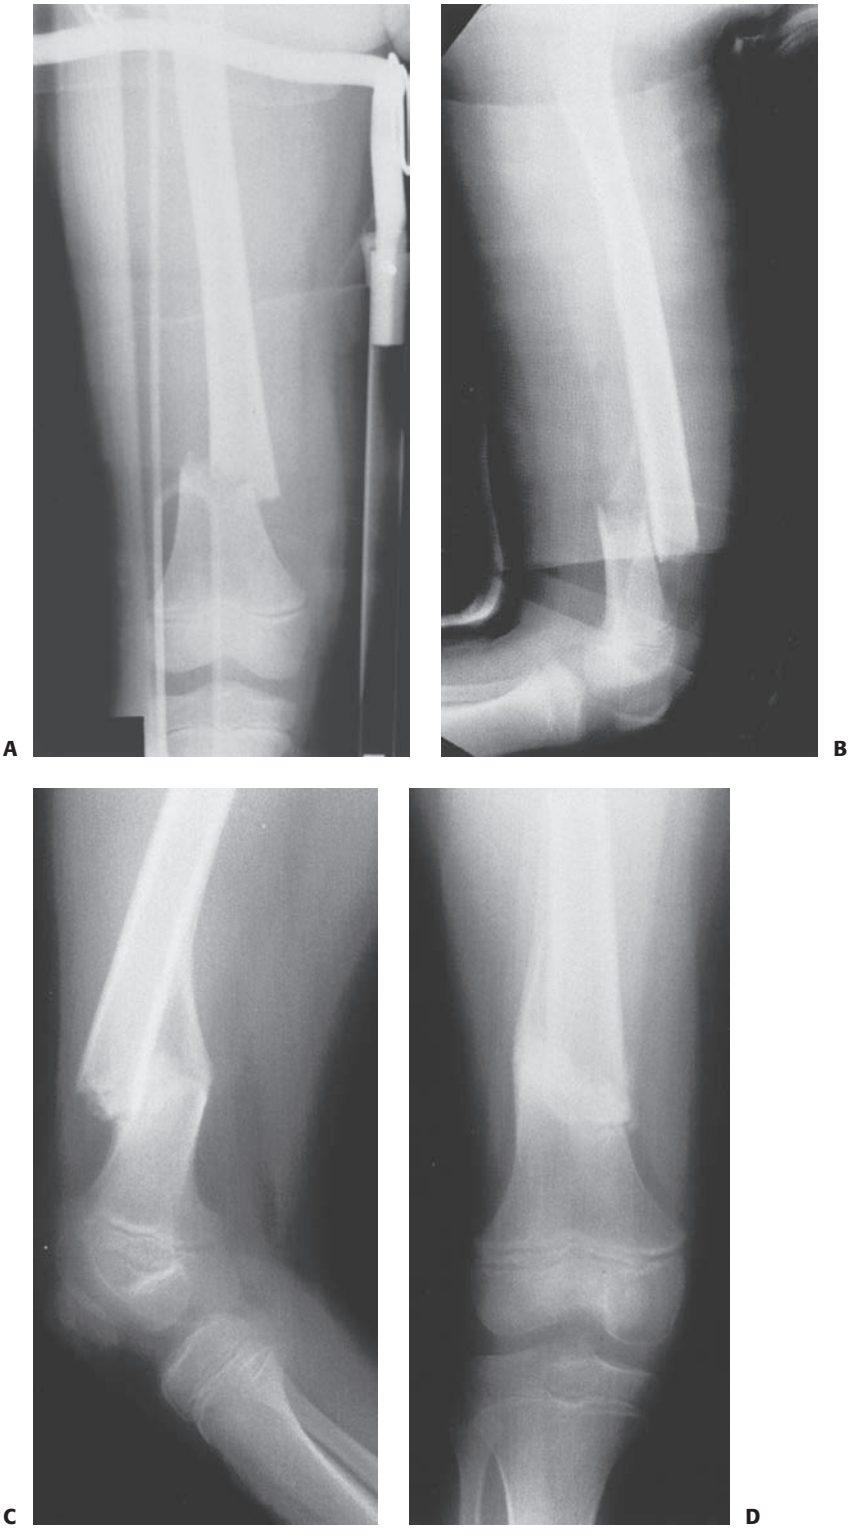

FIGURE 27-37 **A:** This 6-year-old patient sustained an unstable supracondylar fracture of the femur. **B:** The fracture was managed with immediate spica casting with the knee in 90 degrees of flexion, mandatory in such a case to prevent posterior angulation. Bayonet apposition, as shown in this figure (**C:** lateral and **D:** AP) is acceptable in a child of this age.

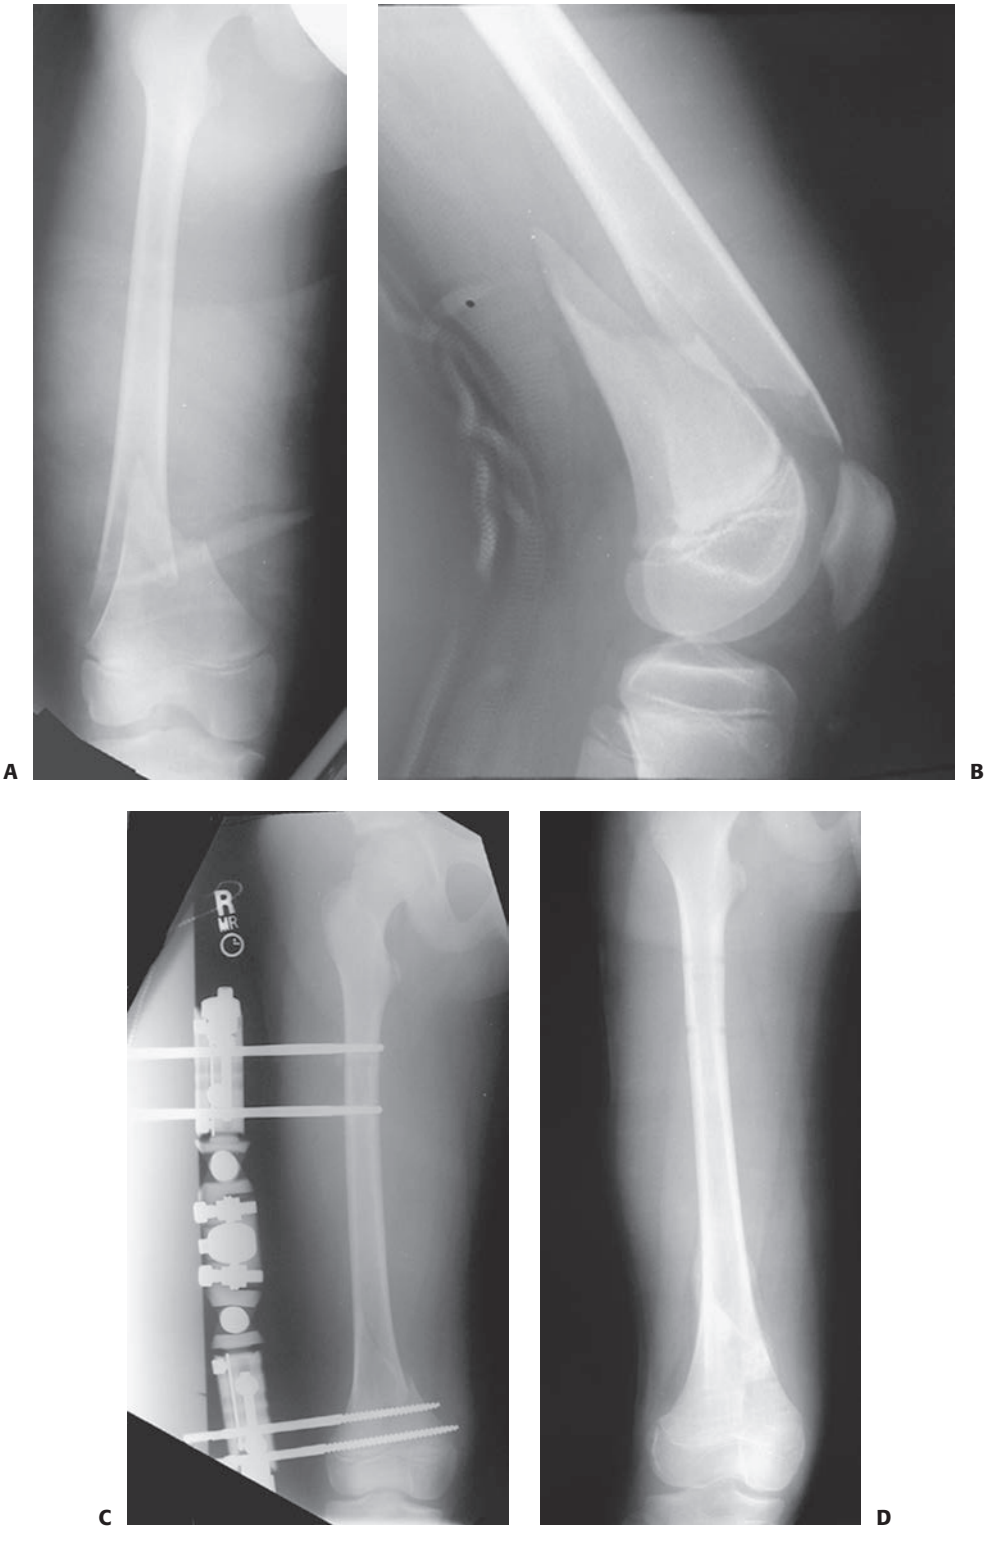

FIGURE 27-38 AP **(A)** and lateral **(B)** radiographs showing a fracture at the junction of the distal femoral metaphysis and diaphysis. **C:** The fractures reduced into near-anatomic alignment and an external fixator was used to control the distal fragment. **D:** The fixator was removed 8 weeks after injury, and after a brief period of weight bearing is tolerated a long leg cast, the fracture has healed in anatomic alignment with no shortening.

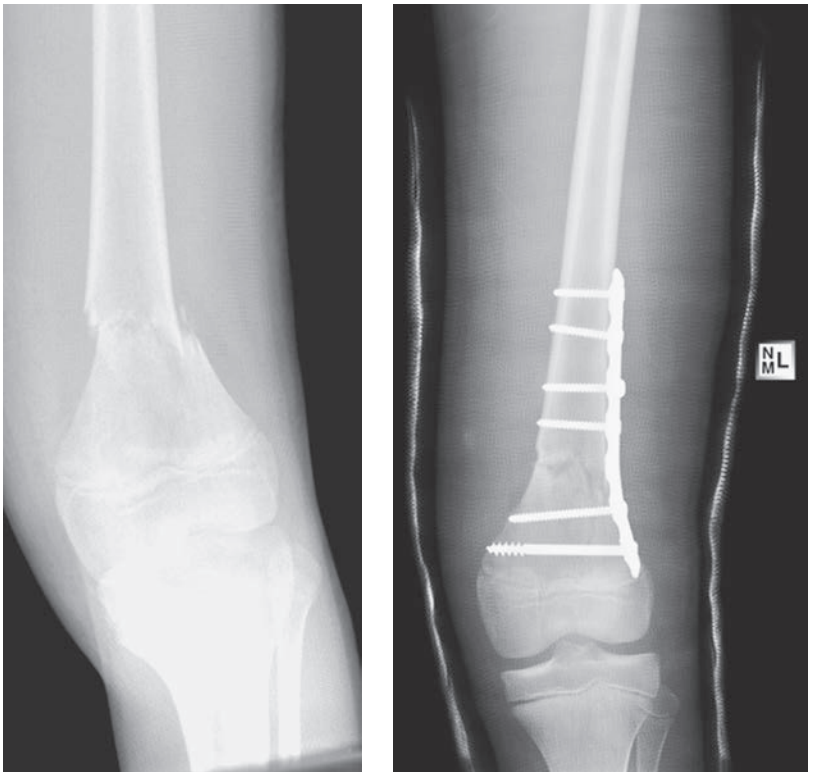

FIGURE 27-39 Preoperative **(A)** and postoperative **(B)** x-rays showing a fracture at the junction of the distal femoral metaphysis and diaphysis treated with plate fixation.

bone loss is extensive. External fixation provides good fracture control, but, as always, family cooperation is required to manage pin and fixator care.

Plate fixation also allows early mobilization as well as anatomic reduction of the femoral fracture. Wound care and treatment of other injuries are made easier in children with multiple trauma. However, this is an invasive technique with the potential for infection and additional injury to the already traumatized soft tissues in the area of the fracture. In emergency situations, plate fixation or intramedullary fixation may be used for Gustilo–Anderson type I and II fractures; type III fractures in older adolescents are better suited for external fixation or intramedullary nailing. Plate breakage can occur if bone grafting is not used for severe medial cortex comminution.

In older adolescents, submuscular plating or trochanteric entry nailing is often the optimal treatment choice. Closed nailing after irrigation and drainage of the fracture allows early mobilization and easy wound care in patients with Gustilo–Anderson type I, II, IIIA, and IIIB injuries, but the risk of osteonecrosis must be recognized.

Femoral Fractures in Patients with Metabolic or Neuromuscular Disorders

For patients with osteogenesis imperfecta who have potential for ambulation, surgical treatment with Rush, Bailey–Dubow, or Fassier rods (see Chapter 8) is recommended for repeated fractures or angular deformity. Cast immobilization is minimized in patients with myelomeningocele or cerebral palsy, because of the frequency of osteoporosis and refracture in these patients. If possible, existing leg braces are modified for treatment of the femoral fracture. In nonambulatory patients, a simple pillow splint is used.

Floating Knee Injuries

These rare injuries occur when ipsilateral fractures of the femoral and tibial shafts leave the knee joint "floating" without distal or proximal bony attachments. They are high-velocity injuries, usually resulting from collision between a child pedestrian or cyclist and a motor vehicle. Most children with floating knee injuries have multiple-system trauma, including severe soft tissue damage, open fractures, and head, chest, or abdominal injuries.

Except in very young children, it is usually best to fix both fractures. If both fractures are open, external fixation of both the tibial and femoral fractures may be appropriate. If immediate mobilization is necessary, fixation of both fractures with external fixation, intramedullary nails, compression plates, or any combination of these may be indicated.

Letts et al.[116] described five patterns of ipsilateral tibial and femoral fractures and made treatment recommendations based on those patterns (Fig. 27-40). Because of the high prevalence of complications after closed treatment, Bohn and Durbin[19] recommended open or closed reduction and internal fixation of the femoral fracture in older children. Arslan et al.[7] evaluated the treatment of the "floating knee" in 29 consecutive cases, finding that those treated operatively had a shorter hospital stay, decreased time to weight bearing, and fewer complications than those managed with splinting casting or traction. Arslan et al.[7] demonstrated that open knee fracture rather than ligamentous injury was a risk factor for poor outcome and that angulation was a predictor of future compromise of function.

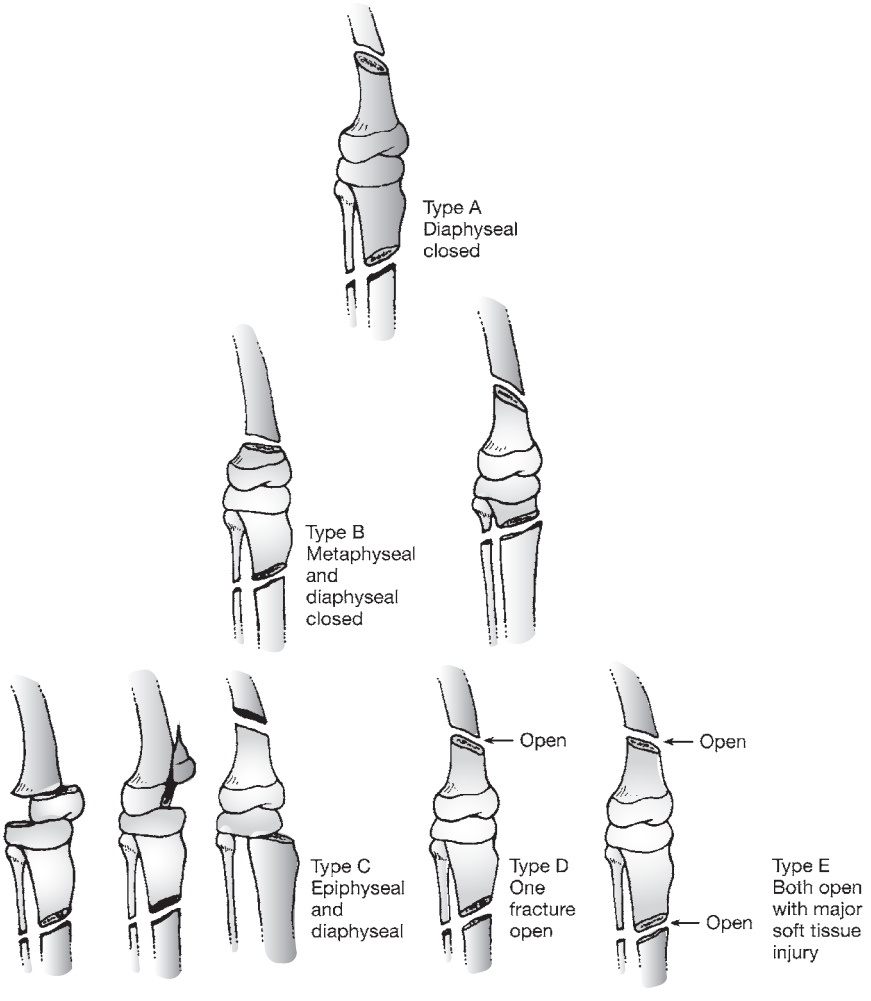

FIGURE 27-40 Classification of floating knee injuries in children. (Redrawn from Letts M, Vincent N, Gouw G. The "floating knee" in children. *J Bone Joint Surg Br.* 1986;68:442, with permission.)

Bohn and Durbin[19] reported that of 19 patients with floating knee injuries, at long-term follow-up 11 had limb length discrepancy secondary to either overgrowth of the bone after the fracture or premature closure of the ipsilateral physis (seven patients), genu valgum associated with fracture of the proximal tibial metaphysis (three patients), or physeal arrest (one patient). Four patients had late diagnosis of ligamentous laxity of the knee that required operation. Other complications included peroneal nerve palsy, infection, nonunion, malunion, and refracture.

Fractures in the Multiple-System Trauma Patient

In a study of 387 previously healthy children with femoral fractures, the authors evaluated the effect of stabilization on pulmonary function. Patients with severe head trauma or cervical spine trauma are at greatest risk for pulmonary complications. Timing of treatment of femoral fractures appears to not affect the prevalence of pulmonary complications in children. Mendelson et al.[139] similarly showed no effect of timing of femoral fixation on long-term outcome but early fracture fixation did decrease hospital stay without increasing the risk of central nervous system or pulmonary complications.

28 FRACTURES OF THE DISTAL FEMORAL PHYSIS

Martin J. Herman and Brian G. Smith

Introduction to Fractures of the Distal Femoral Physis

Distal femoral physeal injuries are uncommon, accounting for fewer than 2% of all physeal injuries.[40,52,65] However, complications requiring additional surgery occur after approximately 40% to 60% of these injuries.[2,24,29,37,50,71,82,83] The most common complication is growth disturbance of the distal femur resulting in angular deformity and/or shortening. In one meta-analysis of the published literature from 1950 to 2007 that included 564 fractures, 52% of fractures resulted in a growth disturbance.[7] This complication has been reported in patients of all ages regardless of the mechanism of injury, type of fracture, anatomic reduction of the fracture, and the type of treatment.[2,24,29,37,50,82,83] In addition to growth complications, knee stiffness, ligamentous disruption, neurovascular injuries, and compartment syndrome may occur as a result of these injuries.[24,29,71,80,83] Although the prognosis is better for very young children and nondisplaced fractures, complications may occur after any distal femoral physeal injury. Careful clinical assessment, complete diagnostic imaging, anatomic reduction, and secure immobilization or fixation to maintain reduction are

necessary to ensure the best possible outcomes. Close follow-up at regular 6-month intervals after fracture healing until skeletal maturity is recommended to allow for early detection and treatment of clinically significant growth disturbances.

Assessment of Fractures of the Distal Femoral Physis

Mechanisms of Injury of Fractures of the Distal Femoral Physis

Prior to the advent of radiography, this injury was termed the "wagon-wheel injury" or "cartwheel injury" because it occurred when a child attempted to jump onto or fell from a moving wagon and the leg became entrapped between the spokes of the moving wheel. Because adequate methods of evaluation and orthopedic management had not yet been developed, this injury often led to amputation frequently because of associated neurovascular trauma.[36] Today, most distal femoral physeal fractures are the result of high-energy mechanisms, such as motor vehicle or sports-related trauma, and occur in older children and adolescents. Children between the ages of 2 and 11 years are less likely to sustain these fractures compared to adolescents, or even infants.[71]

Infants and Toddlers

Neonates are susceptible to distal femoral physeal fractures from birth trauma. Factors that predispose the newborn to this injury include breech presentation, macrosomia, difficult vaginal delivery, and rapid labor and delivery.[42] This injury has been also reported after delivery by caesarean section.[38] Child abuse should be suspected in infants and toddlers when a small peripheral metaphyseal fragment of bone, also called a "corner fracture," or the "classic metaphyseal lesion," is identified in association with widening of the distal femoral physis on radiographs of the femur or knee (Fig. 28-1).[48] This radiographic finding is pathognomonic for child abuse. If this radiographic sign is identified, regardless of the reported mechanism of injury, the child should be carefully examined for other signs of mistreatment; a skeletal survey is obtained to identify other skeletal injuries and an immediate referral to your institution's child protection team and local child welfare services must be initiated.

Pathologic Fractures

Underlying conditions such as neuromuscular disorders, joint contractures, or nutritional deficiencies may predispose some children, regardless of age, for separation of the distal femoral epiphysis.[3–5,51,63] Like other pathologic fractures, distal femoral physeal separations that occur in children with underlying conditions typically result from low-energy mechanisms, such as inadvertent twisting of the limb during transferring from a bed or stretching during physical therapy. Nonambulatory children, such as children with cerebral palsy, are particularly susceptible to pathologic fractures due to disuse osteopenia. Ambulatory children with spina bifida may develop epiphysiolysis, or a chronic separation of the distal femoral physis, and be unaware of it because of altered sensation. Salter–Harris fractures of the distal femur have been reported during manipulation of the knee under anesthesia in children who had developed knee contractures secondary to arthrofibrosis after treatment of displaced tibial eminence fractures.[86]

FIGURE 28-1 Lateral radiograph of a swollen knee in a 3-month-old girl who reportedly fell out of her crib 8 days earlier. Subperiosteal ossification along the distal femoral shaft indicates separation of the distal femoral epiphysis. Note evidence of fracture separation of the proximal tibial epiphysis as well. Final diagnosis: Abused child.

Biomeachanics of the Injury of Fractures of the Distal Femoral Physis

In the adolescent with open growth plates about the knee, the most common mechanism of fracture of the distal femoral physis is a varus or valgus stress (Fig. 28-2) across the knee joint from a direct blow or buckling while landing from a jump or fall from a height. In most cases, this medially or laterally directed force is coupled with a torsional moment from direct application of force to the foot, or more commonly, from twisting of the knee on the planted foot. In an animal model, the physis is least able to resist torsional forces.[15] Knee hyperextension or hyperflexion forces result in sagittal plane displacement. The combination of forces applied to the physis, however, determines the direction of displacement of the distal fragment.

Loading the limb to failure across the immature knee is more likely to lead to physeal disruption due to tensile stresses that are transmitted through the ligaments to the adjacent physis than it is to disruption of the major knee ligaments.[25] Varus or valgus forces (Fig. 28-3A) create tension on one side of the physis and compression on the opposite side. The result is the

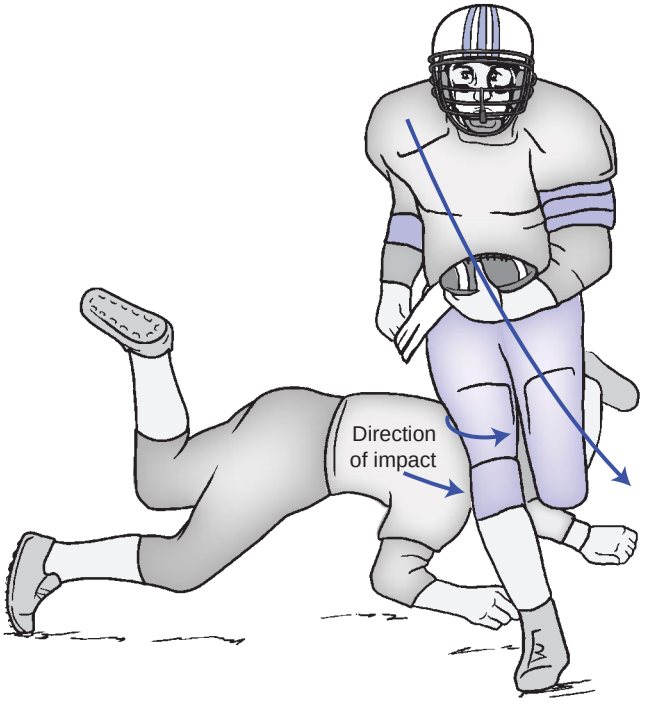

FIGURE 28-2 Valgus and torsional stress across the knee may cause a ligament injury or physeal separation.

disruption of the periosteum, which may become entrapped between the epiphysis and the metaphysis, and the perichondrial ring on the tension side, followed by a fracture plane that begins in the hypertrophic zone and proceeds in an irregular manner through the physis.[15] In adults, a similar mechanism of injury is more likely to cause ligamentous disruption rather than bone failure because ligaments of the mature knee are less able to withstand extreme tensile forces compared to the bone of the adult distal femur and proximal tibia (Fig. 28-3B).

Associated Injuries with Fractures of the Distal Femoral Physis

Because many of these injuries are the result of high-energy mechanisms such as traffic accidents and motor sports, associated visceral injuries occur in approximately 5% of patients.[24] Other musculoskeletal injuries are seen in association with distal femoral physeal fractures in 10% to 15% of patients.[24,83] Other long bone fractures, as well as pelvic and spine fractures, must be ruled out, especially if the mechanism of injury is high-energy motor trauma (Fig. 28-4). Knee ligament disruption, however, is the most common concomitant musculoskeletal injury. Knee instability is diagnosed in 8% to 37% of patients[11,24] and is typically diagnosed after fracture healing with the initiation of rehabilitation and return to activities. Salter–Harris type III fractures of the medial femoral condyle are most frequently associated with anterior cruciate ligament injuries.[16,54,68,85] Open fractures and vascular injuries are uncommon associated injuries, occurring in about 3% of patients. Peroneal nerve injury occurs in about 2% to 7% of patients with displaced fractures.[10,24]

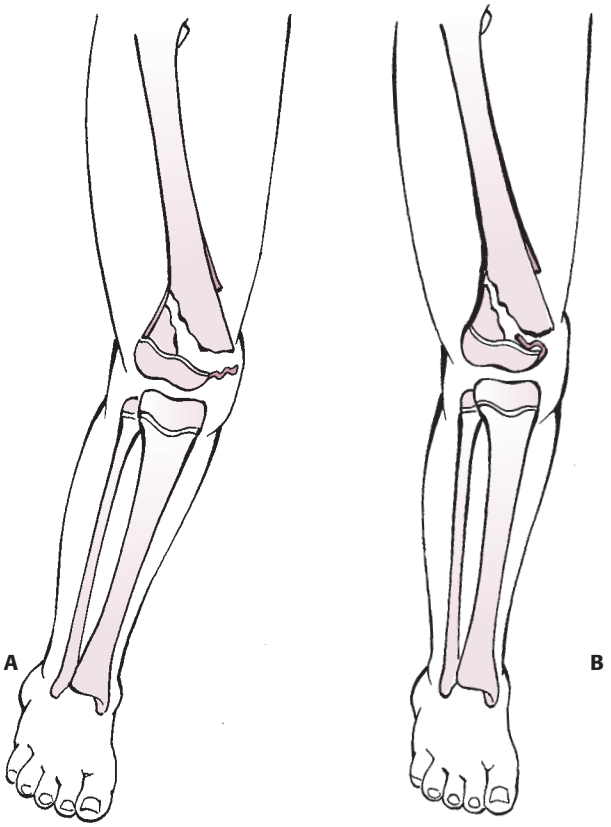

FIGURE 28-3 **A:** In a skeletally immature patient, valgus force at the knee is more likely to cause a physeal fracture of the distal femur than a medial collateral ligament tear, an injury that occurs in adults. **B:** With correction of the valgus deformity, periosteum may become entrapped. (Reprinted with permission from Skaggs DL, Flynn JF. Trauma about the knee, tibia, and foot. In: Skaggs DL, Flynn JF, eds. *Staying Out of Trouble in Pediatric Orthopaedics*. Philadelphia, PA: Lippincott Williams & Wilkins; 2006.)

Signs and Symptoms of Fractures of the Distal Femoral Physis

Presentation

Emergency department assessment for children who are victims of high-energy trauma with a suspected distal femoral physeal separation should be initially evaluated by the trauma team to identify potential life-threatening injuries, to evaluate the ABCs, and to initiate resuscitation protocols if indicated. On the initial survey, head trauma, thoracoabdominal injuries, unstable spine and pelvic fractures, and limb-threatening extremity injuries are the priorities. After stabilization of the cardiovascular status, a thorough secondary survey should focus on the extremities. Long-bone fractures and ligamentous injuries of the extremities are identified with a careful orthopedic examination of all four extremities. Although severe injuries may occur in association with fractures of the distal femoral physis, this fracture, however, occurs as an isolated injury in most patients.

For patients with displaced distal femoral physeal fractures, the diagnosis may be obvious. Patients typically describe severe pain, giving way of the limb and obvious knee deformity

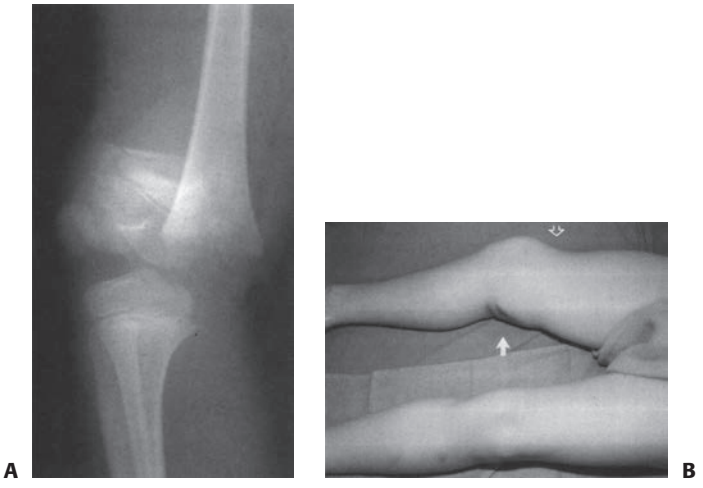
FIGURE 28-4 A 7-year-old girl struck by a car sustained this closed injury while crossing the street. Radiographs (**A,** AP and **B,** lat) reveal an anteriorly displaced distal femoral physeal separation and a tibial shaft fracture. Upon admission she had no pulse in the extremity. She underwent emergency open reduction and fixation of the distal femur and IM nail fixation of the tibia **(C–E).** Her pulses returned to normal after femur reduction. She did not develop a compartment syndrome.

after a sports injury, motor vehicle accident, or other high-energy mechanism and are unable to walk or bear weight on the injured limb. On examination, visible limb malalignment, severe swelling, and often ecchymosis at the apex of the knee deformity are identified. In fractures with severe displacement, the skin at the apex may be tented or puckered from protrusion of the metaphyseal distal femur through the periosteum and quadriceps muscle into the dermis. Hematoma may be palpable beneath the skin. Abrasions or laceration of the overlying soft tissues may be a clue to the mechanism of injury or to an open fracture (Fig. 28-5). Assessment of knee range of motion and ligament stability is not possible in most cases with obvious displacement because of pain and the poor reliability of the examination in the face of fracture instability. Aggressive manipulation is also potentially harmful to the fractured physis or neurovascular structures that are already compromised.

Patients with nondisplaced fractures are more difficult to diagnose. Many children with nondisplaced distal femoral physeal fractures present with knee pain or mild knee swelling after a twisting injury or blow to the knee but are able to bear weight, albeit with often a painful limp. Point tenderness at the level of the distal femoral physis, either medially or laterally about the knee, is perhaps the most reliable way to detect this injury. Range of motion is typically painful but may not be severely restricted in all cases, and fracture crepitus is absent because the periosteum is not fully disrupted. Varus/valgus stress testing of the knee ligaments is usually painful and, in some cases, may reveal subtle movement or suggest instability. The examiner, however, must be mindful that a skeletally immature patient with point tenderness at the physis is more likely to have sustained a physeal fracture of the distal femur, compared to disruption of the medial or lateral collateral ligaments of the knee. Therefore, forceful or repeated stress testing of the knee in these cases should be avoided to minimize trauma to the injured physis.

Motor and Sensory Testing

Careful neurovascular examination of the lower leg and foot must be performed for all children with suspected fractures of the distal femoral physis, especially for those with obvious limb deformity.



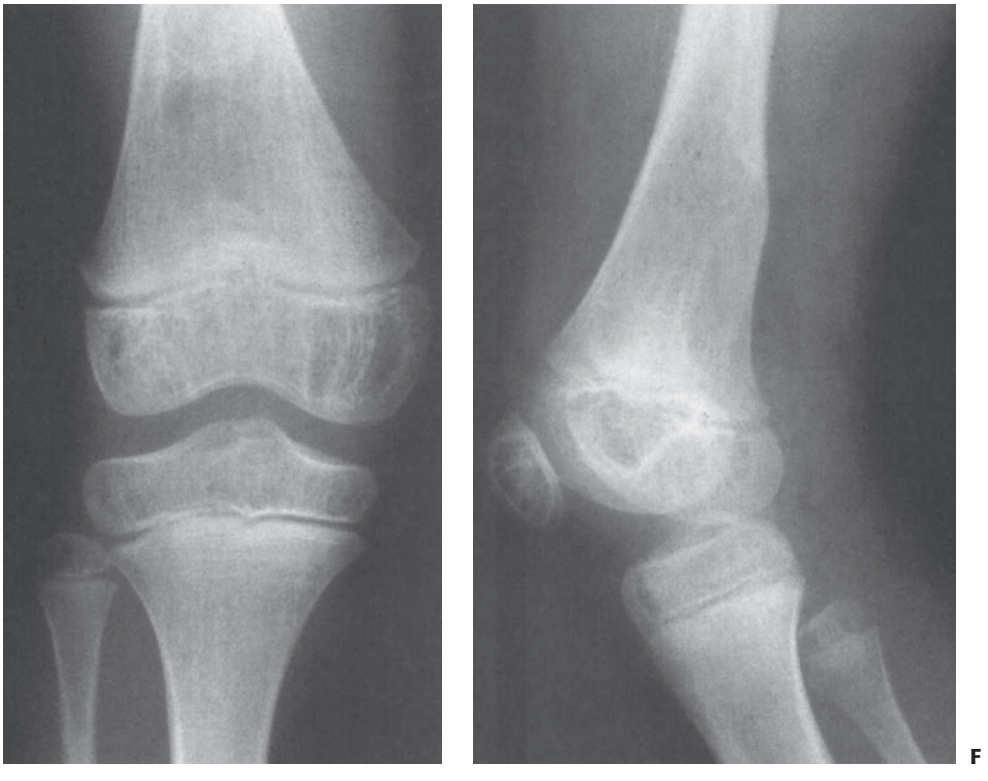


FIGURE 28-5 **A:** Completely displaced Salter–Harris type II fracture of the distal femur in a 6-year-old girl whose foot was on the back of the driver's headrest when the automobile in which she was riding was involved in an accident. **B:** Ecchymosis in the popliteal fossa and anterior displacement of the distal femur are evident. Clinical examination revealed absence of peroneal nerve function and a cold, pulseless foot. The fracture was irreducible by closed methods and required open reduction, internal fixation, and repair of a popliteal artery laceration. **C, D:** Follow-up x-rays show excellent healing after pin removal. The reduction had been incomplete with 25 degrees of posterior angulation remaining. **E, F:** Four years later, remodeling has occurred and no growth disturbance is noted. Results such as this cannot be relied upon, and early anatomic reduction is recommended.

Complete motor and sensory testing of the distal limb is necessary to identify injury of the sciatic nerve and its branches, the tibial and common peroneal nerves. Because the peroneal nerve is injured in about 2% of patients with displaced fractures[10] and is the most commonly injured nerve related to this fracture,[24] it is especially important that anterior (deep branch) and lateral (superficial branch) compartment muscle function and lower leg sensation be carefully documented. This nerve injury is typically a neurapraxia, the result of stretching from anterior or medial displacement of the distal femoral epiphysis.

Vascular Assessment

Although vascular injuries are rare after fractures of the distal femoral physis,[24,50,71,83] the vascular status must also be evaluated carefully. The distal pulses are palpated in the foot and ankle and other signs of adequate perfusion are evaluated. These other signs include assessment of capillary refill, skin temperature, and signs of venous insufficiency such as distal swelling or cyanosis. Doppler ultrasound and measurement of ankle-brachial indices are methods available in the emergency department which are useful for detecting less obvious vascular injury when pulses and other signs are equivocal. Laceration, intimal tear, and thrombosis in the popliteal artery may occur by direct injury to the artery by the distal end of the metaphysis when the epiphysis is displaced anteriorly during a hyperextension injury.[10,24,74] Because anteriorly displaced fractures have an increased risk of neurovascular damage in general compared to other directions of displacement,[21,80] the patient must be particularly suspicious for a vascular injury with obvious hyperextension deformity of the knee.

Compartment syndrome after distal femoral physeal fracture is rare but in one series occurred in 1.2% of patients.[24] Signs of compartment syndrome in the lower leg such as severe swelling, tenseness or tenderness of compartments, and examination abnormalities consistent with the diagnosis are also evaluated. Compartmental pressure recordings should be obtained if there are clinical findings of compartment syndrome of the lower leg. Compartment syndrome in association with this fracture is more likely to manifest hours after injury; however, not at the time of initial presentation. Patients at risk for developing a delayed compartment syndrome after fracture are those with other injuries of the lower leg, such as tibial shaft fractures, and those with compromised vascularity.[24]

Imaging and Other Diagnostic Studies for Fractures of the Distal Femoral Physis

Radiographs

High-quality orthogonal radiographic views of the femur and knee are for diagnosing distal femoral physeal separations (Table 28-1). On the AP radiographic, physeal widening and the presence of a fracture line proximally in the metaphysis or distally in the epiphysis allows the surgeon to differentiate between the four most common Salter–Harris types, i.e., types 1 to 4. In addition, epiphyseal varus (also called apex lateral angulation) or valgus (also called apex medial angulation) and medial or lateral translation in the coronal plane are determined on the AP view. The lateral projection defines the amount of angulation and translation of the epiphysis in the sagittal plane. The anteriorly displaced epiphysis is usually tilted so that the distal articular surface faces anteriorly. This direction of displacement is alternatively called hyperextension of the epiphysis or apex posterior angulation. The posteriorly displaced epiphysis is tilted downward so that the distal articular surface faces the popliteal fossa, sometimes described as hyperflexion of the epiphysis or apex anterior angulation. Minor degrees of displacement may be difficult to measure on plain films unless the x-ray projection is precisely in line with the plane of fracture. Even small amounts of displacement are

TABLE 28-1 Imaging Studies in the Evaluation of Distal Femoral Physeal Fractures

Study	Indications	Limitations
Standard radiographs	First study, often sufficient	May miss nondisplaced Salter–Harris type I or III fractures or underestimate fracture displacement
CT scan	Best defines fracture pattern and amount of displacement	Poor cartilage visualization. Increased radiation exposure
	Useful for planning surgery, especially for metaphyseal comminution	Less useful than MRI in evaluating for occult Salter–Harris type I or III fractures
MRI	Evaluation of occult Salter–Harris type I fracture, especially in infants with little epiphyseal ossification	Availability, cost, duration of procedure
	Identifies associated soft tissue injuries, especially with Salter–Harris type III fractures	Fracture geometry less clear than with CT scans
Stress views	Differentiate occult Salter–Harris fracture from ligament injury	Painful, muscle spasm may not permit opening of fracture if patient awake. Potentially harmful to physis
Contralateral radiographs	Infants, or to assess physeal width Follow-up to compare growth	Usually not helpful in acute fractures
Ultrasonography Arthrography	Infants to assess swelling and displacement of epiphysis	Not useful after infancy

significant.[37,50] Rotational malalignment of the distal fragment relative to the proximal fragment may be identified on either view and is dramatic in some cases with severe displacement.

Diagnosis of minimally displaced distal femoral physeal fractures is challenging. Because the physis normally is radiolucent, injury is typically identified because of physeal widening, epiphyseal displacement, or metaphyseal bone injury suggestive of a fracture. Without obvious radiographic abnormalities, nondisplaced Salter–Harris type I or III fracture without separation can be easily overlooked.[5,72,85] Oblique views of the distal femur may reveal an occult fracture through the epiphysis or metaphysis. In the past, stress views of the distal femur were recommended for patients with negative radiographs who have an effusion or tenderness localized to the physis.[78] However, it is our practice to forego stress radiographs because they are painful to the patient and may damage the already compromised physis. Presumptive S-H I fractures are then either immobilized for 1 to 2 weeks and reexamined or are further evaluated with MRI.[54,78,81,85]

MRI

MRI is the most commonly used advanced imaging study for evaluating traumatic knee injuries in children and adolescents. The primary utility of MRI is to identify acute knee injuries when the examination and radiographs are nondiagnostic or to confirm diagnostic suspicions. In one large MRI study of 315 adolescents with acute traumatic knee injuries, physeal injuries of the distal femur were diagnosed in seven patients with negative plain radiographs.[19] MRI also facilitates identification of knee ligament tears, meniscal pathology, and osteochondral fractures that may occur concomitantly with distal femoral physeal fractures,[54] both in the acute setting and after fracture healing. MR arteriography is one method of evaluating vascular anatomy and flow in patients with an abnormal vascular examination in association with displaced distal femoral physeal fractures.

CT Scan

Computed tomography (CT) scan is recommended for all patients with Salter–Harris III and IV fractures diagnosed on plain radiographs. In one study, CT identified fracture displacement and comminution that was not recognized on plain radiographs of the knee. The authors encouraged its use for evaluation of these fractures to identify displacement, define fracture geometry, and plan surgical fixation.[46] CT may also be useful to identify fractures and displacement in cases where the plain radiographs are negative but the examination is suspicious for a distal femoral physeal fracture.

Special Situations of Fractures of the Distal Femoral Physis

Neonate

Separation of the distal femoral epiphysis in a neonate is particularly difficult to diagnose on initial X-rays unless there is displacement, because only the center of the epiphysis is ossified at birth. This ossification center is in line with the axis of the femoral shaft on both AP and lateral views in normal infants. Any degree of malalignment of the ossification center from the shaft should raise suspicion for this fracture. Comparison views of the opposite knee and other modalities may also be helpful to identify its presence in neonates when radiographs of the affected leg are equivocal. MRI, performed under anesthesia, is another commonly used diagnostic imaging study that may help to identify a separation of the unossified femoral epiphysis.[88]

Unique to the neonate is the use of ultrasonography[35] to evaluate distal femoral physeal separation. Typically used to evaluate the immature hip for developmental dysplasia of the hip, diagnostic ultrasound imaging may also be used to evaluate the cartilaginous distal femur in a young child with incomplete ossification of the distal femoral epiphysis. Although this study is safe and readily available, it is unfamiliar to many technicians and radiologists, making its reliability questionable unless performed by an experienced team. This modality may be used not only to diagnose injuries but also to guide reduction. Knee arthrography, another option for evaluating the immature distal femoral epiphysis for possible disruption, is primarily used to facilitate reduction and fixation in the operating room.

Physeal Arrest

The best method for determining the viability of the physis after healing of a traumatic injury is MRI performed with fat-suppressed three-dimensional spoiled gradient-recalled echo sequences.[22] Impending growth disturbance can be identified early with this MRI[22,26] technique and MRI can be used to map the extent of physeal bony bar formation to determine if excision is an option for treatment.[22,49] Although CT may also be used to map the location and area of physeal bars, it is out preference to use MRI because it does not expose the child to radiation and evaluates the quality of the physeal cartilage adjacent to the bar, a possible predictor of the success of physeal excision.

Classifications of Fractures of the Distal Femoral Physis

Salter–Harris Classification

Several types of classification schemes have been used to describe fractures of the distal femoral physis, each with some merit because of the information that its use provides to the surgeon. The Salter–Harris classification[74] is the most widely used classification scheme (Fig. 28-6). This familiar classification system, based on plain radiographs, is useful for the description of the types of physeal fractures of the distal femur. As opposed to its application to other physeal fractures, however, the Salter–Harris scheme is not as reliable in predicting the risk of growth disturbance as it relates to the fracture types.[24,50] For many physeal fractures in other anatomic sites, risk of growth disturbance is smaller after type I and II fractures and higher after types III and IV. Distal femoral physeal fractures, however, are at risk for significant growth disturbance regardless of type.[7,50,82] This classification scheme is useful for treatment planning and is also a good indicator of the mechanism of injury.[21]

Salter–Harris I Fractures. The Salter–Harris type I pattern is a fracture that traverses the distal femoral physis, without extension either proximally into the metaphysis or distally into

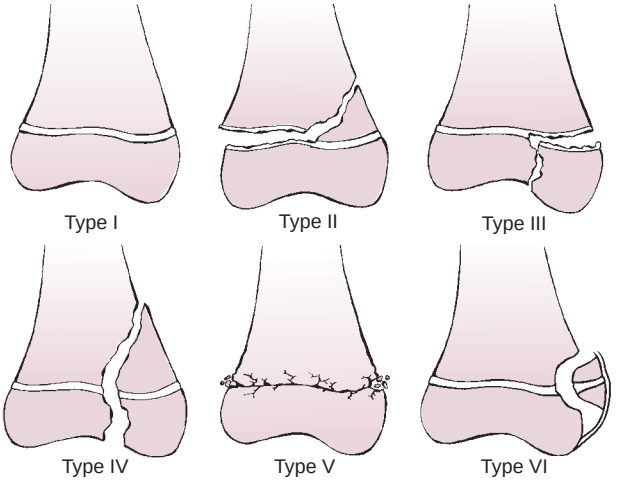

FIGURE 28-6 The Salter–Harris classification of fractures involving the distal femoral physis.

the epiphysis or knee joint (Fig. 28-7). Anatomically, this fracture cleaves the physis predominately across the physeal zones of cell hypertrophy and provisional calcification. Because of the undulation of the distal femoral physis, likely evolutionarily developed to increase the stability of the physeal plate when subject to shear stress, most distal femoral physeal fractures do not propagate cleanly across these zones but instead also extend into the germinal zones of the physis. This encroachment of the fracture line into cartilage precursor cells is likely the explanation for increased rates of growth disturbance after S-H I and S-H II fracture types.

Although this fracture pattern may be seen in any age group of skeletally immature patients, it occurs more frequently in infants, the result of birth trauma or abuse, and in adolescents with sports-related trauma. Many S-H I fractures are nondisplaced and may go undetected. Sometimes, the diagnosis is made only in retrospect, after subperiosteal new bone formation occurs along the adjacent metaphysis, evident on

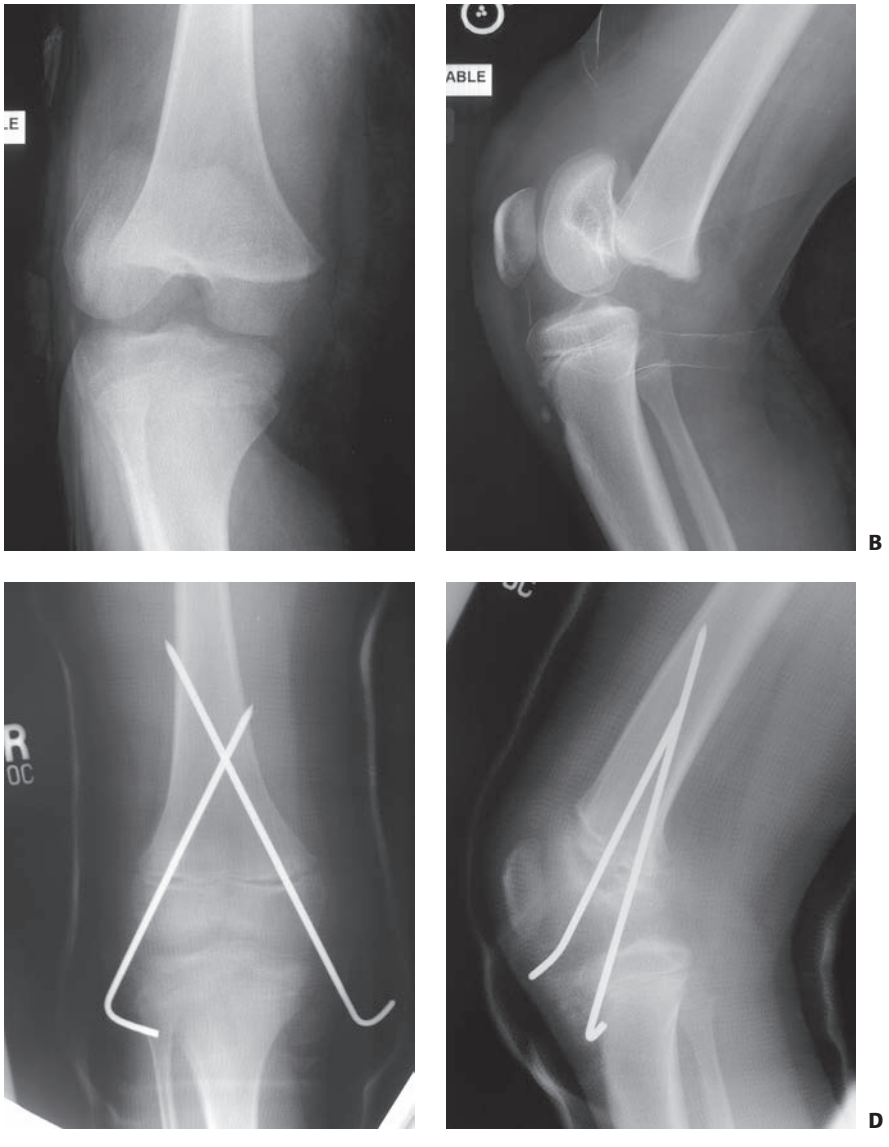

FIGURE 28-7 **A:** Salter–Harris type I fracture of the distal femur in an 8-year old. **B:** Lateral view shows hyperextension. **C:** Fixation following closed reduction under general anesthesia. Note that pins are widely separated at the fracture site. **D:** Lateral view of fixation.

follow-up radiographs 10 to 14 days after injury or by MRI. When displacement is present before the age of 2 years, it usually occurs in the sagittal plane. Approximately 15% of physeal fractures of the distal femur are type I fractures.[7]

Salter–Harris II Fractures. The Salter–Harris type II pattern is the most common type of separation of the distal femoral epiphysis (Fig. 28-8). This pattern is characterized by a fracture line that extends through the physis incompletely

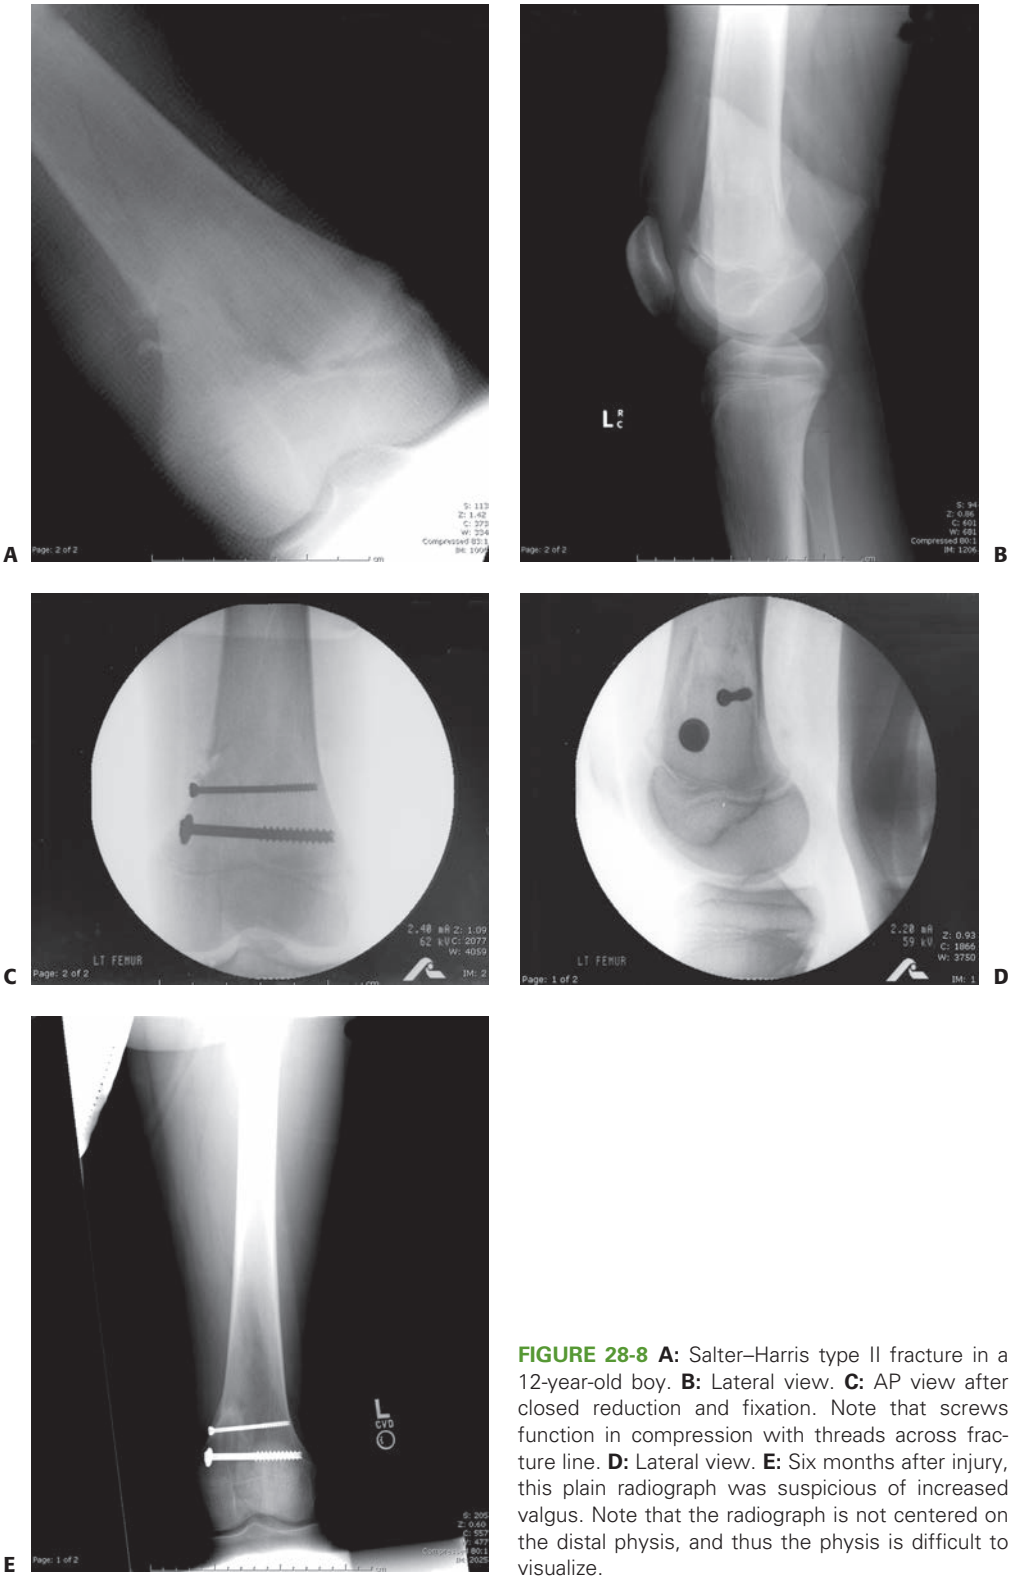

FIGURE 28-8 **A:** Salter–Harris type II fracture in a 12-year-old boy. **B:** Lateral view. **C:** AP view after closed reduction and fixation. Note that screws function in compression with threads across fracture line. **D:** Lateral view. **E:** Six months after injury, this plain radiograph was suspicious of increased valgus. Note that the radiograph is not centered on the distal physis, and thus the physis is difficult to visualize.

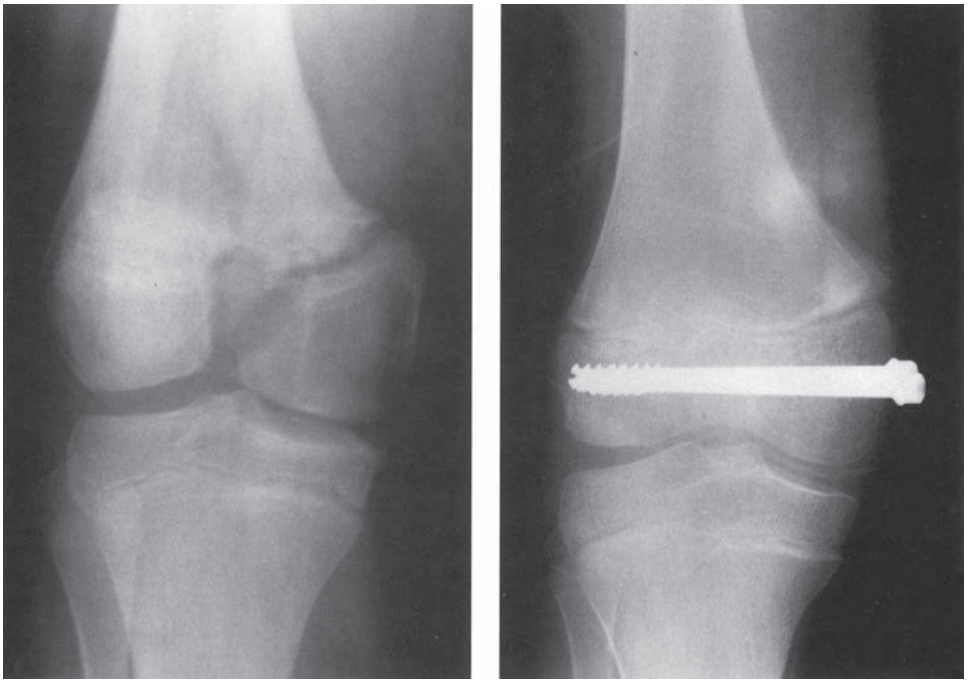

FIGURE 28-9 **A:** Salter–Harris type III fracture separation of the distal femur. Note the vertical fracture line extending from the physis distally into the intercondylar notch with displacement. **B:** After reduction and fixation with two compression screws extending transversely across the epiphyseal fragments. Note closure and healing of the vertical fracture line in the epiphysis, with restoration of the articular surface.

and then exits proximally via an oblique extension of the fracture line through the metaphysis. The metaphyseal corner that remains attached to the epiphysis is called the Thurston Holland fragment. Although the direction of displacement varies, typically the direction of displacement is also the location of the metaphyseal fragment because the metaphyseal spike occurs on the side of compression forces. This fracture type may also be seen in children of all ages but is more common in adolescents. Slightly more than half (57%) of all distal femoral physeal fractures are S-H II fractures.[7]

Salter–Harris III Fractures. The Salter–Harris type III injury has a fracture line that traverses part of the physis then exits distally, with extension of the fracture line vertically across the physis, epiphysis, and its articular surface (Fig. 28-9). Most Salter–Harris type III injuries of the distal femur traverse the medial physis and extend into the joint, separating the medial condyle from the lateral condyle of the distal femur. These injuries are often produced by valgus stress across the knee, the same mechanism of injury that produces medial collateral and cruciate ligament disruption in skeletally mature patients may have an associated injury to the cruciate ligaments.[16,66] This fracture occurs most frequently in older children and adolescents and comprises about 10% of all distal femoral physeal fractures.[7]

Nondisplaced S-H III and IV fractures and other more complex patterns of distal femoral physeal fracture may not always be detectable or fully delineated on plain radiographs, requiring MRI or CT to identify.[45,53,54,58] It has been hypothesized that the Salter–Harris type III fracture, seen mostly in older children and adolescents, may occur as a consequence of the progression of closure of the distal femoral physis. This pattern of fracture occurs near skeletal maturity when the central portion of the distal femoral physis begins to close before the medial and lateral parts of the physis, similar to a juvenile Tillaux fracture of the distal tibia.[54] Occasionally, a type III fracture may occur in the coronal plane of the distal femoral condyle, more commonly the medial femoral condyle, similar to the "Hoffa fracture" of the posterior condyle seen in adults.[45,58] This fracture is difficult to diagnose with standard x-rays[72]and is also challenging to reduce and fix. A triplane fracture of the distal femur, a fracture that appears as an S-H I injury in the sagittal plane and an S-H III fracture in the coronal and sagittal planes, has also been described.[53] This triplane fracture is not completely analogous to the classic triplane fracture of the ankle, however, because, while the fracture line extends in three dimensions about the physis, the distal femoral physis is completely open.

Salter–Harris IV Fractures. In Salter–Harris type IV injuries of the distal femur, the fracture line extends vertically through the metaphysis, across the physis, ultimately extending through the epiphysis and its articular surface (Fig. 28-10). It is at times difficult to distinguish between S-H III and S-H IV fractures because the metaphyseal fragment may be small and difficult to identify on plain radiographs. S-H III and IV fractures likely occur from similar mechanisms and in the same age ranges, with both presenting management challenges that require anatomic realignment of the joint line and physis to minimize risk of growth disturbance. Of fractures of the distal femoral physis, this fracture type is seen slightly more frequently than type III fractures, accounting for about 12% of fractures.[7]

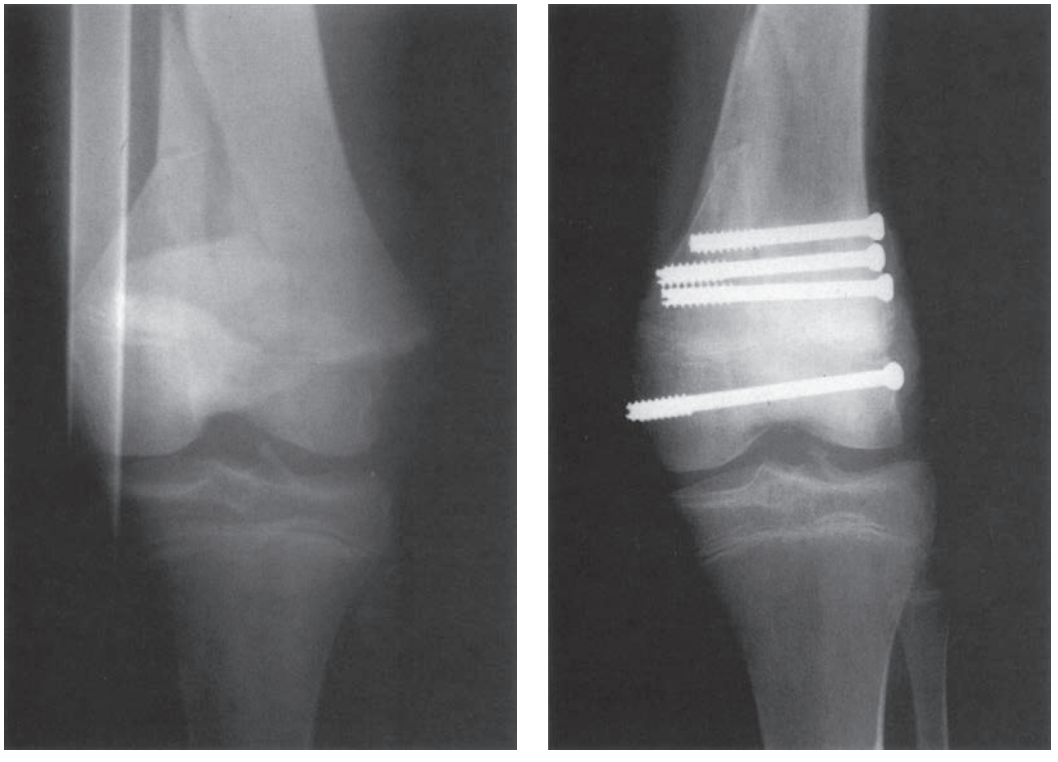

FIGURE 28-10 **A:** Comminuted Salter–Harris type IV fracture of the distal femur in a 14-year-old boy involved in a motor vehicle accident. **B:** Six months after open reduction and internal fixation with cannulated screws in the metaphysis and epiphysis.

Salter–Harris V Fractures. When initial radiographs of the distal femur are normal but subsequent imaging months after the traumatic injury identify a growth arrest, this fracture is termed a Salter–Harris V.[79] It is hypothesized that compression forces across the physis causes damage to the cartilage-producing cells in the growth plate but no epiphyseal displacement. Axial loading of the limb, such as from a fall from a height, is considered the classic mechanism of injury. It important to bear in mind, however, that premature growth arrest also may occur in association with nonphyseal fractures of the femoral and tibial shafts.[8,33,57,76] MRI may identify bone contusion on both sides of the growth plate after a traumatic injury that may be a harbinger to its occurrence.[76]Approximately 3% of physeal separations of the distal femur are Salter–Harris V fractures.

Salter–Harris VI. Rang[59,70] proposed a sixth type of Salter–Harris fracture that applies to the distal femur in children and adolescents with open growth plates. A type VI injury is an avulsion fracture of the periphery of the physis, resulting in an osteocartilaginous fragment comprising a portion of the perichondrial ring of the physis as well as small pieces of metaphyseal and epiphyseal bone. These may occur at many different anatomic sites but are seen most commonly about the physes of the distal fibula, distal femur, and distal tibia.[32] The mechanism of distal femur injury is typically an indirect force such as varus stress that causes avulsion of the fragment from partial detachment of the proximal lateral collateral ligament, often resulting in no displacement of the epiphysis. Alternatively, open injuries that abrade or skeletonize the area around the physis or loss of a peripheral portion of the physis, such as occurs from lawnmower injuries or motor vehicle trauma, and burns around the physis are other possible mechanisms. This injury is not included in many large series of physeal fractures of the femur but it is exceedingly rare. In one series of 29,878 children's fractures, only 36 were identified as Salter–Harris VI injuries.[32]

Classification by Displacement

Several authors have evaluated direction and magnitude of displacement to predict final outcome.[2,37,50,83] Direction of displacement may guide treatment but does not predict the frequency of poor outcomes.[2,37,80] Anterior displacement of the epiphysis, or apex posterior angulation, resulting from violent hyperextension of the knee is associated with an increased risk of neurovascular damage.[21,80] Peroneal nerve injury may occur with significant medial or lateral displacement of the epiphysis. Otherwise, direction of displacement has not been shown to correlate with other complications such as angular deformity, growth disturbance, or loss of motion.

By contrast, the magnitude of displacement has been shown to be predictive of complications.[2,37,83] The critical amount of displacement that is associated with worsening outcomes varies but, generally, displaced fractures of all S-H types are more likely to develop complications compared to nondisplaced fractures. In one study, fractures with displacement of greater than

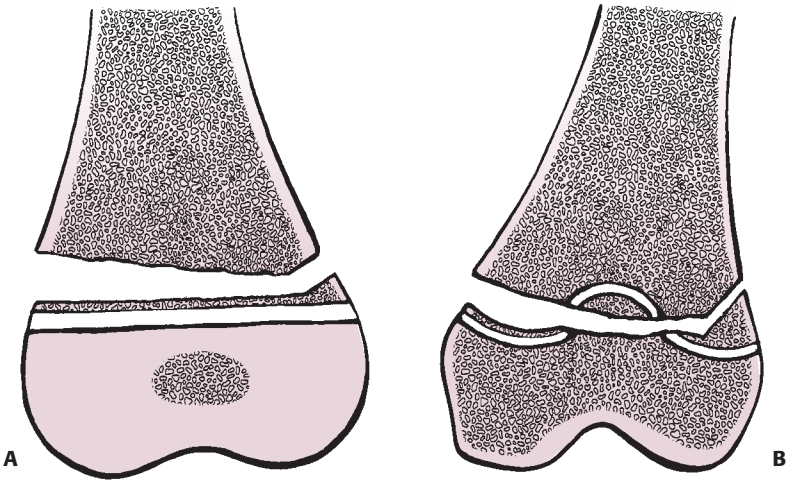

FIGURE 28-11 A: Distal femoral physeal separation prior to the age of 2 years may not disrupt growth because the physis is flat. **B:** After the age of 2 years, a central ridge and four quadrants of undulation develop in the distal femur. Fractures in this age group are more likely to cross multiple planes of bone and cartilage.

50% of the transverse diameter of the distal femoral metaphysis on either radiographic view were more likely to develop growth complications compared to less displaced fractures.[83] Others have determined that displacement of more than one-third of bone width correlates with more frequent complications.[2,37,50,83] Fractures without bony contact between the fragments and those with metaphyseal comminution,[37] both radiographic indicators of high-energy trauma, have also been correlated with an increased risk of complications.

Classification by Age

Age at the time of injury also correlates with the frequency and severity of complications.[71] Distal femoral epiphyseal fractures in children aged 2 to 11 years typically result from high-energy mechanisms and have a poorer prognosis compared to fractures in children younger than 2 years of age or older than 11 years.[24,71] Separations of the distal femoral epiphysis before the age of 2 years generally have satisfactory outcomes,[71,83] possibly because epiphyseal undulations and the central peak are not as prominent in infants (Fig. 28-11A), allowing fractures to occur with less force and less damage to germinal cells and their blood supply.[61] In adolescents, low-energy sports injuries are the most frequent cause of epiphyseal separation. Because children in this age group have little growth remaining, the consequences of growth disturbance, should this complication occur, are often trivial. In juveniles and adolescents, the fracture may pass through the central prominence and lead to central growth arrest because of interference with vascularity in this region or because of the fracture plane exiting and reentering the central physis (Fig. 28-11B).[61,71,81]

Outcome Measures of Fractures of the Distal Femoral Physis

In the largest published series[2,24,83] outcomes of distal femoral physeal fractures are determined by clinical assessment and radiographic parameters at follow-up. The primary clinical factors are the resulting neurovascular status of the affected limb and the range of motion of the knee. Secondarily, knee stability is assessed by subjective reporting of symptoms of instability and objective clinical stress testing of the knee ligaments. No study reported knee scores or the results of instrumented tests of knee ligament laxity.

Radiographic assessment of the injured limb is utilized in most studies to assess fracture healing, to identify physeal bar formation, to measure angular deformity about the knee, and to assess for leg-length discrepancies that may result from a growth disturbance. Fracture healing is determined subjectively by identifying fracture line bridging as well as clinical signs of healing. Physeal bar formation may be identified on plain radiographs but also is assessed by MRI or CT scan. Angular deformity is determined by measuring angulation of the fracture fragments or the tibiofemoral angle. Although limb-length discrepancy may be determined clinically, bilateral lower extremity scanograms, obtained by the Bell–Thompson method or by CT scanning, are utilized to assess the true LLD.

Surgical and Applied Anatomy Relating to Fractures of the Distal Femoral Physis

Ossification and Growth

The epiphysis of the distal femur is the first epiphysis to ossify and is present at birth, appearing as a small round bony structure distal to and in line with the axis of the metaphysis. This epiphyseal ossification center is the only radiographic sign of the larger cartilaginous anlagen of the distal femur. With maturation, the bony distal epiphysis enlarges as the cartilage model ossifies and becomes bicondylar, at times appearing irregular along the distal articular surface as ossification proceeds. From birth to skeletal maturity, the distal femoral physis contributes 70% of the growth of the femur and 37% of the growth of the lower extremity. The annual rate of growth is approximately three-eighths of an inch or 9 to 10 mm. The growth of the distal femur, like the physes of other long bones, ceases at a mean skeletal age of 14 years in girls and 16 years in boys, with a wide range of variability.[1,87]

Physeal Anatomy

At birth, the distal femoral physis is flat, or planar, making this physis in infants the least stable compared to other age groups. With maturation, the physis assumes an undulating and more convoluted shape.[47] By the age of 2 to 3 years, the physis develops an intercondylar groove, or central prominence, as well as sulci that traverse medial and lateral proximal to each condyle. This configuration effectively divides the physis into four quadrants, each with concave surfaces that match the four convex surfaces of the distal femoral metaphysis over a large surface area. The complex physeal geometry and large area of the distal femoral physis contribute to its stability by better resisting shear and torsional forces compared to the smaller, flat physes of infants. The perichondral ring also circumferentially reinforces the physis at its periphery. This structure, combined with the some reinforcement of the physeal periphery by the knee ligaments, provides additional resistance to disruption of the physis.[18,56] During adolescence, however, the perichondrial ring becomes thinner. It is hypothesized that this change contributes to relative weakening of the distal femoral physis, partially explaining the fact that fractures of this physis in adolescents are more frequent and generally occur from lower energy mechanisms compared to children of 2 to 11 years of age.

The irregular configuration of the physis, while contributing to stability, however, also is an important factor in the high incidence of growth disturbance from these fractures. Fracture lines, instead of cleanly traversing the hypertrophic zone and area of provisional calcification, extend through multiple regions of the physis and damage germinal cells regardless of fracture type.[71] In addition, during reduction of displaced fractures, epiphyseal ridges may grind against the metaphyseal projections and further damage cartilage-producing resting cells. Minimizing contact and shear across the physis during reduction is preferable to improve the chances of normal growth after injury. Reductions in the operating room with muscle-relaxing agents, use of traction during reduction, and limiting the number of closed manipulation attempts before converting to open reduction are some techniques that are generally recommended.

Bony Anatomy

Proximal to the medial border of the medial condyle, a small area of the metaphysis of the distal femur widens abruptly, forming the adductor tubercle. The lateral metaphysis, by contrast, flares only minimally at the proximal part of the lateral condyle, forming the lateral epicondyle. The distal femur is divided into two discrete condyles at the level of the knee joint, separated by the intercondylar notch. Nearly the entire distal femur is covered by hyaline cartilage for articulation with the proximal tibia. The anterior, or patellar, surface just proximal to the intercondylar notch, has a shallow midline concavity to accommodate the longitudinal convex ridge of the undersurface of the patella. Posteriorly, the distal femur contacts the tibial cartilage as the knee flexes. The posterior condyles, projections of the femoral condyles posteriorly, contain this cartilage that extends on either side of the intercondylar notch and nearly to the posterior margin of the physis.

The distal femur has well-defined normal anatomical alignment parameters. The mechanical axis of the femur is formed by a line between the centers of the hip and knee joints (Fig. 28-12). A line tangential to the distal surfaces of the two condyles (the joint line) is in approximately 3 degrees of valgus relative to the mechanical axis. The longitudinal axis of the diaphysis of the femur inclines medially in a distal direction at an angle of 6 degrees relative to the mechanical axis and an angle of 9 degrees relative to the distal articular plane.[34]

Soft Tissue Anatomy

The distal femoral physis is completely extrasynovial. Anteriorly and posteriorly, the synovial membrane and joint capsule of the knee attach to the femoral epiphysis just distal to the physis.

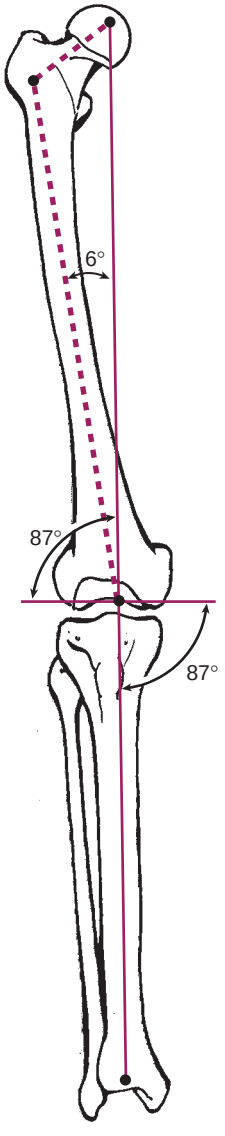

FIGURE 28-12 The mechanical and anatomic axis of the lower extremity. Note that the knee joint is in a mean of 3 degrees of valgus. The femoral shaft intersects the transverse plane of the distal femoral articular surface at an angle of 87 degrees.

The suprapatellar pouch, however, is a ballooning out of the synovium that extends proximally over the anterior surface of the metaphysis. On the medial and lateral surfaces of the epiphysis, the proximal attachment of the synovium and capsule is distal to the physis and separated from the physis by the insertions of the collateral ligaments. The strong posterior capsule and all of the major ligaments of the knee are attached to the epiphysis distal to the physis. Varus/valgus-directed forces that would cause collateral ligament disruption in adults often result in physeal separations in children and adolescents because the tensile strength of the ligaments is greater than that of the physis. The anterior and posterior cruciate ligaments originate in the upward-sloping roof of the intercondylar notch distal to the physis. Compression and tension forces can be transmitted across the extended knee to the epiphysis of the femur by taut ligaments. The medial and lateral heads of the gastrocnemius muscles originate from the distal femur proximal to the joint capsule and physis. Although forces generated by the gastrocnemius are probably not a major factor that contributes to fractures of the distal femoral physis, pull of the muscles may be a deforming force for metaphyseal fractures of the distal femur.

Neurovascular Anatomy

Arterial Anatomy

The popliteal artery runs along the posterior surface of the distal femur, separated from it by only a thin layer of fat.[20] Directly proximal to the femoral condyles, this artery sends off transverse branches medially and laterally, called the medial and lateral superior geniculate arteries, along the surface of the distal femoral metaphysis beneath the overlying muscles which they supply. The popliteal artery then continues distally, adjacent to the posterior capsule of the knee joint between the femoral condyles. At this level, the middle geniculate artery branches from it anteriorly to the posterior surface of the epiphysis, providing the primary blood supply to the distal femoral epiphysis and the physis. The distal femoral epiphysis, however, receives its blood supply from a rich anastomosis of vessels. Because of this, osteonecrosis of this epiphysis is exceedingly rare, occurring only in situations where distal femoral epiphysis is completely stripped of its soft tissue attachments. Since the popliteal artery and its branches course along the posterior distal femur, it is especially vulnerable to injury because of contact with the distal femoral metaphysis from hyperextension injuries of the knee with anterior displacement of the epiphysis. While tenting of the artery causing occlusion and arterial spasm are the most common reasons for vascular abnormalities related to distal femoral physeal fractures, intimal injury and laceration may also occur.

Nerve Supply

The sciatic nerve, extending from the upper thigh, divides into the common peroneal and tibial nerves just proximal to the popliteal space. The peroneal nerve then descends posteriorly, between the biceps femoris muscle and the lateral head of the gastrocnemius muscle, to a point just distal to the head of the fibula. The peroneal nerve then changes course, wrapping around the proximal fibula to enter the anterior compartment of the lower leg, where it divides into the deep and superficial branches. The common peroneal nerve's course between muscles protects it from direct injury from fracture ends. This nerve, however, because of limited excursion due to its anteriorly directed course around the fibular head, is susceptible to injury from stretch. Neurapraxia, and even axonotmesis of the common peroneal nerve, results most commonly from fractures with severe anterior displacement and medial translation (varus displacement).[80] The tibial nerve, coursing through the popliteal space adjacent to the popliteal artery, enters the calf along the arch of the soleus muscle. This nerve is vulnerable to injury from mechanisms that are similar to those that cause injury to the popliteal artery, although clinically tibial nerve injury is rare.

Treatment Options for Fractures of the Distal Femoral Physis

Management Considerations for Fractures of the Distal Femoral Physis

Distal femoral physeal fractures in children and adolescents are challenging fractures that require careful preoperative evaluation and assessment of the injury including both physical and radiographic examinations so as to devise an appropriate treatment plan (Table 28-2). The treatment principles for these injuries can be summarized as follows.

1. Restore the anatomy without iatrogenically compromising the distal femoral physis.
2. Stabilize the fracture in the position of anatomic reduction.

The surgeon must keep in mind that by definition there has already been an injury to the physis and further damage to the physis by repeated or forceful manipulations may contribute to one of the complications of this injury, premature physeal closure. Closed reduction of these injuries must be done gently, preferably under either under IV sedation or general anesthesia, so that this reduction be accomplished easily with minimal force. Once the reduction has been achieved, maintaining it has been shown to be vitally important for influencing outcome (as redisplaced fractures tend to have poor prognosis and higher complication rates).[7,83] Treatment is also guided by the Salter type. Salter types III and IV are intra-articular and require an anatomic reduction to minimize the potential for future arthritis and degenerative joint disease. Therefore these fractures are most commonly treated with open reduction and internal fixation to restore anatomic integrity of the joint surface. The ultimate goals of treatment are to maintain anatomic alignment of the lower extremity, preserve range of motion in the knee joint, and not disturb ongoing growth of the distal femoral physis.[9]

Closed Treatment of Fractures of the Distal Femoral Physis

Nondisplaced or minimally displaced distal femoral physeal fractures especially Salter I or Salter II fractures, may be treated with, a gentle closed reduction and immobilization in a cast. Conceivably even a Salter III or Salter IV fracture that was completely nondisplaced could also be managed in this manner. The treating

TABLE 28-2 Methods of Treatment for Distal Femoral Physeal Fractures

Treatment	Pros	Cons	Indications
Closed reduction and immobilization	Avoids anesthesia	High risk of loss of reduction	Nondisplaced, stable fractures
Closed reduction and screw fixation	Minimal dissection	Only in reducible fractures	Reducible Salter–Harris type II fractures Nondisplaced Salter–Harris type III and IV fractures
Closed reduction and smooth pinning	Minimal dissection	Pins may lead to joint infection or require later removal	Reducible Salter–Harris type I fractures, and Salter–Harris type II fractures with small metaphyseal fragment
Open reduction and screws and/or pins	Anatomic reduction	Stiffness	Irreducible Salter–Harris type I and II fractures, displaced Salter–Harris type III and IV fractures
External fixation	Allows soft tissue access	Pin site (joint) infection	Severe soft tissue injury
Rigid plate crossing physis	Rigid fixation	Can stop future growth when spans physis	Adolescents near the end of growth. Severe injuries with growth disturbance inevitable Possible temporary fixation with extraperiosteal locked plating removed soon after union

surgeon must be cognizant of the fact that displacement may have been far greater at the time of injury than the injury radiographs depict. At the time of the injury, the periosteum and/or resilience of the child's bone as well as reduction at the site of injury may have occurred, rendering the acute trauma or injury films to be either non- or minimally displaced.[9] Evidence of considerable soft tissue injury such as swelling, ecchymosis, and/or other skin changes may also be an indication that the fracture was more displaced at the time of injury.

If minimal force is required to perform a reduction, most series indicate that these fractures can still be successfully managed in this manner. This technique of a closed reduction and immobilization in a long-leg cast has been performed primarily in minimally or nondisplaced Salter I and II fractures.

Careful assessment of stability of the fracture by the surgeon is crucial to having a successful outcome with closed reduction and manipulation. In a recent study of 82 patients immobilized in a long-leg cast, 36% had redisplacement in the first 2 weeks including three patients in a series of 29 immobilized with a hip spica cast.[24] Of the 32 patients that displaced in a cast in this study, only eight were successfully remanipulated. Closed reduction and casting is never the best definitive treatment for displaced or unstable distal femoral physeal fractures because of the significant risk of fracture redisplacement.[2] Persistent widening after provisional reduction may reflect interposed periosteum and lead to reduction less than anatomic and more likely to redisplace.[9] Recent literature suggests that periosteal interposition may theoretically place the physis at increased risk for closure.[75] Anatomic reduction is always the goal with these injuries and if an adequate reduction cannot be obtained by closed means, alternative methods of treatment must be utilized.

Techniques of Reduction

Displaced distal femoral physeal fractures with more than 2 mm of malalignment typically require reduction and surgical stabilization with internal fixation. The overriding principle regarding reduction maneuvers is to avoid further injury to the physis (Fig. 28-13). Most authors recommend that the reductions be done with the patient relaxed with muscle relaxants or under general anesthesia. However, so-called gentle reduction does not preclude the possibility of growth arrest, as has been noted by Thomson et al.[83] The technique of reduction relies on assessment of the fracture pattern. In a general sense, the concave side of the fracture would be gently manipulated to realign it with the long axis or shaft of the femur, essentially closing down the convexity of the fracture. The periosteum is typically intact on the concave side of the injury. For example, the periosteum on the side of the Thurston Holland fragment for Salter II fractures is usually intact, but disrupted on the convex side of the fracture. Periosteal interposition at the fracture site is a frequent occurrence in these fractures and necessitates careful assessment of the postreduction imaging and anatomy.

For a Salter II fracture that is displaced into valgus alignment such as the epiphysis is displaced laterally and there is a lateral Thurston Holland fragment of metaphysis attached to the epiphysis, the reduction maneuver would involve gentle longitudinal traction often with the knee flexed slightly and counter pressure applied over the distal medial femur while the epiphyseal portion of the fracture is gently guided back in place. More challenging reductions occur in the sagittal plain when the epiphysis is displaced either anteriorly or posteriorly. Anteriorly displaced physeal fractures generally require some level of knee flexion to achieve reduction. In all reductions, generally longitudinal traction is the first force applied followed by the gentle manipulation of the epiphysis back into place starting with counterpressure on the proximal segment in an opposite direction. For a displaced epiphysis that is anterior, holding the fracture reduced may require a significant amount of knee flexion, which especially in a swollen knee, which may not be advisable from a neurovascular standpoint. Fractures like these may require internal stabilization with pins simply to be able to splint the knee in slight flexion.

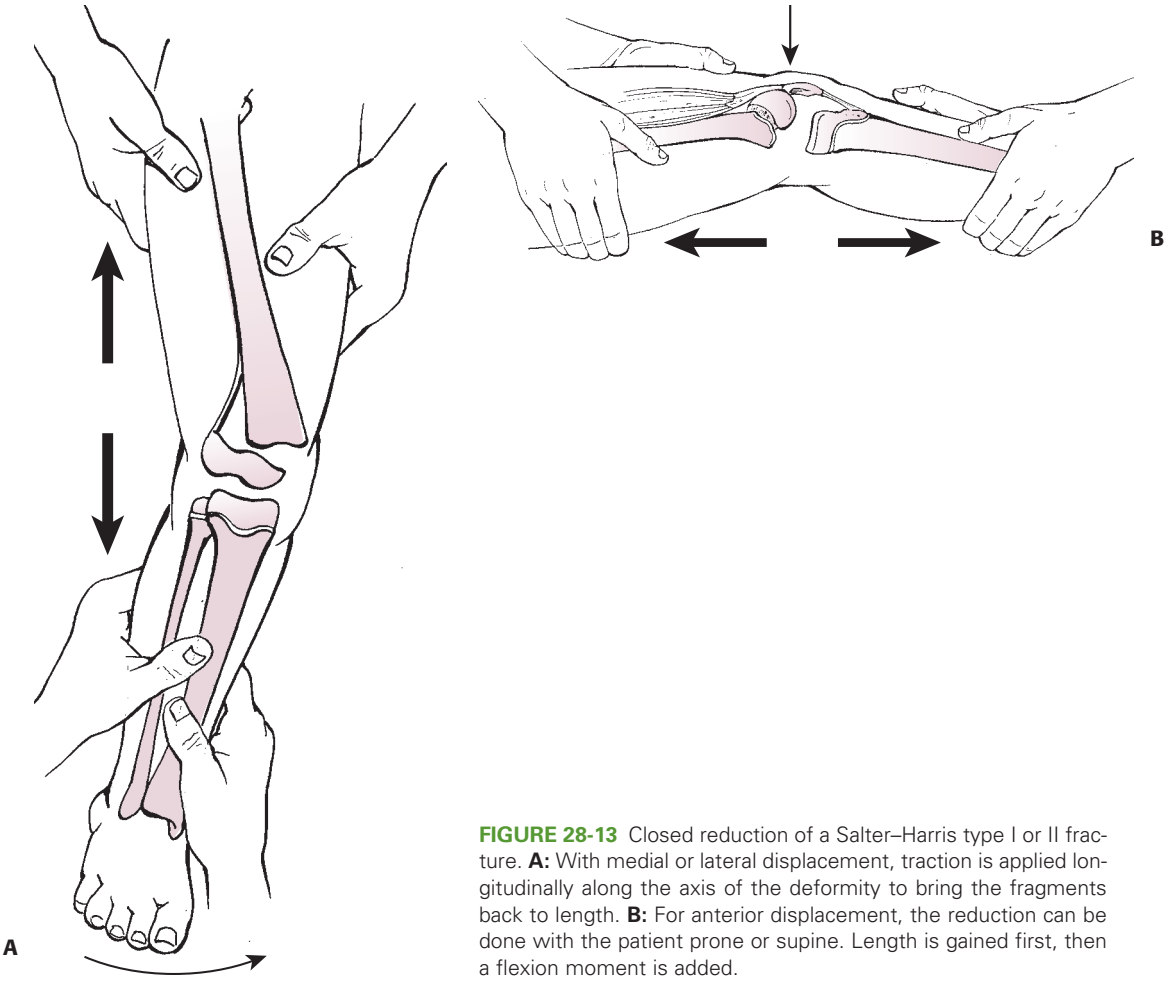

FIGURE 28-13 Closed reduction of a Salter–Harris type I or II fracture. **A:** With medial or lateral displacement, traction is applied longitudinally along the axis of the deformity to bring the fragments back to length. **B:** For anterior displacement, the reduction can be done with the patient prone or supine. Length is gained first, then a flexion moment is added.

Some authors recommend aspiration of the knee or the hematoma that may be present especially in Salter III or IV fractures prior to closed reduction maneuvers. Various reports indicate redisplacement of reduced fractures in a cast of 30% or higher such that there has been a tendency for internal stabilization with implants for displaced fractures.[83] A recent report indicated that internal fixation is the preferred method of treatment for all displaced injuries.[2]

Technique of Closed Reduction and Percutaneous Pinning

One of the most common methods that displaced distal femoral physeal fractures are stabilized is a technique of percutaneous internal fixation with pins or screws (Fig. 28-14). These fractures can often be reduced fairly anatomically and given their propensity to be unstable, fixation with crossed pins or with a screw or two through the Thurston Holland fragment in the case of Salter II fractures provides stable internal fixation of the fracture. Even Salter III and IV fractures can be treated this way if there is minimal displacement on the injury films and an anatomic reduction can be achieved by closed means.

Preoperative planning and room setup for percutaneous pinning would involve the use of a radiolucent table although a traction-type table is usually not necessary. Obviously, imaging must be available, as well as the appropriate instrumentation, typically cannulated large fragment screws and smooth Steinmann pins. Muscle relaxation of the patient provided by the anesthesiology team is especially helpful before initiating reduction maneuvers. Neurovascular status of the extremity should be checked routinely both before and after reduction maneuvers. At times, reduction is facilitated by placing a bump under the patient's thigh. In the case of flexion or extension-type physeal displacement, these injuries may actually be managed in a prone position. The actual technique would require closed reduction to be accomplished with virtually anatomic alignment as discussed previously. In terms of a Salter I or Salter II fracture without a significant Thurston Holland fragment, the technique involves placing typically retrograde two large Steinmann pins. These are frequently 3.2-mm or even larger diameter smooth pins. With x-ray guidance and the reduction held by an assistant, a small incision is usually made laterally over the condyle in midpoint. The placement of the pin is not in the articular

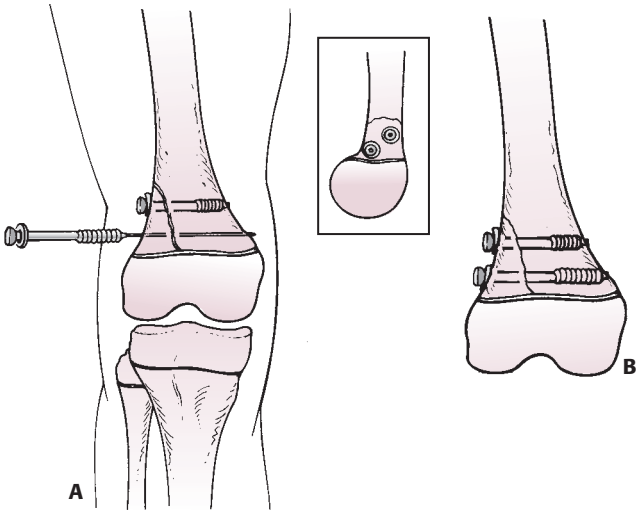

FIGURE 28-14 Screw fixation following closed or open reduction of Salter–Harris type II fracture with a large metaphyseal fragment. **A:** When using cannulated screws, place both guidewires before screw placement to avoid rotation of the fragment while drilling or inserting screw. Screw threads should be past the fracture site to enable compression. Washers help increase compression. Screws may be placed anterior and posterior to each other, which is particularly helpful when trying to fit multiple screws in a small metaphyseal fragment. **B:** This form of fixation is locally "rigid," but must be protected with long-leg immobilization.

cartilage but just off the articular margin in the epiphyseal bone and directed slightly anteriorly to avoid injury to the posterior neurovascular structures (Fig. 28-15). It may be more helpful to start with the pin on the side that was the concave side of the fracture pattern. Two pins are typically placed. Careful assessment radiographically should be done with C-arm imaging in both AP and lateral planes.

Fracture stability may also be assessed by gently applying varus, valgus, or flexion–extension force once pins are in place. Some authors will leave the pins external in this area. Some will bend them slightly and cut them short and leave them under the skin. Other authors advocate driving the pins out and through the metaphysis of the bone such that they are flush with the edge of the epiphysis at the entry site and bend them externally above the knee. One concern with external pins in this area is the issue that the joint itself could be contaminated since the pins are essentially intra-articular, hence the reason some surgeons drive the pins proximally to exit through the metaphysis.[9] Starting the pins proximally in the metaphysis and placing them across the fracture in an antegrade fashion and ending them in the subchondral bone of the epiphysis is becoming more popular in some centers to minimize pin tract infections that could communicate with the joint. Typically patients are immobilized in a fiberglass long-leg cast with the knee gently flexed.

Distal femoral physeal fractures heal readily and are healed within 4 weeks at which point pins may be removed. Touchdown weight bearing in the cast may be allowed in the last week or two prior to pin removal. Often a splint or hinged knee brace is used for a few weeks to facilitate regaining range of motion of the knee with increasing weight bearing, such that most patients are able to bear weight fully about 6 weeks post-op. Pin removal at 4 weeks may be done in the office if the pins are external or as a day surgery procedure if they were buried beneath the skin. The patients are instructed to work on quad strengthening and active range of motion of the knee often facilitated by physical therapy.

Screw Fixation

The technique for stabilizing a Salter II fracture with a significant metaphyseal fragment again involves performing a gentle closed reduction under anesthesia. A small incision is then made in the metaphysis over the Thurston Holland fragment which typically is either on the medial or lateral aspect of the distal femur. The guide pins from the cannulated screw systems are used to help stabilize the fracture. Typically only drilling the outer cortex is necessary and either one or two 6.5 or larger screws are utilized to stabilize the fracture fragment. Care must be taken to ensure that the screws do not approach or cross the physis. Generally, screws are placed in a manner that is parallel to the distal femoral physis. Again assessment of fracture stability by gentle stress with the hardware in and secure is helpful to ensure that internal fixation is adequate in providing optimum stability. Postoperative treatment would be the same with typically long-leg casting for 4 weeks. Screw removal is at the discretion of the family and surgeon at a convenient time in the future. Occasionally the Thurston Holland permits only one screw to be placed. These fractures may be unstable enough that one screw is insufficient to provide adequate internal fixation. It is not uncommon that a single screw in a Salter II fracture may be supplemented with a Steinmann pin in the fashion as described for percutaneous pinning. If one Steinmann pin is to be used, it would ideally enter on the side opposite the entry of the screw to provide stability of the fracture.

Closed Reduction and Screw Fixation of Salter III and IV Fractures

Minimally displaced Salter III fractures may also be managed with percutaneous reduction and screw fixation. The use of reduction bone forceps or clamps may be helpful in closing down a gap or diastasis of the condyles. Again, careful and accurate assessment of intraoperative imaging is essential to ascertain whether the reduction is adequate for percutaneous technique versus an open reduction. Screw placement in a Salter III or IV fracture may be done in the epiphysis with x-ray guidance using a cannulated screw system. Care must be taken not to place the screws too distal in the epiphysis such that they would impinge on the intercondylar notch of the femur. Again typically two screws possibly placed one more anterior and one more posterior would be utilized to stabilize a Salter III fracture internally. A Salter IV fracture may have a metaphyseal fragment that is sufficiently large enough to be stabilized with a screw. The epiphyseal portion or the Salter IV fracture may then be stabilized by another screw (Fig. 28-16).

Challenges or problems with the technique of a closed reduction and internal fixation with pins or screws include an inadequate reduction that may be secondary to periosteal interposition. As mentioned, the periosteum is often torn on the convex side so an incomplete reduction that has still a wide physis on the convex side may need to be opened on that side to extract the periosteum to ensure an adequate, stable, and anatomic reduction. Interposed periosteum has been shown experimentally to increase the risk of growth disturbance.[67] In addition, when trying to utilize this technique for Salter III or Salter IV fractures, if the articular surface cannot be well aligned or if there is comminution present, an open approach would be necessary. Likewise, comminution of the metaphysis may make screw fixation of a Thurston Holland fragment difficult, necessitating that some Salter II fractures be fixed internally in a stable configuration with transphyseal pins and not screws. The technique of utilizing transphyseal pins to stabilize distal femoral physeal fractures requires the use of smooth pins to minimize injury to the physis. A recent paper looked specifically at the issue of physeal injury and subsequent growth arrest to determine if the pins could possibly be the culprit causing the arrest.[27] The conclusion of this work was that the pins themselves were not the primary cause of the subsequent physeal arrest or growth disturbance. This potential for physeal arrest varied with increasing severity based on the Salter–Harris classification and percutaneous smooth pins were not statistically associated with the growth arrest.[27]

Reduction and Internal Fixation

Open reduction and internal fixation is necessary for all irreducible distal femoral physeal fractures. Irreducible fractures may have interposed periosteum on the side of the open physis or the convex side of the fracture. An incision is necessary over that area whether it is medial or lateral; even in sagittal plane displacements, typically the incision is still on the medial or lateral aspect. The periosteum is carefully removed from the physis and care is taken to avoid causing any more injury to the physis by surgical instruments or retractors.[9] Evacuation of organized hematoma is helpful to achieve anatomic reduction. Internal fixation may proceed accordingly with either pins or screws as warranted.

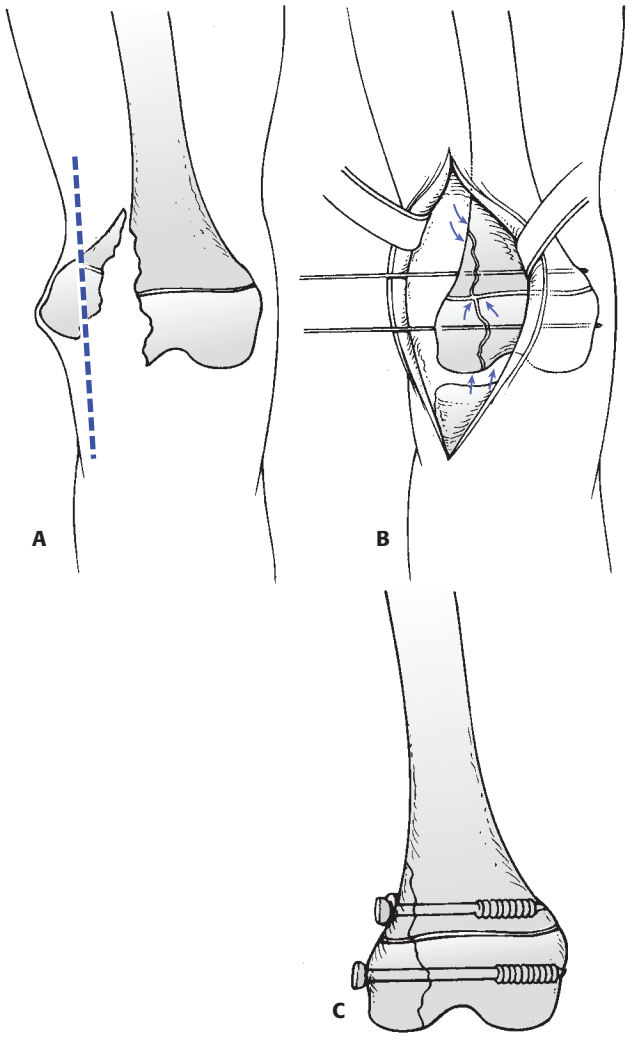

FIGURE 28-16 Open reduction of displaced lateral Salter–Harris type IV fracture of the distal femur. **A:** A longitudinal skin incision is made anteriorly on the knee at the location of the intra-articular fracture or in the midline if fracture severity raises concern of needing a total knee replacement in the future. **B:** Alignment of joint and physis are used to judge reduction. Guidewires for cannulated screws placed above and below physis, parallel to physis. **C:** Screws inserted in compression with washer on metaphyseal fragment. Washer is optional in epiphyseal fragment if later prominence is of more concern than need for additional compression.

Fractures that undergo open reduction and internal fixation may be more prone to get stiff and healing by 4 weeks remains the norm with early mobilization of the knee recommended starting at about 4 weeks.

Other Means of Fixation

The use of external fixators in open fractures of the knee involving the distal femoral physis may be a helpful means of managing severe soft tissue trauma and injuries. Typically one

or even two half pins from an external fixation frame may be placed in the epiphysis of the fracture with 2 pins placed in the femoral shaft. Salter III and IV fractures may be somewhat more difficult to manage with the external fixation technique. Fixation across the knee may be necessary.

Another means of fixation is a plate spanning the physis. A recent paper from France described good outcomes with this technique.[37] The plates were removed at a relatively early interval to minimize any growth disturbance and screw insertion and placement occurred so as to avoid the physis. Absorbable screws have also been utilized in some of these patients. There is little current literature on this technique.

In Salter III and Salter IV fractures, arthroscopically aided reduction of the fracture may be helpful in somewhat minimally displaced fractures to ensure an anatomic reduction of the joint line and articular cartilage.[44] In addition, visualization of the knee joint, whether with arthroscopy or at the time of arthrotomy, permits assessment for other associated injuries such as ligamentous injuries or meniscal injuries.

Most authors recommend dealing with intra-articular ligamentous injuries later after the fracture has healed. Peripheral tears of the meniscus may be repaired primarily at the time of an operative open reduction. As in most current protocols for ACL reconstruction, resolution of the acute phase swelling and in this case fracture healing and rehabilitation would be accomplished prior to consideration of ACL reconstruction.

For those fractures associated with vascular injuries, typically full and rapid reduction of the fracture and stabilization is necessary. If there is still a vascular compromise of the leg, the orthopedic surgical team may consider compartment pressure monitoring and/or fasciotomies as warranted while the vascular team is evaluating the need for intervention for an occluded artery.[9]

Author's Preferred Treatment of Fractures of the Distal Femoral Physis

Key Concepts

The critical factor in distal femoral physeal fractures is the amount of energy sustained by the distal femoral physis which often determines the outcome and future growth of the physis. The management of these fractures must be focused on minimizing further injury or trauma to the physis, especially with reduction maneuvers. Displaced fracture reduction must be done easily, gently, and in a relaxed patient. Often the fractures reduce with longitudinal traction and a little medial or lateral pressure; physeal fractures elsewhere in the skeletal system often do not require a lot of force. Repeated forceful reductions must be avoided to minimize potential iatrogenic injury to the physis. Treatment principles really are based on the Salter–Harris classification as well as the amount and degree of displacement. The authors have a very low threshold for operative stabilization of these fractures with pins or screws as needed.

For nondisplaced and stable fractures regardless of Salter type, the authors are comfortable with a well-molded long-leg cast. In children with certain body types, especially obese patients that are relatively short stature, cast immobilization may not provide fracture stability. Treatment must be individualized to the specific patient and consideration given to the possibility that casting may not adequately stabilize a nondisplaced fracture. The treating surgeon must recall that what appears nondisplaced on radiographs in the emergency room may have displaced and returned to normal anatomic positioning at the time of injury, and not lulled into a false sense of fracture stability for "nondisplaced" fractures.

Should cast immobilization be elected as a treatment option for nondisplaced fractures, seeing the patient back in the office and obtaining the x-rays within 4 to 5 days is recommended to ensure that the fracture reduction is maintained or to identify loss of anatomic position as early as possible. Literature indicates that loss of reduction and rereduction of fractures is associated with a higher incidence of physeal growth arrest, but accepting a malalignment is also less than ideal for the patient's functional outcome.

Displaced Salter–Harris I and II Fractures

Many Salter I and Salter II fractures of the distal femoral physis that are displaced can be managed by a reduction in the operating room and stabilization with internal fixation. If one or two screws can be placed through the Thurston Holland fragment to stabilize a Salter II fracture, it would certainly be the desired treatment. Large Steinmann pins are also commonly utilized to stabilize both Salter I and Salter II fractures as needed. Typically these patients are then managed with 4 weeks of long-leg casting, removal of the cast around 4 weeks, and use of a knee immobilizer or hinged knee brace for initiation of early motion. Therapy may be helpful for these patients to assist with regaining range of motion, but the therapist must be cautioned against any forcible passive manipulation in the early post casting phase. Most patients seem to be off crutches and ambulating fairly well by 7 or 8 weeks postinjury.

Displaced Salter–Harris III and IV Fractures

Displaced intra-articular fractures that involve the distal femoral physis require careful scrutiny of the fracture alignment and pattern preoperatively and especially careful assessment of the intraoperative imaging. Salter III or IV fractures may require open reduction and internal fixation to ensure anatomic restoration of the articular cartilage. This can sometimes be done with a closed percutaneous reduction, sometimes with the bone reduction forceps, and then percutaneous cannulated screw fixation. A number of authors point out that imaging with the image intensifier or C-arm in the OR may not be the most accurate way to assess post-op reduction in a fracture like this. The other option would be to obtain true hard copy radiographs with a standard machine intraoperatively. One option is to utilize arthroscopy as a means to assess the joint alignment and integrity. The authors do not have extensive experience with arthroscopically assisted reduction of these fractures, but in some centers this is becoming a routine procedure for Salter III

and IV fractures. The post-op regimen is the same with casting for 4 weeks and then initiation of early motion and particularly in these patients a hinged knee brace versus knee immobilizer may also be very helpful.

The authors explain to all distal femoral physeal fracture patients and their families that these physeal injuries of all Salter types may have a long-term guarded prognosis regarding growth of the physis. Follow-up is done essentially at monthly intervals for the first several months; usually the 1-month visit is a day surgical procedure to remove pins. Screw removal of the cannulated screws done percutaneously is left to the discretion of the family. Occasionally these are removed if MRI imaging is needed to assess the physis. Follow-up should be scheduled at 3 months, approximately four-and-a-half months and 6 months postinjury to specifically assess alignment of the extremity length and carefully assess radiographs for signs of physeal injury or arrest.

Surgical Complications of Fractures of the Distal Femoral Physis

Impending Complications

As has been mentioned these distal femoral physeal injuries require significant trauma to be sustained by the extremity to cause displacement of the physis. With that amount of force or pressure other associated injuries may occur. Those patients with displaced fractures in particular must be carefully assessed for neurovascular status at the time of injury in the emergency room. For Salter II distal femoral physeal fractures that displace the epiphysis anteriorly, the distal portion of the femoral artery or popliteal artery is at risk from the distal end of the segment of the femur. Careful assessment of the pulses and circulation to the foot are essential. In patients with a documented vascular compromise or white foot, this reduction and surgery is truly an operative emergency and careful assessment post-op for return of vascular status is necessary. Consultation with the vascular surgical team is often necessary if concerns of vascular status remain postreduction. Vascular imaging may be needed to assess circulation if pulses are still diminished following reduction and stabilization of the distal femoral physeal fracture. Likewise some of these patients may sustain such injury to the leg that a compartment syndrome could ensue, so careful monitoring of the compartments by clinical examination or if needed by compartment pressure measurements may be necessary.

Malalignment and Poor Reduction or Loss of Reduction

Often displacement in distal femoral physeal fractures can be significant. In an operating room with muscle relaxation, reduction can often be accomplished without significant force by simply placing traction on the leg and guiding the epiphysis back into position. Careful assessment both clinically and radiographically of leg alignment and fracture reduction needs to be done to ensure that as anatomically as possible a reduction is achieved. Reduction that remains malaligned in either the coronal or sagittal plane may persist in that malalignment and require subsequent late constructive surgery. It is especially critical to accurately assess imaging in the operating room to ensure that physeal widening, which may be subtle, is not present.

Interposed periosteum may cause physeal widening and block a more anatomic reduction as well as contribute to fracture instability that could lead to loss of reduction in a casted patient postoperatively. The treating surgeon should have a low threshold to make an incision and inspect the fracture to ensure there is no soft tissue impeding reduction in cases that may look less than anatomically reduced.

When a loss of reduction of what was thought to be a stable nondisplaced fracture in a cast is noted, the patient should be expeditiously returned to the operating room and anatomic alignment reestablished as easily and safely as possible. In this situation, if the patient had previously been treated with casting only, it is necessary to add internal fixation in the form of pins or screws as appropriate to stabilize that patient's fracture.

Fixation

Many of these fractures do not have sizable Thurston Holland fragments in the Salter I or II category that would enable screw fixation. Many of the patients are managed with pin fixation with transphyseal pinning techniques. The surgeon must ensure that an adequate pin size is used. Typically in the author's experience this is a minimum of 2.4- or 2.8-mm pin diameter and in larger patients even 3.2-mm diameter pins must be used. Intraoperative imaging should ensure that these pins are bicortical and have good purchase in both the distal and proximal fracture fragments.

Infection

The literature substantiates that infection and in fact septic knee arthritis may result from pins left externally that are placed in a retrograde manner in the epiphysis on either side of the knee joint. The author's preferred technique is to not leave these pins exposed outside the skin. If the pin can be gently bent, it is bent and cut in such way that the pin is inside the skin with the wound closed over it. Another technique described by Blaiser[13] places the pins retrograde across the physis and advances them up through the skin proximal to the knee joint. The pins left are flush with edge of the condyle or epiphysis distally. The areas can be closed and the pins are external above the knee joint. Closing the skin over the retrograde pinning entry sites helps minimize the risk of intra-articular sepsis in these patients. In the event of a true infection the patient is returned to the operating room for irrigation and debridement. The pins may have to be left in if the fracture is not sufficiently healed at least 4 weeks postinjury. Appropriate antibiotic treatment and surgical wound management are necessary in these cases of an infection, especially in the first few weeks following the injury.

Management of Expected Adverse Outcomes and Unexpected Complications

In the immediate postoperative period, loss of reduction and neurovascular injuries are important complications. In

TABLE 28-3 Distal Femoral Physeal Fractures: Pitfalls and Prevention

Pitfall	Preventative Strategy
Missed diagnosis	Immobilize and reexamine if uncertain, or MRI Be cognizant of nondisplaced injury in infants, pathologic conditions, multitrauma, or unresponsive patients
Redisplacement of fracture	Pin or screw fixation for all fractures that require reduction. Radiographs at 5–7 days postinjury High long-leg cast with triangular molding proximally or spica cast
Growth disturbance	Minimize trauma at reduction Follow-up at 6, 12, and possibly 24 months with full-length radiographs of both lower extremities
Knee joint instability	Check ligaments when fracture stabilized or healed. Consider MRI, especially for type III fractures
Stiffness	Avoid prolonged immobilization Remove casts in 4 weeks and apply knee immobilizer with gentle range of motion in most cases. Avoid manipulation because of risk of added injury

follow-up, the most common complications of distal femoral physeal fractures include knee ligament injury, growth disturbances of the distal femur, neurovascular complications from the fracture and persistent knee stiffness (Tables 28-3 and 28-4).

Loss of Reduction

Redisplacement after closed reduction of distal femoral physeal separations has been reported in 30% to 70% of patients immobilized in a long-leg cast.[24,29,71,83] Placement of a hip spica cast may reduce this loss of reduction to as low as 10%.[24] Multiple attempts at initial closed reduction, and late reduction after injury or after a failed first attempt at reduction, are potentially damaging to the physis and may increase the risk of growth disturbance.[70] In one experimental rat model, risk of physeal injury was similar for fractures reduced after the equivalent of 7 human days. After 10 days, however, manipulation of physeal fractures led to diaphyseal fractures because of the degree of physeal healing.[23] Based on the experimental evidence and clinical experience, it is reasonable to attempt manipulation, or repeat manipulation, of physeal fractures of the distal femur within 7 to 10 days of injury. After 10 days, however, open reduction may be required to reestablish alignment and to minimize damage to the physis. For children with more than 2 years of growth remaining who have Salter–Harris I and II fractures, observation for remodeling may be more prudent, depending on the degree of deformity. Osteotomy of the femur may be performed later if remodeling is incomplete. Older children with type I and II fractures are best treated with open reduction and fixation possibly combined with epiphysiodesis of the uninjured distal femur. For patients of all ages who present late after sustaining displaced Salter–Harris type III and IV fractures, open reduction is recommended as soon as possible to restore articular surface.[55] Any resultant leg-length discrepancy can be managed in the future.

Neurovascular Abnormalities

Vascular Injury

Vascular injuries are uncommon with this fracture, with most series reporting no vascular injuries.[24,50,71,83] Trauma to the popliteal artery may be caused by trauma from the distal end of the metaphysis and occurs most commonly from fractures caused by forced knee hyperextension resulting in anterior displacement of the epiphysis.[10,24,74] In the emergency department, clinical signs of vascular impairment should prompt the surgeon to perform emergency reduction of the fracture. It is our preference to perform the reduction in the operating room but, in situations when a delay of treatment in the operating room is expected, reduction of the gross deformity and splinting of the fracture is a reasonable course of action. Arteriography is not indicted prior to reduction of the fracture.

In the operating room, the fracture is reduced and stabilized first. If vascular examination is normal after reduction, as evidenced by return of distal pulses, normal capillary refill, and symmetric ankle-brachial indices, the limb is splinted or casted with cut-outs to permit serial evaluation of the pulses easily and the child is admitted for observation. Because intimal injuries of the artery and thrombosis may occur in a delayed fashion, the child's vascular status is monitored closely for 24 hours or so after surgery for signs of worsening vascular status and compartment syndrome. Arteriography is sometimes utilized during the observation period to assess patients with distal perfusion and some abnormality of vascularity, such as diminished pulses, and for those with a worsening of vascular status after reduction and pinning.

If, after reduction and fixation in the operating room, distal perfusion does not return within 15 to 20 minutes, the time course over which vessel spasm typically recovers, immediate exploration of the vessel by a vascular surgeon is indicated. Although ischemia time may be increased when prolonged fracture stabilization is performed first, manipulation of the fracture after vascular surgery may compromise the repair. Arteriography is indicated only if the fracture has occurred in association with an ipsilateral pelvic fracture or another more proximal leg injury to localize the site of vascular injury or to assist the vascular surgeon in planning the type of repair for those with isolated distal femoral physeal fractures. In most cases, thrombectomy and direct vessel repair or bypass of the injury with a vein graft are necessary to restore flow. If ischemia time exceeds 6 to 8 hours, four-compartment fasciotomies of the lower leg are done in conjunction with the vascular repair to minimize the effects of reperfusion and treat prophylactically compartment syndrome of the calf.

Peroneal Nerve Injury

The peroneal nerve is the most frequently injured nerve after distal physeal separations.[24] It is injured primarily from traction, the result of anteromedial displacement most commonly, but may also be damaged from direct trauma as well. Most peroneal nerve injuries are neurapraxias that spontaneously recover within 6 to 12 weeks of injury.[24,80] Persistent neurologic deficit 3 months after fracture warrants electromyographic examination. If the conduction time is prolonged and fibrillation or denervation is present in distal muscles, exploration and microneural reanastomosis or resection of any neuroma may be indicated. Open injuries that result in peroneal nerve transection are best treated with repair or nerve grafting as early as possible after injury based on the child's condition and the status of the soft tissues about the nerve laceration. An ankle-foot orthosis is typically prescribed for patients with peroneal nerve injuries to facilitate rehabilitation and is discontinued after nerve recovery.

Ligamentous Injuries

Symptomatic knee joint instability has been reported in 8% to 40% of patients with distal femoral physeal fractures.[11,24] Although these ligament injuries occur at the time of initial trauma, most are not identified until after the fracture has healed and rehabilitation has been initiated. The anterior cruciate ligament is most commonly disrupted, especially after Salter–Harris type III fractures of the medial femoral condyle.[16,54,68,85] Collateral ligament and posterior cruciate ligament disruptions and meniscal injuries may also occur after these fractures but are less common.

Difficulty with stairs, pain or swelling with activities and episodes of giving way, or knee buckling are typical presenting complaints indicative of knee. The physical examination may identify knee stiffness, signs of ligament instability, and joint line tenderness. Early diagnosis of injuries to the ligaments or menisci can facilitate earlier management[11] but, in many cases, the symptoms related to recovery from the fracture make identifying these other injuries difficult. MRI of the knee after healing of the fracture is the best way to delineate these injuries. Meniscal surgery, especially repair, is ideally done soon after fracture healing to facilitate rehabilitation. Knee ligament reconstruction is best done after knee range of motion has been restored and other factors are taken into account including the degree of instability, the child's age, and level of activity.

Knee Stiffness

Limitation of knee motion after separation of the distal femoral epiphysis is seen in as many as one-third of the patients after fracture healing. This complication is the result of several factors including, intra-articular adhesions, capsular contracture, and muscle contractures, most notably the hamstrings and quadriceps. Initial treatment consists of active and active-assistive range-of-motion exercises. Drop-out casts and dynamic bracing may be of benefit for some with persistent stiffness. For patients with persistent stiffness and loss of functional range of motion despite nonsurgical treatments, surgical interventions may be utilized to restore mobility. Gentle knee manipulation under anesthesia is sometimes useful but is associated with the risk of periarticular fractures of the knee.[18] Surgical release of contractures and adhesions, followed by continuous passive motion, is most reliable for regaining motion.[77]

Growth Disturbance

The most common complication of distal femoral epiphyseal fractures is growth disturbance. This complication is manifested

clinically by the development of angular deformity in cases where the physeal injury is incomplete (Fig. 28-17), shortening of the limb after injuries that result in complete arrest, or, as in some cases, both angulation and limb shortening. In one meta-analysis of case series reported from 1950 to 2007 that included 564 fractures, 52% of fractures resulted in a growth disturbance.[7] Although Salter–Harris type I and II fractures in other areas of the body usually have a low risk of growth arrest, these Salter–Harris fractures in the distal femur are also at risk for premature physeal closure (Fig. 28-18). Of the most common Salter–Harris types, growth abnormalities are seen in 36% of type I fractures, 58% of type II fractures, 49% of type III fractures, and 64% of type IV fractures. Displaced distal femoral physeal fractures are four times more likely to develop growth arrest compared to nondisplaced fractures. Growth disturbance is uncommon in patients younger than 2 years of age who sustain these injuries, possibly because of the flat shape of the physis in this age group[71] which reduces the damage of

FIGURE 28-18 Five-year-old boy hit by car with fracture of the distal femur. **A:** AP radiograph of minimally displaced Salter–Harris type IV fracture of the distal femur. **B:** AP radiograph of healed fracture. From this view, it is difficult to determine if injury to the physis has occurred, though a central growth arrest was suspected. **C:** MRI shows a central growth plate injury probably did occur, although this did not result in formation of a bony bar or growth arrest. (Courtesy of Robert Kay, MD, Los Angeles, CA.)

physeal cartilage precursor cells. Older children who have more than 2 years of growth remaining are at highest risk for this complication and are most likely to have clinically significant deformities resulting from physeal arrest.[71] Although adolescents frequently sustain this fracture and may develop growth complications, the clinical consequences of growth arrest are not as severe, compared to patients between the ages of 2 and 12 years. Increased growth arrest is also seen more commonly in patients who had surgery for these fractures, particularly if transphyseal fixation was utilized.[2]

Diagnosis

Growth arrest is typically evident by 6 months after distal femoral epiphyseal fracture healing. Because the distal femur grows approximately 1 cm a year, complete cessation of growth, or even angular deformity, may not be evident clinically for 12 to 18 months after injury. Subtle radiographic clues may be seen, however, in some cases within 4 to 6 months of injury. Follow-up radiographs after fracture healing should be carefully scrutinized to determine if the physeal line is reconstituted and that Park–Harris growth arrest lines are running parallel to the physis on both AP and lateral views. Growth arrest lines develop when there is a temporary slowing of growth during periods of malnutrition, trauma, chemotherapy, or alcohol consumption, among other things.[28,30,60,62] The normal longitudinal orientation of the zone of provisional calcification becomes dense and interconnected, forming a transverse line in the metaphysis. After growth resumes, this dense layer moves away from the physis and is visible on radiographs as a radiodense line of bone in the metaphysis.[60] If the line is growing symmetrically away from the physis, then normal growth has resumed. Failure of a Park–Harris line to appear is evidence of premature growth arrest if a line is visible in the comparison radiograph of the uninjured distal femur. An oblique Park–Harris line that converges toward the physis indicates asymmetrical growth caused by a bone bridge across the physis that is preventing growth of one side of the physis.

Full-length standing x-rays of both lower extremities may also be a clue to help determine if growth disturbance has occurred. It is our practice to obtain standing radiographs of the lower extremities as soon as possible following the initial injury to document the leg-length difference and limb alignment for children at high risk for growth disturbance. Imaging is then repeated at approximately 6-month intervals so that any leg-length difference or change in angulation may be identified. Bilateral lower extremity scanograms and CT scanograms are also useful for measuring leg-length discrepancies but drawbacks compared to full-length radiographs include inability to assess the mechanical axis and increased radiation exposure, respectively.[73] If growth disturbance is suspected, MRI or CT is utilized to determine its extent; screw removal is typically done before imaging to improve the quality of imaging by eliminating the scatter effect of the metal. Physeal growth arrest is best detected by fat-suppressed three-dimensional spoiled gradient-recalled echo sequence MRI technique and may identify abnormalities as early as 2 months after injury.[22]

Treatment of Physeal Arrest

Progressive Angulation

Early recognition and management of progressive angulation can reduce the need for osteotomy if the diagnosis is made before a clinically significant deformity develops by excising the physeal bar to allow resumption of normal growth. After deformity has developed, however, an osteotomy is generally required whether bar excision is performed or not. The bar is typically located across the portion of the physis that was directly injured. Physeal bars may arise after any fracture type but are most common after type II, III, and IV fractures. When asymmetric growth follows a type II separation, the portion of the physis protected by the Thurston Holland fragment is usually spared, leading to growth inhibition in that portion separated from the metaphyseal fragment. For fractures with a medial metaphyseal spike, the resultant deformity is more likely to be valgus because of lateral growth arrest, whereas the opposite is true for fractures with a lateral metaphyseal spike. For type III and IV fractures, the physeal bar is usually centered on the site of the physis that was traversed by the fracture line.

Excision is generally recommended for posttraumatic physeal bars that constitute less than 50% of the total cross-sectional area of the distal femoral physis in children with a small degree of angulation and at least 2 years of growth remaining.[41,64] In one series, resumption of normal growth was seen in 80% of patients whereas others have reported less stellar results, with growth restoration seen in only 25% to 50% of patients.[12,17,31,89] Because bar excision may be unreliable, it is our practice to perform ipsilateral hemiepiphysiodesis combined with contralateral distal femoral epiphysiodesis for patients with less than 15 to 20 degrees of angulation and less than 3 to 4 cm of growth remaining in the injured physis, a scenario most commonly encountered in older children and adolescents with less than 2 years of growth potential. For children with more than 4 cm of growth remaining, physeal bar excision is attempted for those bars that encompass less than 50% of the physis because the combination of ipsilateral hemiepiphysiodesis and contralateral epiphysiodesis results in unacceptable loss of overall height. For older children and adolescents with physeal bars and angulation exceeding 15 to 20 degrees, distal femoral osteotomy may be done at the time of bilateral distal femoral physeal ablation surgery. Physeal bar excision in combination with distal femoral osteotomy may be considered for those younger children who are candidates for bar resection and have angulation that exceeds 15 to 20 degrees.[41,43,64] If physeal bar excision fails to restore growth, or limb-length discrepancy is severe at the time of diagnosis of the growth disturbance, limb lengthening and other reconstructive procedures are options to consider based on the projected growth remaining and the limb-length difference.

Complete Physeal Arrest with Leg-Length Discrepancy

Limb-length discrepancy is a frequently reported complication of distal femoral physeal fractures[2,24,37,71,83] but only 22% of patients with distal femoral physeal fractures have leg-length

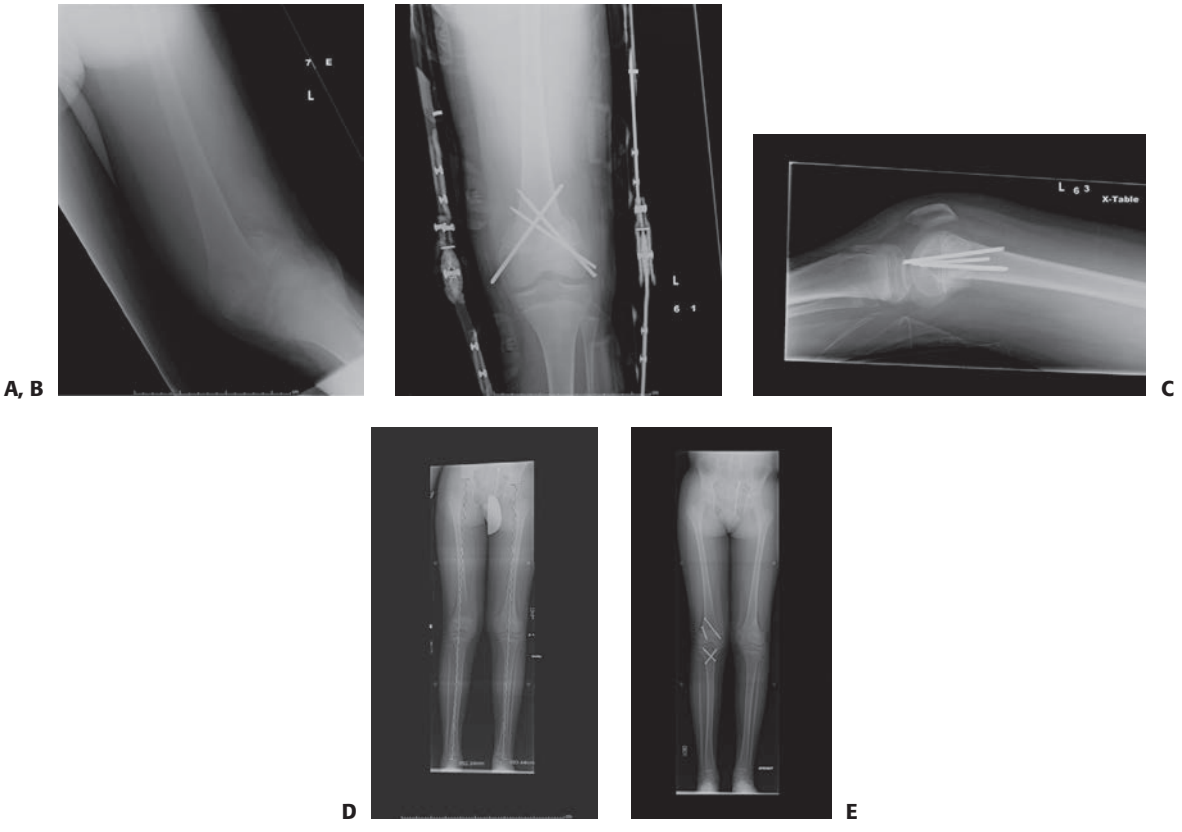

FIGURE 28-19 A 13-year-old male fell off a wall. He sustained a comminuted fracture of the distal femur **(A)** with superficial abrasions over his leg and underwent closed reduction and fixation with smooth wires **(B** and **C).** Eighteen months later he has an LLD of about 2 cm. After a discussion with the family, screw epiphysiodeses of the femur and tibia were done **(D).** At 1-year follow-up he has nearly equal leg-lengths **(E).**

discrepancies measuring greater than 1.5 cm (Fig. 28-19).[7] This is the case because many fractures occur in older children and adolescents with limited growth remaining at the time of injury. The treatment strategy varies, depending on the projected amount of discrepancy. Because the decision for treatment must often be made at the time of diagnosis of the complete arrest, methods of predicting the ultimate leg-length discrepancy that do not require serial measurements, such as the Paley or Menelaus methods, are utilized. Immediate contralateral distal femoral epiphysiodesis is indicated for older children and adolescents with projected discrepancies greater than 2 to 2.5 cm. For children with discrepancies that are projected to be larger than 2.5 cm, planning for limb lengthening is initiated.

Summary, Controversies, and Future Directions Related to Fractures of the Distal Femoral Physis

Summary

Physeal fractures of the distal femur, while relatively uncommon, are associated with a higher incidence of complications compared to other physeal fractures. Although the majority are isolated injuries resulting from sports activities and other relatively low-energy mechanisms, some of these fractures are caused by high-energy trauma. Patient evaluation must focus on identifying possible associated injuries and the neurovascular status of the affected limb. Peroneal nerve and popliteal artery injuries, and compartment syndrome of the leg, may occur in association with fractures of the distal femoral physis. Radiographs and CT scan are utilized to fully delineate the fracture pattern and to guide treatment. Most Salter–Harris I and II fractures may be treated with closed reduction and fixation with smooth wires or screws. Salter–Harris III and IV fractures frequently require open reduction and fixation to ensure anatomic alignment of the joint line and physis. Growth disturbance, manifest as angular deformity and leg-length discrepancy, is the most common complication related to distal femoral physeal separations and is seen in approximately half of the patients, especially those who sustain displaced fractures regardless of Salter–Harris type. Other complications of these injuries include knee ligament tears, knee joint stiffness, and neurologic deficits.

Controversies and Future Directions

Some important issues regarding physeal fractures of the distal femur require clarification and warrant future study. The diagnosis of physeal separations in the face of negative radiographs

by stress radiographs of the distal femur remains somewhat controversial. In a past era when open repair of medial collateral ligament injuries were performed, distinguishing physeal separations from ligament tears by stress views was important for making expedient treatment decisions.[28] Iatrogenic worsening of physeal injury, however, is a concern when performing this diagnostic test. Now, because initial treatment is similar for both injuries, specifically immobilization and not surgery, and with the increasing use of MRI to evaluate acute knee injuries, stress views are no longer routinely utilized for children and adolescents with possible physeal separations with few exceptions.

The best method of advanced imaging for displaced fractures is another area of controversy. For intra-articular fractures, some[46] have recommended the routine use of CT scan as part of the preoperative evaluation to help delineate the fracture pattern and to plan fixation. Others prefer MRI for these injuries, trading some diminution of bone details for the ability to diagnose chondral, meniscal, and ligament injuries.[54,81] In the acute setting, the best choice of imaging studies is unclear. The surgeon must weigh the pros and cons of each modality, taking into consideration, among other concerns, the availability of each of the modalities in the emergency setting, the radiation risk of CT, and familiarity with interpretation of MRI for fracture assessment. Further study is needed.

Despite advanced imaging methods of fracture evaluation and modern surgical techniques for management of displaced fractures, the fact remains that complications, particularly growth disturbance, are a significant problem associated with these fractures. The future research for this injury, as well as other physeal fractures, must focus on the methods that diminish the incidence of growth disruption and restore growth when arrest occurs. The use of stem cells, cartilage cell regeneration, and other novel techniques are being developed to solve the problem of growth arrest after physeal injury in children.[39,69,90]

29 PROXIMAL TIBIAL PHYSEAL FRACTURES

Eric W. Edmonds and Scott J. Mubarak

Introduction to Proximal Tibial Physeal Fractures

Fractures of the proximal tibia physis require a significant amount of force, and therefore these injuries account for less than 1% of all physeal separations.[27,40] Contrasting the distal femur discussed in the previous chapter, the proximal tibial physis has intrinsic varus–valgus and side-to-side translational stability because of the collateral ligaments and the lateral fibular buttress.[6] Although potentially problematic regarding an apophyseal fracture of the tibial tubercle, the metaphyseal overhang of the tubercle can provide anterior–posterior translational support.

An avulsion fracture of the tibial tuberosity is uncommon, accounting for less than 1% of all epiphyseal injuries and approximately 3% of all proximal tibial fractures.[4,27,40] Most fractures concerning the proximal tibial physis result in anterior, anterolateral, and anteromedial epiphysis displacement relative to the metaphysis caused by the anatomic stability mentioned above.[46] In the rare fracture with posterior displacement, the epiphysis and tubercle apophysis are displaced as a single unit.[34] Fractures of the proximal tibial metaphysis usually occur in children aged 3 to 6 years, and may be complete or greenstick. In contrast, the tibial tubercle fracture is most commonly sustained by adolescents.[30] The most critical features of proximal tibial physeal fractures are proximity to the popliteal artery and possible development of compartment syndrome.

Assessment of Proximal Tibial Physeal Fractures

Mechanisms of Injury of Proximal Tibial Physeal Fractures

As mentioned, these injuries require a significant amount of force to propagate a proximal tibial physis fracture, most often motor vehicle trauma, sports injuries, or other traumatic events such as lawn mower accidents. However, Salter–Harris type II fractures have been reported in child abuse cases and Salter–Harris I fractures have been reported in arthogrypotic children undergoing physical therapy stretching.[12,49]

Physeal fractures are often seen after a hyperextension force resulting in the metaphyseal portion of the tibia displacing posteriorly toward the popliteal artery. Valgus stress can open the physis medially with the fibula acting as a lateral resistance force (Fig. 29-1).[54] Rarely, a flexion force can cause a Salter–Harris type II or III fracture. This flexion fracture pattern has a mechanism similar to that of tibial tuberosity avulsion injuries.

Tibial tubercle apophyseal fractures are more frequently the result of jumping activities, especially at the initiation of the jump during eccentric loading at maximal quadriceps force, but may also be seen during eccentric loading while landing (Fig. 29-2).[4,7,8,19,29,30,34] Moreover, tibial tuberosity fractures are reported almost exclusively in boys who tend to have greater quadriceps strength and may overcome the stability of the apophysis with a violent contraction of the muscle.[4,5,7,8,19,26,29,30,34]

Associated Injuries with Proximal Tibial Physeal Fractures

Although the proximal tibial physis and the tibial tubercle apophysis are intimately associated with each other, fractures of the two locations have a unique set of associated injuries. The proximal physis fracture is at risk for ligamentous, vascular, and neurologic injury; whereas, the tubercle apophyseal fractures are also at risk for compartment syndrome.

Ligamentous injuries and internal derangement of the knee joint may occur during Salter–Harris III and IV proximal tibial physeal injuries in 40% of patients.[41] In contrast, the tibial tubercle fractures may rupture the patellar ligament, quadriceps tendon, collateral, and cruciate ligaments in a far greater frequency.[4,28,29,35] Even an avulsion of the anterior tibialis muscle has also been reported.[25,53]

Vascular compromise in proximal tibial physeal fractures can be devastating, but they are uncommon in isolated tubercle injuries.[6,46,55] The popliteal artery is tethered by its major branches near the posterior surface of the proximal tibial epiphysis. The posterior tibial branch passes under the arching fibers of the soleus. The anterior tibial artery travels anteriorly over an aperture above the proximal border of the interosseous membrane. A hyperextension injury that results in posterior displacement of the proximal tibial metaphysis may stretch and tear the tethered popliteal artery (Fig. 29-3). Even a minimally displaced fracture at presentation may have had significant displacement at the time of injury, and should therefore be monitored for vascular injury.[50] Diagnostic workup of these fractures does not mandate routine angiography as long as motor function, pulses, warmth, and color are monitored closely after reduction during the initial 48 to 72 hours.

Regarding vascular injuries, the tibial tubercle avulsion fractures are at risk for bleeding of the anterior tibial recurrent artery (which traverses the base of the tubercle) into the anterior compartment. Rather than resulting in direct ischemia, this vascular compromise is associated with indirect ischemia through the development of compartment syndrome.[37]

A peroneal neuropathy may also be associated with a fracture of the proximal tibial physis, but it will often undergo spontaneous resolution of symptoms.

Signs and Symptoms of Proximal Tibial Physeal Fractures

Physical examination of children with either a proximal physis or tubercle apophysis fracture may not be dissimilar. Pain, knee effusion, and a hemarthrosis will often be present in both. Limb deformity may or may not be present in either fracture type, and hamstring spasm may limit knee extension on examination.

FIGURE 29-1 Jumping on the trampoline is a common mechanism for young children to sustain valgus and varus fractures of the proximal tibia.

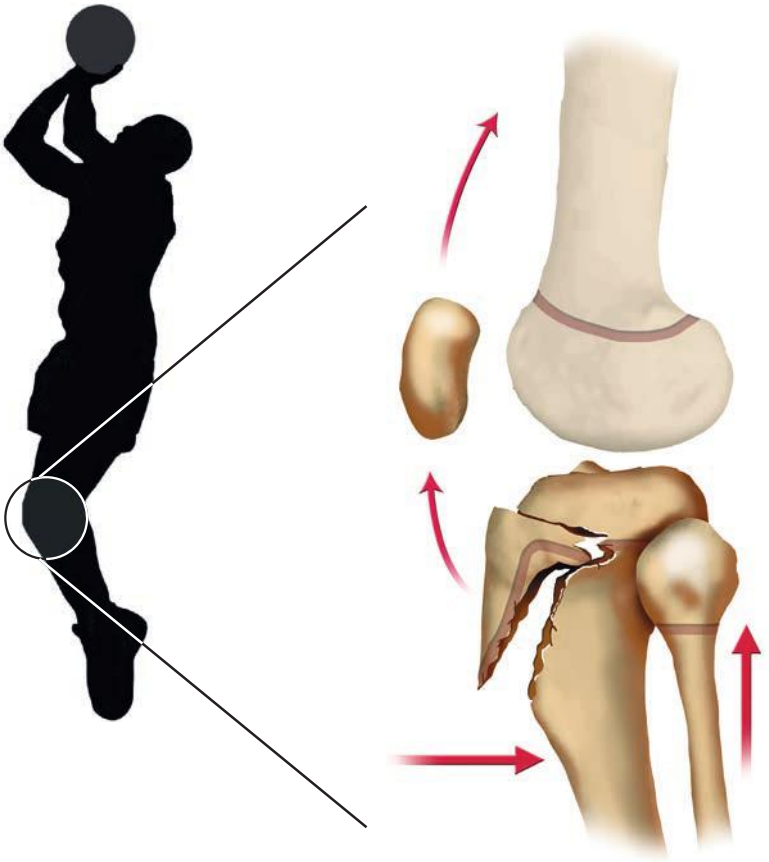

FIGURE 29-2 The tibial tubercle is commonly fractured because of the maximum generated force of the quadriceps contracture during jumping—primarily in male adolescents.

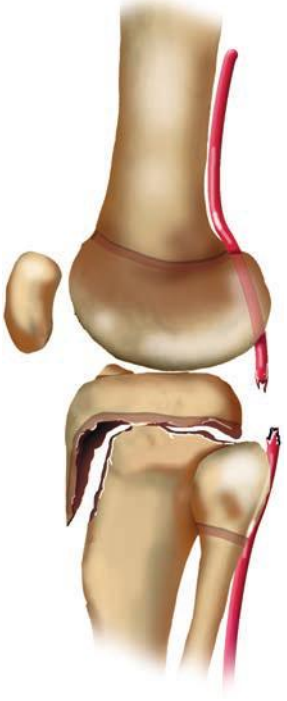

FIGURE 29-3 Tethering of the popliteal artery by the more distal tibial artery creates a situation wherein posterior metaphyseal tibia displacement can rupture the artery.

The physeal injuries will have pain over the tibial physis distal to the joint line, in contrast to the tubercle injuries that will hurt directly anteriorly. Sometimes, the tubercle fractures will have a freely movable osseous fragment palpated subcutaneously between the proximal tibia and the femoral condyles, and may result in skin tenting; whereas, in the physeal fractures, the proximal metaphysis of the tibia is displaced posteriorly creating a concavity that can be palpated anteriorly at the level of the tibial tubercle. A valgus deformity suggests medial displacement of the metaphysis.

The associated injuries need to be identified at this time, as well. Ischemia caused by disruption of the popliteal artery or secondary to compartment syndrome should not be delayed. Poor perfusion, pallor, and distal pain should be recognized for potential signs of vascular compromise. Pulses should be ascertained and compartments should be assessed by palpation and assessment of sensation plus passive and active toe motion.

When the proximal end of the metaphysis protrudes under the subcutaneous tissues on the medial aspect of the knee, a tear of the distal end of the medial collateral ligament should be suspected in association with a physeal fracture. The presence of patella alta may represent either severity of tubercle displacement or rupture of the patella tendon. With a small avulsion, the child may be able to extend the knee actively through intact retinacular tissue, but active extension is impaired with larger injuries.

Imaging and Other Diagnostic Studies for Proximal Tibial Physeal Fractures

Plain radiographs are the mainstay of evaluation for fractures, but nondisplaced physeal fractures may not be visible. Associated hemarthrosis can sometimes be the only indication of fracture and is primarily recognized by identifying an increased separation of the patella from the distal femur on lateral views (Fig. 29-4). Occasionally, relatively nondisplaced physeal fractures may have small Thurston–Holland fragments that extending either into the epiphysis or into the metaphysis. Often, fracture lines may only be visible on oblique view radiographs. At other times the metaphyseal fragments can be quite large (Fig. 29-5). Stress views can often differentiate a proximal tibial physeal fracture from a ligament injury, but there is potential risk for physeal injury and increased pain in a clinical setting when performing these x-rays. Often MRI can be done if indicated, to distinguish these two injury patterns, and it is safe, accurate, and a more comfortable method for diagnosis of obscure fractures or ligamentous injuries than stress radiographs (Fig. 29-6).[48] Moreover, CT scans can define the bony injury better than MRI or plain film and is often helpful to determine treatment for Salter–Harris III and IV injuries (Fig. 29-7).

The standard method of identifying tibial tubercle fractures is via the lateral plain radiograph; however, more severe injuries should warrant advanced diagnostic imaging to help identify articular disruption and internal derangement that is often seen in these fracture patterns. Although, most patients with tibial tubercle fractures are adolescents (with developed secondary ossification of the tibial tubercle), fractures may occur in the more immature child and be seen merely has a small fleck of bone on plain film (Fig. 29-8). In order to improve the utility of diagnostic plain film, the lateral projection view should be done with the tibia rotated slightly internal to bring the tubercle perpendicular to the x-ray cassette.

With regard to the tibial tubercle, it is important to remember that normal ossification may progress from more than one secondary center of ossification. Opposite leg films may be helpful to distinguish normal ossification versus minimally displaced fragments, but patella alta may be more reliable in that comparison.

FIGURE 29-5 Displaced fracture of the proximal tibial physis with a large posterior metaphyseal Thurston–Holland fragment, as well as an anterior conjoined tibial tubercle fragment.

FIGURE 29-4 Often the only radiographic evidence of a physeal fracture may be a joint effusion, as seen in this lateral of a minimally displaced tibial tubercle fracture.

Classification of Proximal Tibial Physeal Fractures

Proximal tibial physeal fractures are most commonly described using the Salter–Harris classification scheme that denotes the direction of fracture propagation relative to the growth plate. A recent study in 2009, proposed the first specific classification for these pediatric proximal tibia fractures that was based on the direction of force and fracture pattern.[30] This classification

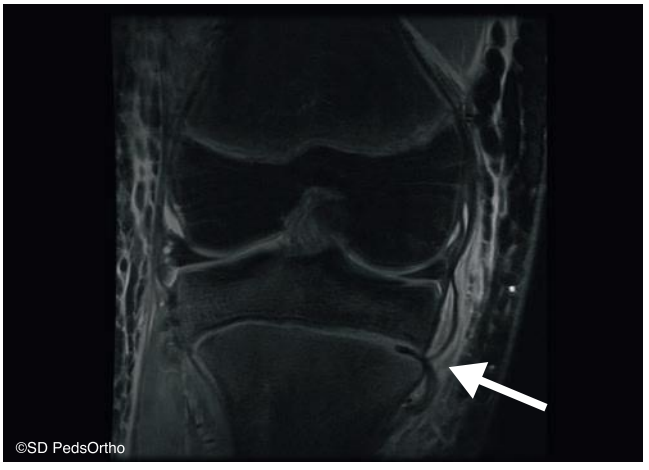

FIGURE 29-6 MRI images can assist in differentiating physeal injuries from ligament ruptures. This coronal image demonstrates a proximal tibial physeal fracture with evidence of entrapped medical collateral ligament (MCL) fibers (*arrow*) limiting reduction.

scheme utilized the following mechanism of injury: Valgus, varus, extension and flexion–avulsion (Fig. 29-9). The youngest children (aged 3 to 9 years) sustain valgus and varus mechanism injuries with resultant metaphyseal fractures from activities such as a trampoline. The slightly older age group of 10 to 12 was more prone to extension mechanism injuries that resulted in tibial spine fractures and the greater than 13-year-old group sustained predominately flexion–avulsion mechanism injuries that resulted in tibial tubercle fractures. Within this mechanism of injury classification, there was also evidence that fracture location was age dependent. The mean age for metaphyseal fractures (including the Cozen fracture) was just under 4 years. The mean age for tibial spine fractures was 10 years old, the mean age for Salter–Harris I and II was 12 years old and Salter–Harris III and IV injuries mean age was about 14 years old (Fig. 29-10).

FIGURE 29-7 Both 3D and standard CT images can help define fracture patterns that involve the joint surface to guide appropriate treatment. This 3D reconstruction demonstrates a tibial tubercle fracture with mild comminution at the joint surface (*arrow*).

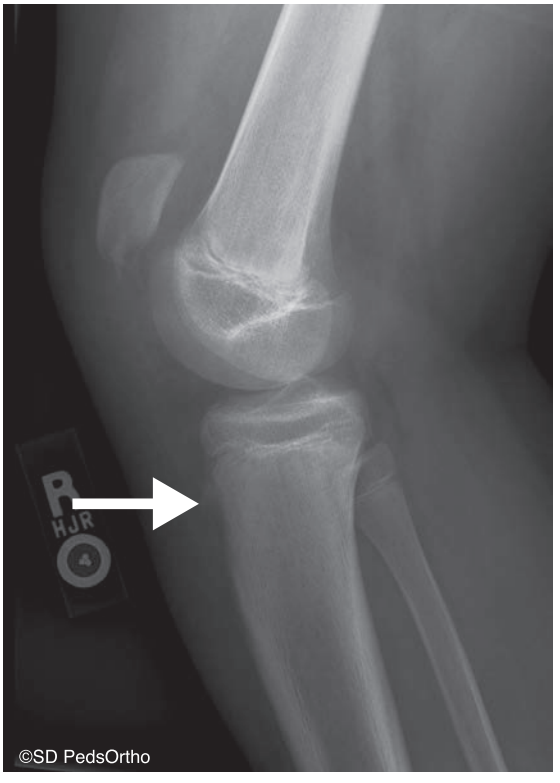

FIGURE 29-8 Young children may only have evidence of a small fleck (*arrow*) to represent an otherwise larger cartilaginous fracture of the tibial tubercle.

Most separations of the proximal tibial epiphysis are Salter–Harris I and II injuries. The frequency of Salter–Harris III injuries in the past literature may be skewed by the inclusion or exclusion of displaced tibial tubercle fractures, but the incidence of Salter–Harris IV injuries depends on whether certain open injuries to the knee are included (i.e., lawnmower injuries).[6,46] If the Salter–Harris classification is utilized, then some predictable findings can be expected.

In Salter–Harris I injuries, 50% are nondisplaced and this may be secondary to the overhanging tubercle preventing

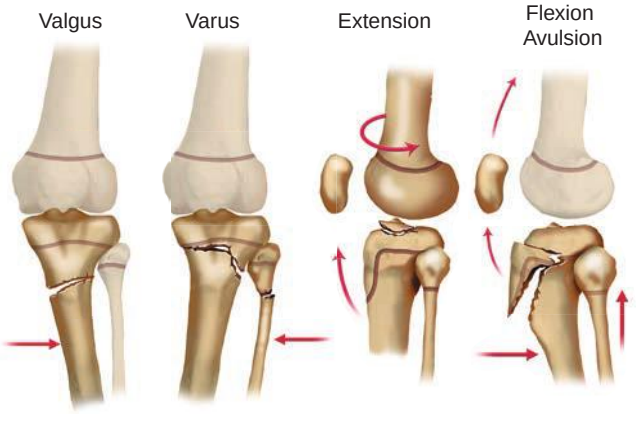

FIGURE 29-9 All proximal tibial physeal fractures can be classified based on the mechanism of injury: Varus/valgus, extension, and flexion avulsion injuries.

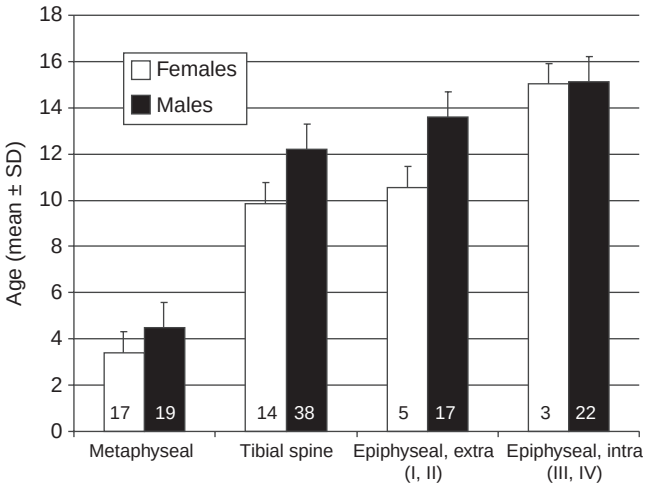

FIGURE 29-10 Bar graph representing the change in fracture patterns seen with increasing age.

anterior displacement and the fibula preventing lateral displacement of the metaphysis. In contrast, about two-thirds of Salter–Harris II fractures are displaced with medial gapping and lateral Thurston–Holland fragment resulting in a valgus deformity and often a proximal fibula fracture. Salter–Harris III fractures are predominately tibial tubercle fractures in children and have their own classification scheme.

Shelton and Canale[46] and Burkhart and Peterson[6] included tubercle avulsions in their reviews of proximal tibial physeal fractures, but these injuries are often considered separately.[34,46,51] Watson-Jones[51] described three types of avulsion fractures of the tibial tubercle, with subsequent modifications by Ogden and associates[34] who noted that the degree of displacement depends on the severity of injury to adjacent soft tissue attachments (Fig. 29-11). Ryu[42] and Inoue[24] proposed a type IV fracture in which the physeal separation occurs through the tibial tuberosity and extends posteriorly into the horizontal tibial physis. A study from San Diego was recently presented by the authors delineating a three-dimensional classification of tibial tubercle fractures, in order to highlight the risk for associated pathology.[36] It is based on skeletal maturity and ossification of the secondary ossification center as it relates to increasing need for surgery and risk for compartment syndrome (Fig. 29-12). San Diego type A tibial tubercle fractures occur in the youngest population (mean age 12.7 years) with most of the physis and apophysis open resulting in a largely cartilaginous fracture that is seen as a fleck of bone at the distal tibial tubercle. These are at low risk for compartment syndrome, but potentially greatest risk for premature physeal closure because of age. They require only sagittal plain radiographs for appropriate diagnostics. The San Diego type B fracture is found in a slightly older population wherein the physeal and apophyseal cartilage is primarily open (Fig. 29-13A and B). These are basically the same has the Ryu variant wherein the apophysis and proximal physis fracture as a single unit, and they are at the greatest risk for compartment syndrome, vascular injury, and growth arrest. The San Diego type C fracture is found in even older patients with closing growth plates that are partially open following a predictable pattern of

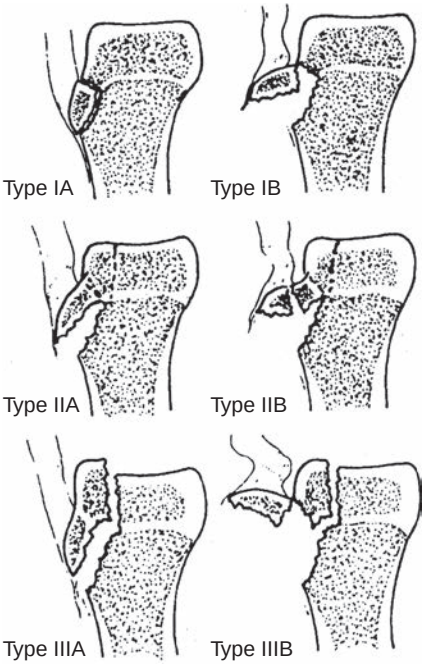

FIGURE 29-11 The Ogden classification of tibial tubercle fractures (Adapted from Ogden JA. *Skeletal Injury in the Child.* 2nd ed. Philadelphia, PA: WB Saunders; 1990: 808).

closure. These fractures always involve the articular surface and require either pre-operative three-dimensional imaging or intra-operative intra-articular evaluation (Fig. 29-14A and B). These fractures almost always require surgical intervention. Finally, the San Diego type D fractures are found in the oldest population and most of the proximal tibial physis and apophysis have closed leaving only the most distal aspect of the tubercle unfused and at risk for fracturing. They look similar to the type A injuries, but occur in more skeletally mature individuals. These have the lowest risk of complications of all the groups and can be treated with either casting or screw fixation (Fig. 29-15A and B).

Outcome Measures for Proximal Tibial Physeal Fractures

There are no specific outcome scores or tools validated for proximal tibial physeal fractures; however, most studies have

FIGURE 29-12 Closure of the proximal tibial growth centers follows a predictable pattern: Posterior to anterior direction and medial to lateral with simultaneous proximal to distal closure of the tubercle apophysis.

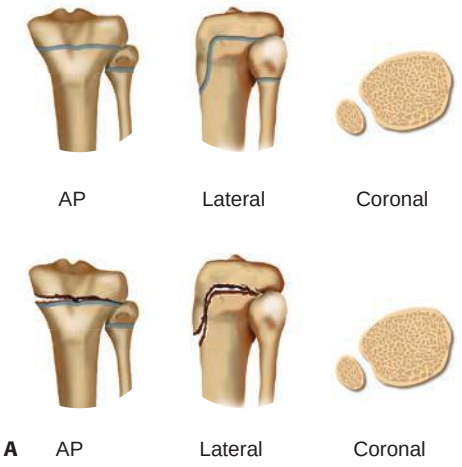

FIGURE 29-13 San Diego type B tibial tubercle fracture. **A:** Upper line drawing indicating area of closed physis (red), lower line drawing demonstrating fracture pattern in three planes; **(B)** radiographic representation of the fracture. These occur in the younger child and have high risk for vascular injury.

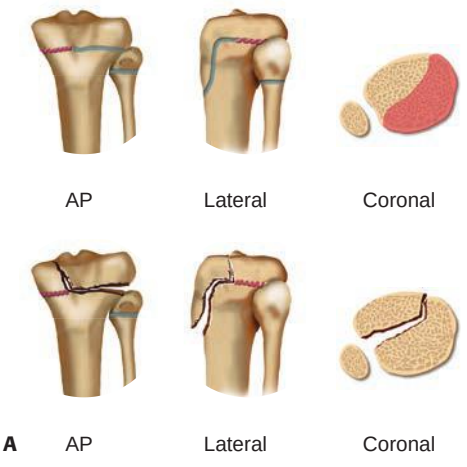

FIGURE 29-14 San Diego type C tibial tubercle fracture. **A:** Upper line drawing indicating area of closed physis (red), lower line drawing demonstrating fracture pattern in three planes; **(B)** radiographic representation of the fracture. These occur in young, but maturing children and have high risk for intra-articular pathology.

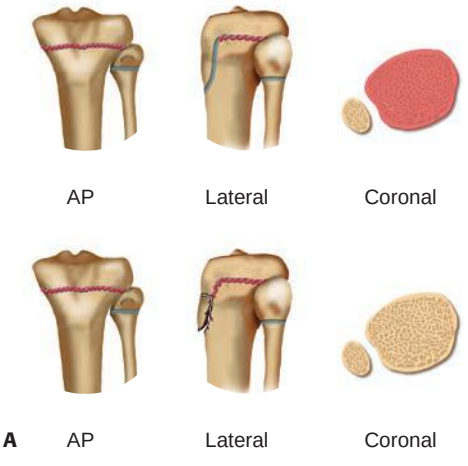

FIGURE 29-15 San Diego type D tibial tubercle fracture. **A:** Upper line drawing indicating area of closed physis (red), lower line drawing demonstrating fracture pattern in three planes; **(B)** radiographic representation of the fracture. These occur in older children and have low associated risks.

utilized plain radiographs to determine healing and a few have utilized return to sports for functional outcomes.

Pathoanatomy and Applied Anatomy Relating to Proximal Tibial Physeal Fractures

Present at birth, the ossific nucleus of the proximal tibial epiphysis lies central in the cartilaginous anlage. Usually singular, it can occasionally have two ossification centers, not including the universal secondary center of ossification of the tubercle that appears between 9 and 14 years of age. Closure of the proximal tibial physis and union between the epiphysis and tubercle centers occurs commonly in girls between 10 and 15 years and in boys between 11 and 17 years of age.

The development of the tibial tubercle has been further defined by Ehrenborg.[15] After birth is the cartilaginous stage that exists prior to development of the secondary ossification center and persists until the age of 9 years in girls and age of 10 years in boys. This is followed by the apophyseal stage, in which the ossification center appears in the tongue of cartilage that drapes over the anterior tibial metaphysis. The epiphyseal stage is marked by the tubercle and epiphyseal bony union, and this is followed by the final bony stage, wherein the proximal tibia becomes fully ossified. There is evidence that closure of the physis follows a predictable pattern.[3,13,18,33,36,45,47] In the sagittal plane, the proximal tibial physis has been shown to close in a posterior to anterior direction, with subsequent progression of closure toward the tubercle apophysis which is closing in a proximal to distal direction, simultaneously. In the coronal planes, the proximal tibial physis is closing in a medial to lateral direction; whereas, in the axial plane, the tibia is closing in a posteromedial to anterolateral direction.

As previously discussed, the anatomy of the collateral ligaments provides some protection from epiphyseal disruption. The superficial portion of the medial collateral ligament extends distal to the physis inserting into the medial metaphysis, therefore acting as a medial buttress. The lateral collateral ligament inserts on the proximal pole of the fibula, and this entire lateral construct acts like a lateral buttress. Anteriorly, the patellar ligament attaches to the secondary ossification center of the tibial tuberosity that is draped over the metaphysis serving as a constraint to posterior displacement. Yet, this design of terminal insertion of the powerful quadriceps at the boundary between the secondary ossification centers of the tubercle and the proximal tibial epiphysis does place the tubercle at risk for isolated or combined avulsion fractures. This risk is minimal until adolescence when the quadriceps mechanism is matured because some fibers of the patella tendon extend distal to the apophysis into the anterior aspect of the upper tibial diaphysis. Therefore, it is important to recognize that these adolescent avulsions often have extensive soft tissue damage that extends down the anterior diaphysis.

The distal portion of the popliteal artery lies close to the posterior aspect of the proximal tibia. Firm connective tissue septa hold the vessel against the knee capsule placing it at risk for injury during proximal tibia physeal fractures (Fig. 29-16). The lateral inferior geniculate artery crosses the surface of the popliteus muscle, anterior to the lateral head of the gastrocnemius, and turns forward underneath the lateral collateral ligament. The medial inferior geniculate artery passes along the proximal border of the popliteus muscle, anterior to the medial head of the gastrocnemius, and extends anterior along the medial aspect of the proximal tibia. The popliteal artery divides into the anterior tibial and posterior tibial branches beneath the arch of the soleus muscle. Much of the blood supply to the proximal tibial epiphysis is derived from an anastomosis between these geniculate arteries.[10,20] The tibial tubercle receives its main blood supply from a plexus of arteries behind the patellar ligament at the level of the attachment to the tibial tubercle.[10] This vascular anastomosis arises from the anterior tibial recurrent artery and may be torn with this fracture.[37,53] Several small branches extend down into the secondary ossification center. A smaller part of the blood supply enters the superficial surface of the tubercle from adjacent periosteal vessels.

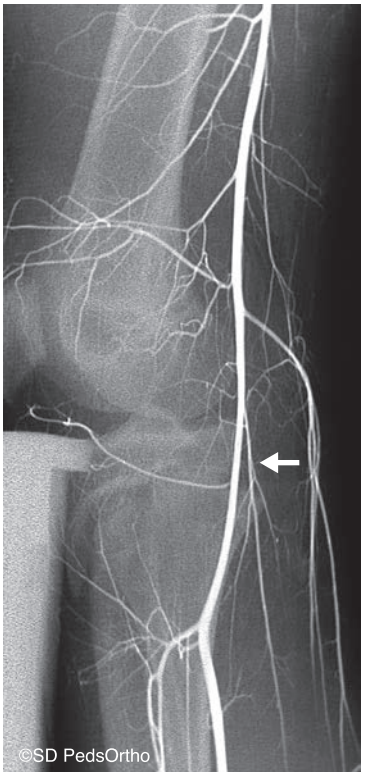

FIGURE 29-16 Arteriogram after a proximal tibial physeal fracture. Even with minimal displacement, note the construction of the popliteal artery (*arrow*).

Treatment Options for Proximal Tibial Physeal Fractures

Nonoperative Treatment of Proximal Tibial Physeal Fractures

Salter–Harris I and II fractures of the proximal tibial physis and San Diego type D tubercle fractures can often be treated with closed reduction (Table 29-1). Traction is important

during reduction to minimize the risk of damage to the physis. Hyperextension fractures are reduced with traction in combination with gentle flexion. A fracture with valgus angulation can usually be reduced by adducting the leg into varus with the knee extended. This should be done with gentle manipulation to decrease the risk of injury to the peroneal nerve. After reduction, a long-leg cast with varus molding is applied with the knee in slight flexion.

Regarding tubercle reductions, a persistant gap between the distal end of the tubercle and the adjacent metaphysis may indicate an interposed flap of periosteum.[8,19] Minimally displaced, small avulsion fragments have been treated successfully with immobilization in a cylinder cast or long-leg cast.[7,8,29,34] The leg is positioned with the knee extended, but even with a long-leg cast, a straight leg raise can place tension on the fracture. Molding above the proximal pole of the patella has been suggested to help maintain reduction.

Indications/Contraindications (Table 29-1)

TABLE 29-1 Proximal Tibial Physeal Fractures

Nonoperative Treatment

Indications	Relative Contraindications
No associated pathology	Joint involvement
No to minimal displacement	Compartment syndrome
Stable fragment	Open fracture

Techniques (Proximal Physis)

Closed reduction is paramount to nonoperative treatment, second only to immobilization. As mentioned, traction during the reduction maneuver will reduce the risk of physeal damage. The reduction should recreate the injury before applying a leveraging force in the opposite direction of displacement whilst maintaining traction on the limb. Prior to closed reduction, a tense knee effusion may be aspirated using sterile technique followed by an injection of 2 to 5 mL of either 0.5% bupivacaine, or 0.2% ropivacaine to relieve pain and augment the reduction attempt. However, many children will not tolerate this method of anesthesia and either moderate conscious sedation or general anesthesia should be employed.

Patients with a nondisplaced (2 mm or less) and stable proximal tibial epiphyseal fracture can be simply placed in a long-leg cast with 20 to 30 degrees of knee flexion. Appropriate padding is important and thick (1/2 inch) foam may be placed either along the popliteal fossa or on the bony prominences to protect the skin. The cast should be either univalved or bivalved to permit swelling. Almost universally, the child is then admitted to the hospital for observation and gentle elevation to monitor for the high incidence of vascular injury and compartment syndrome.

Radiographs should be obtained at the time of reduction and cast placement to confirm appropriate alignment of the fracture. Future films should include both the AP and lateral x-rays at 1 week post-reduction to confirm maintenance of reduction. The cast may be removed 4 to 6 weeks after injury if the fracture demonstrates radiographic and clinical union. Return to normal activities can be permitted about 4 weeks following cast removal.

Techniques (Tibial Tubercle)

Closed reduction can be performed for minimally displaced and extra-articular fractures of the tibial tubercle. Knee extension with a slight mold above the patella to minimize the pull of the quadriceps muscle is appropriate, but this technique may be safer to utilize in patients that can still achieve active knee extension against gravity. Similar to the closed reduction and immobilization of the physeal injuries described above, this fracture should be immobilized with either a cylinder or long-leg cast and they should be admitted to the hospital for observation regarding the possible development of compartment syndrome.

Furthermore, treatment follows the basic outline described above for physeal fractures with regard to follow-up duration, length in cast, and return to activities.

Outcomes

There have been no good outcome studies for nonoperative management of proximal tibial physeal fractures or tibial tubercle fractures. To date, no authors have attempted to utilize a patient-derived satisfaction questionnaire. However, there are a few case series that identify the complications associated with these injuries and their treatment. A discussion of complications is discussed in that section.

Operative Treatment of Proximal Tibial Physeal Fractures

Indications/Contraindications

Salter–Harris type I and II fractures of the proximal tibial physis may be unstable. Those that are reducible via closed methods, but unstable, may be stabilized with crossing percutaneous smooth pins. Likewise, a percutaneous compression screw may be placed in the metaphyseal spike of an unstable Salter–Harris type II fractures as long as it reduces well and the implant does not cross the physis. Salter–Harris II fractures that cannot be anatomically reduced require open reduction for removal of soft tissue interposition (entrapped pes anserinus and periosteum have been reported).[9,49,54] Another relative indication for open reduction and internal fixation of a Salter–Harris type I or II hyperextension injury is to facilitate wound management when a vascular repair is necessary.

Open reduction is also indicated for all displaced Salter–Harris types III and IV injuries. Moreover, open reduction and internal fixation is recommended for displaced or intra-articular tibial tubercle avulsions.[4,7,8,19,29,32,34] Residual displacement greater than 2 to 3 mm may lead to an extensor lag and quadriceps weakness.

Surgical Procedure (Closed Reduction and Percutaneous Fixation)

Preoperative Planning. Depending on the physical location of the initial attempt of closed reduction, a conversion to this surgical procedure could follow a natural progression.

If the reduction is performed in the emergency department but the fracture is deemed unstable, then a temporary splint should be placed and plans to move to the operating room should be made. However, if the initial attempt was undertaken in the operating room and the fracture was deemed unstable, then percutaneous pinning could be done immediately. Moreover, if the fracture cannot be adequately reduced, then the treating surgeon could move directly to open reduction followed by fixation. This procedure will be discussed in its dedicated section.

Therefore, before entering to operating room, there should be an algorithm in place with preparations having been made for the predictable contingencies. First, identification of the fracture pattern must be understood. Is this a pure physeal injury? Is it a tubercle injury? Does the fracture extend into the joint? Based on the answers to these questions, then choices can be made regarding closed reduction attempts and methods of fixation that need to be prepared (Table 29-2).

Positioning. The patient should be placed supine on the bed with leg centered within the width of the bed to limit obscuring radiographic views with metal side bars (if present). No bumps are usually needed, but if the child has excessive femoral retroversion or hip external rotation, then a pelvic bump to keep the patella pointing skyward can be helpful for imaging during the procedure. The C-arm and the back table should be positioned opposite to each other relative to the patient, with the surgeon on the same side as the back table and injured extremity.

Surgical Approach. The closed reduction should be performed as described in that section, and the pinning is done by first determining the appropriate pin size. Pin placement is then determined by the fracture pattern and the method of cross-pinning is utilized to augment the construct. Therefore, one pin will be placed medial and the other will be placed lateral through the metaphysis.

Technique. The process flow for closed reduction and percutaneous pinning starts with the operative room setup. Once the reduction is confirmed by fluoroscopy then pinning may begin. Pin size choice will depend on the size of the tibia, but usually range from a 0.062 inch pin to a 2.5 mm pin in bigger children. Often, four pins will be better than two large pins.

For the proximal tibial physeal fractures that are Salter–Harris types I and II, the pinning should start in the metaphysis, and utilize fluoroscopy guidance. If the first pin starts on the medial metaphyseal cortex, then the surgeon should aim the pin toward the lateral epiphyseal cortex. The opposite is true for the lateral metaphyseal starting point. The pins usually aim from slightly anterior to slightly posterior. They should be bicortical and not cross at the fracture line (Fig. 29-17). Occasionally, for large Thurston–Holland fragments, a percutaneous compression screw may be placed to secure the fracture. Rather than using the crossing pin technique, or in conjunction with that technique, a small stab incision can be made directly over the fragment after reduction. Fluoroscopy guidance is then utilized to place the guide pin from a cannulated screw system, being sure not to violate the physis or the apophysis anteriorly. Length is measured, the proximal cortex drilled, and the screw is inserted and secured into place with fluoroscopy. If a bicortical purchase can be achieved, then that is optimal. Yet, cancellous screws can be utilized if the width of the tibial metaphysis exceeds the screw options (Fig. 29-18).

For the extra-articular tibial tubercle fragments (San Diego type A and D), a choice between the smooth pin (Fig. 29-19) and the compression screw (Fig. 29-20) can be made but the technique is the same. These fractures will often have soft tissue interposition and conversion to open reduction is not uncommon.

With fluoroscopy confirmation that the reduction is anatomic and the pin placement is appropriate, the skin should be cleaned, the pins should be bent perpendicular at the skin and then cut leaving only about an inch of exposed skin on the surface (Table 29-3).

TABLE 29-2 Closed Reduction and Percutaneous Pinning of Proximal Tibial Physeal Fractures

Preoperative Planning Checklist

- OR Table: Radiolucent, preferably without metallic side bars
- Position/positioning aids: Assistant for counter traction
- Fluoroscopy location: Opposite to surgeon and back table
- Equipment: C-arm, smooth pins, unopened trays for open reduction
- Tourniquet (nonsterile): May not need to inflate, unless surgery converted to open reduction

Surgical Procedure (Open Reduction and Internal Fixation)

Preoperative Planning. The preoperative plan for open reduction and internal fixation of these fractures follows the course outlined in the closed reduction and percutaneous pinning section with two exceptions. For the Salter–Harris III and IV physeal injuries including the San Diego type C tubercle fractures, there should be no attempt at closed reduction and percutaneous pinning. An arthrotomy (or arthroscopy) should be performed to assess the articular reduction and associated intra-articular pathologies. Furthermore, even the San Diego type B tubercle fractures are usually extra-articular, open reduction should be performed since the entire proximal tibial physis and apophysis are disrupted (Table 29-4).

Positioning. This is no different than positioning for a closed reduction percutaneous pinning procedure. The patient should be placed supine on the bed with the leg centered within the width of the bed to limit obscuring radiographic views with metal side bars (if present). No bumps are usually needed, but if the child has excessive femoral retroversion or hip external rotation, then a pelvic bump to keep the patella pointing skyward can be helpful for imaging during the procedure. The C-arm and the back table should be positioned opposite to each other relative to the patient, with the surgeon on the same side has the back table and injured extremity.

Surgical Approach. A midline anterior longitudinal incision is required from the inferior pole of the patella to below

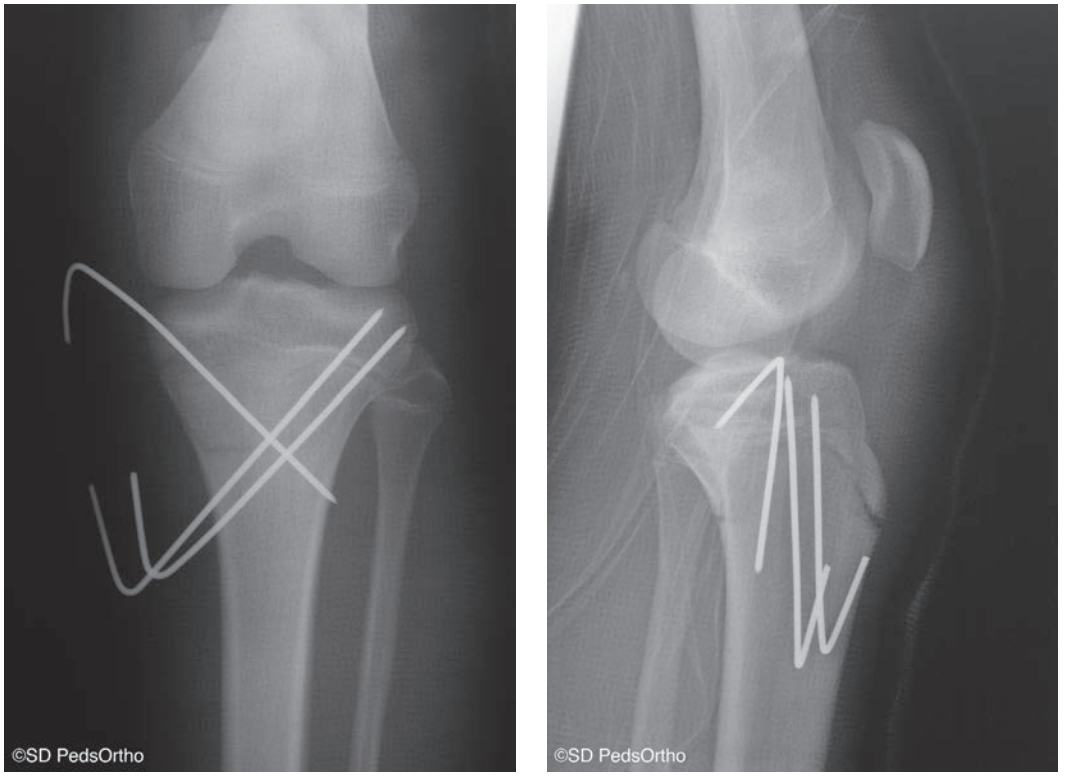

FIGURE 29-17 San Diego type B tibial tubercle, or Salter–Harris type 2 (with posterior metaphyseal fragment and tibial tubercle fracture). **A:** AP radiograph demonstrating cross-pin technique; **(B)** lateral radiograph demonstrating anatomic reduction with fixation.

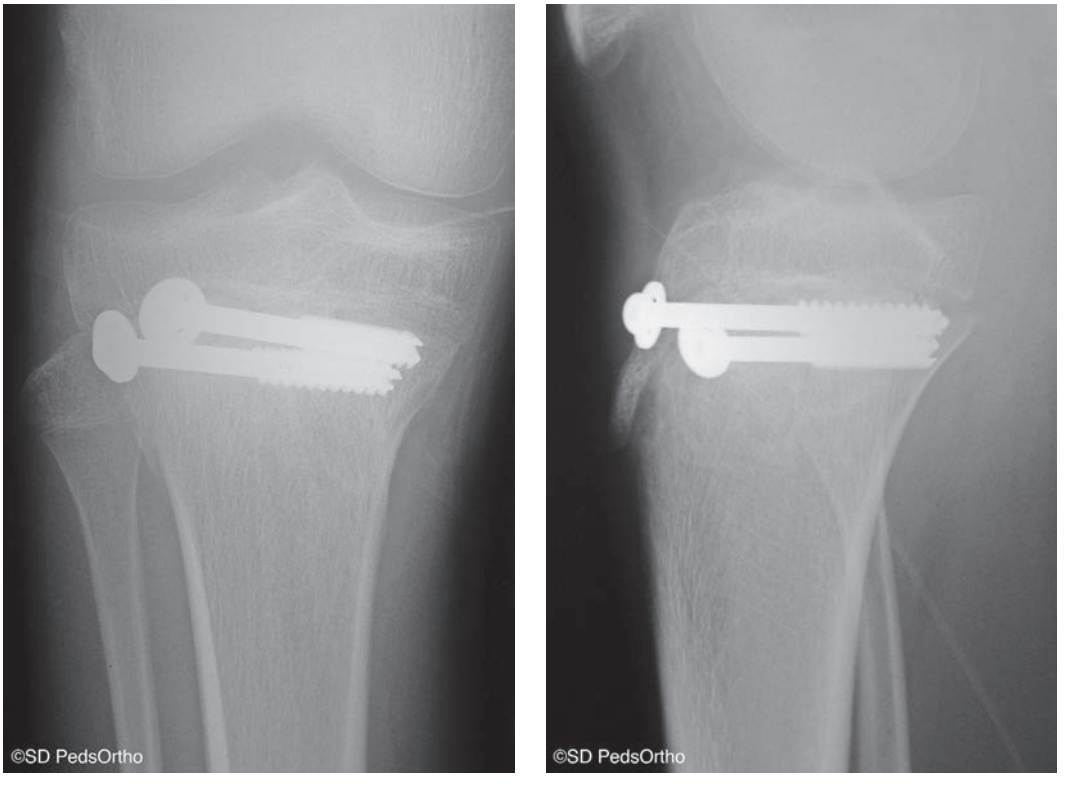

FIGURE 29-18 Salter–Harris type 2 proximal tibial physis fracture with two cannulated, partially threaded cancellous screws in the Thurston–Holland fragment. **A:** AP radiograph; **(B)** lateral radiograph.

FIGURE 29-19 Intra-operative lateral fluoroscopy image demonstrating multiple smooth pin fixation of a tubercle fracture.

FIGURE 29-20 Post-operative lateral radiograph with single compression screw and washer fixation of an extra-articular tibial tubercle fracture.

TABLE 29-3 Closed Reduction and Percutaneous Pinning of Proximal Tibial Physeal Fractures

Surgical Steps

- Closed reduction of the fracture with C-arm guidance
- Option 1: Smooth cross-pinning pin placement (SH type 1 and 2)
- Option 2: Guide pin placement that does not cross physis in the metaphyseal fragment (SH type 2)
  - Drill proximal cortex with cannulated system
    - Compression screw placement
- Option 3: Smooth pin placement that does not cross physis, but crosses apophysis in tibial tubercle fragment
  - Can use this smooth pin as a guide pin for compression screw placement, if desired
- For smooth pin placement, bend and cut pins to be pulled at 4 weeks post-op
- For cannulated screws, close stab incisions with suture
- Place dressing and apply long-leg cast in 30 degrees of knee flexion

the tibia tubercle. Care should be taken not to score or further damage the physis at the perichondral ring of LaCroix during the approach. The incision should be performed adjacent to the tibial tubercle (rather than directly over it) to minimize the potential for scar discomfort over the prominent bone. This full length incision is often required to fully expose the fracture bed, the soft tissue damage, and to perform an adequate arthrotomy to evaluate the articular surface (Fig. 29-21).

There are no vascular or neurologic structures at risk during this approach.

Technique. A tourniquet can be used high on the thigh, but may need to be released if it is hindering reduction of a displaced fracture caused by constriction of the quadriceps muscle. After creating the anterior approach, the fracture bed is carefully cleared of debris such as fracture hematoma and an assessment is taken of the entire fracture personality. For example, a periosteal flap (from the diaphysis) is frequently entrapped in the fracture blocking an anatomic reduction.[8,19]

TABLE 29-4 ORIF of Proximal Tibial Physeal Fractures

Preoperative Planning Checklist

- OR Table: Radiolucent, preferably without metallic side bars
- Position/positioning aids: Assistant for counter traction
- Fluoroscopy location: Opposite to operative limb, surgeon and back table
- Equipment: C-arm, smooth pins, trays for open reduction including a cannulated compression screw system (4.0 to 6.5 mm sizes available)
- Tourniquet (nonsterile): May need to deflate during reduction of tubercle fragments
- Confirm vascular status prior to surgery, and have sterile Doppler available

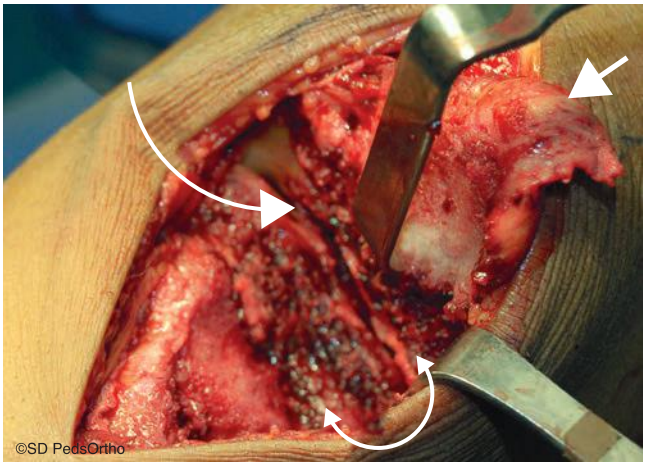

FIGURE 29-21 Intra-operative photograph of a San Diego type C fracture. The patella is to the upper right and foot the lower left, with the physis (*curved arrow*) and fracture bed (*double-headed arrow*). There is evidence of a large periosteal avulsion attached to the tubercle fragment (*arrowhead*).

After extracting the soft tissue, the nonviable portions may be debrided.

At this point, the fracture can often be reduced utilizing the same maneuvers discussed in the closed reduction section utilizing axial traction and leverage in the direction appropriate to reduce displacement. Depending on the fracture pattern, there are a multitude of fixation methods that can be employed. For Salter–Harris type I physeal fractures and San Diego type B tubercle fractures, smooth cross-pins can be utilized. For Salter–Harris II, III, and IV, as well as the other tubercle fractures, either pins or screw fixation can be used (Fig. 29-22). The orientation of the fixation in this latter group is the placement parallel to the tibial physis (but, this will often violate the growth of the apophysis).

Screw fixation is used when the tuberosity fragment, or metaphyseal fragment, is large enough to support this type of fixation. The screw is inserted from anterior to posterior over a guidewire. They should be bicortical, but often the tibial width is greater than the screw lengths and in those situations the screws do not need to engage the posterior cortex, but cancellous lag screws may be used. When there are three or more years of growth remaining or when the fragment is too small for screw fixation, transfixing pins can be used instead of screw fixation. Alternatively for tibial tubercle fractures, a tension band can be passed around the fragment or through the patellar ligament and fixed through a drill hole across the anterior tibia distal to the attachment of the tuberosity. Tension band wiring has even been reported as a first-line method to facilitate rapid rehabilitation in athletes.[32] The wire is driven around the proximal pole of the patella or through a drill hole in the distal pole and then looped distally through a cannulated cortical screw that is inserted across the anterior tibia distal to the patellar tendon insertion. This method may also be useful when the fracture fragments are comminuted or too small for secure fixation to the tibial metaphysis.

FIGURE 29-22 Lateral radiograph demonstrating multiple compression screw fixation of a Salter–Harris type IV proximal tibial physeal fracture.

A variation of these fractures that are similar to patella sleeve avulsion fractures, but originating at the tuberosity can be fixed using this tension band method as well. Davidson and Letts[11] recommended fixation of these injuries with small cancellous screws and heavy nonabsorbable sutures to repair the torn retinaculum and periosteum (Table 29-5).

Author's Preferred Treatment for Proximal Tibial Physeal Fractures

Closed reduction of these fractures is considered when they are extra-articular and minimally displaced. Epiphyseal separation (whether a Salter–Harris type I, or a tibial tubercle San Diego type B) results in a higher risk for vascular injury. Therefore, the first step in the management of these fractures is assessing and then documenting the neurologic and vascular examination. If perfusion is poor, then the child is brought urgently to the operating room for reduction under general anesthesia. If not logistically possible, then a closed reduction is done with conscious sedation in the emergency department. Regardless of the direction of fracture displacement, all physeal fracture closed reductions utilize the technique mentioned above of traction followed by leverage force to minimize a shearing injury to the physis.

This is done with the patient in a supine position with the hip and knee flexed to about 45 degrees. It is important to have

TABLE 29-5 ORIF of Proximal Tibial Physeal Fractures

Surgical Steps

- Anterior midline exposure of proximal tibia (no vascular compromise)
  - If vascular issue, then consider medial approach to combine fracture reduction and vascular repair through a single incision
- Hematoma debridement and identification of all fracture components (fragment, fracture bed, physis, soft tissue injury, joint injury)
- Apply tibial traction and leverage to reduce proximal physeal fractures (key in metaphyseal or epiphyseal fragments for SH II to IV injuries, including tubercle fractures)
- Utilize C-arm fluoroscopy and place tentative smooth wire fixation
  - If planning to use cannulated screws, place smooth wires has guide pins (avoid violating physis)
- Option 1: Smooth cross-pinning pin placement (SH type 1 and 2)
- Option 2: Guide pin placement that does not cross physis in metaphyseal fragment (SH type 2)
  - Drill proximal cortex with cannulated system
    - Compression screw placement
- Option 3: Smooth pin placement that does not cross physis, but crosses apophysis in tibial tubercle fragment
  - Can use this smooth pin as a guide pin for compression screw placement, if desired
- If there is a large periosteal flap and retinacular tear, then place 1 to 2 suture anchors distal in tibia
  - Suture soft tissue back into position
- Closure of incision
- Cast application (long-leg or cylinder) in near full extension

an assistant placing counter traction at the thigh. The surgeon grasps the proximal leg and applies traction while leveraging the metaphysis back into anatomic position. Reduction is then confirmed by fluoroscopy. If deemed stable via gentle knee range of motion, then the leg is placed into a univalved cast. However, if the reduction is not stable, then percutaneous smooth pin fixation is undertaken. The long-leg cast is then applied after reduction in about 30 degrees of flexion, and the child is admitted for observation.

Percutaneous smooth-pin fixation with 2 to 2.5 mm diameter Kirschner wires is reserved for unstable fractures following a closed reduction maneuver. For Salter–Harris types I and II fractures, they are inserted in a crossing fashion through the tibial metaphysis and across the physis to stabilize the epiphysis, as described above. The leg is then immobilized in a univalved cast with the knee in 30 degrees of flexion. Four weeks after reduction and fixation, the pins are removed in clinic, but the child is placed back into a long-leg cast for up to 4 more weeks depending on the radiographic findings at the time of pin removal. Children are released to full activities out about 4 weeks following cast removal.

Open reduction with surgical stabilization is performed when the closed reduction fails to achieve anatomic alignment, or when

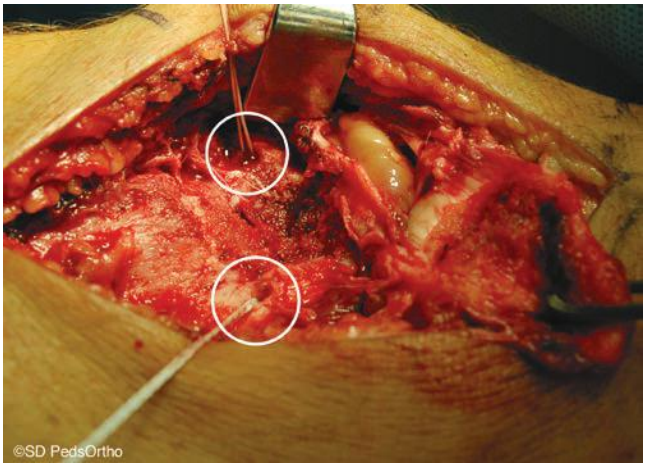

FIGURE 29-23 Intra-operative photograph demonstrating placement of suture anchors (circles) in the meta-diaphyseal tibia to repair the extensive soft tissue injury of a tibial tubercle avulsion.

the fractures extend to the joint surface (Salter–Harris types III and IV physeal fractures and San Diego type B and C tibial tubercle fractures). We will often use a combination of smooth Kirschner wires and cannulated screws to stabilize the fractures, but we prefer cannulated screws inserted parallel to the physis. After internal fixation, the knee may be carefully stressed into valgus to assess the competency of the medial collateral ligament. If an arthrotomy was not performed as part of the reduction, then a gentle Lachman test should be performed to assess anterior cruciate ligament (tibial eminence) integrity. Concerning the large periosteal and retinacular injuries that often accompany these injuries, we often utilize suture anchors to repair the soft tissues back in place to augment the fixation (Fig. 29-23).

During an open reduction, the anterior compartment fascia is released to reduce the risk of compartment syndrome and a drain is placed in the anterior compartment.

Following wound closure, a long-leg or cylinder cast is applied in full knee extension and the patient is observed overnight in the hospital.

Arteriography for isolated injuries but may be helpful when the circulation is questionable. It is usually recommended that fracture fixation be performed prior to vascular repair caused by the manipulation that often accompanies reduction. An extended medial approach will often allow open reduction of the fracture and vessel management for the vascular surgeon through the same incision. However, the posterior approach provides easier access to the popliteal space and can be used with percutaneous fixation of the fracture (Fig. 29-24).

Postoperative Care for Proximal Tibial Physeal Fractures

The cast should be either univalved or bivalved to permit swelling. Almost universally, the child is then admitted to the hospital for observation and gentle elevation to monitor for the high incidence of vascular injury and compartment syndrome.

Shorter periods of immobilization may be used in younger adolescents if fixation is secure. For larger fragments that are

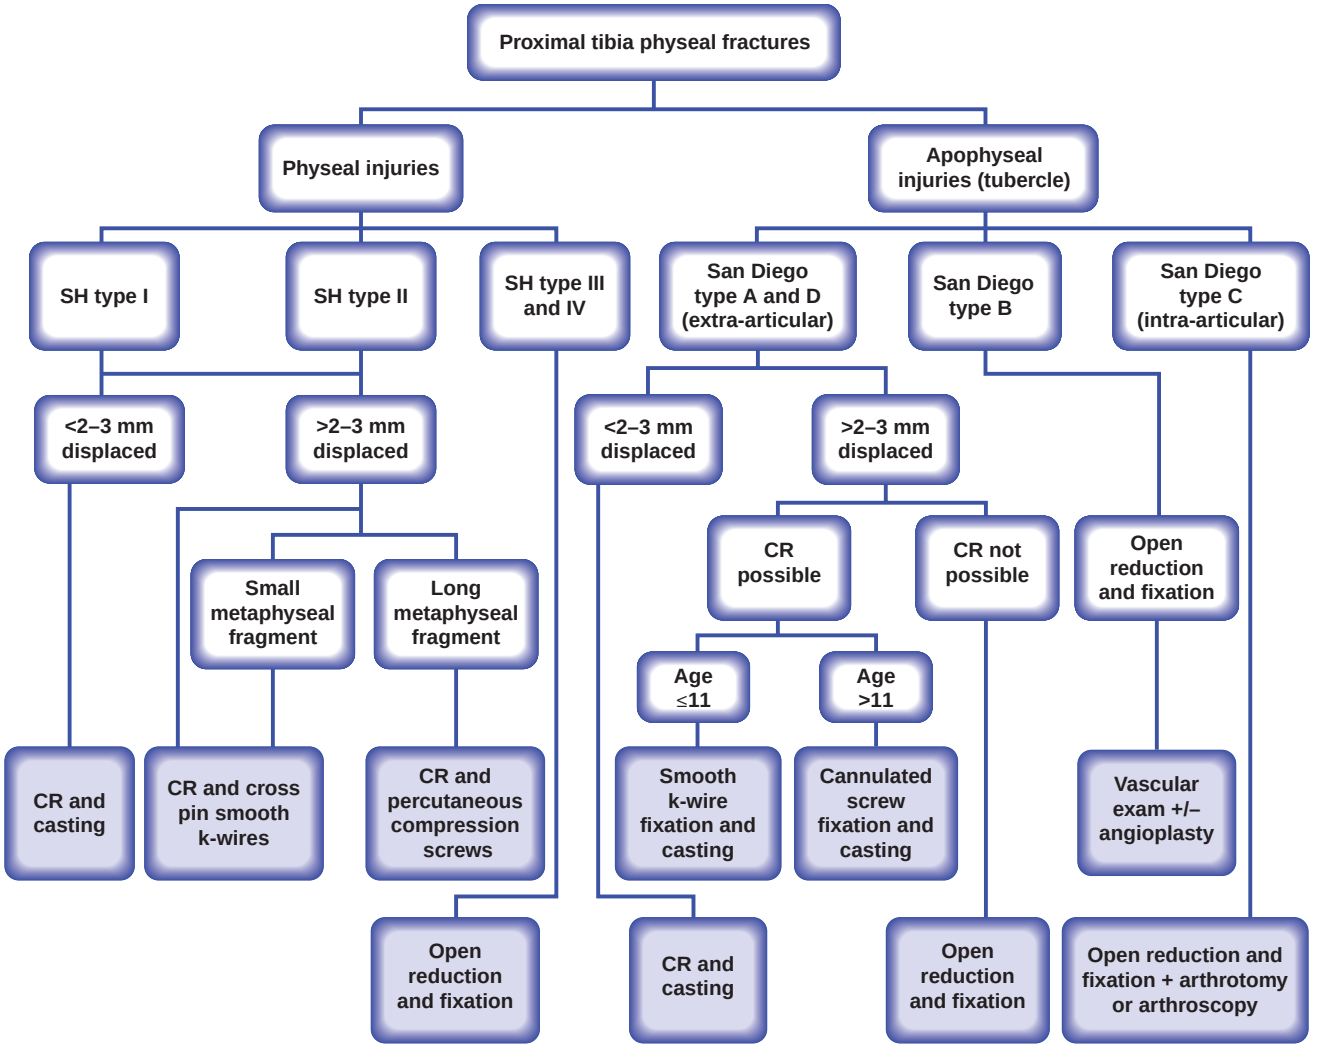

FIGURE 29-24 Author's preferred treatment algorithm for proximal tibial physeal fractures.

securely fixed with two or more screws, a knee immobilizer can be substituted for cast immobilization. Range of motion and quadriceps strengthening are initiated 6 weeks following injury for these patients.

Radiographs should be obtained at the time of reduction and cast placement to confirm appropriate alignment of the fracture. Future films should include both the AP and lateral x-rays at 1 week post-reduction to confirm maintenance of reduction. The cast may be removed 4 to 6 weeks after injury if the fracture demonstrates radiographic and clinical union. Return to normal activities can be permitted about 4 weeks following cast removal. Physis checks should be done between 4 and 6 months post-operatively via plain radiographs.

Potential Pitfalls and Preventative Measures for Proximal Tibial Physeal Fractures

With open physes, children with knee trauma, or those with polytrauma should have their radiographs scrutinized for nondisplaced proximal tibial fractures.[17,44] Overnight observation in the hospital is recommended for all fractures of the proximal tibia because of the risk of vascular injury or development of compartment syndrome. All casts should be at least univalved during early immobilization, and repeated compartment assessments need to be performed and documented (Fig. 29-25). Arterial injuries can go unrecognized, especially in "minimally" displaced fractures, since the full displacement at time of injury is not known. Nondisplaced fractures can be misdiagnosed as medial collateral ligament injuries.[52] Stress radiographs, or preferably an MRI can assist in correct diagnosis. Be cognoscente of the Cozen fracture and the proximal tibial growth disturbance that can occur following metaphyseal fractures.[23,31] Recurvatum is the most common deformity following a physeal injury and should be carefully followed radiographically, with comparisons of the contralateral side. Osteotomies may be necessary for correction.[38] An intra-articular placement of the smooth pins may result in a septic joint and should be avoided. There is an association of anterior cruciate ligament injuries with these proximal fractures that may result in late instability if untreated.

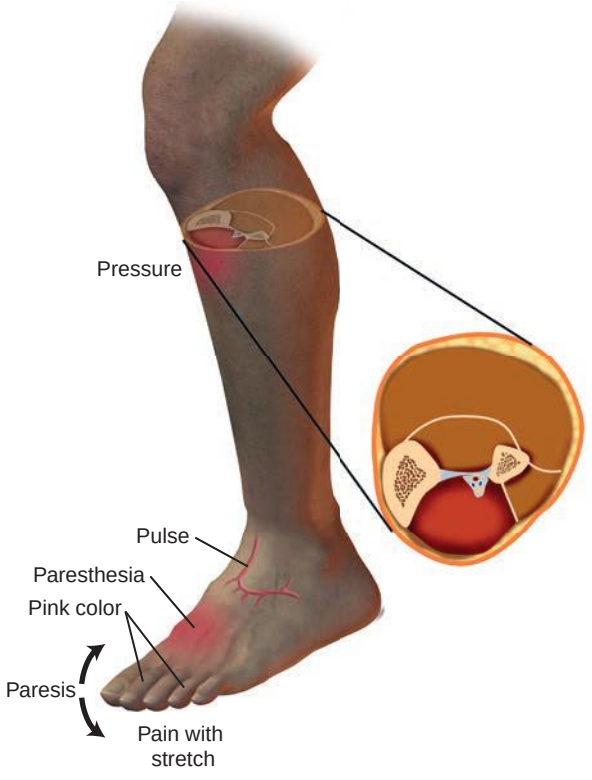

FIGURE 29-25 Physical examination findings in the setting of compartment syndrome.

Tibial tubercle fractures have an increased risk of compartment syndrome caused by bleeding of the recurrent anterior tibial artery into the anterior compartment. Utilization of a tourniquet may bind the quadriceps and hinder reduction of a displaced fracture (Table 29-6).

Treatment-Specific Outcomes for Proximal Tibial Physeal Fractures

Treatment outcomes do not currently exist in the English literature regarding comparisons between methods of treatment for these fractures. However, there is a limited number of case series that discuss the treatment of these fractures. A recent study involving 18 adolescents involved in sports activities who sustained tibial tubercle fractures underwent surgery utilizing a technique of open reduction and fixation with two parallel screws, one proximal and one distal to the physis. No adverse complications were noted and they were all able to resume their previous sports activities. The only other outcome measure was noting that eight children had the screws subsequently removed because of local discomfort.[1]

Other studies, primarily regarding tibial tuberosity fractures, will often have a mixed employment of fixation in the study during their discussion of outcomes.[14,16,21,22,39,54] They suggest that there are few complications after closed management of nondisplaced extra-articular fractures, or reduction and surgical stabilization of displaced fractures. Usually, the primary adverse outcome, as recounted above, is prominent and painful implants.

TABLE 29-6 Proximal Tibial Physeal Fractures

Potential Pitfalls and Preventions

Pitfall	Preventions
Pitfall #1: Unrecognized physeal or apophyseal fracture	Scrutinize radiographs for signs of nondisplaced fractures Obtain stress radiographs or MRI to confirm diagnosis Caution the diagnosis of MCL injury in the very young
Pitfall #2: Unrecognized arterial injury	Understand that maximal displacement at the time of injury can be far greater than that seen at the time of presentation Thorough physical examination particularly concerning the circulatory system Repeat examination during in-hospital observation
Pitfall #3: Compartment syndrome	Vigilance during the first 24 hours to assess compartment status Be aware that a neurologic injury may confound physical examination results Univalve or bivalve cast to allow for swelling post-reduction
Pitfall #4: Growth disruption of the affected physis	Metaphyseal fractures (Cozen injuries) may auto-correct the valgus deformity and observation is warranted Recurvatum is the most common (especially following tubercle injuries) and may require surgical intervention
Pitfall #5: Intra-articular pin placement	May result in septic arthritis and should be avoided
Pitfall #6: Tourniquet utilization in tubercle fractures can hinder reduction	Releasing the tourniquet, and thereby the quadriceps muscle, will assist in the reduction of tubercle fractures

Management of Expected Adverse Outcomes and Unexpected Complications for Proximal Tibial Physeal Fractures

Closed reduction of proximal tibial physeal injuries may be unstable. Often, reductions can be lost if percutaneous pinning or screw placement was not performed in conjunction with the reduction. Being a correctable adverse outcome of the initial treatment, the patients should obtain x-rays at about 1 week after casting to verify the position and alignment of the fracture. A repeat manipulation may be performed at this point, if necessary—keeping in mind that a delay could increase the risk of injuring the physis during reduction maneuvers.

Moreover, these injuries—defined has growth plate injuries—are subject to limb shortening or angulation from subsequent growth arrest (Fig. 29-26). Any of the fracture patterns mentioned above can result in this particular complication; and, as with any physeal (or apophyseal) fracture, an anatomic reduction with fixation reduces the risk of growth disturbance.[43] If a partial or complete growth arrest is diagnosed, there is limited recourse. Surgery can be done to limit deformity progression via epiphysiodesis or excision of an epiphyseal bar depending on estimations of remaining growth and location of the arrest within the physis (Fig. 29-27). Therefore, frequent radiographic follow-up is important to achieve early recognition of the growth arrest and thereby limit the extent of disturbance through early intervention. As a reminder, the proximal tibia grows longitudinally at a mean rate of 6 mm per year. And the mean age of physeal closure at the proximal tibia is 14 years old in girls and 16 years old in boys. If angular growth disturbances are identified late, then an osteotomy can be done to correct the

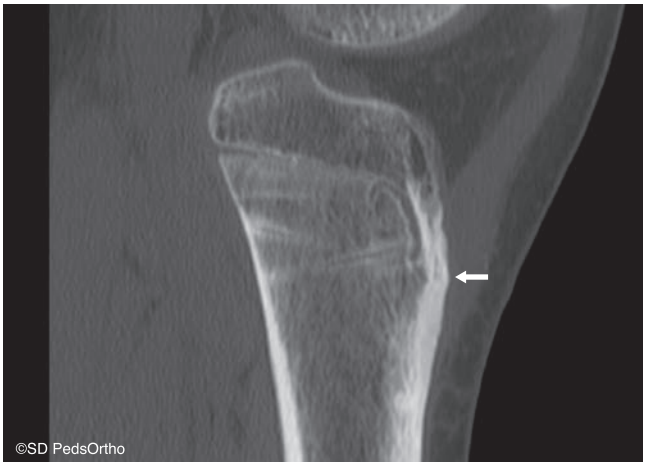

FIGURE 29-26 Sagittal CT scan at 1 year post-reduction and smooth wire fixation of a 12-year-old tibial tubercle fracture (San Diego type A) with subsequent physeal bar formation (*arrow*) and developing genu recurvatum.

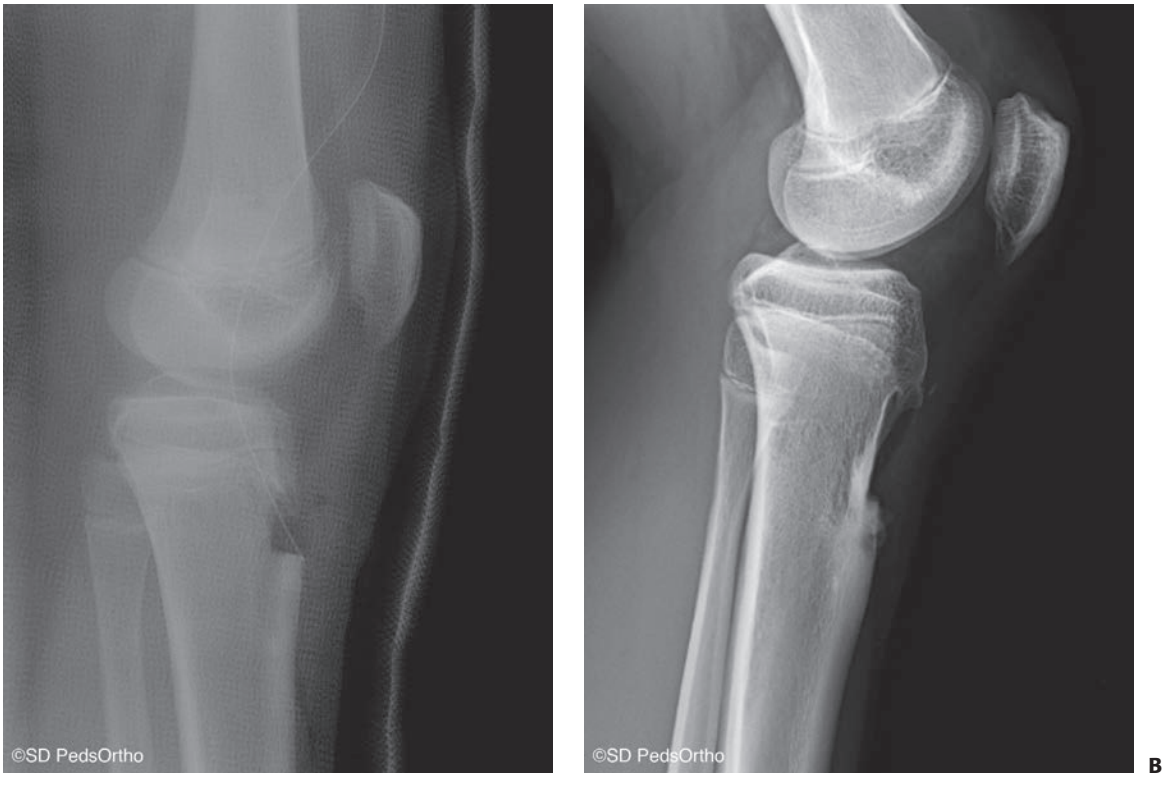

FIGURE 29-27 Same child as the one seen in Figure 29-26, status post physeal bar excision and fat graft placement to correct deformity. **A:** Initial post-corrective surgery lateral; **(B)** 3 years post-corrective surgery with 7 degrees persistent recurvatum compared to contra-lateral limb, but over 2.5 cm of uninhibited longitudinal growth; **(C)** contra-lateral limb at 3 years post-corrective surgery for comparison.

FIGURE 29-27 (*continued*)

deformity. Even recurvatum following a tibial tubercle fracture can be corrected with an osteotomy.[38]

Compartment syndrome may occur following any proximal tibial physeal fracture caused by either a mechanical blockage of the vascular structures by a displaced fracture, damage to the popliteal artery, or tearing of the anterior tibial recurrent vessels that bleed into the anterior compartment.[37,53] It is important to recognize that even a minimally displaced fracture at the time of presentation, may have injured one of these vessels at the moment of fracturing. Furthermore, even minimal posterior displacement of the metaphysis can obstruct popliteal blood flow since that vessel is tethered against the bone by soft tissues and the distal anterior tibial artery.[6] Vigilant monitoring is recommended for all patients with proximal tibial physis or displaced tibial tuberosity avulsion fractures. Prophylactic anterior compartment fasciotomy should be considered at the time of open reduction because of the high risk associated with these fractures.[4]

Bursitis over prominent implants is not uncommon, especially for tibial tubercle fractures.[53] Countersinking the screw heads may not always be impossible without risking fracture of a tuberosity fragment. Fixation with small screws or use of a tension band construct may be good alternatives, but fixation of these fractures should not be sacrificed for a potential risk of bursitis since the pull of the quadriceps muscle can displace fixed fractures. Families should be consulted that approximately 50% of patients may require a secondary procedure for implant removal after successful union of the fracture.

TABLE 29-7 Proximal Tibial Physeal Fractures

Common Adverse Outcomes and Complications
Compartment syndrome and vascular injury
Growth disturbance and leg-length discrepancy
Loss of reduction
Prominent and painful implants
Knee instability

Less frequently, there have been reports of symptomatic knee instability, primarily in children sustaining Salter–Harris types III and IV proximal tibial injuries.[2,41] Refracture has also been reported for tibial tubercle fractures.[4,53] This was seen in two children, one after a rapid return to sports (4 weeks after injury) and one wherein a transverse proximal tibial fracture occurred 7 months postoperatively at the level of the retained screws. There is one report of arthrofibrosis and persistent loss of motion of 25 degrees in a Salter–Harris type III fracture at almost 2 years post-injury.[8] Finally, even a thrombophlebitis has been reported in the literature (Table 29-7).[34]

Summary of Proximal Tibial Physeal Fractures

Fractures of the proximal tibial physis may be relatively uncommon, but they can result in deleterious consequences for the patient if poorly managed. Unrecognized compartment syndrome or arterial injury would be devastating to a young limb. The treatment of these injuries (beyond surgeon diligence to avoid catastrophe) is generalized based on current concepts in the treatment of any physeal injury.

30 INTRA-ARTICULAR INJURIES OF THE KNEE

Benton E. Heyworth and Mininder S. Kocher

Introduction to Fracture of the Tibial Spine (Intercondylar Eminence)

Fractures of the tibial eminence occur because of a chondroepiphyseal avulsion of the anterior cruciate ligament (ACL) insertion on the anteromedial tibial eminence.[305,413] Tibial eminence fractures were once thought to be the pediatric equivalent of midsubstance ACL tears in adults,[39,46,79,151,187,213,240,255,256,311,319,408,410] though recent evidence suggests that the relative incidence of ACL tears in children may be increasing,[353] and that tibial spine fractures in some adult populations may be more common than previously appreciated.[100,205]

Avulsion fracture of the tibial spine is a relatively uncommon injury in children: Skak et al.[361] reported that it occurred in 3 per 100,000 children each year. The most common causes of these fractures are bicycle accidents and athletic activities.[279]

Treatment has evolved from closed treatment of all fractures to operative treatment of certain fractures. Garcia and Neer[133] reported successful closed management in half of the 42 fractures of the tibial spine seen in patients ranging in age from 7 to 60 years. Meyers and McKeever,[280] however, recommended arthrotomy and open reduction for all displaced fractures, followed by cast immobilization with the knee in 20 degrees of flexion rather than hyperextension, believing that hyperextension could aggravate the injury. Gronkvist et al.[151] reported late instability in 16 of 32 children with tibial spine fractures treated nonoperatively, and therefore recommended surgery for all displaced tibial spine fractures, especially in children older than 10 years, because "the older the patient the more the demand on the ACL–tibial spine complex." Notably, Baxter and Wiley[39] noted mild-to-moderate knee laxity at follow-up in 45 patients, even after anatomic reduction of the tibial spine, suggesting that a partial ligamentous stretch injury may occur concomitantly with the spine fracture in many cases. McLennan[271] reported 10 patients with type III intercondylar eminence fractures treated with either closed reduction or arthroscopic reduction, with or without internal fixation. At second look arthroscopy 6 years after the initial injury, those treated with closed reduction had more knee laxity than those treated arthroscopically.

Historically, a variety of treatment options have been reported, including cast immobilization,[240,286] closed reduction with immobilization,[311,410] open reduction with immobilization,[286] open reduction with internal fixation,[289,311] arthroscopic reduction with immobilization,[271] arthroscopic reduction with suture fixation,[171,196,240,255,256] and arthroscopic reduction with wire,[36] screw fixation,[46,240,271] anchor fixation,[397] or bioabsorbable implant fixation.[349] However, modern treatment is based specifically on fracture type. Nondisplaced fractures and hinged or displaced fractures which are able to be reduced can be treated closed. Significantly hinged and displaced fractures which are not able to be reduced require open or arthroscopic reduction with internal fixation.

The prognosis for closed treatment of nondisplaced and reduced tibial spine fractures and for operative treatment of displaced fractures is good. Most series report healing with an excellent functional outcome despite some residual knee laxity.[36,39,46,196,215,240,248,255,256,271,272,286,289,365,408,410] Potential complications include nonunion, malunion, arthrofibrosis, residual knee laxity, and growth disturbance.[36,39,46,196,215,240,255,256,271,272,286,289,365,394,408,410]

Assessment of Fracture of the Tibial Spine (Intercondylar Eminence)

Mechanisms of Injury for Fracture of the Tibial Spine (Intercondylar Eminence)

Historically, the most common mechanism of tibial eminence fracture in children has been a fall from a bicycle.[279,331] However, with increased participation in youth sports at earlier ages and at higher competitive levels, tibial spine fractures resulting from sporting activities are being seen with increased frequency. The most common biomechanical scenario leading to tibial eminence fracture is forced valgus and external rotation of the tibia, although tibial spine avulsion fractures can also occur from hyperflexion, hyperextension,[288] or tibial internal rotation. As with ACL injury, tibial eminence fractures in sport may result from both contact and noncontact injuries.

The actual tissue injury in a tibial eminence fracture is a chondroepiphyseal avulsion of a fragment of the anteromedial tibial eminence from the rest of the central proximal tibial epiphysis via the ACL insertion. In a cadaver study by Roberts and Lovell,[330,331] fracture of the anterior intercondylar eminence was simulated by oblique osteotomy beneath the eminence and traction on the ACL. In each specimen, the displaced fragment could be reduced into its bed by extension of the knee. In adults, the same stress might cause an isolated tear of the ACL, but in children the incompletely ossified tibial spine is generally weaker to tensile stress than the ligament, so failure occurs through the cancellous bone beneath the subchondral bone of the tibial spine. In addition, loading conditions may result in differential injury patterns. In experimental models, midsubstance ACL injuries tend to occur under rapid loading rates, whereas tibial eminence avulsion fractures tend to occur under slower loading rates.[305,413]

Intercondylar notch morphology may also influence injury patterns. In a retrospective case-control study of 25 skeletally immature patients with tibial spine fractures compared to 25 age- and sex-matched skeletally immature patients with midsubstance ACL injuries, Kocher et al.[219] found narrower intercondylar notches in those patients sustaining midsubstance ACL injuries.

Associated Injuries with Fracture of the Tibial Spine (Intercondylar Eminence)

Associated intra-articular injuries are relatively uncommon. Although Shea et al.[352] identified bone bruises in 18 of 20 MRI studies in children with tibial spine fractures, in a series of 80 skeletally immature patients who underwent surgical fixation of tibial eminence fractures Kocher et al. found no intra-articular chondral injuries. Associated meniscal tears (Fig. 30-1) have been reported in 0[183] to 40% of MRI studies, but only 4%[220] of cases in a larger series based on arthroscopic assessment.[220] Associated collateral ligament injury or proximal ACL avulsion are uncommon, but have been described in case reports.[163,332] There is one published series of 21 tibial eminence fractures associated with tibial plateau fractures, but the mean age was 20.8 years, with no reporting of age range or inclusion of pediatric patients.[100]

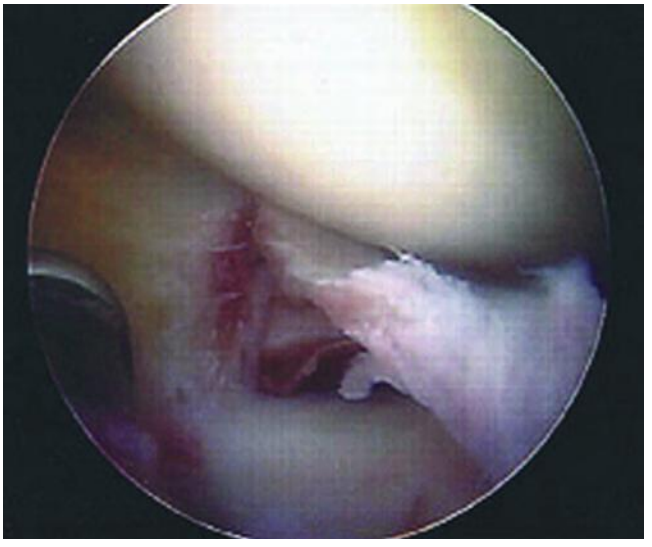

FIGURE 30-1 Longitudinal meniscus tear associated with tibial eminence fracture.

Signs and Symptoms of Fracture of the Tibial Spine (Intercondylar Eminence)

Patients typically present with a painful, swollen knee after an acute traumatic event. They are usually unable to bear weight on their affected extremity. On physical examination, there is often a large hemarthrosis because of the intra-articular fracture and limited motion due to pain, swelling, and occasionally mechanical impingement of the fragment in the intercondylar notch. Sagittal plane laxity is often present, but the contralateral knee should be assessed for physiologic laxity. Gentle stress testing should be performed to detect any tear of the medial collateral ligament (MCL) or lateral collateral ligament (LCL) or physeal fracture of the distal femur or proximal tibia.

Patients with late malunion of a displaced tibial spine fracture may lack full extension because of a mechanical bony block. Patients with late nonunion of a displaced tibial spine fracture may have increased knee laxity, with a positive Lachman examination and pivot-shift examination.

Imaging and Other Diagnostic Studies for Fracture of the Tibial Spine (Intercondylar Eminence)

Radiographs typically demonstrate the fracture, seen best on the lateral and tunnel/notch views. The lateral radiograph is most useful in fracture classification. Radiographs should be carefully scrutinized, as the avulsed fragment may be mostly nonossified cartilage with only a small, thin ossified portion visible on the lateral view.

To guide treatment, important information to ascertain from the radiographs includes the classification type, amount of displacement, size of the fracture fragment, comminution of the fracture fragment, and status of the physes. Bone age radiographs may be obtained for patients around the time of skeletal maturity, if transphyseal screw fixation is being considered.

MRI is typically not required in the diagnosis and management of tibial eminence fractures in children, particularly because operative cases will undergo a thorough diagnostic arthroscopy to assess for possible concurrent intra-articular knee injuries, such as meniscal tears, but may be helpful to confirm the diagnosis in cases with a very thin ossified portion of the avulsed fragment or evaluate for suspected associated injuries.[183,231,352]

Classification of Fracture of the Tibial Spine (Intercondylar Eminence)

The classification system of Meyers and McKeever,[279] which is based on the degree of displacement of the tibial spine fragment, continues to be widely used to classify fractures and guide treatment (Fig. 30-2).

1. Type I—minimal displacement of the fragment from the rest of the proximal tibial epiphysis.
2. Type II—displacement of the anterior ⅓ to ½ of the avulsed fragment, which is lifted upward but remains hinged on its posterior border in contact with the proximal tibial epiphysis.
3. Type III—complete separation of the avulsed fragment from the proximal tibial epiphysis, with upward displacement and rotation.

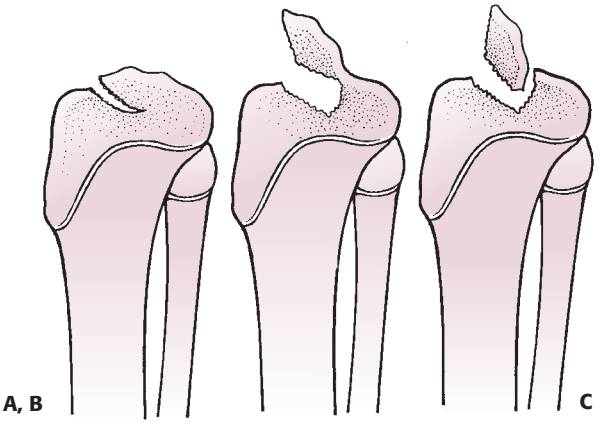

FIGURE 30-2 Classification of tibial spine fractures. **A:** Type I—minimal displacement. **B:** Type II—hinged posteriorly. **C:** Type III—complete separation.

Radiographs of these fracture types are shown in Figure 30-3. The interobserver reliability between type I and type II/III fractures is good; however, differentiation between type II and III fractures may be difficult.[219]

Zaricznyj[421] further classified a type IV fracture to describe comminution of the tibial eminence fragment. An alternative

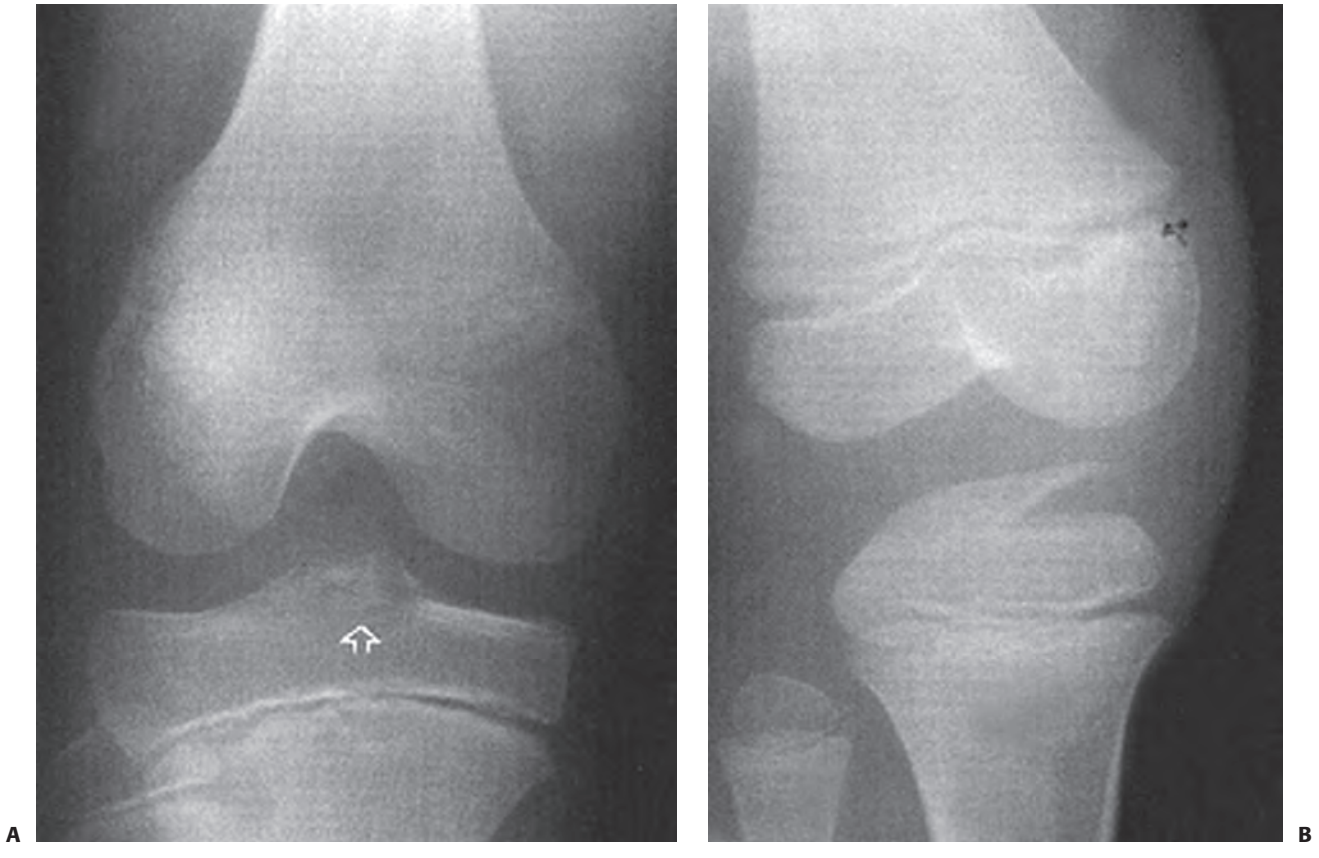

FIGURE 30-3 Stages of displacement of tibial spine fractures. **A:** Type I fracture, minimal displacement (*open arrow*). **B:** Type II fracture, posterior hinge intact.

C

FIGURE 30-3 (*continued*) **C:** Type III fracture, complete displacement and proximal migration.

classification scheme more broadly classifies tibial spine fractures as one of several different types of proximal tibial fractures, based on mechanism of injury, but has not gained wide acceptance or use.[288]

Outcome Measures for Fracture of the Tibial Spine (Intercondylar Eminence)

Although healing of the fracture on radiographs is important for decisions on timing of return to activities, the most important long-term outcome measures used to assess the results of tibial spine fracture fixation include functional knee scores, such as the Pedi-IKDC[225] and Lysholm[364] knee scores, and a patient's ability to make a full return to activities of daily life and sports activities, which can be assessed using the Marx or Tegner activity scores.[264] Asymmetry in the Lachman examination is not uncommon,[39,408] even after anatomic fixation of fractures, but has not been shown to correlate with symptomatic instability or long-term clinic results.

Pathoanatomy and Applied Anatomy Relating to Fracture of the Tibial Spine (Intercondylar Eminence)

The intercondylar eminence is that part of the tibial plateau lying between the anterior poles of the menisci. It is triangular, with the base of the triangle running along the anterior border of the proximal tibia. In the immature skeleton, the proximal surface of the eminence is covered entirely with cartilage. The ACL attaches in the interspinous region of the eminence and just anteriorly to the tibial spines, with separate slips anteriorly and laterally as well (Fig. 30-4). The ligament originates off the posterior margin of the lateral aspect of the intercondylar notch. The anterior horn of the lateral meniscus is typically attached in the region of the tibial intercondylar eminence just adjacent to the ACL insertion. In 12 patients with displaced tibial spine fractures which did not reduce closed, Lowe et al.[249] reported that the anterior horn of the lateral meniscus consistently remained attached to the tibial eminence fracture fragment. The posterior cruciate ligament (PCL) originates off the medial aspect of the intercondylar notch and inserts on the posterior aspect of the proximal tibia, distal to the joint line.

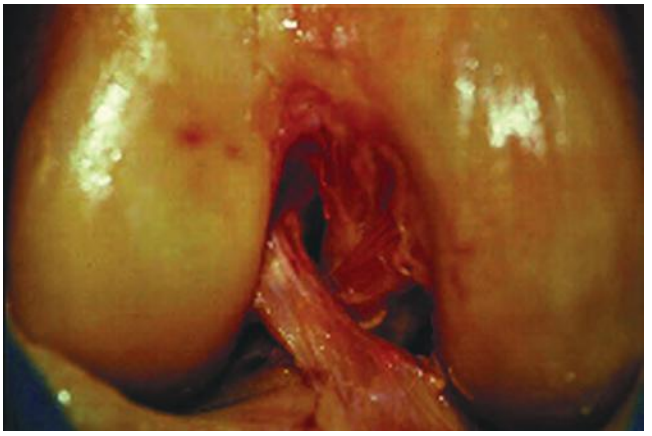

FIGURE 30-4 Anterior cruciate ligament insertion on the tibial eminence.

Meniscal or intermeniscal ligament entrapment under the displaced tibial eminence fragment has been reported and may be a rationale for considering arthroscopic or open reduction in displaced tibial spine fractures (Fig. 30-5).[67,75,119,220] Meniscal entrapment prevents anatomic reduction of the tibial spine fragment, which may result in increase of a block to extension and/or eventual anterior laxity.[151,187,272,311,408] Furthermore, meniscal entrapment itself may cause knee pain after fracture healing.[75] Falstie-Jensen and Sondergard Petersen, Burstein

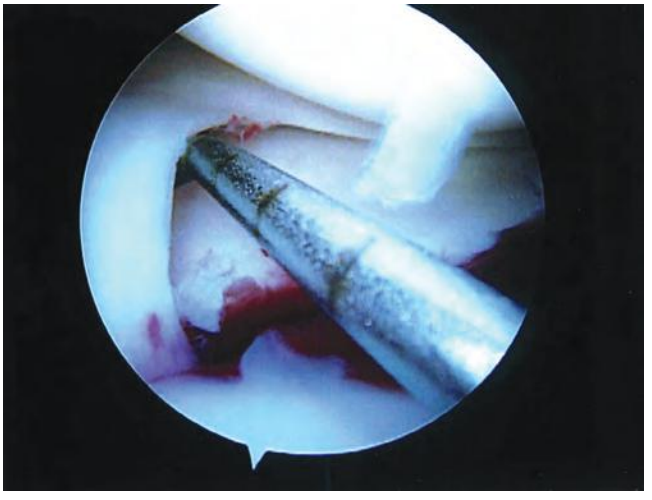

FIGURE 30-5 Meniscal entrapment under a tibial eminence fracture.

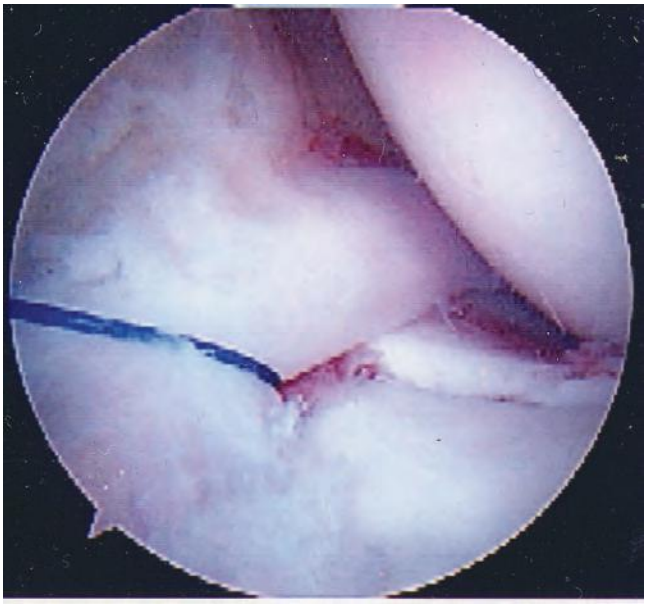

FIGURE 30-6 Retraction of an entrapped anterior horn medial meniscus using a retaining suture.

et al., and Chandler and Miller[67,75,119] have all reported cases of meniscal incarceration blocking reduction of type II or III tibial spine fractures in children. The prevalence of meniscal entrapment in tibial spine fractures may be common for displaced fractures. Although the anterior horn of the lateral meniscus may remain attached to the tibial eminence fracture fragment, it may instead remain attached to the intermeniscal ligament, generating a soft tissue complex that may become incarcerated between the elevated bony or cartilaginous fracture fragment and its underlying bony bed. Mah et al.[255] found medial meniscal entrapment preventing reduction in 8 of 10 children with type III fractures undergoing arthroscopic management. In a consecutive series of 80 skeletally immature patients who underwent surgical fixation of hinged or displaced tibial eminence fractures which did not reduce in extension, Kocher et al.[220] found entrapment of the anterior horn medial meniscus ($n = 36$), intermeniscal ligament ($n = 6$), or anterior horn lateral meniscus ($n = 1$) in 26% (6/23) of hinged (type II) fractures and 65% (37/57) of displaced (type III) fractures. The entrapped meniscus can typically be extracted with an arthroscopic probe and retracted with a retaining suture (Fig. 30-6).

Treatment Options of Fractures of the Tibial Spine (Intercondylar Eminence)

Treatment options include cast immobilization,[240,286] closed reduction with immobilization,[311,409,410] open reduction with immobilization,[286] open reduction with internal fixation,[289,311] arthroscopic reduction with immobilization,[271] arthroscopic reduction with suture fixation,[171,196,240,255,256] or suture mattress technique,[259] and arthroscopic reduction with wire,[36] screw fixation,[46,240] percutaneous K-wire fixation,[131,161,170] anchor fixation,[397] or bioabsorbable fixation.[349,416] Studies of the biomechanical strength of internal fixation suggest similar fixation strength between bioabsorbable and metallic internal fixation[257] and increased fixation strength of suture fixation over internal fixation,[61,111] with advocates of both bioabsorbable implant fixation and suture techniques emphasizing the advantage of avoiding subsequent hardware removal procedures.[259,416]

TABLE 30-1 Fracture of the Tibial Spine (Intercondylar Eminence)

Nonoperative Treatment

Indications	Relative Contraindications
Type I (nondisplaced) fractures	Type III fractures
Anatomic reduction of type II (hinged) fractures	Persistent/recurrent displacement of type II fractures

Nonoperative Treatment of Fracture of the Tibial Spine (Intercondylar Eminence)

Indications/Contraindications

Closed treatment is typically utilized for Type I fractures and for Type II or III fractures that successfully reduce with closed maneuvers (Table 30-1).

Techniques

Closed reduction is usually performed with placement of the knee in full extension or 20 to 30 degrees of flexion. Aspiration of the intra-articular fracture hematoma, with or without the intra-articular injection of a short-acting local anesthetic, has historically been common practice prior to reduction, but is not required for a successful reduction and is performed less commonly today. Radiographs, most importantly the lateral view, are utilized to assess adequacy of reduction. If the proximal fracture fragment includes bony segments of the medial or lateral tibial plateau, extension may affect a reduction through pressure applied by medial or lateral femoral condyle (LFC) congruence (Fig. 30-7). Fractures confined within the intercondylar notch, however, are unlikely to reduce in this manner. Portions of the ACL are tight in all knee flexion positions; therefore there may not be any one position that eliminates the traction effect of the ACL on the fragment. Interposition of the anterior horn medial meniscus or intermeniscal ligament may further block reduction.

Outcomes

Closed reduction can be successful for some type II fractures, but is infrequently successful in type III fractures. While Bakalim and Wilppula[33] reported successful closed reduction in 10 patients, and Meyers and McKeever[280] recommended cast immobilization with the knee in 20 degrees of flexion for all type I and II fractures, Kocher et al.[220] reported successful closed reduction in only 50% of type II fractures (26/49). However, no type III fractures were able to be close reduced (0/57), in their series, and Meyers and McKeever[280] similarly recommended

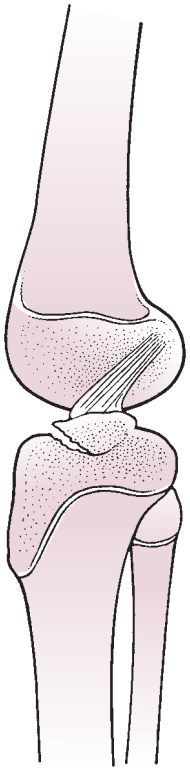

FIGURE 30-7 Reduction of type II tibial fracture with knee in 10 to 20 degrees of flexion.

open reduction or arthroscopic treatment for all type III fractures. Smillie[362] suggested that closed reduction by hyperextension can be accomplished only with a large fragment.

Operative Treatment of Fracture of the Tibial Spine (Intercondylar Eminence)

Indications/Contraindications

Arthroscopic or open reduction with internal fixation of three tibial eminence fractures and type II which do not reduce has been advocated for a variety of reasons, including concern over meniscal entrapment under the fractured tibial eminence preventing anatomic closed reduction,[67,75,119,255] the potential for instability and loss of extension associated with closed reduction and immobilization,[151,187,272,311] the ability to evaluate and treat associated intra-articular meniscal or osteochondral injuries with surgery, and the opportunity for early mobilization following fixation. For displaced fractures, Wiley and Baxter[408] found a correlation between fracture displacement at healing with knee laxity and functional outcome.

Arthroscopic Reduction and Internal Fixation with Epiphyseal Cannulated Screws

Preoperative Planning (Table 30-2)

Technique

General anesthesia is typically used. The patient is positioned supine on the operating room table. A lateral breakaway post is used. Alternatively, a circumferential post can be utilized. A standard arthroscope is used in most patients. A small (2.7 mm) arthroscope is used in younger children. An arthroscopic fluid pump is used at 35 Torr. A tourniquet is routinely used. Standard anteromedial and anterolateral portals are used. Prior to insertion of the arthroscope through the arthroscopic cannula in the anterolateral portal, the large hematoma should be evacuated, and use of up to 2 to 3 L of fluid for repetitive flushing of the joint prior to initiation of the diagnostic arthroscopy should be considered to optimize arthroscopic visualization. An accessory superomedial or superolateral portal can be later developed for guidewire and screw insertion.

A thorough diagnostic arthroscopic examination of the patellofemoral joint, medial compartment, and lateral compartment are essential to evaluate for concomitant injuries. Usually, some anterior fat pad must be excised with an arthroscopic shaver for complete visualization of the intercondylar eminence fragment. Entrapped medial meniscus or intermeniscal ligament is extracted with an arthroscopic probe and retracted with a retention suture (Fig. 30-5). The base of the tibial eminence fragment is elevated (Fig. 30-8A) and the fracture bed debrided with an arthroscopic shaver or hand curette (Fig. 30-8B). Anatomic reduction is obtained using an arthroscopic probe or microfracture pick with the knee in 30 to 90 degrees of flexion (Fig. 30-8C). Cannulated guidewires can be placed through portals just off the superomedial or superolateral border of the patella, using a spinal needle to determine the optimal inferiorly directed vector for fracture fixation and taking care to avoid injury to the chondral surfaces adjacent to the intercondylar notch. The guidewires are placed into the intercondylar eminence at the base of the ACL. Fluoroscopic assistance is utilized to confirm anatomic reduction, to guide correct wire orientation, and to avoid guidewire protrusion across the proximal tibial physis. A cannulated drill is used over the guidewires, taking care to drill the entire depth of the proximal fragment, but avoiding plunging through the proximal tibial physis. One or two screws are placed, based on the size of the tibial eminence fragment (Fig. 30-8D). Partially threaded 3.5-mm diameter screws (Fig. 30-8E) are used in children and either 4- or 4.5-mm diameter screws are used in adolescents. The knee is brought through a range of motion (ROM) to ensure rigid fixation without fracture displacement and to evaluate for impingement of the screw head(s) in extension (Table 30-3).

Arthroscopic Reduction and Internal Fixation with Suture

Preoperative Planning (Table 30-4).

Technique

Arthroscopic setup and examination is similar to the technique described for epiphyseal screw fixation. Accessory superomedial and superolateral portals are not used, though an accessory transpatellar working portal may be considered to facilitate fracture reduction and suture management. The fracture is elevated (Fig. 30-9A) and the fracture base debrided (Fig. 30-9B). The fracture is reduced, and an optimal reduction may be provisionally maintained with a small K-wire directed inferiorly, though reduction of a previously entrapped intermeniscal ligament or anterior meniscal horn over the anterior aspect of the fragment often maintains the reduction adequately. Two superiorly directed guidewires, approximately 2.7 mm in size, are then placed using the tibial ACL guide system from a small

TABLE 30-3 Fracture of the Tibial Spine (Intercondylar Eminence)

Surgical Steps—Screw Fixation

- Flush hemarthrosis from knee prior to diagnostic arthroscopy
- Diagnostic arthroscopy (assess menisci)
- Debride fracture edges (underside of eminence fragment and underlying fracture bed) with motorized shaver and/or currette
- Reduce eminence fragment (retract intermeniscal ligament and/or meniscal anterior horn[s] if interposed) with tagging suture or probe through accessory transpatellar portal
- Maintain reduction with cannulated screw guidewire (appropriate vector usually requires start point medial or lateral to patella, not distal)
- Assess reduction and measure optimal guidewire length with fluoroscopy
- Advance screw over guidewire to achieve fixation (screw tip should be proximal to physis)
- Repeat guidewire/screw steps for second screw if required

TABLE 30-4 Fracture of the Tibial Spine (Intercondylar Eminence)

Preoperative Planning Checklist—Suture Fixation

- **OR table:** Standard table with lateral thigh post
- **Position/positioning aids:** Supine
- **Fluoroscopy:** Optional
- **Equipment:** Knee arthroscopy setup, ACL tibial guide with <3-mm guidewire (but not reamer), suture passing devices (to advance through ACL at level of footprint *and* to retrieve through <3-mm tibial tunnels), repair suture (no. 2 size or greater)
- **Tourniquet (sterile/nonsterile):** Nonsterile

incision made just medial to the tibial tubercle and distal to the proximal tibial physis. Care is taken to create separate starting points for the two guidewires, to ensure a cortical bone bridge for later suture tying, and to place the intra-articular exit points through either side of the base of the intercondylar

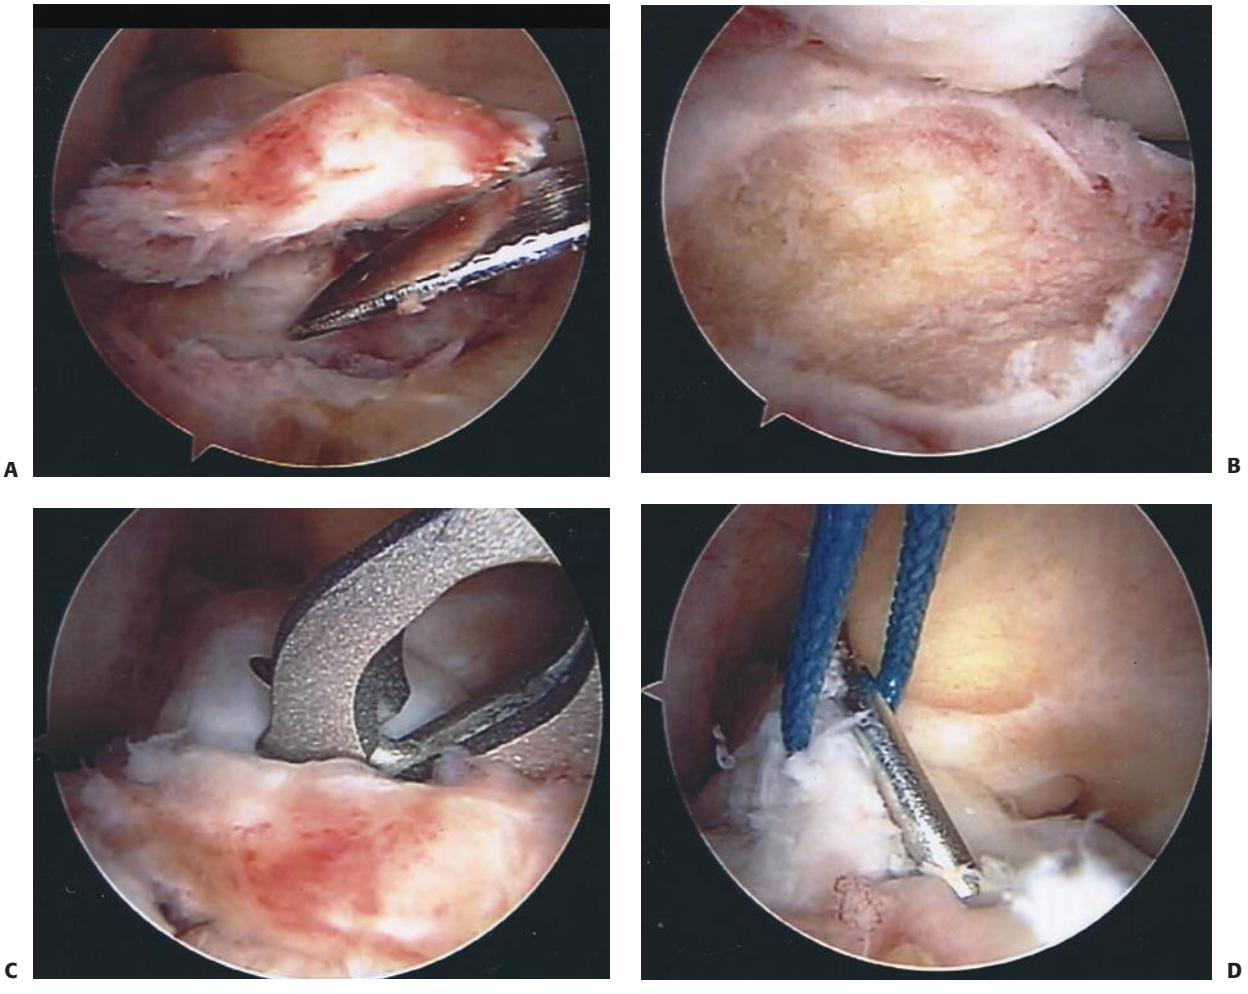

FIGURE 30-9 Arthroscopic reduction and suture fixation of a displaced tibial spine fracture. **A:** Elevation of the tibial eminence. **B:** Debridement of the fracture bed. **C:** Suture passing through the base of the ACL using a suture punch. **D:** Drilling of a tibial tunnel into the tibial eminence fragment using the ACL tibial guide.

eminence fragment (Fig. 30-9D) right along the fracture line. Either suture passing devices or small wire loops (smaller than 2.7 mm in diameter) are then placed up the guidewire tracts, either concomitantly or sequentially, to retrieve a suture, which has been passed through the base of the ACL using a suture punch (Fig. 30-9C) or another suture passer. These transtibial suture passers or retrievers then feed the sutures out through the inferior incision (Fig. 30-9E), and the sutures are tied down onto the tibia over the bony bridge (Fig. 30-9F), using arthroscopic assessment to confirm maintenance of the optimal reduction. The procedure is generally repeated for 1 to 2 additional sutures, so as to space the position of the "suture bridge" over a large segment of the ACL footprint and improve rotational stability of the fragment. Resorbable monofilament suture may be used, though we favor heavier nonabsorbable braided sutures, and there are no published reports of complications associated with growth disturbance secondary to the bony bridging or prolonged nonabsorbable suture retention through the small transtibial guidewire tracts (Table 30-5).

TABLE 30-5 Fracture of the Tibial Spine (Intercondylar Eminence)

Surgical Steps—Suture Fixation

- Flush hemarthrosis from knee prior to diagnostic arthroscopy
- Diagnostic arthroscopy (assess menisci)
- Debride fracture edges (underside of eminence fragment and underlying fracture bed) with motorized shaver and/or currette
- Reduce eminence fragment (retract intermeniscal ligament and/or meniscal anterior horn[s] if interposed) with tagging suture or probe through accessory transpatellar portal
- Pass repair sutures through ACL at level of tibial footprint (one anterior, one posterior to maximize fixation/repair stability)
- Through proximal tibial incision, create tibial tunnels (<3 mm) with ACL guide/guidewire on either side of fragment with cortical bone bridge between tunnel starting points
- Pass trans-ACL sutures through tunnels
- Optimize reduction, tie sutures over bone bridge on maximum tension

Author's Preferred Treatment of Fracture of the Tibial Spine (Intercondylar Eminence)

The author's algorithm to decision making is shown in Figure 30-10. Type I fractures are treated with a locked hinged knee brace in an older child or adolescent or long-leg cast immobilization in a younger child, applied in full extension (0 degrees), to prevent loss of reduction and a flexion contracture, which is generally harder to treat than loss of flexion. The patient and family are cautioned to elevate the leg to avoid swelling. Radiographs are repeated in 1 to 2 weeks to ensure that the fragment

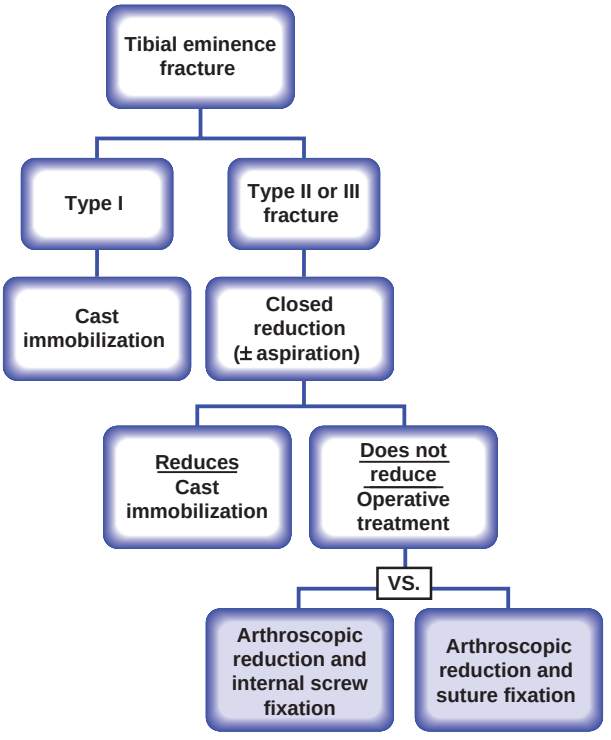

FIGURE 30-10 Algorithm for the management of tibial eminence fractures in children.

has not displaced. The cast is removed 4 to 6 weeks after injury. A hinged knee brace is then used and physical therapy initiated to regain motion and strength. Patients are typically allowed to return to sports 3 to 4 months after injury if they demonstrate fracture healing and adequate motion and strength.

Type II fractures are usually treated with attempted closed reduction. Aspiration of hematoma and injection of local anesthetic under sterile conditions may be considered if the patient is in severe pain, but is not required for a successful reduction. Reduction is usually attempted at full extension, with radiographs taken to assess reduction, though if dynamic fluoroscopy is being used, assessment of reduction should also be performed at 20 degrees of flexion and casted in the optimal position. Follow-up radiographs are performed at 1 and 2 weeks postreduction to ensure maintenance of reduction. Length of casting and postcasting management is similar to type I fractures. If the fracture does not reduce anatomically or if the fracture later displaces, operative treatment should be performed to optimize outcomes.

Type III fractures may be treated with attempted closed reduction; however this is usually unsuccessful, and we favor primary operative treatment in the absence of significant medical comorbidities or surgical contraindications. The author's preferred operative treatment is arthroscopic reduction and internal fixation. However, open reduction through a medial parapatellar incision can also be performed per surgeon preference/experience, or if arthroscopic visualization is difficult. The author's preferred fixation is epiphyseal cannulated screws if the fragment is large or suture fixation if the fragment is small or comminuted.

Postoperative Care of Fracture of the Tibial Spine (Intercondylar Eminence)

Postoperatively, patients are placed in a postoperative hinged knee brace and maintained touch-down weight bearing for 6 weeks postoperatively. Motion is restricted to 0 to 30 degrees for the first 2 weeks, 0 to 60 degrees for the next 2 weeks, and then 0 to 90 for weeks 4 to 6, with full ROM after 6 weeks, provided early radiographic healing is seen. The brace is kept locked in extension at night for the first 6 weeks to prevent a flexion contracture. Radiographs are obtained at each postoperative visit to evaluate maintenance of reduction and fracture healing (Fig. 30-11). Cast immobilization for 4 weeks postoperatively may be considered in younger children if there is concern for inability to comply with protected weight bearing and brace immobilization. Early initiation of physical therapy is routinely utilized to optimize motion, strength, and sport-specific training. Patients are typically allowed to return to sports at 12 to 16 weeks postoperatively, depending on knee function. Screws are not routinely removed. Functional ACL bracing is utilized if there is residual knee laxity.

Potential Pitfalls and Preventative Measures of Fracture of the Tibial Spine (Intercondylar Eminence)

In the closed management of tibial eminence fractures, follow-up radiographs must be obtained at 1 and 2 weeks postinjury to verify maintenance of reduction. Late displacement and malunion can occur, particularly for type II fractures. Though

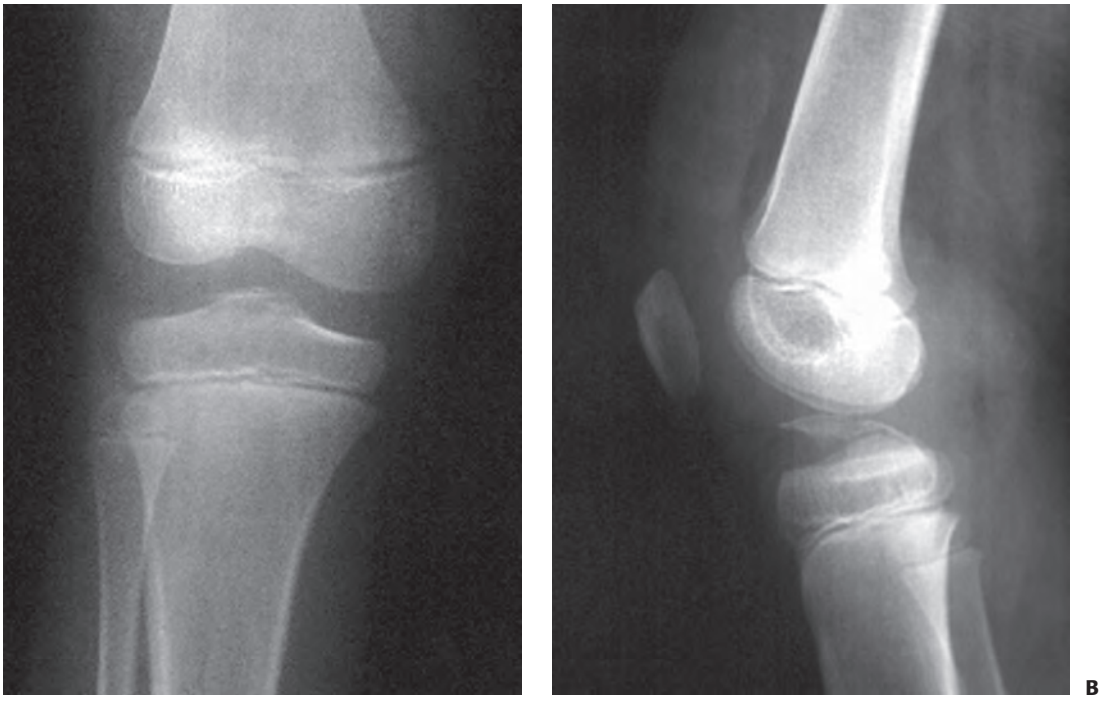

FIGURE 30-11 Type III tibial spine fracture in an 11-year-old male child treated with arthroscopic reduction and 3.5-mm cannulated screw fixation. Preoperative AP **(A)** and lateral **(B)** radiographs. Postoperative AP **(C)** and lateral **(D)** radiographs.

C D

FIGURE 30-11 (*continued*)

generally not necessary, aspiration of hemarthrosis and injection of local anesthetic under sterile conditions can occasionally be helpful to minimize pain and allow for full knee extension at the time of closed reduction.

During arthroscopic reduction and fixation of tibial spine fractures, arthroscopic visualization can be difficult unless the large hematoma is evacuated and flushed prior to introduction of the arthroscope. Adequate inflow and outflow is essential for proper visualization. Careful attention to preparation of the fracture bed is important to provide optimal conditions for bony healing. Attempted epiphyseal cannulated screw fixation of small or comminuted tibial eminence fragments can fail as the screw may further comminute the fragment. In these cases, suture fixation is generally a better method. If epiphyseal cannulated screw fixation is used, fluoroscopy is necessary to ensure that the drill or screw does not traverse the proximal tibial physis, which may result in a proximal tibial physeal growth arrest.

Early mobilization is helpful to avoid arthrofibrosis which can occur with immobilization. However, in younger children (less than 7 years old), compliance with protected weight bearing and brace use can be problematic (Table 30-6).

TABLE 30-6 Fracture of the Tibial Spine (Intercondylar Eminence)

Potential Pitfalls and Preventions

Pitfall	Preventions
Pitfall #1: Failure/loss of reduction of type II	Prevention 1a: Ensure cast is in full extension Prevention 1b: Obtain MRI if meniscal/intermeniscal interposition is suspected Prevention 1c: Follow XRs closely (5–7 days and 12–14 days postreduction)
Pitfall #2: Inadequate visualization during arthroscopy	Prevention 2: Before starting arthroscopy, flush hemarthrosis until arthroscopy fluid clear
Pitfall #3: Comminution of eminence fragments during attempted screw fixation (or upon initial assessment)	Prevention 3: Utilize suture fixation instead of screw fixation
Pitfall #4: Growth disturbance with screw fixation	Prevention 4: Multiple fluoroscopic views to ensure no physeal penetration
Pitfall #5: Postoperative arthrofibrosis	Prevention 5: Ensure adequate fixation to allow early ROM

Treatment-Specific Outcomes for Fracture of the Tibial Spine (Intercondylar Eminence)

The prognosis for closed treatment of nondisplaced and reduced tibial spine fractures and for operative treatment of displaced fractures is good. Most series report healing with an excellent functional outcome despite some residual knee laxity.[36,39,46,196,215,240,255,256,271,272,286,289,365,387,408,410] Potential complications include nonunion, malunion, arthrofibrosis, residual knee laxity, and growth disturbance.[36,39,46,196,215,240,255,256,271,272,286,289,365,391,408,410]

Mild residual knee laxity is seen frequently, even after anatomic reduction and healing of tibial eminence fractures. Baxter and Wiley[39,408] found excellent functional results without symptomatic instability in 17 pediatric knees with displaced tibial spine fractures, despite a positive Lachman examination in 51% of patients and increased mean instrumented knee laxity of 3.5 mm. After ORIF of type III fractures in 13 pediatric knees, Smith[365] identified patient-reported instability in only two patients, despite a positive Lachman examination in 87% of patients. In a group of 50 children after closed or open treatment, Willis et al.[410] found excellent clinical results despite a positive Lachman examination in 64% of patients and instrumented knee laxity of 3.5 mm for type II fractures and 4.5 mm for type III fractures. Similarly, Janarv et al.[187] and Kocher et al.[215] found excellent functional results despite persistent laxity even in anatomically healed fractures. More recent long-term follow-up studies have replicated these findings.[72,387] Despite four patients demonstrating signs, but no symptoms, of instability, Tudisco et al.[387] recently reported good results in 13 of 14 knees followed for a mean of 29 years postinjury, with the one suboptimal result reported in a type III fracture treated nonoperatively.

Persistent laxity despite anatomic reduction and healing of tibial spine fractures in children is likely related to plastic deformation of the collagenous fibers of the ACL occurring in association with tibial spine fracture. At the time of tibial spine fixation, the ACL often appears hemorrhagic within its sheath, but grossly intact and in continuity. In a primate animal model, Noyes et al.[305] found frequent elongation and disruption of ligament architecture despite gross ligament continuity in experimentally produced tibial spine fractures at both slow and fast loading rates. This persistent anteroposterior laxity despite anatomic reduction may be avoided by countersinking the tibial spine fragment within the epiphysis at the time of reduction and fixation. However, ACL injury after previous tibial spine fracture is rare.

Management of Expected Adverse Outcomes and Unexpected Complications in Fracture of the Tibial Spine (Intercondylar Eminence)

Poor results may occur after eminence fractures associated with unrecognized injuries of the collateral ligaments or complications from associated physeal fracture.[278,365,376] In addition, hardware across the proximal tibial physis may result in growth disturbance with recurvatum deformity or shortening.[290]

Malunion of type II and III fractures may cause mechanical impingement of the knee during full extension (Fig. 30-12).[132,255,256]

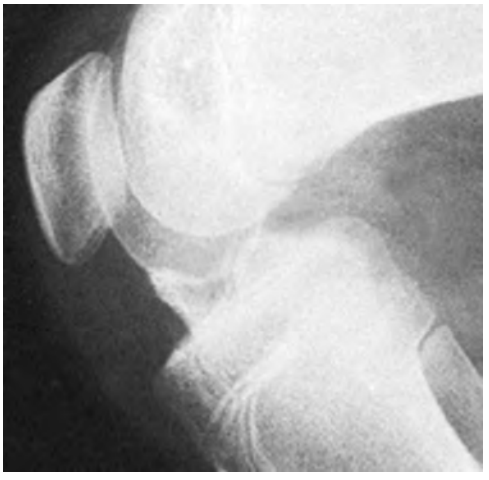

FIGURE 30-12 Lateral radiograph of a malunited displaced fracture of the intercondylar eminence of the tibia with an extension block.

For symptomatic patients, this can be corrected by either osteotomy of the fragment and fixation in a more recessed, anatomic position or excision of the manumitted fragment with anatomic suture repair of the ACL to its bony footprint. Alternatively, excision of the fragment and ACL reconstruction can be considered in adults and older adolescents.

Nonunion of type II and III tibial spine fractures treated closed can usually be managed by arthroscopic or open reduction with internal fixation.[204,247,394] Technically, debridement of the fracture bed and the fracture fragment to fresh, bleeding bone is essential to optimize bony healing. Bone graft may be required in cases of chronic nonunion. Similarly to management of malunions described above, excision of the fragment and ACL reconstruction can alternatively be considered in adults and older adolescents, and may be preferable, given the increasingly favorable reports of outcomes of pediatric ACL reconstruction techniques.

Stiffness and arthrofibrosis can be a challenging problem after both nonoperative and operative management of tibial eminence fractures. The milieu of a major traumatic intra-articular injury, a large hemarthrosis, and immobilization can predispose to arthrofibrosis. Vander Have et al. reported on 20 cases of arthrofibrosis out of 205 patients (10%) from four institutions over a 10-year period who had undergone surgical intervention for tibial spine fracture, as well as 12 additional cases referred from other institutions. Of the 32 total cases, 25 (78%) had been immobilized for 4 to 6 weeks postoperatively without motion, and 24 (75%) required additional operative treatment within 6 months to address debilitating loss of knee motion.[391] The authors concluded that for fractures that undergo fixation, early mobilization utilizing physical therapy can minimize the risk of arthrofibrosis, an approach supported by subsequent analyses.[318] If stiffness is detected, dynamic splinting and aggressive physical therapy can be employed during the first 3 months from fracture. If significant stiffness remains after 3 months from fracture, patients should be managed with manipulation under anesthesia, but only in conjunction with arthroscopic lyses of adhesions, an approach shown

Malunion
ACL laxity

to be successful in resolving the stiffness in majority of cases.[391] Overly vigorous manipulation should be avoided to avert iatrogenic proximal tibial or distal femoral physeal fracture, which may lead to growth arrest or deformity requiring further treatment (Table 30-7).[391]

Introduction to Osteochondral Fractures

Osteochondral fractures in skeletally immature patients are more common than once thought. They are typically associated with acute lateral patellar dislocations. The most common locations for these fractures are the inferior aspect of the patellar median ridge, the inferior medial patellar facet, or the lateral aspect of the LFC (Fig. 30-13). The osteochondral fracture fragments may range from small incidental loose bodies to large portions of the articular surface. The prevalence of osteochondral fractures associated with acute patella dislocation ranges from 19% to 50%.[15,54,120,266,297,302,371] Matelic et al.[266] found 67% of one series of children presenting with an acute hemarthrosis of the knee were found to have an osteochondral fracture.

The diagnosis can be difficult to make because even a large osteochondral fragment may contain only a small ossified portion that is visible on plain radiographs. MRI has therefore emerged as having a critical role in identifying associated osteochondral fractures or chondral-only fragments in cases of traumatic patellar dislocation. Acute osteochondral fractures must be differentiated from acute chondral injuries, which do not involve subchondral bone, and osteochondritis dissecans (OCD),[124,221] which is most often a repetitive overuse lesion of the subchondral bone, which may result in a nonhealing stress fracture that can progress to fragment dissection.

Treatment of osteochondral fractures includes removal of small loose bodies and fixation of larger osteochondral fragments. In cases associated with patellar dislocation, lateral retinacular release, medial retinacular repair, medial patellofemoral ligament (MPFL) repair, or primary reconstruction may be performed adjunctively.

Assessment of Osteochondral Fractures

Mechanisms of Injury for Osteochondral Fractures

There are two primary mechanisms for production of an osteochondral fracture.[15,54,,81,120,122,201,266,273,297,371] First, a direct blow to the knee with a shearing force applied to either the medial or LFC can create an osteochondral fracture. The second mechanism involves a flexion-rotation injury of the knee in which an internal rotation force is placed on a fixed foot, usually coupled with a strong quadriceps contraction. The subsequent contact between the tibia and femur or patella and LFC causes the fracture. This latter contact mechanism occurs during an acute patellar dislocation. When the patella dislocates laterally, the medial retinaculum and the associated medial MPFL tears, while the extensor mechanism still applies significant compressive forces as the patella shears across the LFC. The medial border of the patella then temporarily becomes impacted on the prominent edge of the LFC before it slides back tangentially over the surface of the LFC because of pull of the quadriceps. Either the dislocation or the relocation phase of this injury can cause an osteochondral fracture to the LFC, the medial facet of the patella, or both (Fig. 30-14). Interestingly, osteochondral fractures are uncommon with chronic, recurrent subluxation, or dislocation of the patella. In this situation, the laxity of the medial knee tissues and decreased compressive forces between the patella and the LFC prevent development of excessive shear forces. With more acute or traumatic dislocations, even if a frank osteochondral fracture does not occur, bone bruising is generally seen on MRI on both the patella and LFC, and chondral injuries, such as fissuring of the articular surface of the medial facet and median ridge, are also common.[116,203,300,302]

Ahstrom[10] reported on a series of 18 osteochondral fractures, 14 of which occurred during sports-related activities. Most patients give a history of a twisting injury consistent with acute patellar dislocation, but a few report a direct blow to the lateral or medial femoral condyle, accounting for a shear injury. The prevalence of osteochondral fractures associated with acute patella dislocation ranges from 19% to 50% in the literature.[15,54,120,266,297,302,371] Nietosvaara et al.[297] reported that of 69 acute patellar dislocations in children and adolescents, 62 (90%) of which occurred during or as a result of a fall, 39% had osteochondral fractures.

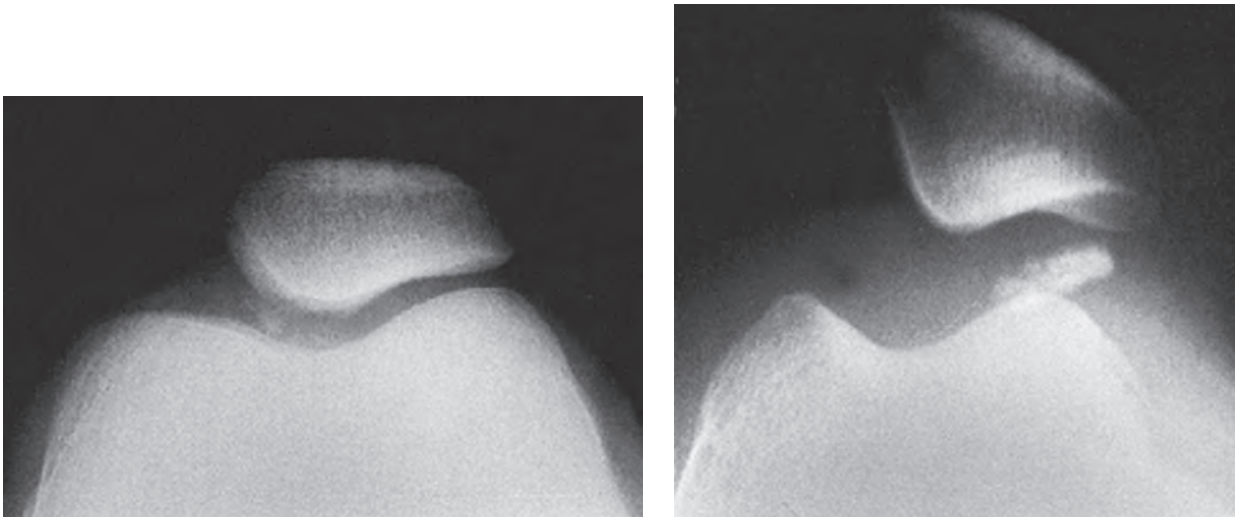

FIGURE 30-14 Osteochondral fractures associated with dislocation of the patella. **A:** Medial facet of patella. **B:** Lateral femoral condyle.

Associated Injuries with Osteochondral Fractures

As described above, common injuries associated with osteochondral fractures caused by patellar dislocation include MPFL tear and bone bruises or impaction injuries to the LFC and medial aspect of the patella. Other osteochondral fractures may occur in association with severe cruciate or collateral ligament tears, as well as knee dislocation.

Signs and Symptoms of Osteochondral Fractures

Acutely, osteochondral fractures present with severe pain, swelling, and difficulty in weight bearing.[2,10,11,32,38,45,81,82,109,142,166,176,177,189,201,242,273,297,308,334,335,348,362,368,411,412] On examination, tenderness to palpation is often most severe over the medial patella and lateral aspect of the LFC, though medial femoral condylar tenderness may also be exhibited, either from a femoral-sided tear of the MPFL from the adductor tubercle region or because of a partial MCL sprain, which is not uncommon in association with patellar dislocation. The patient will usually resist attempts to flex or extend the knee and may hold the knee in 15 to 20 degrees of flexion for comfort. The large hemarthrosis is due to an intra-articular fracture of the highly vascular subchondral bone. Joint aspiration may reveal fatty globules or a supernatant layer of fat if allowed to stand for 15 minutes indicating an intra-articular fracture. Similarly, fluid–fluid levels may be seen on MRI, from the separation of fat and blood. Late examination findings may be similar to those of a loose body with intermittent locking or catching of the knee.

Imaging and Other Diagnostic Studies for Osteochondral Fractures

Radiographic assessment of a possible osteochondral fracture should begin with anteroposterior, lateral, and skyline plain radiographs. However, a roentgenographic diagnosis can be difficult because even a large osteochondral fragment may contain only a small ossified portion that is visible on plain radiographs. A tunnel view may help locate a fragment in the region of the intercondylar notch. Because the osteochondral fragment may be difficult to see on plain radiographs, radiographs should be carefully assessed for even the smallest ossified fragment (Fig. 30-15).

Matelic et al.[266] report that standard radiographs failed to identify the osteochondral fracture in 36% of children who had an osteochondral fracture found during arthroscopy. For this reason, MRI is recommended in most cases, due to the importance of identifying a possible osteochondral fracture despite negative radiographs[60,214,406] or a large chondral fragment. Such cases usually occur in the setting of an acute traumatic patellar dislocation in a patient with a large hemarthrosis, whereas ligamentously lax patients with chronic, recurrent, atraumatic patellar instability are less likely to sustain osteochondral fractures. A high-riding patella may also have a protective effect against associated intra-articular osteochondral fractures. Patients with an Insall index > 1.3 have a decreased chance of sustaining an osteochondral fracture compared with patients who have an Insall index within normal limits.[60] An arthrogram effect is usually present during MRI, given the large hemarthrosis.

Classification of Osteochondral Fractures

The classification of osteochondral fractures of the knee is based on the site, the type, and the mechanism of injury. The classification outlined in Table 30-8 is based on the descriptions of osteochondral fractures by Kennedy[201] and Smillie.[362]

Outcome Measures for Osteochondral Fractures

Healing of osteochondral fractures must be followed closely with radiographs, as healing is the most important predictor of outcome. Once healed, standard outcome measures, such as functional knee metrics (the Pedi-IKDC[225] and Lysholm[364] knee

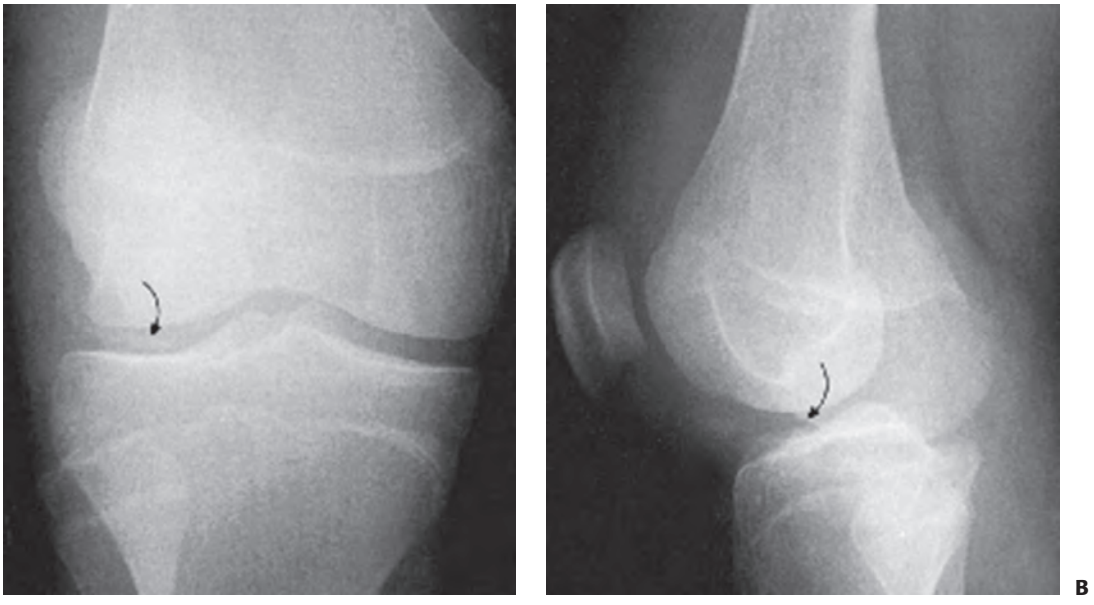

FIGURE 30-15 Osteochondral fracture of lateral femoral condyle after patellar dislocation. **A:** Fragment seen in lateral joint space. **B:** Lateral view.

scores), can be used to assess the results and, paired with the Marx or Tegner activity scores,[264] ascertain a patient's ability to make a full return to activities of daily life and sports activities.

Pathoanatomy and Applied Anatomy Relating to Osteochondral Fractures

The patella tracks in the trochlear groove between the medial and LFCs during flexion and extension of the knee.[142,177] With increasing knee flexion, the contact area on the articular surface of the patella moves from the distal to the proximal aspect of the articular surface of the patella. Between 90 and 135 degrees of flexion, the patella glides into the intercondylar notch between the femoral condyles. The two primary areas of contact are the medial patellar facet with the medial femoral condyle and the superolateral quadrant of the lateral patellar facet with the LFC. Soft tissue support for the patellofemoral joint includes the quadriceps muscle, the MPFL, the patellar tendon, and the vastus medialis and lateralis muscles.

TABLE 30-8 Mechanism of Osteochondral Fractures

Site	Mechanism
Medial femoral condyle	Direct blow (fall) Compression and rotation (tibiofemoral)
Lateral condyle	Direct blow (kick) Compression and rotation (tibiofemoral) Acute patellar dislocation
Patella (medial margin)	Acute patellar dislocation

Dislocation of the patella may tear the medial retinaculum and MPFL, but the rest of the quadriceps muscle–patellar ligament complex continues to apply significant compression forces as the patella dislocates laterally. These forces are believed to cause fracture of the medial patellar facet, the LFC articular rim, or both (Fig. 30-13).[200,201,305,306,308,332,333,335] Osteochondral fractures are uncommon with chronic recurrent subluxation or dislocation of the patella because of relative laxity of the medial retinaculum and lesser compressive forces on the patella and the LFC.

A histopathologic study by Flachsmann et al.[122] helps to explain the occurrence of osteochondral fractures in the skeletally immature at an ultrastructural level. They noted that in the joint of a juvenile, interdigitating fingers of uncalcified cartilage penetrate deep into the subchondral bone providing a relatively strong bond between the articular cartilage and the subchondral bone. In the adult, the articular cartilage is bonded to the subchondral bone by the well-defined calcified cartilage layer, the cement line. When shear stress is applied to the juvenile joint, the forces are transmitted into the subchondral bone by the interdigitating cartilage with the resultant bending forces causing the open pore structure of the trabecular bone to fail. In mature tissue, the plane of failure occurs between the deep and calcified layers of the cartilage, the tidemark, leaving the osteochondral junction undisturbed. Although the juvenile and adult tissue patterns are different, they both provide adequate fracture toughness to the osteochondral region. As the tissue transitions, however, from the juvenile to the adult pattern during adolescence, the fracture toughness is lost. The calcified cartilage layer is only partially formed and the interdigitating cartilage fingers are progressively replaced with calcified matrix. Consequently, the interface between the articular cartilage and the subchondral bone becomes a zone of potential weakness in the joint which may explain why osteochondral fractures are seen frequently in adolescents and young adults.

Treatment Options for Osteochondral Fractures

Nonoperative Treatment of Osteochondral Fractures

Nonoperative treatment of osteochondral fractures is reserved for small fragments, 5 mm or less, that have failed to cause or are unlikely to cause symptoms associated with loose body fragments. Every osteochondral fracture and the injury through which it occurred are different, but treatment should be individualized, to some degree, based on a patient's age and activity level. However, as general principles, the larger the fragment, the more bone attached a given fragment, and the more central the weight-bearing zone from which the fragment was detached, the more consideration should be given to attempted refixation.

Operative Treatment of Osteochondral Fractures

Indications/Contraindications and Surgical Procedure

The recommended management of acute osteochondral fractures of the knee is either surgical removal of the fragment or fixation of the fragment, depending on its size and the quality of the tissue.[213,220] In patients with an osteochondral fracture after acute patellar dislocation, concomitant repair of the medial retinaculum and MPFL, either at the patellar or femoral insertion sites of the ligament, or through an intrasubstance imbrications, at the time of fragment excision or fixation, may decrease the risk of recurrent patellar instability,[7,70,82,334] though there is conflicting evidence whether this repair improves the ultimate redislocation rate.[78,298,299,314]

Fixation

If the lesion is large (≥5 mm), easily accessible, involves a weight-bearing area, and has adequate cortical bone attached to the chondral surface then fixation should be considered.[45,201,362,368,411,412]

Preoperative Planning (Table 30-9)

Surgical Approach and Technique

Fixation can be performed via arthroscopy or arthrotomy. Fixation options include K-wires, Steinmann pins, cannulated or solid metal screws, variable pitch headless screws, or bioabsorbable pins,[76,138,401] tacks, or screws, which have recently increased in popularity and have the advantage of not requiring implant removal.[103] For nonbioabsorbable implants, hardware removal is typically performed after fracture healing, though headless compression screws may be buried beneath the superficial level of the cartilage and may be retained.[242] Traditionally, fixation of chondral fragments with no bone attached was not considered amenable to refixation, because of concerns regarding poor healing capacity. However, new reports have suggested that large chondral-only fragments may be able to heal in children or adolescents if early refixation is pursued (Table 30-10).[291,388]

TABLE 30-10 Fixation of Osteochondral Fractures

Surgical Steps

- Diagnostic arthroscopy to retrieve loose body, assess viability, and assess fracture bed and feasibility of fixation
- If optimal fixation is achievable through arthroscopic means (rare), skip below arthrotomy step
- Arthrotomy (medial parapatellar or lateral parapatellar) to optimize access to fracture bed; if patellar, make long enough to ensure adequate inversion of patella
- Debride/prepare fracture bed and fragment
- Reduce fragment, provisionally fix with small K-wire
- Fixation with bioabsorbable pins/tacks/screws or headless metal compression screws (reserved for larger fragments with adequate bone)
- Repair arthrotomy (taking care not to overtension to avoid increasing patellofemoral contact forces)

Removal of Fragment(s)

If the fracture fragment is small (<5 mm), chronic, or has fractured from a non–weight-bearing region of the knee, then removal of loose bodies is recommended.[11,176,189,238,335,348] The fragment's crater should be debrided to stable edges and the underlying subchondral bone should be perforated through marrow stimulation techniques to encourage fibrocartilage formation.[238]

Author's Preferred Treatment of Osteochondral Fractures

The author's algorithm to decision making is shown in Figure 30-16. In patients with an acute, traumatic patellar dislocation with a large hemarthrosis, MRI is performed, even if initial radiographs do not clearly show any associated osteochondral fracture. If MRI does not reveal any associated osteochondral fracture or any large chondral fragments, these patients are treated with a brief (1 to 2 weeks) period with a hinged knee brace locked in extension for ambulation with crutches for comfort and weight bearing and ROM as tolerated, followed by use of a soft, lateral-stabilizing patellofemoral brace and physical therapy emphasizing patellar mobilization, straight leg raises, progressive resistance exercises, and vastus medialis obliquus (VMO) strengthening. Routine diagnostic arthroscopy and MPFL repair are not performed on initial patellofemoral dislocators. Patients are allowed to return to sports 6 to

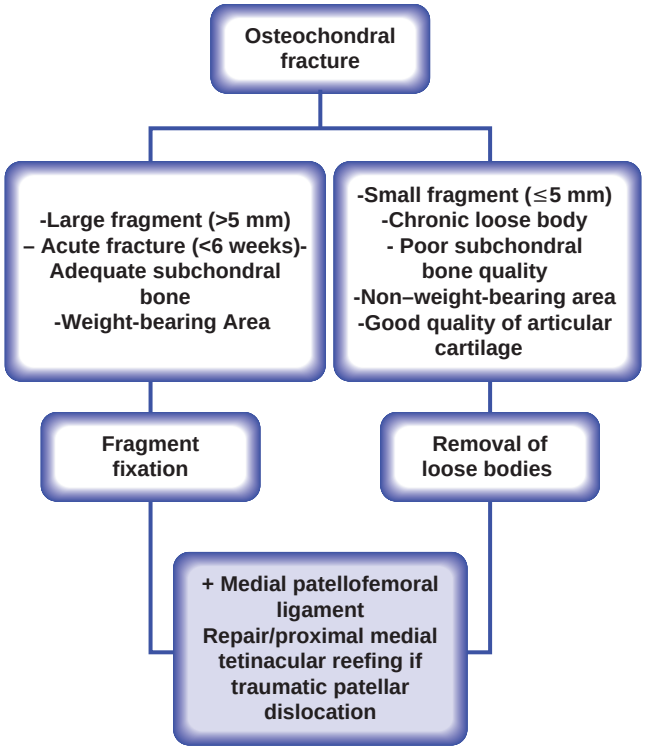

FIGURE 30-16 Algorithm for the management of osteochondral fracture in children.

12 weeks after dislocation depending on their progress with rehabilitation, with use of the lateral-stabilizing brace during sports recommended for those who feel it helps limit pain or apprehension.

Patients with small (≤5 mm) osteochondral fractures or chondral shear fragments, chronic loose bodies, and fractures involving non–weight-bearing areas are treated with arthroscopic removal of loose bodies. Occasionally, a patient may be seen more than 4 weeks following the initial injury with radiologic evidence of a small loose body but no symptoms; in such instances, arthroscopy may be deferred unless the patient develops any mechanical symptoms. If arthroscopy is pursued for a small osteochondral fracture, the fragment's crater is debrided to stable edges to prevent further loose bodies and the underlying subchondral bone should be perforated with marrow stimulation techniques, such as microfracture, to encourage fibrocartilage formation. Lateral retinacular release with medial retinacular/patellofemoral ligament repair is performed adjunctively in cases of traumatic patellofemoral dislocation to decrease the risk of recurrent patellofemoral instability.

Repair may be performed with one or two suture anchors on either the patellar or femoral insertion sites if the site of the tear is clearly appreciated on MRI or intraoperatively. Alternatively, imbrication, a pants-over-vest advancement, or removal of a small elliptical segment of retinacular tissue followed by side-to-side repair are all effective options for an intrasubstance MPFL tear or diffuse attenuation of the retinacular tissue.

Patients with large (>5 mm) osteochondral fractures, and chondral fragments which involve weight-bearing areas in good condition in skeletally immature patients, are treated with fragment fixation. At times, the fragments can be very large, involving nearly the entire weight-bearing surface of the medial patellar facet (Fig. 30-17) or LFC (Fig. 30-18). Medial patellar facet osteochondral fractures can be fixed through an open lateral retinacular release by manually tilting the patella (Fig. 30-17) or a medial parapatellar arthrotomy, which allows for tensioning of the medial retinacular repair during closure. LFC osteochondral fractures typically require a lateral parapatellar arthrotomy for fragment fixation (Fig. 30-18). Z-knee retractors are helpful for exposure and the knee is flexed or extended to optimize visualization of the fracture bed. The osteochondral fracture fragment and the fracture bed are debrided of fibrous tissue to healthy bone. The fragment is replaced anatomically.

Countersunk cannulated screws (3, 3.5, or 4.5 mm) or Herbert screws are often preferable for fixation, compared to bioabsorbable tacks, because of the strength of fixation which allows for fragment compression and early mobilization. Because chondral-only fragments will have no subchondral bone upon which to compress metal screws, bioabsorbable tacks are favored. Lateral retinacular release with medial retinacular/patellofemoral ligament repair is often performed adjunctively in cases of traumatic patellofemoral dislocation to decrease the risk of recurrent patellofemoral instability.

Postoperative Care for Osteochondral Fractures

Postoperatively, patients treated by excision of the fragment can begin ROM exercises immediately. Crutches may be necessary in the immediate postoperative period but patients can progress to weight bearing as tolerated.

After osteochondral or chondral fragment fixation, patients are treated with touch-down weight bearing in a postoperative brace until fracture healing. ROM when not weight bearing is

allowed from 0 to 30 degrees for the first 2 weeks, followed by 0 to 90 degrees until fracture healing. The fracture is typically healed between 6 and 12 weeks postoperatively, and confirmation with follow-up MRI may be utilized. If metal screw fixation was utilized, arthroscopy is performed to confirm fragment healing, remove hardware, and assess the integrity of the articular surface. Return to athletic activities is permitted when full ROM is recovered and strength is symmetric.

Potential Pitfalls and Preventative Measures of Osteochondral Fractures

An important pitfall to avoid is the failure to diagnose osteochondral fractures associated with acute, traumatic patellar dislocations. Radiographs should be scrutinized for small osseous fragments, and MRI should be obtained in cases despite negative radiographs with a clinical suspicion for possible osteochondral fracture.

In cases of arthroscopic removal of loose bodies associated with acute, traumatic patellar dislocation, consideration should be given to repair of the medial structures (medial retinaculum and MPFL) to decrease the risk of recurrent patellar instability, but with care taken not to overtension the medial tissues, so as not to excessively increase patellofemoral contact forces.[384]

In cases of osteochondral fracture fixation, adequate internal fixation must be obtained to allow for early motion. Screw heads must be countersunk or headless, variable pitch screws may be used to avoid scuffing of articular surfaces. When chondral-only fixation is pursued with bioabsorbable tacks, care must be taken to partially countersink the smooth heads below the articular surface without fissuring through the cartilage completely. Moreover, close postoperative clinical monitoring of crepitus, swelling, or new pain must be maintained, with consideration of serial MR imaging if necessary, because of risk of potential back out of the implants not seen on radiographs. In children or adolescents with growth remaining, care must also be taken to prevent crossing the distal femoral physis with hardware (Table 30-11).

Treatment-Specific Outcomes of Osteochondral Fractures

Osteochondral fractures with small fragments not involving the weight-bearing portion of the joint usually has a good prognosis after removal of loose bodies. The prognosis for larger osteochondral fractures involving the weight-bearing surfaces is more variable.[138,345] Excision of large fragments involving the weight-bearing articular surfaces predictably leads to the development of degenerative changes.[20] Fracture fixation resulting in fragment healing with a congruous articular surface offers the best long-term prognosis; however even these cases may develop crepitus, stiffness, and degenerative changes.[10] Recently reported results of chondral-only fragment fixation have been favorable, but only small series or case reports with short-term follow-up have emerged.[291,388]

Management of Expected Adverse Outcomes and Unexpected Complications in Osteochondral Fractures

Among the most common and concerning complications after both excision of loose bodies and fracture fixation is recurrent patellar instability with the possibility of further osteochondral injury. Although studies have suggested that concomitant MPFL repair decreases the risk of recurrent instability,[38,334] this concept remains controversial.[70,78,298,299,314] Stiffness is also a common complication following patellofemoral dislocation, particularly after fracture fixation. Adequate internal fixation is necessary to allow for early motion, which decreases the risk of arthrofibrosis. Stiffness may be treated with aggressive therapy and dynamic splinting during the first 3 to 4 months after injury. Beyond this time frame, arthroscopic lysis of adhesions and manipulation under anesthesia is typically required, with care taken to avoid distal femoral physeal injury through excessive manipulation in skeletally immature patients. Nonunion after fragment fixation may also occur, necessitating further attempts at fracture

TABLE 30-11 Osteochondral Fractures

Potential Pitfalls and Preventions

Pitfall	Preventions
Pitfall no. 1: Further fragmentation of fracture fragment	Prevention 1a: Extend portal incisions adequately for removal Prevention 1b: Arthroscopically position fragment in gutter/anterior recess near arthrotomy site; retrieve only after full arthrotomy
Pitfall no. 2: Fragment does not fit in bed	Prevention 2a: Plan surgery for <7 days postinjury to prevent swelling of fragment Prevention 2b: Trim fragment cartilage to fit bed
Pitfall no. 3: Inadequate fixation	Prevention 3: Achieve at least two points of fixation for rotational stability
Pitfall no. 4: Growth disruption	Prevention 4: In skeletally immature patients, implants should be short enough to avoid physeal trauma during fixation

TABLE 30-12 Osteochondral Fractures

Common Adverse Outcomes and Complications
Arthrofibrosis
Loss of fixation/nonunion
Osteoarthritis/focal chondral degeneration

fixation or fracture excision. Excision of larger osteochondral fractures involving the weight-bearing articular surfaces requires associated chondral resurfacing, such as marrow stimulation procedures (microfracture), osteochondral grafting (mosaicplasty), or autologous chondrocyte implantation,[44,48,321,372] all of which may be more technically challenging, with somewhat less optimal outcomes, when performed for the patellofemoral joint, compared with the tibiofemoral articular surfaces.[121,139,165,258,382] Complications related to hardware for fracture fixation may also occur. Proud screw heads may scuff articular surfaces. Prior to reabsorption, bioabsorbable implants may also scuff the cartilage, and over time may be associated with reactive synovitis, sterile effusions, or fragmentation (Table 30-12).

Introduction to Patellar Dislocation

Compared with other dislocation and subluxation injuries that occur in children, patellar instability is relatively common. Patellar instability involves cases ranging from acute, traumatic patellar dislocation to chronic, recurrent patellar subluxation in a patient with ligamentous laxity.

Acute, traumatic patellar dislocation occurs more commonly in adolescents than other age groups, with the peak age being 15 to 19 years old.[404] Acute patellar dislocations in younger children usually occur in the context of underlying patellofemoral dysplasia.[273] Chronic, atraumatic, recurrent patellofemoral instability occurs most frequently in adolescent females, often with underlying laxity and risk factors related to abnormal coronal and rotational lower extremity alignment, such as genu valgum, femoral anteversion, and external tibial torsion. Despite this subpopulation, in terms of the overall epidemiology of patellar dislocation, sex has recently been shown *not* to be a risk factor.[404] Approximately half of all dislocations occur during athletic activity, with basketball, soccer, and football as the most common sports involved.[404]

Acute, traumatic patellar dislocations without associated osteochondral fracture are primarily treated with a short period of immobilization followed by patellofemoral bracing and rehabilitation. Acute, traumatic patellar dislocations with osteochondral fractures are treated as discussed in the previous section, with removal of loose bodies or fracture fixation. Chronic, recurrent, atraumatic patellofemoral instability is typically treated with patellofemoral bracing, rehabilitation, and orthotics if needed. Recurrent patellofemoral instability which has been recalcitrant to nonoperative treatment can be managed with a variety of proximal and distal realignment procedures.

Assessment of Patellar Dislocation

Mechanisms of Injury for Patellar Dislocation

Patellar dislocations usually occur because of a flexion-rotation injury of the knee in which an internal rotation force is placed on a fixed foot, usually coupled with a strong quadriceps contraction. As the patella dislocates, the medial retinaculum and MPFL tear but the remaining quadriceps muscle–patellar ligament complex still applies significant compressive forces as the patella dislocates laterally and slides across the LFC. This primary injury mechanism, or the subsequent reduction of the patella medially back over the lateral edge of the lateral condyle, may result in associated osteochondral fracture. Recent MRI evidence suggests a predictable constellation of findings in conjunction with patellar dislocation: MPFL injury either at the femoral attachment site, patellar site, or both; VMO edema in most patients; and osteochondral fracture in about one-third of patients, most of which shear off of the medial patellar facet, but more rarely may be from the LFC.[346] Reduction of the patella may occur spontaneously as the patient simply extends the knee after a fall or may require forced manual reduction, often with the need for sedation to allow for quadriceps muscle relaxation.

Less commonly, patellar dislocation can be caused by a direct blow to the medial aspect of the patella. Larsen and Lauridsen[233] found that a direct blow accounted for only 10% of the acute patellar dislocations in one series. Patellar dislocations are more likely to be caused by falls, or during the course of gymnastics, dancing, cheerleading, cutting, and pivoting sports. Along with cruciate or collateral ligament tear and meniscal injury, acute patellar dislocation should be considered in the evaluation of all knee injuries in adolescents and young adults.

Associated Injuries with Patellar Dislocation

Common injuries associated with patellar dislocation include MPFL tear and bone bruises, impaction injuries, or osteochondral fractures to the lateral aspect of the LFC and medial facet or median ridge of the patella.

Signs and Symptoms of Patellar Dislocation

Patients with an acute, traumatic patellar dislocation often give a history of a twisting injury. Patients may remember feeling or seeing the patella in a laterally displaced position. Most acute patellar dislocations spontaneously reduce or reduce with incidental knee extension. It is more unusual to see a patient with a patellar dislocation which is unreduced (Fig. 30-19). Patients may report a "pop" associated with dislocation and a second "pop" associated with spontaneous reduction.

Symptoms include diffuse parapatellar tenderness and pain with any attempt passively to displace the patella. Patients may have a positive lateral apprehension test with lateral translation of the patella. A defect may be palpable in the medial attachment of the VMO to the patella if the medial retinaculum is completely avulsed. Although often difficult to differentiate from diffuse tenderness throughout a swollen knee joint, the

FIGURE 30-19 Acute dislocation of the left patella in a 6-year-old boy.

sites of greatest focal tenderness usually include the medial aspect of the patella (either from a chondral or bony contusion), the medial epicondyle (due to tearing of the femoral attachment of the MPFL), and lateral aspect of the LFC just proximal to the joint line (due to bony contusion). Hemorrhage into the joint may cause hemarthrosis, and severe hemarthrosis should suggest the possibility of an osteochondral fracture.[334] Nietosvaara et al.[297] reported that of 72 patients with acute patellar dislocations, 28 (39%) had associated osteochondral fractures. These fractures included 15 capsular avulsions of the medial patellar margin and 15 loose intra-articular fragments detached from the patella, the LFC, or both. All knee ligaments should be carefully evaluated because the mechanism of patellar dislocation may cause associated ligamentous injuries, such as ACL or MCL tear.

Imaging and Other Diagnostic Studies for Patellar Dislocation

Radiographs after acute dislocation are obtained primarily to detect any associated osteochondral fracture. Occasionally, an osteochondral fragment from the medial aspect of the patella or the LFC is visible on the anteroposterior or lateral view. A "patellar," "skyline," or "sunrise" view is difficult to obtain in a child after acute dislocation because the required flexed positioning of the knee causes pain, but should be attempted if possible. In a recent report, the "sliver sign," an intra-articular linear or curvilinear ossific density representing an osteochondral fragment, was seen on 19% of 219 cases of patellar dislocation, eight of which were visible on a patellar view only.[155] Rarely, stress radiographs may be obtained for evaluation of suspected physeal fracture or ligamentous injury. In the setting of an acute patellar dislocation or recurrent dislocation with severe knee swelling, MRI has emerged as the gold standard of radiologic evaluation, because of its ability to detect the constellation of injuries associated with patellar dislocations, such as chondral shear injuries, cruciate or collateral ligament tears, and severe disruption of the medial retinaculum and MPFL. Moreover, the three-dimensional axial imaging of MRI allows for optimal assessment and quantification of the severity of potential risk factors for recurrence, such as patellar dysplasia (e.g., Wiberg classification),[293] trochlear dysplasia (e.g., Dejour classification),[26,95,322,386] patella alta (e.g., Salvatti–Insall ratio or Blackburne–Peel ratio),[181,182] lateral patellar displacement (e.g., congruence angle),[277] patellar tilt (e.g., lateral patellofemoral angle),[235] and femorotibial alignment at the level of the knee joint (e.g., tibial tubercle-trochlear groove distance [TT-TG]).[34,35,144] In patients assessed to have significant femoral anteversion or abnormal tibial torsion, use of newer MRI-sequencing protocols which additionally incorporate several slices of both the femoral neck and distal tibia in the scout views may be helpful for a formal version analysis to understand if an abnormal femoral and/or tibial rotational profile represents a contributing etiologic factor in the dislocation that may benefit from specific surgical procedures, such as derotational osteotomy.

Classification of Patellar Dislocation

Although there is no specific classification of patellar dislocations in children, acute dislocation should be distinguished clinically from chronic patellar subluxation or dislocation[63,104,127,140] and from congenital patellar dislocation, which is generally not a cause of intra-articular fractures. Whereas acute patellar dislocation is more commonly associated with trauma or severe twisting injuries of the knee, chronic patellar subluxation is associated with lower energy mechanisms, is more common in children with ligamentous laxity or hypermobility syndromes, and has a lower frequency of significant intra-articular knee injuries. Although medial patellar dislocation or subluxation is exceedingly rare, it has been described in association with a medially directed direct blow or following overzealous lateral release.[175]

Outcome Measures for Patellar Dislocation

The rate or occurrence of redislocation after operative or nonoperative treatment of patellar dislocation is the most basic assessment of treatment success. However, standard outcome measures, such as functional knee metrics (the Pedi-IKDC[225] and Lysholm[364] knee scores), should also be used to assess the results and, paired with the Marx or Tegner activity scores,[264] ascertain a patient's ability to make a full return to activities of daily life and sports activities.

Pathoanatomy and Applied Anatomy Relating to Patellar Dislocations

The patella is a sesamoid bone in the quadriceps mechanism. As the insertion site of all muscle components of the quadriceps complex, it serves biomechanically to provide an extension moment during ROM of the knee joint. The trochlear shape of the distal femur stabilizes the patella as it tracks through a ROM. The hyaline cartilage of the patella is the thickest in the body.

At 20 degrees of knee flexion, the inferior pole of the patella contacts a relatively small area of the femoral groove. With further flexion, the contact area moves superiorly and increases in

size. The medial facet of the patella comes in contact with the femoral groove only when flexion reaches 90 to 130 degrees.

The average adult trochlear femoral groove height is 5.2 mm and LFC height is 3.4 mm. The patellar articular cartilage is 6 to 7 mm in its thickest region, the thickest articular cartilage in the body, and is a reflection of the joint's inherent incongruity. The normal lateral alignment of the patella is checked by the medial quadriceps expansion and focal thickening of the capsule in the areas of the MPFL and medial meniscopatellar ligament.[99] Dynamic stability depends on muscle forces, primarily the quadriceps and hamstrings acting through an elegant lower extremity articulated lever system that creates and modulates forces during gait. The quadriceps blends with the joint capsule to provide a combination of dynamic and static balance. Tightness or laxity of any of the factors involved with maintenance of the balance leads to varying levels of instability. Sallay et al.[340] demonstrated avulsions of the MPFL from the femur in 94% (15 of 16) of patients during surgical exploration after acute patellar dislocation. Desio et al.[99] using a cadaveric serial cutting model, found that the MPFL provided 60% of the resistance to lateral patellar translation at 20 degrees of knee flexion. The medial patellomeniscal ligament accounted for an additional 13% of the medial quadrant restraining force. If the deficit produced by attenuation of the medial vectors after acute dislocation is not eliminated, patellofemoral balance is lost, resulting in feelings of giving way and recurrent dislocation.

The patella is under significant biomechanical compressive load during activity. It has been estimated that at 60 degrees of knee flexion, the forces across the patellofemoral articulation are three times the body weight and increase to over seven times the body weight during full knee flexion.

The quadriceps mechanism is aligned in a slightly valgus position in relation to the patellar tendon. This alignment can be approximated by a line drawn from the anterosuperior iliac spine to the center of the patella. The force of the patellar tendon is indicated by a line drawn from the center of the patella to the tibial tubercle. The angle formed by these two lines is called the *quadriceps angle* or *Q angle* (Fig. 30-20). As this angle increases, the pull of the extensor mechanism tends to sublux the patella laterally. Recurrent patellar dislocation is most likely associated with some congenital or developmental deficiency of the extensor mechanism, such as patellofemoral dysplasia, deficiency of the VMO, or an increased Q angle with malalignment of the quadriceps–patellar tendon complex. However, although the Q angle can be difficult to measure clinically, the increasing use of MRI in patients with patellar dislocation has generated heightened interest in, and application of, the TT-TG distance, which many consider an imaging equivalent of the Q angle. When significantly elevated above the normal value of approximately 13 mm – a common threshold for "abnormal" is 20 mm – the TT-TG has been shown to be a risk factor for both primary and recurrent patellar dislocation in adults, adolescents, and children. Interestingly, despite the different technical approach to patellar instability, different authors have used it as an indication for MPFL reconstruction or tibial tubercle osteotomy (TTO).[6,373]

Treatment Options for Patellar Dislocation

Nonoperative Treatment of Patellar Dislocation

Indications/Contraindications

Most acute patellar dislocations in children reduce spontaneously; if they do not, reduction usually can be easily performed. Surgery is usually not indicated for primary acute patellar dislocations in children.[38,81,233] Most patellar dislocations are treated nonoperatively with immobilization in extension, followed by patellofemoral bracing and rehabilitation focused on regaining normal ROM and strengthening of the quadriceps, particularly the VMO (Table 30-13).

Techniques

After appropriate sedation, reduction is achieved by flexing the hip to relax the quadriceps muscle, gradually extending the knee, and gently pushing the patella medially back into its normal position. Gentle reduction should be emphasized to avoid the risk of osteochondral fracture associated with patellar relocation.

TABLE 30-13 Patellar Dislocations

Nonoperative Treatment

Indications	Relative Contraindications
Primary patellar dislocation	Osteochondral fracture/loose body >5 mm seen on XR/MRI
Repeat patellar dislocation with few/no risk factors for recurrence	Recurrent patellar dislocation with underlying/anatomic risk factors for recurrence

Outcomes

The prognosis of patellar dislocations in children, when not associated with osteochondral injury, is generally good. Patients with a younger age at first dislocation are at higher risk for recurrent instability. Cash and Hughston[73] noted 75% satisfactory results after nonoperative treatment in carefully selected patients.

Recurrent patellar dislocations with associated osteochondral injuries can lead to osteoarthritis of the patellofemoral joint. Given that some studies cite rates of chondral injury, which may include not only frank displacement of chondral fragments, but also fissuring, fraying, and impaction injuries, as high as 95%,[302] longer-term studies are needed to better assess functional outcomes in patients who have dislocated.

Operative Treatment of Patellar Dislocation

Indications/Contraindications

Surgical repair may be considered if the VMO and/or MPFL is completely avulsed from the medial aspect of the patella, leaving a large, palpable soft tissue gap and severely lateralized patella. If osteochondral fracture has occurred, arthroscopy/arthrotomy is indicated for removal or repair of an osteochondral loose body, as discussed in the previous section. The importance of performing a concurrent MPFL "repair" is controversial, but an MPFL tightening procedure, sometimes referred to as a "reefing," "imbrication," or "medial retinaculum plasty" procedure, with or without a lateral retinacular "release," which generally involves a longitudinal division of the tissue over the length of the patella, or lateral retinacular lengthening procedure, is still favored by many authors.[70,78,252,298,299,314]

Recurrent instability of the patella which has been recalcitrant to nonoperative treatment is typically managed through one of various proximal and/or distal patellofemoral realignment procedures. Proximal realignment options include isolated or combination procedures including lateral retinacular release or lateral retinacular z-lengthening[74] medial retinacular plication, reefing, or MPFL reconstruction using semitendinosus autograft or, more commonly, allograft.[6,40,53,65,66,77,87,93,105,275,301,333,373]

Surgical Procedure

Preoperative Planning (Table 30-14)

TABLE 30-14 Patellar Dislocation

Preoperative Planning Checklist

- **Position/positioning aids:** Supine
- **Fluoroscopy location:** Nonoperative side, perpendicular to table
- **Equipment:** (If osteochondral fragment fixation planned), small K-wires, bioabsorbable pins/tacks/screws, headless compression screws
- **Tourniquet (sterile/nonsterile):** Nonsterile

Positioning

Arthroscopy is generally pursued prior to any open treatment related to patellar dislocation, so a standard arthroscopy setup should be utilized. However, for both arthroscopic and open techniques, most of the surgery is performed with the knee in full extension. If osteochondral fragment fixation is planned, a bump for both the knee and ankle are helpful to elevate the entire leg and facilitate true lateral XRs, if necessary.

Surgical Approach and Technique

The most common distal realignment approach in skeletally mature patients is the TTO, which may involve straight medialization of the tubercle (the Elmslie–Trillat procedure),[386] straight anteriorization (the Maquet procedure),[261] or a combination anteromedialization (an "AMZ," or the Fulkerson osteotomy).[130] However, these are contraindicated in patients with an open tibial tubercle apophysis because of the risk of a growth arrest, which can result in recurvatum deformity. In cases of significant patella alta, some authors have additionally proposed distalization of the tibial tubercle, with and without patellar tendon tenodesis, designed to shorten the tendon.[96,268] In skeletally immature patients, Galeazzi semitendinosus tenodesis[30,146] or the Roux–Goldthwait reconstruction[262,295] are distal realignment soft tissue procedures that have been traditionally utilized, though more recent studies have suggested that outcomes of these procedures may be less favorable than historically reported.[30,146,295] These perspectives have further stimulated interest in MPFL reconstruction techniques in skeletally immature children. However, there remains controversy about the appropriate technique and location of fixation of the graft on the femoral side, in part because of conflicting data on the true anatomic MPFL attachment relative to the distal femoral physis.[203,351] Literature detailing significant complications associated with MPFL reconstruction have emerged,[275,295,383,384] including inaccurate or inappropriate femoral fixation, making this an evolving topic with imprecise indications (Table 30-15).[31]

TABLE 30-15 Patellar Dislocation

Operative Treatment

Surgical Steps

- (If any questionable findings on MRI) perform diagnostic arthroscopy to assess status of patellar and lateral condylar cartilage, assess patellofemoral alignment/tracking, rule out presence of any intra-articular loose bodies, consider performing arthroscopic lateral release, if indicated by lateral patellar tilt or severe patellar lateralization
- Distal patellar realignment (TTO), if skeletally mature and indicated by elevated TT-TG
- Proximal patellar realignment (proximal medial reefing) versus MPFL reconstruction

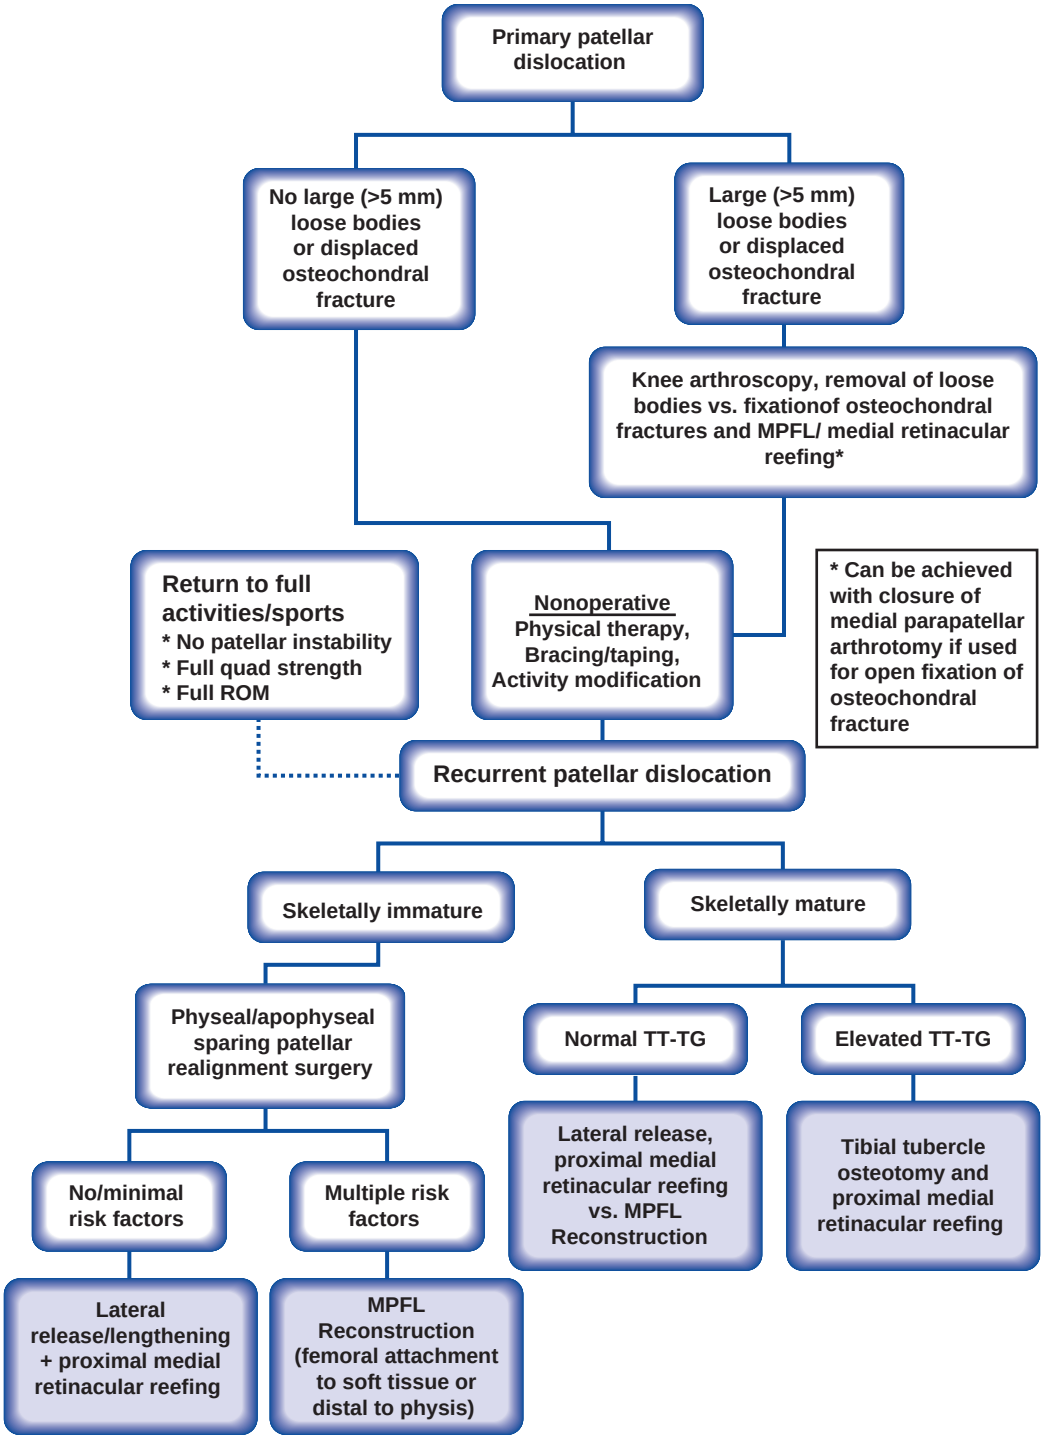

FIGURE 30-21 Algorithm for the management of patellar dislocations in children and adolescents.

Author's Preferred Treatment of Patellar Dislocation

The author's algorithm to decision making is shown in Figure 30-21.

Most acute patellar dislocations in children without osteochondral fracture are treated by closed methods with satisfactory results. A knee immobilizer is generally used for approximately 2 weeks. Patients are allowed full weight bearing as tolerated. After immobilization, the patient is placed in a patellofemoral brace with a lateral bolster. Physical therapy is begun, emphasizing straight leg raises, progressive resistance exercises, patellar mobilization, and vastus medialis strengthening. Patients are allowed to return to sports 6 to 12 weeks

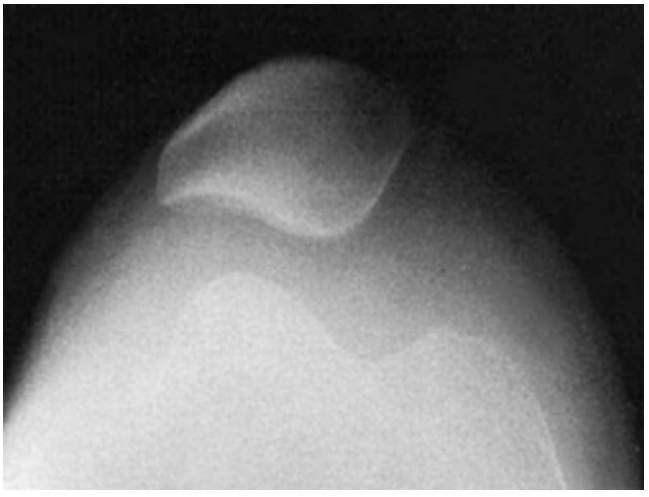

FIGURE 30-22 Chronic lateral patellar subluxation in a 13-year-old girl.

after injury, depending on their patellofemoral mechanics and progress with rehabilitation.

Acute surgical intervention is indicated most commonly for an associated osteochondral fracture. Removal of loose bodies for fragments ≤5 mm or fracture fixation for larger fragments is performed. Adjunctive medial retinacular/MPFL reefing, either through excision of an elliptical segment (usually 1 cm wide, 2 cm long) of attenuated medial parapatellar retinacular tissue, or through a pants-over-vest advancement, is usually also performed to reduce the risk of recurrent patellar instability, with or without lateral retinacular release or lengthening, depending on the tightness of the lateral patellar restraints.

Chronic patellar subluxation or dislocation is most common in adolescents, especially females. Several risk factors have been identified in children likely to have chronic subluxation or dislocation, including age younger than 16 years, abnormal Q angle, significant genu valgum, radiographic evidence of dysplasia of the patella or trochlea, LFC hypoplasia, femoral anteversion or external tibial torsion, significant atrophy of the VMO, connective tissue disorders predisposing to hypermobility of the patella (e.g., Ehlers–Danlos syndrome), elevated TT-TG distance, and multiple previous dislocations (Fig. 30-22).[17,57] Initial treatment of chronic patellar subluxation or dislocation in adolescents is immobilization followed by aggressive physical therapy for rehabilitation of the VMO and quadriceps muscles. Surgical intervention is warranted in children who do not respond to this treatment regimen and continue to have subluxation or dislocation.[50,164,234,254] For the rare patient with minimal risk factors for recurrence or only minor, but recurrent symptomatic subluxation episodes, an isolated proximal soft tissue realignment procedure, consisting of medial retinaculum/MPFL reefing with lateral retinacular release or lengthening, may be considered (Fig. 30-23A).

If subluxation or dislocation persists despite this less invasive approach, or in patients with recurrent instability and multiple underlying risk factors, a more significant proximal realignment procedure or more complex combinations of proximal and distal realignment procedures are indicated. MPFL reconstruction

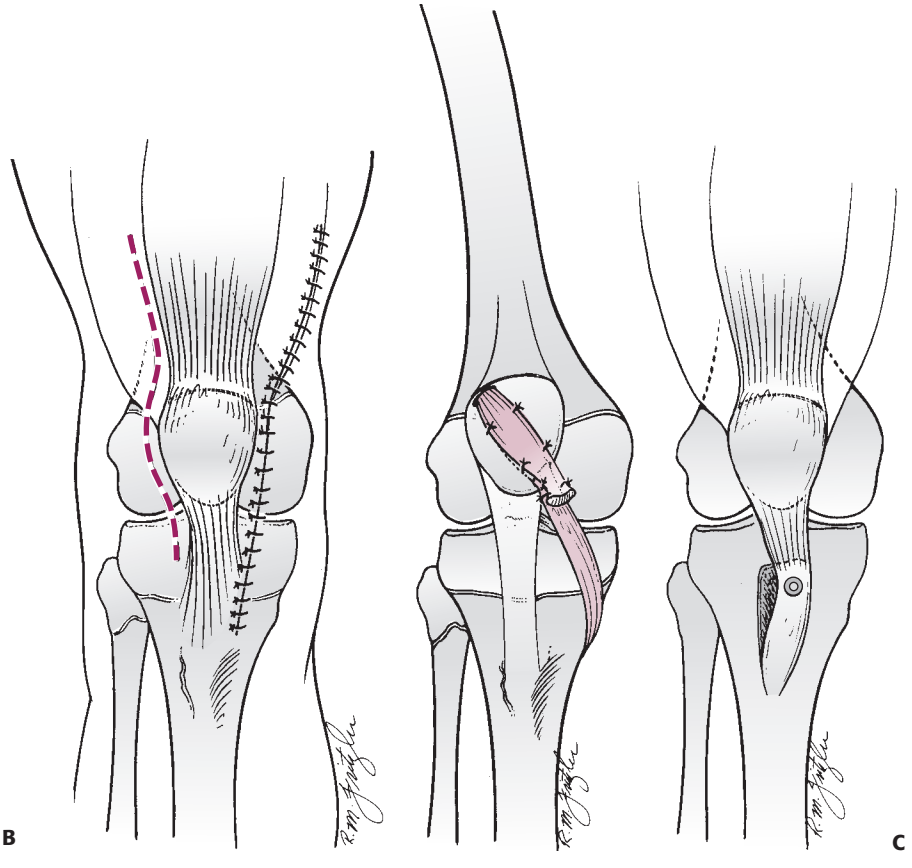

FIGURE 30-23 Surgical technique for treatment of chronic patellar subluxation or dislocation. **A:** Lateral retinacular release and medial imbrication. **B:** Semitendinosus tenodesis. **C:** Elmslie–Trillat procedure.

allows for reconstitution of a robust medial patellar checkrein[40,65,93] and is indicated in patients with attenuation of medial retinacular tissues. Semitendinosus allograft is generally used, with either suture fixation of an appropriately tensioned graft to the femoral and patellar periosteum in younger children, or suture anchor fixation in adolescents, utilizing intraoperative fluoroscopy to place the femoral anchor just distal to the distal femoral physis. Small (≤5 mm), short (≤20 mm), transverse bone tunnels may also be drilled under fluoroscopic guidance at the patellar and femoral MPFL attachment sites, using small biocomposite interference screws for graft fixation.

In skeletally *mature* patients with a significantly abnormal Q angle or TT-TG distance over 20 mm, TTO in conjunction with proximal realignment procedures is preferred. Tubercle medialization with the Elmslie–Trillat procedure (Fig. 30-23C) is effective in improving patellofemoral kinematics in the coronal plane, though a Fulkerson osteotomy incorporating anteriorization of the patella is preferred in cases with pre-existing patellar chondrosis or significant osteochondral injury which has undergone fixation or microfracture. Combined TTO/MPFL reconstruction procedures may give the greatest reduction in risk of redislocation, but represents a maximally invasive approach with significant operative times, increasing risk of stiffness and other complications. More research is needed to justify the benefits of MPFL reconstruction over simpler medial retinacular tightening procedures in conjunction with TTO.

Postoperative Care for Patellar Dislocation

After patellar realignment procedures, patients are treated with touch-down weight bearing in a postoperative brace for 2 weeks. ROM when not weight bearing is limited to 0 to 30 degrees for the first 2 weeks. Patients may begin weight bearing as tolerated after 2 weeks, but only with the hinged knee brace locked in extension. When not ambulating, ROM is advanced to 0 to 60 from post-op weeks 2 to 4 and from 0 to 90 from post-op weeks 4 to 6. At 6 weeks, the brace is unlocked when ambulating and discontinued by week 8, with weight-bearing strengthening exercises initiated. Straight ahead running is allowed around 3 months post-op, with advancement to agility and sport-specific exercises as indicated. Return to athletic activities is permitted when full ROM is recovered, strength is symmetric, and the knee feels stable with agility exercises.

Potential Pitfalls and Preventative Measures of Patellar Dislocation

Unrecognized associated osteochondral fractures may present later as loose bodies. Unrecognized associated ligamentous injury can present later as knee instability. Aggressive nonoperative treatment should be pursued for cases of patellofemoral instability before considering surgical management, and MRI should be obtained for all patellar dislocation patients, particularly primary episodes, to evaluate for associated injuries and underlying anatomic risk factors, such as patellofemoral dysplasia. Overzealous and injudicious use of lateral retinacular release may result in iatrogenic medial patellar instability. For MPFL reconstruction procedures, while there are conflicting reports about the appropriate degrees of knee flexion at which MPFL tensioning and fixation should be pursued, ranging from 30 to 90 degrees,[6,7,16,41,66,77,87,244,275,294,333,373,422] graft isometry and assessment of tension through a wide ROM is indicated to avoid increasing patellar contact forces.[41,275] Fluoroscopy is indicated if short patellar and/or femoral bone tunnels are drilled for graft placement, with bioabsorbable or biocomposite interference screw fixation. We recommend against long tunnels (>20 mm), large diameter tunnels (>5 mm), oblique tunnels, complete transpatellar tunnels, or multiple tunnels, to avoid subsequent patellar fracture in this young, active, athletic patient population.

Treatment-Specific Outcomes for Patellar Dislocation

A variety of surgical approaches are associated with relatively low rates of redislocation and good short-term knee scores in both adults and children.[6,31,70,310,422] However, one recent study suggests that longer-term knee scores and satisfaction in children may be slightly lower than presumed from the low redislocation rates.[251]

Management of Expected Adverse Outcomes and Unexpected Complication in Patellar Dislocation

Complications may occur after surgery for patellar instability. Lateral release alone without medial retinaculum/MPFL repair may not adequately prevent recurrent dislocation. Stiffness, with lack of knee flexion, may occur after MPFL reconstruction or Galeazzi tenodesis, if the graft is overly tensioned. After TTO, nonunion, hardware failure, neurovascular injury, and compartment syndrome have been reported (Table 30-16).

Introduction to Meniscal Injuries

Meniscal injuries in the pediatric athlete are being seen with increased frequency.[1,2,22,52,68,80,125,159,195,208,213,218,260,274,284,287,303,339,390,398,417,420] Meniscal disorders include meniscal tears, discoid meniscus, and meniscal cysts. The exact incidence of meniscal injuries in children and adolescents is unknown, but is known to increase with age within this subpopulation.[92] With adolescence, increased size and speed, and increased athletic demands, come higher energy injuries and an increase of intra-articular lesions. Meniscal injuries under the age of 10 are rare, unless associated with a discoid meniscus.[5,12,14,43,86,101,102,123,129,157,162,179,191,192,193,199,211,220,292,296,307,316,320,326,336,344,363,374,375,393,402,415]

TABLE 30-16 Patellar Dislocation

Common Adverse Outcomes and Complications
Arthrofibrosis
Patellar subluxation/instability
Patellar redislocation

Meniscal injury patterns differ in children compared to adults. It is estimated that longitudinal tears comprise 50% to 90% of meniscal tears in children and adolescents.[213] Bucket-handle displaced tears are not uncommon (Fig. 30-1). Also in these age groups, meniscal injuries are commonly associated with ACL injuries.[71,112,220,260] Cannon and Vittori [71] estimated that repairable meniscal tears occur in 30% of all knees with acute ACL rupture and in 30% of patients under 20 years old. However, a more recent series[341] of 124 ACL tears in skeletally immature patients demonstrated an incidence of associated meniscus tears of 69%. Overall, approximately two-thirds of repairable meniscal tears are associated with ACL rupture, with the majority of these tears involving the posterior horn.

Although there is limited data on the subject, one report suggests that the incidence of medial meniscal tears is greater than lateral meniscal tears in the adolescent age group.[370] The previously mentioned series[341] involving a high rate of meniscus repairs performed with ACL reconstruction (ACL-R) in children with open physes conversely showed a significantly higher rate of lateral meniscal tears compared with medial meniscus tears. There also appears to be a relatively increased incidence of lateral tears in the preadolescent age group, which may in part be because of the existence of lateral discoid menisci.[213]

Assessment of Meniscal Injuries

Mechanisms of Injury for Meniscal Injuries

Injury to the nondiscoid meniscus is virtually always traumatic in nature in children and adolescents. Multiple studies have shown that between 80% and 90% of meniscal injuries in children and adolescents are sustained during sports activities.[5,148,149,260,370] These numbers may be lower in the preadolescent age group. Meniscal tears most commonly occur with cutting, pivoting and twisting motions, such as those performed frequently during football, soccer, and basketball. The mechanism involves rotation of the condyles relative to the tibial plateau, as the flexed knee moves toward extension. This rotational force with the knee partially flexed causes the condyle to force the menisci toward the center of the joint, leading to injury.

Associated Injuries with Meniscal Injuries

Twisting mechanisms may also cause associated ligamentous injuries, and ACL injuries are commonly associated with both medial and lateral meniscal tears in adolescents. More chronically, meniscal injuries also may be associated with degenerative changes, cyst formation, or congenital anomalies.[125]

Signs and Symptoms of Meniscal Injuries

Pain and swelling are the most common chief complaints of a meniscal tear. Other complaints include mechanical symptoms such as snapping, popping, clicking, catching, or locking. A bucket-handle tear that is displaced into the intercondylar notch may present with a locked knee or a knee unable to fully extend.

The differential diagnosis of acute meniscal tear in the pediatric patient includes other conditions that may result in a traumatic effusion, such as a ligamentous injury, osteochondral fracture, chondral injury, or patellofemoral dislocation. In addition, conditions causing pain at or adjacent to the joint line must be distinguished from meniscal tears, such as plica syndrome, iliotibial friction band syndrome, OCD, and bone bruises.[213]

The diagnosis of meniscal tear in children and adolescents can be difficult to make. Because of the diversity of pathology and the difficulty of examination in children, diagnostic accuracy of clinical examination for meniscus tear has been shown to be as low as 29% to 59%.[213,214] An accurate history may be difficult to obtain in a very young child. The older the patient, the more likely a history of specific injury. Pain is reported by approximately 85% of patients, predominantly in the area of the affected joint line. More than half of patients report giving way and effusion of the knee joint.

The most common physical examination signs, similar to adults, are joint line tenderness, pain with hyperflexion and/or hyperextension, and effusion.[22,274] However, some patients may have minimal findings on physical examination. McMurray test may be helpful in the diagnosis of a subacute or chronic lesion, but with acute injury the knee may be too painful to allow these maneuvers.[88] In Vahvanen and Aalto's series of patients with documented meniscal tears,[390] almost one-third of the patients had no significant findings on physical examination. The classic McMurray test may be of little value in this age group whose tears are peripheral and not degenerative posterior horn lesions.[213] Two recent studies, by examiners with pediatric sports medicine experience have shown the diagnostic accuracy of clinical examination to be 86.3% and 93.5% overall.[214,369] When medial meniscus tears were looked at alone, the sensitivity and specificity of clinical examination were 62.1% and 80.7% respectively.[214] The sensitivity and specificity for lateral meniscal tears were 50% and 89.2% respectively.[214]

Imaging and Other Diagnostic Studies for Meniscal Injuries

Routine radiographs are obtained primarily to rule out a fracture, OCD lesion, or other bony sources of knee pain. Arthrography[84] has been described historically to help identify a meniscal tear, but has been used minimally since the advent of arthroscopy and MRI.[287,304]

MRI is the gold standard method for evaluating meniscal injuries in children. MRI accuracy rates reportedly range from 45% to 90% in the diagnosis of meniscal tears.[59,184,323,357] Sensitivity and specificity of 83% and 95% respectively has been shown in skeletally immature patients.[214,369] Kocher et al.[214] showed that for medial meniscal tears the sensitivity and specificity for MRI diagnosis were 79% and 92% respectively.[214] For lateral meniscal tears, these numbers were 67% and 83% respectively.

However, MRI should not be used indiscriminately as a screening procedure, because of significant limitations of the technique in this age group.[58,232,323,380] Only the specificity for medial meniscal tears was significantly higher with MRI as compared to clinical examination.[214] The sensitivity and specificity of MRI decrease in younger children compared to older adolescents.[214,369] In recent studies that compared the diagnostic accuracy of physical examination versus MRI, clinical examination rates were equivalent or superior to MRI.[214,369] These authors recommended judicious use of MRI in evaluating intra-articular knee disorders.

Normal MRI signal changes exist in the posterior horn of the medial and lateral meniscus in children and adolescents.[210,214,369,423] These signal changes do not extend to the superior or inferior articular surfaces of the meniscus and likely represent vascular developmental changes.[213] Takeda et al.[378] reviewed the MRI signal intensity and pattern in the menisci of 108 knees in 80 normal children 8 to 15 (average 12.2) years of age using the classification of Zobal et al.,[423] which allows for equivocation for type III signals. Using tibial tubercle maturity as a definition of skeletal maturity, Takeda et al.[378] found signal intensity to be proportional to age, with high signal (grades II and III) evident in 80% of patients 10 years of age or younger, 65% by 13 years of age, and 33% at 15 years of age, which is similar to the false-positive rate of 29% reported in asymptomatic adults.[137,232] Overall, two-thirds of the patients had positive findings (grades II or III), often grade IIIA, which is equivocal extension through the surface of the meniscus. Takeda et al.[378] suggested that the decrease in signal intensity was proportional to diminution of peripheral vascularity, especially in the posterior horn of the meniscus. These investigators cautioned against misinterpretation of pediatric knee MRIs and emphasized the necessity for correlation of the clinical findings with any imaging study results. When interpreting an MRI of the developing knee, care must be taken to identify a meniscal tear only when linear signal changes extend to the articular surface. As with any test, clinical correlation is mandatory before treatment decisions are made.

Classification of Meniscal Injuries

Classification is generally descriptive in nature, and is based on the meniscus involved (medial vs. lateral), the location of the tear (posterior horn, body/pars intermedia, anterior horn), the chronicity of the tear (acute [<6 weeks], chronic [>6 weeks]), and the tear pattern (vertical/longitudinal, bucket-handle, horizontal cleavage, transverse/radial, or complex) (Fig. 30-24). Other important factors include site of the tear (outer/peripheral ⅓, middle ⅓, inner/central ⅓), stability of the horns or overall meniscus, and associated ligamentous and chondral injuries.

Outcome Measures for Meniscal Injuries

Recurrence or failure to heal a meniscus tear following repair is the most significant predictor of treatment success. Symptoms from retear generally warrant revision repair or, if the recurrent tear is not repairable, partial meniscectomy. On a longer-term basis, standard outcome measures, such as functional knee metrics (the Pedi-IKDC[225] and Lysholm[364] knee scores), should be used to assess results and paired with the Marx or Tegner activity scores[264] to ascertain a patient's ability to make a full return to activities of daily life and sports activities, which are the dual goals of surgery.

Pathoanatomy and Applied Anatomy Relating to Meniscal Injuries

The menisci become clearly defined by as early as 8 weeks of embryologic development.[199] By week 14, they assume the normal mature anatomic relationships. At no point during their embryology are the menisci discoid in morphology.[199] Thus, the discoid meniscus represents an anatomic variant, not a vestigial remnant. The developmental vasculature of the menisci has been studied extensively by Clark and Ogden.[80] The blood

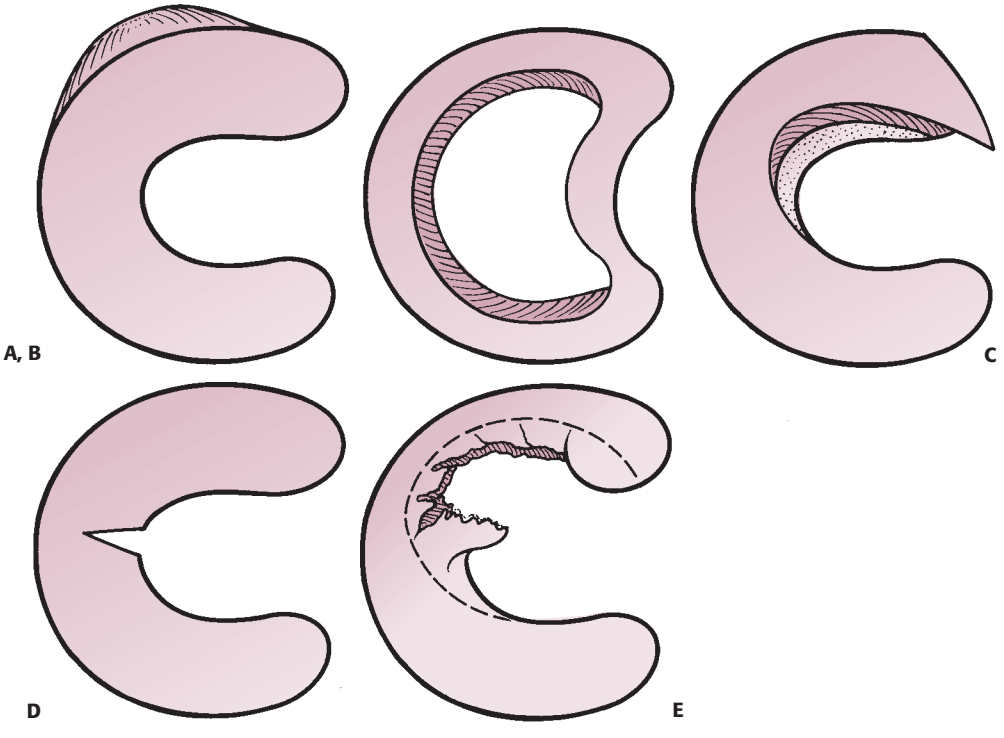

FIGURE 30-24 Meniscal tears in adolescents. **A:** Peripheral. **B:** Bucket handle. **C:** Horizontal cleavage. **D:** Transverse. **E:** Complex.

supply arises from the periphery and supplies the entire meniscus. This vascular pattern persists through birth. During postpartum development, the vasculature begins to recede and by as early as the ninth month, the central 1/3 is avascular. This decrease in vasculature continues until approximately age 10, when the menisci attain their adult vascular pattern. Injection dye studies by Arnoczky and Warren[27] have shown that only the peripheral 10% to 30% of the medial and 10% to 25% of the lateral meniscus receive vascular nourishment.Importantly, the anterior and posterior horns have improved vascularity, compared with the body, or pars intermedia, of both the medial and lateral meniscus.[27]

The medial meniscus is C shaped. The posterior horn is larger in anterior–posterior width than the anterior horn. The medial meniscus covers approximately 50% of the medial tibial plateau. The medial meniscus is attached firmly to the medial joint capsule through the meniscotibial or coronary ligaments. There is a discrete capsular thickening at the level of the meniscal body which constitutes the deep MCL. The inferior surface is flat and the superior surface concave so that the meniscus conforms to its respective tibial and femoral articulations. To maintain this conforming relationship, the medial meniscus translates 2.5 mm posteriorly on the tibia as the femoral condyle rolls backward during knee flexion.[148,149]

The lateral meniscus is more circular in shape and covers a larger portion, approximately 70%, of the lateral tibial plateau. The lateral meniscus is more loosely connected to the lateral joint capsule. There are no attachments in the area of the popliteal hiatus and the fibular collateral ligament does not attach to the lateral meniscus. Accessory meniscofemoral ligaments exist in up to ⅓ of cases. These arise from the posterior meniscus. If a discrete meniscofemoral ligament inserts anterior to the PCL it is known as the ligament of Humphrey, and if it inserts posterior to the PCL, the ligament of Wrisberg. Because of the lack of restraining forces, the lateral meniscus is able to translate four times as much as the medial meniscus, approximately 9 to 11 mm on the tibia with knee flexion. Both menisci are attached anteriorly via the anterior transverse meniscal ligament.[148,149]

The blood supply arises from the superior, inferior, medial, and lateral geniculate arteries. These vessels form a perimeniscal synovial plexus. There may be some contribution from the middle geniculate artery as well. King, in the 1930s, published classic research indicating that the peripheral meniscus did communicate with the vascular supply and therefore was capable of healing.[209] It is believed that the central two-thirds of the meniscus receives its nutrition through diffusion and mechanical pumping.

The menisci are composed primarily of type I collagen, accounting for 60% to 70% of its dry weight. Lesser amounts of types II, III, and VI collagen are also present. The collagen fibers are oriented primarily in a circumferential pattern, parallel with the long access of the meniscus.[148,149] There are also radial, oblique, and vertically oriented fibers in organized layers. Proteoglycans and glycoproteins are present, but in smaller concentrations than in articular cartilage. The menisci also contain neural elements including mechanoreceptors and type I and II sensory fibers. In a sensory mapping study, Dye et al.[107] demonstrated that the probing of the peripheral meniscus led to pain whereas stimulation of the central meniscus elicited little or no discomfort.

Our understanding of the functional importance of the meniscus has evolved. In 1897, Bland-Sutton[56] characterized the menisci as "functionless remnants of intra-articular leg muscles." The sentiment was largely embraced through the 1970s, when menisci were routinely excised. However, Fairbank, in 1948, published the first long-term follow-up study of patients after total meniscectomy.[118] His article demonstrated that degenerative changes followed meniscectomy in a substantial proportion of patients. Now, myriad investigations have established the deleterious consequences of total and even partial meniscectomy on the chronic health of the articular cartilage.[5,112,213,260,274,326,328,390,393,402,417] Nowhere are these principles more important than in children and adolescents, in whom the long-term effects of meniscectomy will be magnified by higher activity levels and simple longevity.

It is now realized that the menisci actually have a number of different functions. The menisci serve to increase contact area and congruency of the femoral tibial articulation. This allows the menisci to participate in load sharing and reduces the contact stresses across the knee joint. It is estimated that the menisci transmit up to 50% to 70% of the load in extension and 85% of the load in 90 degrees of flexion.[8] Baratz et al.[37] showed that after total meniscectomy articular contact areas at a point in time may decrease by 75% and contact stresses on the involved areas increase by 235%. They also documented the deleterious effects of partial meniscectomy, demonstrating that contact stresses increase in proportion to the amount of meniscus removed. Excision of small bucket-handle tears of the medial meniscus increased contact stress by 65%, and resection of 75% of the posterior horn increased contact stresses equivalent to that after total meniscectomy.[37] Repair of meniscal tears, by either arthroscopic or open techniques, reduced the contact stresses to normal. Multiple other studies have corroborated these findings, illustrating the mechanical importance of the meniscus.[148,149]

Meniscal tissue is about ½ as stiff as articular cartilage, allowing it to participate in shock absorption as well. Shock absorption capacity in the normal knee is 20% higher than in the meniscectomized knee.[241,274] The menisci also have a role in joint stability. In the ACL-deficient knee the posterior horn of the medial meniscus plays a very important passive stabilizing role. In the ACL-deficient knee, medial meniscectomy leads to a 58% increase in anterior translation at 90 degrees of flexion.[241,355] Given the presence of neural elements within their substance, it is also theorized that the menisci may have a role in proprioception.

Discoid Lateral Meniscus

Lateral meniscal tears may be seen in association with an underlying discoid lateral meniscus, particularly in younger children. The discoid lateral meniscus represents an anatomical variant of meniscal morphology. The incidence is thought to be 3% to 5% in the general population[102,192,193,213] and slightly higher in Asian populations.[102,192,193,213] Interestingly, OCD has been described associated with discoid lateral meniscus, both before and after saucerization.[51,94,160] Discoid morphology almost exclusively occurs within the lateral meniscus, but

medial discoid menisci have been described in various case reports.[102,192,193,213] Although the incidence of bilateral abnormality has been reported to be as high as 20%,[12,43,320,363] routine screening on the contralateral knee is not indicated as part of treatment of a discoid lateral meniscus, because of the high rates of asymptomatic cases not requiring intervention. A recent study[317] comparing cases of bilateral discoid menisci to those with unilateral discoid demonstrated that the bilateral cases required treatment at an average age 2 years younger than the unilateral cases, but that unilateral cases were more likely to have tearing than bilateral cases.[317] Discoid menisci are classified based on the system of Watanabe et al.[403]: Complete morphology (type I), incomplete morphology (type II), and any morphology that lacks peripheral attachments (type III). One recent study proposed a more complex classification scheme that incorporates description of the presence and location of instability, paired with morphology.[141] Although often synonymous with so-called "snapping knee syndrome," discoid lateral menisci may manifest in a variety of ways. Symptoms are often related to the type of discoid present, peripheral stability of the meniscus, and the presence or absence of an associated meniscal tear.[14,102,123,193,296,336,415] Stable discoid menisci without associated tears will often remain asymptomatic, identified only as incidental findings during MRI or arthroscopy.[207] Unstable discoid menisci are more commonly present in younger children and often produce the so-called "snapping knee syndrome." In such instances, a painless and palpable, audible or visible snap is produced with knee ROM, especially near terminal extension. Discoid menisci with posterior instability and a redundant anterior segment may limit knee extension.[418] In children with stable discoid lateral menisci, symptoms often present when an associated tear is present. Unlike acute meniscal tears, such symptoms may present insidiously without significant previous trauma. Signs and symptoms of a meniscal tear may exist, including pain, swelling, catching, locking, and limited motion. On physical examination, there may be joint line tenderness, popping, limited motion, effusion, terminal motion pain, and positive provocative tests (McMurray test). Degenerative horizontal cleavage tears are the most common type of tear seen in this condition, reported in the largest series to occur in 58% to 98% of symptomatic discoid menisci.[12,43,320] One study showed that Wrisberg types were more likely to require treatment complete discoids, which in turn were more likely to require treatment than incomplete discoids.[317] Instability of a discoid meniscus may be more common than previously thought, with rates as high as 77% in a recent series[141] demonstrating anterior instability to be the most common form (53%), followed by posterior instability (16%) and combined anterior/posterior instability (6%).

Treatment Options for Meniscal Injuries

Nonoperative Treatment of Meniscal Injuries

Indications/Contraindications

Some small (<1 cm), nondisplaced meniscal tears in the peripheral vascular region of the meniscus may heal nonoperatively or may become asymptomatic (Table 30-17).[148,149,213]

TABLE 30-17 Meniscal Injuries

Nonoperative Treatment

Indications	Relative Contraindications
Small, nondisplaced, asymptomatic peripheral, vertical/longitudinal tears	Symptomatic tears Large tears ≥1 cm Radial/flap tears, complex patterns

Techniques

Nonoperative treatment usually consists of rehabilitation of the injured knee with the avoidance of pivoting and sports for 12 weeks, with protection of weight bearing for 4 to 6 weeks to minimize shear forces across the healing meniscus.

Outcomes

As there has been a general evolution to more proactive treatment of meniscus tears, particularly in younger populations, there is sparse literature related to successful nonoperative treatment of meniscus tears. However, Weiss et al.[405] showed that few patients in a series of 80 with "stable" longitudinal, vertical meniscus tears required surgery or were symptomatic at a minimum of 2-year follow-up. The authors concluded that radial tears do not heal with nonoperative treatment and empirically warrant surgery.

Operative Treatment of Meniscal Injuries

Indications/Contraindications

The majority of meniscal tears in pediatric patients is larger and requires surgical treatment.[148,149,213] Arthroscopic management is standard, with either partial meniscectomy using motorized shavers and baskets or meniscal repairs using outside-in, all-inside, or inside-out techniques.[90,148,149]

Arthroscopic Management

Preoperative Planning (Table 30-18)

Positioning

Supine positioning is used, with a nonsterile tourniquet placed on the operative thigh, and a lateral thigh post, which is particularly useful for application of valgus knee stress to access the posterior horn of the medial meniscus in select tears.

TABLE 30-18 Operative Treatment of Meniscal Injuries

Operative Treatment

Preoperative Planning Checklist

- **OR table:** Standard

- **Fluoroscopy location:** N/A
- **Equipment:** Arthroscopy setup, inside-out meniscus repair cannulas, 2 meniscus repair suture, all-inside meniscus repair implants
- **Tourniquet (sterile/nonsterile):** Nonsterile, thigh

Surgical Approach and Technique

The historical treatment of a torn meniscus had been meniscectomy, but numerous reports[5,25,52,112,172,208,213,229,260,274,326,328,380,390,393,402,417] indicating the poor long-term results of meniscectomy in children have made this less common. Up to 60% to 75% of patients may have degenerative changes after meniscectomy. Manzione et al.[260] reported 60% poor results in 20 children and adolescents after meniscectomy. In cadaver studies, Baratz et al.[37] showed that the contact stresses on the tibiofemoral articulation increase in proportion to the amount of the meniscus removed and the degree of disruption of the meniscal structure. As a clear principle, as much of the meniscus should be preserved as possible.

The exact meniscal injury and potential for repair can be determined arthroscopically to help formulate treatment plans. Zaman and Leonard[420] recommended observation of small peripheral tears, repair of larger peripheral tears, and, when necessary, partial meniscectomy, leaving as much of the meniscus as possible. They concluded that total meniscectomy is contraindicated in young patients. In general, peripheral tears, which are most common in children, and longitudinal/vertical tears are good candidates for repair, with success rates of up to 90% reported.[89,158,167,263,287]

Although it was believed that longitudinal meniscal tears could heal if communication with peripheral blood supply existed, it was not until the work of Arnoczky et al.[28] in the 1980s that meniscal repairs were popularized, based on documentation of the meniscal blood supply. They believed that tears within 3 mm of the meniscosynovial junction were vascularized, and ones more than 5 mm away were avascular unless bleeding was seen at surgery. Tears in the 3- to 5-mm range had inconsistent vascularity. Children and adolescents may have greater healing potential for meniscal repair. In adults, meniscal repair is indicated for tears involving the outer ⅓. In children and adolescents, repair of tears in the middle ⅓ zone typically heal as well,[89,158,167,263,287] making repair of both red–red and red–white zone tears the standard of care for vertical tears in this young population. Horizontal cleavage tears, transverse/radial tears, flap tears extending from the central ⅓, and complex or degenerative tears most often should undergo partial meniscectomy, taking care to preserve as much meniscal tissue as possible, and establish smooth, stable edges to the trimmed meniscus. Occasionally, a complete radial tear will occur in a child, which would require a total or subtotal meniscectomy if treated with debridement. In these instances, side-to-side repair of the peripheral two-thirds of the torn meniscus with multiple nonabsorbable sutures should be trialed, at times in conjunction with partial debridement of the most central edges (white-white zone) of the tear, which may not heal due to diminished vascularity. The stability of the peripheral attachments should always be assessed meticulously with a probe, both before and after any meniscal interventions, to ensure there are no concomitant peripheral tears or underlying instability warranting repair. Familiarity with the arthroscopic appearance of normal meniscal mobility, and the differences between the medial and lateral side, is critical to the success of this assessment (Table 30-19).

TABLE 30-19 Operative Treatment of Meniscal Injuries

Operative Treatment
Surgical Steps
• Diagnostic arthroscopy, assess position/pattern/size of tear
• For unrepairable tears (radial/flap/complex/degenerative), perform partial meniscectomy
◦ Use basket/punch instruments to trim torn portion, preserving as much of intact meniscus as possible
◦ Smooth transition zones between native/meniscectomized tissue
• For repairable tears, reduce any displaced portions to anatomic position
◦ Use meniscal rasp, shaver to freshen edges of meniscal tissue and/or peripheral capsular to stimulate healed
◦ Place meniscus repair sutures (preferably in vertical mattress pattern, inside-out)
◦ For posterior horn, select all-inside approach versus inside-out with mini-open protection of posterior structures
• Assess stability of repaired meniscus

Treatment of Discoid Lateral Meniscus in Meniscal Injuries

Several treatment options exist if the diagnosis of a discoid lateral meniscus is confirmed. For asymptomatic discoid lateral menisci, even if found incidentally on arthroscopy, no treatment is indicated. For stable, complete, or incomplete discoid menisci, partial meniscectomy, "saucerization," is the treatment of choice (Fig. 30-25). If meniscal instability with detachment is also identified during the arthroscopic examination, meniscal repair should be performed. Historically, complete meniscectomy via open or arthroscopic means was suggested for such lesions, but has been clearly associated with poor long-term results and early degenerative changes,[5,9,112,156,213,239,260,274,309,326,328,390,393,417] so is contraindicated. Although there may be a rare instance where salvage of a degenerative or torn discoid meniscus may seem unobtainable, better arthroscopic technology and techniques have made meniscal preservation the ideal treatment through saucerization and repair.[4]

Author's Preferred Treatment of Meniscal Injuries

The author's treatment algorithm for meniscal tears in children and adolescents is shown in Figure 30-26. Treatment is based on size, site, shape and stability of the tear, acuity of the lesion, and knee stability. In a stable knee with an acute, arthroscopically documented outer third peripheral tear that is less than 1 cm long and cannot be displaced more than 3 mm, the tear may be allowed to heal. For a similarly sized tear in a chronic setting, we arthroscopically rasp or trephinate the interface between the meniscal edges and perform a repair. Protected weight bearing and limitation of flexion beyond 90 degrees is prescribed for 4 to 6 weeks. Healing can be assessed based on physical examination.

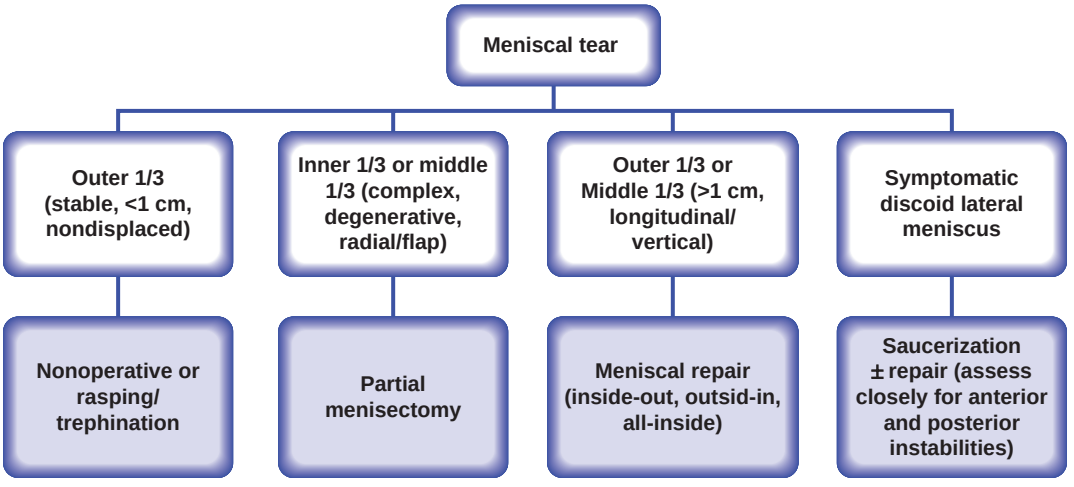

FIGURE 30-26 Algorithm for the management of meniscal tears in children and adolescents.

Return to sports and activities is based on the absence of physical examination findings and adequate rehabilitation, usually at 3 to 4 months postoperatively with a small tear.

For larger tears involving the outer 1/3 or middle 1/3, which are longitudinal with an intact inner segment that can be reduced anatomically, meniscal repair is performed. In the chronic setting, rasping of the fragment edge, trephination, and use of a fibrin clot may enhance healing. Patients are protected postoperatively to allow for meniscal healing. Our postoperative protocol for isolated meniscal repair involves touch-down weight bearing for 6 weeks postoperatively. ROM is restricted from 0 to 30 degrees for the first 2 weeks followed by 0 to 90 degrees for the next 6 weeks. Progressive mobilization and strengthening are pursued from 6 to 12 weeks, and sports-specific therapy and agility exercises are initiated at 3 months under the direction of a physical therapist, provided sufficient strength has been achieved for dynamic knee stability. Return to sports is allowed at 4 to 5 months postoperatively, if there is full ROM, near-symmetric strength, no symptoms (pain, swelling, locking), and resolution of physical examination findings (joint line tenderness, McMurray maneuvers, terminal range joint line pain). Follow-up MRI is performed only in patients with persistent symptoms or concerning physical examination findings. Partial meniscectomy is performed for tears involving the inner 1/3 or middle 1/3 tears that are macerated, horizontal, degenerative, or complex. Care should be taken to preserve as much tissue as possible (Fig. 30-27). With horizontal tears, the smaller of the two leaves is resected. Rehabilitation after partial meniscectomy includes weight bearing as tolerated with crutches for comfort, ROM and strengthening. Return to sports and activities is based on the absence of physical examination findings and adequate rehabilitation, usually at 2 to 3 months postoperatively. Patients who have undergone complete or near-total meniscectomy, should be followed long-term and periodically into young adulthood, to assess the possible development of degenerative changes. Weight-bearing radiographs in slight flexion to measure any compromise in the joint space represent a standard monitoring approach. In symptomatic patients or those with loss of joint space or degenerative changes, such as early osteophytes, replacement with an allograft meniscus or synthetic scaffold transplant procedure may be considered.

In children and adolescents, the emphasis should be on meniscal repair over meniscectomy whenever possible because of greater healing potential in this age group, the long life span of these patients, the poor results of total and near-total meniscectomy, and the lack of reassuring longer-term results of partial meniscectomy. Meniscal repair techniques include inside-out techniques, outside-in techniques, and all-inside techniques. Outside-in techniques can be useful for anterior horn medial or lateral meniscal tears. For body and posterior horn tears, the traditional technique of meniscal repair has been inside-out repair with vertical or horizontal sutures (Fig. 30-28). Zone-specific cannulae are helpful to direct the small caliber, flexible suture needles to the appropriate position to avoid neurovascular structures. In addition, we frequently make an incision posteromedially or posterolaterally to retrieve the suture needles and tie the sutures onto the joint capsule, thus protecting the saphenous nerve and vein medially and the peroneal nerve laterally. Newer all-inside devices have made the technique of meniscal repair more efficient, but a lack of longer-term studies makes the relative effectiveness unknown (Fig. 30-29). In addition, reports of articular cartilage damage from the heads of bioabsorbable arrows and darts exist,[148,149] and these devices may cause slightly more trauma to the meniscal tissue than repair needles upon entry. Finally, many of the available devices extend too far through the capsule in the small pediatric knee, with potential for neurovascular injury. We prefer more recent all-inside suture devices with a low profile in the joint, and at times will utilize these for posterior horn tears in adolescent knees or the posterior horn portion of larger tears, with repair of the body through inside-out techniques. In place of a larger posterior incision, a smaller, portal-sized lateral or medial incision may be made, with retrieval of the percutaneous suture ends at the level of the capsule with a small curved clamp or arthroscopic probe. An arthroscopic knot pusher may be helpful to position the knots deep to these incisions, directly at their exit point through the capsule, to maintain optimal tightness of the repair suture. For smaller tears without substantial displacement,

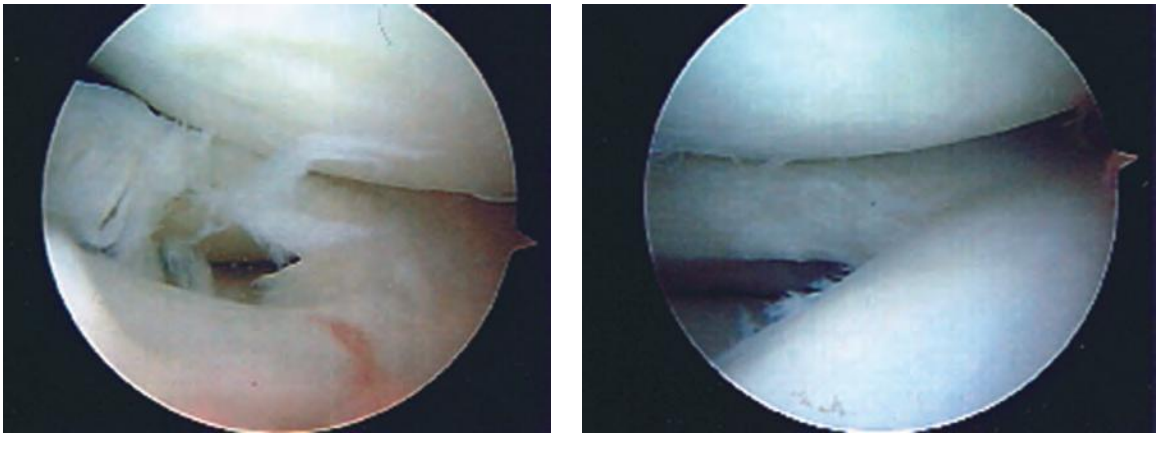

FIGURE 30-27 Complex inner 1/3 tear of the meniscus **(A)** treated with partial meniscectomy **(B).**

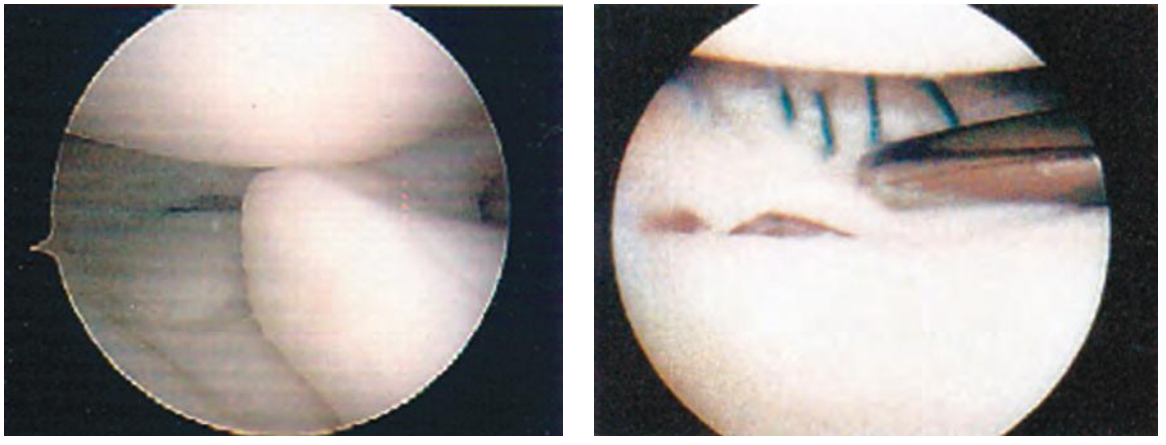

FIGURE 30-28 Longitudinal middle ⅓ tear of the meniscus **(A)** treated with inside-out meniscal repair **(B).**

all-inside techniques are often used alone, whereas larger tears with displacement such as displaced bucket-handle tears will be addressed with an incision to safely accommodate all-inside technique throughout or in the above described "hybrid" manner with both all-inside (posterior horn) and inside-out (meniscal body) sutures.

Bucket-handle displaced tears with a locked knee are treated urgently to allow for reduction and meniscal repair, and to avoid further injury to the meniscus. Meniscal tears in association with ACL injuries are usually treated concurrently with ACL reconstruction. ACL reconstruction is essential to provide a stable environment for meniscal healing and prevention of further meniscal tears. Moreover, healing rates are higher with concurrent ACL reconstruction than with isolated meniscal repair, perhaps because of the healing environment of the associated postoperative hemarthrosis from the bone tunnels. For meniscal repair in association with ACL reconstruction, return to sports is dictated by the ACL reconstruction, usually at 6 months postoperatively.

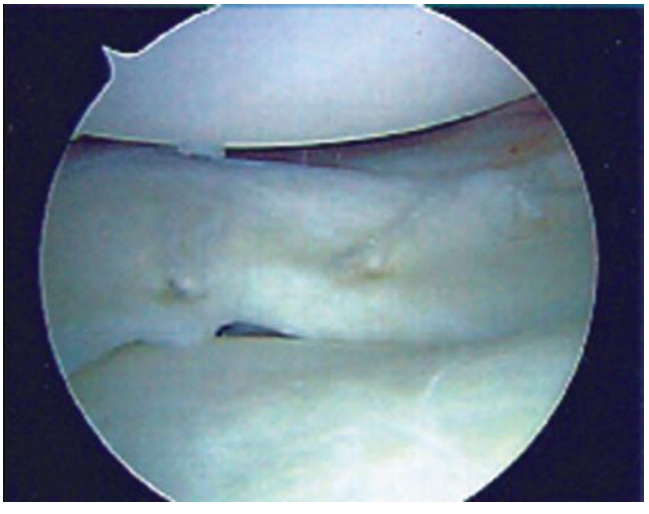

FIGURE 30-29 Longitudinal tear of the outer ⅓ of the posterior horn meniscus treated with all-inside fixation devices.

Postoperative Care for Meniscal Injuries

A variety of rehabilitation approaches may be employed in association with meniscus repair, with individualization of the regimen, depending on the severity of the tear and nature of the repair. Smaller tears that are discovered incidentally or well approximated by one or two repair sutures in association with ACL reconstruction may allow for normal weight bearing and advancement of ROM as those protocols not involving meniscus repair. However, given that most tears in children are larger and involve a number of inside-out repair sutures, the standard protocol involves protection of weight bearing for 6 weeks with crutches and limiting ROM to 0 to 90 degrees.

Potential Pitfalls and Preventative Measures of Meniscal Injuries

Making the diagnosis of a meniscal tear can sometimes be difficult in the child or adolescent. The differential diagnosis is varied and includes other injuries and disorders that cause pain and swelling or that cause joint line pain. Physical examination findings can be variable. MRI scans must be carefully scrutinized by the orthopedist because of the relatively high prevalence of normal signal change in the posterior horns from the improved vascularity of the peripheral meniscal tissue, relative to adults. Extension of the meniscal signal to the superior or inferior edge of the meniscus must be confirmed before considering the MRI diagnostic of a meniscal tear.

Total or near-total meniscectomy should be avoided in children and adolescents if at all possible to avoid the development of degenerative changes. Patients who have had near-total or total meniscectomy should be counseled regarding the risk of arthritis and the potential for meniscus replacement with allograft or synthetic scaffolds.

Several technical pitfalls exist during meniscal repair. During inside-out meniscal repair of the posterior horn, a posterolateral incision should be made for lateral meniscus repair to avoid iatrogenic injury to the peroneal nerve and a posteromedial incision should be made for medial meniscus repair to avoid iatrogenic injury to the saphenous vein or nerve.

TABLE 30-20 Meniscal Injuries

Potential Pitfalls and Preventions

Pitfall	Preventions
Pitfall no. 1: Posteromedial (saphenous nerve) or posterolateral (peroneal) nerve injury with inside-out repair of posterior horn	Prevention 1a: Incision to achieve adequate retraction/protection of structures (assistant must see posterior capsule)
Pitfall no. 2: Popliteal artery injury with all-inside repair of posterior horn	Prevention 2a: Cut protective cannula to appropriate length for size of patient (especially in pediatric knee) Prevention 2b: Direct cannula/device in appropriate vector to avoid central third of posterior knee
Pitfall no. 3: Chondral injury to medial femoral condyle or lateral femoral condyle	Prevention 3a: For tight medial compartment, consider trephination of MCL to open joint space, with post-op bracing Prevention 3b: For tight lateral compartment, elevation of foot in figure-four position

During all-inside repair with meniscal repair devices, consideration must be given to the size of the implant relative to the pediatric knee. Implants that protrude too far may injure neurovascular structures or cause local irritation or cysts. Implants that are high-profile or protrude, may damage the articular surface of the femoral condyle. Sterile effusions and synovitis may occur with bioabsorbable implants (Table 30-20).

Treatment-Specific Outcomes for Meniscal Injuries

The prognosis after complete or near-total meniscectomy is poor with numerous reports[5,25,52,112,172,208,213,229,260,274,326,328,380,390,393,396,417] indicating poor long-term results with degenerative changes. The prognosis of meniscus repair in appropriately selected cases is good. Mintzer and Richmond reported on meniscal repair in 29 patients under the age of 18 (25 had closed physes and 17 underwent concomitant ACL reconstruction). They reported 100% clinical healing at an average follow-up of 5 years.[284] Noyes and Barber-Westin looked at meniscal tears extending into the avascular zone in patients younger than 20 years old.[303,338] Skeletal maturity had been reached in 88%. Their success rate in this group was 75%. This study showed a higher rate of healing with concomitant ACL reconstruction. Despite these historical improved results with concomitant ACL-R, a recent study in children[230] reported a 26% failure rate in meniscal repair with ACL-R, with risk factors for failure being complex or bucket-handle tears. Other studies of pediatric populations[392] have suggested that the time to return to sports is longer (8.2 months) in patients with meniscus repair performed with ACL-R, compared with those with isolated meniscus repairs (5.6 months). Eggli et al.[112] found an overall healing rate for repair of isolated meniscal tears of 88% in patients younger than 30, compared to 67% in patients over age 30. Johnson et al.[190] showed a 76% healing rate at an average follow-up of greater than 10 years in a population that averaged 20 years old at the time of surgery. Factors that have been shown to correlate with increased healing of meniscal repairs include: Younger age, peripheral tears, repairs of the lateral meniscus, concomitant ACL reconstruction, time from injury to surgery of less than 8 weeks, and tear length of less than 2.5 cm.[3,69,71,112,148,149,190,381] One recent series of 25 meniscal tears in children[228] demonstrated that healing rates of lateral and meniscal repairs were comparably high, with a mean Lysholm score of 95, regardless of zone or pattern, but that recurrent tears are more likely to occur in the body of the meniscus than the anterior or posterior horn.

Management of Expected Adverse Outcomes and Unexpected Complications in Meniscal Injuries

Complications after either arthroscopic or open repair may include hemorrhage, infection, persistent effusion, stiffness, and nerve injury. Both the popliteal artery and inferior geniculate branches are close to the posterior capsule and are easily lacerated. Postoperative infection should be suspected if swelling or pain persists with an elevated temperature. Swelling is best treated with external compression dressings, and stiffness is best prevented by appropriate postoperative rehabilitation (Table 30-21).

Introduction to Ligament Injuries

Ligamentous injuries of the knee in children and adolescents were once considered rare.[83,327] Tibial eminence avulsion fractures were considered the pediatric ACL injury equivalent.[215,219,220,327] However, major ligamentous injuries are being seen with increased frequency and have received increased attention.[13,18,21,23,29,42,47,49,55,62,64,79,98,109,113,114,115,117,128,145,152,154,169,178,186,193,194,198,206,212,222,223,227,245,246,250,265,267,269,270,281,282,285,287,315,324,329,343,354,356,358,359,366,367,370,377,389,399,400,407] The increased frequency of diagnosis of knee ligament injuries in children is likely related to increased participation in youth sports at higher competitive levels, the advent of arthroscopy and MRI, and an increased awareness of injuries in this age group.

ACL injury has been reported in 10% to 65% of pediatric knees with acute traumatic hemarthroses in series ranging from

TABLE 30-21 Meniscal Injuries

Common Adverse Outcomes and Complications

Failure to heal/retear of meniscus repair

Neurovascular injury (saphenous nerve, peroneal nerve, popliteal artery)

35 to 138 patients.[115,212,214,250,370,389] Stanitski et al.[369] reported 70 children and adolescents with acute traumatic knee hemarthroses; arthroscopic examination revealed ACL injuries in 47% of those 7 to 12 years of age and in 65% of those 13 to 18 years of age. They determined that boys 16 to 18 years of age engaged in organized sports and girls 13 to 15 years of age engaged in unorganized sports had the highest risk for complete ACL tears; 60% of these patients had isolated ACL tears.

Injury patterns in the skeletally immature knee are dependent on the loading conditions and the developmental anatomy. Fractures of the epiphyses or physes about the knee are more common than ligamentous injuries alone. Historical literature suggested that isolated knee ligament injury in children younger than 14 years of age was rare because of the relative strength of the ligaments compared to the physes.[108,194,269,400] However, a recent report investigating rates of pediatric knee injuries presenting to a large children's hospital emergency room suggested that over a 12-year period, the rate of tibial spine fractures increased by 1%, whereas cases of ACL tears had increased by 11%.[342] The inherent ligamentous laxity in children also may offer some protection against ligament injury, but this decreases as the adolescent approaches skeletal maturity. Faster loading conditions favor ligamentous injuries, whereas slower loading conditions favor fracture. Narrowing of the intercondylar notch during skeletal development may also predispose to ligamentous injury.[219] Fractures and ligamentous injuries may also occur concurrently. Bertin and Goble,[49] after reviewing 29 fractures, concluded that physeal fractures about the knee are associated with a higher incidence of ligamentous injury. In addition, tibial eminence fractures, even after anatomic fixation and healing, tend to demonstrate persistent ACL laxity.[215]

Before the 1990s, reports of ligamentous injuries in children were isolated case reports, and most recommendations were for conservative treatment. More recent reports have indicated an increased awareness of ligament injury in association with physeal fractures,[83] as well as isolated ligament injuries, and a more aggressive approach, especially in adolescents approaching skeletal maturity.[47,113,114,287,356,377] Management of some of these injuries, particularly ACL injuries in skeletally immature patients, is controversial. Nonreconstructive treatment of complete tears typically results in recurrent functional instability with risk of injury to meniscal and articular cartilage. A variety of reconstructive techniques have been utilized, including physeal-sparing, partial transphyseal, and transphyseal methods using various grafts. Conventional adult ACL reconstruction techniques risk potential iatrogenic growth disturbance due to physeal violation. Growth disturbances after ACL reconstruction in skeletally immature patients have been reported.

Assessment of Ligament Injuries

Mechanism of Injury for Ligament Injuries

The mechanism of ligamentous injury varies with the child's age. In younger children, ligamentous injury is often associated with significant polytrauma. Clanton et al.[79] reported that five of nine children with acute knee ligament injuries were struck by automobiles. In contrast, adolescents are more likely to sustain ligamentous injury during contact sports or sports that require "cutting" maneuvers while running.[361] As exact a description as possible of the mechanism of injury should be obtained, including the position of the knee at the time of injury, the weight-supporting status of the injured knee, whether the force applied was direct or indirect (generated by the patient's own momentum), and the position of the extremity after injury. Older adolescents may describe the knee as buckling or moving or jumping out of place and can usually relate the location and severity of their pain as well as the time between injury and onset of pain and swelling. Rapid intra-articular effusion within 2 hours of injury suggests hemarthrosis, most commonly from injury to the ACL.

Palmer[313] described four mechanisms capable of producing disruption of the ligamentous structures about the knee: Abduction, flexion, and internal rotation of the femur on the tibia; adduction, flexion, and external rotation of the femur on the tibia; hyperextension; and anterior–posterior displacement. The most common mechanism in adolescents is abduction, flexion, and internal rotation of the femur on the tibia occurring during athletic competition when the weight-bearing extremity is struck from the lateral side. The classic abduction, flexion, and internal rotation injury in the adolescent may cause the "unhappy triad" of O'Donoghue: Tears of the MCL and ACL and injury to the medial meniscus.

Isolated injury of the LCL is rare in children, but a direct blow to the medial aspect of the knee may tear the LCL, usually with avulsion from the fibula or a physeal injury through the distal femur.[180] Isolated injuries of the ACL and PCL are more common[174,180,269] Disruption of the ACL with minimal injury to other supporting structures may be caused by hyperextension, marked internal rotation of the tibia on the femur, and pure deceleration. In contrast, isolated injury of the PCL most often is caused by a direct blow to the front of the tibia with the knee in flexion. The most extensive description of PCL injuries in children to date recently demonstrated that the majority of these injuries are sustained during sports, with less common causes including falls from height, trampoline injuries, and motor vehicle accidents.[224]

Associated Injuries with Ligament Injuries

Common injuries associated with ACL tear include meniscus injuries (lateral more commonly than medial, in the acute setting), and MCL tears. Posterolateral corner and PCL injuries frequently occur in conjunction with each other. Complete and partial knee dislocations may have a variety of patterns of associated injuries, as described above.

Signs and Symptoms of Ligament Injuries

Both lower extremities are examined for comparison. Large areas of ecchymosis and extensive effusion are easily identified, but smaller areas may require careful palpation. In general, acute hemarthrosis suggests rupture of a cruciate ligament, an osteochondral fracture, a peripheral tear in the vascular portion of a meniscus, or a tear in the deep portion of the joint capsule.[88,91] The absence of hemarthrosis is

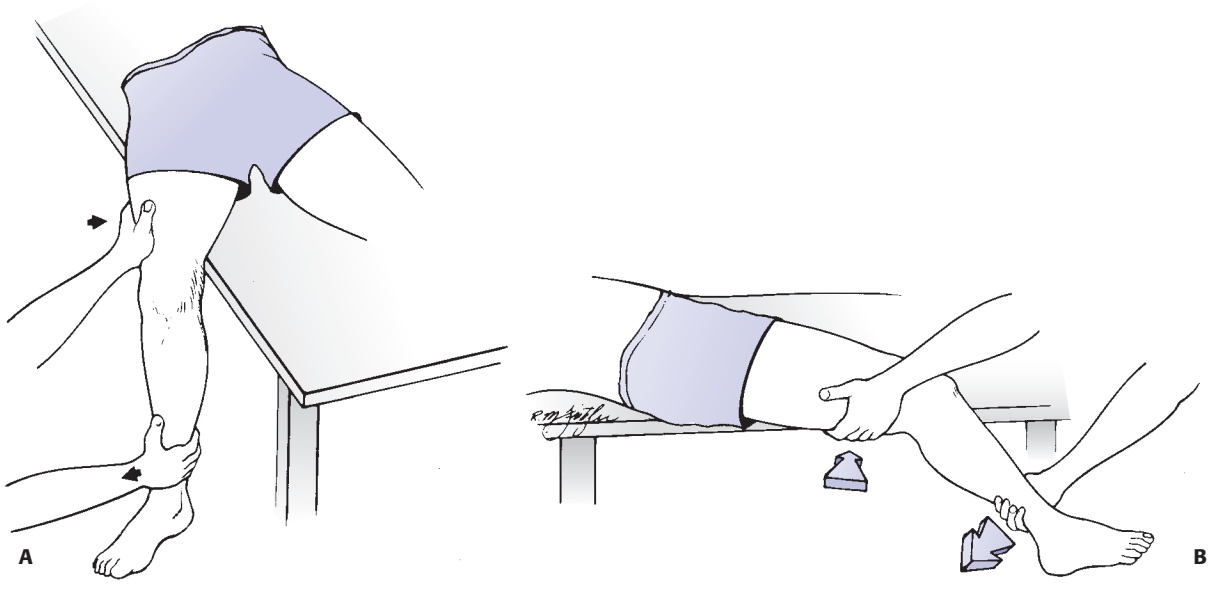

FIGURE 30-30 Valgus stress test of medial collateral ligament. Extremity is abducted off table, knee is flexed to 20 degrees, and valgus stress is applied. **A:** Frontal view. **B:** Lateral view.

not, however, an indication of a less severe ligament injury, because with complete disruption, the blood in the knee joint may escape into the soft tissues rather than distend the joint. Palpation of the collateral ligaments and their bony origins and insertions should locate tenderness at the site of the ligament injury. A defect in the collateral ligaments often can be felt if the MCL is avulsed from its insertion on the tibia or if the LCL is avulsed from the fibular head. If the neurovascular status is normal, stability should be evaluated by varus/valgus stress testing, which may be done immediately after injury in cooperative adolescents but can be more difficult in younger ages or those with significant pain. Beginning the examination by testing the uninjured knee often calms patients and makes them more cooperative; it also establishes a baseline for assessing the ligamentous stability of the injured knee as knee laxity varies during childhood.[168] Valgus and varus stress testing of the MCL and LCL should be done at both 20 degrees of flexion and full extension, which may demonstrate gross instability if there is cruciate ligament rupture as well (Fig. 30-30).

The anterior drawer test, as described by Slocum, is the classic maneuver for testing the stability of the ACL (Fig. 30-31). The Lachman and pivot-shift tests, however, are considered more sensitive for evaluating ACL injury when the examination can be done in a relaxed, cooperative adolescent, but may be confounded if there is significant guarding. The posterior drawer test (Fig. 30-32), quad active test, and assessment of the posterior sag sign are the key maneuvers for evaluation of the integrity of the PCL.

Imaging and Other Diagnostic Studies for Ligament Injuries

Anteroposterior and lateral radiographs are obtained when any ligament injury of the knee is suspected in children. The radiographs are carefully inspected for evidence of occult epiphyseal or physeal fractures or bony avulsions. The intercondylar notch, especially, is inspected to detect a tibial spine fracture, which is confirmed by anterior or posterior instability on physical examination. Occasionally, a small fragment of bone avulsed from the medial femur or proximal tibia indicates injury to the MCL. Similarly, avulsion of a small fragment of bone from the proximal fibular epiphysis or the lateral aspect of the distal femur may indicate LCL injury.

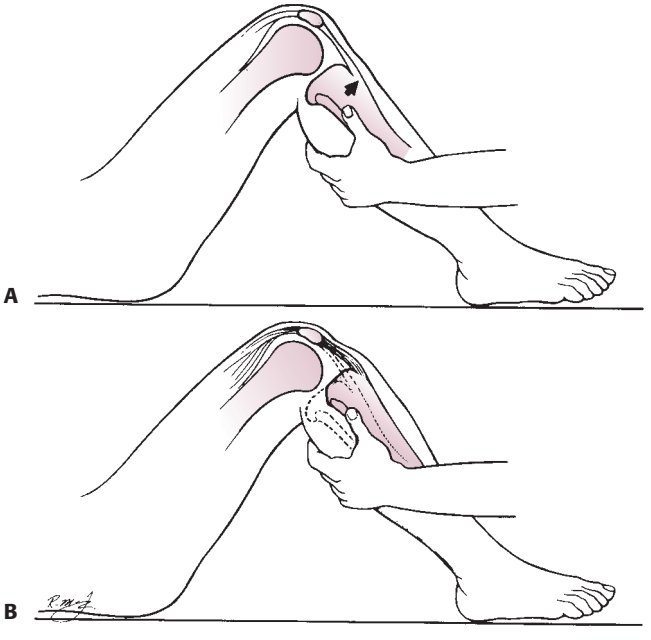

FIGURE 30-31 Anterior drawer test of anterior cruciate ligament. Foot is positioned in internal, external, and neutral rotation during examination. With anterior cruciate insufficiency, an anterior force **(A)** displaces the tibia forward **(B).**

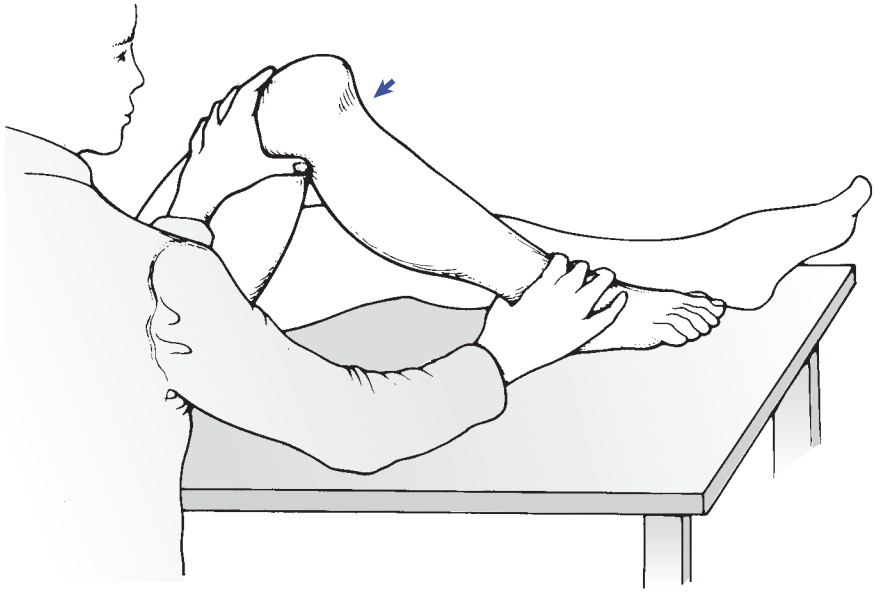

FIGURE 30-32 Posterior cruciate ligament injury. Note posterior sagging of the tibia with posterior cruciate injury.

In children with open physes, stress radiographs may be considered to evaluate medial and lateral instabilities associated with physeal fractures. MRI is frequently used to further delineate ligamentous injuries in the knee. MRI should be used to confirm an uncertain diagnosis or to gain further information that may affect treatment. Conventional MRI can give information regarding MCL injury, LCL injury, ACL injury, PCL injury, posterolateral corner injury, bone bruising, chondral injury, and meniscal injury.

Classification of Ligament Injuries

Classification of knee ligament injuries is based on the severity of the injury, the specific anatomic location of the injury, and the direction of the subsequent instability caused by an isolated ligament injury or combination of ligament injuries.

A first-degree ligament sprain is a tear of a minimal number of fibers of the ligament with localized tenderness but no instability. A second-degree sprain is disruption of more ligamentous fibers, causing asymmetry with stress testing, compared with the contralateral knee, but minimal or minor instability. A third-degree sprain is complete disruption of the ligament, resulting in gross instability. Although difficult to assess clinically, the degree of sprain also is determined with collateral ligaments during stress testing by the amount of separation of the joint surfaces: First-degree sprain, 5 mm or less (normal/baseline); second-degree sprain, 5 to 10 mm; and third-degree sprain, more than 10 mm.

The anatomic classification of knee ligament injuries (femoral attachment avulsion, midsubstance/interstitial tear, or tibial attachment avulsion) describes the exact location of the disruption,[126] whether in the MCL (Fig. 30-33), ACL, LCL (Fig. 30-34), or PCL. Finally, the instability of the knee joint caused by the ligament disruption may be classified as having one-plane instability (simple or straight), rotary instability (anteromedial, anterolateral, posterolateral, or posteromedial), or combined instability (anterolateral–posterolateral, anterolateral–anteromedial, or anteromedial–posteromedial),[173,360] which may be helpful in planning treatment.

Outcome Measures for Ligament Injuries

Even though retear of a reconstructed ligament, particularly the ACL, is a well-described phenomenon that can occur even without any technical error or oversight in rehabilitation, it remains the most important assessment of outcome. However, for athletes, particularly elite athletes, return to sports and the ability to play at the previous level of competition may be important metrics as well. On a longer-term basis, standard outcome measures, such as functional knee measures (the Pedi-IKDC[225] and Lysholm[364] knee scores), should be used to assess results and paired with the Marx or Tegner activity scores[264] to assess surgical outcomes.

Pathoanatomy and Applied Anatomy Relating to Ligament Injuries

The MCL and LCL of the knee originate from the distal femoral epiphysis and insert into the proximal tibial and fibular epiphyses, respectively, except for the superficial portion of the MCL, which inserts into the proximal tibial metaphysis distal to the physis (Fig. 30-35). In children, these ligaments are generally stronger than the physes, and significant tensile stresses usually produce epiphyseal or physeal fractures rather than ligamentous injury. The ACL originates from the posterolateral intercondylar notch and inserts into the tibia slightly anterior to the intercondylar eminence. The ACL in children has collagen fibers continuous with the perichondrium of the tibial epiphyseal cartilage; in adults, the ligament inserts directly into the proximal tibia by way of Sharpey fibers. This anatomic difference probably accounts for the fact that fracture of the anterior tibial spine occurs more frequently in children than does ACL injury. The PCL originates from the anteromedial aspect of the intercondylar notch and attaches on the posterior aspect of the proximal tibial epiphysis.

Treatment Options for Ligament Injuries

Nonoperative Treatment of Ligament Injuries

Indications/Contraindications

Isolated collateral ligament injuries are usually successfully treated with bracing and rehabilitation (Table 30-22).

TABLE 30-22 Ligament Injuries

Nonoperative Treatment

Indications	Relative Contraindications
Partial ACL tear (<50% fibers, negative pivot-shift test, younger child)	>50% tear, positive pivot shift, older adolescent Symptomatic instability Associated injury requiring operative treatment with prolonged rehabilitation regimen and maximum knee stability (e.g., meniscus repair)
Primary (midsubstance) PCL tear	Complete bony avulsion injury of footprint
Partial/incomplete LCL/PCL injury	Symptomatic instability despite prolonged PT regimen (quad strengthening)

Outcomes

Nonoperative management of partial tears may be successful in some patients, with better results expected for younger children, those with a negative pivot-shift test, and those with less than 50% of the ACL fibers ruptured.[222] The prognosis of nonoperative management of complete tears in skeletally immature patients is generally poor, with recurrent instability leading to further meniscal and chondral injuries, which has implications in terms of development of degenerative joint disease.[13,145,186,236,270,282,285,324]

Operative Treatment of Ligament Injuries

Indications/Contraindications

Complete collateral ligament tears or avulsions of the bony attachments that are severely displaced or associated with chronic instability warrant consideration of acute repair or chronic reconstruction, respectively.

Surgical Procedure—ACL

Preoperative Planning (Table 30-23)

Positioning

Standard positioning for arthroscopy is utilized, though some surgeons prefer a circumferential knee holder or standard table placed in "the ACL position," which involves a small amount of Trendelenburg angulation to the table, with the foot of the table dropped to the floor, with the contralateral knee in a well-leg holder or hanging free as well.

Surgical Approaches and Technique

The general approach to complete ACL ruptures in skeletally immature children has evolved over the last two to three decades, and has been the source of considerable controversy. Nonoperative management of partial tears may be successful in some patients.[222] However, nonoperative management of complete tears in skeletally immature patients, which may include functional bracing, physical therapy, and activity modification, generally has a poor prognosis, with recurrent instability leading to further meniscal and chondral injuries which has implications in terms of development of degenerative joint disease.[13,145,186,270,282,285,324] Graf et al., Mizuta et al., and Janarv et al.[145,186,285] have reported instability symptoms, subsequent meniscal tears, decreased activity level, and need for ACL reconstruction in the majority of skeletally immature patients treated nonoperatively in a series of 8, 18, and 23 patients,

respectively. Similarly, when comparing the results of operative versus nonoperative management of complete ACL injuries in adolescents, McCarroll et al.[270] and Pressman et al.[324] found that those managed by ACL reconstruction had less instability, higher activity and return to sport levels, and lower rates of subsequent reinjury and meniscal tears. Additional studies have found that a longer duration between the time of ACL injury and that of reconstructive surgery is associated with higher rates of meniscal and chondral injury in both children[106,236,282] and the general athletic population.[24]

Conventional surgical reconstruction techniques risk potential iatrogenic growth disturbance due to physeal violation. Cases of growth disturbance have been reported in animal models[109,152,169] and clinical series.[223,227,245] Animal models have demonstrated mixed results regarding growth disturbances from soft tissue grafts across the physes. In a canine model with iliotibial band grafts through 5/32-in tunnels, Stadelmaier et al.[366] found no evidence of growth arrest in the four animals with soft tissue graft across the physis, whereas the four animals with drill holes and no graft demonstrated physeal arrest. In a sheep model of transphyseal reconstruction, Seil et al.[347] did not find clinically relevant growth disturbances despite consistent physeal damage. In a rabbit model using a semitendinosus graft through 2-mm tunnels, Guzzanti et al.[152] did have cases of growth disturbance, however these were not common: 5% relative extremity shortening (1/21) and 10% distal femoral valgus deformity (2/21). Janarv et al.[188] quantified the size of various transphyseal tunnels as a percentage of the total cross-sectional area of the physis, and reported that 7% to 9% as was the lower threshold at which growth disturbances could be expected in a rabbit model. Examining the effect of a tensioned soft tissue graft across the physis, Edwards et al.[110] found a substantial rate of deformity. In a canine model with iliotibial band graft tensioned to 80 N, these investigators found significant increases, compared to the nonoperated control limb, in distal femoral valgus deformity and proximal tibial varus deformity despite no evidence of a bony bar. Similarly, Houle et al.[169] reported growth disturbance after a tensioned tendon graft in a bone tunnel across the rabbit physis. A recent radiologic study[419] investigated 43 pubertal skeletally immature patients who underwent transphyseal ACL reconstruction with metaphyseal fixation of quadruple hamstring autograft. The authors identified MRI evidence of focal bone bridges within or adjacent to the femoral or tibial tunnels in 12% of patients. Although no gross growth disturbances were perceived clinically, premature physeal closure was identified radiologically in two of the patients, all of whom had less than 3 years of growth remaining, by bone age assessment. These data, derived from bone tunnels with cross-sectional areas all under 3% of that of the physes (significantly lower than the threshold previously identified by Janarv et al.[188]), underscore the potential adverse sequelae of transphyseal techniques in younger patients with more significant growth remaining.

Despite these published basic science and radiologic data, clinical reports of growth deformity after ACL reconstruction remain relatively sparse, in part because most authors, secondary to early reports of growth-related complications, have exercised caution in surgeries compromising physeal integrity. Lipscomb and Anderson[245] reported one case of 20-mm shortening in a series of 24 skeletally immature patients reconstructed with transphyseal semitendinosus and gracilis grafts. This was associated with staple graft fixation across the physis itself. Koman and Sanders[227] reported a case of distal femoral valgus deformity requiring osteotomy and contralateral epiphysiodesis after transphyseal reconstruction with a doubled semitendinosus graft. This case was also associated with fixation across the distal femoral physis. Kocher et al.[223] reported an additional 15 cases of growth disturbances gleaned from a questionnaire of expert experience, including eight cases of distal femoral valgus deformity with an arrest of the lateral distal femoral physis, three cases of tibial recurvatum with an arrest of the tibial tubercle apophysis, two cases of genu valgum without arrest because of a lateral extra-articular tether, and two cases of leg length discrepancy (one shortening and one overgrowth). Associated risk factors for disturbance or deformity included fixation hardware placed across the lateral distal femoral physis in three cases, bone plugs of a patellar tendon graft across the distal femoral physis in three cases, large (12 mm) tunnels in two cases, lateral extra-articular tenodesis in two cases, fixation hardware across the tibial tubercle apophysis in two cases, of the over-the-top femoral position in one case, and suturing near the tibial tubercle apophysis in one case.

Surgical techniques to address ACL insufficiency in skeletally immature patients include primary repair, extra-articular tenodesis, transphyseal reconstruction, partial transphyseal reconstruction, and physeal-sparing reconstruction. Primary ligament repair[79,117] and extra-articular tenodesis alone[145,270] have had poor results in children and adolescents, similar to adults. Transphyseal reconstructions with tunnels that violate both the distal femoral and proximal tibial physes have been performed with hamstrings autograft, patellar tendon autograft, and allograft tissue.[13,23,29,109,128,226,243,265,270,354,358,367,399] Partial transphyseal reconstructions violate only one physis with a tunnel through the proximal tibial physis and over-the-top positioning on the femur or a tunnel through the distal femoral physis with an epiphyseal tunnel in the tibia.[21,55,154] A variety of physeal-sparing reconstructions have been described to avoid tunnels across either the distal femoral or proximal tibial physis.[18,64,98,153,206,216,217,237,281,315,389]

In prepubescent patients, physeal-sparing techniques have been described that utilize hamstrings tendons under the intermeniscal ligament and over-the-top on the femur, through all-epiphyseal femoral and tibial tunnels, and with a femoral epiphyseal staple.[18,64,98,153,206,216,217,281,315,389] In adolescent patients with growth remaining, transphyseal reconstructions have been performed with hamstrings autograft, patellar tendon autograft, quadriceps tendon autograft, and allograft tissue.[13,23,29,109,128,135,136,226,265,270,354,358,367,399] In addition, partial transphyseal reconstructions have been described with a tunnel through the proximal tibial physis and over-the-top positioning on the femur or a tunnel through the distal femoral physis with an epiphyseal tunnel in the tibia (Table 30-24).[21,55,154,246]

TABLE 30-24 Operative Treatment of Ligament Injuries—IT Band Physeal-Sparing ACL Reconstruction

Surgical Steps

- (If positive Lachman/pivot-shift tests on examination under anesthesia), expose distal ITB
- Leave distal attachment to ITB intact, detach 1-cm band of ITB proximally with meniscotome/closed tendon stripper, tubularize/tag free end with ***no.*** 2 braided suture
- Perform diagnostic arthroscopy, debride ACL tissue/stump
- Retrieve free end of ITB autograft with extralong curved snap through posterolateral capsular aperture (over-the-top position)
- Create 2-cm trough in proximal medial tibial cortex (distal to physis, medial to tibial tubercle apophysis) with adjacent periosteal flaps
- Use curved snap to create space for graft passage supra-periosteally on proximal tibial, under intermeniscal ligament intra-articularly
- Create trough (with curved, rat-toothed rasp)in proximal tibial epiphysis at site of ACL footprint via tibial
- Use curved snap to pass free limb of graft from inside joint to proximal tibial incision
- With knee in 70–90 degrees flexion, suture proximal ITB to lateral capsule and periosteum adjacent to capsular aperture
- With knee in 20–30 degrees flexion, suture free end of ITB to proximal tibial periosteum on maximum tension

Author's Preferred Treatment of Ligament Injuries

Medial Collateral Ligament

Isolated grade I or II sprains of the MCL are treated with a hinged knee brace for 1 to 3 weeks, with a shorter course of crutches for comfort. Return to athletic activities is allowed when a full, painless ROM is achieved and the patient can run and cut without pain. Isolated complete (grade III) disruption of the MCL can be treated with 6 weeks of immobilization in a hinged knee brace followed by formal physical therapy focused on rehabilitation of the quadriceps muscles and knee motion, provided this is an isolated injury. The physician must ensure that there is no associated injury to the ACL before pursuing nonoperative treatment for a grade III MCL injury. Grade III disruptions of the MCL in adolescents associated with injury of the ACL are usually treated with ACL reconstruction (ACL-R) without formal MCL repair, but medial stability must be gently assessed during the examination under anesthesia prior to the ACL-R procedure, which should be delayed at least 4 to 6 weeks following injury to ensure resolution of the inflammatory phase of injury, resolution of full ROM, and adequate time for early MCL healing. While some authors do not routinely employ hinged knee bracing following ACL-R, in the presence of an MCL tear, we recommend protecting the MCL with a hinged knee brace to complete the collateral ligament's healing process in the early postoperative period.

Anterior Cruciate Ligament

The overall goal of treatment of ACL rupture is reestablishment of a functional knee without progressive intra-articular damage or predisposition to premature osteoarthrosis. All skeletally immature patients (i.e., those with open physes) are not the same. Some have a tremendous amount of growth remaining, whereas others are essentially done growing. The consequences of growth disturbance in the former group would be severe, requiring osteotomy and/or limb lengthening. However, the consequences of growth disturbance in the latter group would be minimal. When treating a skeletally immature athlete with an ACL injury, it is important to know their chronologic age, their skeletal age, and their physiologic age. Skeletal age can be determined from an anteroposterior radiograph of the left hand and wrist as per the atlas of Greulich and Pyle.[150] Alternatively, skeletal age can be estimated from knee radiographs as per the atlas of Pyle and Hoerr.[325] Physiologic age is established using the Tanner staging system (Table 30-25).[379] In the office, the patient can be informally staged by questioning. In the operating room, after the induction of anesthesia, Tanner staging can be confirmed. The vast majority of ACL injuries in skeletally immature patients occur in adolescents. The management of these injuries in preadolescent children can be more challenging, given the poor prognosis with nonoperative management, the substantial growth remaining, and the consequences of potential growth disturbance.

Our algorithm to ACL-R in the skeletally immature patient is based on physiologic age (Fig. 30-36). However, regardless of age, because of growing evidence that prolonged delays in timing of ACL-R is associated with great risk of meniscal and chondral injuries in children and adolescents,[106,236] we advise that the surgery be performed relatively soon after preoperative rehabilitation to restore ROM and allow resolution of swelling. In prepubescent patients, we perform a physeal-sparing, combined intra-articular and extra-articular reconstruction utilizing autogenous iliotibial band.[216,217] In adolescent patients with significant growth remaining, we perform transphyseal ACL reconstruction with autogenous hamstrings tendons with fixation away from the physes.[226] In older adolescent patients approaching skeletal maturity, we perform conventional adult ACL reconstruction with interference screw fixation using either autogenous central third patellar tendon or autogenous hamstrings.

In skeletally immature patients as in adult patients, acute ACL reconstruction is not performed within the first 3 weeks after injury to minimize the risk of arthrofibrosis. Prereconstructive rehabilitation is performed to regain ROM, decrease swelling, and resolve the reflex inhibition of the quadriceps. Rarely, consideration of staged ACL reconstruction may be given in some cases if there is a displaced, bucket-handle tear of the meniscus that requires extensive repair to protect the meniscal repair from the early mobilization prescribed by ACL reconstruction. Skeletally immature patients must be emotionally mature enough to actively participate in the extensive rehabilitation required after ACL reconstruction.

TABLE 30-25 Tanner Staging Classification of Secondary Sexual Characteristics

Tanner Stage		Male	Female
Stage 1 (Prepubertal)	Growth Development	5–6 cm/y Testes <4 mL or <2.5 cm No pubic hair	5–6 cm/y No breast development No pubic hair
Stage 2	Growth Development	5–6 cm/y Testes 4 mL or 2.5–3.2 cm Minimal pubic hair at base of penis	7–8 cm/y Breast buds Minimal pubic hair on labia
Stage 3	Growth Development	7–8 cm/y Testes 12 mL or 3.6 cm Pubic hair over pubis Voice changes Muscle mass increases	8 cm/y Elevation of breast; areolae enlarge Pubic hair of mons pubis Axillary hair Acne
Stage 4	Growth Development	10 cm/y Testes 4.1–4.5 cm Pubic hair as adult Axillary hair Acne	7 cm/y Areolae enlarge Pubic hair as adult
Stage 5	Growth Development	No growth Testes as adult Pubic hair as adult Facial hair as adult Mature physique	No growth Adult breast contour Pubic hair as adult
Other		Peak height velocity: 13.5 y	Adrenarche: 6–8 y Menarche 12.7 y Peak height velocity: 11.5 y

Prepubescent Patient: Physeal-Sparing ACL Reconstruction

In the prepubescent patient with a complete ACL tear, we perform a physeal-sparing, combined intra-articular and extra-articular reconstruction utilizing autogenous iliotibial band (Fig. 30-37).[216,217] This procedure is a modification of the combined intra-articular and extra-articular reconstruction described by MacIntosh and Darby.[253] Our rationale for utilization of this technique is to provide knee stability and improve function in prepubescent skeletally immature patients with complete intrasubstance ACL injuries while avoiding the risk of iatrogenic growth disturbance by violating the distal femoral and/or proximal tibial physes. In our opinion, the consequences of potential iatrogenic growth disturbance caused by transphyseal reconstruction in these young patients is prohibitive, and the outcomes of this physeal-sparing technique[216] are comparable or superior to many series of adult-type reconstructions. Moreover, in a recent cadaveric kinematics study, Kennedy et al.[200] demonstrated that the iliotibial band physeal-sparing construct better restored both anterior–posterior and rotational stability than the all-epiphyseal and transphyseal over-the-top reconstruction techniques.

The procedure is performed under general anesthesia, with or without a femoral nerve block for regional anesthesia, as an overnight observation procedure to ensure good pain control and understanding and compliance with rehabilitation protocols. The child is positioned supine on the operating table with a pneumatic tourniquet about the upper thigh which is used routinely. Examination under anesthesia is performed to confirm ACL insufficiency.

First, the iliotibial band graft is obtained. An incision of approximately 6 cm is made obliquely from the lateral joint line to the superior border of the iliotibial band (Fig. 30-38A). Proximally, the iliotibial band is separated from subcutaneous tissue using a periosteal elevator under the skin of the lateral thigh. The anterior and posterior borders of the iliotibial band are incised and the incisions carried proximally under the skin using curved meniscotomes (Fig. 30-38A). The iliotibial band is detached proximally under the skin using a curved meniscotome or an open tendon stripper. Alternatively, a counterincision can be made at

FIGURE 30-38 Technique of physeal-sparing combined intra-articular and extra-articular anterior cruciate ligament reconstruction using iliotibial band. **A:** The iliotibial band is harvested through an oblique lateral knee incision. **B:** The iliotibial band graft is detached proximally, left attached distally, and dissected free from the lateral patellar retinaculum. **C:** The iliotibial band graft is brought through the knee using a full-length clamp placed from the anteromedial portal through the over-the-top position into the lateral incision. **D:** The graft is then brought through the over-the-top position. **E:** A clamp is placed from a proximal medial leg incision under the intermeniscal ligament. A groove is made in the anteromedial tibial epiphysis using a rasp. **F:** The graft is brought through the knee in the over-the-top position and under the intermeniscal ligament.

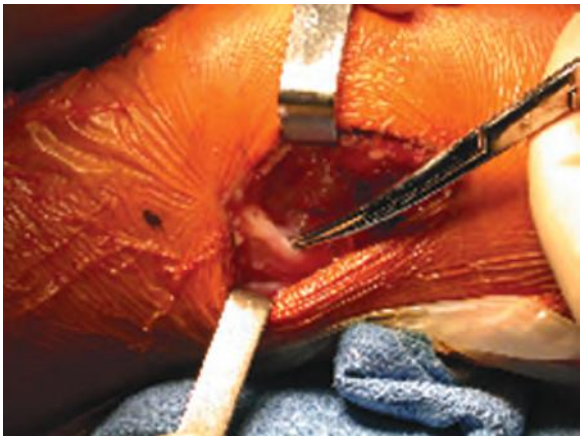
G



H

FIGURE 30-38 (*continued*) **G:** The graft is brought out the proximal medial leg incision. **H:** It is sutured to the intermuscular septum and periosteum of the lateral femoral condyle through the lateral knee incision and it is sutured in a trough to the periosteum of the proximal medial tibial metaphysis.

the upper thigh to release the tendon. The iliotibial band is left attached distally at Gerdy tubercle. Dissection is performed distally to separate the iliotibial band from the joint capsule and from the lateral patellar retinaculum (Fig. 30-38B). The free proximal end of the iliotibial band is then tubularized with a no. 2 high-tensile strength braided suture with a whip stitch construct.

Arthroscopy of the knee is then performed through standard anterolateral viewing and anteromedial working portals. Management of meniscal injury or chondral injury is performed if present. The ACL remnant is excised. The over-the-top position on the femur and the over-the-front position under the intermeniscal ligament are identified. Minimal notchplasty is performed to avoid iatrogenic injury to the perichondrial ring of the distal femoral physis which is in very close proximity to the over-the-top position.[42] The free end of the iliotibial band graft is brought through the over-the-top position using a full-length clamp (Fig. 30-38C) or a two-incision rear-entry guide (Fig. 30-37) and out the anteromedial portal (Fig. 30-38D).

A second incision of approximately 4.5 cm is made over the proximal medial tibia in the region of the pes anserinus insertion. Dissection is carried through the subcutaneous tissue to the periosteum. A curved clamp is advanced extraperiosteally from this incision proximally along the anterior proximal tibial cortex into the joint under the intermeniscal ligament (Fig. 30-38E). A small groove is made in the anteromedial proximal tibial epiphysis under the intermeniscal ligament using a curved rat-tail rasp to bring the tibial graft placement more posterior and allow for future intra-articular biologic tendon-to-bone healing. The free end of the graft is then brought through the joint (Fig. 30-38F), under the intermeniscal ligament in the anteromedial epiphyseal groove, and out the medial tibial incision (Fig. 30-38G). The graft is fixed on the femoral side through the lateral incision with the knee at 70 to 90 degrees flexion using figure-of-eight sutures to the periosteum of the LFC to effect an extra-articular reconstruction (Fig. 30-38H). The tibial side is then fixed through the medial incision with the knee flexed 30 degrees and tension applied to the graft. Within the medial tibial incision, the periosteum is divided and a trough is made in the proximal tibial medial metaphyseal cortex. The graft is sutured to the periosteum on either side of the trough with figure-of-eight sutures (Fig. 30-37).

Postoperatively, the patient is maintained touch-down weight bearing for 6 weeks. ROM may be progressed slowly in 2-week intervals but generally is limited from 0 to 90 degrees for the first 6 weeks, followed by progressive full ROM. A continuous passive motion (CPM) and cryotherapy are used for 2 weeks postoperatively. A protective postoperative brace is used for 6 weeks postoperatively, after which the rehabilitation regimen progresses to more advanced strengthening exercises from 6 to 12 weeks postoperatively, straight ahead running in the brace at around 3 months postoperatively, agility exercises around 4 to 5 months postoperatively, and return to sports around 6 months postoperatively, provided sufficient quad and hamstring strength have been achieved.

Skeletally Immature Adolescent Patient: Transphyseal ACL Reconstruction

For adolescent patients with growth remaining who have a complete ACL tear, we perform transphyseal ACL reconstruction with autogenous hamstrings tendons with fixation away from the physes.[226] The procedure is performed under general anesthesia as an ambulatory outpatient procedure, unless there are specific concerns about pain control or underlying medical conditions, in which case overnight observation can be pursued. Given our access to anesthesiologists skilled in regional anesthesia techniques, we favor use of a femoral nerve block for most patients to facilitate early pain control and initiation of range-of-motion exercises in the CPM. The patient is positioned supine on the operating table with a pneumatic tourniquet about the upper thigh which is not used routinely. Examination under anesthesia is performed to confirm ACL insufficiency.

First, the hamstrings tendons are harvested. If the diagnosis is in doubt, arthroscopy can be performed first to confirm ACL tear. A 3-cm incision is made over the palpable pes anserinus

FIGURE 30-39 Transphyseal reconstruction with autogenous hamstrings for adolescents with growth remaining. **A:** The gracilis and semitendinosus tendons are harvested through an incision over the proximal medial tibia. **B:** The tibial guide is used to drill the tibial tunnel. **C:** The transtibial over-the-top offset guide is used to drill the femoral tunnel.

tendons on the medial side of the upper tibia (Fig. 30-39A). Dissection is carried through skin to the sartorius fascia. Care is taken to protect superficial sensory nerves. The sartorius tendon is incised longitudinally and the gracilis and semitendinosus tendons are identified. The tendons are dissected free distally and their free ends whip-stitched with a no. 2 braided suture. They are dissected proximally using sharp and blunt dissection. Fibrous bands to the medial head of gastrocnemius should be identified and released. A closed tendon stripper is used to dissect the tendons free proximally. Alternatively, the tendons can be left attached distally, and an open tendon stripper used to release the tendons proximally. The tendons are taken to the back table, where excess muscle is removed and the remaining ends are whip-stitched with additional no. 2 sutures. The tendons are folded over a suspensory fixation button. The graft diameter is sized and the graft is placed under tension.

Arthroscopy of the knee is then performed through standard anterolateral viewing and anteromedial working portals. Management of meniscal injury or chondral injury is performed if present. The ACL remnant is excised. The over-the-top position on the femur is identified. Minimal notchplasty may be performed if notably stenotic. A tibial tunnel guide (set at 55 degrees) is used through the anteromedial portal (Fig. 30-39B). A guidewire is drilled through the hamstrings harvest incision into the posterior aspect of the ACL tibial footprint. The guidewire entry point on the tibia should be kept medial to avoid injury to the tibial tubercle apophysis. The guidewire is reamed with the appropriate diameter reamer. Excess soft tissue at the tibial tunnel is excised to avoid arthrofibrosis or a "cyclops lesion."[185] The transtibial over-the-top guide of the appropriate offset to ensure a 1- or 2-mm back wall is used to pass the femoral guide pin (Fig. 30-39C). Slight overdrilling to accommodate the diameter of the suspensory fixation button is completed, then full diameter reaming up to the lateral femoral cortex to accommodate the graft. The graft is then pulled into the joint using the tagging sutures placed on the slotted end of the guidewire, and graft is advanced into optimal position via the suspensory fixation system of choice. The knee is then extended to ensure no graft impingement. The knee is then cycled approximately 10 times with tension applied to the graft. The graft is fixed on the tibial side with the knee in 20 to 30 degrees of flexion, tension applied to the graft, and a posterior force placed on the tibia. On the tibial side, the graft is either fixed with a soft tissue interference screw if there is adequate tunnel distance below the physis to ensure metaphyseal placement of the screw or with a post and spiked washer. Fluoroscopy can be used to ensure that the fixation is away from the physes. Postoperative radiographs are shown in Figure 30-40.

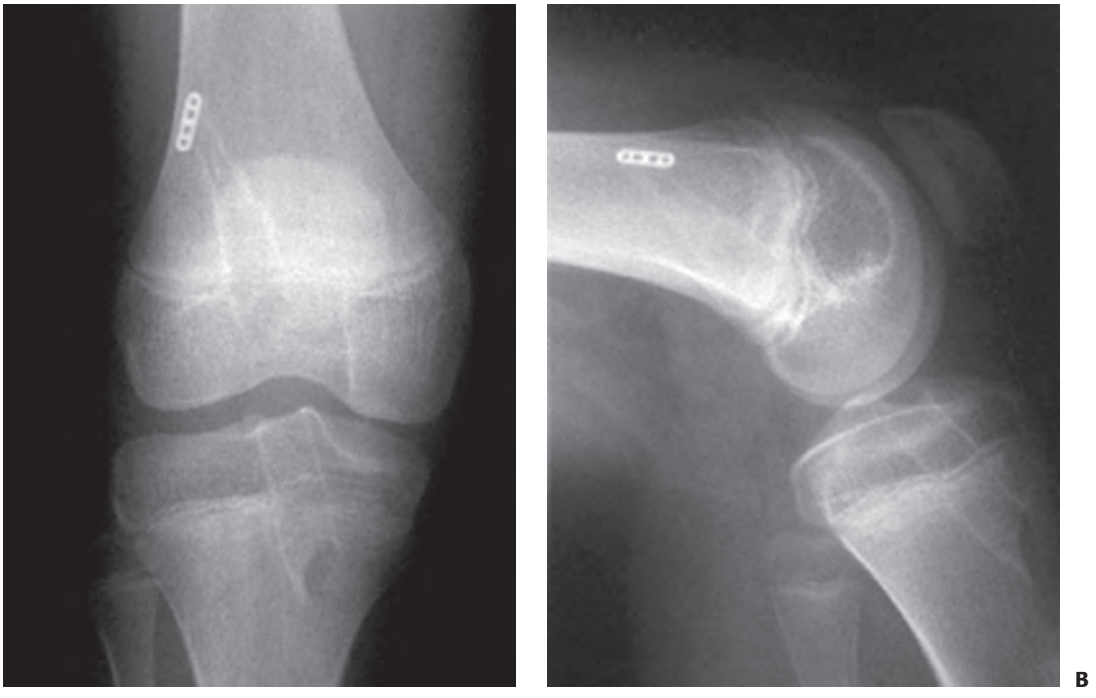


FIGURE 30-40 Transphyseal reconstruction with autogenous hamstrings for adolescents with growth remaining. Postoperative anteroposterior **(A)** and lateral **(B)** radiographs.

Postoperative Care

Postoperatively, the patient is maintained partial weight bearing for 2 weeks. ROM is limited from 0 to 90 degrees for the first 2 weeks, followed by progressive full ROM. A CPM from 0 to 90 degrees and cryotherapy are used for 2 weeks postoperatively. A protective postoperative brace is used for 6 weeks postoperatively.

Lateral Collateral Ligament

Grade III injuries of the LCL are extremely rare in children. Occasionally, the lateral capsular sign[414] is seen on radiographs obtained for evaluation of knee injury. Most often, the LCL is avulsed from the proximal fibular epiphysis, with or without a cortical fleck fragment, as proximal and midsubstance tears are uncommon. This injury is treated in the same manner as injury to the MCL. For isolated grade III injuries, a 6-week period of immobilization in a hinged knee brace is recommended. If ACL injury is associated with minor LCL injury, treatment is as described above for combined injuries of the MCL and ACL. In the setting of a complete LCL avulsion with complete ACL tear, repair of the LCL, in conjunction with ACL reconstruction is pursued, usually between 2 and 4 weeks, so as to optimize the healing potential of the collateral ligament without undue risk of arthrofibrosis.

Posterior Cruciate Ligament

In general, PCL injuries have traditionally been considered quite rare in children, with most case reports describing a bony avulsion injury.[143,337,385] Kocher et al.[224] recently described a series of 26 knees in patients 18 or younger with PCL injuries, 15 of which underwent surgery for gross instability secondary to either a partial tear (n = 1, 7%), a complete ligamentous tear (n = 4, 27%), or an osteochondral avulsion fragment from either the tibial or femoral footprint (n = 10, 67%). Of note, 53% of the operative cohort had a concomitant ligamentous injury, and 60% had concomitant meniscal tear. For skeletally immature patients, we prefer to perform arthroscopic-assisted suture repair of avulsions that occur directly from either footprint through small bony tunnels, with the limbs of suture tied over a cortical bone bridge, similar to the technique described above for tibial spine fractures. For skeletally mature adolescents, we will perform a PCL reconstruction with adult-based techniques, generally with an Achilles allograft.

Knee Dislocation

Acute dislocations of the knee are uncommon in children because the forces required to produce dislocation are more likely to fracture the distal femoral or proximal tibial epiphysis.[134] Acute knee dislocation usually involves major injuries of associated soft tissues and ligaments and often neurovascular injuries. Injuries typically occur in older skeletally mature adolescents from high-energy trauma, such as motor vehicle injuries, pedestrian versus motor vehicle injury, bicycle versus motor vehicle injury, trampoline injuries, and high-energy contact sports.

Adequate follow-up studies of acute knee dislocations in children younger than 10 years of age are few,[97] and most information has been obtained from reports of knee dislocations in adults. Because of the potential for associated vascular injury, acute knee dislocations in children may be emergent situations.

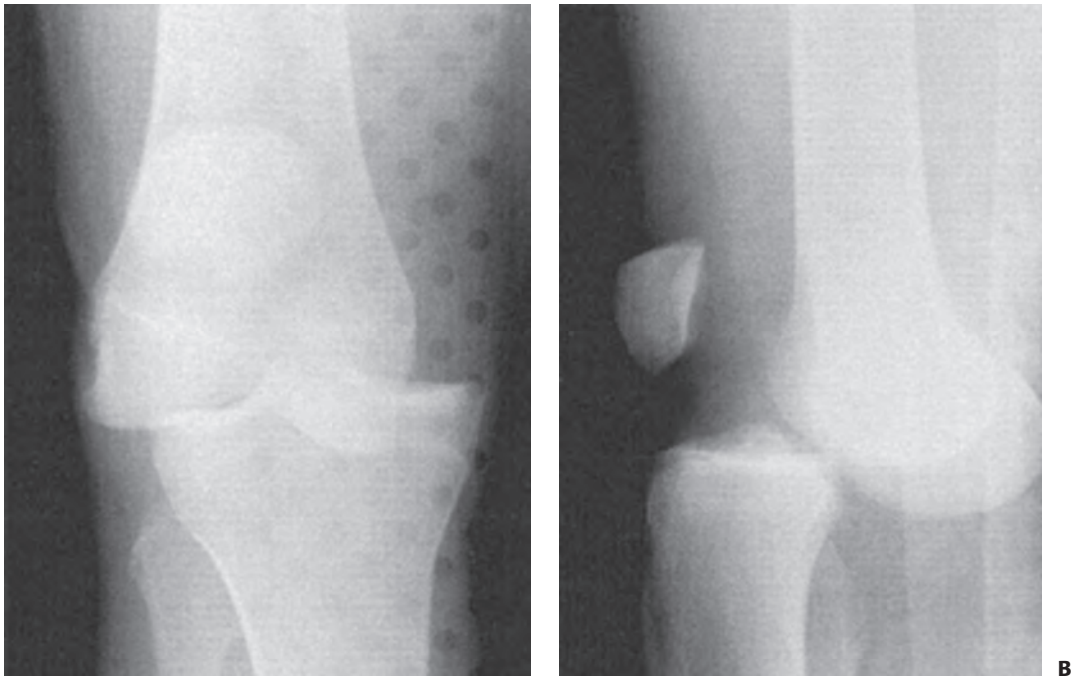

FIGURE 30-41 Dislocation of the knee. **A, B:** Anteromedial dislocation of the knee in a 14-year-old girl.

The dislocation causes obvious deformity about the knee. With anterior dislocation, the tibia is prominent in an abnormal anterior position (Fig. 30-41). With posterior dislocation, the femoral condyles are abnormally prominent anteriorly.

After the dislocation is reduced, the stability of the knee should be evaluated with gentle stress testing. For isolated anterior or posterior dislocations, the integrity of the collateral ligaments should be carefully evaluated. Some knees may spontaneously reduce after dislocation or reduce with manipulation of the leg for transport.

The neurovascular status of the extremity should be carefully evaluated both before and after reduction, especially the dorsalis pedis and posterior tibial pulses and peroneal nerve function. There is increasing evidence[283] supporting the diagnostic and prognostic value of the ankle-brachial index, which may be positive (<0.9) because of significant vascular injury, despite normal pulses and Doppler. Any abnormal vascular findings, either before or after reduction, require arteriography, which may be done in the operating room to facilitate rapid transition to repair. Popliteal artery laceration or intimal tear may occur in 20% to 35% of cases.[85,97,134,147,202] Abnormalities in the sensory or motor function of the foot and distribution of the peroneal nerve function should be noted. Peroneal nerve injury has been reported in 16% to 40% of cases.[85,97,134,147,202] MRI is usually performed to assess the integrity of the cruciate and collateral ligaments, the posterolateral and posteromedial corners, the menisci, and the articular surfaces.

Knee dislocation usually occurs with disruption of both cruciate ligaments. With direct anterior or posterior dislocation, the collateral ligaments and the soft tissues may be retained because the femoral condyles are stripped out of their capsular and collateral ligament attachments, and when reduced slip back inside them. Associated medial displacement is often accompanied by LCL disruption. Associated lateral displacement is often accompanied by MCL disruption. Knee dislocations in adolescents have been associated with tibial spine fractures, osteochondral fractures of the femur or tibia, meniscal injuries, and peroneal nerve injuries.[85]

Treatment of knee dislocations includes both acute and delayed reconstructive management. Acutely, the knee is reduced under anesthesia. If emergent vascular surgery is performed, fasciotomies are usually also performed. However, ligamentous reconstruction is typically delayed. The knee is braced with protected weight bearing and limited motion, or occasionally application of external fixation is warranted to protect the vascular repair.

Reconstruction may be delayed approximately 2 to 4 weeks after injury, depending on the pattern. Primary ligament repairs become more difficult after this period of time because of scarring and lack of definition of tissues. Reconstructions may be staged or performed in a single multi-ligamentous knee procedure. Surgery often combines arthroscopic and open techniques. General principles include ligament repair for collateral ligament injuries, ligament reconstruction for midsubstance cruciate ligament injuries, and meniscal repair. Allograft tissue is often used because of the multiligamentous nature of the injury and the need to minimize tourniquet time and any additional knee trauma that would come from graft harvesting. Postoperatively, prolonged immobilization should be avoided because of the substantial risk of stiffness after knee dislocation surgery. Limited motion in a hinged knee brace and protected weight bearing are utilized, followed by mobilization and strengthening.

Potential Pitfalls and Preventative Measures of Ligament Injuries

If a family wishes to pursue nonoperative treatment of complete ACL tears in children and adolescents, sufficient counseling must be performed so that the patient and the family understand the relative risks and benefits of nonoperative treatment versus ACL reconstruction. In such instances, compliance with bracing and activity restriction must be monitored. Careful regular follow-up is necessary to evaluate for instability episodes and further meniscal/chondral injury. Should further meniscal or chondral injury occurs, ACL reconstruction should be reemphasized, because of the risk of degenerative joint disease associated with injury episodes.

Pitfalls to avoid with the physeal-sparing iliotibial band reconstruction in prepubescents include harvesting a short graft insufficient to reach the medial tibial incision, difficulty passing the graft through the posterior joint capsule, and difficulty passing the graft under the intermeniscal ligament. Pitfalls to avoid with the transphyseal hamstrings reconstruction in adolescents with growth remaining include amputation of the hamstring grafts, poor tunnel placement, and graft impingement.

Based on the 15 cases of growth disturbance after ACL reconstruction in skeletally immature patients that we reported, we recommend careful attention to technical details during ACL reconstruction in skeletally immature patients, particularly the avoidance of fixation hardware across the lateral distal femoral epiphyseal plate.[223] Care should also be taken to avoid injury to the vulnerable tibial tubercle apophysis.[219,350] Given the cases of growth disturbances associated with transphyseal placement of patellar tendon graft bone blocks, we recommend the use of soft tissue grafts. Large tunnels should likely be avoided as likelihood of arrest is associated with greater violation of epiphyseal plate cross-sectional area. The reported cases and growing anecdotal evidence of genu valgum without arrest associated with lateral extra-articular tenodesis raise additional concerns about the effect of tension on physeal growth. Finally, care should be taken to avoid dissection or notching around the posterolateral aspect of the physis during over-the-top nonphyseal femoral placement to avoid potential injury to the very close perichondrial ring and subsequent deformity (Table 30-26).[219]

TABLE 30-26 Ligament Injuries

Potential Pitfalls and Preventions

Pitfall	Preventions
Pitfall #1: Growth disturbance	Prevention 1a: Failure to assess accurate bone age Prevention 1b: Use soft tissue graft Prevention 1c: Avoid transphyseal fixation/screw placement
Pitfall #2: ACL Retear	Prevention 2a: Ensure adequate postoperative rehab, optimization of dynamic knee stability Prevention 2b: Avoid allograft tissue

Treatment-Specific Outcomes for Ligament Injuries

The prognosis of ACL reconstruction depends on the surgical procedure. Several case series exist regarding ACL reconstruction in skeletally immature patients. However, most series are small and variably report the patients' skeletal age and growth remaining. Primary ligament repair[79,117] and extra-articular tenodesis alone[145,270] have had poor results in children and adolescents, similar to adults. Transphyseal reconstructions with tunnels that violate both the distal femoral and proximal tibial physes have been performed with hamstrings autograft, patellar tendon autograft, and allograft tissue.[13,23,29,109,128,265,270,354,358,367,399] These anatomic ACL reconstruction procedures have high success rates as in adult patients, however risk injury to the physis, particularly in prepubescent patients. However, those adolescents in the intermediate group – pubescent patients with still open growth plates – in whom transphyseal tunnels are used with "physeal-respecting" principles, are unlikely to have any risk of growth disturbance. In one follow-up outcome study of 61 knees in 59 skeletally immature Tanner stage 3 adolescents with growth remaining (mean chronologic age: 14.7 years old, range: 11.6 to 16.9 years old) who underwent transphyseal reconstruction with autogenous hamstrings graft and metaphyseal fixation, we found a revision rate of 3% with excellent functional outcome, return to competitive sports, and no cases of growth disturbance.[226] Partial transphyseal reconstructions violate only one physis with a tunnel through the proximal tibial physis and over-the-top positioning on the femur or a tunnel through the distal femoral physis with an epiphyseal tunnel in the tibia.[21,55,154] These procedures are also near anatomic with good clinical results, however the potential for growth disturbance exists.

A variety of physeal-sparing reconstructions have been described to avoid tunnels across either the distal femoral or proximal tibial physis.[18,64,98,153,206,281,315,389] In general these procedures are nonanatomic and may have some persistent knee laxity. However they avoid physeal violation, and rates of graft rupture, persistent or recurrent instability have generally been low. In a follow-up outcome study of 44 skeletally immature prepubescent children who were Tanner stage 1 or 2 (mean chronologic age: 10.3 years old; range: 3.6 to 14 years old) who underwent the physeal-sparing combined intra-articular and extra-articular ACL reconstruction technique using autogenous iliotibial band that we describe above, we found a revision ACL reconstruction rate of 4.5% with excellent functional outcome, return to competitive sports, and no cases of growth disturbance.[216,217] Anderson[18,19] described a more anatomic physeal-sparing reconstruction in prepubescent children by utilizing carefully placed epiphyseal femoral and tibial tunnels with an autogenous hamstrings graft and epiphyseal fixation (Fig. 30-42). In 12 skeletally immature patients with mean age 13.3 years old (SD: 1.4), he found excellent functional outcome without growth disturbance.

As interest in ACL-R techniques in skeletally immature patients has increased, however, the concept of transphyseal tunnel creation across open physes has remained controversial, as some authors contend that soft tissue graft placement

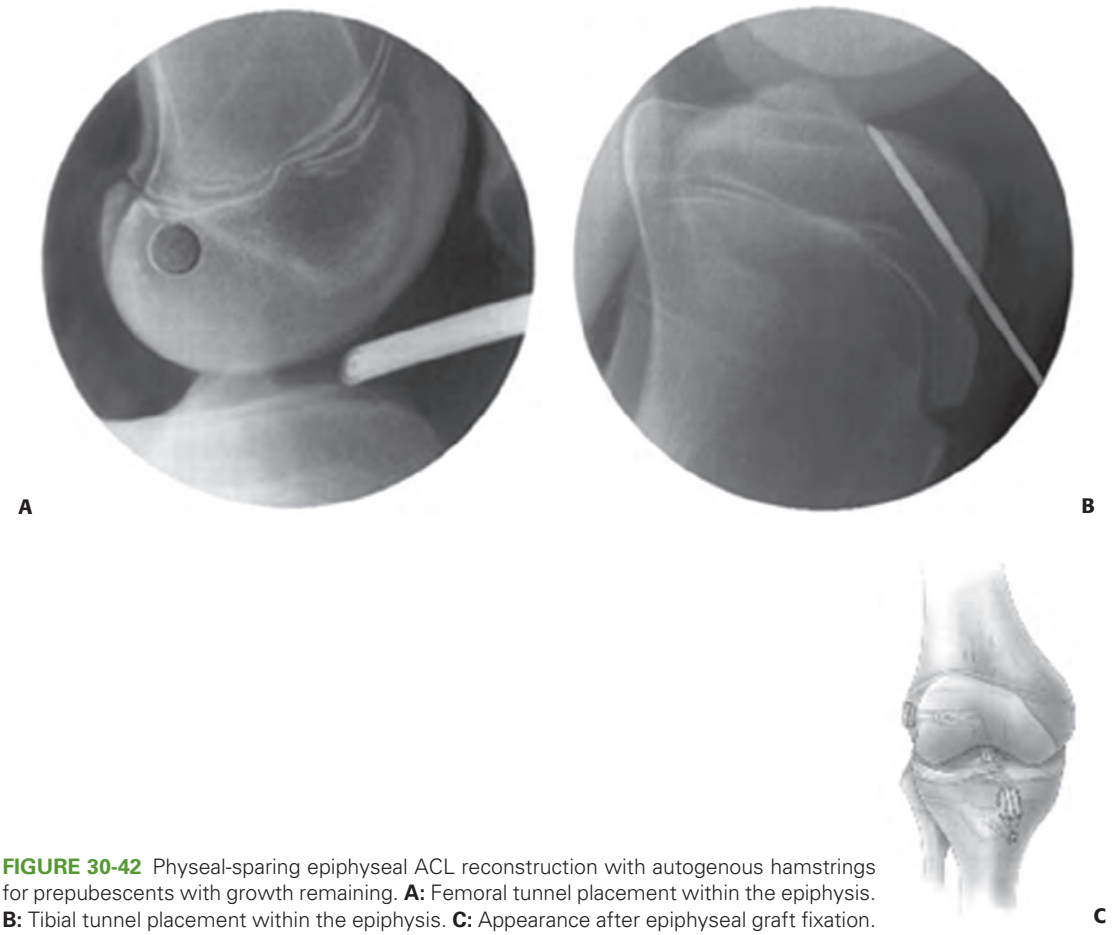

FIGURE 30-42 Physeal-sparing epiphyseal ACL reconstruction with autogenous hamstrings for prepubescents with growth remaining. **A:** Femoral tunnel placement within the epiphysis. **B:** Tibial tunnel placement within the epiphysis. **C:** Appearance after epiphyseal graft fixation.

without hardware across tunnels eliminates the risk of growth disturbance,[136,197,312,395] a notion supported by some animal models.[276] A recent European multicenter study compared 68 adolescent patients with a mean age of 12.5 years, 40 of whom were skeletally immature and underwent one of three different reconstruction techniques involving transphyseal tunnels. One of three different graft choices was used: 16 hamstring autografts, 12 quadriceps, and 12 fascia lata. No growth disturbances were seen at a mean follow-up of 33 months. One meta-analysis of 55 original studies assessed results in 935 patients with a median age of 13 at mean follow-up of 40 months, concluding that risk of angular deformity or leg length discrepancy was 1.8%, and was actually lower in transphyseal transosseous reconstruction than physeal-sparing transosseous reconstruction, perhaps because of the more parallel orientation of the tunnels relative to the physis in the latter technique.

Management of Expected Adverse Outcomes and Unexpected Complications In Ligament Injuries

Complications after ligament injury in children are similar to adults: Arthrofibrosis,[306] persistent instability, unrecognized concomitant injury, infection, graft failure, neurovascular injury, and donor site morbidity. A recent study of 933 ACL-R cases in children and adolescents with a mean age of 15 showed an arthrofibrosis rate of 8.3%, with older age (16 to 18 years), female age, concurrent meniscal repair, and patellar tendon autograft representing risk factors for arthrofibrosis requiring treatment. Although arthroscopic lysis of adhesions and manipulation under anesthesia were effective in improving ROM in this series of patients, 20% complained of some persistent pain at 6.3 years of mean follow-up.

In skeletally immature patients, despite continued controversy, growth disturbance can occur from iatrogenic physeal injury and remains important area of continued research (Table 30-27).

31 FRACTURES OF THE SHAFT OF THE TIBIA AND FIBULA

James F. Mooney, III and William L. Hennrikus

Epidemiology of Fractures of the Shaft of the Tibia and Fibula

Tibial and fibular fractures are the third most common pediatric long bone injuries (15%) after radial/ulnar and femoral fractures.[63,114,140,149] The prevalence of tibial fractures in both boys and girls has increased since 1950.[82] The average age of occurrence is 8 years, and the frequency of occurrence does not change significantly with age.[63] Seventy percent of pediatric tibial fractures are isolated injuries; ipsilateral fibular fractures occur with 30% of tibial fractures.[20,149,159] Fifty percent to 70% of tibial fractures occur in the distal third, and 19% to 39% in the middle third. The least commonly affected portion of the tibia is the proximal third, yet these may be the most problematic. Thirty-five percent of pediatric tibial fractures are oblique, 32% comminuted, 20% transverse, and 13% spiral.[140] Tibial fractures in children under 4 years of age usually are isolated spiral or short oblique fractures in the distal and the middle one-third of the bone. Most tibial fractures in older children and adolescents are in the distal third.

Rotational forces produce an oblique or a spiral fracture, and are responsible for approximately 81% of all tibial fractures that present without an associated fibular fracture.[12,20,51,102,140] Most tibial fractures in children of 4 to 14 years of age are the result of sporting or traffic accidents.[12,20,53,82,102,140] More than 50% of ipsilateral tibial and fibular fractures result from vehicular trauma. Most isolated fibular fractures result from a direct blow.[63,150] The tibia is the second most commonly fractured long bone in abused children. Approximately 11% to 26% of all abused children with a fracture have an injured tibia.[85,98,120] Nine percent

TABLE 31-1 Muscle Origins and Insertions on the Tibia

Muscle Origins and Insertions on the Tibia

Muscle	Origin or Insertion
Semimembranosus	Inserts on the inner tuberosity of the proximal tibia
Tibialis anterior, EDL, biceps femoris	Attach to lateral condyle of the tibia
Sartorius, gracilis, semitendinosus	Insert on the proximal medial surface of the tibial metaphysis
Tibialis anterior	Arises on the lateral surface of the tibial diaphysis
Popliteus, soleus, FDL, tibialis posterior	Attaches to the posterior diaphysis of the tibia
Patellar tendon	Inserts into the tibial tubercle
Tensor fascia lata	Attaches to Gerdy tubercle, the lateral aspect of the proximal tibial metaphysis
Secondary slip of the tensor fascia lata	Occasionally inserts into the tibial tubercle

of pediatric tibial fractures are open. Concomitant fractures of the ankle and foot are the most common injuries associated with fractures of the tibia and fibula, followed by humeral, femoral, and radial/ulnar fractures.[15] In a 1994 report, the average Injury Severity Score of a child with a tibial fracture was 10 (range, 0 to 45) with an average hospital stay of 6.5 days (range, 1 to 50 days).[15] There have been no updates of this information in the recent English literature; however, it would seem certain that the current average hospital stay is significantly less.

Classification of Fractures of the Shaft of the Tibia and Fibula

Nonphyseal injuries of the tibia and the fibula can be classified into three major categories based on the combination of bones fractured and the location of the injuries. These include fractures of the proximal or distal tibial metaphysis, and those involving the diaphyseal region.

Surgical Anatomy of Fractures of the Shaft of the Tibia and Fibula

Bony Structure of the Tibia and Fibula

The tibia ("flute") is the second largest bone in the body. There are two concave condyles at the proximal aspect of the tibia. The medial condyle is larger, deeper, and narrower than the lateral condyle. An elevated process, the tibial tubercle, located between the two condyles, is the site of attachment of the patellar tendon. The shaft of the tibia is prismoid, with a broad proximal extent that decreases in size until the distal third, where it gradually increases again in size. The tibial crest is prominent medially from the tibial tubercle to the tibial plafond and is subcutaneous without the overlying musculature.[51]

The tibia develops from three ossification centers: One in the shaft and one in each epiphysis. The tibial diaphysis ossifies at 7 weeks of gestation and expands both proximally and distally. The proximal epiphyseal center appears shortly after birth and unites with the shaft between 14 and 16 years of age. The distal epiphyseal ossification center appears in the second year of life, and the distal tibial physis closes between 14 and 15 years of age. Additional ossification centers are found occasionally in the medial malleolus and in the tibial tubercle.[51]

The tibia articulates with the condyles of the femur proximally, with the fibula at the knee and the ankle, and with the talus distally.[49] Twelve muscles have either their origin or insertion on the tibia (Table 31-1). The fibula articulates with the tibia and the talus. The fibular diaphysis ossifies at about

TABLE 31-2 Muscle Origins and Insertions on the Fibula

Muscle Insertions and Origins on the Fibula

Muscle	Origin or Insertion
Soleus, FHL	Arise from the posterior aspect of the fibular diaphysis
Peroneus longus, peroneus brevis	Arise from the lateral aspect of the fibular diaphysis
Biceps femoris, soleus, peroneus longus	Attach to the head of the fibula
Extensor digitorum longus, peroneus tertius, EHL	Attach to the anterior surface of the fibular shaft
Tibialis posterior	Arise from the medial aspect of the fibular diaphysis

8 weeks of gestation. The distal epiphysis is visible at 2 years of age, and the proximal secondary ossification center at 4 years. The distal fibular physis closes at approximately 16 years; the proximal physis closes later, between the ages of 15 and 18 years.[51] Nine muscles have either their origin or insertion on the fibula (Table 31-2).[51]

Vascular Anatomy of Fractures of the Shaft of the Tibia and Fibula

The popliteal artery descends vertically between the condyles of the femur and passes between the medial and lateral heads of the gastrocnemius muscle. It ends at the distal border of the popliteus muscle, where it divides into the anterior and posterior tibial arteries. The anterior tibial artery passes between the tibia and the fibula over the proximal aspect of the intraosseous membrane, and enters the anterior compartment of the lower leg. The posterior tibial artery divides several centimeters distal to this point, giving rise to the peroneal artery (Fig. 31-1).[51]

Neural Anatomy of the Tibia and Fibula

The posterior tibial nerve runs adjacent and posterior to the popliteal artery in the popliteal fossa, and then enters the deep posterior compartment of the leg. This nerve provides innervation to the muscles of the deep posterior compartment and sensation to the plantar aspect of the foot. The common peroneal nerve passes laterally around the proximal neck of the fibula. It divides into the deep and superficial branches, and then passes into the anterior and the lateral compartments of the lower leg, respectively. Each branch innervates the muscles within its compartment. The deep peroneal nerve provides sensation to the first web space. The superficial branch is responsible for sensation across the dorsal and lateral aspects of the foot.

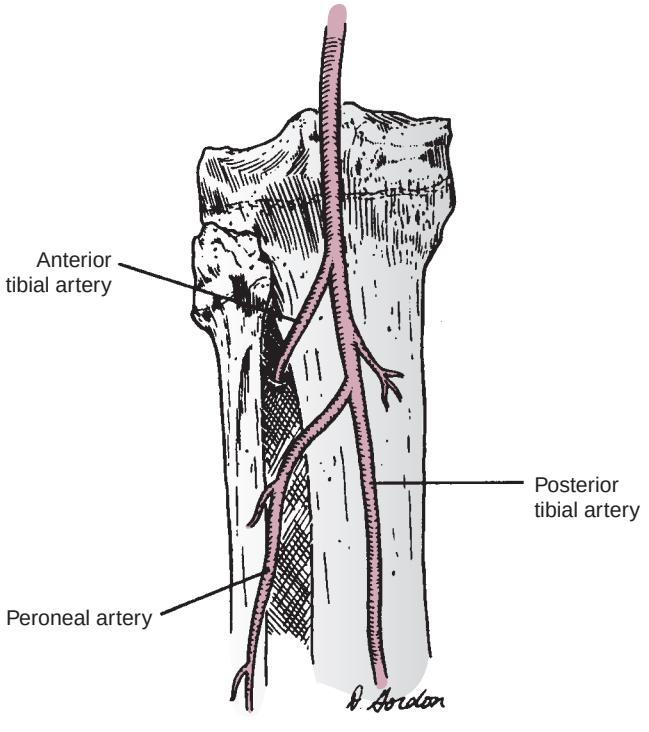

FIGURE 31-1 Vascular anatomy of the proximal tibia.

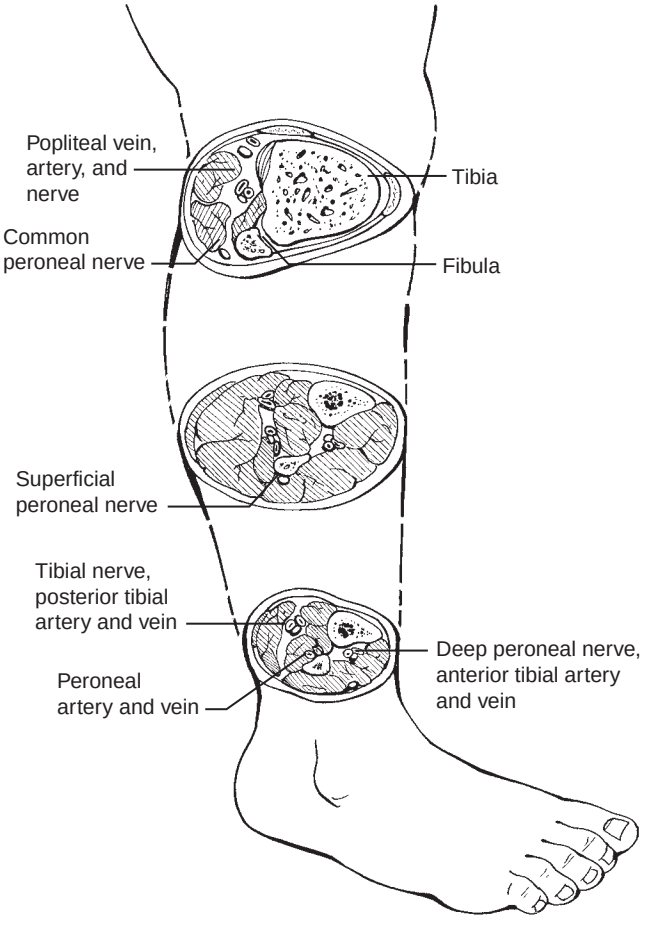

FIGURE 31-2 Fibroosseous compartments of the leg.

Fascial Compartments

The lower leg has four fascial compartments (Fig. 31-2). The anterior compartment contains the extensor digitorum longus, the extensor hallucis longus, and the tibialis anterior muscles; the anterior tibial artery and deep peroneal nerve run in this compartment. The lateral compartment contains the peroneus longus and brevis muscles. The superficial peroneal nerve runs through this compartment. The superficial posterior compartment contains the soleus and gastrocnemius muscles. The deep posterior compartment contains the flexor digitorum longus, the flexor hallucis longus, and the tibialis posterior muscles. The posterior tibial artery, peroneal artery, and posterior tibial nerve run in this compartment.[51]

Fractures of the Proximal Tibial Metaphysis

The peak incidence for proximal tibia metaphyseal fractures is between the ages of 3 and 6 years. The most common mechanism of injury is a low energy force applied to the lateral aspect

of the extended knee generating a valgus moment. The cortex of the medial tibial metaphysis fails in tension, often resulting in an incomplete greenstick fracture. Compression (torus) and complete fractures can occur in this area, but are less common. The fibula generally escapes injury, although plastic deformation may occur.[4,6,23,24,53,75,79,84,116,134,142,148,153,158,163,164]

Children with proximal tibia metaphyseal fractures present with pain, swelling, and tenderness in the region of the fracture. Motion of the knee causes moderate pain, and in most cases the child will not walk. Crepitance is seldom identified on physical examination, especially if the fracture is incomplete.[4,6,23,24,53,75,79,84,116,134,142,148,153,158,164] Radiographs usually show a complete or incomplete fracture of the proximal tibial metaphysis. The medial aspect of the fracture often is widened, producing a valgus deformity.

A possible sequela of a proximal tibial metaphyseal fracture is development of a progressive valgus deformity (Fig. 31-3). In 1953, Cozen[24] was the first to report valgus deformity following a proximal tibial metaphyseal fracture. He described four patients with valgus deformities after fractures in this area. In two cases, the valgus was present at the time of cast removal, suggesting loss of reduction as a potential cause of the deformity. In the other two patients the tibia valga developed gradually during subsequent growth of the patient. Since that time, many other investigators[6,23,52,53,75,79,94,116,149,153,158] have reported development of tibia valga, even in fractures without any significant malalignment at the time of initial treatment. Nenopoulos reported a 90% incidence of progressive tibial valgus deformity in patients with minimally or nondisplaced proximal tibia metaphyseal fractures.[113]

Many theories have been proposed to explain the development of a valgus deformity after a proximal tibial metaphyseal fracture (Table 31-3). In some cases, proximal tibia valga can be the result of an inadequate reduction or the loss of satisfactory reduction in the weeks following the manipulation.[142,163] Lehner and Dubas[94] suggested that an expanding medial callus

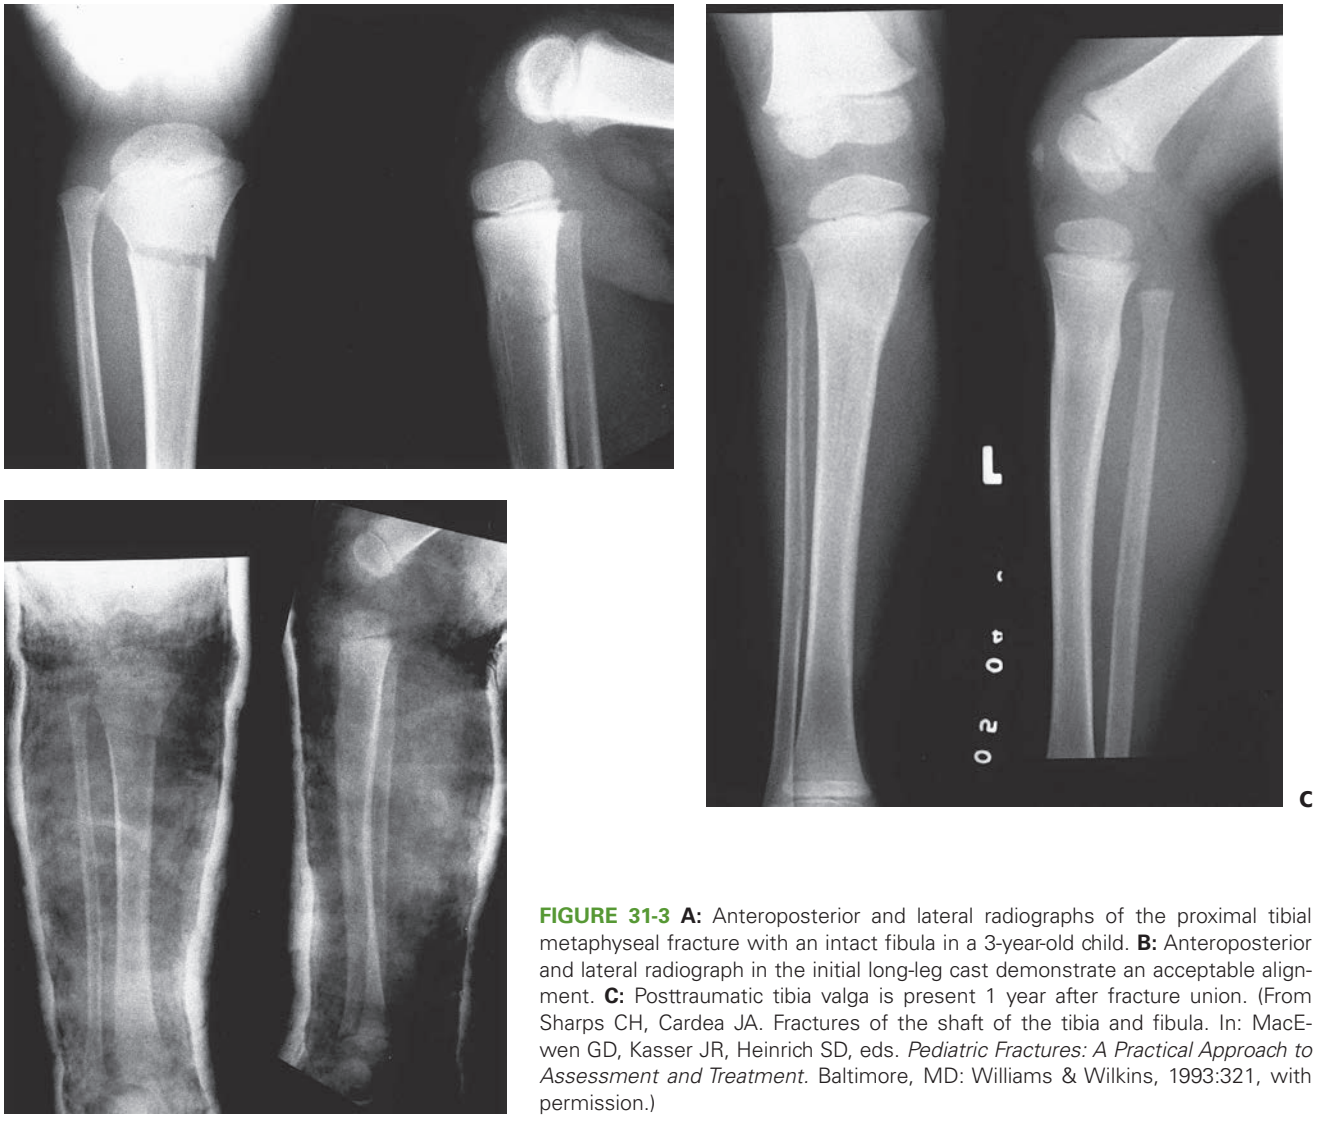

FIGURE 31-3 **A:** Anteroposterior and lateral radiographs of the proximal tibial metaphyseal fracture with an intact fibula in a 3-year-old child. **B:** Anteroposterior and lateral radiograph in the initial long-leg cast demonstrate an acceptable alignment. **C:** Posttraumatic tibia valga is present 1 year after fracture union. (From Sharps CH, Cardea JA. Fractures of the shaft of the tibia and fibula. Inadequate reduction
Interposed soft tissue (medial collateral ligament/pes anserinus)
Loss of tethering effect of pes anserinus
Tethering effect of fibula
Early weight bearing producing developmental valgus

produced a valgus deformity, whereas Goff[47] and Keret et al.[84] believed that the lateral aspect of the proximal tibial physis was injured at the time of the initial fracture (Salter–Harris type V injury), resulting in asymmetric growth. Taylor[153] believed that the valgus deformity was secondary to postfracture stimulation of the tibial physis without a corresponding stimulation of the fibular physis. Pollen[122] suggested that premature weight bearing produced an angular deformity of the fracture before union. Rooker and Salter[130] believed that the periosteum was trapped in the medial aspect of the fracture, producing an increase in medial physeal growth and a developmental valgus deformity.

Another theory postulates that the progressive valgus deformity occurs secondary to an increase in vascular flow to the medial proximal tibial physis after fracture, producing an asymmetric physeal response that causes increased medial growth.[79] Support for this theory includes quantitative bone scans performed months after proximal tibia metaphyseal fractures that have shown increased tracer uptake in the medial aspect of the physis compared with the lateral aspect.[163] Ogden[116] identified an increase in the collateral geniculate vascularity to the medial proximal tibia in a cadaver angiography study of a 5-year-old child with a previous fracture. This further supports the theory that medial overgrowth occurs secondary to an increase in the blood flow supplying the medial aspect of the proximal tibia following injury.

Recent studies suggest that the postfracture tibia valga is the result of an injury to the pes anserinus tendon plate. It is suggested that the pes anserinus tethers the medial aspect of the physis, just as the fibula appears to tether the lateral aspect of the proximal tibial physis. Multiple authors believe that the proximal tibial fracture disrupts the tendon plate, producing a loss of the tethering effect. This, then, may lead to medial physeal overgrowth and a functional hemichondrodiastasis (physeal lengthening).[6,27,29,158,164] Exploration of the fracture, followed by removal and repair of the infolded periosteum that forms the foundation of the pes anserinus tendon plate, has been suggested as an approach that may decrease the risk of a developmental valgus deformity. This theory is supported by the work of Houghton and Rooker, who demonstrated that division of the periosteum around the medial half of the proximal tibia in rabbits induced a valgus deformity. They hypothesized that the increasing valgus angulation was because of a mechanical release of the restraints that the periosteum imposes on activity of the physis.[71]

Developmental tibia valga has been reported to occur after simple excision of a bone graft from the proximal tibial metaphysis,[153] proximal tibial osteotomy,[4,75] and osteomyelitis of the proximal tibial metaphysis.[4,153] Tibia valga deformity can occur after healing of a nondisplaced fracture, and can recur after corrective tibial osteotomy, further supporting the premise that asymmetric physeal growth is the cause of most posttraumatic tibia valga deformities.[163]

The natural history of postfracture proximal tibia valga is one of slow progression of the deformity, followed by gradual restoration of normal alignment over time. The deformity usually is apparent by 5 months post injury, and may progress for up to 18 to 24 months. Zionts and MacEwen[164] followed seven children with progressive valgus deformities of the tibia for an average of 39 months after metaphyseal fractures (Fig. 31-4). Most of the deformity developed during the first year after injury. The tibia continued to angulate at a slower rate for up to 17 months after injury. Six of their seven patients had spontaneous clinical corrections. At follow-up, all children had less than a 10-degree deformity.

Robert et al.[127] analyzed 25 patients with proximal tibial fractures. Twelve children with a greenstick or a complete fracture developed valgus deformities, whereas no child with a torus fracture developed a deformity. Altered growth at the distal tibial physis appeared to compensate for the proximal tibia valga in three children. Corrective osteotomies were performed in four children. The valgus deformity recurred in two of these four children, and two had iatrogenic compartment syndromes. If surgical correction is deemed necessary, it is important to remember that tibial osteotomy is not a benign procedure, and has a risk of significant complications. Gradual correction of the deformity with a proximal medial tibial hemiepiphysiodesis may be more appropriate, and certainly safer, treatment for recalcitrant postfracture tibia valga in a child with significant growth remaining.[12,117,127,133,148,153]

Author's Preferred Treatment

Nondisplaced proximal tibia metaphyseal fractures should be stabilized in a long-leg cast with the knee in 5 to 10 degrees of flexion and with a varus mold (Fig. 31-5). Displaced proximal tibial fractures require closed reduction with general anesthesia in the operating room or in an emergency room setting with adequate sedation. An anatomic reduction or slight varus positioning should be verified radiographically. If an acceptable closed reduction cannot be obtained, open reduction is indicated. Open reduction includes removal of any soft tissue interposed within the fracture site and repair of the pes anserinus plate if ruptured. After reduction, either closed or open, the child is placed into a long-leg, straight-knee cast with a varus mold, and the alignment is checked once again radiographically.

FIGURE 31-5 Anteroposterior and lateral radiographs of the proximal tibia and distal femur in a child who sustained a nondisplaced fracture of the proximal tibial and fibular metaphysis. The knee is casted in extension which facilitates accurate measurements of fracture alignment.

In rare instances, percutaneous fixation with smooth pins, or an external fixator, may be required (Fig. 31-6).

When the child initially presents for treatment of a tibia fracture at risk of developing genu valgum, it is crucial that the possibility of this unpredictable postfracture problem is discussed with the family. Regular follow-up visits are required to verify maintenance of the reduction. If there is loss of reduction, cast wedging or repeat reduction efforts may be indicated. The cast is removed approximately 6 weeks after injury. The child may return to normal activities after recovery of normal knee and ankle range of motion. Long-term follow-up with forewarning to the family of the possibility of progressive tibial deformity is mandatory.

A child with a posttraumatic valgus deformity is followed until adequate spontaneous correction occurs. This may take 18 to 36 months. Surgical intervention may be indicated in patients more than 18 months post injury with a mechanical axis deviation greater than 10 degrees as a result of tibial valgus. Tibial osteotomies are not recommended in patients

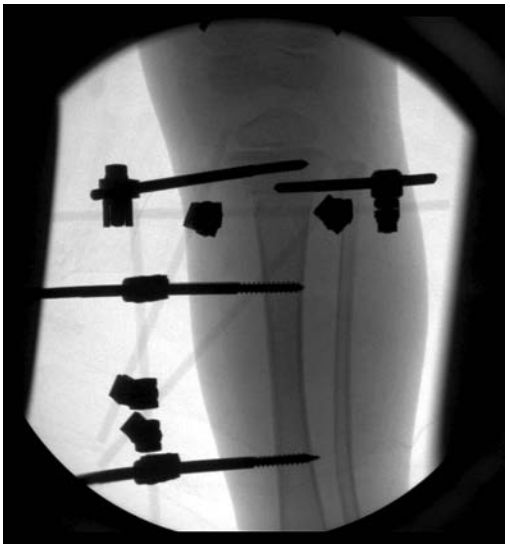

FIGURE 31-6 Anteroposterior radiograph of a 3-year-old female with a severe closed head injury, ipsilateral femur, and proximal tibia metaphyseal fractures. The tibia fracture was stabilized with a modified uniplanar external fixator.

with postfracture valgus if they have significant growth remaining (Fig. 31-7). Instead, a proximal tibial medial hemiepiphysiodesis can restore alignment without many of the risks of osteotomy. Hemiepiphysiodesis may be accomplished through a variety of methods utilizing staples, screws, or tension band plate and screw devices (Fig. 31-8A,B).[104,148] Bracing does not alter the natural history of posttraumatic tibia valga and are not recommended.[74] Because the valgus deformity usually is associated with some element of overgrowth, a contralateral shoe lift of appropriate size may make the deformity appear less apparent.

Diaphyseal Fractures of the Tibia and Fibula

Seventy percent of pediatric tibial fractures are isolated injuries.[140,159] The fractures can be incomplete (torus, greenstick) or complete. Most tibial fractures in children under 11 years of age are caused by a torsional force and occur in the distal third of the tibial diaphysis. These oblique and spiral fractures occur when the body rotates with the foot in a fixed position on the ground. The fracture line generally starts in the distal anteromedial aspect of the bone and propagates proximally in a posterolateral direction. If there is not an associated fibula fracture, the intact fibula prevents significant shortening of the tibia; however, varus angulation develops in approximately 60% of isolated tibial fractures within the first 2 weeks after injury (Fig. 31-9).[161] In these cases, forces generated by contraction of the long flexor muscles of the lower leg are converted into an angular moment by the intact fibula producing varus malalignment (Fig. 31-10A). Isolated transverse and comminuted fractures of the tibia most commonly are caused

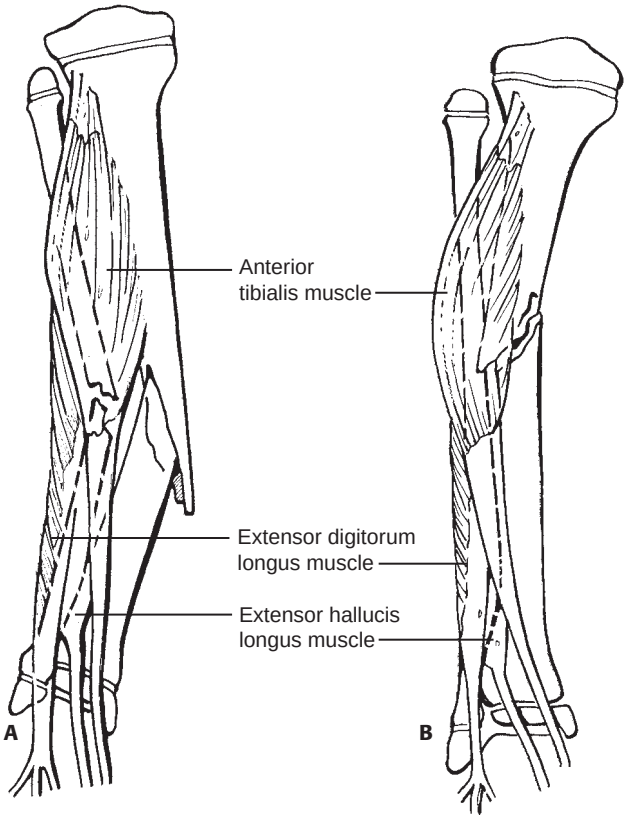

FIGURE 31-10 **A:** Fractures involving the middle third of the tibia and fibula may shift into a valgus alignment because of the activity of the muscles in the anterior and the lateral compartments of the lower leg. **B:** Fracture of the middle tibia without an associated fibular fracture tend to shift into varus because of the force created by the anterior compartment musculature of the lower leg and the tethering effect of the intact fibula.

by direct trauma. Transverse fractures of the tibia with an intact fibula generally are stable, and seldom displace significantly.[14,80] Comminuted or segmental tibial fractures with an intact fibula tend to drift into varus alignment similar to oblique and spiral fractures.[14,80,161]

Approximately 30% of pediatric tibial diaphyseal fractures have an associated fibular fracture.[142,159,161] The fibular fracture may be either complete or incomplete with some element of plastic deformation. A tibial diaphyseal fracture with an associated displaced fracture of the fibula often results in valgus malalignment because of the action of the muscles in the anterolateral aspect of the leg (see Figs. 31-10B and 31-11). Any fibular injury must be identified and corrected to minimize the risk of recurrence of angulation after reduction (Fig. 31-12A–C).

An isolated fracture of the fibular shaft is rare in children, and results most commonly from a direct blow to the lateral aspect of the leg (Fig. 31-13). Most isolated fractures of the fibular shaft are nondisplaced and heal quickly with symptomatic care and immobilization (Fig. 31-14).

Signs and Symptoms of Fractures of the Tibia and Fibula

The signs and symptoms associated with tibial and fibular diaphyseal fractures vary with the severity of the injury and the mechanism by which it was produced. Pain is the most common symptom. Children with fractures of the tibia or fibula have swelling at the fracture site, and the area is tender to palpation. Almost all children with any type of tibia fracture will refuse to ambulate on the injured limb. If there is significant injury to the periosteum and fracture displacement, a bony defect or prominence may be palpable. Immediate neurologic impairment is rare except with fibular neck fractures causing injury to the common peroneal nerve.

Although arterial disruption is uncommon in pediatric tibial and fibular diaphyseal fractures, both the dorsalis pedis and the

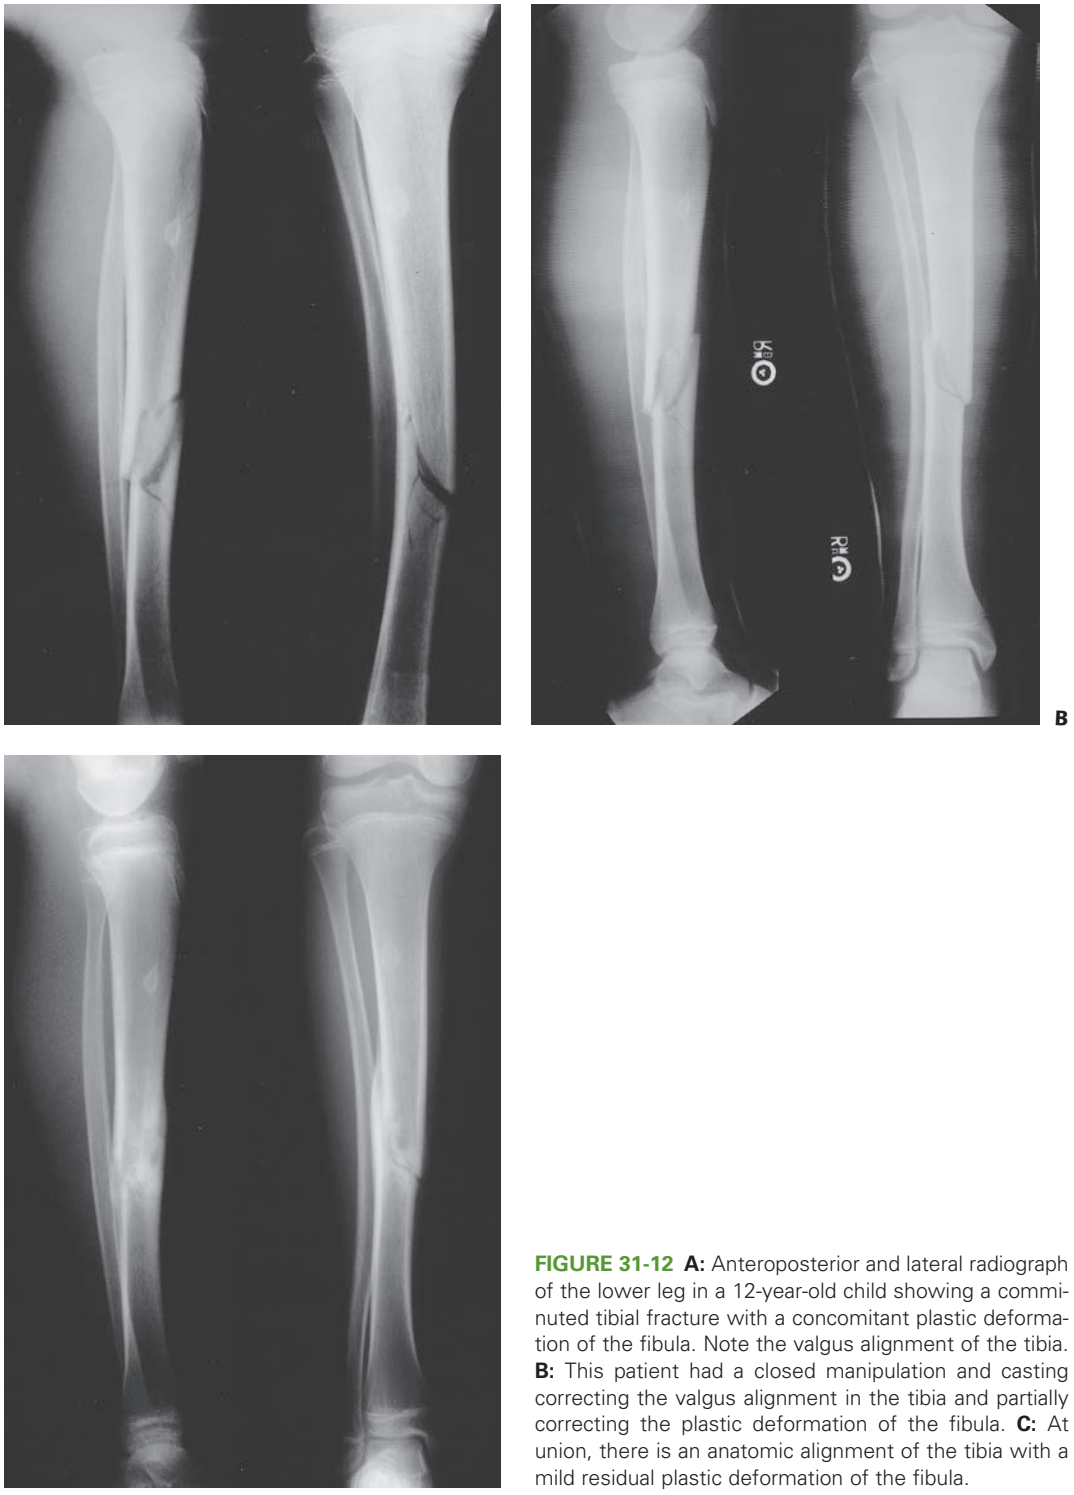

FIGURE 31-12 **A:** Anteroposterior and lateral radiograph of the lower leg in a 12-year-old child showing a comminuted tibial fracture with a concomitant plastic deformation of the fibula. Note the valgus alignment of the tibia. **B:** This patient had a closed manipulation and casting correcting the valgus alignment in the tibia and partially correcting the plastic deformation of the fibula. **C:** At union, there is an anatomic alignment of the tibia with a mild residual plastic deformation of the fibula.

posterior tibial pulses should be assessed, and a Doppler examination should be performed if they are not palpable. Capillary refill, sensation, and pain response patterns, particularly pain with passive motion, should be monitored. Concomitant soft tissue injuries must be evaluated carefully. Open fractures must be treated aggressively to reduce the risk of late complications.

Radiographic Evaluation of Fractures of the Tibia and Fibula

Anteroposterior and lateral radiographs that include the knee and ankle joints (Fig. 31-15) should be obtained whenever a tibial and/or fibular shaft fracture is/are suspected. Though

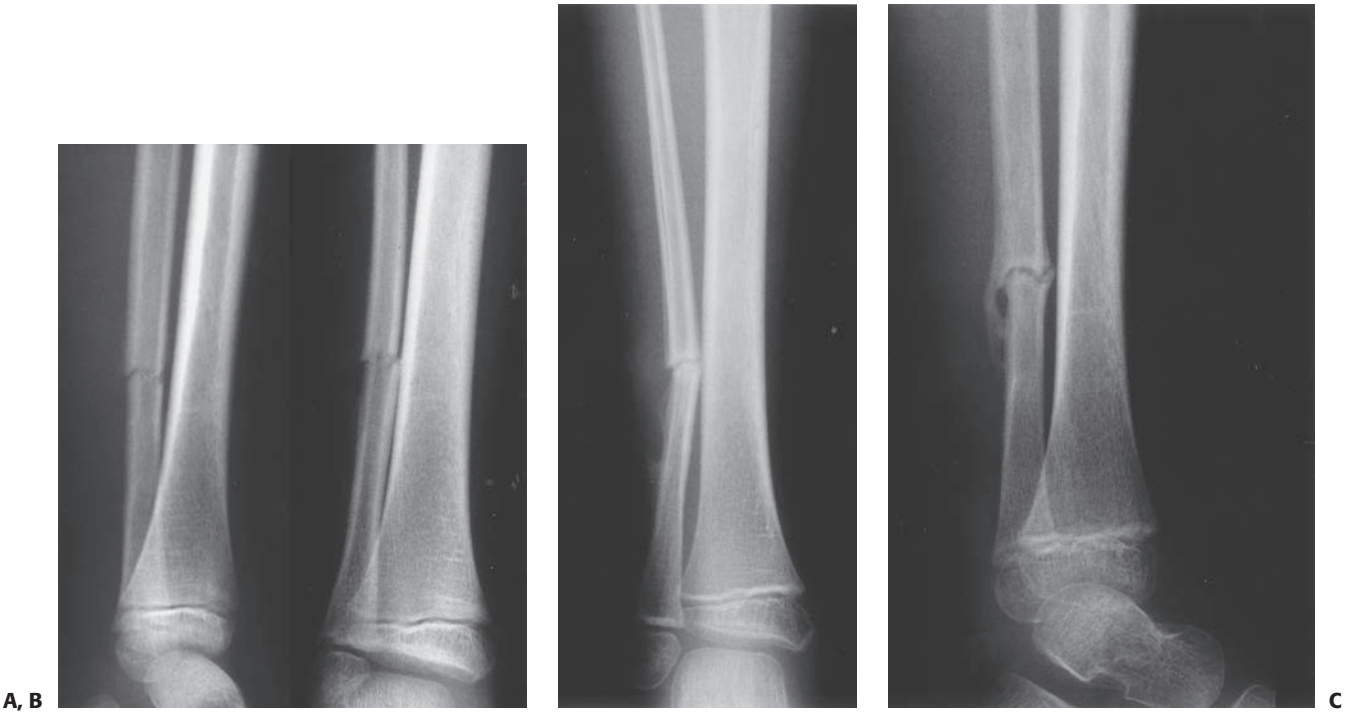

FIGURE 31-13 **A:** Anteroposterior and lateral radiograph of a 7-year-old child with an isolated open fibula fracture secondary to a bite by a pit bull. **B:** Anteroposterior radiograph 6 weeks after injury demonstrating consolidation at the fracture site. **C:** Lateral radiograph showing bridging callus 6 weeks after injury.

FIGURE 31-15 **A:** Spiral fracture of the distal tibia. The fracture is difficult to identify on the anteroposterior radiograph. **B:** The fracture is easily identified on the lateral radiograph.

uncommon, tibial shaft fractures may occur in combination with transitional fractures involving the distal tibial metaphysis, and as such, close evaluation of the ankle radiographs is essential (Fig. 31-16A–D). Comparison views of the uninvolved leg normally are not indicated. Children with suspected fractures not apparent on the initial radiographs may need to be treated with supportive splinting or casting to control symptoms associated with the injuries. Technetium radionuclide scans obtained at least 3 days after injury are useful to identify fractures that are unapparent on radiographs; however, in most cases, patients with clinical findings consistent with a fracture are treated as though a fracture is present. Periosteal new bone formation evident on plain radiographs obtained 10 to 14 days after injury confirms the diagnosis in most cases.

Treatment for Fractures of the Tibia and Fibula

Cast Immobilization

The vast majority of uncomplicated pediatric diaphyseal tibial shaft factures, with/or without associated fibular shaft fractures,

FIGURE 31-16 **A:** Anteroposterior radiograph of an adolescent patient with a tibial shaft fracture. **B–D:** Anteroposterior, lateral, and mortise views of the ankle demonstrate an associated triplane fracture.

can be treated by closed manipulation and casting.[67] Fractures of the tibial shaft without concomitant fibular fracture may develop varus malalignment. Valgus angulation and shortening can present a significant problem in children who have complete fractures of both the tibia and the fibula.

Displaced fractures should be managed with reduction under appropriate sedation, using fluoroscopic assistance when available. This can be done in the emergency room or in the operating room depending on the availability of sedation and fluoroscopy. A reduction plan should be made before manipulation based on review of the deforming forces associated with the specific fracture pattern. A short-leg cast is applied with the foot in the appropriate position with either a varus or valgus mold, depending on the fracture pattern and alignment. The cast material is taken to the inferior aspect of the patella anteriorly and to a point 2 cm distal to the popliteal flexion crease posteriorly. It may be best to use plaster for the initial cast because of its ability to mold to the contour of the leg and the ease with which it can be manipulated while setting. The alignment of the fracture is reassessed after the short-leg cast has been applied. The cast is then extended to the proximal thigh with the knee flexed. Most children with complete, unstable diaphyseal tibial fractures are placed into a bent-knee (45 degree) long-leg cast to control rotation at the fracture site and to assist in maintaining non–weight-bearing status during the initial healing phase. The child's ankle initially may be left in some plantar flexion (20 degrees for fractures of the middle and distal thirds, 10 degrees for fractures of the proximal third) to prevent generation of apex posterior angulation (recurvatum) at the fracture site. In a child, there is little risk of developing a permanent equinus contracture, as any initial plantar flexion can be corrected at a cast change once the fracture becomes more stable.

The alignment of the fracture should be checked weekly during the first 3 weeks after the cast has been applied. Muscle atrophy and a reduction in tissue edema may cause the fracture to drift into unacceptable alignment. Cast wedging may be performed in an attempt to improve alignment, and in some cases a second cast application with remanipulation of the fracture under general anesthesia may be necessary to obtain acceptable alignment. Acceptable position is somewhat controversial and varies based on patient age as well as location and direction of the deformity.[37] Remodeling of angular deformity is limited in the tibia. (Table 31-4) No absolute numbers can be given, but the following general guidelines may be beneficial in decision making:

- Varus and valgus deformity in the upper and midshaft tibia remodel slowly, if at all. Up to 10 degrees of deformity can be accepted in patients less than 8 years old, and a little more than 5 degrees of angulation in those older than 8 years of age.
- Moderate translation of the shaft of the tibia in a young child is acceptable, whereas in an adolescent, at least 50% apposition is recommended.
- Up to 10 degrees of apex anterior angulation may be tolerated, although remodeling is slow.

TABLE 31-4 Indications for Surgical Stabilization

Diaphyseal Tibia Fractures

Surgical Indications	
Absolute	**Relative**
Failure to attain or maintain adequate closed reduction	Open fracture Fracture associated with significant soft tissue injury Fracture associated with compartment syndrome Floating knee Fracture associated with closed head injury and/or multitrauma

- Minimal apex posterior angulation (recurvatum) can be accepted, as this forces the knee into extension at heel strike during gait.
- Up to 1 cm of shortening is acceptable.

Cast Wedging

Patients with a loss of fracture reduction and unacceptable angulation may benefit from remanipulation of the fracture. This can be attempted in the clinic setting through the use of cast "wedging." Fracture alignment in the cast can be altered by creation of a closing wedge, an opening wedge, or a combination of wedges. Unfortunately, this technique is labor intensive and has become something of a lost art. The location for wedge placement is determined by evaluating the child's leg radiographically, and marking the midpoint of the tibial fracture on the outside of the cast. If fluoroscopy is not available, a series of paper clips are placed at 2-cm intervals on the cast and anteroposterior and lateral radiographs are then taken. The paper clips define the location of the fracture and the location most suitable for cast manipulation.

Closing Wedge Technique. A wedge of cast material is removed which encompasses 90% of the circumference of the leg with its base over the apex of the fracture. The exact width of the wedge is proportional to the amount of correction desired and therefore varies in each patient, and can be determined geometrically utilizing the amount of desired angular correction and the width of the cast in the location of the wedge. The cast is left intact opposite the apex of the fracture in the plane of proposed correction. The edges of the cast are brought together to correct the angulation at the fracture. This wedging technique may produce mild fracture shortening, and care must be taken to avoid pinching the skin at the site of cast reapproximation. Theoretically, the closing wedge technique may increase exterior constrictive pressure, as the total volume of the cast is reduced. In light of these concerns, it may be preferable to use the opening wedge technique whenever possible.

Opening Wedge Technique. The side of the cast opposite the apex of the fracture is cut perpendicular to the long axis of the bone. A small segment of the cast is left intact directly over the apex of the malaligned fracture (~25%). A cast spreader

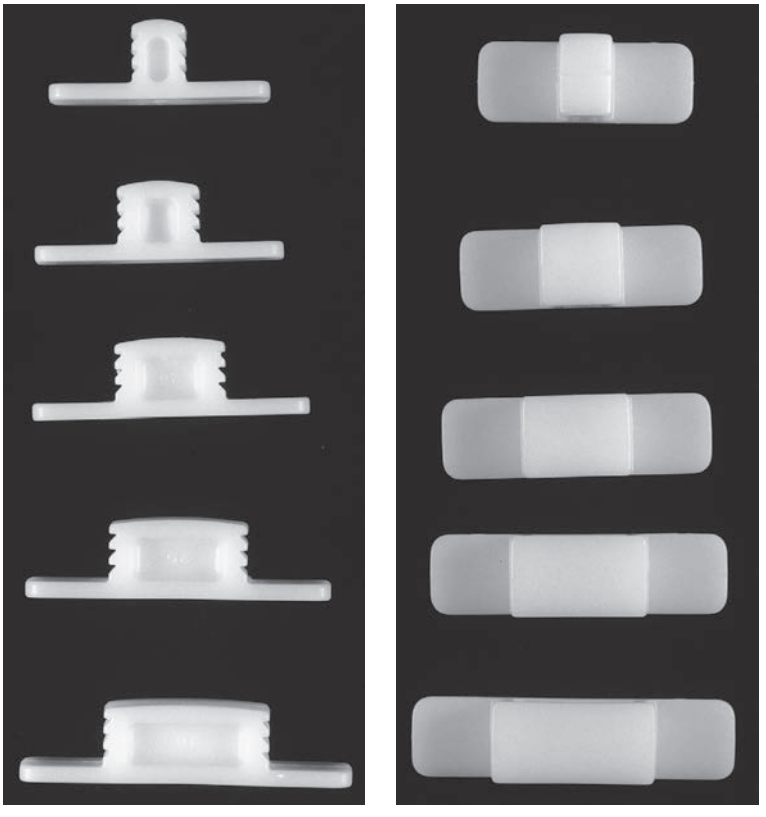

FIGURE 31-17 **A,B:** Blocks used to hold casts open after wedge corrections of malaligned fractures. The wings on the blocks prevent the blocks from migrating toward the skin.

is used to "jack" or spread the cast open. Plastic shims (Fig. 31-17) or a stack of tongue depressors of the appropriate size are placed into the open segment to maintain the distraction of the site, and the cast is wrapped with new casting material after the alignment has been assessed radiographically (Fig. 31-18). When using any wedging material, it is imperative that the edges do not protrude into the cast padding or cause pressure on the underlying skin. This wedging technique effectively lengthens the tibia while correcting the malalignment (Figs. 31-19A–D).

After any cast wedging, especially early after injury when there may be residual leg swelling, it is recommended to observe the patient for a short period of time to be certain that signs and symptoms of compartment syndrome do not develop. Cast wedging may be somewhat painful for a brief period of time, but that discomfort should subside. The family should be alerted that if increasing pain develops after cast wedging, the patient should return urgently for evaluation.

Operative Treatment

Historically, operative treatment has been recommended infrequently for tibial shaft fractures in children. Weber et al.[159] reported that only 29 (4.5%) of 638 pediatric tibial fractures in their study required surgical intervention. However, in the last decade there has been an increasing interest in surgical stabilization, particularly for unstable closed tibial shaft fractures as well as open fractures or those with associated soft tissue injuries. The current indications for operative treatment include open fractures, most fractures with an associated compartment syndrome, some fractures in children with spasticity (head

injury or cerebral palsy), fractures in which open treatment facilitates nursing care (floating knee, multiple long bone fractures, multiple system injuries), and unstable fractures in which adequate alignment cannot be either attained or maintained (Table 31-5).[5,11,26,38,41,44,54,72,83] Common methods of fixation for tibial fractures requiring operative treatment include percutaneous metallic pins, bioabsorbable pins,[8] external fixation,[30,110,138] and plates with screws; the use of flexible intramedullary titanium or stainless steel nails or, in some cases, intramedullary Steinmann pins, is becoming increasingly common.[45,48,50,91,110,115,124,132,155] Kubiak et al.[91] compared the use of titanium flexible nails with external fixation in a mixed group of patients with open and closed tibial fractures. Although the

TABLE 31-5 Acceptable Alignment of a Pediatric Diaphyseal Tibial Fracture

Patient Age	<8 Years	≥8 Years
Valgus	5 degrees	5 degrees
Varus	10 degrees	5 degrees
Angulation anterior	10 degrees	5 degrees
Posterior angulation	5 degrees	0 degrees
Shortening	10 mm	5 mm
Rotation	5 degrees	5 degrees

groups were not matched and were reviewed retrospectively, the authors reported a clinically significant decrease in time to union with titanium nails compared to external fixation. Gordon et al.[49] retrospectively reviewed 60 pediatric patients with open or closed tibial shaft fractures managed with flexible nails. They found an 18% complication rate; the most common complication was delayed union. In this study, those patients with delayed time to union tended to be older (mean age 14.1 years) versus the mean age of the study population (11.7 years). Srivastava et al.[146] reviewed a mixed group of 24 patients with open or closed tibial shaft fractures managed with titanium nails. All patients went on to union at an average of 20.4 weeks. The total complication rate was 20%, including two patients with mild sagittal plane malunions at final follow-up.

Open Tibial Fractures

Most open tibial fractures in children involve the diaphyseal region, and are treated similarly to comparable injuries in adults. In addition, these fractures and associated soft tissue injuries are classified utilizing the Gustilo and Anderson System (Fig. 31-20).[57] Most open fractures of the tibia result from high-velocity/high-energy injuries.[19,129]

Treatment Principles for Open Tibial Fractures

Management principles for open tibial fractures include:

- Timely debridement, irrigation, and initiation of appropriate antibiotic therapy[121]
- Fracture reduction followed by stabilization with either internal or external devices
- Intraoperative angiography (after rapid fracture stabilization) and management of possible elevation of compartment pressures when sufficiency of the vascular perfusion is unclear
- Open wound treatment with loose gauze packing or other methods[30,108]
- Staged debridement of necrotic soft tissue and bone in the operating room as needed until the wounds are ready for closure or coverage.
- Delayed closure or application of a split thickness skin graft when possible; use of delayed local or free vascularized flaps as needed
- Cancellous bone grafting (autologous or allograft) for bone defects or delayed union after maturation of soft tissue coverage

These principles are similar to those utilized in adult patients. However, there is evidence that differences exist between pediatric and adult fracture patients. As such, the principles of treatment for open tibial fractures in adults are altered somewhat by the unique characteristics of the pediatric skeleton. These differences include the following.[5,22,26,48,56,145]

- Comparable soft tissue and bony injuries heal more reliably in children than in adults, particularly in patients less than 11 years of age.[78]
- Devitalized uncontaminated bone that can be covered with soft tissue can incorporate into the fracture callus, and in some cases may be left within the wound.
- External fixation can be maintained, when necessary, until fracture consolidation with fewer concerns about delayed or nonunions than in adults.
- Retained periosteum can regenerate bone, even after segmental bone loss in younger children.
- After thorough irrigation and debridement, many uncontaminated grade I open wounds may be closed primarily without an increased risk of infection.

Buckley et al.[16] reported 41 children with 42 open fractures of the tibia (18 grade II, 6 grade IIIA, 4 grade IIIB, and 2 grade IIIC). Twenty-two (52%) of the fractures were comminuted. All wounds were irrigated and debrided, and antibiotics were administered for at least 48 hours. Twenty-two fractures were treated with reduction and cast application, and 20 with external fixation. Three children had early infections, and one of these patients developed late osteomyelitis. All infections had resolved at final reported follow-up. The average time to union was 5 months (range, 2 to 21 months). The time to union was directly proportional to the severity of the soft tissue injury. Fracture pattern also had an effect on time to union. Segmental bone loss, infection, and the use of an external fixation device were associated with delayed union. Four angular malunions of more than 10 degrees occurred, three of which spontaneously corrected. Four children had more than 1 cm of overgrowth.

In a series of 40 open lower extremity diaphyseal fractures in 35 children, Cramer et al.[25] reported 22 tibial fractures (1 grade I, 10 grade II, and 11 grade III). External fixation was used for 15 fractures, casting for five, and internal fixation for two. Two children required early amputation, four required soft tissue flap coverage, and 13 children had skin grafts. Two additional children with initially closed injuries required fasciotomy for compartment syndrome and were included in the group of open tibial fractures. Ten of the 24 injuries healed within 24 weeks. Five children required bone grafting before healing.

Hope and Cole[69] reported the results of open tibial fractures in 92 children (22 grade I, 51 grade II, and 19 grade III). Irrigation and debridement were performed on admission, intravenous (IV) antibiotics were given for 48 hours, and tetanus prophylaxis was administered when necessary. Primary closure was performed in 51 children, and 41 traumatic wounds were left open. Eighteen soft tissue injuries healed secondarily, and 23 required either a split thickness skin graft or a tissue flap. Sixty-five (71%) of the 92 fractures were reduced and immobilized in an above-the-knee plaster cast. External fixation was used for unstable fractures, injuries with significant soft tissue loss, and fractures in patients with multiple system injuries. Early complications of open tibial fractures in these children were comparable with those in adults. Primary closure did not increase the risk of infection if the wound was small and uncontaminated. At reevaluation 1.5 to 9.8 years after injury, the authors found that 50% of the patients complained of pain at the fracture site; 23% reported decreased abilities to participate in sports, joint stiffness, and cosmetic defects; and 64% had leg length inequalities.

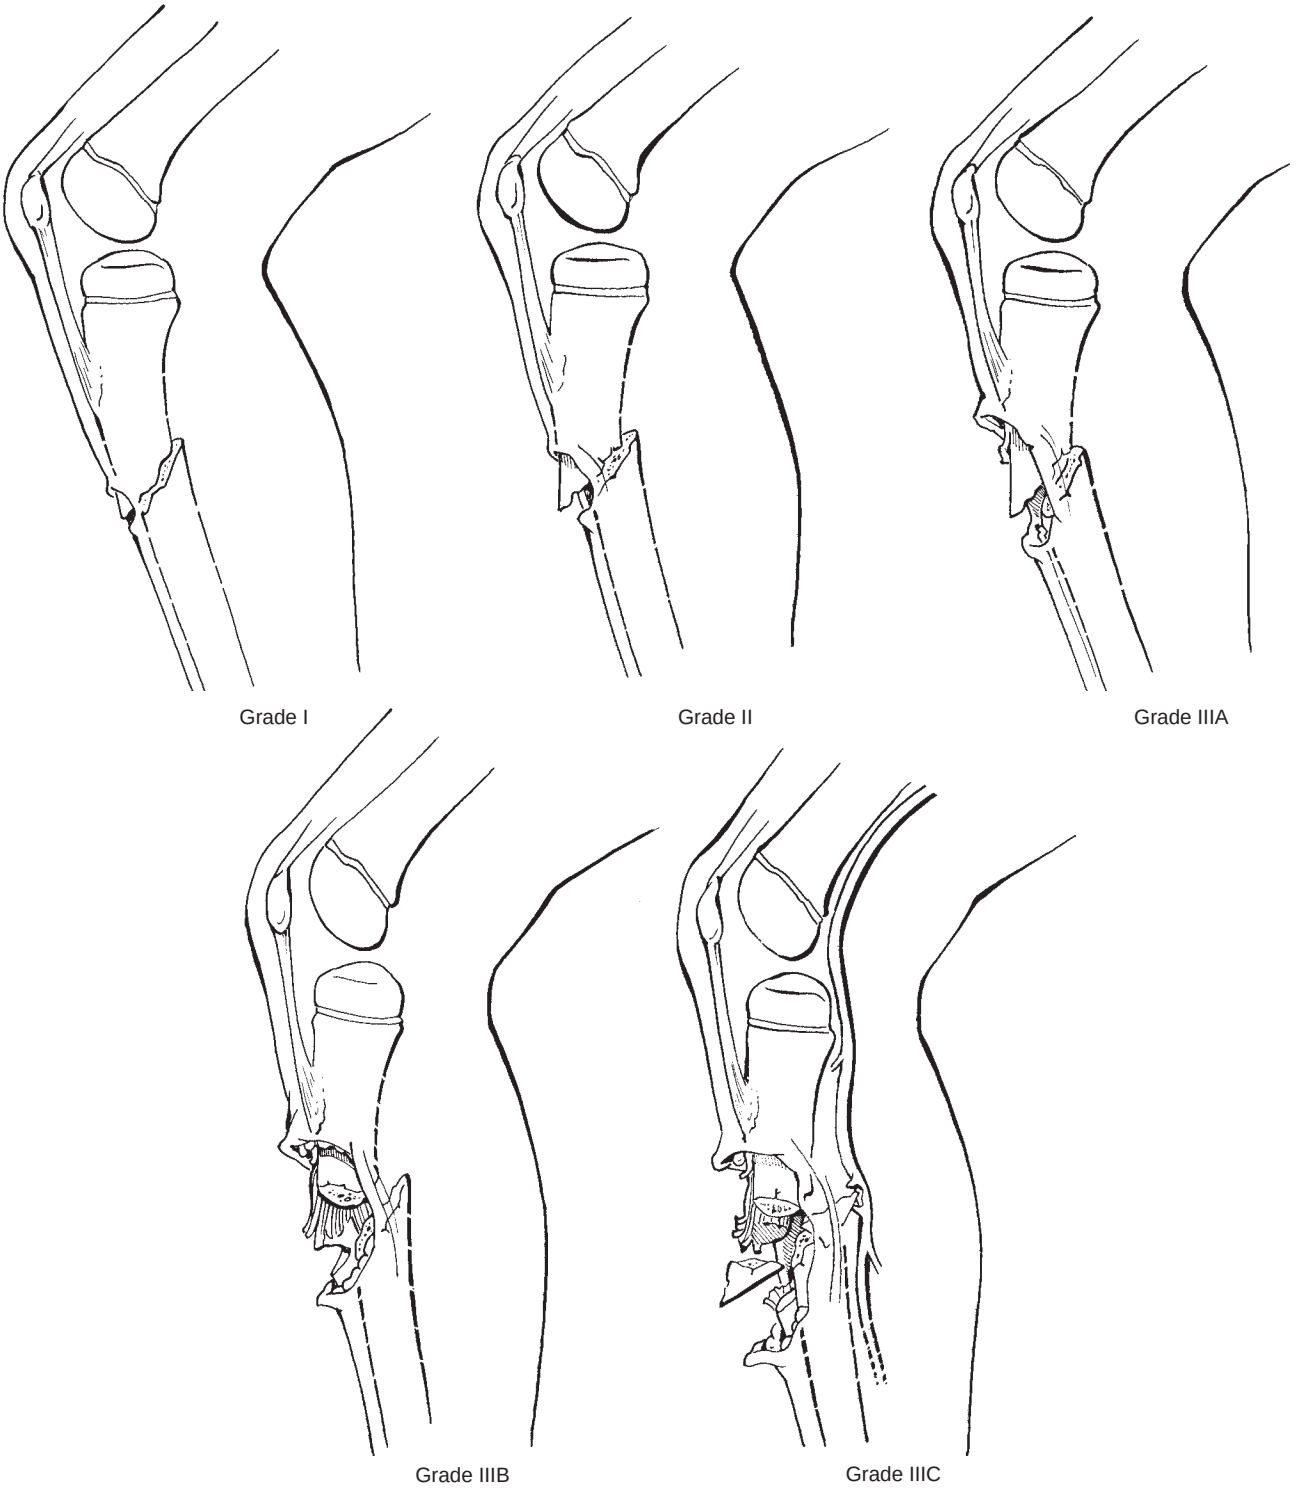

FIGURE 31-20 Gustilo and Anderson classification of open fractures. **Grade I:** The skin wound measures less than 1 cm long, usually from within, with little or no skin contusion. **Grade II:** The skin wound measures more than 1 cm long, with skin and soft tissue contusion but no loss of muscle or bone. **Grade IIIA:** There is a large severe skin wound with extensive soft tissue contusion, muscle crushing or loss, and severe periosteal stripping. **Grade IIIB:** Like grade IIIA but with bone loss and nerve or tendon injury. **Grade IIIC:** Like grade IIIA or B with associated vascular injury. (From Alonso JE. The initial management of the injured child: Musculoskeletal injuries. In: MacEwen GD, Kasser J, Heinrich SD, eds. *Pediatric Fractures: A Practical Approach to Assessment and Treatment*. Baltimore, MD: Williams & Wilkins; 1993:32, with permission.)

Levy et al.[96] found comparable late sequelae after open tibial fractures in children, including a 25% prevalence of nightmares surrounding the events of the accident. Blasier and Barnes[10] and Song et al.[145] found that most late complications associated with pediatric open tibial fractures occurred in children over the age 12 and 11 years, respectively.

Skaggs et al.[141] reviewed their experience with open tibial fractures and found no increased incidence of infection in patients initially debrided more than 6 hours after injury when compared to children treated similarly less than 6 hours after fracture. However, it appears that fractures with more severe soft tissue injuries were more likely to receive more expedient treatment, thereby complicating the analysis. This apparent selection bias in some ways limits the overall usefulness of the study.

There is some published data that provides concerns about the use of external fixators in tibia fractures in pediatric patients. Myers et al.[110] reviewed 31 consecutive high-energy tibia fractures in children treated with external fixation. Nineteen of the fractures were open, with mean follow-up of 15 months. The authors found a high rate of complications in this patient population, including delayed union (particularly in patients of at least 12 years of age), malunion, leg-length discrepancy, and pin tract infections. However, Monsell et al. reported no nonunions and no complications in a group of 10 pediatric patients with open diaphyseal tibia fractures managed with a programmable circular external fixator. In addition, they had no patients with deep infection, nor were there any cases of refracture after fixator removal.[107] To date, there are no published studies which directly and prospectively compare the use of flexible intramedullary nails with external fixation for open pediatric tibial shaft fractures.

Overall, a recent systematic review of the literature demonstrates that the philosophy of treatment on pediatric open tibia fracture has remained essentially unchanged over the last 30 years.[3] The authors found a strong correlation between Gustilo–Anderson classification and the incidence of infection, and that the fracture union rate was influenced negatively by the extent of the associated soft tissue injury.[3]

Open Tibia Fractures—Associated Issues

Soft Tissue Closure

Expedient coverage of an open tibial fracture that cannot be closed primarily reduces the morbidity associated with this injury.[46,86,109] Delayed primary closure can be performed if the wound is clean and does not involve significant skin and muscle loss. In such cases, it is imperative that closure under tension is avoided. Other options include a wide variety of local rotational or pedicled myocutaneous flaps. Vascularized free flaps are viable options in cases for which no other method of closure is appropriate.

Most of the literature addressing the subject of soft tissue coverage for open tibia fractures involves adult patients, and as such, must be extrapolated to pediatric fracture management.[58] In a series of 168 open tibial fractures with late secondary wound closure, Small and Mollan[143] found increased complications with early pedicled or rotational fasciocutaneous flaps and late free flaps, but no complications with fasciocutaneous flaps created more than 1 month after injury. Complications associated with free flaps were decreased if the procedure was performed within 7 days of injury. Hallock et al.[60] reviewed 11 free flaps for coverage in pediatric patients. They reported a 91% success rate, which was similar to their rate in adults. However, they reported a significant rate of complications at both the donor and the recipient sites.[60] Rinker et al.[126] reported their experience with free vascularized muscle transfers for traumatic lower extremity trauma in pediatric patients performed between 1992 and 2002. At their institution, 26 patients received 28 flaps during that period. The latissimus dorsi was used most commonly as the origin of the transfer. Twelve of the flaps were performed for coverage of open tibia fractures. There was a 62% overall complication rate, with infection and partial skin-graft loss being the most common problems. The authors concluded that patients receiving free flap coverage within 7 days of injury had a statistically significant lower complication rate than those covered later.[126]

Ostermann et al. reported 115 grade II and 239 grade III tibial fractures in a series of 1,085 open fractures. All patients were treated with early broad-spectrum antibiotics, serial debridements, and the application of an external fixation device. Tobramycin-impregnated polymethylmethacrylate was placed into the wounds, and dressings were changed every 48 to 72 hours until the wounds spontaneously closed, underwent delayed primary closure, or received flap coverage. No infections occurred in grade I fractures; approximately 3% of grade II fractures and 8% of grade III fractures developed infections. No infections occurred in patients who had the wound closed within 8 days of injury. On the basis of these and other analyses, it is now recommended that wounds associated with open tibial fractures be covered within 7 days of injury whenever possible.[18,19,21,82,118,156]

Multiple authors have reported on the use of subatmospheric pressure dressings in the management of soft tissue injuries in pediatric patients. Dedmond et al.[30] reviewed the Wake Forest experience with negative pressure dressings in pediatric patients with type III open tibia fractures. They found that use of this device decreased the need for free tissue transfer to obtain coverage in this patient population. When focusing on the rate of infection, Halvorson et al.[62] found that use of negative pressure dressings in the management of open fractures, including open tibia fractures, appeared to be safe and effective when compared to historical controls.

Vascular Injuries

Vascular injuries have been reported in approximately 5% of children with open tibial fractures. Arterial injuries associated with open tibial fractures include those to the popliteal artery, the posterior tibial artery, the anterior tibial artery, and the peroneal artery. Complications are common in patients with open tibial fractures and associated vascular injuries. Amputation rates as high as 79% have been reported with grade IIIC fractures. Isolated anterior tibial and peroneal artery injuries generally have a good prognosis, whereas injuries of the posterior tibial and popliteal arteries have much less satisfactory

prognoses, and more commonly require vascular repairs or reconstructions.[1,59,68] Patients with open tibial fractures and vascular disruption may benefit from temporary arterial, and possibly venous, shunting before the bony reconstruction is performed. This approach allows meticulous debridement and repair of the fracture, while maintaining limb perfusion until the primary vascular repair is performed.[44] However, in most cases, rapid fracture stabilization, usually utilizing external fixation, can be performed before vascular reconstruction without the need for temporary shunts.

Author's Preferred Treatment

Closed Diaphyseal Fractures

Simple pediatric diaphyseal tibial fractures unite quickly in most cases, and cast immobilization can be used without affecting the long-term range of motion of the knee and the ankle. A bent-knee, long-leg cast provides maximal comfort to the patient and controls rotation of the fracture fragments. The cast should be bivalved initially to limit the effect of any swelling. Children with nondisplaced or minimally displaced fractures that do not require manipulation generally are not admitted to the hospital. Children with more extensive injuries should be admitted for neurovascular observation and instruction in wheelchair, crutch, or walker use.

Significantly displaced fractures disrupt the surrounding soft tissues and produce a large hematoma in the fascial compartments of the lower leg. Circulation, sensation, and both active and passive movement of the toes should be monitored carefully after injury. The child should be admitted to the hospital, and reduction should be performed with adequate sedation and fluoroscopy if available. Most fractures are casted after reduction, and the cast may be bivalved or split to allow room for swelling. The fracture must be evaluated clinically and radiographically within a week of initial manipulation to verify maintenance of the reduction. The cast can be wedged to correct minor alignment problems. Significant loss of reduction requires repeat reduction with adequate anesthesia and/or utilization of a more rigid fixation method. The long-leg cast may be changed to a short-leg, weight-bearing cast at 4 to 6 weeks after injury. Children over 11 years of age may be placed into a patellar tendon-bearing cast after removal of the long-leg cast.[135] Weight-bearing immobilization is maintained until sufficient callus is evident.

Fractures in patients with complicating factors including spasticity, a floating knee, multiple long-bone fractures, an associated transitional ankle fracture, extensive soft tissue damage, multiple system injuries, or an inability to obtain or maintain an acceptable reduction should be stabilized with a more rigid fixation method, such as external fixation or flexible intramedullary nails (Figs. 31-21 and 31-22). It is the author's preference to use either stainless steel or titanium flexible intramedullary nails, if at all possible, in these situations. In closed fractures, external fixation is reserved for comminuted or highly unstable fracture patterns and is used infrequently.

Open Tibia Fractures

Open tibial fractures of any grade should have a thorough and expedient irrigation and debridement of the wound, although there is some evidence that infection rate is similar in injuries

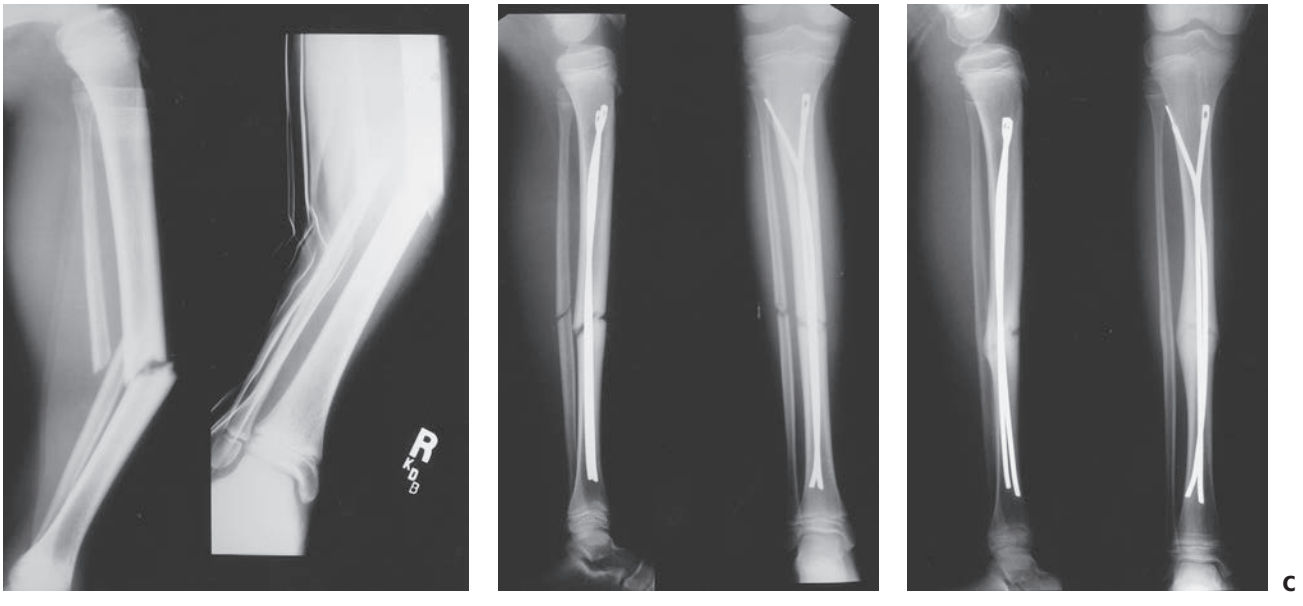

FIGURE 31-21 **A:** Anteroposterior and lateral radiographs of a 12-year old who was involved in a motor vehicle accident sustaining a grade I open middle one-third tibial and fibular fractures. **B:** This injury was treated with intramedullary nail fixation. **C:** At union, the patient has an anatomic alignment and no evidence of a growth disturbance.

FIGURE 31-22 Anteroposterior radiograph of a 14-year old who was involved in a motor vehicle accident sustaining a distal one-third tibial fracture and comminuted distal fibular fracture. This was stabilized with titanium elastic nails.

managed at less than 6 hours after injury and those treated later.[145] The patient's tetanus status is determined, and prophylaxis is administered as indicated. Appropriate IV antibiotic treatment is initiated as soon as possible and maintained as required based on the severity of the open fracture. In the operating room, the soft tissue wounds should be extended to be certain that the area is cleansed and debrided of all nonviable tissue and foreign material. Devitalized bone may be left in place if it is clean and can be covered by soft tissue, and this is determined on a case-by-case basis. The operative wound extension may be closed along with the open segment in clean grade I injuries. The traumatic wound is allowed to heal by secondary intention if there is moderate contamination after irrigation and debridement. Patients with uncomplicated grade I fractures can be placed in a splint or a cast, or simple smooth pin fixation will prevent displacement of the fracture (Fig. 31-23). Use of this limited fixation does not preclude supplemental splinting or casting. Wounds associated with grade II and III fractures are debrided of devitalized tissue and foreign material. Most children with grade II and all children with grade III wounds require more rigid fracture stabilization. External fixation or intramedullary nails may be used at the surgeon's discretion based on fracture stability and personal experience. More rigid fixation limits the need for significant external splinting, thereby allowing better access for wound care and sequential compartment evaluation as needed.

The most versatile and most widely available external fixation device for open pediatric tibial fractures is a unilateral frame (Fig. 31-24). The unilateral frame is easy to apply and allows

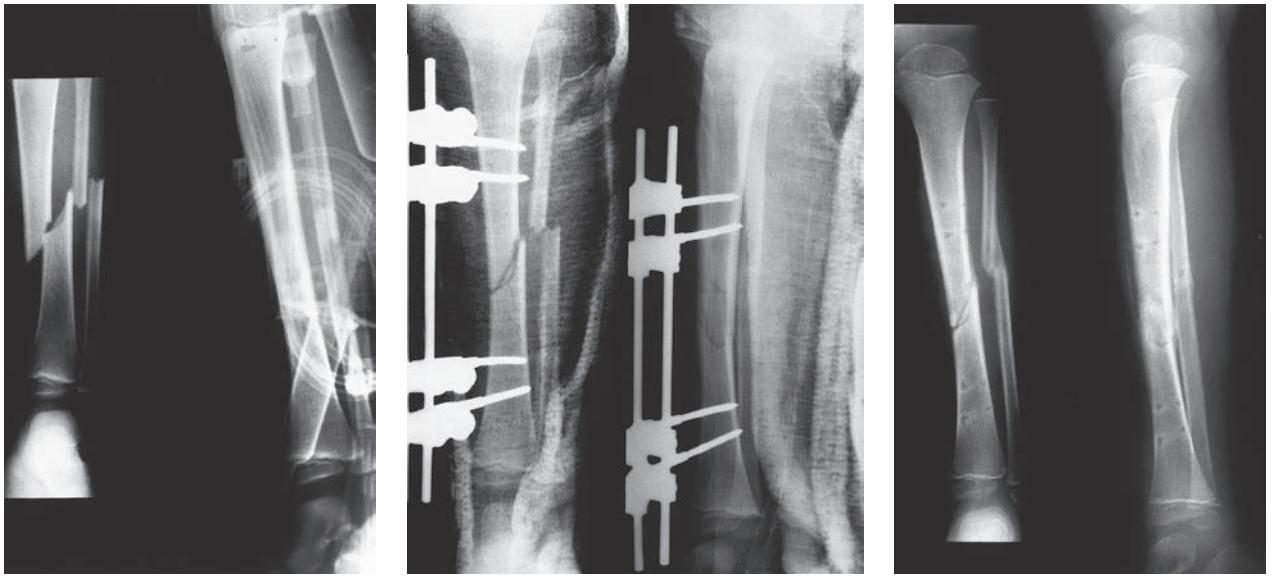

FIGURE 31-24 **A,B:** Type II open fracture of the tibia in a 5-year-old boy treated with débridement, unilateral external fixation, and split thickness skin graft. **C:** Four months after removal of the external fixation.

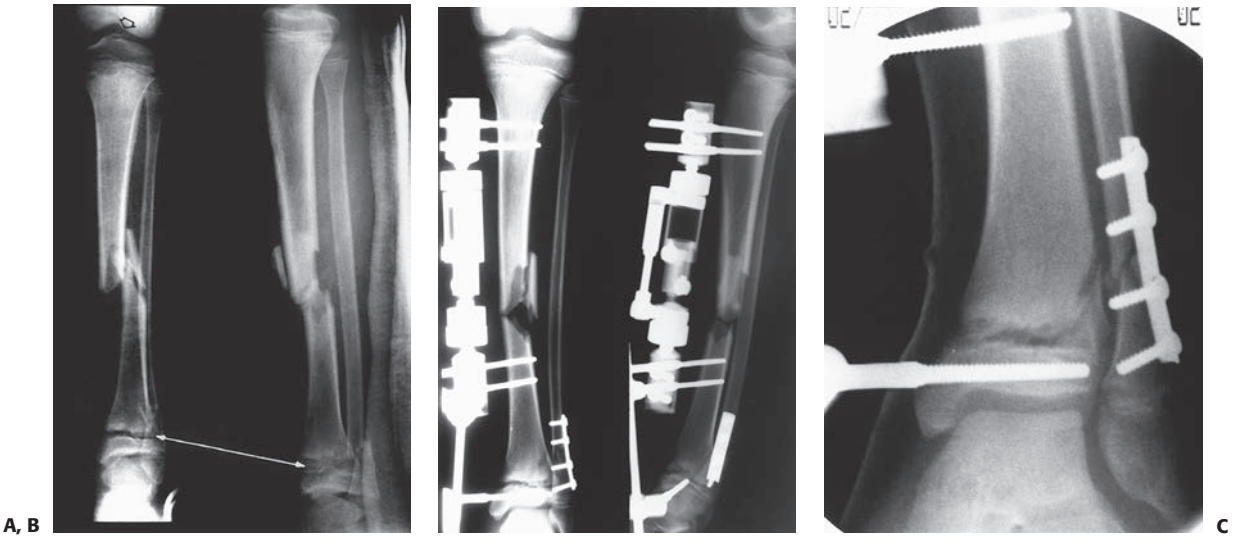

FIGURE 31-25 **A:** Anteroposterior and lateral radiographs of the tibia of a 12-year-old boy who was struck by a car. This child sustained a grade IIIB open middle one-third tibial fracture, a Salter–Harris type II fracture of the distal tibial physis with associated distal fibular fracture (*closed arrows*), and a tibial eminence fracture (*open arrow*). **B:** Irrigation and débridement and application of an external fixation device were performed. **C:** The fracture of distal tibial physis was stabilized with a supplemental pin attached to the external fixation device. Open reduction and internal fixation of the fibula was performed to enhance the stability of the external fixator in the distal tibia. **D:** Anteroposterior and lateral radiographs of the tibia approximately 9 months after injury demonstrate healing of the tibial eminence fracture, the comminuted middle one-third tibial fracture, and the distal tibial physeal fracture. The distal tibial physis remains open at this time.

minor corrections in angular alignment and length. Secondary pins can be used for added support (Fig. 31-25); these are connected to the standard pins or the body of the external fixation device. This allows control of segmental fragments as needed. Fracture reduction tools can be applied to the pin clamps to assist in manipulating the fracture. A small-pin or thin-wire circular frame may be indicated for complicated fractures adjacent to the joint.[22] Unilateral frames may be placed to span the joint in question so as to use ligamentotaxis as an indirect reduction method to establish and maintain alignment (Fig. 31-26).

If at all possible, external fixation pins are placed no closer than 1 cm to the physis. The external fixation device is applied, and a reduction maneuver is performed. All of the connections in the external fixation device are tightened after reduction has been obtained. Secondary pins to improve fracture stability are placed at this time. Limited internal fixation of the fracture can

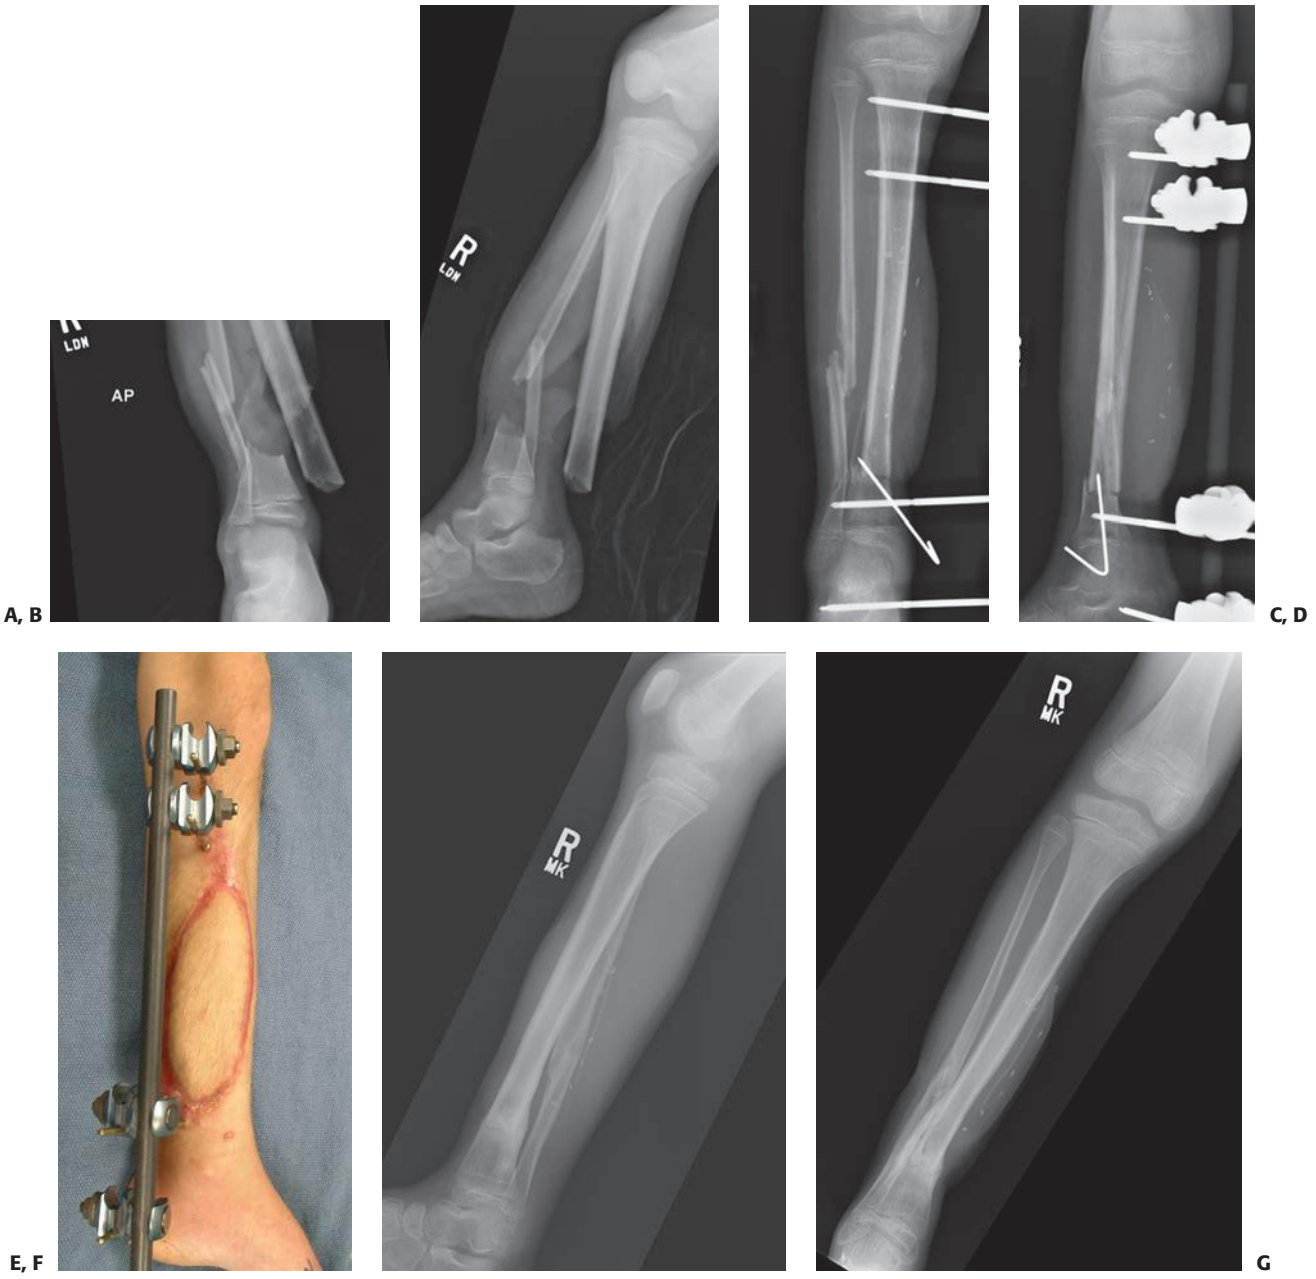

FIGURE 31-26 **A** and **B:** Anteroposterior and lateral radiographs of a grade IIIB open tibia/fibula fractures sustained by a 9-year-old male in an agricultural accident. **C,D,E:** Anteroposterior/lateral radiographs, and clinical image of a patient 8 weeks after placement of spanning monolateral external fixator with additional percutaneous pin fixation, and delayed coverage with anterior thigh free flap. **F** and **G:** Anteroposterior and lateral radiographs of a patient 9 months post injury. Patient had excellent clinical result.

be used to aid in controlling fracture alignment. A posterior splint may be applied to prevent the foot from dropping into plantar flexion. This splint should be easy to remove for subsequent pin care and dressing changes of the open injury. Splinting to maintain position of the ankle and foot can be avoided by external fixation, be it unilateral or circular, to the forefoot.

Intramedullary fixation is performed most commonly in children using prebent stainless steel Enders nails or titanium elastic nails. In most cases, the implants are placed in a proximal to distal fashion from medial and lateral proximal insertion points. Retrograde fixation through the medial malleolus may be used in rare instances because of soft tissue injuries about the planned proximal insertion sites. Fluoroscopy is required for accurate placement. Care must be taken to avoid injury to the proximal tibial physes, including the tibial tubercle apophysis. Use of supplemental external splinting is at the discretion of the treating surgeon (Tables 31-6 and 31-7). There are some older teenaged patients who may be managed with reamed or unreamed tibial nails. There is no data in the literature that looks specifically at which skeletal age this would be considered acceptable, and at which age the possible risk of injury to the proximal tibial physis is minimized. However, the authors generally reserve these "adult style" devices for patients with a bone age of 15 years or greater, or with a radiographically closed, or closing, proximally tibial physis.

Immobilization

The length of immobilization varies with the child's age and the type of fracture. The duration of immobilization was 8 to 10 weeks in the Steinert and Bennek series.[149] Hansen et al.[63] found that healing time ranged from 5 to 8 weeks for "fissures and infractions" and from 5 to 13 weeks for oblique, transverse, and comminuted fractures. Hoaglund and States[66] reported that in 43 closed fractures in children, the average time in a cast was 2.5 months (range, 1.5 to 5.5 months), whereas the five children with open fractures were immobilized for 3 months.

Kreder and Armstrong[90] found an average time to union of 5.4 months (range, 1.5 to 24.8 months) in a series of 56 open tibial fractures in 55 children. The factor with the most effect on union time was the age of the patient. Grimard et al.[56] reported that the age of the patient and the grade of the fracture were significantly associated with union time. Blasier and Barnes[10] found that children under 12 years of age required less aggressive surgical treatment and healed faster than older children. They also found that younger children were more resistant to infection and had fewer complications than older children.

TABLE 31-6 Surgical Stabilization of Diaphyseal Tibia Fractures

Preoperative Planning Checklist

- OR Table: Radiolucent
- Position/positioning aids: Supine with a small bump under ipsilateral hip
- Fluoroscopy location: Contralateral side for flexible nails, ipsilateral side for ex fix
- Equipment: Flexible nails or external fixator of choice
- Tourniquet (sterile/nonsterile): Nonsterile, but do not elevate unless necessary
- Preoperative antibiotics

Note: Must have general anesthesia with adequate muscle relaxation

Note: Must have femoral distractor available or adequate assistance for intraoperative traction

TABLE 31-7 Flexible IM Nailing of Diaphyseal Tibia Fractures

Surgical Steps

- Supine position with ipsilateral bump on a radiolucent table
- Prep extremity toes-to-thigh tourniquet
- Have adequate soft blanket bumps or knee triangle available
- Medial and lateral proximal tibial incisions
  - Distal aspect of incision at the point of proposed nail insertion sites
- Starting holes medially and laterally at, or just proximal to, the level of tibial tubercle. Use drill or awl
- Contour and pass nails to fracture site. Reduce fracture with traction and manipulation
  - Pass nails into distal metaphysis. Ensure fracture does not distract
- Check lateral view on C-arm. Rotate nails as necessary to minimize possible recurvatum deformity

Rehabilitation

Most children with a tibial fracture do not require extensive rehabilitation, beyond basic crutch or walker training. Most children limp with an out-toeing rotation gait on the involved extremity for several weeks to a month after external immobilization is removed. This is secondary to muscle weakness, joint stiffness, and a tendency to circumduct the limb during swing phase, rather than a malalignment of the fracture. As the muscle atrophy and weakness resolve, the limp improves. In very rare situations, formal physical therapy may be required for some children after a tibial fracture. Knee range-of-motion exercises and quadriceps strengthening may be useful in an older child progressing from a bent-knee cast to weight bearing on a short-leg cast. The child may return to sports when the fracture is healed and the patient has regained strength and function comparable to that of the uninjured leg.

Complications Associated with Diaphyseal Fractures of the Tibia and Fibula

Compartment Syndrome

A compartment syndrome may occur after any type of tibia fracture, ranging from a seemingly minor closed fracture to a severe, comminuted fracture.[93] The prevalence of compartment syndromes in adults with open tibial fractures ranges from 6% to 9%.[11,31,92] The true incidence of compartment syndrome associated with open pediatric tibial fractures is unknown. Regardless, it is important to remember that compartment syndrome

may occur in the face of significant soft tissue injury associated with extensively open fractures, as well as with closed injuries. Flynn et al. provided the most recent major review of a single hospital experience with lower leg compartment syndrome. In that study, 83% of all patients with compartment syndrome had an ipsilateral tibia fracture.[42] Schrock[139] described compartment syndromes after derotational osteotomies of the tibia in children, and compartment syndrome is a well-known complication of tibial osteotomy for angular deformity correction.

Diagnosis

Patients with a compartment syndrome often complain of pain out of proportion to the apparent severity of the injury. Increasing pain, often noted as increasing analgesic requirements, is the most important early sign of potential compartment syndrome in children. Pain with passive range of motion appears to be an early and strong clinical finding. Late complications of untreated lower extremity compartment syndrome include clawed toes, dorsal bunion, and limited subtalar motion secondary to necrosis and subsequent fibrous contracture of the muscles originating in the deep posterior compartment.[81]

Treatment

Any cast or splint should be bivalved or loosened, and the padding divided, in a patient with increased or increasing pain associated with treatment of a tibia fracture. If, after removal of all encircling wraps, there is no relief, compartment syndrome should be considered. Any child who has objective or subjective evidence of a compartment syndrome should undergo an emergent fasciotomy. Hyperesthesia, motor deficits, and decreased pulses are late changes and denote significant tissue injury. These signs occur only after the ischemia has been well established and the injury is permanent.[81,160] Although, there is some controversy in the literature, symptomatic patients with compartment pressures greater than 30 mm Hg may benefit from fasciotomy.[76,147,160]

The two-incision technique is used most widely for fasciotomies, although a single incision, perifibular release is favored at some centers (Fig. 31-27A,B).[100,101] The fascia surrounding each compartment of concern should be opened widely. The wounds are left open and a delayed primary closure is performed when possible. Negative pressure wound dressings may be of benefit in the management of fasciotomy wounds before closure or coverage. Split thickness skin grafting of the wounds may be necessary in some cases. Fibulectomy has been recommended by some authors as a method by which all compartments can be released through a single approach. Most literature does not support its use, and this procedure should not be performed in skeletally immature patients because of potential proximal migration of the distal fibular remnant and resulting ankle valgus. Long-term ankle valgus may result in external tibial torsion, gait impairment, and potentially problematic foot and ankle deformity.

In a long-term review of patients from the Children's Hospital of Philadelphia, Flynn et al. found that most children with lower extremity compartment syndrome, including those associated with tibia fractures, had good or excellent clinical results. This appeared to be true even in those patients with long time periods from injury to fasciotomy.[42]

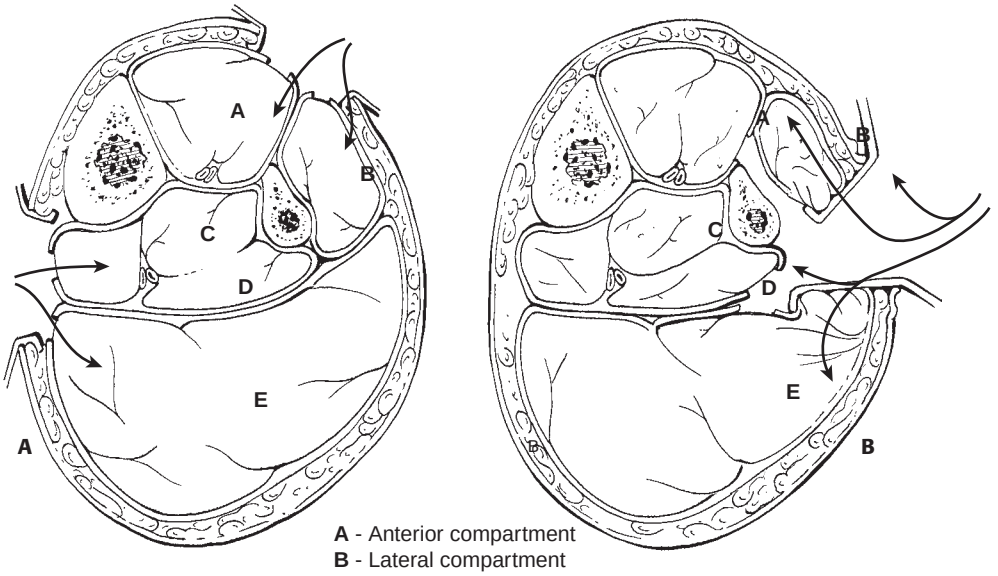

FIGURE 31-27 **A:** Decompressive fasciotomies through a two-incision approach. The anterior lateral incision allows decompression of the anterior and lateral compartments. The medial incision allows decompression of the superficial posterior and the deep posterior compartments. **B:** A one-incision decompression fasciotomy can be performed through a lateral approach that allows a dissection of all four compartments.

Vascular Injuries

Vascular injuries associated with tibial fractures are uncommon in children; however, when they do occur, the sequelae can be devastating. In an evaluation of 14 patients with lower extremity fractures and concomitant vascular injuries, Allen et al.[1] noted that only three children returned to normal function. One factor leading to a poor outcome was a delay in diagnosis. Evaluation for vascular compromise is imperative in all children with tibial fractures.

The displaced proximal tibial metaphyseal fracture is the pattern of injury most frequently associated with vascular injury, and often involves the anterior tibial artery as it passes between the fibula and the tibia into the anterior compartment.[59,68] The anterior tibial artery may be injured with distal tibial fractures, as the vessel may be injured if the distal fragment translates posteriorly. Posterior tibial artery injuries are rare, except in fractures associated with crushing or shearing caused by accidents involving heavy machinery, or those secondary to gunshot wounds involving the lower leg and ankle region.

Angular Deformity

Spontaneous correction of significant axial malalignment after a diaphyseal fracture of a child's forearm or femur is common. Remodeling of an angulated tibial shaft fracture, however, often is incomplete (Fig. 31-28).[13] As such, the goal of treatment should be to obtain as close to anatomic alignment as possible. Swaan and Oppers[151] evaluated 86 children treated for fractures of the tibia. The original angulation of the fracture was measured on radiographs in the sagittal and frontal projections. Girls 1 to 8 years of age and boys 1 to 10 years of age demonstrated moderate spontaneous correction of residual angulation after union. In girls 9 to 12 years of age and boys 11 to 12 years of age, approximately 50% of the angulation was corrected. No more than 25% of the deformity was corrected in children over 13 years of age.

FIGURE 31-28 A 4 year 2 mo-old child with a middle one-third transverse tibial fracture and a plastically deformed fibular fracture. **A:** Lateral view shows 20-degree posterior angulation. **B:** The deformity is still 15 degrees 4 years after the injury.

Bennek and Steinert[7] found that recurvatum malunion of more than 10 degrees did not correct completely. In this study, 26 of 28 children with varus or valgus deformities at union had significant residual angular deformities at follow-up. Valgus deformities had a worse outcome because the tibiotalar joint was left in a relatively unstable position. Weber et al.[159] demonstrated that a fracture with varus malalignment of 5 to 13 degrees completely corrected at the level of the physis. Most children with valgus deformities of 5 to 7 degrees did not have a full correction.

Hansen et al.[63] reported 102 pediatric tibial fractures, 25 of which had malunions of 4 to 19 degrees. Residual angular malunions ranged from 3 to 19 degrees at final follow-up, without a single patient having a complete correction. The spontaneous correction was approximately 13.5% of the total deformity. Shannak[140] reviewed the results of treatment of 117 children with tibial shaft fractures treated in above-the-knee casts. Multiplanar deformities did not remodel as completely as those in a single plane. The least correction occurred in apex posterior angulated fractures, followed by fractures with valgus malalignment (Fig. 31-29). Spontaneous remodeling of malunited tibial fractures in children appears to be limited to the first 18 months after fracture.[34,35,63]

Malrotation

Because rotational malalignment of the tibia does not correct spontaneously with remodeling,[63] any malrotation should be avoided. A computerized tomographic (CT) evaluation of tibial rotation can be performed if there is any question about the rotational alignment of the fracture that is not evident on clinical examination.

Rotational malunion of more than 10 degrees may produce significant functional impairment and may necessitate a subsequent derotational osteotomy of the tibia. Most commonly, derotational osteotomy of the tibia is performed in the supramalleolar aspect of the distal tibia. The fibula may be left intact, particularly for planned derotation of less than 20 degrees. Maintaining continuity of the fibula adds stability and limits the possibility of introducing an iatrogenic angular deformity to the distal tibia.

Leg-Length Discrepancy

Hyperemia associated with fracture repair may stimulate the physes in the involved leg, producing growth acceleration, particularly in younger children. Tibial growth acceleration after fracture is less than that seen after femoral fractures in children of comparable ages. Shannak[140] showed that the average growth

FIGURE 31-29 **A:** Anteroposterior and lateral radiographs 2 months after injury in a 6-year-old boy reveal a valgus and anterior malunion at the fracture. **B:** One year later, the child still has a moderate valgus and anterior malalignment of the distal fractured segment. This malalignment produced painful hyperextension of the knee at heel strike during ambulation.

acceleration of a child's tibia after fracture is approximately 4.5 mm. Comminuted fractures appear to have the greatest risk of accelerated growth and overgrowth.

Swaan and Oppers[151] reported that young children have a greater chance for overgrowth than older children. Accelerated growth after tibial fracture generally occurs in children under 10 years of age, whereas older children may have a mild growth inhibition associated with the fracture.[63] The amount of fracture shortening also has an effect on growth stimulation. Fractures with significant shortening have more physeal growth after fracture union than injuries without shortening at union.[102] The presence of angulation at union does not appear to affect the amount of overgrowth.[54]

Anterior Tibial Physeal Closure

Morton and Starr[109] reported closure of the anterior tibial physis after fracture in two children. Both patients sustained a comminuted fracture of the tibial diaphysis without a concomitant injury of the knee. The fractures were reduced and stabilized with Kirschner wires reportedly placed distal to the tibial tubercle. A genu recurvatum deformity developed after premature closure of the anterior physis. Smillie[144] reported one child who had an open tibial fracture complicated by a second fracture involving the supracondylar aspect of the femur. This patient also developed a recurvatum deformity secondary to closure of the anterior proximal tibial physis. At present, no universally acceptable explanation can be given for this phenomenon.

Patients have demonstrated apparently iatrogenic closure after placement of a proximal tibial traction pin, the application of pins and plaster, and after application of an external fixation device. Some children may have an undiagnosed injury of the tibial physis at the time of the ipsilateral tibial diaphyseal fracture.[87] Regardless of etiology, premature closure of the physis produces a progressive recurvatum deformity and loss of the normal anterior to posterior slope of the proximal tibia as the child grows. Management may require surgical intervention including proximal tibial osteotomy with all the inherent risks and potential complications of that procedure.

Delayed Union and Nonunion

Delayed union and nonunion are uncommon after low-energy tibial fractures in children. The use of an external fixation device may lengthen the time to union in some patients, particularly those with open fractures resulting from high-energy injury.[30,97,110] In patients treated with external fixation, care must be taken to advance weight bearing appropriately and to dynamize the fixator frame as soon as possible to maximize bone healing. Inadequate immobilization that allows patterned micro- or macromotion also can slow the rate of healing and lead to delayed or nonunion. In patients with a suspected delayed union or nonunion, a 1-cm fibulectomy will allow increased compression at the delayed union or nonunion site with weight bearing and often will induce healing (Fig. 31-30). Posterolateral bone grafting is an excellent technique to produce union in children (Fig. 31-31). Adolescents near skeletal maturity with a delayed or nonunion can be managed with a reamed intramedullary nail, concomitant fibular osteotomy, and correction of any angulation at the nonunion site as necessary (Fig. 31-32).

Fractures of the Distal Tibial Metaphysis

Fractures of the distal tibial metaphysis are often greenstick injuries resulting from increased compressive forces along the anterior tibial cortex. This fracture often occurs secondary to an axial load on a dorsiflexed foot. The anterior cortex is impacted while the posterior cortex is displaced under

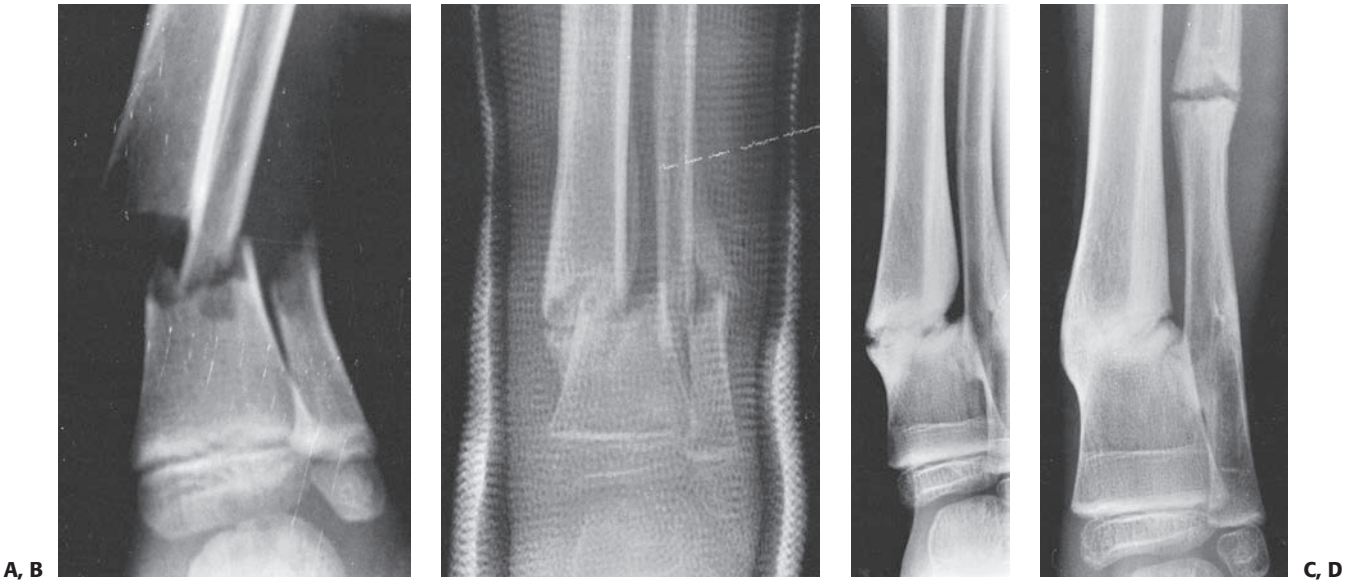

FIGURE 31-30 **A:** Anteroposterior radiograph of the distal tibia and fibula in a 5-year-old boy with an open fracture. **B:** Early callus formation is seen 1 month after injury. **C:** The tibia has failed to unite 10 months after injury. **D:** The patient underwent a fibulectomy 4 cm proximal to the tibial nonunion. The tibial fracture united 8 weeks after surgery.

tension, with a tear of the overlying periosteum. A combined valgus and recurvatum deformity may occur (Fig. 31-33). This fracture pattern was termed the "Robert Gillespie fracture" by Mercer Rang.[125]

Reduction of these injuries should be performed with adequate sedation and maintained with a long-leg cast. In cases in which the fracture has angulated into recurvatum, the foot should be left in moderate plantar flexion to prevent recurrence of apex posterior angulation at the fracture site. The foot is brought up to neutral after 3 to 4 weeks, and a short-leg walking cast is applied. Nondisplaced fractures can be immobilized in either a short- or long-leg cast at the surgeon's discretion. Unstable, displaced fractures can be treated with closed reduction and percutaneous pins (Fig. 31-34), antegrade flexible nails, or with open reduction and internal fixation as needed (Fig. 31-35). Open reduction and internal fixation of an associated distal fibula fracture, may prevent malalignment in an unstable distal tibia fracture.

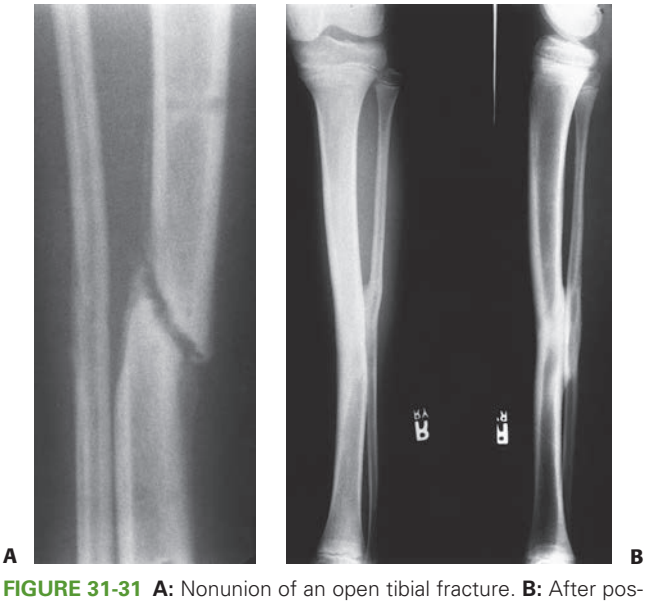

FIGURE 31-31 **A:** Nonunion of an open tibial fracture. **B:** After posterolateral tibial bone graft.

Special Fractures

Toddler's Fractures

External rotation of the foot with the knee fixed in an infant or toddler can produce a spiral fracture of the tibia without a concomitant fibular fracture, and is termed a "toddler's fracture" (Fig. 31-36). This fracture pattern was first reported by Dunbar et al.[36] in 1964. The traumatic episode often is unwitnessed by the parent or adult caretaker.[119] Of those injuries that are witnessed, most caregivers report a seemingly minor, low-energy, twisting mechanism. For example, these injuries may occur when a toddler falls or attempts to extricate the foot from between the bars of a playpen or crib. Most children with this injury are under 6 years of age, and in one study the average age was 27 months. Sixty-three of 76 such fractures reported by Dunbar et al.[36] were in children under 2.5 years of age. Toddler's fractures occur in boys more often than in girls and in the right leg more often than in the left. Occasionally, a child may sustain a toddler's fracture in a fall from a height.[29,154]

Oujhane et al.[119] analyzed the radiographs of 500 acutely limping toddlers and identified 100 in whom a fracture was the etiology of the gait disturbance. The most common site of fracture was the distal metaphysis of the tibia.

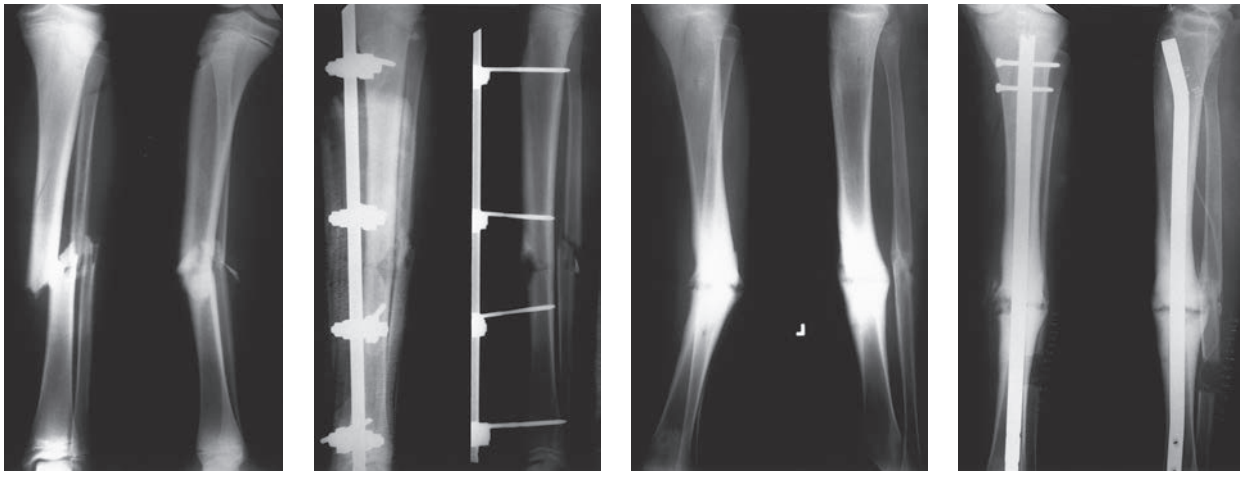

FIGURE 31-32 **A:** Anteroposterior and lateral radiographs of a 14-year-old adolescent who was struck by a car, sustaining a grade IIIB open fracture of the tibia. **B:** Anteroposterior and lateral radiographs of the tibia after irrigation and débridement, and application of an external fixation device. **C:** The patient developed a nonunion at the tibia, which progressively deformed into an unacceptable varus alignment. **D:** The nonunion was treated with a fibular osteotomy followed by a closed angular correction of the deformity and internal fixation with a reamed intramedullary nail.

The examination and physical findings of the patient with a possible toddler's fracture are often subtle. The child typically presents with a history of a new onset limp or refusal to bear weight on the limb. The examination should begin with an evaluation of the uninvolved side, as this serves as a control for the symptomatic extremity. The examination begins at the hip and proceeds to the thigh, knee, lower leg, ankle, and foot. It is important to note areas of point tenderness, any increase in local or systemic temperature, and any swelling or bruising of the leg.[154] Radiographs of the tibia and fibula should be obtained in the anteroposterior, lateral, and internal rotation oblique projections. An internally rotated oblique view can be helpful in identifying a nondisplaced toddler's fracture. Occasionally, fluoroscopy may be beneficial in the identification of subtle fractures. In cases in which initial radiographs are negative, but the history and examination are consistent with diagnosis of a toddler's fracture, treatment with a cast is indicated.[61,63] In these cases, follow-up radiographs will often demonstrate periosteal new bone formation approximately 10 to 14 days after injury (Fig. 31-37). Technetium radionuclide bone scan can assist in the diagnosis of unapparent fractures, but is rarely indicated. A bone scan of a patient with a toddler's fracture will demonstrate diffuse increased uptake of tracer throughout the affected bone ("black tibia"). This can

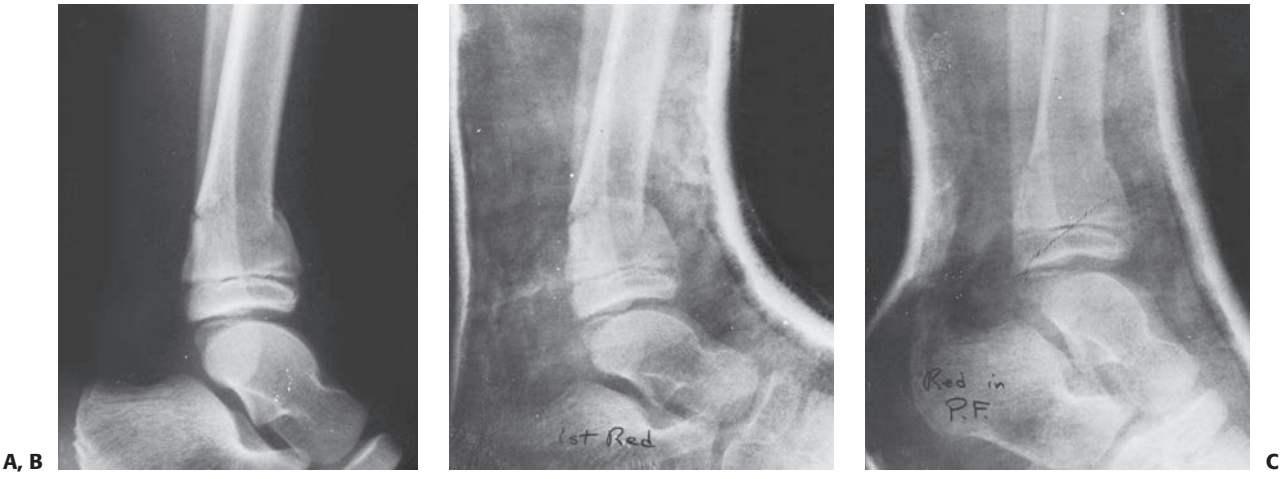

FIGURE 31-33 **A:** Fracture of the distal tibia in a 7-year-old child. The lateral radiograph demonstrates a mild recurvatum deformity. **B:** The ankle was initially immobilized in an ankle neutral position, producing an increased recurvatum deformity. The cast was removed and the ankle remanipulated into plantar flexion to reduce the deformity. **C:** The ankle was then immobilized in plantar flexion, which is the proper position for this type of fracture.

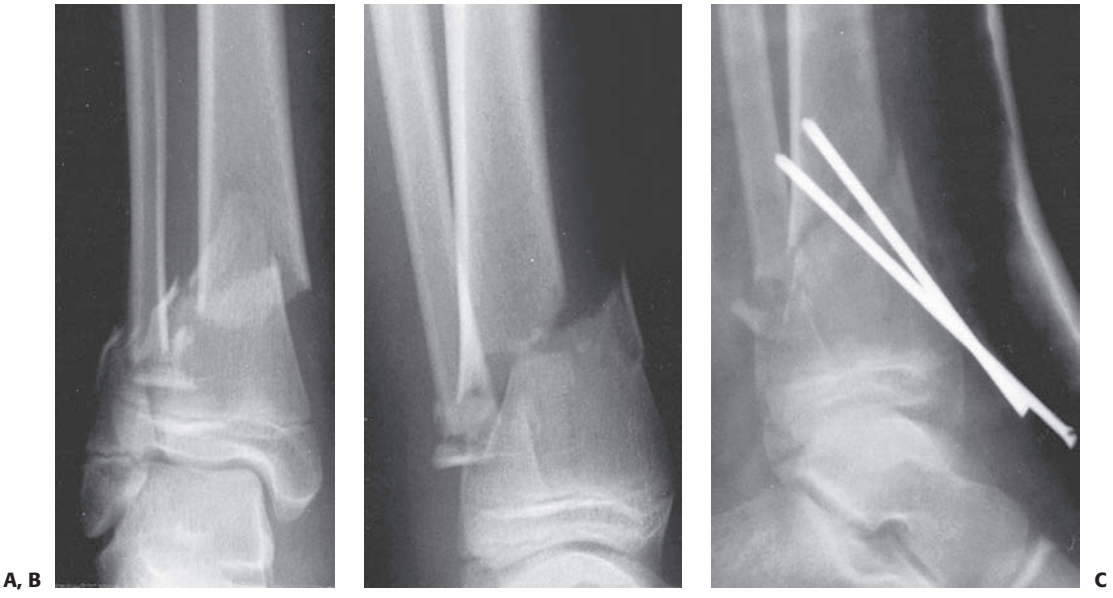

FIGURE 31-34 **A,B:** Unstable distal metadiaphyseal fractures of the tibia and fibula in a 15-year-old girl. **C:** This fracture was stabilized with percutaneous pins because of marked swelling and fracture instability.

be differentiated from infection as infection tends to produce a more localized area of increased tracer uptake.[36]

A child with a toddler's fracture maybe immobilized in a long-leg or short-leg cast for approximately 3 to 4 weeks. Short-leg casts are sufficient for patients with fractures of the distal half of the tibia. The fracture is stable, and the patient may bear weight on the cast when comfortable.

Floating Knee

Although uncommon in children, significant trauma can cause ipsilateral fractures involving both the tibia and the femur. The term "floating knee" describes the flail knee joint resulting from fractures of the shaft or metaphyseal region of the ipsilateral femur and tibia.[2,95] The most common mechanism of trauma resulting in this injury pattern involves either a pedestrian or bicyclist struck by an automobile[13,95] In the past, these injuries often were treated with traction and casting (Fig. 31-38). The extent of the injuries often left permanent functional deficits, including malunion, limb-length discrepancy, and knee stiffness when not managed aggressively.[13]

Today most children with ipsilateral tibia and femoral fractures are treated with operative stabilization of the femur and

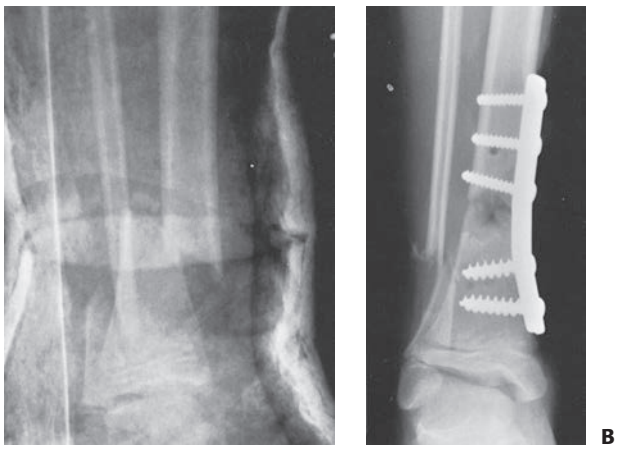

FIGURE 31-35 **A:** Anteroposterior radiograph of a distal one-third tibial and fibular fractures in a 9-year-old girl with a closed head injury and severe spasticity. The initial reduction in a cast could not be maintained. **B:** Open reduction and internal fixation with a medial buttress plate was used to achieve and maintain the alignment.

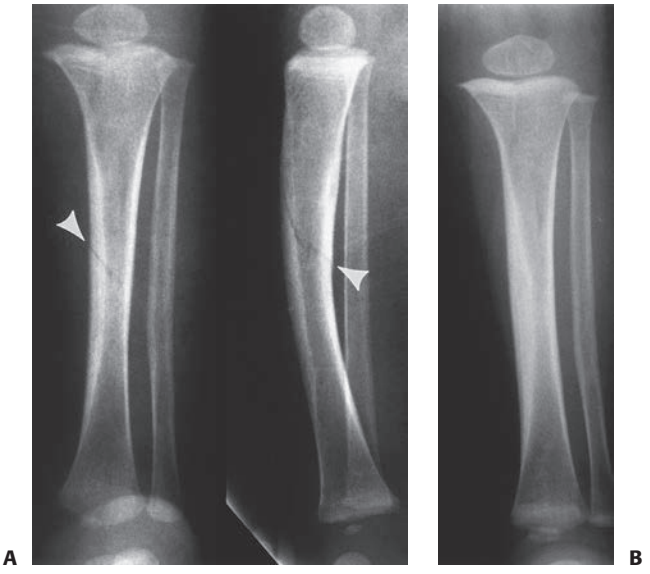

FIGURE 31-36 **A:** Anteroposterior and lateral radiographs of an 18-month-old child who presented with refusal to bear weight on her leg. Note the spiral middle one-third "toddler's" fracture (*arrow heads*). **B:** This fracture healed uneventfully after 4 weeks of immobilization in a cast.

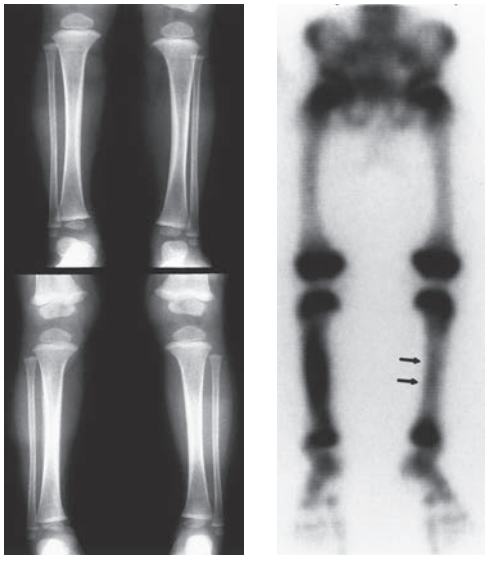

FIGURE 31-37 **A:** Anteroposterior radiograph of the tibia in a 3-year-old child who refused to bear weight on the right leg 3 weeks before presentation. The history of obvious trauma was absent. The radiographs revealed periosteal new bone formation in the midshaft of the right tibia. There was also tenderness to palpation in the left midtibia as well despite normal radiographs. **B:** A bone scan showed increased uptake in both the left and right tibia. There was significantly less uptake on the left side (*arrows*) the more recent injury.

either cast immobilization after closed reduction or operative fixation of the tibia.[162] In pediatric patients, multiple treatment combinations can be utilized to care for a patient with floating knee injury. For example, the femoral fracture can be stabilized with a unilateral external fixator, plate and screw constructs, or flexible nails. Patients near skeletal maturity may be candidates for lateral entry reamed femoral nails, although the other options remain viable as well. Plate fixation, either open or percutaneous, is useful for fractures in the subtrochanteric or supracondylar area of the femur in adolescents, although external fixation may be useful in these areas as well. The tibial fracture is reduced and stabilized after the femoral fracture has been stabilized. Closed tibial fractures in these situations may be treated with cast immobilization or operative intervention. Open tibial fractures associated with an ipsilateral femoral fracture should be stabilized with an external fixator or flexible intramedullary nails whenever possible (Fig. 31-39). Stable fixation of both fractures allows early range of motion of the knee, earlier weight bearing, and improves overall function.[162]

Stress Fractures of the Tibia and Fibula

Roberts and Vogt[128] in 1939 reported an "unusual type of lesion" in the tibia of 12 children. All were determined to be stress fractures involving the proximal third of the tibial shaft. Since then, numerous reports of stress fractures involving the tibia and the fibula have been published.[9,33,152]

The pattern of stress fractures in children differs from that in adults.[32,33,137] In adults, the fibula is involved in stress fractures twice as often as the tibia; in children, the tibia is affected more often than the fibula (Fig. 31-40). The prevalence of stress fractures in boys and girls appears to be equal, although recently stress fractures have been reported to be increasingly common in females with eating disorders[111] These injuries typically occur in pediatric and adolescent athletes older than 10 years of age, and have a history of insidious onset of pain that worsens with sporting activities.[53,157]

Stress fractures occur when the repetitive force applied to a bone is exceeded by the bone's capacity to withstand it.

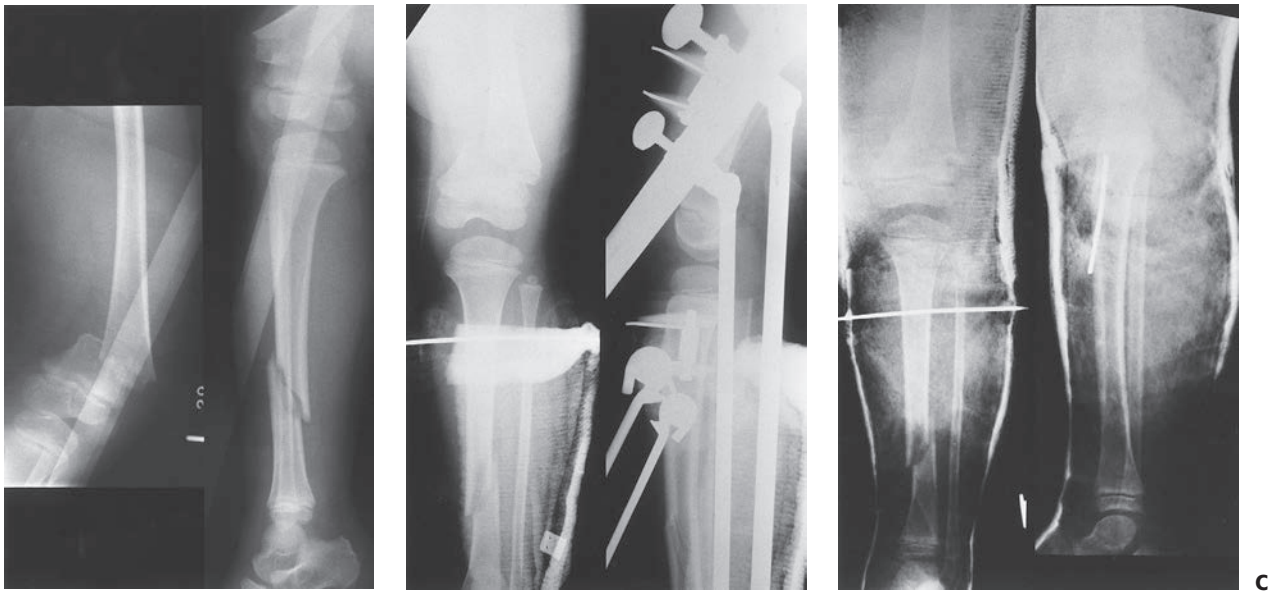

FIGURE 31-38 **A:** Ipsilateral fractures of the distal femur and tibia without an ipsilateral fibular fracture in a 5-year old. **B:** The child was treated with tibial pin traction for the femoral injury (pin applied below the tibial tubercle) and a short-leg splint for the tibial fracture initially. **C:** The child was placed into a spica cast after 2 weeks of traction. The tibial traction pin was used to help stabilize both fractures.

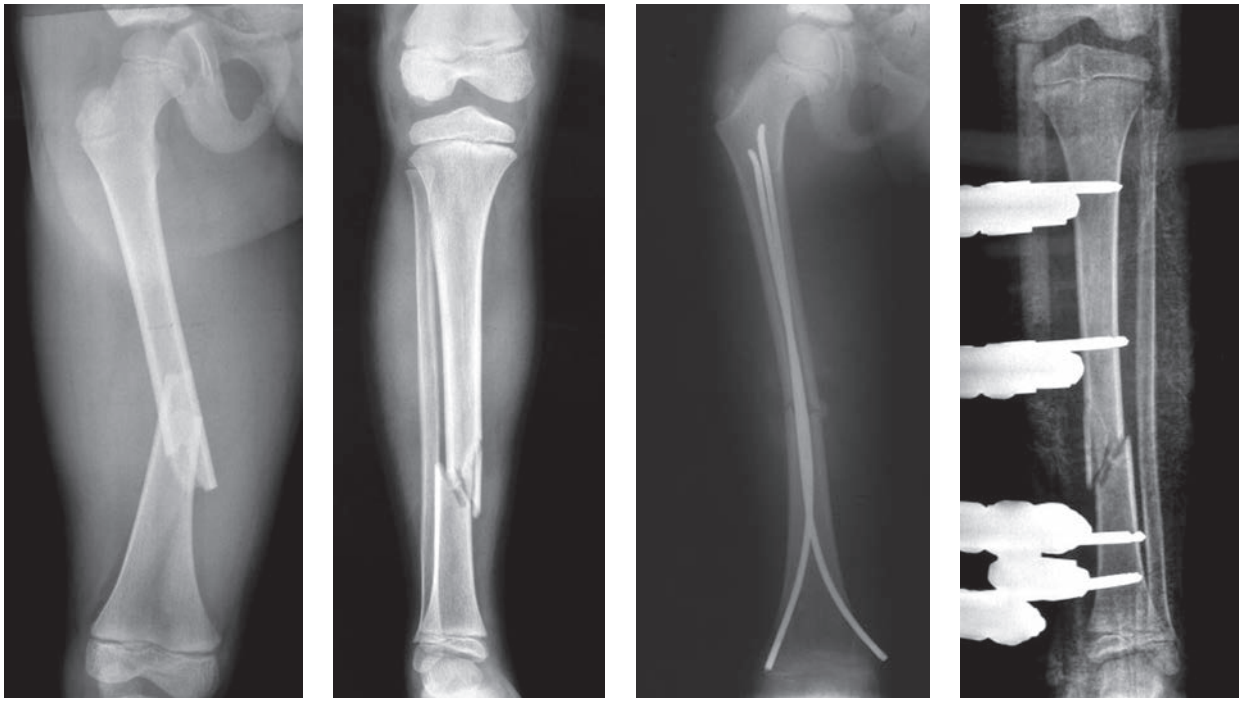

FIGURE 31-39 **A,B:** Floating knee injury in a 7-year-old boy. **C:** Femoral fracture was fixed with flexible intramedullary nails. **D:** Tibial fracture was stabilized with external fixation.

Initially, osteoclastic tunnel formation increases. These tunnels normally fill with mature bone. With continued force, cortical reabsorption accelerates. Woven bone is produced to splint the weakened cortex. However, this bone is disorganized and does not have the strength of the bone it replaces. A fracture occurs when bone reabsorption outstrips bone production. When the offending force is reduced or eliminated, bone production exceeds bone reabsorption. This produces cortical and endosteal widening with dense repair bone that later remodels to mature bone.[39,77,119]

FIGURE 31-40 Bilateral midtibial stress fractures in an adolescent with genu varus.

A child with a tibial stress fracture usually has an insidious onset of symptoms.[33,136] There is evidence of local tenderness that worsens with activity. The pain tends to be worse in the day and improves at night and with rest. The knee and the ankle have full ranges of motion. Usually, there is minimal, if any, swelling at the fracture site.[17,33,40,70,88,128]

Initial radiographs may be normal. Radiographic changes consistent with a stress fracture generally become evident approximately 2 weeks after the onset of symptoms.[33] Radiographic findings consistent with fracture repair can manifest in one of three ways: Localized periosteal new bone formation, endosteal thickening, or, rarely, a radiolucent cortical fracture line (Fig. 31-41).[32,33,88,136]

In cases in which the plain radiographs are normal, technetium radionuclide bone scanning may be helpful. When positive, the bone scan reveals a local area of increased tracer uptake at the site of the fracture (Fig. 31-42). CT rarely demonstrates the fracture line, but often delineates increased marrow density, endosteal and periosteal new bone formation, and may show soft tissue edema within the area of concern. Magnetic resonance (MR) imaging[70,88] shows a localized band of very low signal intensity continuous with the cortex. These MR findings can be diagnostic for a stress fracture, and will differentiate such lesions from malignancy, thereby obviating the need for biopsy.

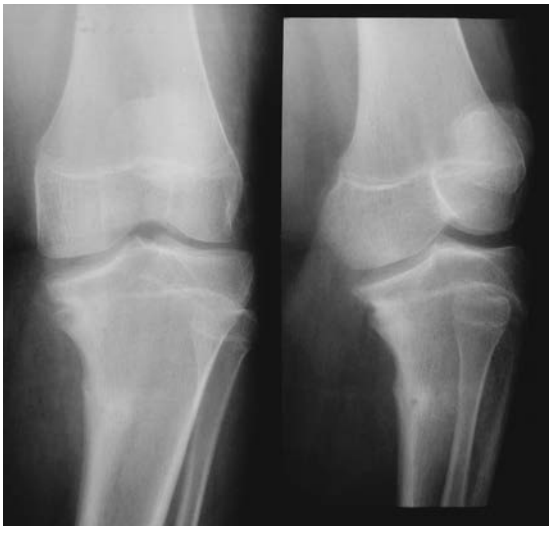

FIGURE 31-41 Anteroposterior and lateral radiographs of the knee of a 15-year old with adolescent onset tibia vara. Note the posteromedial stress fracture.

Tibia

The most common location for a tibial stress fracture is in the proximal third.[43,64] The child normally has a painful limp of gradual onset with no history of a specific injury. The pain is described as dull, occurring in the calf near the upper end of the tibia on its medial aspect, and occasionally is bilateral. Physical findings include local tenderness on one or both sides of the tibial crest with a varying degree of swelling.

The treatment of a child with a stress fracture of the tibia begins with activity modification. An active child can rest in a prefabricated walking boot for 4 to 6 weeks followed by gradual increase in activity.[112] Nonunions of stress fractures of the tibia have been described. Green[53] reported six nonunions, each in the middle third of the tibia. Three of these nonunions were in children. Two required excision of the nonunion site with iliac crest bone grafting. The third was treated by electromagnetic stimulation. In cases of stress fractures involving female athletes with dietary, nutritional, and menstrual irregularities, collaboration between pediatric orthopedists, primary care physicians, endocrinologists, and nutritionist is recommended.[65]

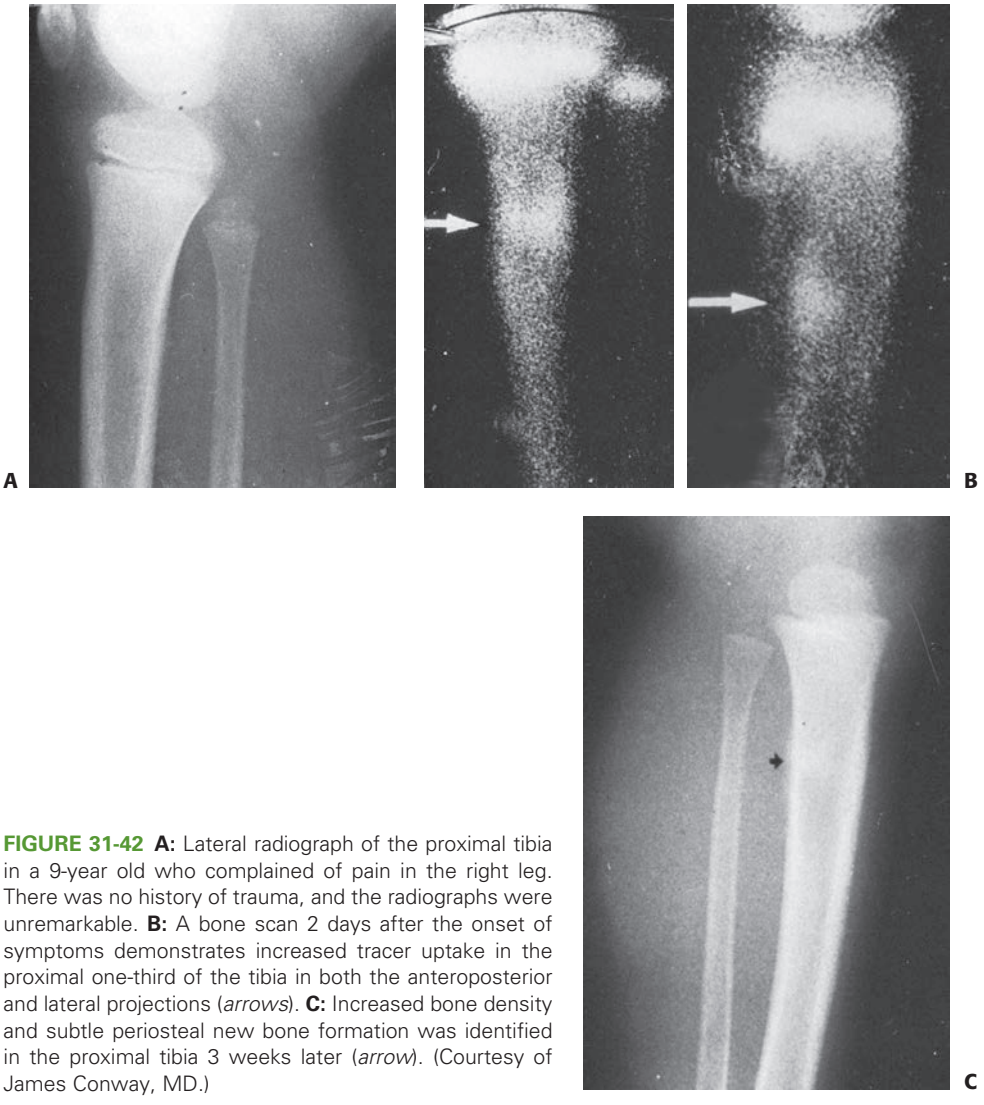

FIGURE 31-42 **A:** Lateral radiograph of the proximal tibia in a 9-year old who complained of pain in the right leg. There was no history of trauma, and the radiographs were unremarkable. **B:** A bone scan 2 days after the onset of symptoms demonstrates increased tracer uptake in the proximal one-third of the tibia in both the anteroposterior and lateral projections (*arrows*). **C:** Increased bone density and subtle periosteal new bone formation was identified in the proximal tibia 3 weeks later (*arrow*). (Courtesy of James Conway, MD.)

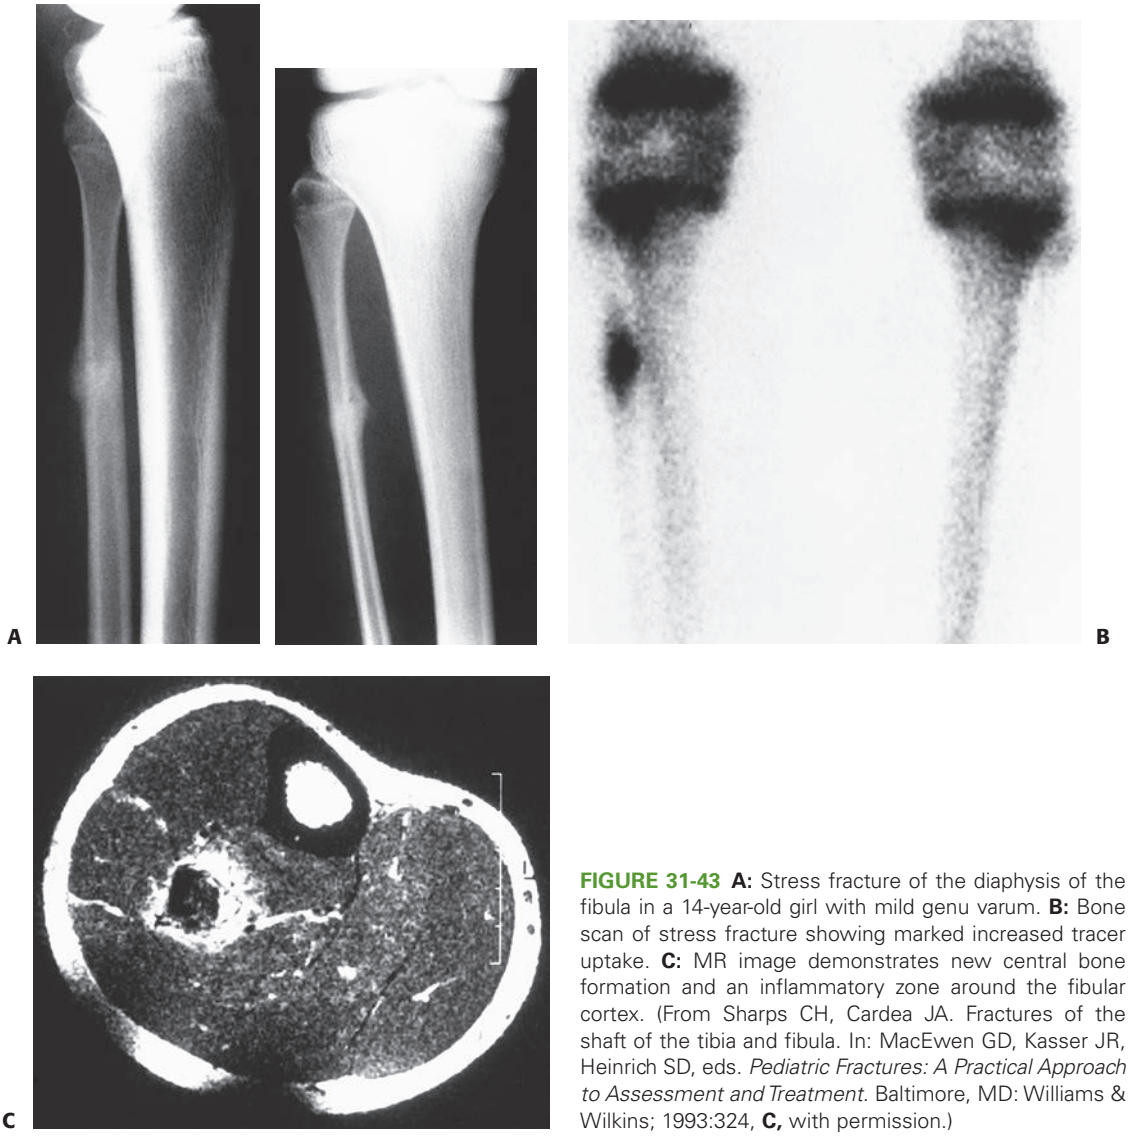

FIGURE 31-43 **A:** Stress fracture of the diaphysis of the fibula in a 14-year-old girl with mild genu varum. **B:** Bone scan of stress fracture showing marked increased tracer uptake. **C:** MR image demonstrates new central bone formation and an inflammatory zone around the fibular cortex. (From Sharps CH, Cardea JA. Fractures of the shaft of the tibia and fibula. In: MacEwen GD, Kasser JR, Heinrich SD, eds. *Pediatric Fractures: A Practical Approach to Assessment and Treatment.* Baltimore, MD: Williams & Wilkins; 1993:324, **C,** with permission.)

Fibula

Pediatric fibular stress fractures normally occur between the ages of 2 and 8 years.[55,89] The fractures are normally localized to the distal third of the fibula. The child presents with a limp and may complain of pain. Tenderness is localized to the distal half of the fibular shaft. Swelling normally is not present. The obvious bony mass commonly seen in a stress fracture of the fibula in an adult is normally not seen in a comparable fracture in a child.

Often the earliest plain radiographic sign of a stress fracture of the fibula is the presence of "eggshell" callus along the shaft of the fibula.[17] The fracture itself cannot always be seen because the periosteal callus may obscure the changes in the narrow canal. Radionuclide bone imaging can help to identify stress fractures before the presence of radiographic changes (Fig. 31-43).

The differential diagnosis includes sarcoma of bone, osteomyelitis, and a soft tissue injury without accompanying bony injury. A careful history, physical examination, laboratory workup, and use of necessary radiographic imaging can usually allow differentiation of a stress fracture from infection or neoplasm.[157] Once a diagnosis of a fibular stress fracture is made, treatment is similar to that utilized in tibial injuries.

32 ANKLE FRACTURES

Kevin G. Shea and Steven L. Frick

Introduction to Distal Tibial and Fibular Fractures

Injuries to the distal tibial and fibular physes are generally reported to account for 25% to 38% of all physeal fractures,[88,173] second in frequency only to distal radial physeal fractures[157]; however, Peterson et al.[159] reported that phalangeal physeal fractures were most common, followed by physeal injuries of the radius and ankle. In skeletally immature individuals, physeal ankle fractures are slightly more common than fractures of the tibial or fibular diaphysis,[130] and these fractures are a common cause of hospital admission in children.[49]

Participation in sports is associated with a significant number of ankle injuries, including sprains and fractures. Up to 58% of physeal ankle fractures occur during sports activities[73,215] and account for 10% to 40% of all injuries to skeletally immature athletes.[147,152,177,200] Physeal ankle fractures are more common in males than in females in some studies.[196] Other studies have demonstrated that ankle injuries may be more likely in young female soccer athletes compared with males.[115] Fractures of the ankle are associated with the following sport activities: Trampolines,[188] scooters,[129] soccer,[115] basketball,[53] skating,[145] and downhill skiing.[17] Increased BMI is also a risk factor for ankle injury in the skeletally immature.[216]

In addition to sports, higher-energy trauma is associated with a significant number of distal tibia and fibular fractures in children. These fractures occur in approximately 10% to 20% of trauma patients presenting to the emergency room.[17] Tibial physeal fractures are most common between the ages of 8 and 15 years, and fibular fractures are most common between 8 and 14 years of age.[196]

Assessment of Distal Tibial and Fibular Fractures

Mechanisms of Injury and Classification of Distal Tibial and Fibular Fractures

Fracture classifications are usually based upon anatomy[2,149,158,196] or mechanism of injury descriptions.[5,13,113] Anatomical classifications distinguish fractures based on the regions of the metaphysis, physis, and epiphysis. Mechanism-of-injury classifications incorporate the forces, which produce the fracture and the anatomic position of the foot and ankle that existed at the time of the injury. Most mechanism-of-injury classifications include the anatomical type of injury produced by a particular mechanism.

Since its description, the Salter–Harris classification system has been widely used to describe the anatomic features of fractures associated with open physes. This straightforward anatomic classification (Fig. 32-1) is effective for rapid communication. It has five distinct categories, which can be applied to most periarticular regions.

Injury classifications based upon the mechanism of injury may have some advantages. The description of the injury includes the anatomic deformity and the forces that produced the injury. An understanding of these forces can facilitate reduction of a displaced fracture. Advanced imaging techniques that allow for comprehensive three-dimensional visualization of the fracture anatomy also facilitate surgical planning and reduction techniques.

Both anatomical and mechanism-of-injury classifications can provide useful information for determining appropriate treatment. The prognoses for growth and deformity have been predicted on the basis of both types of classification.[98,99,196] A theoretical advantage of mechanism-of-injury classifications is that identification of the force producing the injury might give even more information about the possible development of growth arrest than anatomical classifications. For example, a Salter–Harris type III or IV fracture of the tibia produced by a shearing or crushing force might be more likely to result in growth arrest than is a similar injury produced by an avulsion force (Fig. 32-2). However, it is difficult to establish that one type of classification is superior to the other in this regard because of the relatively small numbers of patients reported, the varying ages of patients in most series, and questions about the reproducibility of various classifications.

Ideally, classification systems should have high interobserver and intraobserver agreement. Thomsen et al.[204] studied the reproducibility of the Lauge-Hansen (mechanism-of-injury) and Weber (anatomical) classifications in a series of adult ankle fractures. After all investigators in the study had received a tutorial on both systems and their application, they were asked to classify 94 fractures. On the first attempt, only the Weber classification produced an acceptable level of interobserver agreement. On a second attempt, the Weber classification and most of the Lauge-Hansen classification achieved an acceptable level of interobserver

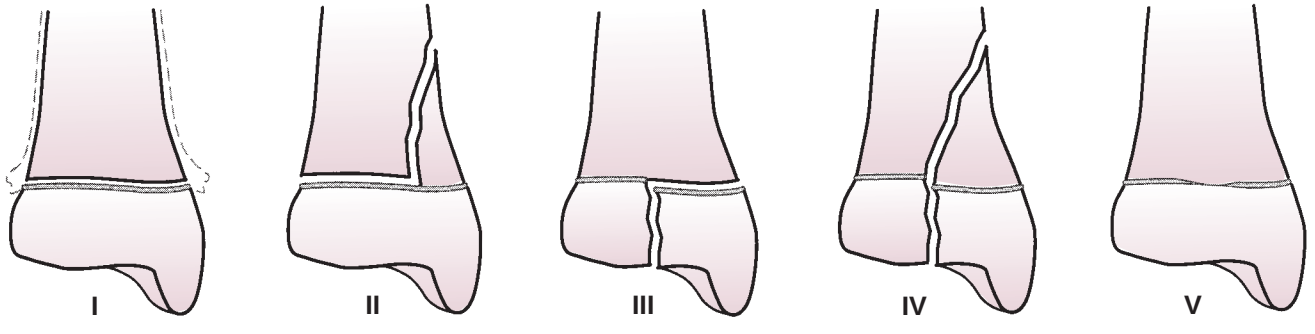

FIGURE 32-1 Salter–Harris anatomic classification as applied to injuries of the distal tibial epiphysis.

FIGURE 32-2 Comminuted Salter–Harris type IV fracture of the distal tibia and displaced Salter–Harris type I fracture of the distal fibula produced by an inversion (shearing) mechanism in a 10-year-old girl.

agreement. These authors concluded that all fracture classification systems should have demonstrably acceptable interobserver agreement rates before they are adopted, an argument made even more forcefully in an editorial by Burstein.[33] Vahvanen and Aalto[207] compared their ability to classify 310 ankle fractures in children with the Weber, Lauge-Hansen, and Salter–Harris classifications. They found that they were "largely unsuccessful" using the Weber and Lauge-Hansen classifications, but could easily classify the fractures using the Salter–Harris system.

The most widely accepted mechanism-of-injury classification of ankle fractures in children is that described by Dias and Tachdjian,[57] who modified the Lauge-Hansen classification based on their review of 71 fractures (Fig. 32-3). Their original classification (1978) consisted of four types in which the first word refers to the position of the foot at the time of injury and the second word refers to the force that produces the injury.

Other fracture types were subsequently added, including axial compression, juvenile Tillaux, triplane, and other physeal injuries by Tachdjian.[201] Syndesmosis injuries have also been recently described.[51] "Axial compression injury" describes the mechanism of injury but not the position of the foot. Juvenile Tillaux and triplane fractures are called transitional fractures as they occur when the physis is transitioning from open to closed, and are believed to be caused by external rotation.[175] The final category, "other physeal injuries," includes diverse injuries, many of which have no specific mechanism of injury.

Classification of Ankle Fracture in Children (Dias–Tachdjian) (Fig. 32-3)

Supination–Inversion

- Grade I: The adduction or inversion force avulses the distal fibular epiphysis (Salter–Harris type I or II fracture). Occasionally, the fracture is transepiphyseal; rarely, the lateral ligaments fail.
- Grade II (Fig. 32-4): Further inversion produces a tibial fracture, usually a Salter–Harris type III or IV and rarely a Salter–Harris type I or II injury, or the fracture passes through the medial malleolus below the physis (Fig. 32-5).

Supination–Plantarflexion

The plantarflexion force displaces the epiphysis directly posteriorly, resulting in a Salter–Harris type I or II fracture. Fibular fractures were not reported with this mechanism. The tibial fracture may be difficult to see on anteroposterior radiographs (Fig. 32-6).

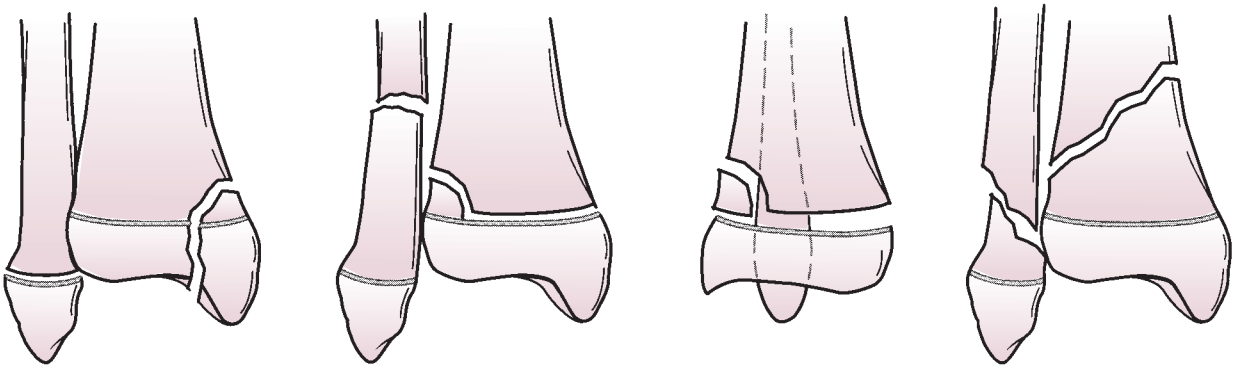

FIGURE 32-3 Dias–Tachdjian classification of physeal injuries of the distal tibia and fibula.

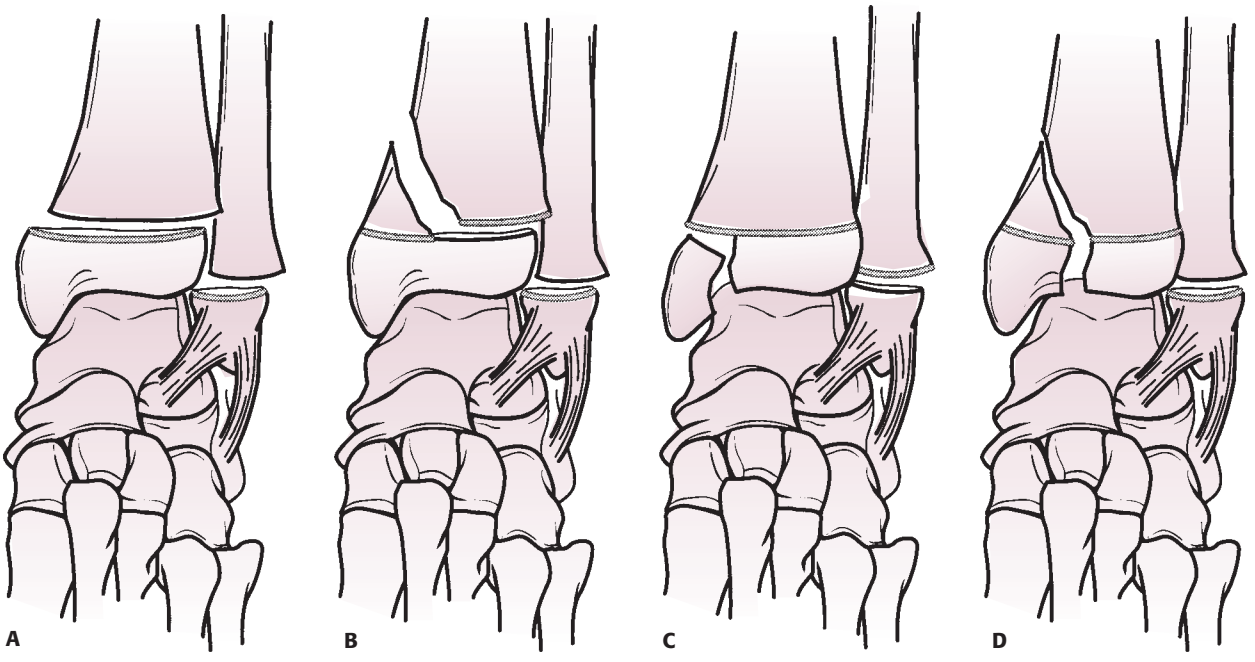

FIGURE 32-4 Variants of grade II supination–inversion injuries (Dias–Tachdjian classification). **A:** Salter–Harris type I fracture of the distal tibia and fibula. **B:** Salter–Harris type I fracture of the fibula, Salter–Harris type II tibial fracture. **C:** Salter–Harris type I fibular fracture, Salter–Harris type III tibial fracture. **D:** Salter–Harris type I fibular fracture, Salter–Harris type IV tibial fracture.

FIGURE 32-5 Severe supination–inversion injury with displaced fracture of the medial malleolus distal to the physis of the tibia.

FIGURE 32-6 Lateral view of a supination–plantarflexion injury.

Supination–External Rotation

- Grade I: The external rotation force results in a Salter–Harris type II fracture of the distal tibia (Fig. 32-7). The distal fragment is displaced posteriorly, as in a supination–plantarflexion injury, but the Thurston–Holland fragment is visible on the anteroposterior radiographs, with the fracture line extending proximally and medially. Occasionally, the distal tibial epiphysis is rotated but not displaced.
- Grade II: With further external rotation, a spiral fracture of the fibula is produced, running from anteroinferior to posterosuperior (Fig. 32.8).

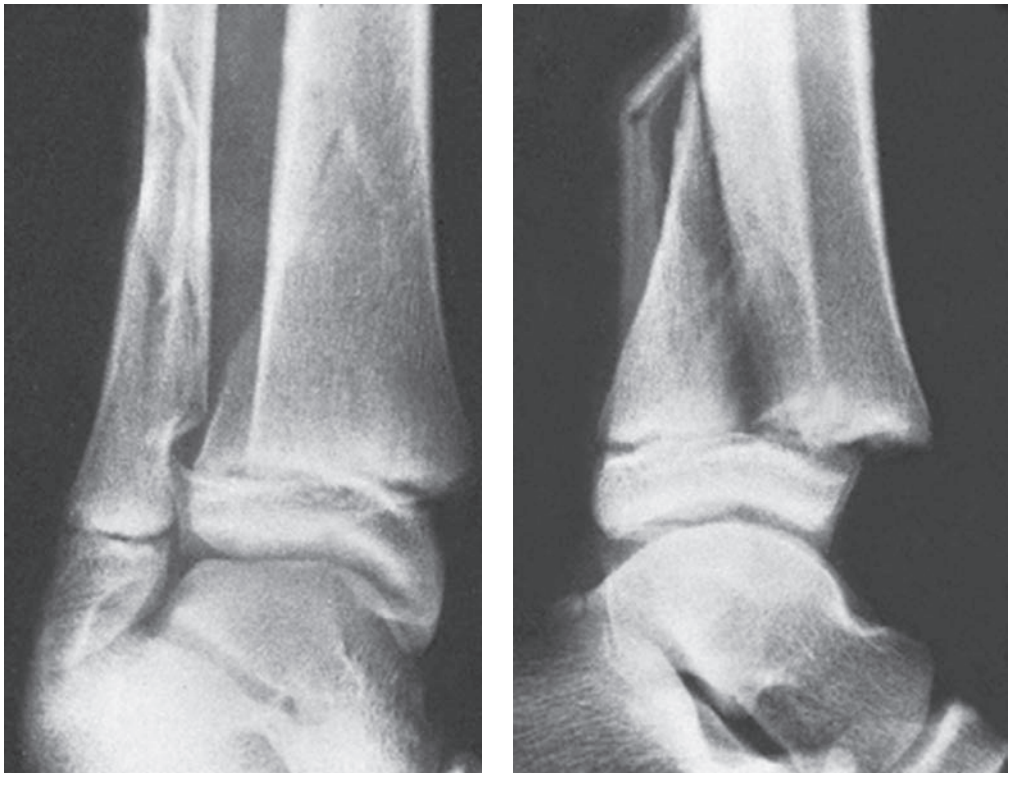
Pronation–Eversion–External Rotation

A Salter–Harris type I or II fracture of the distal tibia occurs simultaneously with a transverse fibular fracture. The distal tibial fragment is displaced laterally and the Thurston–Holland fragment, when present, is lateral or posterolateral (Fig. 32-9). Less frequently, a transepiphyseal fracture occurs through the medial malleolus (Salter–Harris type II). Such injuries may be associated with diastasis of the ankle joint, which is uncommon in children.

Axial Compression

This results in a Salter–Harris type V injury of the distal tibial physis. Initial radiographs usually show no abnormality, and the diagnosis is established when growth arrest is demonstrated on follow-up radiographs.

FIGURE 32-7 Stage I supination–external rotation injury in a 10-year-old child; the Salter–Harris type II fracture begins laterally.



A **B**

FIGURE 32-8 Stage II supination–external rotation injury. **A:** Oblique fibular fracture also is visible on anteroposterior view. **B:** Lateral view shows the posterior metaphyseal fragment and posterior displacement.

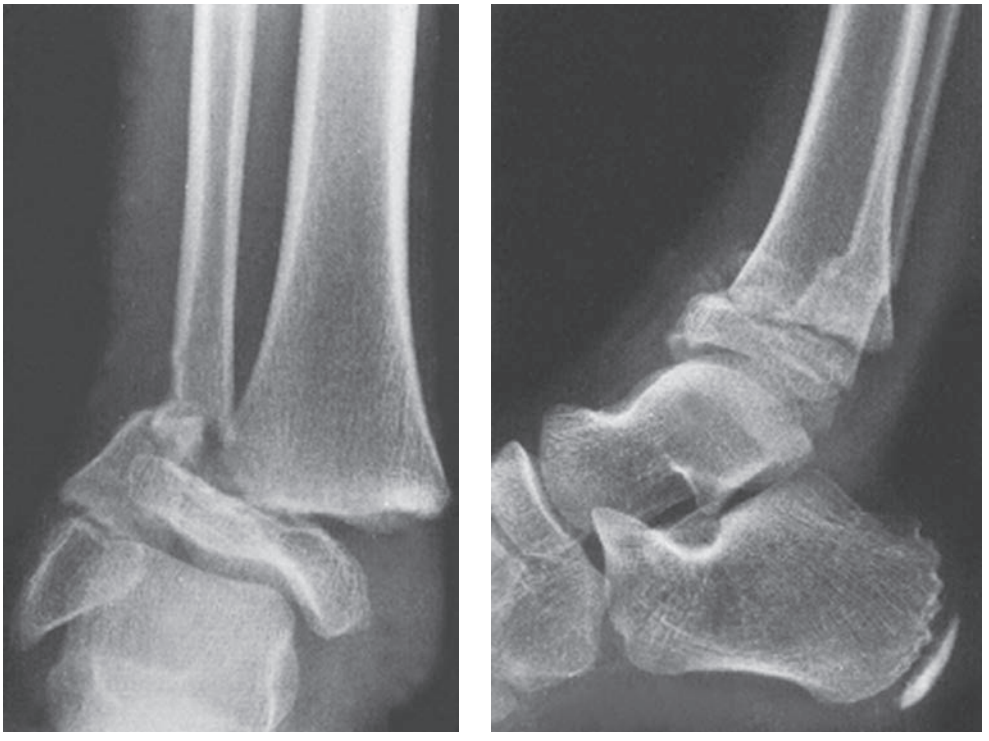


FIGURE 32-9 **A:** According to the Dias–Tachdjian classification, this injury in a 12-year-old boy would be considered a pronation–eversion–external rotation injury resulting in a Salter–Harris type II fracture of the distal tibia and a transverse fibular fracture. **B:** The anterior displacement of the epiphysis, visible on the lateral view, however, makes external rotation an unlikely component of the mechanism of injury; the mechanism is more likely pronation–dorsiflexion.

Transitional Fractures of the Distal Tibia and Fibula

Because the distal tibial physis closes in an asymmetric pattern over a period of about 18 months, injuries sustained during this period can produce fracture patterns that are not seen in younger children with completely open physes.[126] This group of fractures has been labeled "transitional" fractures because they occur during the transition from a skeletally immature ankle to a skeletally mature ankle. Such fractures, which include juvenile Tillaux and "triplane" fractures with two to four fracture fragments, have been described by Kleiger and Mankin,[108] Marmor,[131] Cooperman et al.,[46] Kärrholm et al.,[97] and Denton and Fischer.[54] The adolescent pilon fracture has been described by Letts et al.[117] The incisural fracture has been described by Cummings and Hahn.[52] Syndesmosis injuries have been described by Cummings.[51]

Classification of these fractures is even more confusing than that of other distal tibial fractures. Advocates of mechanism-of-injury systems agree that most juvenile Tillaux and triplane fractures are caused by external rotation, but they disagree as to the position of the foot at the time of the injury.[55,56,164] Some authors[56] classify juvenile Tillaux fractures as stage I injuries, with further external rotation causing triplane fractures, and still further external rotation causing stage II injuries with fibular fracture. Others emphasize the extent of physeal closure as the only determinant of fracture pattern.[45]

Advocates of anatomical classifications are handicapped by the different anatomical configurations triplane fractures may exhibit on different radiograph projections, making tomography, computed tomography (CT) scanning, or examination at open reduction necessary to determine fracture anatomy and number of fragments. Because these fractures occur near the end of growth, growth disturbance is rare. Anatomical classification is, therefore, more useful for descriptive purposes than for prognosis.

Juvenile Tillaux Fracture of the Distal Tibia and Fibula

The juvenile Tillaux fracture is a Salter–Harris type III fracture involving the anterolateral distal tibia. The portion of the physis not involved in the fracture is closed (Fig. 32-10).

Triplane Fracture of the Distal Tibia and Fibula

A group of fractures that have in common the appearance of a Salter–Harris type III fracture on the anteroposterior radiographs and of a Salter–Harris type II fracture on the lateral radiographs (Fig. 32-11). CT scans can be very helpful to understand the complex anatomy of these fractures (Fig. 32-11).[14,49,107] Ipsilateral triplane and diaphyseal fractures have been reported, and one of the fractures can be missed if adequate images are not obtained.[14,49,91]

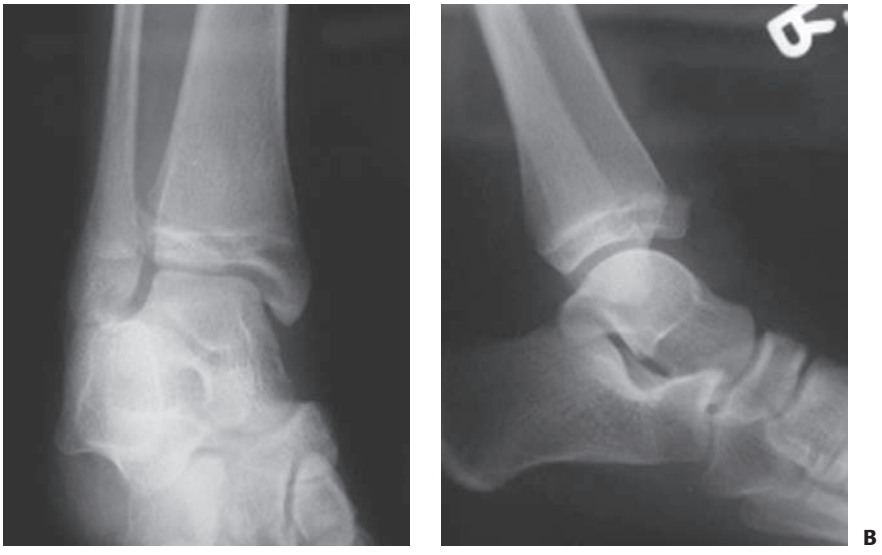

FIGURE 32-10 **A:** Anteroposterior radiograph of Salter–Harris type III/juvenile Tillaux fracture. **B:** Lateral radiograph of Salter–Harris type III/juvenile Tillaux fracture.

FIGURE 32-12 Anteroposterior and lateral radiographs of a pilon fracture in an adolescent.

Adolescent Pilon Fractures of the Distal Tibia and Fibula

The pediatric/adolescent pilon fracture[117] is defined as a fracture of the "tibial plafond with articular and physeal involvement, variable talar and fibular involvement, variable comminution, and greater than 5 mm of displacement" (Fig. 32-12). Based upon a small number of cases, Letts et al. developed a three-part classification system. Type I fractures have minimal comminution and no physeal displacement. Type II fractures have marked comminution and less than 5 mm of physeal displacement. Type III fractures have marked comminution and more than 5 mm of physeal displacement.

A, B **C**

FIGURE 32-13 Anteroposterior **(A)**, lateral **(B)**, and oblique **(C)** views of the ankle demonstrating an apparent small juvenile Tillaux fracture in a 14-year-old girl.

Incisura Fractures of the Distal Tibia and Fibula

Incisural fractures are fractures that resemble Tillaux on standard radiographs, but the size of the fragment is smaller than that typically seen with the Tillaux fractures (Fig. 32-13).[52] On the CT scan, this fracture does not extend to the anterior cortex of the distal tibia (Fig. 32-14). The mechanism of injury may be an avulsion of the fragment by the interosseous ligament. This may be a variant of an adult tibiofibular diastasis injury.

Syndesmosis Injuries of the Distal Tibial and Fibular Fractures

The authors have seen syndesmosis injuries in young patients. These have been associated with fractures of the distal fibula, Tillaux injuries, S-H I fractures, and proximal fibula fractures (Figs. 32-15, 32-16, 32-17). These fractures are probably rare and there is very limited literature on this injury.[156]

Stress Fractures of the Distal Tibia and Fibula

Stress fractures can occur in the distal tibial metaphyseal area (Fig. 32-18), or through the distal fibular physis (Fig. 32-19). These patients may present with warmth, swelling, and pain around the metaphyseal or physeal regions. In our experience, these injuries are more common in gymnasts, ice skaters, and running/endurance athletes. We have seen stress fractures through the distal fibular physeal scar in running athletes.

Signs and Symptoms of Distal Tibial and Fibular Fractures

Patients with significantly displaced fractures have severe pain and obvious deformity. The position of the foot relative to the leg may provide important information about the mechanism of injury (Fig. 32-20) and should be considered in planning

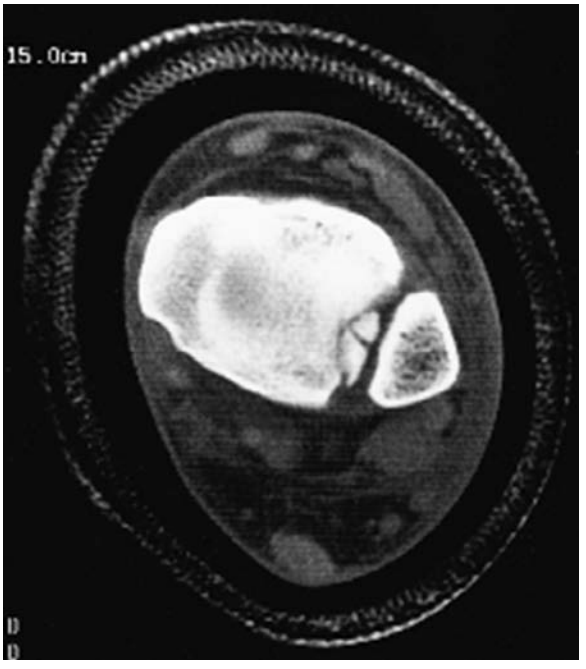

FIGURE 32-14 Incisural fracture: CT scan at the level of the tibiotalar joint demonstrates that the fracture fragment does not include the attachment of the anterior-inferior tibiofibular ligament.

reduction. The status of the skin, pulses, and sensory and motor function should be determined and recorded. Tenderness, swelling, and deformity in the ipsilateral leg and foot should be noted. In patients with tibial shaft fractures, the ankle should be carefully evaluated clinically and radiographically.

Although compartment syndromes are rare, they do occur in these locations.[47,139] If patients are admitted to the hospital, discussion with the nursing staff about signs and symptoms of compartment syndrome is important. If patients are treated as

FIGURE 32-15 **A:** Syndesmosis injury with distal fibula fracture. Radiographs with comparison of right and left sides. Note the widening of the medial clear space and the syndesmosis. **B:** Use of two percutaneously placed cannulated screws to reduce the syndesmosis.

outpatients, the patient and family should be informed about the possibility of compartment syndrome and instructed to return to the hospital for evaluation if problems with pain control develop.

Imaging and Other Diagnostic Studies for Distal Tibial and Fibular Fractures

Patients with nondisplaced or minimally displaced ankle fractures often have no deformity, minimal swelling, and moderate pain. Because of their benign clinical appearance, such fractures may be easily missed if radiographs are not obtained. Petit et al.[161] reviewed 2,470 radiographs from pediatric emergency rooms, demonstrating abnormal radiographic findings in 9%. Guidelines known as The Ottawa Ankle Rules have been established for adults to try to determine which injuries require radiographs.[199] The Ottawa Ankle Rules have also been evaluated in children over the age of 5. These rules appear to be a reliable tool to exclude fractures in children greater than 5 years of age presenting with ankle and midfoot injuries and may significantly decrease x-ray use with a low likelihood of missing a fracture.[59] The indications for radiographs according to the guidelines are complaints of pain near a malleolus with either inability to bear weight or tenderness to palpation at the malleolus. Chande[43] prospectively studied 71 children with acute ankle injuries to determine if these guidelines could be applied to pediatric patients with ankle injuries. It was determined that if radiographs were obtained only in children with tenderness over the malleoli, and inability to bear weight, a 25% reduction in radiographic examinations could be achieved without missing any fractures. The physical examination should focus upon physeal areas of the tibia and fibula, when evaluating ankle injuries, to determine if radiographs are necessary. Interpretation of radiographs should focus upon signs of physeal injury, including soft tissue swelling in these regions.

For patients with obvious deformities, anteroposterior, mortise, and lateral radiographs centered over the ankle may provide sufficient information to plan treatment. Although obtaining views of the joint above and below is recommended for most fractures, obtaining a film centered over the midtibia to include the knee and ankle joints on the radiographs significantly decreases the quality of ankle views and is not recommended.

FIGURE 32-19 Stress fracture of distal fibula. A 16-year-old male with 6 weeks of pain while running track. Anteroposterior radiograph shows widened physis. The clinical examination shows point tenderness over the fibular physis.

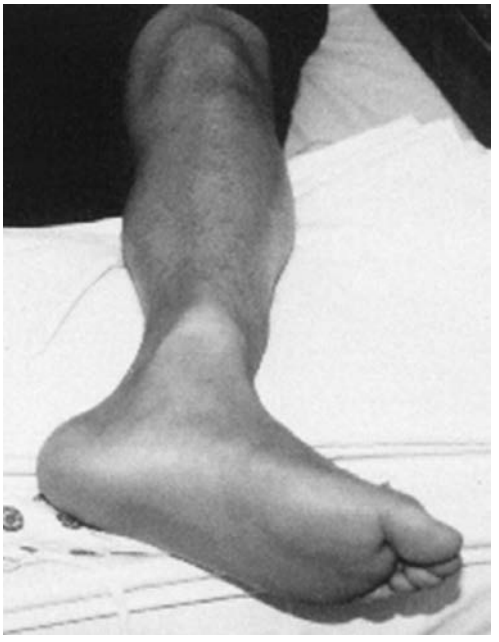

FIGURE 32-20 Severe clinical deformity in a 14-year-old boy with an ankle fracture. It is obvious without radiographs that internal rotation will be needed to reduce this fracture.

For patients without obvious deformities, a high-quality mortise view of the ankle is essential in addition to anteroposterior and lateral views. On a standard anteroposterior view, the lateral portion of the distal tibial physis is usually partially obscured by the distal fibula. The vertical component of a triplane or Tillaux fracture can be hidden behind the overlying fibular cortical shadow.[119] A study by Vangsness et al.[208] found that diagnostic accuracy was essentially equal when using anteroposterior, lateral, and mortise views compared with using only mortise and lateral views. Therefore, if only two views are to be obtained, the anteroposterior view may be omitted and lateral and mortise views obtained.

Haraguchi et al.,[79] described two special views designed to detect avulsion fractures from the lateral malleolus that are not visible on routine views, and to distinguish whether they represent avulsions of the anterior tibiofibular ligament or the calcaneofibular ligament attachments. The anterior tibiofibular ligament view is made by positioning the foot in 45 degrees of plantarflexion and elevating the medial border of the foot 15 degrees. The calcaneofibular ligament view is obtained by rotating the leg 45 degrees inward.

Stress views are occasionally recommended historically to rule out ligamentous instability, but the authors see only rare indications for stress radiography in skeletally immature patients. The discomfort of stress views in an acute injury can be avoided by using other imaging options, such as magnetic resonance imaging (MRI).

Bozic et al.[27] studied the age at which the radiographic appearance of the incisura fibularis, tibiofibular clear space, and tibiofibular overlap develops in children.[27] The purpose of their study was to facilitate the diagnosis of distal tibiofibular syndesmotic injury in children. They found that the incisura became detectable at a mean age of 8.2 years for girls and 11.2 years for boys. The mean age at which tibiofibular overlap appeared on the AP view was 5 years for both sexes; on the mortise view, it was 10 years for girls and 16 years for boys. The range of clear space measurements in normal children was 2 to 8 mm, with 23% of children having a clear space greater than 6 mm—a distance considered abnormal in adults.

CT is useful in the evaluation of intra-articular fractures, especially juvenile Tillaux and triplane fractures (Fig. 32-21).[7,14,31,49,66,95,107] Transverse images are obtained with thin cuts localized to the joint, and high-quality reconstructions can be produced in the coronal and sagittal planes without repositioning the ankle. Three-dimensional CT reconstructions may add further useful information, and readily available software packages allow easy production of such images (Fig. 32-22). These images can assist with minimally invasive approaches, the use of percutaneous reduction clamps, and positioning of fixation screws.

MRI may be useful in the evaluation of complex fractures of the distal tibia and ankle in patients with open physes. Smith et al.[195] found that of four patients with acute (3 to 10 days) physeal injuries, MRI showed that three had more severe

fractures than indicated on plain films (Fig. 32-23). Early MRI studies (3 to 17 weeks after injury) not only added information about the pattern of physeal disruption but also supplied early information about the possibility of growth abnormality. MRI has been reported to be occasionally helpful in the identification of osteochondral injuries to the joint surfaces in children with ankle fractures.[105] Although these injuries may be more common in adult fractures, we believe that these types of injuries are very rare in younger patients.

Carey et al.[36] obtained MRI studies on 14 patients with known or suspected growth plate injury. The MRI detected five radiographically occult fractures in the 14 patients, changed the Salter–Harris classification in two cases, and resulted in a change in treatment plan in 5 of the 14 patients studied. These

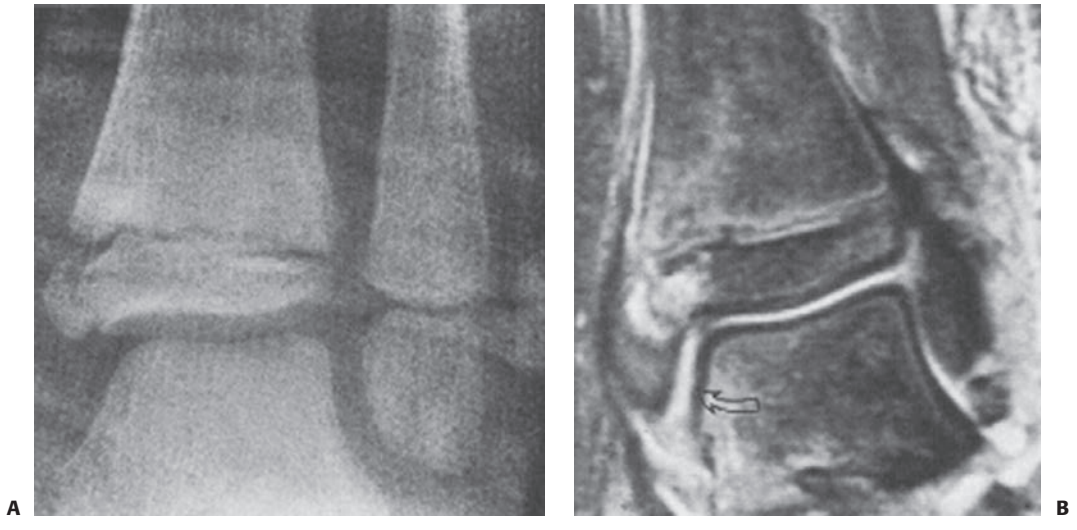

FIGURE 32-23 **A:** Follow-up radiograph of a 7-year-old boy 1 week after an initially nondisplaced Salter–Harris type III fracture from a supination–inversion injury of the distal tibia. **B:** Because of the incomplete ossification of this area and concern that the fracture might have displaced, MRI was performed. Note that the distance between the medial malleolus and the talus is greater than the distance between the talus and the distal tibia or lateral malleolus, confirming displacement of the fracture.

studies would seem to contradict an earlier study by Petit et al.,[1] that showed only one patient in a series of 29 patients in whom MRI revealed a diagnosis different from that made on plain films. Iwinska-Zelder et al.[90] found that the MRI changed the management in 4 of 10 patients with ankle fractures seen on plain radiographs. Seifert et al.[187] found the MRI identified physeal injuries that were not identified by plain radiographs. At this time, the indications for MRI in the evaluation of ankle fractures in skeletally immature patients are still being defined, but this imaging modality may be a more sensitivity tool for identification of minimally displaced or more complex injuries.[14] In a recent prospective study of skeletally immature patients with clinically diagnosed Salter I fractures of the distal fibula, none of the 18 patients imaged by MRI had evidence of physeal injury. The patients had a mean age of 8 years, and over 70% had evidence of ligamentous sprain on MRI. This questions the principle that the physis is the weak link in the musculoskeletal system in this age group.[24] If physeal arrest occurs, MRI scans are useful for mapping physeal bars.[69,82]

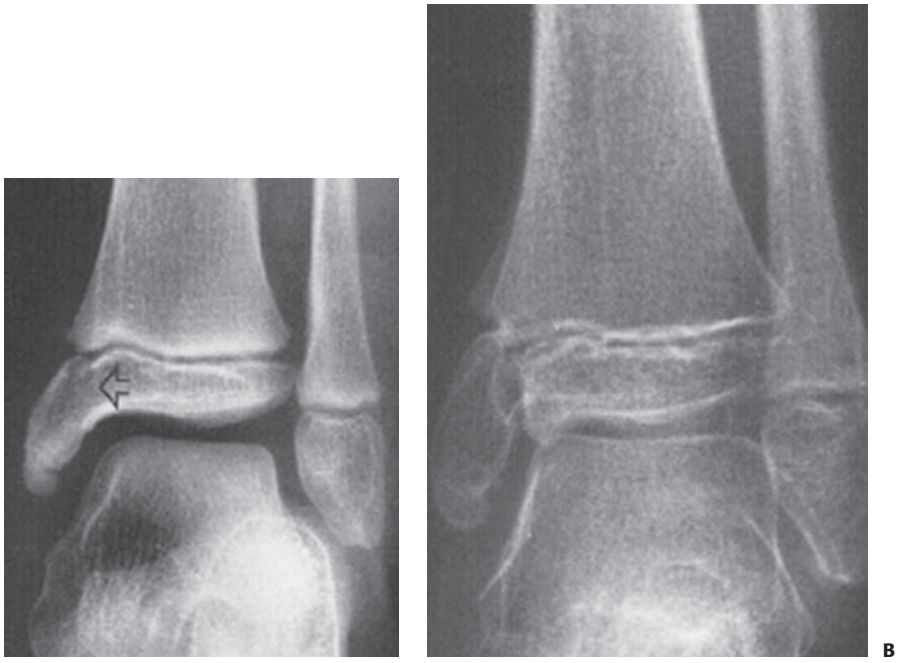
The use of ultrasound to detect radiographically occult fractures may be used for pediatric ankle fractures.[192]

Pitfalls in Diagnosis

A number of accessory ossification centers and normal anatomical variations may cause confusion in the interpretation of plain films of the ankle (Fig. 32-24). In a group of 100 children between the ages of 6 and 12 years, Powell[165] found accessory ossification centers on the medial side (os subtibiale) in 20% and on the lateral side (os subfibulare) in 1%. If they are asymptomatic on clinical examination, these ossification centers are of little concern, but tenderness localized to them may indicate an injury. Stress views to determine motion of the fragments or MRI scanning may occasionally be considered if an injury to an accessory ossification center is suspected.

FIGURE 32-24 Secondary ossification center in the lateral malleolus (*arrows*) of a 10-year-old girl. Note the smooth border of the fibula and the ossification center. She also has a secondary ossification center in the medial malleolus.

Clefts in the lateral side of the tibial epiphysis may simulate juvenile Tillaux fractures, and clefts in the medial side may simulate Salter–Harris type III fractures.[104] The presence of these clefts on radiographs of a child with an ankle injury may result in overtreatment if they are misdiagnosed as a fracture. Conversely, attributing a painful irregularity in these areas to anatomical variation may lead to undertreatment (Fig. 32-25). Other anatomical variations include a bump on the distal fibula that simulates a torus fracture and an apparent offset of the distal fibular epiphysis that simulates a fracture.



A **B**

FIGURE 32-25 **A:** Mortise view of the ankle of a 10-year-old girl who had slight swelling and tenderness at the medial malleolus after an "ankle sprain." The ossicle at the tip of the medial malleolus was correctly identified as an os subtibiale. A subtle line extending from the medial physis to just distal to the medial tibial plafond (*arrow*) was also believed to be an anatomic variant. **B:** Four weeks after injury, soreness persisted and radiographs clearly demonstrated a displaced Salter–Harris type III fracture.

These radiographic findings should be correlated with physical examination findings of focal swelling and point tenderness that correspond with the imaging in the diagnosis of skeletal injury.

Pathoanatomy and Applied Anatomy Relating to Distal Tibial and Fibular Fractures

The ankle joint closely approximates a hinge joint. It is the articulation between the talus and the ankle mortise, which is a syndesmosis consisting of the distal tibial articular surface, the medial malleolus, and the distal fibula or lateral malleolus.

Four ligamentous structures bind the distal tibia and fibula into the ankle mortise (Fig. 32-26). The anterior and posterior-inferior tibiofibular ligaments course inferiorly from the anterior and posterior surfaces of the distal lateral tibia to the anterior and posterior surfaces of the lateral malleolus. The anterior ligament is important in the pathomechanics of "transitional" ankle fractures. Just anterior to the posterior-inferior tibiofibular ligament is the broad, thick inferior transverse ligament, which extends down from the lateral malleolus along the posterior border of the articular surface of the tibia, almost to the medial malleolus. This ligament serves as a part of the articular surface for the talus. Between the anterior and posterior-inferior tibiofibular ligaments, the tibia and fibula are bound by the interosseous ligament, which is continuous with the interosseous membrane above. This ligament may be important in the pathomechanics of what we have termed incisural fractures.

On the medial side of the ankle, the talus is bound to the ankle mortise by the deltoid ligament (Fig. 32-27). This ligament arises from the medial malleolus and divides into superficial and deep layers. Three parts of the superficial layer are identified by their attachments: Tibionavicular, calcaneotibial, and posterior talotibial ligaments. The deep layer is known as the anterior talotibial ligament, again reflecting its insertion and origin. On the lateral side, the anterior and posterior talofibular ligament, with the calcaneofibular ligaments, make up the lateral collateral ligament (Fig. 32-28).

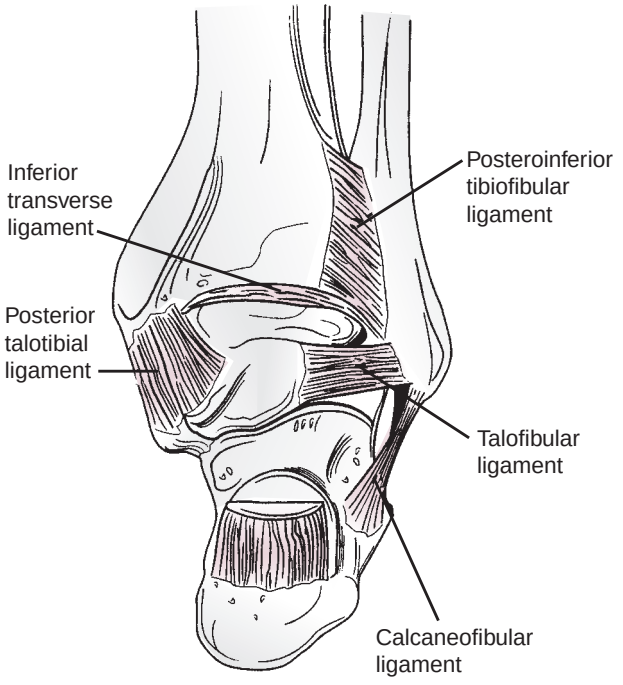


FIGURE 32-26 Posterior view of the distal tibia and fibula and the ligaments making up the ankle mortise.

In children, all medial and lateral ligaments originate distal to the tibial or fibular physis. Because the ligaments are often stronger than the physes, physeal fractures have generally been viewed as more common than ligamentous injuries in children. Advanced imaging studies have shown that the rate of ankle fractures compared to ligamentous injuries is variable,[63] and

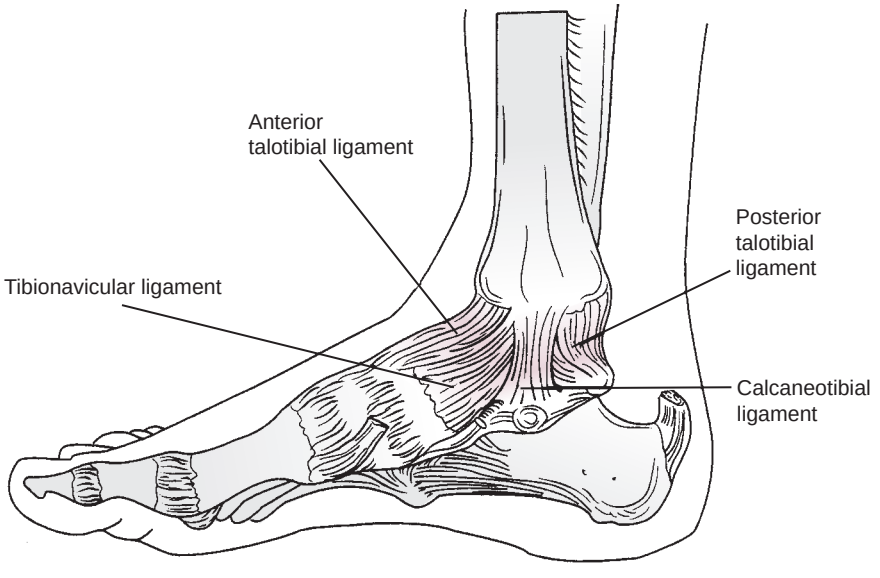

FIGURE 32-27 Medial view of the ankle demonstrating the components of the deltoid ligament.

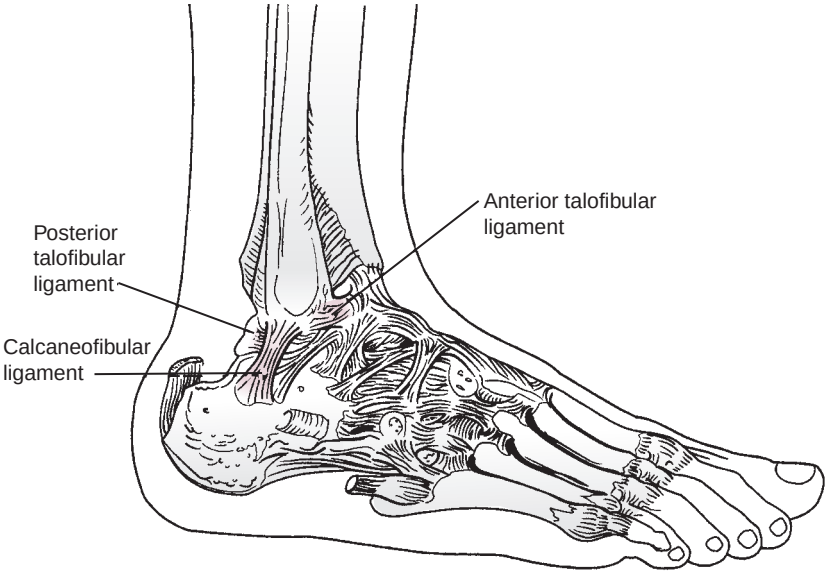

FIGURE 32-28 Lateral view of the ankle demonstrating the anterior and posterior talofibular ligaments and the calcaneofibular ligament.

this is likely dependent on multiple factors such as the mechanism of injury, rate of force application, relative strength of the physis, and age of the patient. When distal tibia and fibular fragments are displaced together, the syndesmosis at the level of the fracture is usually intact (Fig. 32-29).

The distal tibial ossification center generally appears at 6 to 24 months of age. Its malleolar extension begins to form around the age of 7 or 8 years and is mature or complete at the age of 10 years. The medial malleolus develops as an elongation of the distal tibia ossific nucleus, although in 20% of cases, this may originate from a separate ossification center, the os tibial. This can be mistaken as a fracture.[102] The physis usually closes around the age of 15 years in girls and 17 years in boys. This process takes approximately 18 months and occurs first in the central part of the physis, extending next to the medial side, and finally ending laterally. This asymmetric closure sequence is an important anatomical feature of the growing ankle and is responsible for certain fracture patterns in adolescents, especially transitional fractures (Fig. 32-30).

The distal fibular ossification center appears around the age of 9 to 24 months. This physis is located at the level of the ankle joint initially, and moves distally with growth.[100,214] Closure of this physis generally follows closure of the distal tibial physis by 12 to 24 months.

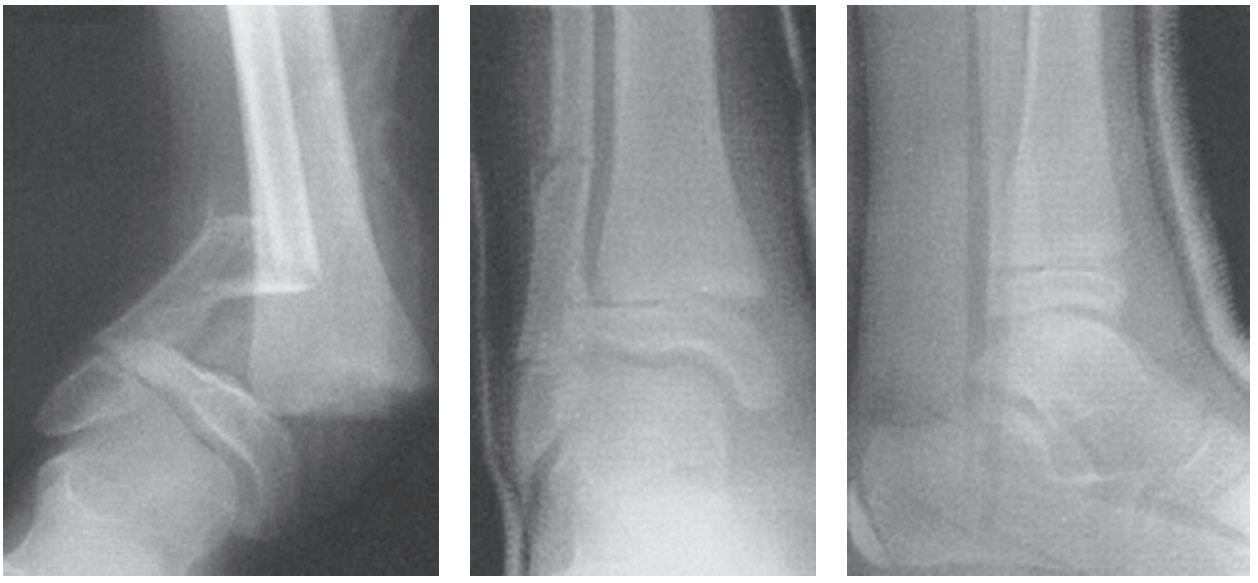

FIGURE 32-29 **A:** Pronation–external rotation injury resulting in a Salter–Harris type I fracture of the distal tibial physis. Note that despite this severe displacement, the relationship between the distal epiphysis of the tibia and distal fibula is preserved, and widening of the syndesmosis between the tibia and fibula is not present in this region. **B, C:** Anteroposterior and lateral radiographs demonstrate satisfactory closed reduction.

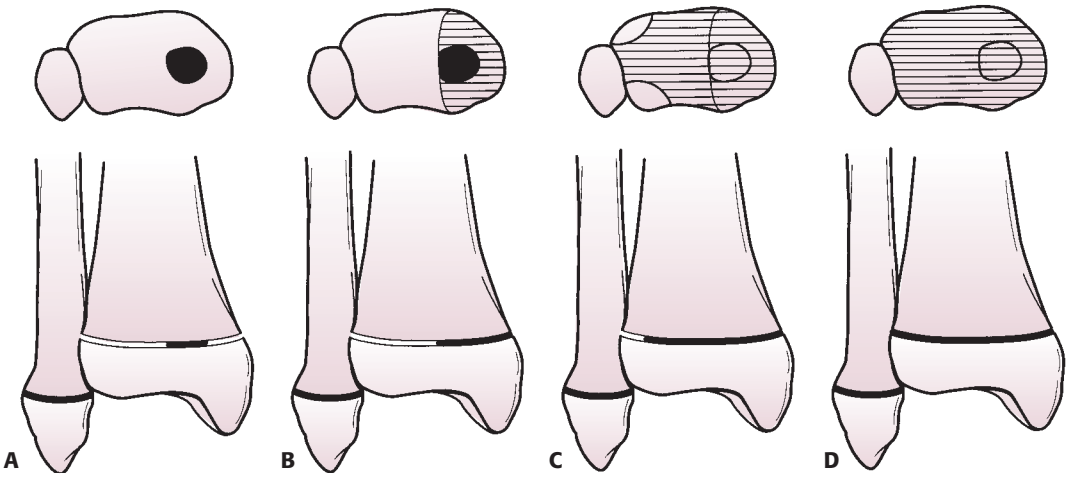

FIGURE 32-30 Closure of the distal tibial physis begins centrally **(A),** extends medially **(B),** and then laterally **(C)** before final closure **(D).**

The locations of the sensory nerves are important anatomic landmarks, as surgical exposures should aim to protect these structures. The superficial peroneal nerve branches may be most vulnerable around the ankle, especially during arthroscopic and arthrotomy approaches for triplane and Tillaux fractures.[15] This is important when arthroscopic and percutaneous reduction techniques are employed for fracture treatment (refer to section on Fracture Reduction Tips, Arthroscopic Assistance, Use of Percutaneous Clamps, Implants).

Treatment Options for Distal Tibial and Fibular Fractures

Appropriate treatment of ankle fractures in children depends on the location of the fracture, the degree of displacement, and the age of the child (Table 32-1). Nondisplaced fractures may be simply immobilized. A recent randomized clinical trial for minimally displaced low-risk ankle fractures compared a fiberglass posterior splint to a removable ankle stirrup brace. This study demonstrated good outcomes in both groups.[8] Closed reduction and cast immobilization may be appropriate for displaced fractures; if the closed reduction cannot be maintained with casting, skeletal fixation may be necessary. If closed reduction is not possible, open reduction may be indicated, followed by internal fixation or cast immobilization.

The anatomical type of the fracture (usually defined by the Salter–Harris classification), the mechanism of injury, and the amount of displacement of the fragments are important considerations. When the articular surface is disrupted, the amount of articular step-off or separation must be measured. The neurologic and vascular status of the limb or the status of the skin may require emergency treatment of the fracture and associated problems. The general health of the patient and the time since injury must also be considered.

TABLE 32-1 Current Treatment Options

Fracture	Options	Pro	Cons
Distal tibia physis	Above-knee versus below-knee cast	Below-knee casts may allow for less knee stiffness and muscle atrophy of the thigh	For fractures with potential for displacement, the below-knee cast may increase the risk of displacement.
	Local anesthesia with sedation versus general anesthesia (closed reduction of fractures)	Local anesthesia techniques combined with sedation in the ER may be less expensive, and allow for early reduction	Guidelines for sedation techniques must follow guidelines established by the American Society of Anesthesiologists, and adequate facilities and personnel may not be available in all emergency rooms.
	Minimally invasive approaches (including arthroscopic assistance) versus traditional open surgical exposures	Arthroscopic-assisted procedures may allow for smaller incisions, and better assessment of articular reductions than open exposures	Additional equipment and OR staffing requirements for arthroscopy are necessary. Surgeon experience with arthroscopy may be more limited.
	Bioabsorbable versus metal implants	Bioabsorbable devices do not require removal, and subsequent imaging studies (CT, MRI) are not affected by these implants	First-generation implants have a higher risk of local inflammation, and the quality of fixation may be less secure.

Distal Tibial Fractures

Salter–Harris Type I and II Fractures

According to Dias and Tachdjian,[57,201] Salter–Harris type I fractures of the distal tibia can be caused by any of the four mechanisms: Supination–inversion, supination–plantarflexion, supination–external rotation, or pronation–eversion–external rotation. Spiegel et al.[196] reported that these fractures accounted for 15.2% of 237 ankle injuries in their series and occurred in children significantly younger (average age, 10.5 years) than those with other Salter–Harris types of fractures.

The mechanism of injury is deduced primarily by the direction of displacement of the distal tibial epiphysis; for example, straight posterior displacement indicates a supination–plantarflexion mechanism. The type of associated fibular fracture is also indicative of the mechanism of injury; for example, a high, oblique or transverse fibular fracture indicates a pronation–eversion–external injury, whereas a lower spiral fibular fracture indicates a supination–external rotation injury. Lovell,[124] Broock and Greer,[27] and Nevelös and Colton[145] reported unusual Salter–Harris type I fractures in which the distal tibial epiphysis was externally rotated 90 degrees without fracture of the fibula or displacement of the tibial epiphysis in any direction in the transverse plane.

Cast immobilization is generally sufficient treatment for nondisplaced Salter–Harris type I fractures of the distal tibia. A below-knee cast worn for 3 to 4 weeks may suffice, with the first 2 to 3 weeks limited to nonweight bearing. An above-knee cast may also be used, although this may not be necessary as these fractures are usually very stable. In very active patients who may not comply with activity/weight-bearing restrictions, this type of cast may be an advantage. After cast removal, use of a removable leg/ankle walking boot may be used, followed by a therapy program in older patients or those trying to return to competitive sports at an earlier time. In our experience, formal supervised therapy is not necessary in younger patients. The normal activity of these children is usually sufficient therapy.

Most displaced fractures can be treated with closed reduction and cast immobilization. An above-knee non–weight-bearing cast is preferable initially, as this should reduce the risk of displacement after reduction. These casts may be changed to a short-leg walking cast or removable walking boot at 3 to 4 weeks. These fractures can displace in the first 1 to 2 weeks postoperatively, and close follow-up with radiographic surveillance for this is necessary. One of the authors (KS) frequently places one or two Kirschner wires at the time of closed reduction, to prevent displacement after reduction under anesthesia (Fig. 32-31). These pins are usually removed in the clinic 2 to 3 weeks after placement. Under these circumstances, a below-knee cast can be used.

Salter–Harris Type II Fractures

Salter–Harris type II fractures can also be caused by any of the four mechanisms of injury described by Dias and Giegerich.[56] In the series of Spiegel et al.,[196] Salter–Harris type II fractures were the most common injuries (44.8%). In addition to the direction of displacement of the distal tibial epiphysis and the nature of any associated fibular fracture, the location of the Thurston–Holland fragment is helpful in determining the mechanism of injury; for example, a lateral fragment indicates a pronation–eversion–external rotation injury; a posteromedial fragment, a supination–external rotation injury; and a posterior fragment, a supination–plantarflexion injury (Fig. 32-32).

Nondisplaced fractures can be treated with cast immobilization usually with an above-knee cast for 3 to 4 weeks, followed by a below-knee walking cast or removable cast/walking boot for another 3 to 4 weeks.

Although most authors agree that closed reduction of significantly displaced Salter–Harris type II ankle fracture should be attempted, opinions differ as to what degree of residual displacement or angulation is unacceptable and requires open reduction. Based on follow-up of 33 Salter–Harris type II ankle fractures, Carothers and Crenshaw[37] concluded that "accurate reposition of the displaced epiphysis at the expense of forced or repeated manipulation or operative intervention is not indicated since spontaneous realignment of the ankle occurs even late in the growing period." They found no residual angulation at follow-up in patients who had up to 12 degrees of tilt after reduction, even in patients as old as 13 years of age at the time of injury. Spiegel et al.,[196] however, reported complications at follow-up in 11 of 16 patients with Salter–Harris type II ankle

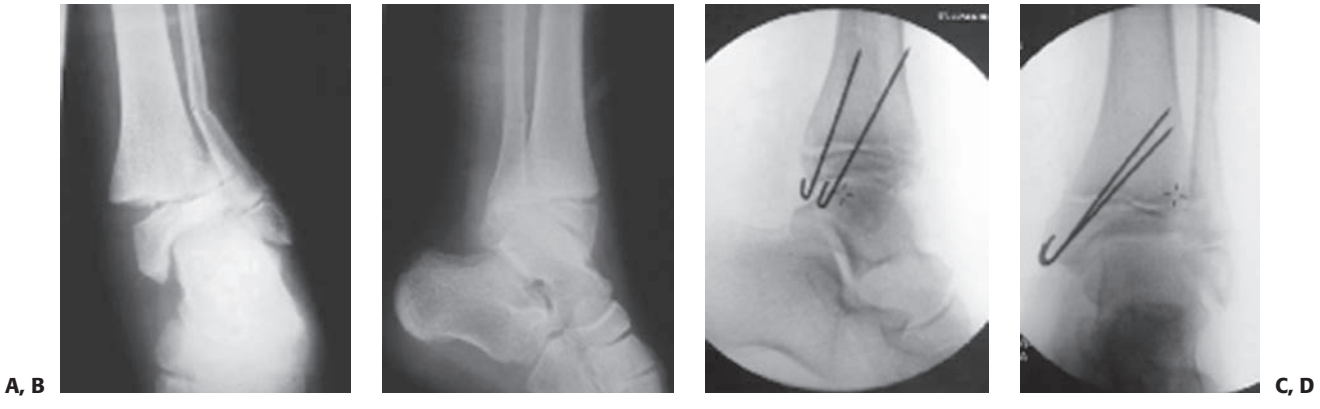

FIGURE 32-31 **A, B:** Displaced distal tibial Salter–Harris type II fracture, with distal diaphyseal fibula fracture. **C, D:** Fracture treated with closed reduction and internal fixation.

FIGURE 32-32 A: Severe plantarflexion injury with severe swelling of the ankle and foot; the reduction obtained was unstable. **B:** The reduction was stabilized by two transmetaphyseal screws placed percutaneously. **C:** Anteroposterior view confirms an anatomic reduction.

fractures. Because 6 of these 11 patients had angular deformities that were attributed to lack of adequate reduction of the fracture, Spiegel et al. recommend "precise anatomical reduction."

Barmada et al.[7] reviewed a series of Salter–Harris type I and II fractures. In patients with more than 3 mm of physeal widening, the risk of premature physeal closure was 60%, compared with 17% in patients with less than 3 mm of physeal widening. Although they were unable to demonstrate a significant decrease in partial physeal arrest in those treated with surgery, they recommended open reduction and removal of the entrapped periosteal flap. Leary et al.[113] studied 15 distal tibia fractures with premature physeal closure, and found residual gap and number of reduction attempts did not predict early closure, but initial displacement did. The literature on the value of open reduction and removal of interposed periosteum to lower the incidence of premature physeal closure is conflicted in these fractures, and it is likely that multiple variables are involved (energy of initial injury, amount of displacement, number of reduction attempts, age of patient).

Incomplete reduction is frequently caused by interposition of soft tissue between the fracture fragments. Grace[75] reported three patients in whom the interposed soft tissue included the neurovascular bundle, resulting in circulatory embarrassment when closed reduction was attempted. In this situation, open reduction and extraction of the soft tissue obviously is required. As noted above, a less definitive indication for open reduction is interposition of the periosteum, which causes physeal widening with no or minimal angulation. Good results have been reported after open reduction and extraction of the periosteal flap (Fig. 32-33).[110] It is not clear that failure to extract the periosteum in such cases results in physeal arrest sufficient to warrant operative treatment. Wattenbarger et al.[211] and Phieffer et al.[163] have attempted to determine the relationship between physeal bar formation and interposed periosteum, although at

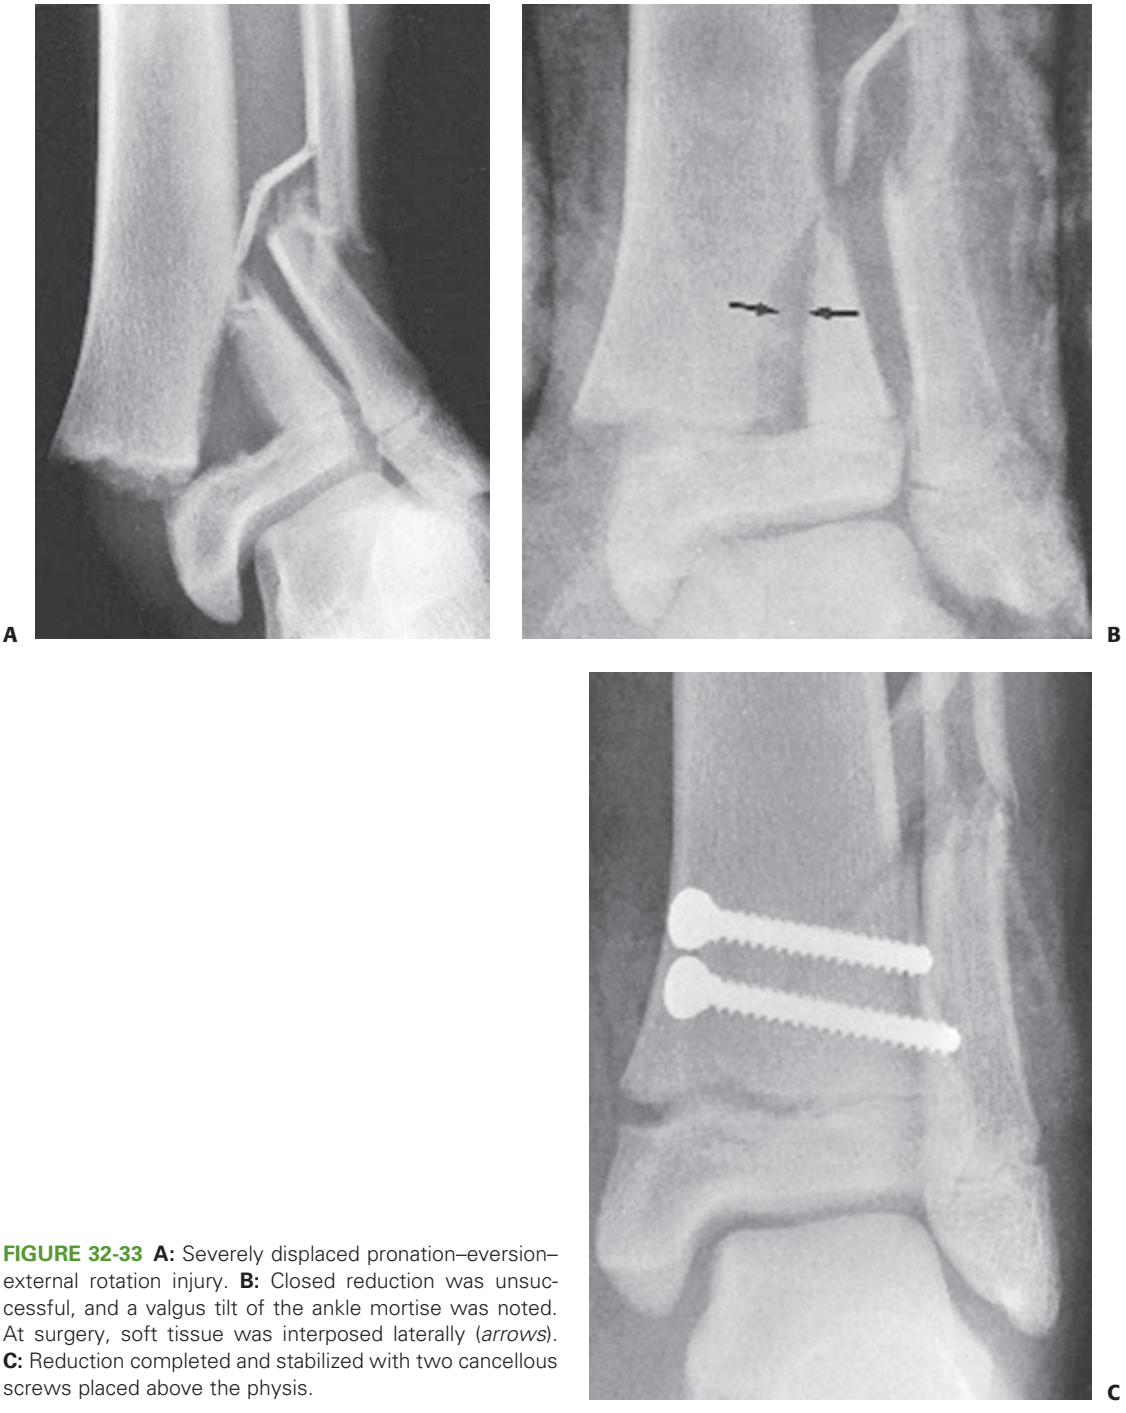

FIGURE 32-33 **A:** Severely displaced pronation–eversion–external rotation injury. **B:** Closed reduction was unsuccessful, and a valgus tilt of the ankle mortise was noted. At surgery, soft tissue was interposed laterally (*arrows*). **C:** Reduction completed and stabilized with two cancellous screws placed above the physis.

this time it is unclear if the periosteal flap increases the risk of physeal arrest.

Because of risk of iatrogenic damage to the distal tibial physis during closed reduction, many authors recommend the use of general anesthesia with adequate muscle relaxation for children with Salter–Harris type II distal tibial fractures. However, no study has compared the frequency of growth abnormalities in patients with these fractures reduced under sedation and local analgesia to those with fractures reduced with the use of general anesthesia. One of the authors (KS) uses general anesthesia, and an arthroscopic ankle distractor to distract the fracture before reduction, with the theoretical advantage of reducing the risk of physeal damage during the reduction maneuver (Fig. 32-34).

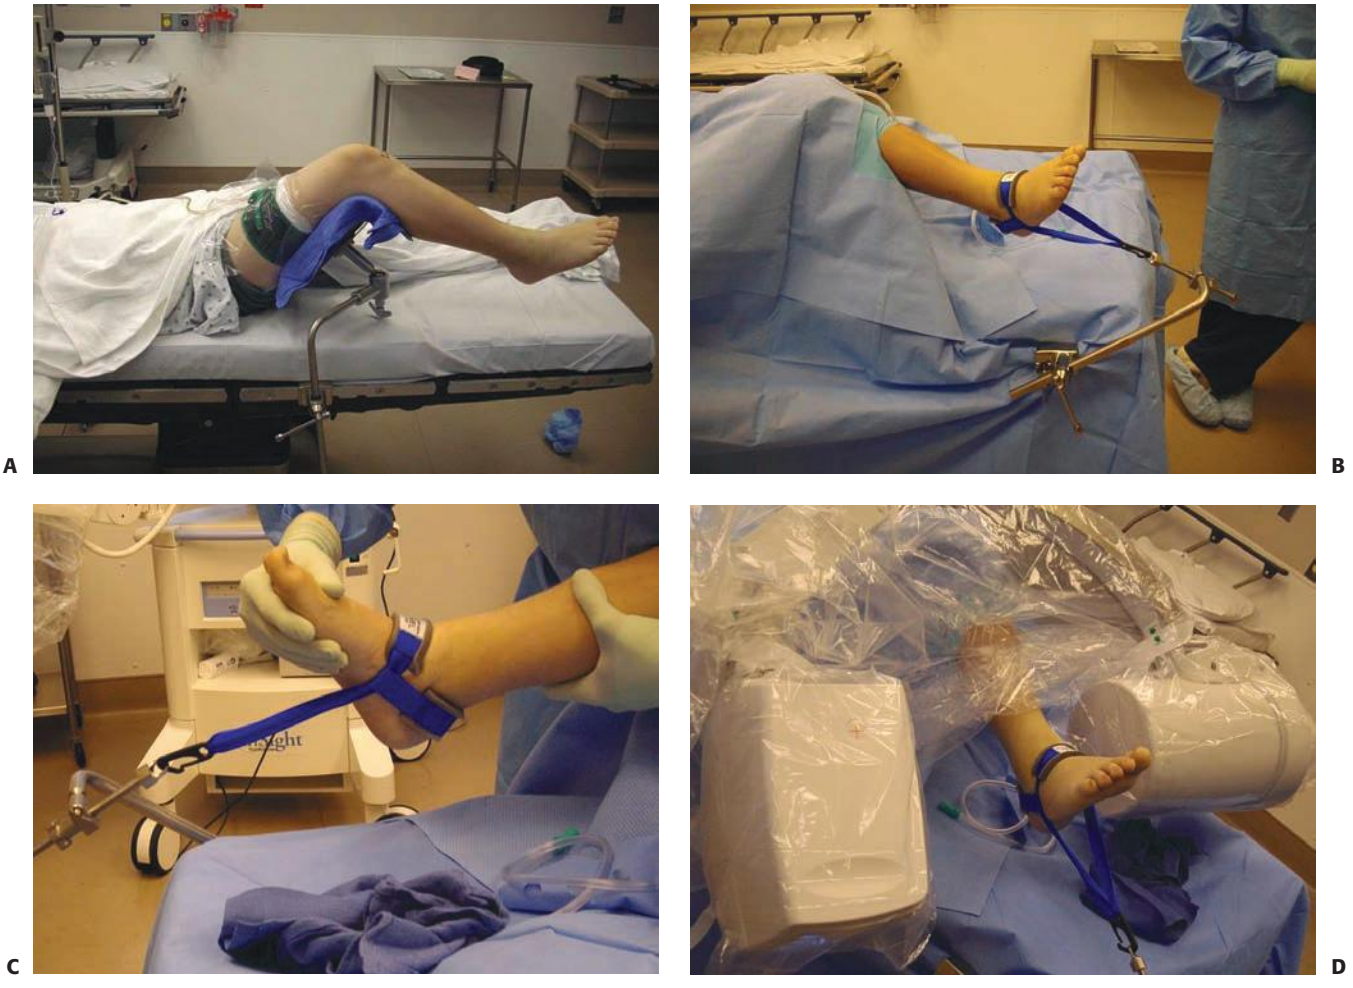

FIGURE 32-34 Use of ankle distractor. **A:** Thigh positioner to allow for ankle distractor. **B:** Sterile ankle distractor in place. **C:** Distractor can remain in place during reduction maneuvers. **D:** C-arm can be brought into the field to evaluate the reduction.

When closed reductions are not performed under general anesthesia, they are usually done under IV sedation. Alioto et al. demonstrated significantly improved pain relief with hematoma block for ankle fractures in a study comparing patients treated with IV sedation to patients receiving hematoma block.[54] Intravenous regional anesthesia or Bier block has also been reported to be effective for pain relief in lower extremity injuries.[114]

One advantage of reduction in the operating room with general anesthesia is the ease with which percutaneous pins can be placed to maintain reduction of the fractures. It is the experience of one of the authors that Salter–Harris I and II fractures will occasionally displace after closed reduction and above-knee casting. If there is any concern about redisplacement or stability, smooth pins can be placed at that time.

Surgeons using regional block anesthesia within the first 2 to 3 days after the fracture should consider the potential for compartment syndrome. In fractures that have a higher risk of compartment syndrome, regional anesthesia, especially peripheral nerve blocks with longer-acting agents, might delay the recognition of a compartment syndrome.[140]

Salter–Harris Type III and IV Fractures

Salter–Harris type III and IV fractures are discussed together because the mechanism of injury is the same (supination–inversion) and their treatment and prognosis are similar. Juvenile Tillaux and triplane fractures are considered separately. In the series of Spiegel et al.,[196] 24.1% of the fractures were Salter–Harris type III injuries and 1.4% were type IV. These injuries are usually produced by the medial corner of the talus being driven into the junction of the distal tibial articular surface and the medial malleolus. As the talus shears off the medial malleolus, the physis may also be damaged (Fig. 32-35).

Nondisplaced Salter–Harris types III and IV fractures can be treated with above-knee cast immobilization, but care must be taken to be sure that the significant intra-articular displacement is not present. Radiographs frequently underestimate the degree of intra-articular involvement and step-off of the articular surfaces. CT imaging may be necessary to fully appreciate

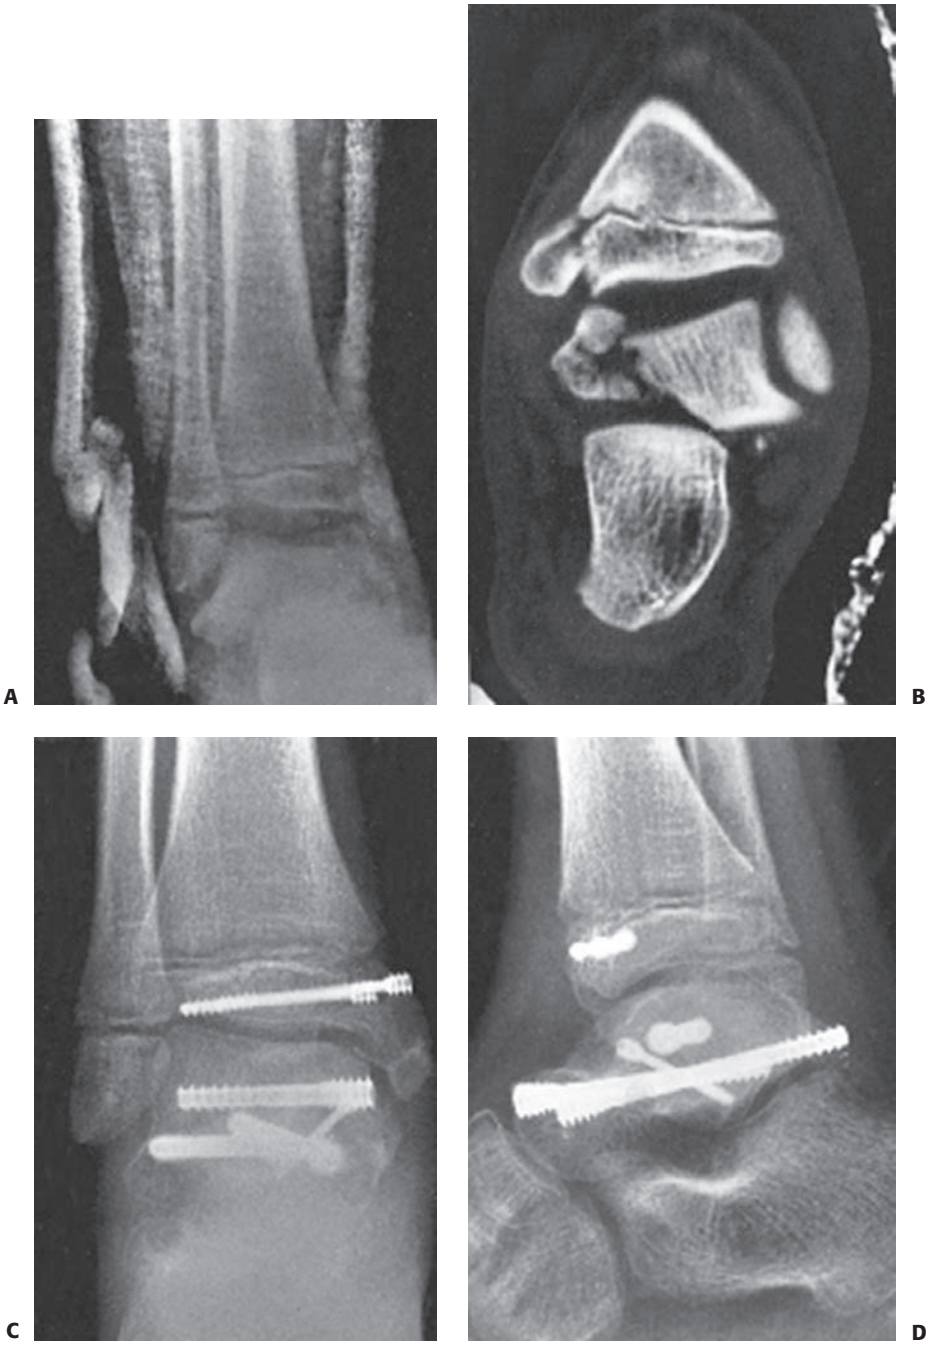

FIGURE 32-35 A: Severe ankle injury sustained by an 8-year-old involved in a car accident. The anteroposterior view in the splint does not clearly show the Salter–Harris type IV fracture of the tibia. The dome of the talus appears abnormal. **B:** CT scan shows the displaced Salter–Harris type IV fracture of the medial malleolus and a severe displaced intra-articular fracture of the body of the talus. **C, D:** Open reduction of both fractures was performed, and Herbert screws were used for internal fixation. (Courtesy of Armen Kelikian, MD.)

the degree of displacement (Fig. 32-11). Follow-up radiographs and/or CT scans in the first 2 weeks may also be necessary to confirm that no displacement occurs after casting.

Salter–Harris type III fractures of the medial malleolus may have a higher risk of physeal arrest. One study suggested that the rate of physeal arrest could be reduced by the use of open reduction and internal fixation.[102,111] Luhmann et al.[125] have recently studied a series of medial malleolar fractures with growth disturbance following treatment, and recommends anatomic reduction as fractures with as little as 2 mm of step-off went on to premature physeal closure. Others have also emphasized the importance of anatomic reduction and early treatment to reduce the risk of physeal arrest.[162]

Based upon principles of fracture treatment in adults, displaced intra-articular fractures are treated with as anatomical a reduction as possible. Studies in children confirming the importance of articular reduction to within 2 mm are few (66), although most recommend anatomic articular reduction in displaced fractures involving the articular surface. Failure to obtain anatomical reduction may result in articular incongruity and posttraumatic arthritis, which often becomes symptomatic 5 to 8 years after skeletal maturity.[40] The risk of growth arrest

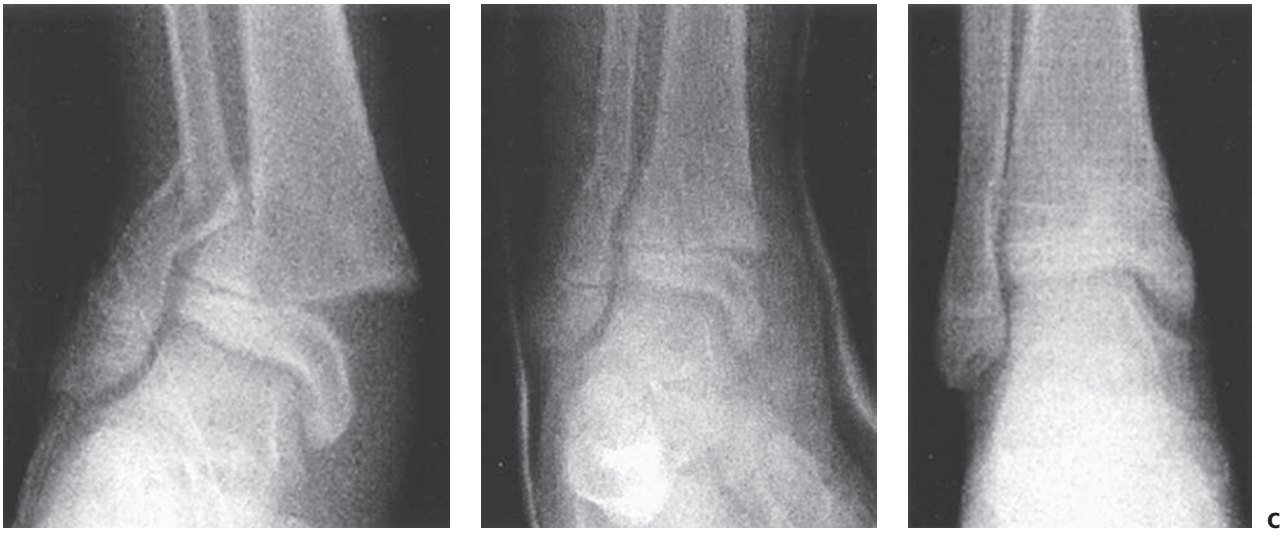

FIGURE 32-36 **A:** Anteroposterior view of a patient with a pronation–eversion–external rotation fracture. **B:** Postreduction view shows residual gapping of physis suggesting periosteal interposition. **C:** Anteroposterior view obtained for a new injury (medial malleolar fracture) shows premature closure of the physis.

has also been linked to the adequacy of reduction, although the literature is still unclear if anatomic reduction reduces the risk of physeal arrest (Fig. 32-36).[111] Some recent series suggest early anatomic reduction is associated with a lower risk of physeal arrest.[186] Closed reduction may be attempted but is likely to succeed only in minimally displaced fractures. If closed reduction is obtained, it can be maintained with a cast or with percutaneous pins or screws supplemented by a cast.

If anatomical reduction cannot be obtained by closed methods, open reduction and internal fixation or mini-open arthroscopic reduction should be carried out. Lintecum and Blasier[120] described a technique of open reduction achieved through a limited exposure of the fracture with the incision centered over the fracture site combined with percutaneous cannulated screw fixation. This technique was performed on 13 patients, 8 Salter–Harris IV fractures, 4 Salter–Harris III fractures, and 1 triplane fracture. The authors reported one growth arrest at follow-up averaging 12 months. Beaty and Linton[10] reported a Salter–Harris type III fracture with an intra-articular fragment (Fig. 32-37); these fractures require open reduction for inspection of the joint to ensure that no osteochondral fragments are impeding reduction. Arthroscopic evaluation of the joint may also be an option. Internal fixation devices should be inserted within the epiphysis, parallel to the physis in patients

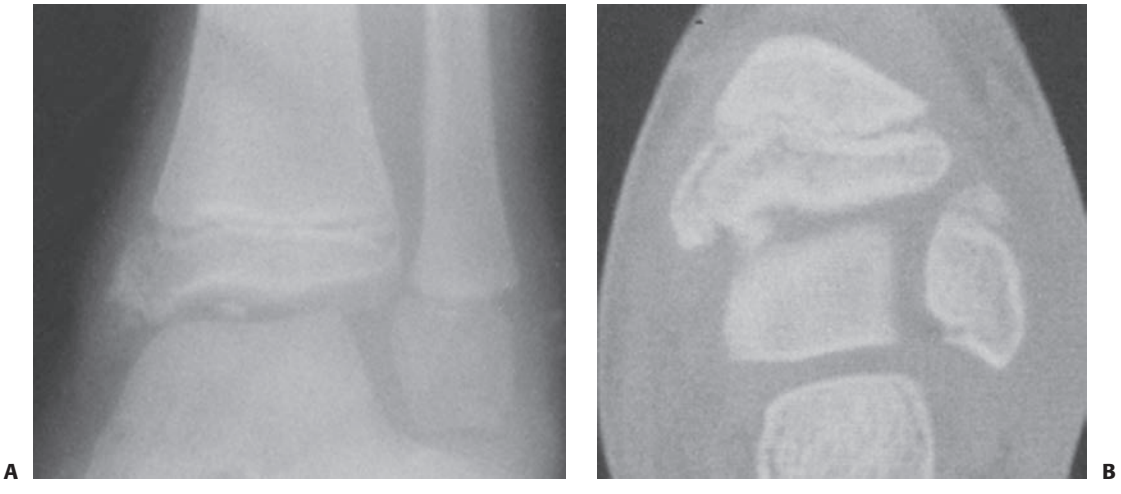

FIGURE 32-37 **A:** Salter–Harris type III fracture of the medial malleolus and Salter–Harris type I fracture of the fibula in a 9-year-old girl. An intra-articular fragment was visible only on a mortise view radiograph. **B:** CT scan outlined the Salter–Harris type III fracture of the medial malleolus and the fragment of bone.

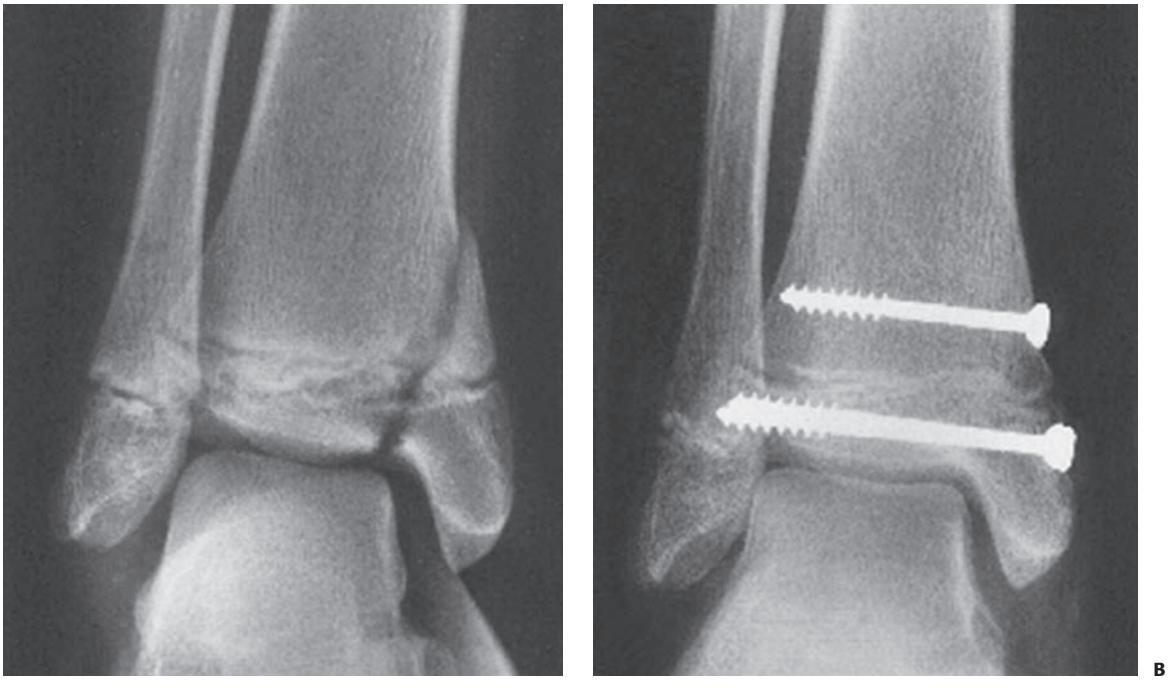
with greater than 2 years of growth remaining, and should avoid entering ankle joint (Figs. 32-21 and 32-38).

Arthroscopic-assisted fixation of fractures with intra-articular involvement have been described by several centers. Jennings et al.[92] presented a series of five triplane and one Tillaux fractures treated with arthroscopic assistance. The outcome was excellent for fracture reduction and ankle function. Kaya et al.[103] review 10 patients with juvenile Tillaux fractures treated with arthroscopic assistance, demonstrating excellent reduction and clinical outcomes.[153] One of the primary advantages of arthroscopic fixation is that it allows for visualization of the articular surfaces, although the need for open reduction of the metaphyseal and epiphyseal regions may still require open incisions.

Options for internal fixation include smooth Kirschner wires, small fragment cortical and cancellous screws, and 4-mm cannulated screws (Fig. 32-39). Several reports[12,20,32] have advocated the use of absorbable pins for internal fixation of ankle fractures. Benz et al.[12] reported no complications or growth abnormalities after the use of absorbable pins with metal screw supplementation for fixation of five ankle fractures in patients between the ages of 5 and 13 years. In reports of the use of absorbable pins without supplemental metal fixation in adults,[19,21,68,86] complications have included displacement (14.5%), sterile fluid accumulation requiring incision and drainage (8.1%), pseudarthrosis (8%), distal tibiofibular synostosis (3.8%), and infection (1.6%). Bucholz et al.[32] reported few complications in a series of fractures in adults fixed with absorbable screws made of polylactide and suggested that complications in earlier series might be related to the fact that those pins were made of polyglycolide. A report in 1993 by Böstman et al.,[20] however, included few complications in a series of fractures in children fixed with polyglycolide pins. A follow-up report by Rokkanen et al.,[175] in 1996 reported 3.6% infection and 3.7% failure of fixation.



A B

FIGURE 32-38 **A:** Grade II supination–inversion injury in a 12-year-old girl, resulting in a displaced Salter–Harris type IV fracture of the distal tibia and a nondisplaced Salter–Harris type I fracture of the distal fibula. **B:** After anatomic open reduction and stable internal fixation.

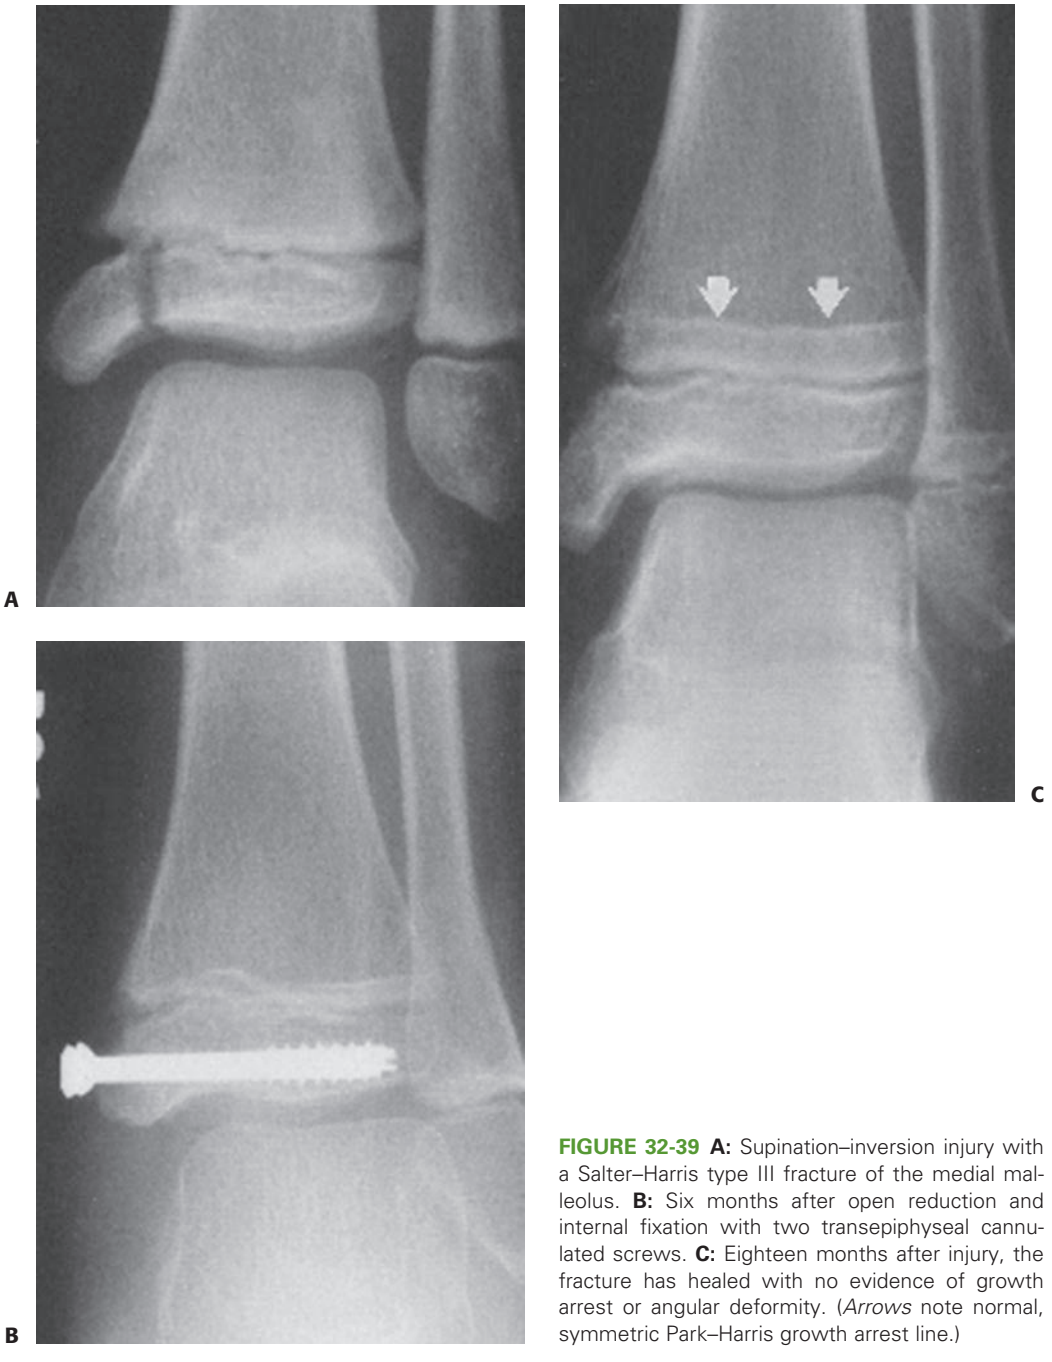


FIGURE 32-39 **A:** Supination–inversion injury with a Salter–Harris type III fracture of the medial malleolus. **B:** Six months after open reduction and internal fixation with two transepiphyseal cannulated screws. **C:** Eighteen months after injury, the fracture has healed with no evidence of growth arrest or angular deformity. (*Arrows* note normal, symmetric Park–Harris growth arrest line.)

The main advantage of absorbable pins and screws is that hardware removal is avoided. Böstman compared the cost-effectiveness of absorbable implants in 994 patients treated with absorbable implants to 1,173 patients treated with metallic implants. To be cost-effective, the hardware removal rates required were calculated to range from 19% for metacarpal fractures to 54% for trimalleolar fractures.[22] At this time, the indications for absorbable pins remain unclear.

Recent studies in the adult literature suggest second-generation bioabsorbable screws have lower complication rates, and their use may be increasing.[167,194] Additional studies in adult patients using ultrasound and MRI have not detected deleterious effects on healing with newer screw designs.[78,132] Because children are typically smaller and lighter than adults, the implants used for fixation may not need to be as strong or large as those required by adult patients. This suggests that younger patients may be better candidates for these bioabsorbable implants. The presence of the physis, and the low-grade inflammation that may accompany the dissolution of these implants, however, may increase the risk of physeal arrest, and additional studies in adult and pediatric patients will be necessary to confirm the effectiveness and safety of these devices.[101]

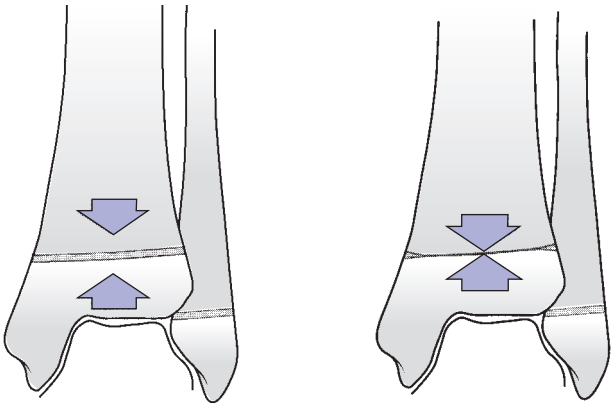

FIGURE 32-40 Compression-type injury of the tibial physis. Early physeal arrest can cause leg-length discrepancy.

Salter–Harris Type V Fractures

Salter–Harris type V fractures of the ankle are believed to be caused by severe axial compression and crushing of the physis (Fig. 32-40). As originally described, these injuries are not usually associated with significant displacement of the epiphysis relative to the metaphysis, which make diagnosis of acute injury impossible from plain radiographs; the diagnosis can only be made on follow-up radiographs when premature physeal closure is evident. Spiegel et al.[196] have designated comminuted fractures that are otherwise unclassifiable as Salter–Harris type V injuries.

The incidence of Salter–Harris type V ankle fractures is difficult to establish because of the difficulty of diagnosing acute injuries. Spiegel et al.[196] included two type V fractures in their series, but both were comminuted fractures rather than the classic crush injury without initial radiographic abnormality.

Because of the uncertain nature of this injury, no specific treatment recommendations have been formulated. Treatment is usually directed primarily toward the sequelae of growth arrest that invariably follows Salter–Harris type V fractures. Perhaps more sophisticated scanning techniques will eventually allow identification and localization of areas of physeal injury so that irreparable damaged cells can be removed and replaced with interposition materials to prevent growth problems, but at present this diagnosis is made only several months after injury.

Other Fractures of the Distal Tibia

Accessory ossification centers of the distal tibia (os subtibiale) and distal fibula (os fibulare) are common and may be injured. Treatment usually consists of cast immobilization for 3 to 4 weeks. Ogden and Lee[150] reported good results after cast immobilization in 26 of 27 patients with injuries involving the medial side of the tibia; only one patient required surgery. In contrast, 5 to 11 patients with injuries involving the lateral side had persistent symptoms that required excision.

Injuries to the perichondral ring of the distal tibial and fibular physes, with physeal disruption, have been described.[83] Most of these injuries are caused by skiving of the bone by machinery such as lawn mowers. They may result in growth arrest or retardation and in angular deformities. (See Open Fractures and Lawn Mower Injuries.)

Juvenile Tillaux Fractures

This fracture is the adolescent counterpart of the fracture described in adults by the French surgeon Tillaux. It occurs when with external rotation of the foot, the anterior-inferior tibiofibular ligament through its attachments to the anterolateral tibia, avulses a fragment of bone corresponding to the portion of the distal tibial physis that is still open (Fig. 32-41). In the series of Spiegel et al.,[196] these fractures occurred in 2.9% of patients.

Tillaux fractures may be isolated injuries or may be associated with ipsilateral tibial shaft fractures.[48] The fibula usually prevents marked displacement of the fracture and clinical deformity is generally absent. Swelling is usually slight, and local tenderness is at the anterior lateral joint line, in contrast to ankle sprains where the tenderness tends to be below the level of the ankle joint.

A mortise view is essential to see the distal tibial epiphysis unobstructed by the fibula (Fig. 32-42). Steinlauf et al.[197] reported a patient in whom the Tillaux fragment became entrapped between the distal tibia and fibula producing apparent diastasis of the ankle joint. To allow measurement of displacement from plain films, the radiograph beam would have to be directly in line with the fracture site, which makes CT confirmation of reduction desired after all closed reductions of these fractures.

Both below-knee and above-knee casts have been used for immobilization of nondisplaced juvenile Tillaux and triplane fractures. Fractures with more than 2 mm of displacement, especially those associated with articular incongruity, may be best treated with closed or open reduction.[49,103] Closed reduction is attempted by internally rotating the foot and applying direct pressure over the anterolateral tibia. If necessary, percutaneous pins can be used for stabilization of the reduction. If closed reduction is not successful, open reduction or percutaneous reduction with arthroscopic assistance may be needed.

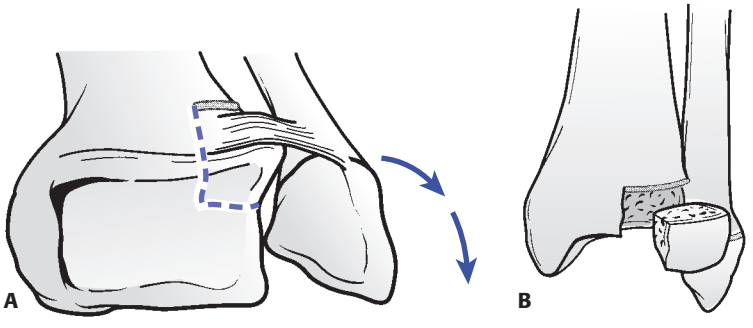

FIGURE 32-41 Juvenile Tillaux fracture. Mechanism of injury: The anteroinferior tibiofibular ligament avulses a fragment of the lateral epiphysis **(A)** corresponding to the portion of the physis that is still open **(B)**.

FIGURE 32-42 Anteroposterior mortise view of a 14-year-old who sustained a juvenile Tillaux fracture.

Occasionally, percutaneously inserted pins can be used to manipulate the displaced fragment into anatomical position and then advanced to fix the fragment in place.[184] Screw fixation within the epiphysis is usually the preferred fixation method (Fig. 32-21; see section on Fracture Reduction Tips, Arthroscopic Assistance, Use of Percutaneous Clamps, Implants).

Triplane Fracture

Kärrholm attributes the original description of this injury to Bartl,[9] in 1957, and notes that Gerner-Smidt,[71] in 1963, described triplane and Tillaux fractures as different stages of the same injury. In 1957, Johnson and Fahl[93] described a triplane fracture in their report of 27 physeal ankle injuries and reported that they had seen 10 such fractures. Despite these earlier reports, the nature of triplane fractures was not appreciated until Marmor's[131] report in 1970 of an irreducible ankle fracture that at surgery was found to consist of three parts (Fig. 32-43). Two years after Marmor's report, Lynn[126] reported two additional such fractures and coined

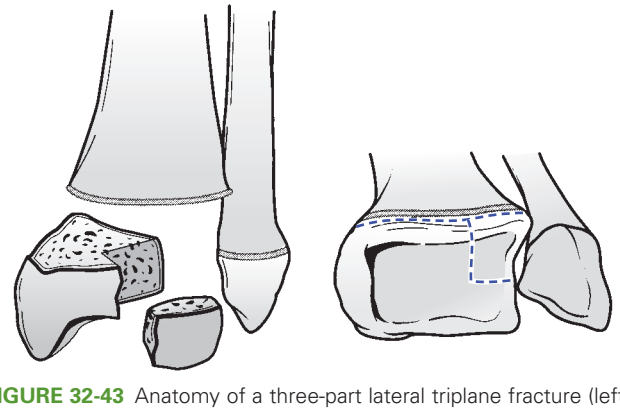

FIGURE 32-43 Anatomy of a three-part lateral triplane fracture (left ankle). Note the large epiphyseal fragment with its metaphyseal component and the smaller anterolateral epiphyseal fragment.

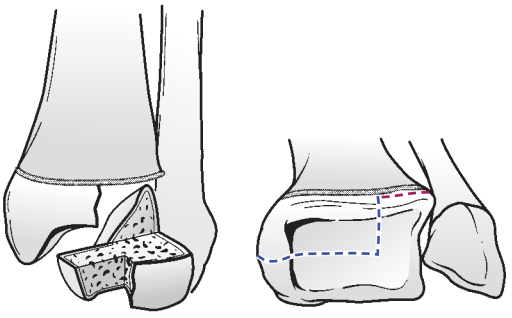

FIGURE 32-44 Anatomy of a two-part lateral triplane fracture (left ankle). Note the large posterolateral epiphyseal fragment with its posterior metaphyseal fragment. The anterior portion of the medial malleolus remains intact.

the term triplane fracture. He described the fracture as consisting of three major fragments: (1) The anterolateral quadrant of the distal tibial epiphysis, (2) the medial and posterior portions of the epiphysis in addition to a posterior metaphyseal spike, and (3) the tibial metaphysis. Cooperman et al.,[46] however, in their 1978 report of 15 such fractures concluded that, based on tomographic studies, most were two-part fractures produced by external rotation (Fig. 32-44). Variations in fracture patterns were attributed to the extent of physeal closure at the time of injury. Kärrholm et al.[97] reported that CT evaluation of four adolescents with triplane fractures confirmed the existence of two-part and three-part fractures and also revealed four-part fractures (Fig. 32-45). Denton and Fischer[54] described a two-part "medial triplane fracture" that they believed was caused by adduction and axial loading, and Peiró et al.[155] reported a three-part medial triplane fracture.

El-Karef et al.[61] studied 21 triplane fractures, identifying 19 as lateral triplane variants, and two as medial variants. Twelve were two-part fractures, six were three-part fractures, and three were four-part.

Von Laer[209] described a subgroup of two-part and three-part triplane fractures in which the fracture line on the anteroposterior

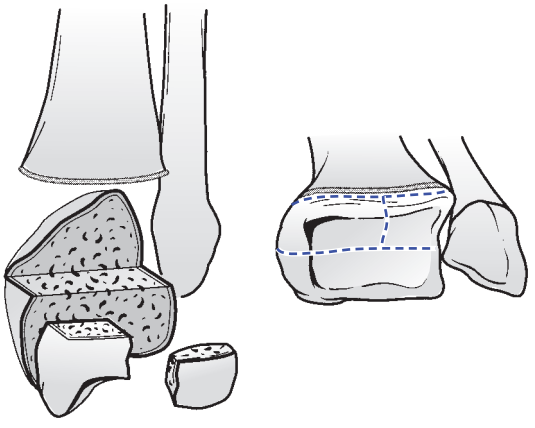

FIGURE 32-45 Anatomy of a four-part lateral triplane fracture (left ankle). The anterior epiphysis has split into two fragments, and the posterior epiphysis is the larger fragment with its metaphyseal component.

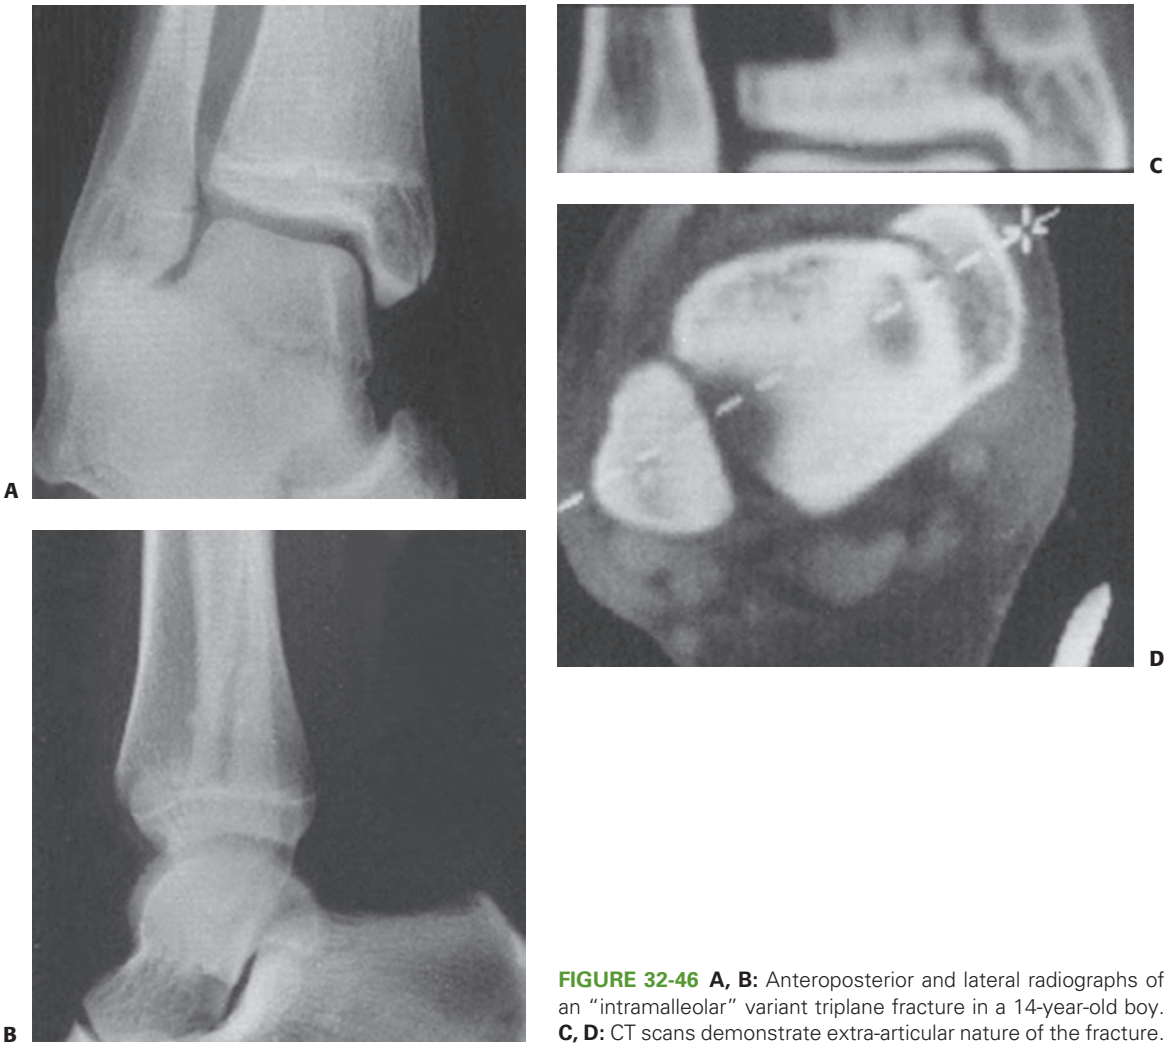

FIGURE 32-46 **A, B:** Anteroposterior and lateral radiographs of an "intramalleolar" variant triplane fracture in a 14-year-old boy. **C, D:** CT scans demonstrate extra-articular nature of the fracture.

radiographs did not extend into the ankle joint but into the medial malleolus instead (Fig. 32-46). Feldman et al.[64] also reported a case of an extra-articular triplane fracture in a skeletally immature patient. Shin et al.,[189] reported five patients with intramalleolar triplane variants. They divided these into three types: Type I, an intramalleolar intra-articular fracture; type II, an intramalleolar, intra-articular fracture outside the weight-bearing surface; and type III, an intramalleolar, extra-articular fracture (Fig. 32-47). These authors found that CT scans with three-dimensional reconstruction were helpful in determining displacement and deciding if surgery is indicated.

In the series of Spiegel et al.,[196] 7.3% were triplane fractures. Kärrholm[96] reviewed 209 triplane fracture patients and found the mean age at the time of injury was 14.8 for boys and 12.8 for girls. This type of injury did not occur in children younger than 10 or older than 16.7 years. The incidence is higher in males than females.[185] Patients with triplane fractures may have completely open physes. Swelling is usually more severe than with Tillaux fractures, and deformity may be more

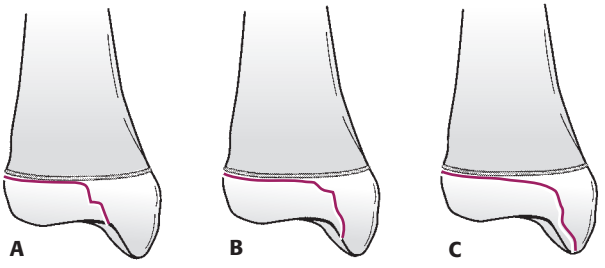

FIGURE 32-47 Schematic drawing of the immature distal tibial physis demonstrating types I, II, and III intramalleolar triplane fractures. **A:** Type I intramalleolar, intra-articular fracture at the junction of the tibial plafond and the medial malleolus. **B:** Type II intramalleolar, intra-articular fracture outside the weight-bearing zone of the tibial plafond. **C:** Type III intramalleolar, extra-articular fracture. severe, especially if the fibula is also fractured. Radiographic views should include anteroposterior, lateral, and mortise views. Rapariz et al.,[169] found that 48% of triplane fractures were associated with fibular fracture and 8.5% were associated with ipsilateral tibial shaft fracture. Healy et al.,[84] reported a triplane fracture associated with a proximal fibula fracture and syndesmotic injury (Maisonneuve equivalent). Failure to detect such injury may lead to chronic instability. Therefore, tenderness proximal to the ankle should be sought and if found is an indication for radiographs of the proximal leg. CT scans have largely replaced plain tomograms for evaluation of the articular surface and the fracture anatomy (Fig. 32-48).

Nondisplaced triplane fractures, those with less than 2 mm of displacement, as well as extra-articular fractures can be treated with long-leg cast immobilization with the foot in internal rotation for lateral fractures and in eversion for medial fractures. These are rotational injuries, so the ability of a well-molded below-knee cast to maintain the reduction is questioned by some; a comparative study of below-knee and above-knee casts has not been done. Fractures with more than 2 mm of

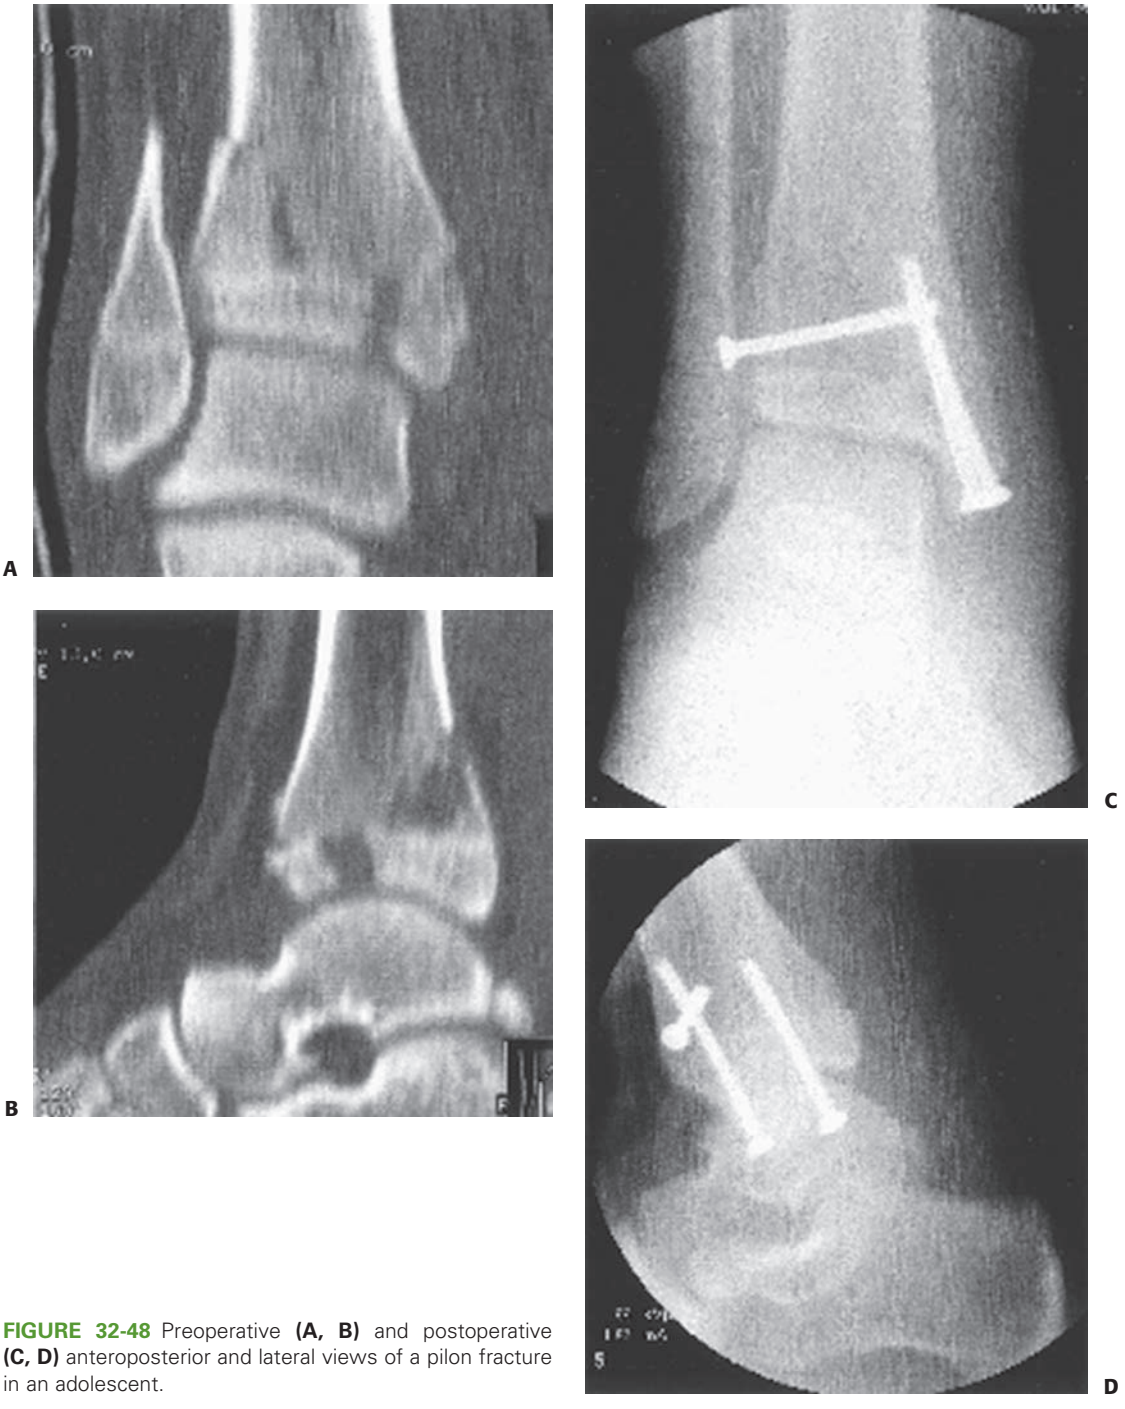

FIGURE 32-48 Preoperative **(A, B)** and postoperative **(C, D)** anteroposterior and lateral views of a pilon fracture in an adolescent.

displacement (65% of the injuries in Kärrholm's series) require reduction; this may be attempted in the emergency department or in the operating room with the use of general anesthesia. Closed reduction of lateral triplane fractures is attempted by internally rotating the foot. Based on the mechanism of injury, the most logic maneuver for reduction of medial triplane fractures is abduction. If closed reduction is shown to be adequate by image intensification as is the case in about half the time, a long-leg cast is applied or percutaneous screws are inserted for fixation if necessary. Well-placed percutaneous screws will prevent secondary displacement in a cast, and may make follow-up radiographs and clinical visits less frequent. If closed reduction is done in the emergency department, a limited CT scan of the ankle joint in the cast is helpful to confirm adequate reduction. If closed reduction is unsuccessful, open reduction is required. This can be accomplished through an anterolateral approach for lateral triplane fractures or through an anteromedial approach for medial triplane fractures. Additional incisions may be necessary for adequate exposure.

The use of well-placed percutaneous clamps and arthroscopic assistance may help with the reduction and minimize the need for incisions. Careful review of the CT scans can help guide percutaneous clamp and screw placement that improves the biomechanics of clamp reduction and screw placement.[95] Care should be taken to avoid injury to neurologic and vascular structures during clamp or percutaneous screw placement. (See section on Fracture Reduction Tips, Arthroscopic Assistance, Use of Percutaneous Clamps, Implants.)

Pilon Fractures

Although these fractures are relatively rare in young patients, they can be associated with severe soft tissue swelling and edema. Similar to the treatment in adults with these injuries, management of the soft tissues is critical to prevent complications of skin loss, infection, wound healing problems, etc.[60,203] Initial approaches may consist of application of external fixation, or dressings to address swelling and edema, with delay in surgical intervention for 5 to 15 days (Fig. 32-49).[60]

Letts et al.[117] have described a small series of pilon fractures in the skeletally immature. The patients in this series did not have wound/skin complications, and only 2/8 developed postoperative osteoarthritis at short-term follow-up. As these fractures may be at higher risk for complications, we believe that treatment principles used in adult patients should be applied to this patient population as well.[6,16,116,117,154,172]

Fractures of the Incisura

One of the authors (JC) has seen two patients with fractures of the incisura injuries.[52] Despite 12 weeks of immobilization, these fractures had not healed. Despite the appearance of nonunion on radiographs, these patients remained symptom free at 2 years follow-up. One patient developed mild symptoms of ankle pain several years later. If there is evidence of syndesmotic injury, syndesmosis reduction and internal fixation should probably be considered.

Syndesmosis Injuries

Several publications have described triplane fracture in association with a syndesmosis injury,[84,193] and the authors have identified a small series of syndesmosis type injuries in their practice.[51] These have been associated with the following fracture patterns: Distal fibula, Salter I and II, triplane, and Tillaux. Medial joint space widening may be an important anatomic factor to evaluate during treatment of external rotation mechanism injuries, and this should improve after surgical treatment.[74] During surgical treatment of pediatric/adolescent ankle fractures, evaluation for syndesmosis injuries should probably be performed in a manner similar to the treatment of adult fractures. Syndesmosis reduction and fixation may be necessary (Fig. 32-15), in some cases.

Open Fractures and Lawn Mower Injuries

Severe open ankle fractures are often produced by high-velocity motor vehicular accidents or lawn mower injuries (Fig. 32-50).[76,83] Approximately 25,000 lawn mower injuries

FIGURE 32-49 Pilon fracture treated with spatial frame. **A, B:** Preoperative anteroposterior and lateral view of adolescent pilon fracture with depressed articular region. **C:** Axial CT scan showing comminution of articular surface.

occur each year, 20% of which are in children. Ride-on mowers produce the most severe injuries, requiring more surgical procedures and resulting in more functional limitations.[1,4,58,179,210] Loder et al.,[121] reviewed 144 children injured by lawn mowers. The average age at the time of injury was 7 years. The child was a bystander in 84 cases. Sixty-seven children required amputation. Soft tissue infection occurred in 8 of 118 and osteomyelitis in 6 of 117.

Principles of treatment are the same as in adults: Copious irrigation and debridement, tetanus toxoid, and intravenous antibiotics. Gaglani et al.,[70] reported the bacteriologic findings in three children with infections secondary to lawn mower injuries. They found that organisms infecting the wounds were frequently different than those found on initial debridement, calling into question the value of intraoperative cultures. Gram-negative organisms were common and all three patients were infected with fungi as well. In children with lawn mower injuries, grass, dirt, and debris are pushed and blown into the wound under pressure, and removal of these embedded foreign objects requires meticulous mechanical debridement.

In most patients, the articular surface and physis should be aligned and fixed with smooth pins that do not cross the physis at the time of initial treatment. Exposed physeal surfaces can be covered with local fat to help prevent union of the metaphysis to the epiphysis. An external fixator may be used if neurovascular structures are injured, but small pins should be used through the metaphysis and epiphysis, avoiding the physis.[87,94,123,170,178] Wound closure may be a problem in cases with significant soft tissue injury and exposed bone. Skin coverage with local tissue is ideal; but if local coverage is not possible, split-thickness skin grafting is generally the next choice. Free vascular flaps and rotational flaps may be required for adequate coverage. Klein et al.,[109] reported two cases that had associated vascular injury precluding such flaps, that were covered successfully with local advancement flaps made possible by multiple relaxing incisions. Mooney et al.,[138] reported cross-extremity flaps for such cases. They found external fixation for linkage of the lower extremities during the procedure to be valuable. After fixation removal, range of motion returned readily.

Vosburgh et al.[210] reported 33 patients with lawn mower injuries to the foot and ankle. They found that the most severe injuries were to the posterior plantar aspect of the foot and ankle. Of their patients, five required split-thickness skin grafts and one vascularized flap for soft tissue coverage. Two ultimately required Syme amputation. Four of the patients had complete disruption of the Achilles tendon. Three had no repair or reconstruction of the triceps surae tendon, and one had delayed reconstruction 3 months after injury. Vosburgh et al.[210] speculate that dense scarring in the posterior ankle results in a "physiologic tendon" and that extensive reconstructive surgery is not always necessary for satisfactory function. Boyer et al.,[26] reported a patient with deltoid ligament loss because of a severe grinding injury that was reconstructed with a free plantaris tendon graft. Soft tissue coverage was achieved using a free muscle transfer. Rinker et al.[171] have also described the use of soft tissue transfer to assist pediatric patients with severe soft tissue loss.

The development of vacuum-assisted closure devices had been a dramatic improvement in the treatment of these injuries, and may reduce the need for tissue transfers.[85] Referral to centers with experience with these treatment protocols may be necessary for these severe injuries. Our experience with the use of vacuum-assisted closure devices in high-energy trauma with severe soft tissue injury has shown very good results for limb salvage.

Distal Fibula Fracture

Fractures involving the fibular physis are most commonly Salter–Harris type I or II fractures that are caused by a supination–inversion injury. Isolated fibular fractures are usually minimally displaced and can be treated with immobilization in a below-knee cast for 3 to 4 weeks. Significantly displaced fibular fractures often accompany Salter–Harris types III and IV tibial fractures and usually reduce when the tibial fracture is reduced. Internal fixation of the tibial fracture generally results in stability of the fibular fracture such that cast immobilization is sufficient. If the fibular fracture is unstable after reduction and fixation of the tibial fracture, fixation with a smooth intramedullary or obliquely inserted Kirschner wire is recommended (Fig. 32-51). In older adolescents in whom growth is not a consideration, an intramedullary rod, screw, or plate-and-screw device may be used as in adults (Fig. 32-52).

Avulsion fractures from the lateral malleolus are seen in children with inversion "sprain" type injuries to the ankle. These may fail to unite with cast immobilization. Patients with such nonunions may have pain without associated instability. In such patients simple excision of the ununited fragment usually relieves their pain.[54,81] When the nonunions are associated with instability, reconstruction of one or more of the lateral ankle ligaments is needed.[29,30] (See Lateral Ankle Sprains.)

Avulsion fracture of the accessory ossification centers of the distal fibula (os subfibulare) is also common. In the series report by Ogden and Lee,[150] 5 of 11 patients with injuries treated with casting had persistent symptoms and required excision.

Lateral Ankle Sprains

In 1984 Vahvanen published a prospective study of 559 children who presented with severe supination injuries or sprains of the ankle.[212] Forty patients, 28 boys and 12 girls, with an average age of 12 years (range 5 to 14) were surgically explored. The indications for surgery included swelling, pain over the anterior talofibular ligament, limp, clinical instability, and when visible, a displaced avulsion fracture. Such fractures were visible radiographically in only 8 patients but were found at surgery in 19. Thirty-six ankles were found to have injury of the anterior talofibular ligament at surgery. Only 16 of these had either a positive lateral or anterior drawer stress test. At follow-up all patients were pain free and none complained of instability. Based upon the incidence of residual disability after such injuries in adults reported in the literature (21% to 58%), these authors suggested primary surgical repair may be indicated in some cases. In our clinical experience, acute surgical repair of ankle sprains is very rarely indicated in the skeletally immature.

C D

FIGURE 32-52 (*continued*) **C:** Stress films showed complete disruption of the deltoid ligament. **D:** The fibular fracture was fixed with a cannulated screw; the deltoid ligament was not repaired.

In cases with residual laxity and associated symptoms, delayed surgical repair may be necessary in older patients. Busconi and Pappas[35] reported 60 skeletally immature children with chronic ankle pain and instability. Fifty of these children responded to rehabilitation, but 10 had persistent symptoms. Although three of these patients' initial radiographs were within normal limits, all patients with persistent symptoms eventually were found to have ununited osteochondral fractures of the fibular epiphysis. All 10 patients with persistent symptoms were treated with excision of the ununited osteochondral fracture and a Broström reconstruction of the lateral collateral ligament. All were able to return to activities and none reported further pain or instability.

Ankle Dislocations

Nusem et al.,[148] reported a 12-year-old girl who was seen with a posterior dislocation of the ankle without associated fracture. This was a closed injury and resulted from forced inversion of a maximally plantarflexed foot. The dislocation was reduced under IV sedation and the ankle immobilized in a short-leg cast for 5 weeks. The patient was asymptomatic at follow-up 4 years postinjury. The inversion stress views at that time revealed only a three-degree increase laxity compared to the uninjured side. The anterior drawer sign was negative. There was no evidence of avascular necrosis of the talus on follow-up radiographs. Mazur et al.[133] have also reported ankle dislocation without a fracture in a pediatric patient.

For current treatment options, see Table 32-1.

Author's Preferred Treatment of Distal Tibial and Fibular Fractures

Salter–Harris Type I and II Fractures of the Distal Tibia

We prefer to treat nondisplaced Salter–Harris type I and II fractures initially with immobilization using either an above-knee or below-knee cast dependent on patient characteristics. Nonweight bearing is continued until 2 to 4 weeks postinjury, when the cast is changed to a below-knee walking cast or walking boot which is worn for an additional 2 to 3 weeks. Follow-up radiographs are obtained every 6 months for 1 to 2 years or until a Park–Harris growth arrest line parallel to the physis is visible and there is no evidence of physeal deformity.

For displaced fractures in children with at least 3 years of growth remaining, our objective is to obtain no more than 10 to 15 degrees of plantar tilt for posteriorly displaced fractures, 5 to 10 degrees of valgus for laterally displaced fractures, and 0 degrees of varus for medially displaced fractures (Fig. 32-53). Studies in the adult literature suggest that minor alteration in alignment of the ankle joint may have significant effect on tibiotalar contact pressures.[102,204,206] If there is a question about the ability to remodel the fracture, it is probably best to perform a reduction. For children with 2 years or less of growth remaining, the amount of acceptable angulation is reduced to 5 degrees or less. We recognize that all of the recommendations

FIGURE 32-53 **A:** Displaced pronation–eversion–external rotation fracture of the distal tibia in a 12-year-old boy was treated with closed reduction and cast immobilization. **B:** After cast removal, a 10-degree valgus tilt was present. **C:** At maturity, the deformity has completely resolved.

about acceptable alignment are based on clinical experience and judgment, and none have been rigorously studied.

If resources are available, we may attempt reduction of markedly displaced fractures with the use of general anesthesia with good muscle relaxation and image intensifier control. The use of an ankle distractor can facilitate distraction across the fracture, and may facilitate reduction (Fig. 32-34). In children with mildly displaced fractures, especially if anesthesia is not going to be available for many hours, an attempt at gentle closed reduction under a hematoma block supplemented as needed by well-monitored intravenous sedation is a good option. Many emergency rooms are well equipped and have adequate staff to perform appropriate and safe sedation for treatment of fractures and dislocation. This approach may allow for more timely treatment, especially if operating room access is limited. Once adequately reduced, the fractures are usually stable and a long-leg cast can be used for immobilization. Rarely, for markedly unstable fractures or severe soft tissue injuries that require multiple debridements, percutaneous screws are used when the Thurston–Holland fragment is large enough to accept screw fixation. When the fragment is too small, smooth wire fixation across the physis is the only alternative. Repeated attempts at closed manipulation of these fractures may increase the risk of growth abnormality and should be avoided. In patients with fractures that are not seen until 7 to 10 days after injury, residual displacement is probably best accepted, unless significant deformity or angulation is present. If growth does not sufficiently correct malunion, corrective osteotomy can be performed later.

Open reduction of these fractures is occasionally indicated. The exception usually has been pronation–eversion–external rotation fractures with interposed soft tissue, which may include lateral and posterior displacement. For cases that have undergone an attempt at closed reduction, close inspection of the medial physis should be performed with image intensification. In some cases, the medial physeal space will appear abnormally widened, which may suggest incarceration of a large flap of periosteum in the physis. For these fractures, a small anteromedial incision is made and any interposed soft tissues, such as periosteum or tendons, are extracted. Even though reduction is usually stable, we generally use internal fixation. Fixation options include screw fixation through both the metaphyseal and epiphyseal fragments, avoiding fixation across the physis if possible (Fig. 32-54). Percutaneous smooth pins can also be placed from the medial malleolus, oriented proximally to engage the metaphysis (Figs. 32-31 and 32-55).

Salter–Harris Types III and IV Fractures of the Distal Tibia

Treatment of nondisplaced Salter–Harris type III and IV fractures is the same as for nondisplaced type I and II fractures with three modifications. First, after casting with a long-leg cast, the alignment is confirmed with a CT scan and/or radiographs. Second, these patients are examined more frequently (once a week) for the first 2 to 3 weeks after cast application to ensure that the fragments do not become displaced. Third, these patients are examined every 6 to 12 months after cast removal for 24 to 36 months to detect any growth abnormality.

Fractures with 2 mm or more of displacement after the best possible closed reduction may be treated with open reduction and internal fixation with anatomical alignment of the physis and intra-articular fracture fragments.

For minimally displaced fractures, closed reduction is attempted in the emergency room or the operating room, depending on local resources and practices. Reduction may be attempted by applying longitudinal traction to the foot,

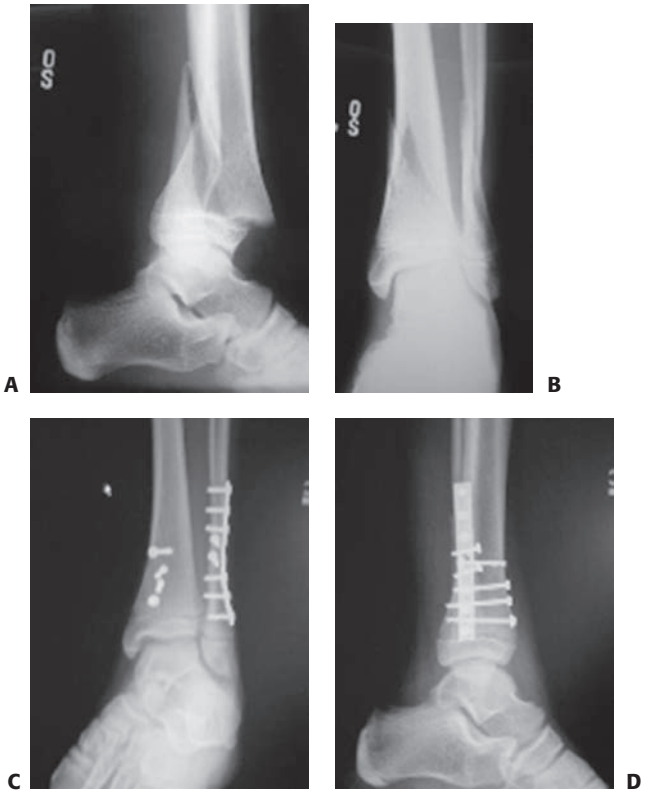

FIGURE 32-54 Salter–Harris type II distal tibial fracture with fibular fracture. **A:** Lateral view. **B:** Anteroposterior view. **C, D:** After percutaneous placement of tibial screws and plating of fibular fracture.

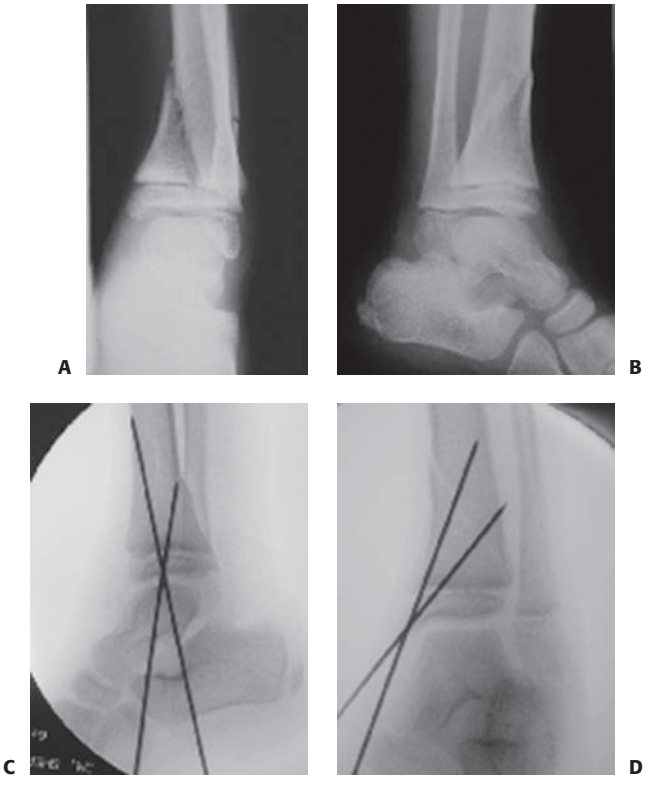

FIGURE 32-55 Salter–Harris type II distal tibial fracture with fibular fracture. **A:** Anteroposterior view. **B:** Lateral view. **C, D:** Percutaneous placement of Kirschner wires.

followed by eversion of the foot and direct digital pressure over the medial malleolus. If image intensification confirms anatomical reduction, but the fracture is unstable, the fracture may be fixed with two percutaneous smooth wires placed in the epiphysis parallel to the physis. Reduction is confirmed by a short, continuous fluoroscopic examination. Percutaneous clamp placement may also facilitate reduction in some of these cases. Cannulated screws can be inserted if the epiphysis is large enough. For fractures that are seen more than 7 to 14 days after injury, we may accept up to 2 mm of displacement without attempting closed or open reduction. Reliable patients whose fractures are fixed with pins and/or screws may be immobilized in below-knee casts. Above-knee casts are used for other patients.

In cases where arthroscopic assistance is used, the visualization of the ankle joint can also assist with the evaluation of reduction. In some cases, the fractures may still have a small gap present with the articular surface, but the presence of step-off or intra-articular incongruity can be clearly evaluated with the scope visualization of the articular surface. It has been our experience that the C-arm views may show excellent reduction of the subchondral bone of the articular surface, and the arthroscopic views may show that the cartilage surfaces are not as well reduced as one would expect based upon these radiographic images.

Fractures with more than 2 mm of displacement or step-off should be reduced, regardless of whether the fracture is acute or not. Closed reduction can be attempted, but these fractures may require open reduction, arthroscopic-assisted reduction, or mini-open reduction with arthroscopic assistance. Occasionally, primary debridement of callus and soft tissue back to normal-appearing physis and fat grafting has been successful for fractures that are more than 2 weeks old.

For fractures stabilized with internal fixation, below-knee casts may be used. If there is concern about fracture stability, above-knee casts can be used.

Open Reduction and Internal Fixation of Salter–Harris Type III or IV Fracture of the Distal Tibia

The patient is placed supine on an operating table that is radiolucent at the lower extremity. For wide exposure, a hockey-stick incision is made, extending from approximately 4 cm above the ankle joint to 1 cm posterior to the tip of the medial malleolus. The image intensifier can be used to locate the vertical incision for articular exposure directly over the fracture line in the sagittal plane, and this can limit the length of incision needed. Alternatively, if more anterior exposure is required, a 4- to 6-cm transverse incision is made from the posterior aspect of the medial malleolus to the anterior aspect of the ankle. The saphenous

FIGURE 32-56 Salter–Harris type V distal fibula fracture. **A:** Anteroposterior ankle radiograph of crush injury to the medial malleolus. **B:** Coronal CT scan of medial malleolus crush injury. **C:** Sagittal CT scan of medial malleolus crush injury.

vein is identified, dissected free, and retracted. The fracture site is identified, and an anteromedial capsulotomy of the ankle joint is performed. The fracture surfaces are exposed and gently cleaned with irrigation and forceps (curettage is not used).

For Salter–Harris type IV fractures, the periosteum may be elevated several millimeters from the metaphyseal fracture edges. The epiphyseal edges and joint surfaces are examined through the arthrotomy. The perichondral ring should not be elevated from the physis. For Salter–Harris type III fractures, the reduction is evaluated by checking the joint surface and epiphyseal fracture edges through the arthrotomy. The epiphyseal fragment is grasped with a small towel clip or reduction forceps, and the fracture is reduced. Internal fixation is performed under direct vision and fluoroscopic control. It is important to view both the lateral and anteroposterior projections because of the curved shape of the distal tibial articular surface. If the fragment is large enough, 4-mm cannulated lag screws are inserted through the epiphyseal fragment; if the fragment is too small for screws, smooth Kirschner wires are used. The reduction and the position of the internal fixation are checked through the arthrotomy. In fractures with a significant Thurston–Holland fragment, a metaphyseal screw may be used if a gap exists after the epiphyseal screws are inserted. After reduction of the tibial fracture, an associated Salter–Harris type I or II fibular fracture usually reduces and is stable. If it is not, closed reduction and fixation with percutaneous oblique smooth Kirschner wires are performed.

The patient is kept nonweight bearing for 3 weeks, and then the cast is changed to a below-knee walking cast, which is worn for an additional 3 weeks. Frequent follow-up evaluations (every 3 to 6 months for the first year and yearly thereafter until normal growth resumes) are necessary to detect growth abnormalities.

Salter–Harris Type V Fractures of the Distal Tibia

These injuries are quite rare. The risk of physeal arrest is thought to be quite high for this injury pattern, because of direct

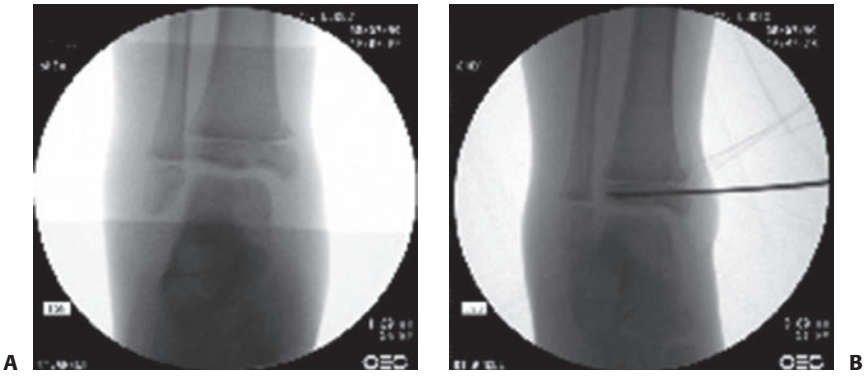

FIGURE 32-57 Salter–Harris type V patterns with crush injury to medial malleolus. **A:** Crush injury to medial malleolus and distal tibia metaphysis. **B:** The percutaneous pins can be used to manipulate the fracture.

damage of the germinal layer of the physis.[102] We have seen a variant of these fractures associated with a varus load to the ankle joint, leading to a crush-type injury to the medial malleolus (Figs. 32-56 and 32-57). These fractures can be treated with reduction of the joint and physeal surface, using minimally invasive techniques that avoid the physis and perichondral ring (Fig. 32-57).

The prognosis for this injury is poor, and treatment is usually focused upon treating the complications of angular deformity and/or physeal arrest.[102]

Juvenile Tillaux Fractures

For nondisplaced fractures and fractures displaced less than 2 mm, we prefer immobilization in an above-knee cast with the knee flexed 30 degrees and the foot neutral or internally rotated. If the position appears acceptable on plain films, CT scanning in the transverse plane with coronal and sagittal reconstructions may be used to confirm acceptable reduction. For fractures with more than 2 mm of initial displacement, manipulation may be attempted by internal rotation of the foot and application of direct pressure over the anterolateral joint line. If reduction is not obtained with this maneuver, reduction can be attempted by dorsiflexing the pronated foot and then internally rotating the foot.[128] If successful reduction is obtained, percutaneous fixation (screws or pins) can be placed with C-arm guidance. Percutaneous clamps can be used to obtain and hold reduction during screw placement. If there are questions about the adequacy of reduction, this can be confirmed by use of an arthrotomy or ankle arthroscope.

In cases where the reduction is not ideal, there are several options. Schlesinger and Wedge[184] have described a technique using percutaneous manipulation of a Tillaux fragment with a Steinmann pin.[102] Small Kirschner wires or the threaded tip wires from a cannulated screw set can be inserted into the Tillaux fragment under fluoroscopic control, to act as a "joystick" to reduce the fracture (Fig. 32-58). Ideally, one or both of these pins can then be passed across the fracture site after reduction has been obtained if the guidewire is carefully placed initially, and the cannulated screw can then be placed over the pins (Figs. 32-59 and 32-60).

If reduction is not successful, open reduction is performed through an anterolateral approach, again using fluoroscopy to position the incision over the vertically oriented fracture line. Arthroscopic assistance can also be used to obtain anatomic reduction. For open techniques, the following protocol is used. The patient is placed in a supine position, and a vertical incision is placed over the fracture. A small incision is made, perhaps 2 to 3 cm, to allow for visualization. The fracture plane is identified, and direct pressure or clamps can be applied to maintain the reduction. If necessary, a small arthrotomy or arthroscope can be used to evaluate the articular reduction. A guidewire from the cannulated screw system (a 4-mm cannulated system usually works well in this age group) is placed, followed by placement of the screw.

A short-leg, non–weight-bearing cast is worn for 3 weeks, followed by a weight-bearing cast or walking boot for another 3 weeks.

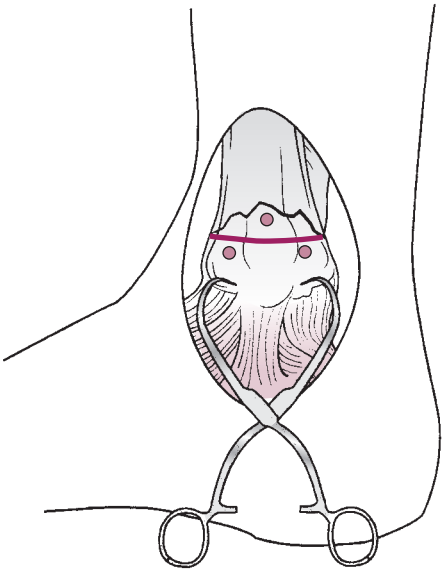

FIGURE 32-58 Technique for reduction of a Salter–Harris type IV fracture of the distal tibia.

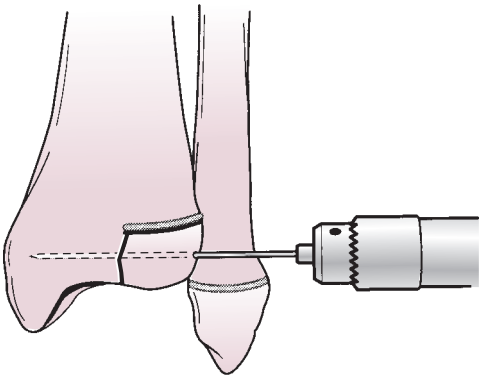

FIGURE 32-59 Advancement of pin after reduction of juvenile Tillaux fracture.

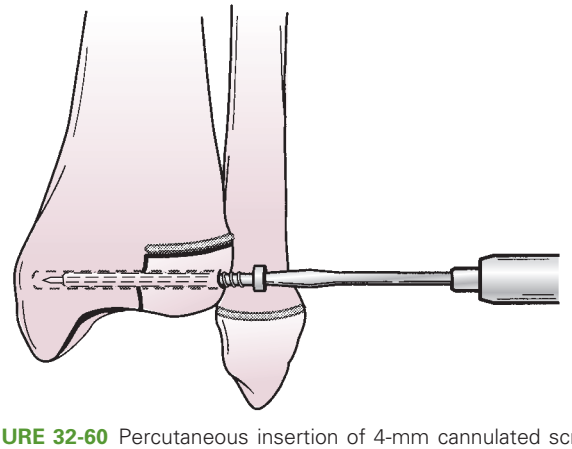

FIGURE 32-60 Percutaneous insertion of 4-mm cannulated screw over pin that has been advanced into the medial distal tibia after reduction of the juvenile Tillaux fracture fragment.

Triplane Fractures

For nondisplaced or minimally displaced (less than 2 mm) fractures, we prefer immobilization in a long-leg cast with the knee flexed 30 to 40 degrees. The position of the foot is determined by whether the fracture is lateral (internal rotation) or medial (eversion). A CT scan may be obtained after reduction and casting to document adequate reduction. Plain films or CT scans are obtained approximately 7 days after cast application to verify that displacement has not recurred. At 3 to 4 weeks, the cast is changed to a below-knee walking cast or walking boot, which is worn another 3 to 4 weeks.

The ability to reduce fractures in the ER with appropriate conscious sedation varies among institutions. For institutions that have such capabilities, fracture reduction can be attempted in the ER. For fractures with more than 2 mm of displacement, an attempt closed reduction with sedation in the emergency department. An above-knee cast is applied. If plain radiographs show satisfactory reduction, a CT scan is obtained. If reduction is acceptable, treatment is the same as for nondisplaced fractures.

If the reduction is unacceptable, closed reduction is attempted in the operating room with the use of general anesthesia. If fluoroscopy shows an acceptable reduction, percutaneous screws are inserted, avoiding the physis, and a short-leg cast is applied. If closed reduction is unacceptable, open reduction or mini-open reduction with the use of percutaneous clamps is performed. Preoperative CT scanning may be helpful for evaluating the position of the fracture fragments in the anteroposterior and lateral planes and for determining the appropriate skin incisions, percutaneous clamp placements, and screw location.

Open Reduction of Triplane Fracture

The patient is placed supine on a radiolucent operating table with padded elevation behind the hip on the affected side. The surgical approach depends on the fracture anatomy as determined by the preoperative CT scan. A two-part medial triplane fracture can be approached through a hockey-stick anteromedial incision. The fracture fragments are irrigated to remove debris, and any interposed periosteum is removed. The fracture is reduced, and reduction is confirmed by direct observation through an anteromedial arthrotomy and by image intensification. Two 4-mm cancellous screws are inserted from medial to lateral or from anterior to posterior or both, depending on the fracture pattern (Fig. 32-61). Anterior-to-posterior screw placement may require an additional anterolateral incision or the screws may be inserted percutaneously. Arthroscopic-assisted techniques, with the use of percutaneous clamps and screws may also be used (Fig. 32-62).

For two-part lateral triplane fractures, these can be approached with a hockey-stick anterolateral approach. The fracture is reduced and stabilized with two screws placed from lateral to medial or from anterior to posterior or both, and reduction is confirmed through direct observation and by image intensification. In addition to open techniques, arthroscopic-assisted techniques with the use of percutaneous clamps and screws may also be used (Fig. 32-62).

Fractures with three or more parts may occasionally require more exposure for reduction and internal fixation. If the fibula is fractured, posterior exposure of the tibial fracture can be readily obtained by detaching the anterior and posterior-inferior tibiofibular ligaments and turning down the distal fibula on the lateral collateral ligament (Fig. 32-63). If the fibula is not fractured, a fibular osteotomy may be needed in rare circumstances for adequate visualization of the articular surface. Careful dissection is necessary to avoid iatrogenic fractures through the physis of the fibula. Medial exposure is obtained through an anteromedial or posteromedial incision. Reduction and internal fixation are carried out in a stepwise fashion. For typical three-part fractures, the Salter–Harris type II fracture may be reduced first by provisional fixation to the distal tibia through the metaphyseal fragment. Usually, the Salter–Harris

type III fragment can then be reduced and provisionally fixed to the stabilized type II fragment (Fig. 32-64). Occasionally, the order of reduction and fixation should be reversed. Fractures with four or more fragments require additional steps, but fixation of the Salter–Harris type II or IV fragment through the metaphysis to the distal tibia is usually best performed first. This step can be followed by fixation of the Salter–Harris type III fragment or fragments (Fig. 32-65). After reduction, reliable patients may be treated with immobilization in a short-leg, non–weight-bearing cast for 3 to 4 weeks. At 3 to 4 weeks, they may be converted to a weight-bearing cast or walking boot for an additional 3 to 4 weeks.

Fracture Reduction Tips, Arthroscopic Assistance, Use of Percutaneous Clamps, Implants

Ankle Distraction

Use of the ankle distractor (normally used for arthroscopy procedures) can assist with reduction of displaced extra-articular fractures, such as Salter–Harris type I or II patterns. When combined with the relaxation of general anesthesia, a few minutes of distraction across the physis can facilitate reduction. The distraction across the fracture may increase the likelihood that the first attempt at reduction will be successful; this may reduce the trauma to the physis during the reduction, perhaps reducing the risk of physeal arrest. Juvenile Tillaux and triplane fracture reduction can also be facilitated with ankle distraction, and this will also facilitate arthroscopic ankle visualization. The ankle distractor obviates the need to have the surgeon pull manually for several minutes. The surgeon can then focus on the application of other forces, such as

rotation or varus/valgus to facilitate fracture reduction. Although skeletal traction using a calcaneal pin is an option,[39] we prefer to use an ankle strap and special distractor routinely used for arthroscopy (Arthrex, Naples, Florida). The ankle distractor can be positioned to allow for anteroposterior and lateral mini C-arm images (Fig. 32-34).

Imaging Studies

Use of CT scans can be very beneficial for evaluating intra-articular fractures or multiplanar fractures. High resolution scans with three-dimensional reconstructions provide excellent anatomic detail. For minimally invasive approaches using percutaneous screw fixation, these images can be used for precise screw placement during surgery. The CT scan can also facilitate percutaneous placement of clamps, to allow for compression perpendicular to the plane of the fracture. A clear preoperative evaluation should determine optimal screw position and orientation, and these images should also be available during the procedure to assist with screw placement.

Arthroscopy

The use of arthroscopy can facilitate minimally invasive procedures. Several clinical series document the effectiveness of arthroscopic assistance for Tillaux fractures[92,135,153] and triplane fractures.[89,92] The joint surfaces can be readily visualized through small incisions, avoiding the need for a larger arthrotomy. Even in cases where an arthrotomy is used, the scope can be utilized either with or without fluid to visualize the reduction of the fragments (Fig. 32-66). The fluid of the arthroscopy pump can also be used to wash out the fracture site, increasing visualization during reduction. Avoidance of high pump pressure will minimize the risks of soft tissue infiltration.

Different size scopes are available, including 2.8 and 5 mm. We prefer to use smaller diameter scopes, especially in younger patients. The smaller scope has a smaller field of view, but this does not seem to be much of a disadvantage for viewing the displaced cartilage surfaces. The smaller scope also delivers less fluid to the joint, which may require additional time to clean

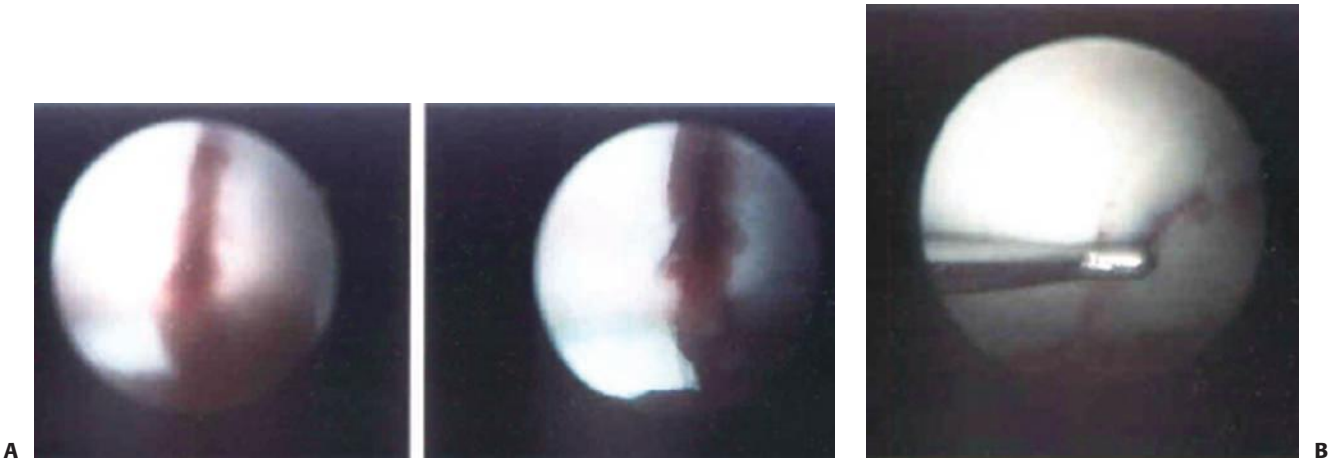

FIGURE 32-66 Ankle arthroscopy. **A:** Arthroscopic view of fracture gap in distal tibia articular surface. **B:** Arthroscopic view of fracture gap in distal tibial articular surface after reduction.

the hematoma from the joint and fracture, but has a lower risk of causing soft tissue infiltration around the joint.

Use of Small C-Arm Unit

The small C-arm unit will also assist with minimally invasive approaches. This can be easily rotated to allow for AP or lateral views. If the ankle distractor is used, position the foot and distractor to allow easy access by the C-arm (Fig. 32-34).

Percutaneous Clamps

Precise placement of clamps can facilitate the reduction of fractures. Careful study of imaging studies, especially CT scans, can guide precise placement of clamps to provide maximal compression across fracture planes. Forces normal or near normal to the fracture planes are ideal. Care should be taken during placement, to prevent injury to neurologic and vascular structures, including sensory nerves. The skin can be divided, and then deeper dissection through the subcutaneous tissues can be performed with a hemostat. The hemostat is used to bluntly distract the tissues away from the skin portal, and then advanced to the bone surface. The tips of the clamp can now be placed with minimal risk to neurovascular structures. The clamp can be compressed, to facilitate reduction of triplane and Tillaux fractures (Figs. 32-51 and 32-62).

Implants

Different implants are available for fixation of ankle fractures. Smooth pins have the advantage that they do not place a threaded tip across the physis, therefore reducing the risk of iatrogenic physeal arrest. The main disadvantage of smooth pins is that they do not allow for compression. These pins can also migrate through bone, and into soft tissues. Bending the ends at the surface of the bone to prevent migration is important. These pins should be removed early, as soon as the fracture stability is adequate. In most cases, we remove the pins between 14 and 21 days after surgery. Careful management of the pin/skin interface with dressings that limit motion is believed to lower the risk of pin inflammation and infection.

In most physeal injuries, the use of screws or threaded devices across the physis should be avoided when possible. In some cases, a screw implant may be necessary to cross a physis, to maintain an articular reduction. The adequacy of reduction of the joint surface is probably more important than the physis. In patients approaching skeletal maturity, the use of screw implants across a physis that is approaching closure is probably a reasonable choice, especially in case where compression and/or stability are important, such as juvenile Tillaux fractures (Fig. 32-67).

Fractures Involving the Distal Fibula

We usually treat nondisplaced fibular physeal fractures with immobilization in a below-knee walking cast for 3 to 4 weeks. Recent studies found use of a removable ankle brace to be as effective, and to be preferable from a patient satisfaction and economic standpoint when compared to fiberglass posterior splints.[8,25] Closed reduction of displaced Salter–Harris types I and II fibular fractures, is usually successful. In cases where reduction is unsuccessful, one may accept up to 50% displacement without problems at long-term follow-up, especially in those with 3 to 4 years of growth remaining. Acceptance of this displacement may be more reasonable in young patients with significant remodeling potential, although in older patients, displaced fractures may have more effect on ankle function, and more anatomic reduction may be advantageous. Dias and

FIGURE 32-67 **A, B:** Displaced juvenile Tillaux fracture. Closed reduction was not successful.
(*continues*)

C

FIGURE 32-67 (*continued*) **C:** After open reduction with internal fixation with a small fragment screw.

Giegerich,[56] however, reported a patient with a symptomatic spike that required excision after incomplete reduction.

Lateral Ankle Sprains and Lateral Ligament Avulsion Injuries

The diagnosis of an ankle sprain is less common in younger patients, although recognition of ankle sprain injuries in children is becoming more common with advanced imaging using ultrasound and MRI. If the pain can be localized to the ligaments, and there is no pain over the distal fibular physis, then ankle sprain is the likely diagnosis. The authors prefer functional treatment for ankle sprains, allowing weight bearing as tolerated in a supportive device until the patient is pain free (typically 3 weeks), and then progressive return to activities. Surgical treatment is reserved for those patients who develop late symptoms. Chronic pain and instability can occur in young patients, especially adolescents. In these cases, a Broström-type reconstruction[30] may be appropriate, although Letts et al.[118] have described nonanatomic reconstruction in younger patients (Evans, Watson–Jones, Chrisman, and Snook).

Avulsion fractures can be identified that originate from the distal fibula, and special radiographic views may facilitate diagnosis.[79] These avulsion-type injuries can lead to symptoms, and a high index of suspicion is important in younger patients. Haraguchi et al.[80] evaluated a series of severe ankle sprains, and found that 26% had evidence of distal fibular avulsion injury. Children and adults over 40 years of age had the highest incidence of this injury. Patients were treated with weight-bearing casts for 3 to 4 weeks. Nonoperative treatment yielded satisfactory results in this series.

Rehabilitation

For patients treated with cast immobilization, quadriceps, hamstring, and abductor exercises are begun as soon as pain and swelling allow. Usually a below-knee cast is worn during the last 2 to 3 weeks of immobilization, and weight bearing to tolerance is allowed during this time. After immobilization is discontinued, ankle range-of-motion exercises and strengthening exercises are begun. Protective splinting or bracing is usually not required after cast removal. Running is restricted until the patient demonstrates an essentially full, painless range of ankle and foot motion and can walk without a limp. Running progresses from jogging to more strenuous running and jumping as soreness and endurance dictate. For athletes, unrestricted running and jumping ability should be achieved before returning to sports. Protective measures such as taping or bracing may be beneficial for return to sports.

Younger patients with physeal ankle fractures recover quickly and require little or no formal physical therapy. For this reason, and because of compliance considerations, fractures treated with internal fixation are usually protected with below-knee casting instead of starting an early range-of-motion program in a removable splint. In older patients who may have a higher risk of arthrofibrosis, we may start early motion in a removable boot, and have them start a formal supervised physical therapy program.

Management of Expected Adverse Outcomes and Unexpected Complications of Distal Tibial and Fibular Fractures

Delayed Union and Nonunion

Delayed union and nonunion are extremely rare after distal tibial physeal fractures (Fig. 32-68). Dias and Giegerich[56] reported one patient with a delayed union and one patient with a previous physeal bar excision who had a nonunion that healed after open reduction, internal fixation, and bone grafting. Siffert and

FIGURE 32-68 Complex nonunion of a Salter–Harris type III fracture of the medial malleolus in an 8-year-old boy. Note that the distal tibial epiphysis is in valgus, whereas the talus is in varus. (Courtesy of Brent Broztman, MD.)

Arkin[191] reported nonunion in a patient with avascular necrosis of the distal tibial epiphysis. We have seen two younger patients with Salter–Harris type III fractures that appeared to be progressing to nonunion. Because neither patient had any complaints of pain nor any evidence of progressive displacement of the fracture and stress views showed no instability, no treatment was undertaken. Both fractures eventually united. We have seen one patient with a nonunion after open reduction and internal fixation in whom pin fixation and cast immobilization were discontinued prematurely. The fracture healed after repeat open reduction and internal fixation.

Nonunion of a fracture of the fibular epiphysis has been reported by Mirmiran and Schuberth.[136] This was treated successfully with open reduction and internal fixation.

Deformity Secondary to Malunion

Rotational malunion usually occurs after triplane fractures that are either incompletely reduced or are initially immobilized in below-knee casts. It has also been reported after Salter–Harris type I and II injuries. Phan et al. reported an increase in the outward foot progression angle in children following transitional fractures, but it is not known if perhaps an outwardly rotated foot predisposes one to these fractures. Derotational osteotomy may be performed for extra-articular fractures if discomfort and stiffness occur. Guille et al.,[77] reported a rotational malunion of lateral malleolar fracture that lead to a stress fracture of the distal fibula that went on to delayed union. Their patient improved after correction of the malrotated distal fibula and bone grafting of the delayed union site.

Anterior angulation or plantarflexion deformity usually occurs after supination–plantarflexion Salter–Harris type II fractures. Theoretically, an equinus deformity might occur if the angulation exceeds the range of ankle dorsiflexion before fracture, but this is very rare, probably because the deformity is in the plane of joint motion and tends to remodel with growth.

Valgus deformity is most common after external rotation Salter–Harris type II fractures. The degree to which the deformity may spontaneously resolve or remodel with growth is controversial. Carothers and Crenshaw[37] reported resolution of a 12-degree valgus deformity in a 13½-year-old boy, but Spiegel et al.[196] reported persistent residual deformity in a significant number of their patients (Fig. 32-69). Varus deformity most often results from growth abnormality and infrequently is the result of simple malunion.

If significant angular deformity persists at the completion of growth, supramalleolar osteotomy can be performed.[11]

Moon et al.,[137] followed nine children with posttraumatic varus deformities of the ankle secondary to supination–inversion injuries. These patients developed medial subluxation of their ankles with associated internal rotational deformity. Takakura et al.,[202] described successful open wedge osteotomy for varus deformity in nine patients. Scheffer and Peterson[181] recommend opening wedge osteotomy when the angular deformity is 25 degrees or less and the limb length discrepancy is or will be 25 mm or less at maturity. Preoperative planning should include templating the various types of osteotomies to determine which technique will maintain the proper mechanical alignment of the tibia and ankle joint and will not make the malleoli unduly prominent. Osteotomy is not recommended for malunion of intra-articular fractures because it cannot correct the joint incongruity that results from malunion (Fig. 32-70).

FIGURE 32-69 Radiograph of a 14-year-old boy, 4 months after pronation–eversion–external rotation injury, reveals 16 degrees of valgus angulation.

The use of the Taylor Spatial Frame continues to evolve. Its use for correction of complex deformities can allow for multiplanar corrections, including rotation, length, and angular deformity. For more complex deformities, this device may be useful for correction.[65,190]

Physeal Arrest or Growth Disturbance

Deformity caused by growth arrest usually occurs after Salter–Harris types III and IV fractures in which a physeal bar develops at the fracture site, leading to varus deformity that progresses with continued growth. Spiegel et al.[196] reported growth problems in 9 of 66 patients with Salter–Harris type II fractures.

Earlier reports[37,50,72] attributed the development of physeal bars to crushing of the physis at the time of injury, but more recent reports[93,111] discount this explanation and claim that with anatomical reduction (open reduction and internal fixation if needed), the incidence of physeal bar formation can be decreased. The validity of this claim is difficult to determine from published reports. One problem is the small numbers of patients in all series, and the even smaller numbers within each group in each series. Another problem is the age of the patients in operative and nonoperative groups in the various series; for example, many children reported to do well with a particular treatment method and have so little growth remaining that treatment may have had little or no effect on growth.

A recent study by Rohmiller et al.[174] analyzed the outcome of 91 Salter–Harris I and II fractures of the distal tibia. They identified premature physeal closure in 40%. This series identified a trend toward increased premature physeal closure in

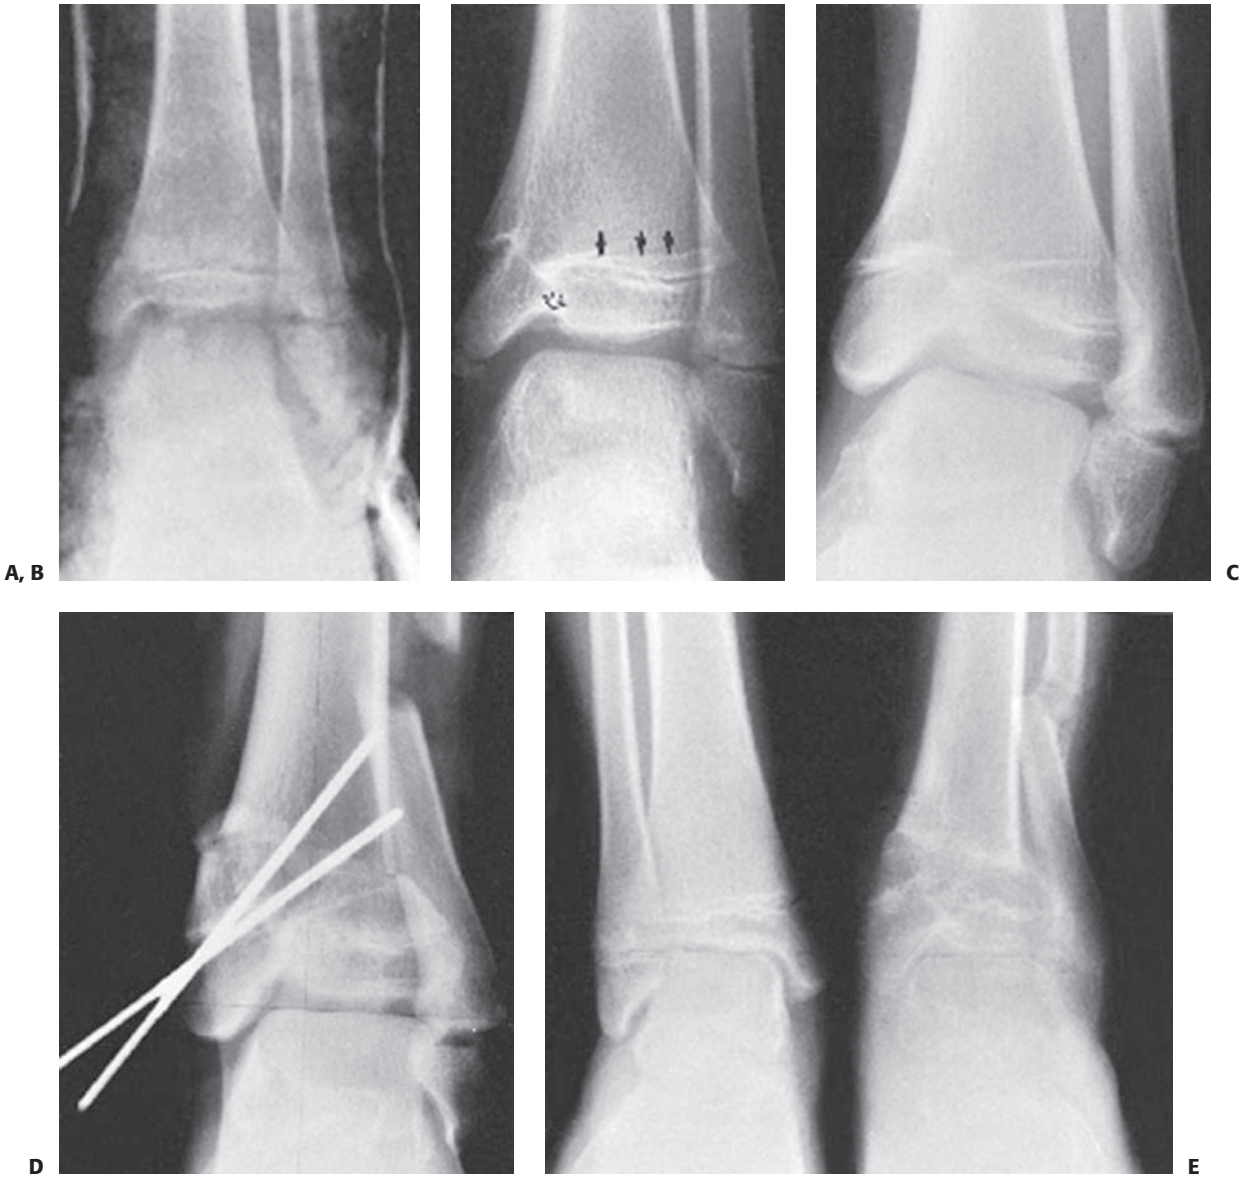

FIGURE 32-70 **A:** This apparently nondisplaced medial malleolar fracture in an 11-year-old boy was treated with immobilization in a long-leg cast. **B:** Fourteen months after injury, there is a clear medial osseous bridge and asymmetric growth of the Park–Harris growth arrest lines (*black arrows*). Note the early inhibition of growth on the subchondral surface of the fracture (*open arrow*). **C:** Five years after injury, the varus deformity has increased significantly and fibular overgrowth is apparent. **D:** The deformity was treated with a medial opening-wedge osteotomy of the tibia, an osteotomy of the fibula, and epiphysiodesis of the most lateral portion of the tibial physis and fibula. **E:** Three months after surgery, the osteotomies are healed and the varus deformity is corrected; the joint surface remains irregular. (Courtesy of Earl A. Stanley, Jr., MD.)

fractures that had worse displacement after reduction. They recommended operative reduction to restore anatomic alignment, to reduce the risk of premature physeal closure.

Kling et al.[111] reported physeal bars in two of five patients treated nonoperatively and in none of three patients treated operatively in children 10 years of age and younger. In another series of 65 physeal ankle fractures, Kling[110] concluded that the frequency of growth-related deformities could be reduced by open reduction and internal fixation of Salter–Harris III and IV fractures.

However, in one of the authors experience with eight patients (JC), two of five treated operatively developed physeal bars, whereas none of the three patients treated nonoperatively had physeal bars. This supports the conclusion of Cass and Peterson,[38] Ogden,[149] and others that growth problems after these injuries may not always be prevented by open reduction and internal fixation. Open reduction of displaced Salter–Harris type III and IV ankle fractures would seem advisable to restore joint congruity, regardless of whether growth potential can be preserved.

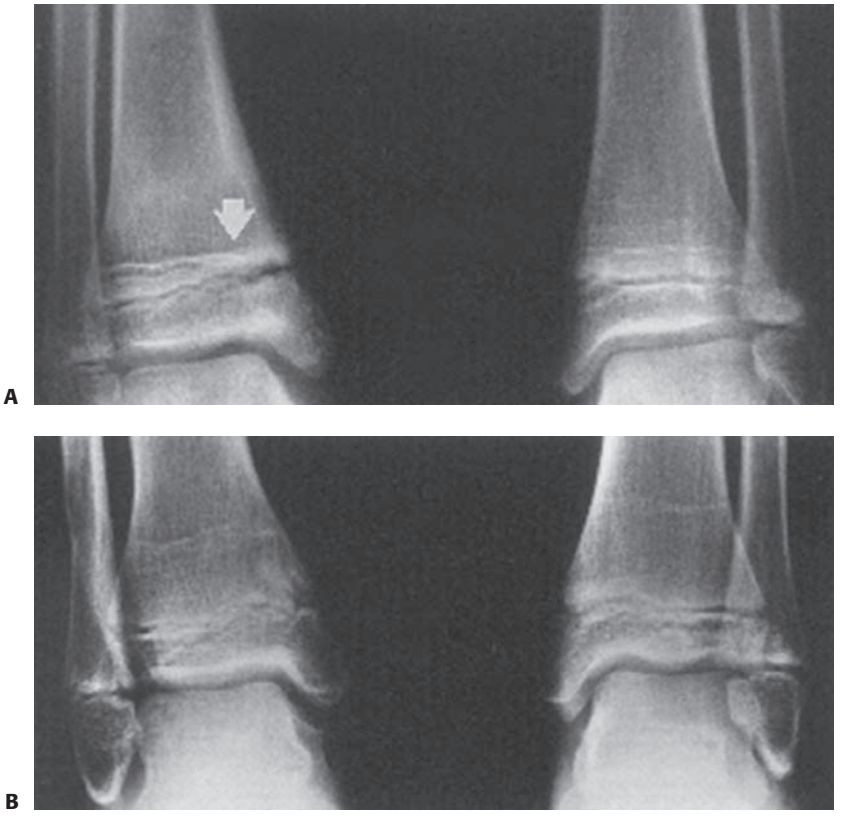

FIGURE 32-71 **A:** Six months after cast immobilization of a nondisplaced supination–inversion Salter–Harris type III fracture of the right distal tibia in an 8-year-old boy. The Park–Harris growth arrest line (*arrow*) appears to end in the physis medially and diverge from the physis laterally. **B:** Two years later, no physeal bar is present and growth is normal.

Harris growth lines have been reported to be reliable predictors of growth abnormality,[88] but one of the authors (JC) has found that, although lines parallel to the physis are reliable, lines that appear to diverge from the physis may be misleading (Fig. 32-71). The use of MRI and/or CT scan may assist with evaluation of physeal bars. Spontaneous resolution of physeal bars has been reported[23,42] but is rare. Most patients require excision of small bony bars and may require correction of significant angular deformity with osteotomy (Fig. 32-72). Another option to treat secondary deformity is the use of

FIGURE 32-72 **A:** One year after open reduction and internal fixation of a Salter–Harris type III fracture of the distal tibia in a 7-year-old boy, varus deformity has been caused by a physeal bar. **B:** Two years after excision of the physeal bar and insertion of cranioplast, satisfactory growth has resumed and the deformity has resolved.

FIGURE 32-73 Valgus deformity of the ankle, lateral displacement of the talus with widening of the joint medially, and severe shortening of the fibula after early physeal arrest in a child who sustained an ankle injury at 6 years of age. (Courtesy of James Roach, MD.)

"guided growth," the use of medial malleolar screws or medial stapling devices.[197]

Kärrholm et al.[100] reported progressive ankle deformity caused by complete growth arrest of the fibula with normal growth of the tibia (Fig. 32-73). They found that continued fibular growth with complete arrest of tibial growth was usually compensated by proximal migration of the fibula so that varus deformity did not occur.

Because the amount of growth remaining in the distal tibial physis is small (approximately 0.25 in per year) in most older patients with these injuries, the amount of leg-length discrepancy resulting from complete growth arrest tends to be relatively small. Treatment may be required if the anticipated discrepancy is projected to be clinically significant.

Imaging techniques to identify physeal arrest and bars include plane radiographs, tomography, computerized tomography, and MRI. In most imaging departments, standard tomography has been replaced by computerized tomography. CT scans can be useful for clear delineation of the anatomy, especially in cases in which surgical intervention is necessary. Recent studies have also used MRI scans.[69,122,180] Although the resolution capability is more limited, the avoidance of ionizing radiation is a major advantage of MRI scans over CT scans.

Physeal arrest of the distal tibia has been reported after fracture of the tibial diaphysis, in the absence of obvious physeal injury.[142]

Medial Malleolus Overgrowth

Overgrowth of the medial malleolus has been reported after fractures of the distal tibia metaphysis and epiphysis. A recent series of 83 patients with fractures in this region demonstrated 2 patients with medial malleolus overgrowth. In both cases, there was no evidence of functional impairment.[144]

Arthritis

Epiphyseal ankle fractures that do not extend into the joint have a low risk of posttraumatic arthritis, but injuries that extend into the joint may produce this complication. Caterini et al.[40] found that 8 of 68 (12%) patients had pain and stiffness that began from 5 to 8 years after skeletal maturity. Ertl et al.[62] found that 18 to 36 months after injury, 20 patients with triplane fractures were asymptomatic, but at 36 months to 13 years after injury only 8 of 15 patients evaluated were asymptomatic.

Ramsey and Hamilton[168] demonstrated in a cadaver study that 1 mm of lateral talar displacement decreases tibiotalar contact area by 42%, which greatly increases the stress on this weight-bearing joint. More recently, Michelson et al.[134] reported that a cadaver study using unconstrained specimens suggested that some lateral talar displacement occurs with normal weight bearing. Because of their findings, they questioned the current criterion of 2 mm of displacement for unstable ankle fractures. However, the results of Ramsey and Hamilton's study correlate well with other studies that have shown increased symptoms in patients in whom more than 2 mm of displacement was accepted.[40,62]

Implant removal after fracture surgery remains controversial, and the indications for removal are not well defined in the literature.[34] Charlton et al.[44] have demonstrated that the peri-epiphyseal or subchondral screws may alter the joint contact pressures about the ankle. After removal of the screws from the subchondral bone, the contact pressure is normalized. For hardware in the subchondral bone, Charlton's study suggests that implant removal of transepiphyseal screws may be appropriate.

Chondrolysis

Chondrolysis is a rare complication of adolescent ankle fractures.[18,180] Treatment options include therapy, nonsteroidal anti-inflammatories, etc. Recent clinical studies have evaluated the effects of joint distraction for posttraumatic chondrolysis, although experience with this technique in young patients is very limited.[180]

Osteonecrosis of the Distal Tibial Epiphysis

Siffert and Arkin[191] in 1950, were the first to call attention to this complication of distal tibial fractures. In their patient, the combination of nonunion of a medial malleolar fracture and avascular necrosis caused pain that required an arthrodesis 14 months after injury. Dias[55] and Pugely et al.[166] have recently reported this complication, which can lead to significant growth disturbance. We have seen few patients with this complication. One patient had significant joint stiffness and developed a valgus deformity secondary to collapse. After revascularization of the epiphysis, the ankle was realigned with a supramalleolar osteotomy, and 5 years later the patient had satisfactory function without pain.

Compartment Syndrome

This complication is discussed in detail in Chapter 6. Fractures of the distal tibia and ankle joint are infrequently associated with compartment syndromes,[47,139] unlike more proximal leg fractures. Mubarak[139] has described a unique compartment syndrome associated with distal tibial physeal fractures in six patients. These patients had clinical symptoms of severe pain and swelling, with associated sensory and motor deficits. The compartment pressure below the superior extensor retinaculum was above 40 mm in all cases, and the pressure was less than 20 mm in the anterior compartment. These patients were treated with limited fascial release of the superior extensor retinaculum and fracture stabilization.

The development of claw toes after tibial fracture has been described, and this development may be related to a subclinical compartment syndrome which develops in the distal part of the deep posterior compartment.[67]

Osteochondral Defects

Osteochondral injuries, primarily of the talus, are increasingly recognized after ankle injury in adults and the skeletally immature.[127,151,183] MRI may play a role in identification of treatment of these injuries.[14]

Synostosis

Posttraumatic tibiofibular synostosis is a rare complication of fractures in this region. This can lead to growth disturbance, including angular deformity and lower extremity length discrepancy.[142,214] Synostosis in this area alters the normal pattern of movement between the tibia and fibula, and has been associated with pain in some patients. In a small clinical series, Mubarak et al.[141] demonstrated symptoms of pain, prominence of the fibula, and ankle deformity in 5/8 patients with this synostosis. In this series, the normal growth pattern of distal migration of the fibula was altered, resulting in decreased distances between the proximal physes of the tibia and fibula, and proximal positioning of the distal fibula with respect to the distal tibia. Munjal et al.[142] demonstrated successful synostosis excision in a 7-year-old patient, which lead to normalization of the ankle joint at 16 months post surgery.

Reflex Sympathetic Dystrophy/ Complex Regional Pain Syndrome

Reflex sympathetic dystrophy or complex regional pain syndrome occasionally develops after ankle injuries, and is treated initially with an intensive formal physical therapy regimen that encourages range of motion and weight bearing.[102,213] For patients who do not respond quickly to such a program, physical therapy in association with continuous epidural analgesia may be considered.[213]

Osteopenia

Recent studies have identified the development of osteopenia after ankle fracture treatment in the pediatric population.[41] Although the implications of osteopenia are not clear, appropriate return to early weight bearing may be an important factor to minimize this complication.

Summary, Controversies, and Future Directions Related to Distal Tibial and Fibular Fractures

Many questions remain unanswered about the optimal treatment of ankle fractures in skeletally immature patients and will have to be answered with clinical trials. The relationship between physeal displacement and the development of subsequent physeal arrest is still unclear. Interposition of periosteum in the fracture may play a role in physeal arrest, although this has not been clarified in animal models or clinical trials.

Recent studies in the adult literature have suggested that minimally angular deformities about the distal tibia can have pronounced effects on the tibiotalar contact pressures.[102,204,206] The limits of fracture remodeling and the magnitude of acceptable deformity in growing children are still not well defined in the literature.

Advanced imaging techniques have improved our understanding of these fractures, and may play an increasing role in the use of computer-aided reduction techniques and other forms of minimally invasive surgery. CT scanning requires ionizing radiation, but provides high resolution model reconstruction. Future MRI modalities may allow for higher-quality images, including three-dimensional reconstructions; this would avoid the need for ionizing radiation. In addition, recent studies utilizing advanced imaging have cast doubt on the commonly accepted principle that the physis is always weaker than ankle ligaments. It appears that ankle sprain injuries are more common than previously believed, and are often misdiagnosed as Salter I fractures of the distal fibula.

The use of cultured chondrocytes and gene therapy may eventually play a role in the treatment of these fractures, either to prevent or treat a physeal arrest.[106] The surgical treatment of physeal bars to restore normal growth remains unsuccessful in a substantial percentage of cases, and further understanding of the basic mechanisms controlling physeal growth may help us develop more successful strategies.

ACKNOWLEDGMENTS

The authors and editors wish to acknowledge Drs. Luciano Dias and Jay Cummings, for the past contributions to this chapter.

33 FRACTURES AND DISLOCATIONS OF THE FOOT

Haemish Crawford

Introduction to Fractures and Dislocations of the Foot

Trauma to the pediatric foot was traditionally treated nonoperatively by orthopedic surgeons.[16,141] The dogma existed that the bones of the foot were predominantly cartilaginous and would remodel as the child matures. Few, if any, long-term studies exist to measure the outcomes of these treatments.

Children are now involved in sports and activities of greater physical intensity that lead to more complex fractures and dislocations.[4,40,44,136] It is not uncommon for young children to be competing in motocross, extreme skiing, and rock climbing.[4,164] Professional sport has brought about more intense training and greater expectations from the child, the parent, and the coach. Injuries need to be treated "quicker" and rehabilitation time decreased to allow early return to the sport. These expectations should not get in the way of treating the child's foot injury in the best possible way.

As the child grows into a young adult, the largely cartilaginous foot becomes ossified and fracture and dislocation patterns change. Ogden[124] showed that the cartilaginous bones were elastic and absorbed the energy from the trauma and dissipated it differently from the adult foot. This resulted in different fracture patterns.[124] The management algorithms for the adolescent foot are therefore quite different from the infant's foot; however, the exact age at which this occurs needs to be individualized for each patient. The amount of fracture angulation and joint line displacement to accept is one of the real challenges in treating the skeletally immature foot. Some complex fractures of the talus and calcaneus in adolescents are in fact best internally fixed according to the principles used to treat adult trauma.

An in-depth knowledge of the anatomy of the growing foot is helpful as the variable ossification centers, apophyses, and physes make fracture recognition difficult. Most of the papers quoted in this chapter are level IV (uncontrolled case series) or level V (expert consensus). One of the problems with pediatric foot and ankle research is that long follow-up intervals are necessary to validate treatments. There are no pediatric outcome scores for children's foot trauma, so prediction of outcome is dependent on orthopedic first principles of anatomic reduction, union, and effective rehabilitation. Long-term retrospective studies also have the difficulty of locating children treated decades earlier and, therefore, the follow-up rate is low.

Anatomy of the Growing Foot

The child's foot is different from the adult foot in that the bones are largely cartilaginous until adolescence. Although the mechanisms of injury are similar, the resulting fracture is usually less severe in the child as the energy of the injury is dissipated by the elasticity of the cartilage. The cartilage also makes interpretation of imaging more difficult and fractures may not be appreciated on plain radiograph. Computed tomography (CT) and magnetic resonance imaging (MRI) scans assist in clarification of anatomy and identification of fractures. The remodeling potential of cartilage allows some displacement and angulation of fractures to be accepted in children, whereas in adults it may be unacceptable.

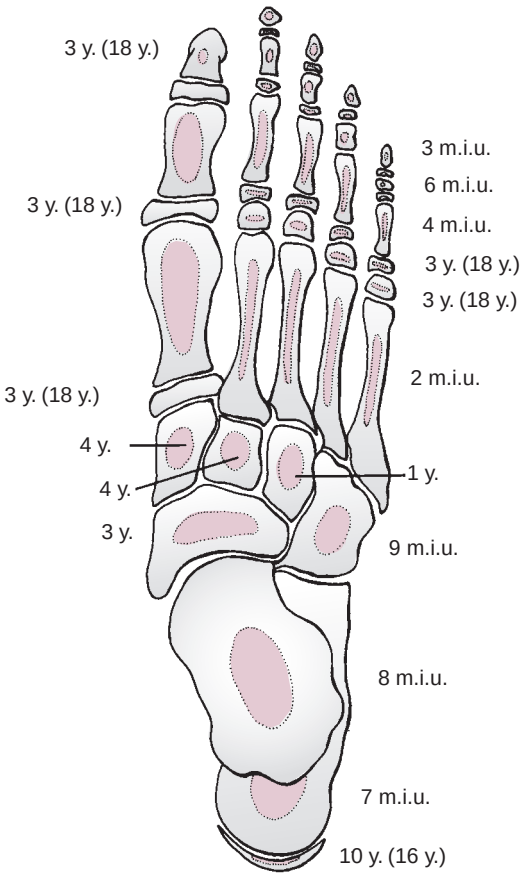

FIGURE 33-1 Appearance and fusion times of foot ossification centers, with figures in parentheses indicating the time of fusion of the primary and secondary ossification centers (y., years; m.i.u., months in utero). (From Aitken JT, Joseph J, Causey G, et al. *A Manual of Human Anatomy*. 2nd ed. London: E & S Livingstone;1966:80, with permission).

Secondary areas of ossification, accessory bones, and growth plates also make fracture recognition more difficult. The appearance of the ossification centers are summarized in Figure 33-1.[5] The calcaneus and talus are usually ossified at birth and the cuboid ossification center usually becomes evident shortly after.[157] The navicular does not develop its primary ossification center until the child is around 3 years of age. Figure 33-2 shows the accessory ossicles and sesamoid bones in the foot which can also be confused with fractures especially if they are bipartite or if the accessory bones are closely adhered. It is useful clinically to radiograph the opposite foot if any doubt exists as to what may be normal or pathologic.

History and Examination of Fractures and Dislocations of the Foot

The history is not always accurate in childhood trauma; however, every attempt should be made to ascertain the mechanism of injury. Often, other children or adults who witnessed the accident can give a more accurate account than the patient. The degree of force, the speed and height of the fall, and the way

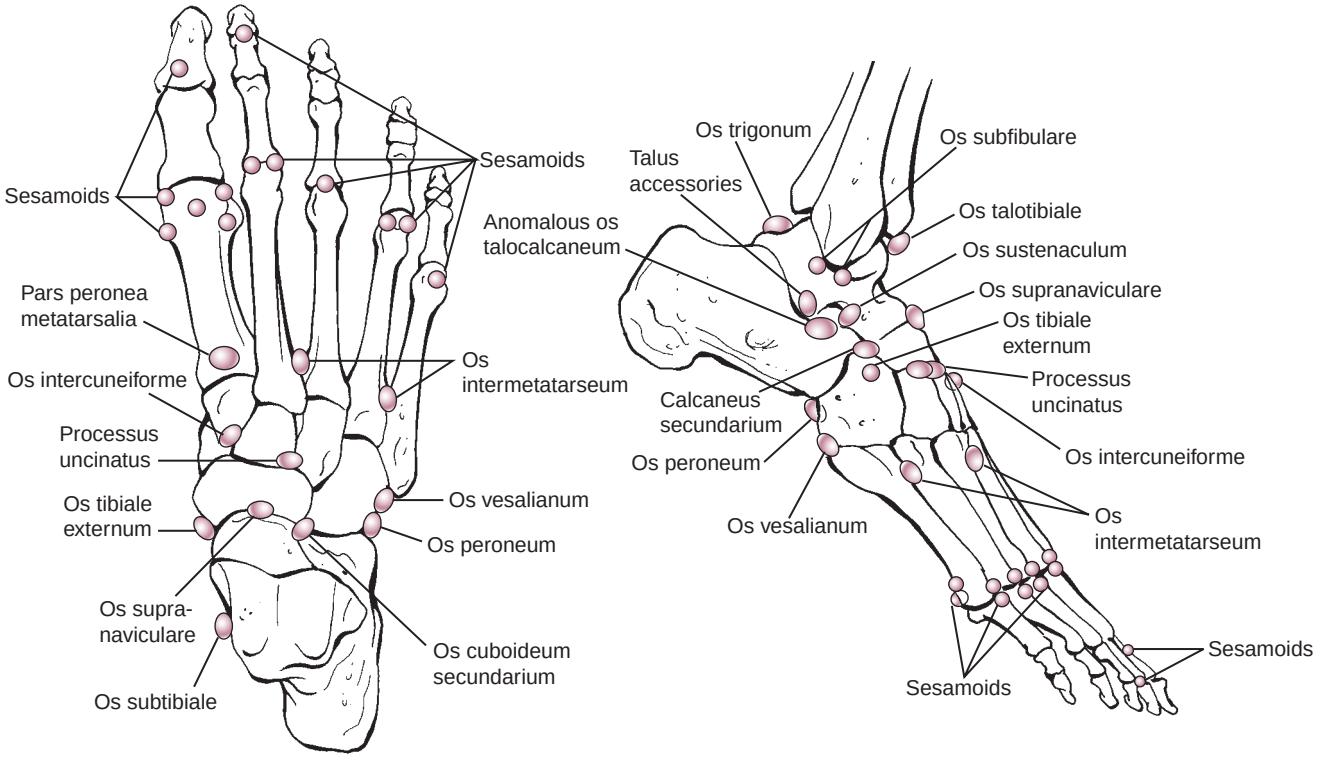

FIGURE 33-2 Diagrammatic representation of accessory ossicles and sesamoid bones about the foot and ankle. Note that the sesamoid bones can be bipartite and that accessory ossicles can be multicentric. (From Traughber PD. Imaging of the foot and ankle. In Coughlin MJ, Mann RA. *Surgery of the Foot and Ankle*. 7th ed. St. Louis, MO: Mosby, 1999.)

the foot is twisted all help predict the degree of displacement or severity of the injury. In more subtle injuries, the ability to weight bear, degree of instability, and the location of the pain are vital parts of the history.

Careful examination of the foot will guide the surgeon to the site of injury. The child often complains of the whole foot "hurting"; however, systematic palpation helps localize the most painful site. Appropriate radiographs can then be taken. Bruising and swelling will also help predict the injury pattern. Isolated bruising on the sole of the midfoot often overlies a subtle Lisfranc injury whereas excessive dorsal swelling may predict a more severe fracture-dislocation.[145] In a soft tissue injury such as a crush injury, the possibility of increased compartment pressures should be considered.

Multiple trauma must also be ruled out. A complete secondary survey should be undertaken to exclude other injuries. For example, bilateral calcaneus fractures following a fall may be associated with a tibial fracture or spinal column injury.

Talar Fractures

Management of Talar Fractures

Fractures of the talus are very rare in children and adolescents.[37,124] Talus fractures most commonly occur through the neck and occasionally the body. Although rare, talus fractures are important to recognize because of the possible complication of avascular necrosis (AVN). This can occur because of the precarious blood supply and fracture patterns. In children, AVN seems more prevalent in innocuous fractures when compared to adults with similar injuries.[140] The majority of talus fractures in children can be treated with cast immobilization whereas displaced fractures in adolescents need to be treated operatively similar to an adult fracture.

Mechanism of Injury

A fall from a height is the predominant mechanism of injury causing talar fractures.[79,98,111] The foot is forcibly dorsiflexed and the neck of the talus impinges against the anterior lip of the distal tibia. This shear force usually results in a vertical or slightly oblique fracture line at the junction of the body and neck of the talus. When the dorsiflexion is combined with supination of the foot, the impingement occurs more medially and the medial malleolus may be fractured as well. With displaced fractures, the subtalar joint may become subluxed. The force required to fracture a child's talus is almost twice that required to fracture the other ankle and tarsal bones.[131] One must be thorough in looking for other injuries that may coexist as a result of the severe trauma. The talus can also be fractured with crushing injuries, and open fractures are well described in lawnmower accidents.[124] Fractures of the lateral process of the talus have been described recently in snowboarding accidents

where the mechanism appears to be forced dorsiflexion and inversion of the ankle.[95]

Signs and Symptoms of Talar Fractures

The history of forced dorsiflexion of the ankle especially associated with a fall from a height should lead to a suspicion of a talus fracture. The same mechanism of injury can cause other foot fractures and dislocations as well. The ankle and foot are extremely swollen and the foot is usually held plantarflexed. Because of this soft tissue swelling, the foot needs to be examined closely for increased compartment pressure. As with all fractures, the soft tissues need to be inspected for any puncture wounds, abrasions, or fracture blisters as these are important in determining the management of the patient.

In these patients, there may be less swelling so careful palpation around the talus is needed to detect the source of the pain. Once the foot has been clinically assessed, the appropriate radiographic investigations can be performed.

Associated Injuries with Talar Fractures

Because of the level of force that is often required to fracture a talus, other injuries often coexist.[131] A number of studies have found fractures of the calcaneus, malleoli, tibia, and lumbar spine in the presence of a talus fracture.[20,26,65,127,128] Hawkins,[65] in his study, on adult talus fractures found 64% of the patients had an associated musculoskeletal injury.

Imaging Evaluation of Talar Fractures

The routine radiographs for a fractured talus include an anteroposterior (AP), lateral, and oblique views. Canale and Kelly[26] have described a pronated oblique view of the talus which may demonstrate the fracture more clearly. The fractures are not always easy to see in young children, as the talus is largely cartilaginous until the second decade.[111] The cartilage anlage often leads to an underestimation of fracture displacement. Some authors have even suggested the use of MRI to show the morphology better in children less than 10 years old.[124,173]

Once the fracture is identified, a CT scan is useful in assessing the fracture plane, comminution, degree of displacement, and any other associated foot or ankle fractures. This is particularly useful preoperatively when pain prohibits the full range of radiographs mentioned above to be taken. If an open reduction is planned, the CT scan will also aid in the preoperative planning of the size and placement of the screws. Hawkins[65] described an x-ray classification to define the different types of fractures of the talar neck and used it to predict the risk of AVN (Fig. 33-3):

Type I fracture: Undisplaced talar neck fracture

Type II fracture: Displaced talar neck fracture with subtalar subluxation or dislocation

Type III fracture: Displaced fracture of the talar neck with dislocation of both the subtalar and ankle joints

Hawkins[65] also described a subchondral lucent line, the "Hawkins sign," that indicates normal blood flow to the talar

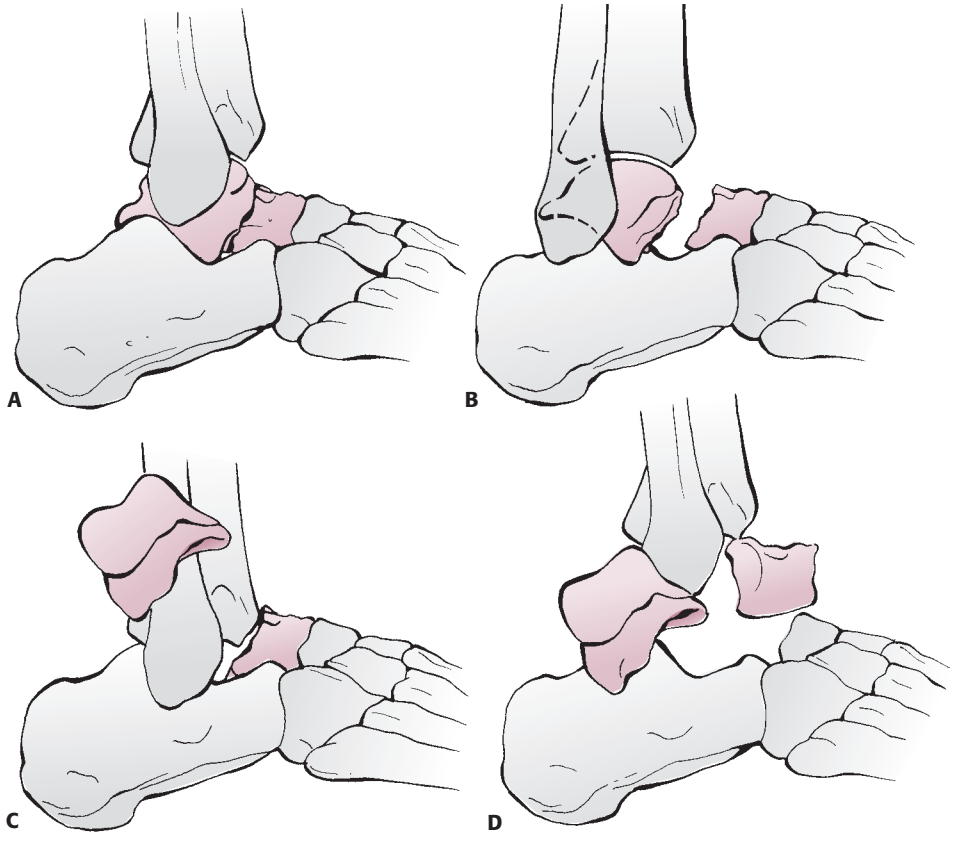

FIGURE 33-3 Hawkins classification of talar neck fractures (see text for details). **A:** Type I, nondisplaced fracture of the talar neck. **B:** Type II, displaced talar neck fracture with subluxation or dislocation of the subtalar joint. **C:** Type III, displaced talar neck fracture with associated dislocation of the talar body from both the subtalar and tibiotalar joints. **D:** Type IV, as suggested by Canale and Kelly, displaced talar neck fracture with an associated dislocation of the talar body from subtalar and tibiotalar joints and dislocation of the head and neck fragment from the talonavicular joint. (From Canale ST, Kelly FB Jr. Fractures of the neck of the talus: Long-term evaluation of seventy-one cases. *J Bone Joint Surg Am.* 1978;60:143–156.)

body. The absence of this lucency may indicate the development of osteonecrosis (see complications of talar fractures).

Diagnosis and Classification of Talar Fractures

Fractures of the talus can be classified as occurring either in the body or the neck. Some authors suggest classifying talar fractures based on the age of the patient as children less than 6 years of age generally have a better prognosis.[111]

Fractures of the Talar Neck

The majority of talar fractures in children are of the talar neck. Hawkins[65] has classified these into three different types depending on whether the fracture is displaced and the degree of subluxation of the subtalar and ankle joints (Fig. 33-3). This classification was developed so it could be used to predict if the talus would become avascular because of the disruption of the tenuous blood supply. Canale and Kelly[26] later modified the classification (Fig. 33-3) to include a type IV injury in which there is subluxation or dislocation of the ankle, subtalar, and talonavicular joints. In the adult literature, the majority of talar fractures are type II and III.[26,65] This classification of talus fractures can help predict the type of treatment required and the outcome one can expect (Table 33-1).

Treatment of Talar Neck Fractures

The treatment of talar fractures is based on the severity of the fracture and the age of the child. The Hawkins classification system is useful in directing the treatment. In a child less than 8 years of age, a less than perfect reduction of the fracture can be accepted because of the remodeling potential.[79,98,111] Adolescent fractures should be treated the same way as an adult injury.

Hawkins Type I Fractures

Undisplaced fractures of the talar neck can be treated for 6 to 8 weeks non–weight-bearing in a below-knee cast. The child can then start taking full weight if the fracture has healed radiographically. Canale and Kelly[26] accepted 5 mm of displacement and 5 degrees of angulation of the talar neck in their series.

Hawkins Type II Fractures

A displaced or severely angulated talar neck fracture usually presents with significant soft tissue swelling and pain. This makes management more difficult than type I injuries. Achieving adequate radiographs to assess the degree of displacement is difficult without sedation. The distal fragment of the neck is usually displaced dorsally and medially.

The fracture and subluxation of the subtalar joint should be reduced under general anesthesia, most often by gentle plantarflexion and pronation of the foot. If a stable reduction is achieved, a well-molded below-knee cast can be applied with the foot in plantarflexion. This initial cast is changed to a more neutral position at 4 weeks and then removed 8 weeks following fracture reduction. Postoperative serial radiographs or a CT scan should be performed as the fracture position may be lost when the soft tissue swelling subsides. If the fracture is unstable after reduction, percutaneous Kirschner wire (K-wire) fixation is useful to hold the fracture. Two K-wires can be passed through a small dorsomedial incision and across the fracture. The incision should be on the medial side of extensor hallucis longus to avoid damage to the tibial vessels. Although the amount of residual displacement or angulation acceptable is not clearly defined, it may be better to accept a few millimeters of offset and up to 10 degrees of angulation rather than perform an open reduction and risk devascularizing the talus further.

Hawkins Type III Fractures

These fractures are a result of a serious injury and require urgent surgery to openly reduce and internally fix the talus.

TABLE 33-1 Hawkins Classification of Talar Neck Fractures

Type	Description	Treatment	Affect on Blood Supply[a]	Osteonecrosis Rate
Type I	Stable, undisplaced vertical fracture through talar neck.	8 weeks in cast, 4 weeks in CAM cast.	Theoretical damage to only one vessel entering talar neck.	0–10%
Type II	Displaced fracture with subtalar joint subluxation or dislocation; normal ankle joint.	Immediate closed reduction.[b] A near anatomic reduction delays surgical treatment.	Two of three blood supply vessels lost: Neck vessel and one entering the tarsal canal.	20–50%
Type III	Same as type II but with subluxation or dislocation of both the ankle and subtalar joint.	Direct to operating room for combined anteromedial and anterolateral surgical approach (see text).	All three sources of blood affected.	80–100%
Type IV	Very rare; basically a type III with talonavicular joint displacement.	Same as type III.	Not related to blood supply.	100%

CAM, controlled active motion.

[a]See text for further details of blood supply to the talus.

[b]Reduction maneuver: Maximal plantarflexion and foot traction to realign head and body in sagittal plane. Varus/valgus with or without supination/pronation stress realigns neck in coronal plane.

Surgical Approaches

There are three surgical approaches to the fractured talus:

1. Posterolateral
2. Anteromedial
3. Anterolateral

The decision on the approach depends on the condition of the soft tissues and the familiarity of the approach by the surgeon. Occasionally, more than one approach is required if adequate reduction cannot be achieved. It is preferable to use the posterolateral approach as this causes less potential disruption to the blood supply; however, direct visualization of the talar neck is not possible. The timing of the open reduction of these fractures is somewhat controversial. With such a tenuous blood supply, one would think that urgent reduction and internal fixation is indicated. Lindvall et al.[102] compared the results of surgery within 6 hours to delayed surgery in 26 fractures of the talus in adult patients and found no significant difference in outcome. Kellam et al.,[84] in another similar study, concluded that the severity of the injury, the quality of the reduction, and the surgical outcomes had a bigger influence on long-term outcome than if the surgery was fixed emergently or delayed (greater than 12 hours).

Posterolateral Approach. This approach is commonly used to internally fix fractures of the talar neck once it has been reduced. The patient is positioned supine so the other approaches can be utilized if necessary. The incision is made just lateral to the Achilles tendon. Blunt dissection is then carried out down to the joint capsule avoiding damage to the sural nerve. The posterior joint capsule can then be opened if not already torn by the injury and the posterior process of the talus can be identified. If possible, two partially threaded cannulated 4.5- or 6.5-mm screws can be used to provide compression across the fracture. It is preferable to use titanium screws which are MRI compatible to allow investigation of AVN during fracture healing if necessary. If only one screw is used, a separate K-wire should also be passed across the fracture for rotational stability. These posterior screws are more stable biomechanically than anterior screws (Fig. 33-4).[166]

Anteromedial Approach. This approach is useful to visualize the talar neck and directly reduce the fracture. Often, there is comminution of the medial wall of the neck which makes restoring length difficult. With the patient supine, the incision is made from just anterior to the medial malleolus and directly distally down the midfoot. Deeper dissection is carried out medial to the tibialis anterior and the extensor hallucis longus tendons. The dissection down to the capsule is in the interval between the tibialis anterior and tibialis posterior tendons. This approach avoids damage to the deltoid branch of the posterior tibial artery and the medial branches of the anterior tibial artery. This approach is potentially less harmful to the blood supply of the talus when compared to the anterolateral approach.[3]

Anterolateral Approach. One advantage of this approach is that it permits excellent exposure of the lateral talar neck which is not usually comminuted allowing anatomic reduction.

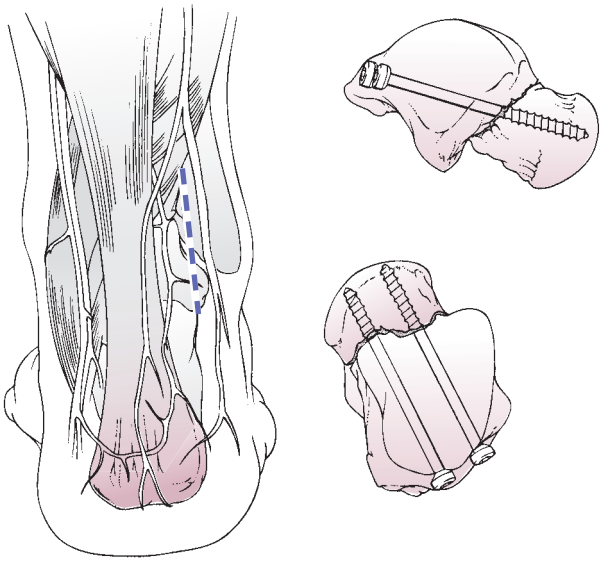

FIGURE 33-4 Posterolateral approach to the talus. Incision is based lateral to the Achilles tendon. The Achilles tendon and flexor hallucis longus are reflected medially. The posterolateral talar tubercle is the starting point for the guide pin. **Right:** Screws are directed in line with the long axis of the neck of the talus in a plantar-medial direction such that the distal threads of the screw are all in the distal fragment (talar head), beyond the fracture line to allow for compression. Combinations of two screws or one screw and one smooth pin are determined by size and anatomy. (From Adelaar RS. Complex fractures of the talus. *Instr Course Lect.* 1997;46:328, with permission.)

The approach also gives good access to the subtalar joint. The disadvantage to this approach is that it may disrupt the blood supply more than the other approaches. The incision starts at the tip of the lateral malleolus and extends to the base of the fourth metatarsal. Care must be taken to avoid damaging the sural nerve with deeper dissection. In the base of the incision is the artery of the sinus tarsi which should be visualized if possible.

Following open reduction and internal fixation of talar neck fractures, the foot is placed in a non–weight-bearing below-knee cast for 6 to 8 weeks. Radiographs are then taken to assess fracture healing and the presence or absence of the Hawkins sign. If the subchondral lucent line is present, one can assume there is adequate blood supply to the body of the talus and osteonecrosis is unlikely to occur. If the fracture has also healed, the child can start progressive weight bearing as tolerated. The absence of a subchondral lucency during healing should alert the surgeon to the possible development of osteonecrosis (Fig. 33-5). The patient should continue to be non–weight-bearing until the lucency is present. If it is still not present 3 months postinjury, an MRI scan should be performed which will assess the vascularity more accurately.[67] The use of titanium screws in the open reduction makes this possible. The decision on the amount of weight bearing in the presence of altered blood supply to the talus is not clear. AVN of the talus often takes 18 months to 2 years to revascularize so it would be impractical, if not impossible, to keep a child non–weight-bearing for this period in the hope it will prevent premature collapse of the body.

FIGURE 33-5 A 14-year-old girl with a talar neck fracture and a positive Hawkins sign. Disuse osteoporosis leads to halo-like image of the talus on the AP view denoting adequate talar dome vascularization; if there had been no blood supply, there would be no blood flow to loose calcium. If this happens, the dome of the talus would become denser and more radio-opaque than the surrounding bones that are undergoing diffuse osteoporosis.

Surgical and Applied Anatomy of Talar Neck Fractures

The talus is comprised of three parts: A body, neck, and head. Ossification starts from one center that appears in the sixth intrauterine month. The talus ossification process starts in the head and neck and proceeds in a retrograde direction toward the subchondral bone of the body. Approximately two-thirds of the talar body is articular cartilage with just a small area of bare bone on the neck where the bone receives its nutrient blood supply. There are no tendon insertions into the talus. The stability is provided by the capsular and ligamentous attachments to the surrounding bones.

The superior articular surface of the talus is wider anteriorly than it is posteriorly. Traditional teaching suggests the foot should generally be immobilized in neutral dorsiflexion so this widest part of the talus is engaged in the ankle mortise to help prevent an equinus contracture. This is of less importance in younger children who are less likely to develop equinus contractures. The lateral wall of the superior articular surface curves posteriorly whereas the medial wall is straight. The two walls converge posteriorly to form the posterior tubercle of the talus. Often, there is a separate ossification centre (os trigonum) that appears here on radiographs at 11 to 13 years of age in boys and 8 to 10 years of age in girls. It usually fuses to the talus 1 year after it appears (Fig. 33-6).[113]

The short neck of the talus is medially deviated approximately 10 to 44 degrees and plantarflexed between 5 and 50 degrees in relation to the axis of the body.[56] Beneath the talar neck is the tarsal canal, a funnel-shaped area that contains the anastomotic ring formed between the artery of the tarsal canal

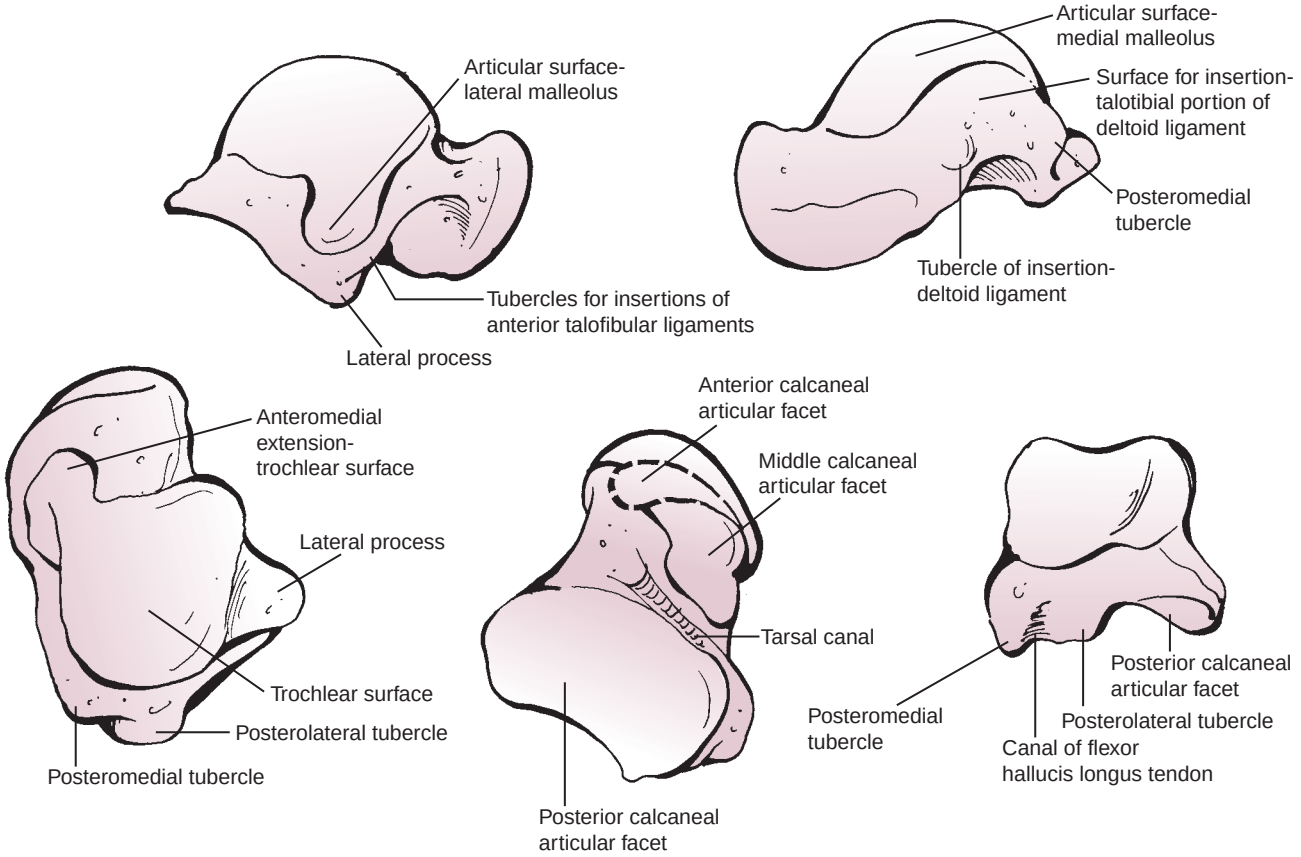

FIGURE 33-6 Anatomic details of the talus are important when correlating high-definition imaging, such as CT scans, with normal anatomy for the purposes of fracture management decision making.

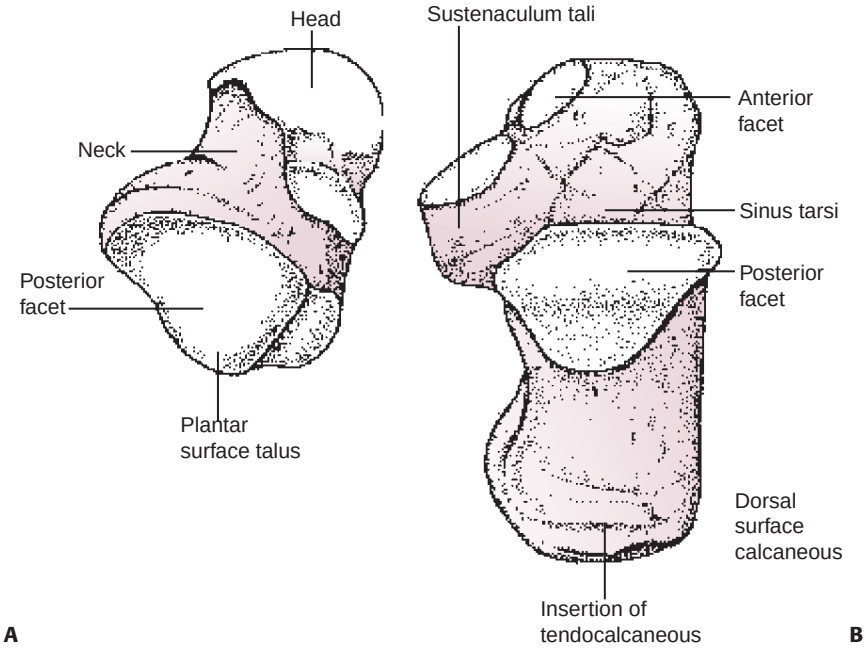

FIGURE 33-7 Subtalar joint opened such that the medial borders of the joint face each other. **A:** Plantar surface of the talus, which articulates with the dorsal surface of the calcaneus. Note the extensive area of the talus that is articular cartilage. **B:** Dorsal surface of the calcaneus with the articular facets occupying the anterior half of the calcaneus. (From Sammarco GJ. Anatomy. In: Helal B, Rowley D, Cracchiolo AC, et al, eds. *Surgery of Disorders of the Foot and Ankle.* Philadelphia, PA: Lippincott-Raven, 1996.)

and the artery of the tarsal sinus.[118] The broad interosseous ligament joining the calcaneus and talus is also within the canal.

The tarsal canal is conical in shape and runs from posteromedial (apex) to anterolateral where the base of the cone is known as the sinus tarsi (Fig. 33-7).

The lateral process of the talus is a large wedge-shaped process that is covered in articular cartilage. It articulates with the fibular superiorly and laterally and with the subtalar joint inferiorly. The lateral talocalcaneal ligament is attached to the most distal part of the process.[64,66]

The head of the talus is entirely cartilaginous, convex, and articulates with the concave surface of the navicular. The undersurface of the talus is comprised of three articulating surfaces for the calcaneus: The posterior, middle, and anterior facet. Between the posterior and middle facets is a transverse groove which forms the roof of the tarsal canal.

Blood Supply

The blood supply of the talus has been extensively studied.[9,62,118] The nutrient arteries are derived from the three major vessels that cross the ankle joint: Posterior tibial artery, tibialis anterior artery, and peroneal artery (Fig. 33-8). Branches of these three vessels perforate circumferentially the short talar neck which is the only part of the talus denude of articular cartilage. A fracture in this area can disrupt this intricate anastomosis of vessels and lead to AVN of the body of the talus.

The main blood supply to the talus is through the artery of the tarsal canal. This artery branches off the posterior tibial artery approximately 1 cm proximal to the origin of the medial and lateral plantar arteries. It passes between flexor digitorum longus and flexor hallucis longus before entering the tarsal canal where it anastomoses with the artery of the tarsal sinus. Before entering the canal, the artery of the tarsal canal gives off a deltoid branch that penetrates the deltoid ligament and supplies the medial third of the talar body.[57] A dorsal vessel of the deltoid branch anastomoses with the medial branch of the dorsalis pedis artery to enter the talar neck.

The second source of blood supply is from the anterior tibial artery and its terminal extension, the dorsalis pedis artery. Multiple vessels from these arteries penetrate the dorsal neck of the talus. The third source of blood supply is from the peroneal artery. Small branches supply the posterior process of the talus and a larger branch forms the artery of the sinus tarsi to supply the lateral aspect of the talus.

Within the capsular and ligamentous attachments to the talus there are small vessels that also contribute to the blood supply.[130]

Fractures of the Talar Body and Dome

Fractures of the talar body are less common than of the neck. In 1977, Sneppen et al.[163] described a classification system based on the anatomic position of the fracture in the talus. This was later modified by DeLee[42] and the result is a five-part classification.

Fractures of the talar body are rare in adults and children (Table 33-2). In a long-term follow-up of 14 talus fractures in children Jensen et al.[79] found only four (29%) were fractures through the body. Undisplaced fractures can be treated in a

TABLE 33-2 Sneppen Classification System of Talar Body Fractures

Sneppen Grade	Fracture Type
1	Transchondral/osteochondral
2	Coronal, sagittal, or horizontal shear
3	Posterior tubercle
4	Lateral process
5	Crush fracture

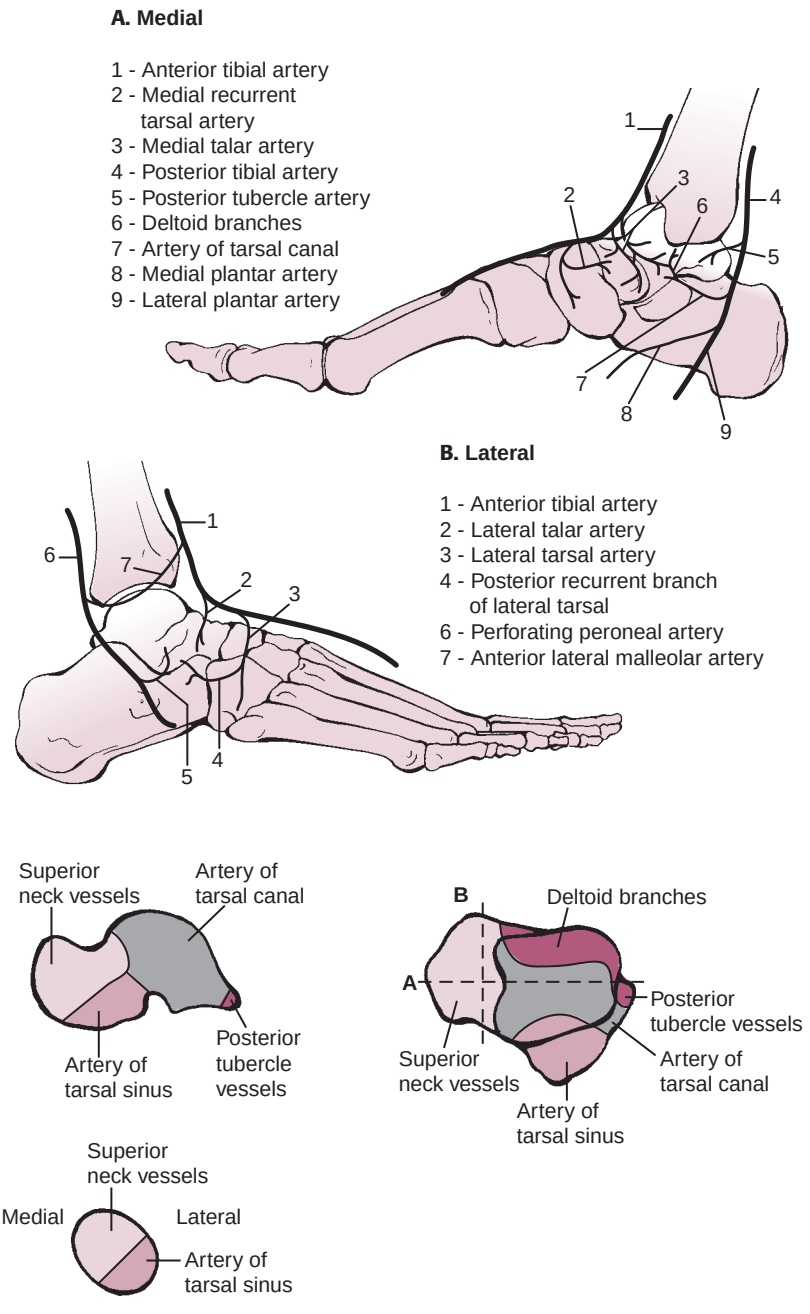

FIGURE 33-8 Arterial blood supply to the talus. Medial blood supply **(A)** and lateral blood supply **(B).** Dorsal view with sagittal cut through length (*a*) of talus and transverse cut through neck of talus (*b*). (From Gelberman RH, Mortensen WW. The arterial anatomy of the talus. *Foot Ankle.* 1983;4:64–72.)

non–weight-bearing below-knee cast for 6 to 8 weeks until the fracture is healed and the outcome is excellent. Undisplaced intra-articular fractures can be treated in the same way; however, serial radiographs must be taken to confirm displacement does not occur. Anatomic reduction of displaced fractures has been recommended because residual displacement of the articular surfaces leads to degenerative osteoarthritis.[97]

Fractures of the Lateral Process of the Talar Body

Fractures of the lateral process of the talus are rare in adults and children, and a high level of suspicion is required if the diagnosis is to be made. The lateral process is a wedge-shaped prominence that forms almost the whole lateral wall of the talus. It is covered entirely in articular cartilage and is the articulating surface of the talus with the fibular. The talocalcaneal ligament inserts into the tip of the lateral process. The mechanism of injury is a forced dorsiflexion injury with inversion of the foot.[64] The talocalcaneal ligament may avulse the lateral process.

Isolated fractures of the lateral process of the talus are often not recognized on the initial radiographs.[64,66,112] Leibner et al.[95] suggested that this may occur in 46% of the cases. The lateral process is best visualized on the mortise view so the fibula is not overlying it. On the lateral radiograph, the lateral process is seen just superior to the angle of Gissane.[66] This is the angle between a line drawn along the lateral border of posterior facet

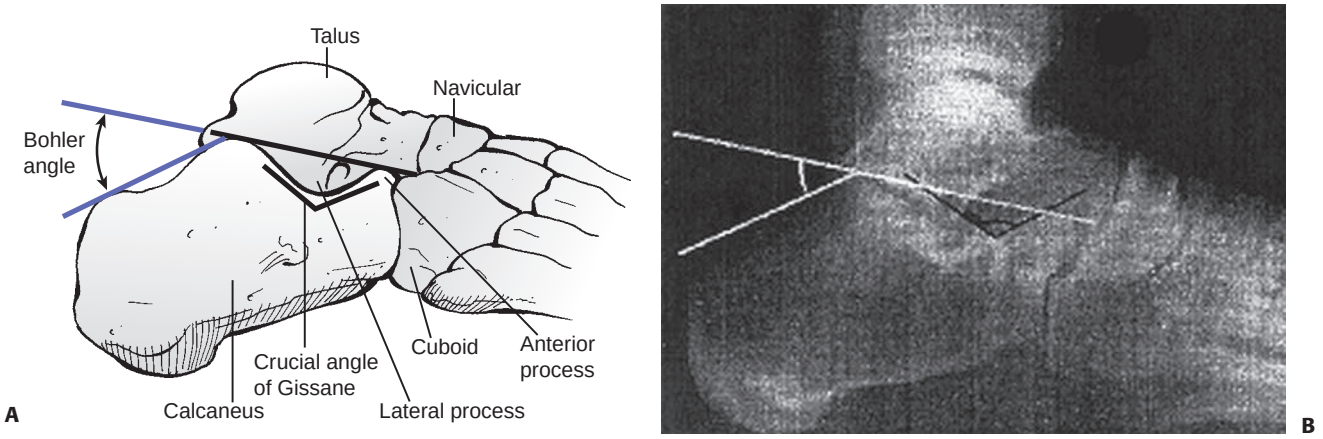

FIGURE 33-9 Diagrammatic depictions of the crucial angle of Gissane **(A)** and the Bohler angle **(B).** The Bohler angle is more frequently used for decision making regarding fracture management. For measuring the Bohler angle, the landmarks on the lateral radiograph of the calcaneus are the anterior and posterior facets and the superior margin of the calcaneal tuberosity.

and a line drawn along the anterior process (Fig. 33-9). If there is persistent pain laterally around the ankle following an inversion ankle injury, one should have a high suspicion for a lateral process fracture or an osteochondral injury. If not clearly seen on the plain films, a CT scan should be performed to assess the talus and rule out any other coexisting fractures.[87,123]

The incidence of this rare injury is increasing because of the increased popularity of snowboarding.[87,95,122] Kirkpatrick et al.[87] reviewed 3,213 snowboarding injuries and found an unusually high incidence of lateral process fractures. They comprised 34% of all ankle fractures.[87]

The treatment of nondisplaced fractures of the lateral process is with a non–weight-bearing cast for 6 to 8 weeks. Displaced fractures are best treated with open reduction and internal fixation; however, the degree of displacement that is acceptable in a child is not clearly defined. What may be more important is the congruity of the joint surface of the talus. A step or gap in the articular surface of more than 2 to 3 mm may be useful criteria as to when to open reduce the fracture. The fracture can be held with one 3.5-mm partially threaded cancellous screw inserted from lateral to medial perpendicular to the fracture line. A below-knee cast is then worn for 6 weeks.[64,66,95,172]

Fractures of the Osteochondral Surface of the Talus

Damage to the osteochondral surface of the talus can be caused by direct trauma or may be caused by an underlying osteochondral lesion (osteochondritis dissecans [OCD]) that may have been present for some time and has been made symptomatic by the injury. The pathogenesis and etiology of OCD are controversial; however, most authors report preceding trauma as a cause of the defects (Canale and Bedding[25] 80%, Letts et al.[97] 79%, Higuera et al.[69] 63%, and Perumal et al.[129] 47%). The medial lesion is usually deeper and cup-shaped compared to the thinner "wafer" type lateral lesion. The lateral lesion is more often associated with trauma and more symptomatic than the medial lesions. It is postulated that the medial lesions may be because of more repetitive microtrauma.[25,26] Berndt and Harty,[12] in 1959, used freshly amputated legs to biomechanically reproduce injuries to the ankle and observe the injuries inflicted. They showed that the anterolateral talus hits the medial aspect of the fibula with dorsiflexion and inversion and that plantarflexion and inversion caused posteromedial osteochondral lesions (Fig. 33-10).

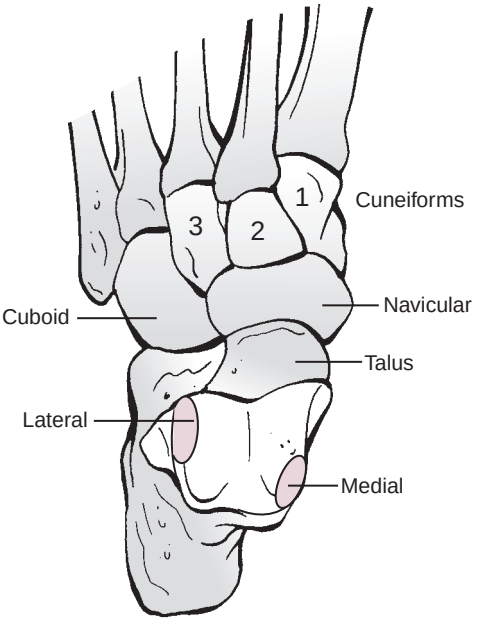

FIGURE 33-10 Typical positions of osteochondral lesions of the talus. Berndt and Harty[12] found that of 201 osteochondral lesions in adults 56% were on the medial side and 44% on the lateral side. Letts et al. found medial lesions in 79% of 24 children, lateral lesions in 21%, and central lesions in 1%. (From Letts M, Davidson D, Ahmer A. Osteochondritis dissecans of the talus in children. *J Pediatr Orthop.* 2003;23:617–625, with permission.)

The initial radiographs following an ankle injury in a child should be closely assessed for an osteochondral injury. If pain and swelling persist for over 2 months after an "ankle sprain," then further investigations should be carried out to look for an osteochondral lesion. This will initially be a further radiograph series; however, an MRI scan is often more useful at this stage to look for an osteochondral lesion as a small percentage are purely cartilaginous. Some consider an MRI arthrogram useful in further determining whether the fragment is detached or not as occasionally the arthrographic contrast can be seen deep to the osteochondral lesion. The bone scan has largely been superseded by the MRI scan in the diagnosis and assessment of these lesions. The bone scan is useful, however, when it is not clear if the pain in the child's ankle is coming from the osteochondral lesion or some other pathology. A normal bone scan in the presence of a stage I or II osteochondral lesion may indicate a soft tissue lesion as being a source of the pain.

Mechanical symptoms of locking and catching are not as common as one would think but can occur with these lesions if the loose fragment becomes trapped within the joint. The pain seems to be related to the synovitis and effusion that develops secondary to the uneven articular surface. On examination, the ankle is slightly swollen and can be painful on passive movement as the loose fragment passes under the tibia. With plantarflexion of the foot, the anterolateral talus can be palpated directly and a lesion here can be painful on direct pressure.

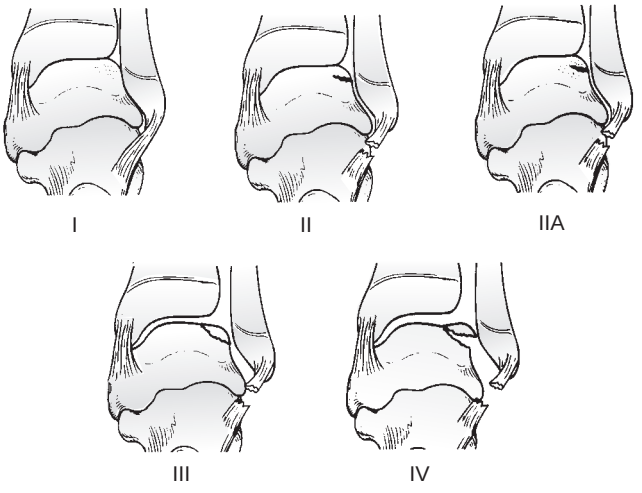

FIGURE 33-11 Adaptation of the Berndt and Harty[12] (1959) classification of osteochondral injuries of the talus by Anderson et al.[8] Stage I is identified only by MRI scanning, which demonstrates trabecular compression of subchondral bone; stage II lesions have incomplete separation of the osteochondral fragment from the talus. If a subchondral cyst also is present, the lesion is designated stage IIa. Stage III lesions occur when the fragment is no longer attached to the talus but is undisplaced. Stage IV indicates both complete detachment and displacement. (From Alexander IF, Chrichton KI, Grattan-Smith Y, et al. Osteochondral fractures of the dome of the talus. *J Bone Joint Surg Am.* 1989;71:1143, with permission.)

Classification of Osteochondral Fractures

Berndt and Harty[12] classified osteochondral fractures of the talar dome into four stages based on radiographic criteria (Fig. 33-11):

Stage I: Subchondral trabecular compression fracture (not seen radiographically)

Stage II: Incomplete separation of an osteochondral fragment

Stage III: The osteochondral fragment is unattached but undisplaced

Stage IV: A displaced osteochondral fragment

Anderson et al.[8] modified this classification after correlating clinical findings with radiographs and MRI scans. They described the stage I lesion as not visible on plain radiographs but visible on an MRI scan. They also introduced a stage IIa lesion, which is an undisplaced osteochondral lesion with a subchondral cyst adjacent to the floor of the lesion. Anderson et al.[8] felt a stage IIa lesion should be treated surgically whereas a stage II lesion can initially be treated nonoperatively (Fig. 33-12).

A further classification was proposed by Pritsch et al.[135] in 1986 based on the arthroscopic appearance of the articular cartilage at the time of surgery. The quality of the articular cartilage was placed into one of three grades:

Grade I: Intact, firm, and shiny articular cartilage

Grade II: Intact but soft articular cartilage

Grade III: Frayed articular cartilage

They used this classification to determine which lesions should be treated with activity modification (grade I), who should have arthroscopic drilling (grade II), and finally which patients require arthroscopic curettage and microfracture (grade III).

Treatment of Osteochondral Fractures

The treatment of osteochondral lesions of the talus in children is challenging. Only a few papers purely address this condition in children,[69,97,129] and the rest of the literature is a combination of adult and childhood lesions. It is important

FIGURE 33-12 This CT scan clearly shows a well-circumscribed cyst at the base of a stage II osteochondral lesion. This would be classified by Anderson et al.[8] as a stage IIa lesion.

to distinguish between an acute osteochondral fracture and a chronic osteochondral lesion as the two may require different treatment strategies.

To enable thorough assessment, these patients need to be followed up for a minimum of 2 years as it takes this long for the lesion to become radiographically healed despite the child often being clinically normal.[129]

Nonoperative Management

Most authors agree that the primary treatment of stage I and stage II lesions is nonoperative.[12,69,97,129] The symptomatic patient can be immobilized for 6 weeks in a below-knee walking cast or a Cam walker (Fig. 33-13). This usually relieves the acute symptoms; over the next 6 weeks, the patient has activity modification maintaining a pain-free range of movement. This allows the fracture to heal before returning to active sport. Higuera et al.[69] treated their stage III lesions nonoperatively as well and all seven patients had good outcomes.

Surgical Treatment

The outcomes of surgery for osteochondral fractures of the talus are controversial. It is hard to compare results between authors as they have often used different outcome measures. Some authors use pain as their primary outcome[97] whereas others also consider radiologic healing. The long-term outcome of an asymptomatic subchondral lucency in the talar body is unknown. In some series, the patients have had arthrotomies[97] whereas others had arthroscopic debridement.[129] The staging of the lesions are also subject to interobserver variability.[97] Letts et al.[95] performed surgery in 24 patients with osteochondral lesions. They used arthroscopy in three patients only and two of those patients required arthrotomy as well.[95] With modern ankle arthroscopy equipment and newer surgical techniques, ankle arthroscopy has become the primary surgical treatment for both medial and lateral lesions of the talar dome. The anterolateral lesions are more accessible; however, with good ankle distraction and different portal placement posteromedial lesions are accessible.

Recently, Perumal et al.[129] reviewed 31 patients with juvenile OCD with a minimum of 6-month follow-up. They recommended nonoperative treatment with an ankle brace and activity modification in most cases for 6 months. Only 16% of the lesions healed radiographically in that timeframe. If pain continues after this time and the lesion is still present, further immobilization and activity modification is recommended. They recommend arthroscopic surgery for patients with type II lesions who are not prepared to modify their activities longer than 6 months and patients with type III lateral lesions and all stage IV lesions. Thirteen of the 31 patients were treated surgically.

Arthroscopic treatment options include:

1. Drilling the lesion (antegrade or retrograde)[88]
2. Curettage and microfracture
3. Internal fixation with bioabsorbable nails
4. Bone grafting and internal fixation

In stage II lesions with intact articular cartilage, Kumai et al.[56] showed excellent results drilling through the lesion into the subchondral bone. They also found that in skeletally immature patients, there may be an increased tendency for the lesion to heal when compared to the adult patients. Retrograde drilling can be performed using specific tip directed instrumentation.[168] This avoids damage to the articular cartilage and may prevent fragmentation of a small lesion. Access to a posteromedial lesion can be difficult. One approach is to use a transmalleolar portal after drilling a 3.5-mm drill through the medial malleolus or to use a posteromedial portal taking care to avoid damaging the neurovascular bundle.

Curettage and microfracture is a very effective, relatively straightforward procedure. It is particularly useful in small stage III and stage IV lesions where the fragment is too small to internally fix or there is no subchondral bone on the lesion for healing. The articular cartilage is debrided back to stable tissue and the subchondral bone is curettaged until bleeding occurs. Either a microfracture pick or 2-mm drill is then used in the subchondral bone. Anderson et al.[8] would suggest this treatment for all stage IIa lesions where a subchondral cyst is present.

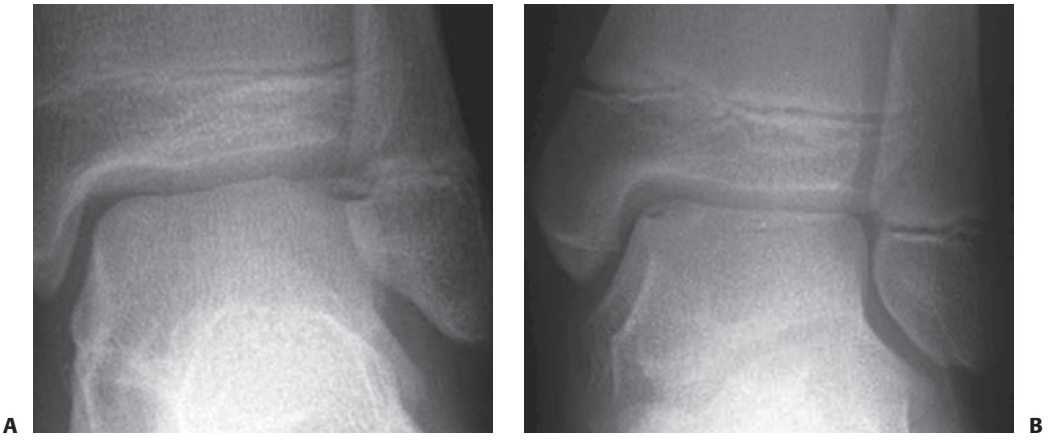

FIGURE 33-13 **A:** Anterolateral stage III osteochondral lesion that was treated by arthroscopic excision and microfracture. **B:** Posteromedial stage II osteochondral lesion that was treated successfully nonoperatively.

Internal fixation with or without bone grafting is a difficult procedure for the inexperienced arthroscopist. It is preferable to use absorbable pegs or nails rather than metallic implants. In large stage III and IV acute osteochondral lesions, this is probably the treatment of choice rather than excising the fragment.

Author's Preferred Treatment

For simple undisplaced fractures, a below-knee nonwalking cast is applied for 6 weeks.

Displaced lateral process fractures need to be anatomically reduced especially if they are intra-articular and there is 2 to 3 mm of incongruity in the joint surface. A lateral approach is used and a single compression screw inserted across the fracture. The foot is immobilized in a below-knee cast for 6 weeks.

Displaced talar neck fractures should be operated on as soon as possible. If the fracture can be reduced closed, the author prefers a posterolateral approach to insert the compression screws as this helps preserve the tenuous blood supply (Fig. 33-4). These screws are best inserted through this open approach so an accurate starting point can be found and neurovascular structures protected. The author has no hesitation to use an anteromedial approach as well to help with fracture reduction before inserting the screws. Through this approach, the neck fragment can be stabilized while the screws are being compressed and anatomic fracture reduction can be seen. Usually, two 4.5-mm partially threaded titanium screws are used depending on the size of the talus and degree of fragmentation. The titanium screws allow MRI postoperatively if osteonecrosis is suspected.

Acute osteochondral injuries need to be recognized and distinguished from OCD lesions. Acute lesions should be repaired after assessing the amount of bone present on the lesion. This can be initially assessed arthrocopically but is repaired through an arthrotomy depending on the position on the talus. The author prefers to repair the lesion with dissolvable nails.

The author treats types I to III OCD lesions nonoperatively for 6 months. Initially, the child or adolescent wears a Cam walker for 4 to 6 weeks to help the symptoms settle and then an elastic ankle support and activity modification. If symptoms persist, the author performs a repeat MRI scan and, if the staging has worsened, proceeds to an arthroscopic debridement and microfracture or stabilization. For patients with displaced fragments on presentation (stage IV), the author recommends arthroscopic removal and microfracture or repair if possible.

Complications

Osteonecrosis of the Talus

Osteonecrosis of the talus is the most serious complication of talus fractures. This has been reported in a number of large series of predominantly adult patients.[26,65] Osteonecrosis of the body of the talus occurs when the blood supply has been disrupted by a fracture of the talar neck. The result is necrosis of the talar dome and possible collapse of the articular surface. It appears that this process of necrosis can start as early as the first month following the fracture. Hawkins[65] described the presence of a subchondral lucent line, the "Hawkins sign," as prognostic of a good outcome as it indicates adequate blood flow to the talar body. The absence of the sign on a 6- to 8-week radiograph implies there is inadequate blood supply and osteonecrosis may evolve.

In adults, the incidence of osteonecrosis seems directly related to the degree of displacement of the femoral neck fracture. Hawkins[65] showed that type I fractures had a 0% to 10% AVN rate, type II fractures a 20% to 50% AVN rate, type III an 80% to 100% AVN rate, and all type IV fractures develop AVN. Canale and Kelly[26] had similar long-term results.

Osteonecrosis has also been seen in pediatric talus fractures; however, it does not seem to be as predictable as the adult literature suggests. The Hawkins sign was described in adults, and Ogden[124] suggests this sign may not be as reliable in the cartilaginous talar dome of a child. Mazel et al.[111] reported on seven complete fractures of the talar neck in children over 6 years of age and two developed AVN. Similarly, Letts and Gibeault[98] had three children with AVN after talus fractures. Interestingly, two of these patients had undisplaced fractures of the talus at the time of their injury that were not initially picked up. Subsequent radiographs revealed the AVN.[98] Rammelt et al.[140] also reported on a 5-year-old whose undisplaced talar neck fracture was missed who went on to develop AVN. In a literature search, they found a 16% incidence of AVN of the talus in undisplaced talar fractures in children. They suggest that the pediatric talus is more susceptible to AVN than the adult counterpart.[140] Jensen et al.,[79] on the other hand, had no cases of AVN in 14 children with talus fractures.

The dilemma for the treating surgeon is what to advise the patient regarding weight bearing when the Hawkins sign is not present by 8 weeks. Some of the above series report AVN occurring 6 months after the injury and not resolving for many years. There does not appear to be any series comparing outcomes in patients who bear weight over this period and those who do not. If the Hawkins sign is not present, it is advisable to perform an MRI scan at 3 months to establish if AVN is present or not.[67,170] If present, it may be advisable to encourage the child to avoid impact activities to prevent collapse rather than have a prolonged period of non–weight-bearing.

Calcaneal Fractures

Epidemiology of Calcaneal Fractures

Fractures of the calcaneus are rare in children with an incidence of only 1 in 100,000 fractures.[181] The treatment of these fractures has historically been nonoperative, relying on the largely cartilaginous bone to remodel with time. The majority of fractures in children less than 14 years old are extra-articular whereas in older children the fracture pattern resembles those in adults. Children appear to have more coexisting lower limb fractures than adults but fewer fractures of the axial skeleton.[156]

Calcaneal fractures in young children are often missed or are diagnosed late on radiographs or bone scan when the child is still limping long after the injury. At the other end of the spectrum, the adolescent patient has often had a major fall and has a displaced intra-articular fracture. This older age group

should be treated like the adult population with open reduction and internal fixation restoring the joint congruity and calcaneal height and width. The challenge for the surgeon is at what age and what degree of displacement is this more aggressive treatment indicated in a group of patients traditionally treated nonoperatively.

Management of Calcaneal Fractures

Mechanism of Injury

The most common mechanism of injury is a fall from a height. This axial load drives the talus into the calcaneus resulting in the fracture. The degree of comminution appears to be less in children even though they often fall from greater heights than adults.[20] Wiley and Profitt[181] found that in young children, the fall was usually less than 4 feet and in children older than 10 years the fall was greater than 14 feet. They noted that the minor falls in the younger children often resulted in undisplaced fractures that were diagnosed late.

Schmidt and Weiner[156] reviewed 56 children with calcaneal fractures of which 25 (45%) were caused by a fall from a height. They also found that children less than 14 years of age predominantly had extra-articular fractures, hypothesizing that the calcaneus in this age bracket absorbs the compression force rather than dissipating it through the joint.

Vehicle-related injuries were the second biggest cause of calcaneal fractures in both Schmidt and Weiner[156] and Wiley and Profitt's reviews.[181]

Fractures of the calcaneus can also occur in major crush injuries when compartment syndrome may coexist and open fractures are common in lawnmower injuries.

Signs and Symptoms of Calcaneal Fractures

Any child who has fallen from a height and landed on their feet should be examined carefully for a calcaneal fracture. Associated injuries should also be evaluated with a thorough secondary survey, especially of the lower limbs and spine.

The foot will often be extremely swollen with bruising around the heel and dorsum of the foot. Symptoms and signs of compartment syndrome, including excessive pain, pallor, paresthesia, and pulselessness should be assessed. In more subtle injuries, careful palpation is necessary to elucidate areas of pain which may disclose an underlying undisplaced fracture.

Many calcaneal fractures in children are initially missed and diagnosed late. Often, the fracture line is not evident on the initial radiographs. Inokuchi et al.[75] reported that 44% of fractures in their series were initially missed, as were 55% of those reported by Schantz and Rasmussen[154] and 44% of those reported by Wiley and Profitt.[181]

A differential diagnosis must be kept in mind for other causes of heel pain in a child. These include Sever disease, osteomyelitis, a unicameral bone cyst, or a stress fracture.[126]

Associated Injuries with Calcaneal Fractures

Schmidt and Weiner[156] reviewed 59 children with 62 calcaneal fractures and found a number of associated injuries. These included fractures of the lumbar spine, lower limb fractures, a pelvic fracture, and upper extremity fractures. These other skeletal injuries were more frequent in children over 13 years of age. Associated lower limb fractures occurred twice as frequently as in adults; however, injuries to the axial skeleton occurred half as often as in adults. Wiley and Profitt,[181] however, only had two patients with accompanying significant injuries in their series of 32 pediatric calcaneal fractures.

Diagnosis and Classification of Calcaneal Fractures

Plain Radiographs

Calcaneal fractures in children often missed as the radiographic findings are usually more subtle than in adults.[89,110,156,165,181] Subsequent radiographs at 10 to 14 days often show the fracture line. The majority of these missed fractures are extra-articular.[156]

The standard views for a suspected calcaneal fracture are posteroanterior, lateral, and axial views. The posteroanterior view shows the calcaneocuboid and talonavicular joints well. The lateral view is excellent at showing the congruity of the posterior articular facet and allows calculation of Bohler angle (Fig. 33-9). The axial view demonstrates the tuberosity, the body, the sustenaculum tali, and the posterior facet of the calcaneus Oblique views are also useful and will show a fracture of the anterior process more clearly (Fig. 33-14).[142] The oblique views also define the subtalar joint well so are very useful in intra-articular fractures. Broden views can also be taken that look at the posterior facet of the calcaneus. These are taken with the leg internally rotated 40 degrees and the x-ray beam angled between 15 to 40 degrees toward the head.[18] This is a

FIGURE 33-14 Fracture of the anterior process of the talus.

difficult radiograph for the technicians to master and almost the same information can be achieved by ordering a mortise view of the ankle and looking at the posterior facet of the subtalar joint.

The lateral view is useful for measuring the Bohler angle. This is the angle between a line drawn from the highest point of the anterior process to the highest point of the posterior facet and a line drawn tangential to the highest point of the calcaneal tuberosity. The normal value in an adult is between 20 and 40 degrees. In a child, the angle is slightly less than in an adult and may be caused by the incomplete ossification of the calcaneus. It is advisable to perform a lateral radiograph of the contralateral calcaneus to use as a comparison rather than accept the absolute value of Bohler angle. The child's calcaneus does not resemble that of an adult until after 10 years of age.[71,73,124,173] Another angle which is not so easy to measure is "the crucial angle of Gissane." This is the angle formed by two strong cortical struts seen on the lateral radiograph. One runs along the lateral margin of the posterior facet and the other runs up to the anterior process of the calcaneus. The angle between them ranges from 95 to 105 degrees (Fig. 33-9).[51]

When reviewing radiographs of children's feet, it is always important to be cognizant of the normally appearing ossification centers and accessory bones about the growing foot, which often are confused with fractures (Figs. 33-1 and 33-2).[27] The os calcis is the earliest tarsal bone to ossify with the primary ossification center appearing in the third intrauterine month. The secondary ossification center appears around 6 to 8 years and is the crescentic epiphysis seen posteriorly that gives rise to Sever disease. This epiphysis fuses to the body of the calcaneus when the adolescent is 14 to 16 years old.

The use of a technetium-labeled bone scan in diagnosing calcaneal fractures is uncommon with the ready availability of MRI scans. The bone scan is useful in evaluating a nonlocalized painful limp in a toddler and in this setting a calcaneal fracture may be diagnosed. Laliotis et al.[89] used bone scans and identified five calcaneal fractures in seven toddlers less than 36 months of age who had no history of significant injury. Bone scanning is sensitive for bone pathology but not specific and will be positive when other conditions are present like infection, Sever disease, juvenile arthritis, and some neoplasms. A CT scan is a useful investigation to evaluate the positive bone scan.

Computed Tomography Scanning

CT scanning has evolved as the best method to evaluate the fractured calcaneus. Not only does it clearly show the fracture lines and altered anatomy, but also reveals injuries to adjacent bones. Sanders et al.[152] have used CT scans to develop a classification system that is particularly useful in the preoperative planning of open reduction of these fractures. The primary and secondary fracture lines are identified and the degree of comminution and position of the fragments is more accurately seen than in the radiographs. The primary fracture line usually runs obliquely from plantar medial to dorsolateral exiting the posterior facet. Secondary fracture lines that develop off this primary line are also seen and their pattern determines the classification of the fracture (Fig. 33-15). The CT scan also allows a three-dimensional reconstruction to be made which again is useful in visualizing the fracture lines for possible internal fixation.

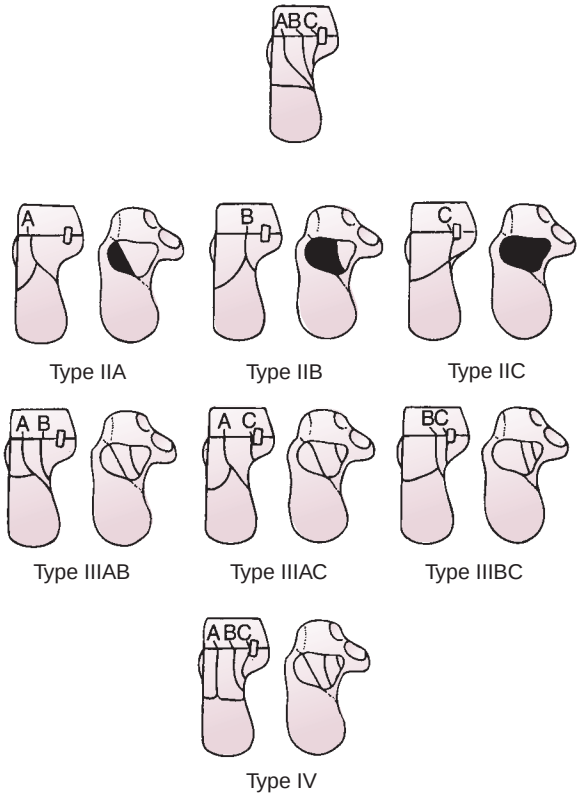

FIGURE 33-15 Sanders CT-based classification of intra-articular fractures of the calcaneus in adults. (From Sanders R. Intraarticular fractures of the calcaneus: Present state of the art. *J Orthop Trauma.* 1992;6:254, with permission.)

Buckingham et al.[20] and Ogden[124] reviewed nine patients with 10 calcaneal fractures and performed CT scans on all of them. They found the fracture patterns in these adolescents (average 13.4 years old) to be very similar to those found in adults. They did find less comminution in children than in adults, even though the children reportedly had fallen from greater heights.

The use of MRI scans is largely unnecessary for the majority of calcaneal fractures. They can be useful in young children when the calcaneus is still largely cartilaginous and a fracture is not seen on plain films or CT.

Classification of Calcaneal Fractures

Children's calcaneal fractures were traditionally classified according to their adult counterparts using the Essex-Lopresti[51] and Letournal[96] classifications. Schmidt and Weiner[156] reviewed 62 calcaneal fractures in children and compared them to the adult literature.[147] They used the classification systems of Essex-Lopresti[51] and Chapman and Galway[32] and added a new fracture type (type VI) to develop a classification for pediatric calcaneal fractures which is in routine use today (Fig. 33-16).

For adolescent fractures, it is probably more appropriate to use the Sanders classification.[152] This is an adult classification

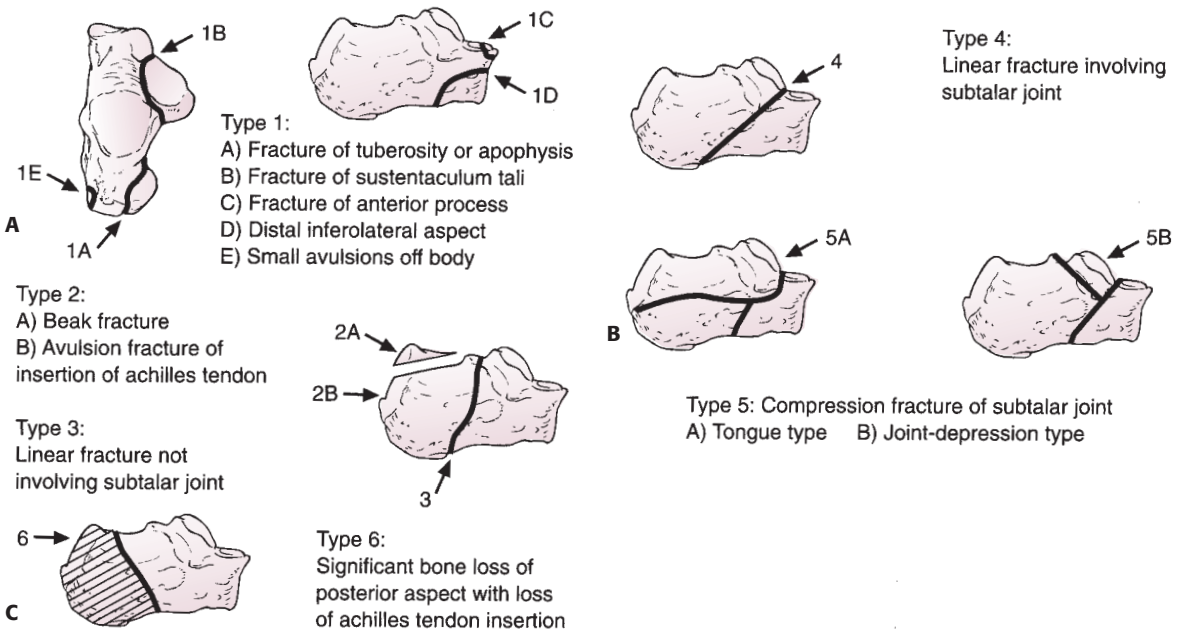

FIGURE 33-16 Schmidt and Weiner classification of calcaneal fracture patterns in children. **A:** Extra-articular fractures. **B:** Intra-articular fractures. **C:** Type VI fracture pattern with significant bone loss, soft tissue injury, and loss of Achilles tendon insertion. (From Schmidt TL, Weiner DS. Calcaneus fractures in children: An evaluation of the nature of injury in 56 children. *Clin Orthop Relat Res.* 1982;171:150, with permission.)

system that was developed after reviewing the CT scans on 120 cases preoperatively and at minimum 1-year follow-up. The follow-up CT scans were correlated with the clinical outcome scores to help validate the classification system used.

Surgical and Applied Anatomy of Calcaneal Fractures

The calcaneus is the largest tarsal bone and has quite an unusual shape. It has three articular facets (anterior, middle, and posterior) on the superior surface where it articulates with the talus to form the subtalar joint (Fig. 33-7) and anteriorly there is a saddle-shaped articular surface for the cuboid. The posterior facet is the largest facet and is slightly convex. The middle facet is anterior and medial to the posterior facet lying on the sustenaculum tali. It is concave like the anterior facet with which it is often contiguous. Between the middle and posterior facets lies the calcaneal groove, which forms the inferior wall of the sinus tarsi. Posteriorly, the tendoachilles inserts into the tuberosity of the calcaneus which is the whole area behind the posterior facet. On the lateral surface of the calcaneus are two shallow grooves with a small ridge in between (the peroneal trochlea). The peroneus longus and brevis run either side of this trochlea. The medial side is concave and is structurally stronger than the lateral side. The sustentaculum tali projects from the medial wall and supports the middle articular facet on its surface. The tendon of flexor hallucis longus runs on the undersurface of the sustenaculum. On the plantar surface are the medial and lateral processes for the origin of the abductor hallucis and abductor digiti minimi muscles, respectively (Fig. 33-17).

Secondary ossification occurs in the calcaneal apophysis between the ages of 6 and 10 years. Inflammation in the apophysis around this age causes heel pain and is referred to as Sever disease.

The use of CT scans has defined the surgical anatomy of the calcaneus to help make treatment decisions. The coronal views show the important posterior facet and the sustenaculum tali and the height and width of the heel. The position of the peroneal tendons and flexor hallucis tendon can also be seen. The sagittal views provide additional information about the posterior facet and also show the anterior process well. The axial views visualize the calcaneocuboid joint well, the anterior-inferior aspect of the posterior facet, and the sustenaculum tali. This information can then be used in planning the reconstruction of the calcaneus.[149,150]

Current Treatment Options for Calcaneal Fractures

Calcaneal fractures in growing children are usually less severe than in the adult population and often do well without operative intervention. The adolescent, on the other hand, often has fracture patterns similar to adults and requires open reduction and internal fixation. The challenge to the orthopedic surgeon is to recognize the patient that requires this form of surgery. There is a degree of remodeling that will take place in the child and hence the amount of growth remaining, degree of ossification, and difference in morphology from the contralateral side all need to be considered in making the treatment decisions.

Extra-articular fractures of the calcaneus are treated by cast immobilization for 6 weeks. The child can start weight bearing

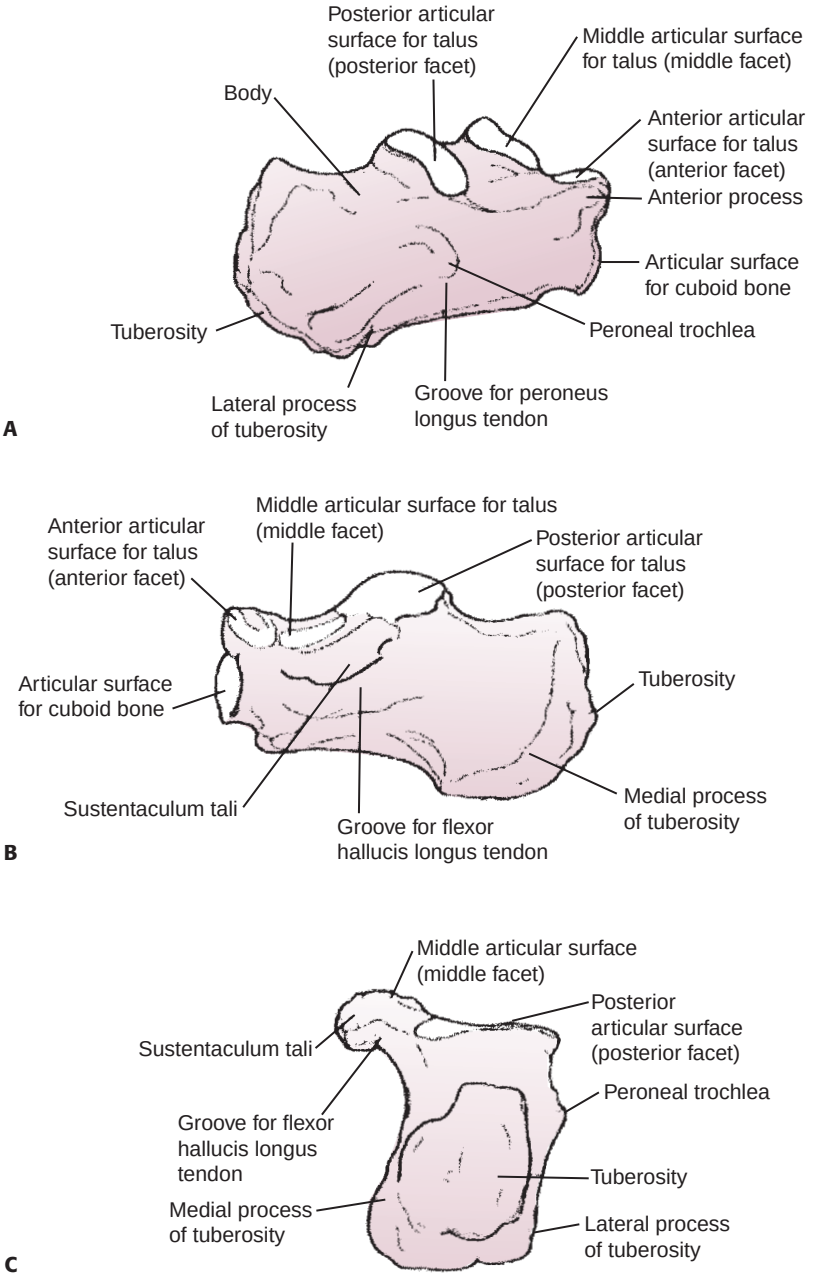

FIGURE 33-17 Anatomic details of various angles of the calcaneus including lateral **(A),** medial **(B),** and coronal **(C)** views through the level of the sustentaculum tali, which correlate with the CT scan view important in reconstruction of the posterior facet.

in this cast when comfortable and can be changed to a Cam walker for the final few weeks if necessary.[19,75]

Tongue-type fractures can be treated nonoperatively if the posterior gap is less than 1 cm and the Achilles tendon has not been significantly shortened by bringing the fragment up proximally. Occasionally, the technique described by Essex-Lopresti[51] for percutaneous reduction of tongue-type fractures (Fig. 33-18) is useful.

Open reduction and internal fixation is reserved for the severe intra-articular fractures with displacement of the fragments and depression of the joint surfaces. These fractures occur almost exclusively in the adolescent patient where the ossification process is complete. The adult literature abounds with indications for internal fixation, surgical approaches, rehabilitation, complications, and outcome measures (Fig. 33-19).[10,132,149–152] These series only have a few adolescent fractures among them, and therefore it is difficult to draw any conclusions specifically about children's calcaneal fractures. The literature on the management of displaced intra-articular fractures in children is somewhat conflicting in the indications for surgery. Schantz and Rasmussen[154] reported on the outcome of displaced intra-articular fractures in children less than 15 years old treated nonoperatively. The majority of the patients had a good outcome; however, four complained of pain an average of 12 years after injury.[154,169] Brunet[19] believes the outcome does not correlate to the severity of the fracture. This is most likely

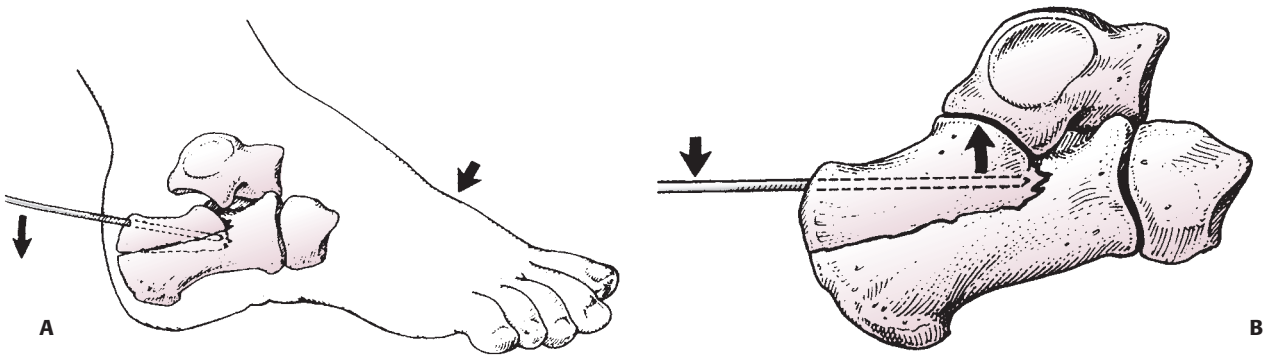

FIGURE 33-18 Percutaneous reduction technique for tongue-type fractures of the calcaneus, as described by Essex-Lopresti[51]. This technique remains an alternative to conservative treatment and open reduction with internal fixation of displaced, tongue-type fractures. **A:** A pin is inserted into the tongue fragment and used as a joystick to manipulate the fragment into better position, usually with a downward force on the pin and the forefoot (plantarflexion). **B:** After reduction, the pin is driven across the fracture to maintain reduction. (From Tornetta a III. The Essex-Lopresti reduction for calcaneal fractures revisited. *J Orthop Trauma.* 1998;12:471, with permission.)

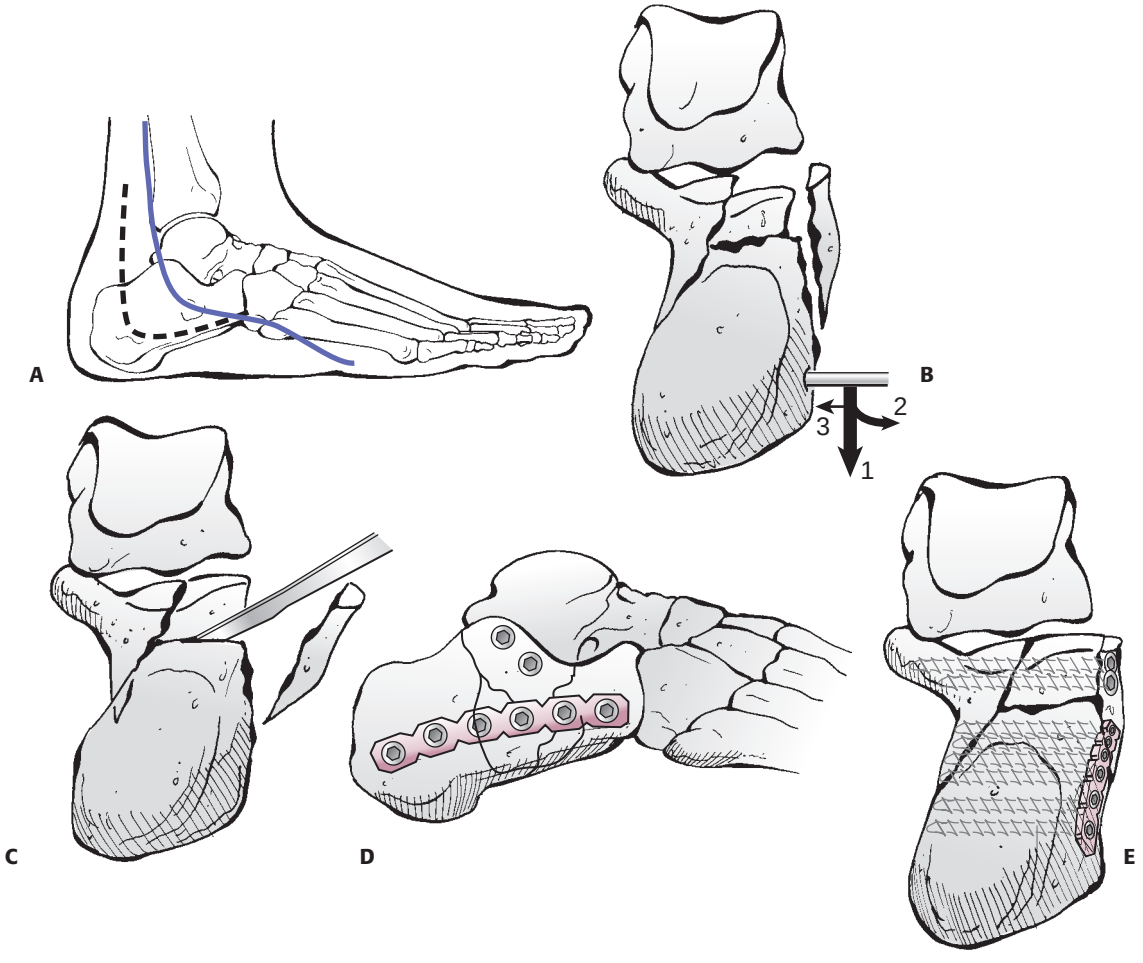

FIGURE 33-19 **A:** Lateral L-shaped approach to displaced intra-articular calcaneal fractures. The incision (*dashed line*) is laterally based, with the proximal arm approximately half the distance from the fibula to the posterior border of the foot and the distal arm halfway from the tip of the fibula to the sole of the foot. The sural nerve is illustrated. A full-thickness, subperiosteal flap exposes the entire lateral calcaneus. **B:** Reduction maneuvers 1, 2, and 3 (*densest arrow indicates greatest displacement*) with a Schanz screw are used to pull the tuberosity down and allow access to disimpact the posterior facet **(C)** after the lateral wall of the calcaneus is levered open. The posterior facet is then reduced anatomically, held provisionally with K-wires, and then fixed with two partially threaded cancellous screws (outside of plate) into the sustentaculum tali. Lateral view **(D)** of reduced calcaneus and axial view **(E)** of reduced fracture with hardware. (From Benirschke SK, Sangeorzan BJ. Extraarticular fractures of the foot: Surgical management of calcaneal fractures [Review]. *Clin Orthop Relat Res.* 1993;292:128–134, with permission.)

because of the remodeling potential of the calcaneus in this age group. This concept also was supported by Mora et al.,[117] who concluded that open reduction may be suitable only for severely displaced fractures in adolescents. The difficulty is defining the age or maturity of the patient that may predict a poor outcome if the fracture is left unreduced. Using validated quality-of-life scales 2 to 8 years after surgery, Buckley et al.[21] found that younger patients (adults under the age of 30 years) who had operative treatment had better gait satisfaction scores than those who did not have surgery. Allmacher et al.[6] questioned whether short-term or intermediate results of displaced intra-articular calcaneal fractures can predict long-term functional outcome. Using validated outcome instruments, they studied adult patients treated nonoperatively and found that nonoperative treatment often led to pain and loss of function, which increased in the second decade after injury.

Pickle et al.[132] reviewed the results of open reduction with internal fixation of displaced intra-articular calcaneal fractures in six adolescent patients (average age, 13 years) and found good short-term results at an average of 30 months after injury. None of the six patients (seven calcaneal fractures) developed any of the serious complications reported in adults. Four of the seven feet were completely pain-free, and three had some minor pain with sports or hard floors. Ceccarelli[28] found that adolescents with displaced intra-articular fractures had better clinical and radiologic outcomes if treated by open reduction rather than nonoperatively. Buckingham et al.[20] reviewed 10 adolescent patients and reported good or excellent outcomes in eight patients. They had no wound complications and the range in motion was hardly affected in seven patients. They recommended the routine removal of the screws and plates after fracture healing as this had improved the symptoms in six of eight patients.[20]

The surgery for these fractures is technically demanding, and if the treating surgeon is not experienced with the approach, the child is best referred to a colleague who is.

Author's Preferred Treatment

The key decision in treating children's calcaneal fractures is which one requires surgical intervention and which one can be treated in a cast. Almost all closed fractures in children less than 10 years of age can be treated nonoperatively because of the remodeling potential. This includes intra-articular fractures that are displaced.

Extra-articular fractures of the calcaneus can be treated by nonoperative means with a below-knee cast for 6 weeks. Weight bearing in the cast can start after 2 to 3 weeks as the patient becomes more comfortable.

Undisplaced intra-articular fractures can also be treated in a below-knee cast. In this group of patients, it is advisable for them to be non–weight-bearing for 6 weeks or until the fracture is healed to prevent further displacement.

Adolescent patients with displaced intra-articular fractures are best treated by open reduction and internal fixation (Figs. 33-19 and 33-20). Before embarking on this surgery, a thorough assessment of the skin needs to be performed. Surgery should be delayed to allow swelling to subside and fracture blisters to resolve. This will decrease some of the wound complications commonly seen after open fixation of adult calcaneal fractures. The key point in performing this surgery is to maintain thick skin flaps, restore joint congruity, use specialized calcaneal plates, and be prepared to bone graft the defect. An outline of the surgical technique is in Table 33-3.

Complications in Calcaneal Fractures

Wound Complications

Wound dehiscence is the most common complication following open reduction of adult calcaneal fractures.[10,72,99,152]

Although reported to occur in up to 25% of adult fractures, the incidence is lower in children. Pickle et al.[132] had no wound problems in the six adolescents (age range: 11 to 16 years) they treated with open reduction and internal fixation. All the patients were treated with an extensile lateral approach an average of 10.5 days from the time of injury. The lower incidence in children reflects fewer risk factors in this group when compared to the adult population. Smoking, obesity, and diabetes all contribute to wound problems.

Wound dehiscence can be decreased by meticulous closure of the incision. In adults, it has been shown that a two-layer closure is preferable to a single layer of sutures.[1,55] Wound dehiscence can occur from days to weeks after the surgery. The best initial treatment is immobilization of the foot and ankle to decrease any tension on the wound edges. This is best accomplished in a below-knee cast with a large window cut around the entire incision. This allows space for wound dressing changes and debridements as necessary. Oral antibiotics may be required if superficial infection is also present. Once the wound is healed, gradual mobilization can be reinstated.

In serious deep wound infections, the patient will require rehospitalization, repeat surgical debridements, and intravenous antibiotics. Often, the use of a suction dressing (Vacuum-Assisted Closure [VAC], KCI, Inc., San Antonio, TX) is advisable in recalcitrant wounds. This VAC device has been shown to be safe and effective by Mooney et al.[116] for traumatic wounds in pediatric patients of all ages. Skin closure is usually not possible following such radical debridement. It is very helpful to consult with plastic surgeons early in the course of treatment as the patient often requires tissue transfer to cover the exposed metalware.

Complex Regional Pain Syndrome

This syndrome, previously known as reflex sympathetic dystrophy (RSD), is a devastating painful disorder that can occur following operative or nonoperative management of a calcaneal fracture or other trauma about the foot. The condition is usually diagnosed when there is severe pain present out of proportion to the severity of the injury following the acute phase of healing. The pain is difficult to control even with oral narcotics. The child will not bear weight or even allow the foot to be examined. Light touch even by water may stimulate an unusual pain response. The foot clinically demonstrates the signs of

TABLE 33-3 Operative Planning for Open Reduction and Internal Fixation of Intra-Articular Calcaneal Fractures in Adolescents

Equipment
- Radiolucent table
- Image Intensifier
- K-wires with driver
- Lambotte osteotomes
- Periosteal elevators
- AO modular foot set
- Synthes calcaneal plates, 2.7-mm reconstruction plates, H cervical plates

Positioning
- Lateral decubitus on contralateral side
- Upper thigh pneumatic tourniquet
- Hip flexed 45 degrees, knee flexed 90 degrees
- Seattle cushions
- Radiolucent operating table

Incision
- L-shaped incision (Letournel, Regazzoni, Bernirschke) Curved at apex
- Proximal extent 3 cm cephalid to tip of fibula anterior to lateral border of Achilles tendon
- Distal extent tip of base of fifth metatarsal

Exposure
- Blunt dissection with scissors proximally to identify the short saphenous vein and sural nerve
- Sharp dissection with no. 15 blade direct to lateral wall of os calcaneus Subperiosteal reflection with scalpel
- Sharp dissection and reflection of peroneal tendons and attachment of calcaneofibular ligament dorsally
- Keep dorsal to the muscle belly of abductor digiti minimi
- Protect peroneal tendons with baby Hoffmann retractors when exposing the anterior process and calcaneocuboid joint
- Elevate flap dorsally to expose the posterior facet of the talus and sinus tarsi
- Maintain flap anteriorly with K-wires placed into the body and neck of the talus and the fibula
- Deflate tourniquet when exposure complete

Reduction
- Place Schanz pin in inferior aspect of posterior tuber
- Reduce fracture by traction on the Schanz pin displacing posterior tuber inferiorly and thence medially
- Reflect lateral wall laterally if necessary
- Reduce anterior process first, then posterior facet, and finally restore alignment of the os calcis by confirming reduction and alignment of the crucial angle
- Thus reduce anterior to posterior, medial to lateral, and dorsal to plantar
- Provisional reduction maintained with multiple K-wires
- Reduction and alignment confirmed by screening with image intensifier

Fixation
- Contour 2.7-mm reconstruction plate or an AO calcaneal plate to the lateral wall of the os calcis and fix to anterior process and the posterior tuber
- Maintain posterior facet reduction with two interfragmentary screws angled well inferiorly to avoid the inferiorly curved medial surface of the calcaneal posterior facet and to engage the sustenactulum

Closure
- Irrigation
- Always drain
- Two-layered closure
- 2-0 Vicryl to the subcutaneous tissues (Interrupted vertical. Place all sutures on clips, tie individually commencing at the apex of the incision)
- Skin closure with interrupted 3-0 Nylon Donati All-gower sutures (all placed on clips and then tied individually commencing at the apex moving symmetrically to the proximal and distal extent of the wound holding multiple sutures to maintain even tension)

Dressings
- Gelnet dressing

Postoperative
- Well padded below knee popliteal joint back slab supporting toes
- Elevation on two pillows
- IV antibiotics
- CT scan to check reduction and exclude screw malposition
- Remove drain when drainage is less than 10 mL over an 8-hr period
- Review wound for hematoma and skin viability within 48 hrs
- Continue splintage, elevation, and restricted mobility non–weight-bearing until sutures removed 14–18 days postsurgery

Courtesy of Dr. ACL Campbell, FRACS, Adult Foot and Ankle Surgeon, Auckland City Hospital, New Zealand.

FIGURE 33-20 Intra-articular depressed fracture of the calcaneus in a 13-year-old boy. **A:** Preoperative sagittal CT shows the depression of the posterior facet into the body of the calcaneus. **B:** Coronal CT shows the displacement of the fracture fragments. **C:** Postoperative CT scans are useful at checking the fracture reduction and length and position of the screws. **D, E:** Postoperative radiographs confirm restoration of the Bohler angle.

autonomic dysfunction. There is often a grayish discoloration, cold clammy skin, and decreased hair growth. Through disuse of the foot, the calf will atrophy. If radiographs are taken, the bones of the foot will show patchy disuse osteopenia.

There is a marked preponderance of lower extremity cases in children compared to adults.[177] Sarrail et al.[153] reviewed RSD in 24 children and adolescents and found that 73% had foot or ankle injuries. Wilder et al.[178] reviewed 70 children (average age, 12.5 years) with RSD and 87% had injuries to the lower limb. Eighty-four percent of their patients were girls, and on average the time from injury to a diagnosis of RSD was 12 months. Despite multidisciplinary treatments, 54% of patients still had persistent symptoms of RSD at 3 years after diagnosis. They emphasized that complex regional pain syndrome (CRPS) has a different disease course in children when compared with adults and needs to be treated appropriately. CRPS occurs most commonly in girls with the incidence peaking at or just before puberty.[177]

Most tertiary children's hospitals now have multidisciplinary pain teams that treat CRPS. These comprise a physician (anesthetist or pediatrician), a psychiatrist or clinical psychologist, a physiotherapist, and sometimes an occupational therapist. The child initially undergoes a multidisciplinary assessment that involves both schooling and social circumstances. The physiotherapist carries out a thorough functional assessment.

The treatment focuses on improving function and therefore extensive physiotherapy is performed initially. Analgesics need to be used to facilitate this and include anti-inflammatory drugs, amitriptyline, and gabapentin. In severe cases, regional blocks occasionally need to be used to control the pain. Children appear to respond to physiotherapy better than adults and they require less medication and invasive procedures. On the other hand, the recurrence rate of CRPS is higher in children; however, they respond well to the reinitiation of treatment.[177]

Peroneal Tendonitis/Dislocation

Peroneal tendon pain can occur in both the operated and nonoperated foot. Pain in the peroneal tendons on movement or direct palpation may indicate prominent underlying metalware. Simply removing the offending screw or plate may help. Buckingham et al.[20] recommended the routine removal of metalware in their series of adolescent calcaneal fractures as this resulted in resolution of pain in their patients.

The extensile L-shaped lateral incision has largely prevented the peroneal tendon subluxation that used to occur with the Kocher incision. Care has to be taken at the proximal and distal ends of this incision as the sural nerve can be damaged and a painful neuroma develops.

In patients with calcaneal fractures treated nonoperatively, a displaced lateral wall can sublux or even dislocate the peroneal tendons. Lateral impingement pain can also result from the fragment coming in direct contact with the fibula.

Diagnostic local anesthetic injections have been useful in differentiating the cause of pain in the adult foot but its use in children is limited. It should, however, be considered in adolescents who are willing to cooperate.

Subtalar Dislocation

Subtalar dislocations (peritalar dislocation) occur infrequently and are particularly uncommon in children. They occur most often in young adult males. There are no series published on this condition in children; however, Dimentberg and Rosman[44] reported on five talonavicular dislocations.

A medial dislocation is the most common type (85%) and results from a forced inversion injury to the foot. The talonavicular and talocalcaneal ligaments rupture whereas the calcaneonavicular ligament stays intact. The result is that all the bones of the foot dislocate medially whereas the talus remains in the ankle mortise (Fig. 33-21). The foot looks markedly deformed and the talar head can be palpated laterally. A lateral dislocation is caused by a forced eversion injury and results in a laterally displaced "flatfoot."

FIGURE 33-21 Posterior view demonstrating cavovarus deformity of the left foot. (Courtesy of Dr. Thomas Lee, MD.)

FIGURE 33-22 Lateral view showing subluxation of the subtalar joint. There is incongruity of the calcaneocuboid joint. (Courtesy of Dr. Thomas Lee, MD.)

Radiographs are difficult to interpret in this unusual injury (Figs. 33-22 and 33-23). The key is to look for the "empty navicular" where the talar head no longer articulates with it. A CT scan is useful to look for any associated fractures or osteochondral damage; however, it is probably more useful to

FIGURE 33-23 AP view demonstrating translation of the transverse tarsal joint. (Courtesy of Dr. Thomas Lee, MD.)

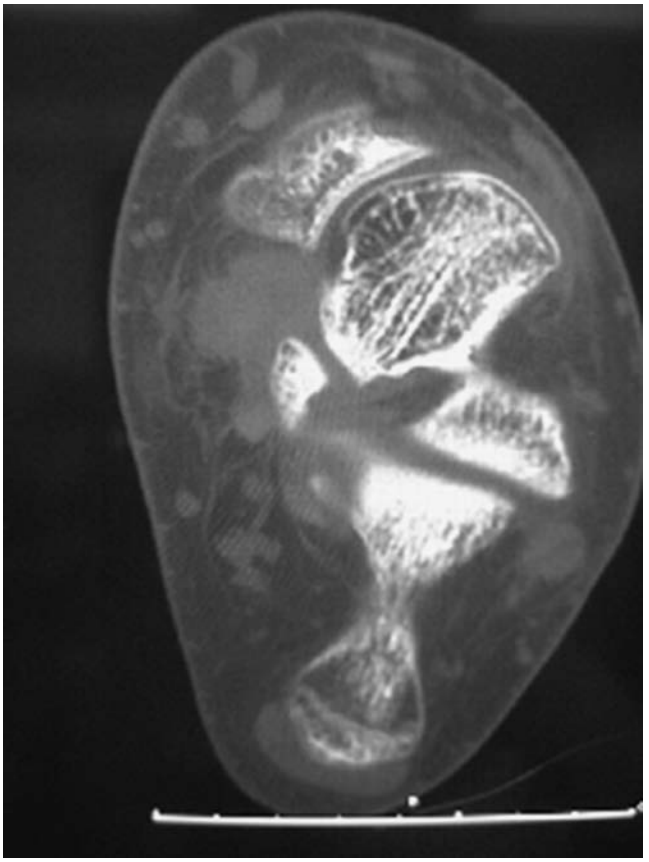

FIGURE 33-24 CT scan axial view shows marked talar head uncoverage ("ball is not in cup"). There is also significant incongruity of the subtalar joint. (Courtesy of Dr. Thomas Lee, MD.)

perform this after a closed reduction to confirm anatomic alignment as well (Fig. 33-24).

The treatment for a closed subtalar dislocation is a reduction under general anesthesia. The knee should be flexed to relax the tendoachilles and then the deformity accentuated before a reduction is carried out by relocating the deformed foot. Usually, the reduction is stable and anatomic reduction can be confirmed by radiographs and CT scan. The foot is immobilized until the child is comfortable enough to start gentle mobilizations. K-wire stabilization and 6 weeks of immobilization are necessary for unstable dislocations.

Occasionally, the subtalar dislocation is irreducible by closed means and has to be opened through an anteromedial approach. The bone or soft tissue (often the tibialis posterior tendon) is removed from the joint and the foot reduced.

Midtarsal Injuries

Fractures and dislocations of the navicular, cuboid, and cuneiforms are rare pediatric foot injuries. The midtarsal region extends from the calcaneocuboid and talonavicular joints (Cho-part's joint) to the metatarsals. It includes the cuboid, navicular, and three cuneiform bones. These bones are interlinked by extremely strong ligaments especially on the plantar surface. The lateral side of the midfoot is more stable than the medial side. The shape of these small bones and strength of their ligaments help maintain the longitudinal and transverse arch of the foot. Disruption of this rigid anatomy therefore requires a large force especially in the cartilaginous bones of a child's foot. Isolated injuries to this area are rare and one needs to look for other associated fractures and dislocations.

Midtarsal injuries have been classified in adults by Main and Jowett.[106] This classification uses five broad categories based on the direction of the force causing the injury and the direction that the fragment is displaced. In parentheses are the percentages of this type of injury in Main and Jowett's[106] review of 71 midtarsal injuries.

Longitudinal stress (40%)

Medial stress (30%)

Lateral stress (17%)

Plantar stress (7%)

Crush injury (6%)

Hosking and Hoffman[70] reviewed four cases of midtarsal dislocations in children, and this is the only report in the literature of this injury in the pediatric age group. The children had an average age of 9.5 years, and the mechanism of injury was forced supination in three of the patients. They all had associated midtarsal injuries and presented with significant swelling. The key to making the diagnosis, which was delayed in three of the patients, was subluxation or dislocation of the calcaneocuboid joint on the lateral radiograph. The AP view only showed the dislocation in two patients and the oblique view showed it in only one patient.

The dislocation can usually be reduced closed and held with percutaneous K-wires. If an anatomic reduction is not possible closed, then one must proceed to an open reduction.

A CT scan should be performed to more clearly define the associated injuries to both the midtarsal bones and rest of the foot. One of the patients in Hosking and Hoffman's[70] series had an ipsilateral tibial fracture so associated injuries may be present because of the amount of force required to cause a midfoot disruption in a child.

Isolated fractures of the mid tarsal bones are rare. The navicular, cuboid, and cuneiforms are usually fractured in association with a Chopart joint (talonavicular and calcaneocuboid) dislocation or a serious Lisfranc injury. The navicular has a number of conditions that can mimic a fracture. Between the ages of 2 and 5 years, the navicular can become avascular (Kohler disease) and cause pain and limp whereas the changes seen on radiograph can look similar to a fracture (Fig. 33-25). Likewise, an accessory navicular may be present that may mimic an avulsion fracture of the navicular tuberosity. These can be differentiated from a fracture as they have smooth, rounded edges and are usually symmetrical when a radiograph is taken of the other foot. Stress fractures of the navicular are also becoming an increasingly common problem as children and adolescents train more aggressively for competitions (see stress fractures of the foot). These stress fractures usually run in the sagittal plane in the middle third of the bone. They are often difficult to see

FIGURE 33-25 Kohler disease of the navicular that can occasionally be confused with a stress fracture.

on plain radiographs but are more easily seen on bone scans, CT, and MRI.

Cuboid Fractures

Cuboid fractures were considered a rare foot injury in children and were usually associated with other foot fractures. Recent literature, however, reveals that this fracture may occur more often than we thought and commonly in isolation. Senaran et al.[158] reported on 28 consecutive cuboid fractures in preschool children from 1998 to 2004. They found most patients had an avoidance gait pattern and walked on the outside of their foot. They used the "nutcracker" maneuver to help diagnose the fracture. To perform this test, the heel is stabilized by the examiner and the forefoot is abducted. Pain in the lateral aspect of the foot usually confirms a fracture of the cuboid. The diagnosis was then confirmed on initial or subsequent radiographs. A below-knee cast or Cam walker was used for 2 to 3 weeks and all fractures healed without complications. Six patients had ipsilateral fractures in the tibia or foot. Interestingly, eight patients had an associated genetic or systemic abnormality.[158] Cuboid fractures have been classified by Weber and Locher[176] into distal impaction shear-type fractures (type 1) and burst fractures (type 2).

Ceroni et al.[30] reported on four female teenagers who had equestrian injuries and cuboid fractures. The mechanism of the injury in all cases was a crush to the foot when the horse fell and abduction of the forefoot while it was still in the stirrup. All four cuboid fractures were associated with multiple midfoot fractures and the authors recommend CT scans in all patients in this age group with a cuboid fracture. Two patients required surgical reconstruction. This was performed through a lateral incision from the tip of the fibula to the base of the fifth metatarsal. The interval is then developed between the peroneal tendons and the extensor digitorum brevis. The lateral column length is then restored using an allograft block.[30]

Tarsometatarsal Injuries (Lisfranc Fracture-Dislocation)

Tarsometatarsal (TMT) injuries, more commonly referred to as a Lisfranc injury, are more common in adults than they are in children.[182] The degree of injury varies from a subtle disruption of the Lisfranc ligament to an extensive fracture-dislocation of the forefoot. Subtle injury can be difficult to diagnose especially if it is not thought about and if left untreated can develop into a painful chronic problem.

Although mostly described as isolated case reports,[17,29,139] a series of 18 TMT joint injuries in children was reported by Wiley[180] in 1981, and more recently Buoncristiani et al.[22] described an additional eight such injuries in skeletally immature patients.

Management of Tarsometatarsal Injuries

Mechanism of Injury

TMT injuries are either caused by a direct blow to the foot, usually secondary to a falling object, or indirect, where there is forced plantarflexion of the forefoot combined with a rotational force (Fig. 33-26).[179,180]

Traumatic Impact in the Tiptoe Position. This is an indirect injury where a load is applied to the foot while it is in the tiptoe position. A common example of this injury is jumping to the ground and landing awkwardly on the toes, producing acute plantarflexion at the TMT joint. The result is a TMT joint dislocation and usually a fracture at the base of the second metatarsal. Another example would be by putting the foot down suddenly to reduce speed while riding a bike.

Heel-to-Toe Compression. In this situation, the patient is in a kneeling position when the impact load strikes the heel. This is an example of a direct compression type injury and usually results in lateral dislocation of the lesser metatarsals and fracture of the base of the second metatarsal.

The Fixed Forefoot. In this third mechanism, the child falls backward while the forefoot is fixed to the ground by a heavy weight. An example would be a fall backward while the foot was pinned under the wheel of a car. The patient's heel, which is resting on the ground, becomes the fulcrum for the forefoot injury.

In Wiley's[180] review of 18 patients with TMT joint injuries, 10 (56%) were a fall from a height in the "tiptoe" position, three (18%) suffered "heel-to-toe" compression, and four (22%) sustained a fall backward while their forefoot was pinned to the ground. One patient could not recall their mechanism of injury following a motorbike collision.

Atypical Lisfranc injuries have recently been reported in mini scooter injuries where the foot is planted to break speed. The resulting dorsiflexion, axial loading, and abduction cause

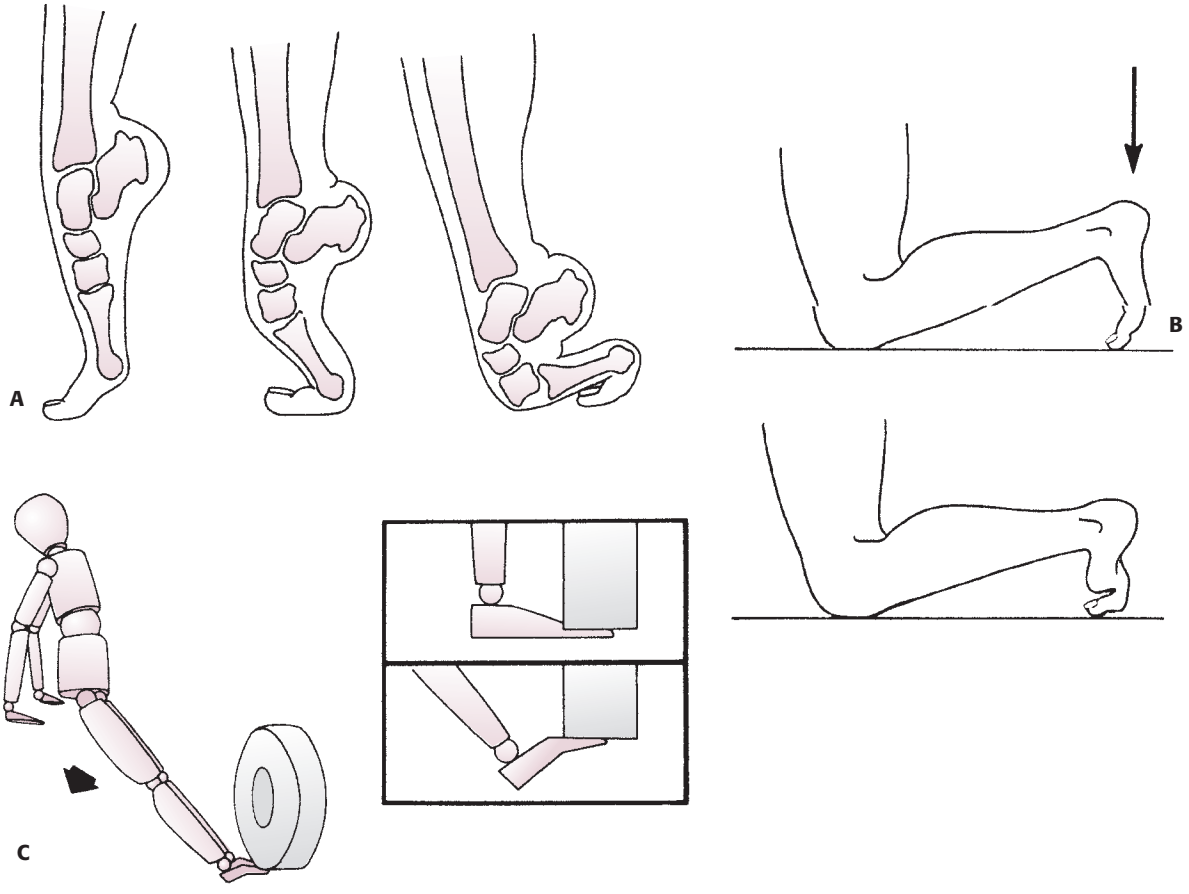

FIGURE 33-26 Mechanism of Lisfranc injuries. **A:** The most common mechanism of injury: Progression from the "tiptoe" position to complete collapse of the TMT joint. **B:** Plantarflexion injury: Direct heel-to-toe compression produces acute plantar flexion of the TMT joint. **C:** Backward fall with the forefoot pinned.

the metatarsals to be impacted laterally. The result is a fracture of the base of the second metatarsal and a crush fracture of the cuboid.[13]

Signs and Symptoms of Tarsometatarsal Injuries

The diagnosis of these injuries may be difficult, and in adults as many as 20% of injuries are misdiagnosed or overlooked.[23,144] Some of the injuries are subtle and will present with minor pain and swelling at the base of the first and second metatarsals. This can be accompanied by ecchymosis on the plantar aspect of the midfoot where the TMT ligaments have been torn (Fig. 33-27).[145] This can be confirmed by gently abducting and pronating the forefoot while the hindfoot is held fixed with the other hand,[120] though this would be quite painful acutely. Alternatively, the child can be asked to try and perform a single limb heel lift. Pain in the midfoot often implies a TMT joint injury. With significant trauma, there is greater ligamentous injury and the resulting swelling makes it difficult to recognize any bony anatomy. It is important to assess the foot for a compartment syndrome in such circumstances, particularly when the foot has been crushed as part of the mechanism of injury.

The examiner of any child's foot following trauma needs to have a high level of suspicion for a Lisfranc injury as they are

FIGURE 33-27 Plantar ecchymosis sign. Ecchymosis along the plantar aspect of the midfoot is an important clinical finding in subtle Lisfranc TMT injuries. (From RossG, Cronin R, HauzenblasJ, et.al. Plantar ecchymosis sign: A clinical aid to diagnosis of occult Lisfranc tarsometatarsal injuries. *J Orthop Trauma.* 1996;10:120.)

uncommon and difficult to diagnose but have a poor prognosis if left untreated.

Classification of Tarsometatarsal Injuries

Hardcastle et al.[63] developed a classification system based on the one developed by Queno and Kuss[137] in 1909 (Fig. 33-28). The classification comprises three types upon which treatment can be based.

Type A: Total incongruity. There is total incongruity of the entire metatarsal joint in a single plane. This can be either coronal or sagittal or combined.

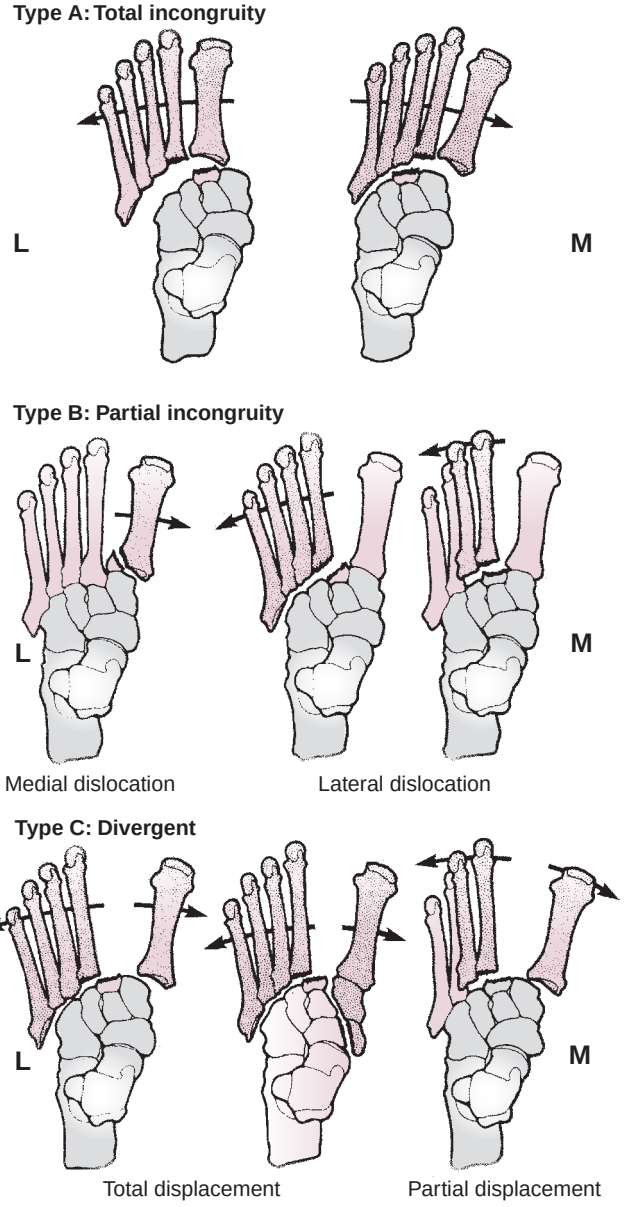

FIGURE 33-28 Classification of TMT dislocations. L, lateral; M, medial. (From DeLee JC. Fractures and dislocations of the foot. In: Mann RA, Coughlin MJ. *Surgery of the Foot and Ankle.* 6th ed. St. Louis, MO: Mosby, 1993:1465–1703, with permission; From Hardcastle PH, Reschauer R, Kutscha-Lissberg E, et al. Injuries to the tarsometatarsal joint: Incidence, classification, and treatment. *J Bone Joint Surg Br.* 1982;64:349–356.)

Type B: Partial incongruity. Only partial incongruity of the joint is seen involving either medial displacement of the first metatarsal or lateral displacement to the four lateral metatarsals. The medial dislocation involves displacement of the first metatarsal from the first cuneiform because of disruption of the Lisfranc ligament or fracture at the base of the metatarsal, which remains attached to the ligament.

Type C: Divergent pattern. The first metatarsal is displaced medially; any combination of the lateral four metatarsals may be displaced laterally. This is associated with partial or total incongruity.

This classification does not address the nondisplaced TMT joint injury which can often be overlooked on initial assessment.

Most children's injuries are type B with minimal displacement, whereas types A and C are rare.[63,137,180]

Imaging Evaluation of Tarsometatarsal Injuries

The initial x-ray evaluation includes AP, lateral, and oblique views of the foot. These should be performed weight bearing if possible to stress the joint complex.

On the AP radiograph, the lateral border of the first metatarsal should be in line with the lateral border of the medial cuneiform and the medial border of the second metatarsal should line up with the medial border of the middle cuneiform. On the oblique radiograph, the medial border of the fourth metatarsal should be in line with the medial border of the cuboid. The examiner looks for a disruption in these lines or diastases of greater than 2 mm between the base of the first and second metatarsals. It is very useful to obtain a weight-bearing radiograph of the opposite foot for comparison (Fig. 33-29). When the radiographs appear normal or minimally displaced and a Lisfranc injury is still suspected, alternative imaging with CT or MRI scans is strongly recommended. The CT scan will often show a small avulsion fracture of the first TMT ligament and will show any other associated fractures in the foot.[59,93,105] The MRI scan can accurately visualize a partial tear or complete rupture of the first TMT ligament.[134]

A fracture of the base of the second metatarsal should alert the examiner to the possibility of a TMT dislocation because these injuries can spontaneously reduce. Likewise, a cuboid fracture in combination with a fracture of the base of the second metatarsal is highly suspicious for a Lisfranc injury (Fig. 33-30).

If weight-bearing radiographs are not possible, an abduction stress view can be obtained; however, in children these are difficult to obtain without general anesthesia. Bone scans may be helpful in the diagnosis of this injury when radiographs are normal, although they are not specific for the severity of the injury[61] and less useful than MRI or CT.

Surgical and Applied Anatomy of Tarsometatarsal Injuries

The TMT joint complex comprises the TMT joints, the intertarsal joints, and the intermetatarsal joints. The area represents the apex of the longitudinal and transverse arches of the foot and therefore its structural integrity is crucial in maintaining

FIGURE 33-29 Weight-bearing radiographs show a subtle Lisfranc injury to the right foot. Weight-bearing radiographs are essential for diagnosis; using the opposite foot for comparison is also helpful.

normal foot function. At the same time, there needs to be enough motion between the joints to allow the transfer of weight evenly from the hindfoot to the forefoot during the walking cycle. This intricate relationship is achieved by the anatomy of the tarsal and metatarsal bones and the arrangement of the ligaments. These midfoot bones are trapezoidal in cross section with their base dorsal. This creates a "Roman arch" effect, which is structurally very strong and helps maintain the transverse arch in the midfoot. The TMT joint complex can be divided up into a medial column and a lateral column. The medial column is a continuation of the talus and navicular and includes the cuneiforms and the medial three metatarsals. The lateral column is a continuation of the calcaneus and comprises the cuboid and the fourth and fifth metatarsals which articulate with it. The medial column has far less mobility than the lateral column, reflecting the increased need for stability on the medial side of the foot to maintain the longitudinal arch. This stability is also provided by the second metatarsal which is "keyed" into the step formed by the cuneiforms. This explains why the second metatarsal is usually fractured when a dislocation occurs across the TMT joint. The ligaments also play a big role in maintaining stability medially and movement laterally. The plantar ligaments are extremely strong compared to the weaker dorsal ligaments. The intermetatarsal ligaments help bind the lateral four metatarsals together but are absent between the first and second metatarsals. Instead, the second metatarsal is connected to the medial cuneiform by Lisfranc ligament (medial interosseous ligament) and an avulsion fracture of this strong ligament can sometimes be seen on radiograph (Fig. 33-31).[180]

The dorsalis pedis artery crosses the cuneiforms before it courses between the first and second metatarsals to form the plantar arterial branch. The deep peroneal nerve travels beside the artery but continues on to supply sensation to the first web space. This neurovascular bundle can be damaged by the injury and care must be taken protect these structures when internally fixing these fracture-dislocations. The tibialis anterior tendon inserts into the base of the first metatarsal and medial cuneiform. The peroneous longus tendon inserts into the plantar surface of the base of the first metatarsal and acts as a flexor of this bone. Together, these two muscles and their tendon insertions give added stability to the medial column of the foot.

Treatment Options for Tarsometatarsal Injuries

The key to treating these TMT injuries is to recognize the extent of the injury and the degree of instability. Once this is established, the appropriate treatment can be instigated. In all these injuries, a weight-bearing radiograph at the end of treatment should confirm anatomic congruency of the TMT joint complex.

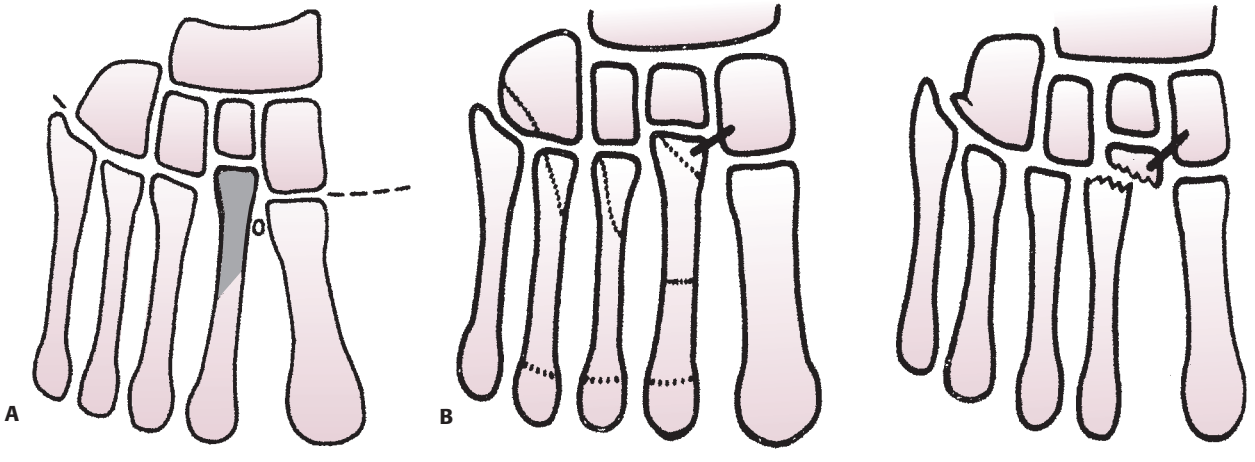

FIGURE 33-30 **A:** Second metatarsal is the "keystone" of the locking mechanism. **B:** Fractures of the cuboid and second metatarsal are pathognomonic signs of disruption of the TMT joints.

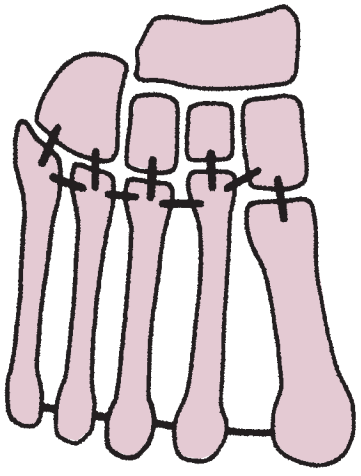

FIGURE 33-31 The ligamentous attachments at the TMT joints. There is only a flimsy connection between the bases of the first and second metatarsals (not illustrated). The second metatarsal is recessed and firmly anchored. (From Wiley JJ. The mechanism of tarsometatarsal joint injuries. *J Bone Joint Surg Br.* 1971;53:474, with permission.)

When a clinical diagnosis of a "sprain" is made, the foot should be immobilized in a below-knee cast for 6 weeks. The MRI scan may confirm a partial tear of the first TMT ligament, but regardless this painful injury takes time to heal and immobilization is the best treatment. In young adult athletes, these injuries can take a long time to heal.[114] When there is complete intraligamentous rupture or an avulsion fracture of the first TMT ligament and no displacement of the joint surfaces, a below-knee cast for 6 weeks is advised. Whether the patient should be weight bearing or not for the entire 6 weeks is debatable. Wiley[180] treated the children with undisplaced TMT joint injuries in his series with 3 to 4 weeks of immobilization with good results.

Displaced fractures of the TMT joint need to be anatomically reduced and stabilized. Meyerson et al.[120] found that following a closed reduction greater than 2-mm displacement or a talometatarsal angle of greater than 15 degrees would lead to a poor outcome. A closed reduction is best carried out under a general anesthetic when the acute swelling has subsided. "Finger traps" can help with traction on the toes while the displaced metatarsals are manipulated into place. If a stable anatomic reduction is achieved clinically and this is confirmed radiologically, a well-molded below-knee cast can be applied. Radiographs in the cast should also be taken while the patient is under anesthesia to confirm the reduction has been held. The non–weight-bearing cast is worn for 6 weeks with radiographs taken at 1 and 2 weeks to confirm the fracture-dislocation has remained reduced.

If the closed reduction results in an anatomic reduction but the fragments are unstable, then K-wire fixation is used to hold the alignment of the foot. Stout 0.062-in smooth K-wires should be used. Their placement is determined by the direction of displacement of the metatarsals and how many are involved. The most important wire is used to stabilize the second metatarsal to the medial cuneiform. Additional wires can be used between the first metatarsal and the medial cuneiform, and between the lesser metatarsals and their corresponding tarsal bones. A useful wire can also be passed from the first metatarsal to the second metatarsal. These K-wires are left bent over outside of the skin and are removed at 4 to 6 weeks when mobilization is initiated if the radiographs confirm healing. Again, full weight-bearing radiographs are necessary when comfort allows and after K-wire removal to confirm adequate stability. Wiley[180] used K-wire fixation in four patients. He removed these at 3 to 4 weeks and the alignment was maintained in all the children. There were some joint incongruities from intra-articular fractures that were not surgically addressed but they did not seem to alter the clinical outcome.

Open reduction and internal fixation is rarely required for these fractures. It is indicated if there is greater than 1 to 2 mm of joint displacement. The impediments to reduction are

1. Tibialis anterior tendon
2. Interposition of fracture fragments in the second metatarsal-middle cuneiform joint.
3. Incongruity of the first metatarsal-medial cuneiform articulation[15]

The entire TMT joint complex can be visualized using two longitudinal incisions.[155] One is made over the first second metatarsal space and the second in line with the fourth metatarsal. The medial incision allows identification of the neurovascular bundle and access to the first and second metatarsal cuneiform joints. The lateral incision allows the joints of the lesser TMT joints to be clearly seen. After anatomic reduction, the joints can held reduced with K-wires or internally fixed with 3.5-mm screws (Fig. 33-32). Small chondral defects can be excised and larger ones repaired. Care must be taken to avoid the proximal growth plate of the first metatarsal if screw fixation is used. The adult literature supports the use of K-wire stabilization of the lesser metatarsals rather than screws as it is important to maintain the mobility in these joints long-term.[47] Debate exists as to when to remove the screws across these weight-bearing joints. In a child, it would seem appropriate to remove the screws once pain free weight bearing is established as the ligaments and bone would have healed by this stage and further displacement is unlikely. Leaving the screws in for longer than 3 months risks damage to the joint and possible screw breakage.

Author's Preferred Treatment

The majority of children have a type B TMT dislocation with minimal displacement. The most important step in treating these patients is confirming this diagnosis accurately and treating them until the joint is stable. If any doubt in the diagnosis exists, the author takes a comparable radiograph of the other foot. The author routinely orders a CT scan of the midfoot to assess the extent of the injury and to look for any associated injuries.

An injury with less than 1 to 2 mm of displacement is treated in a below-knee non–weight-bearing cast for 6 weeks. Weight-bearing radiographs are taken on removal of the cast to assess stability. These radiographs are repeated 6 weeks later

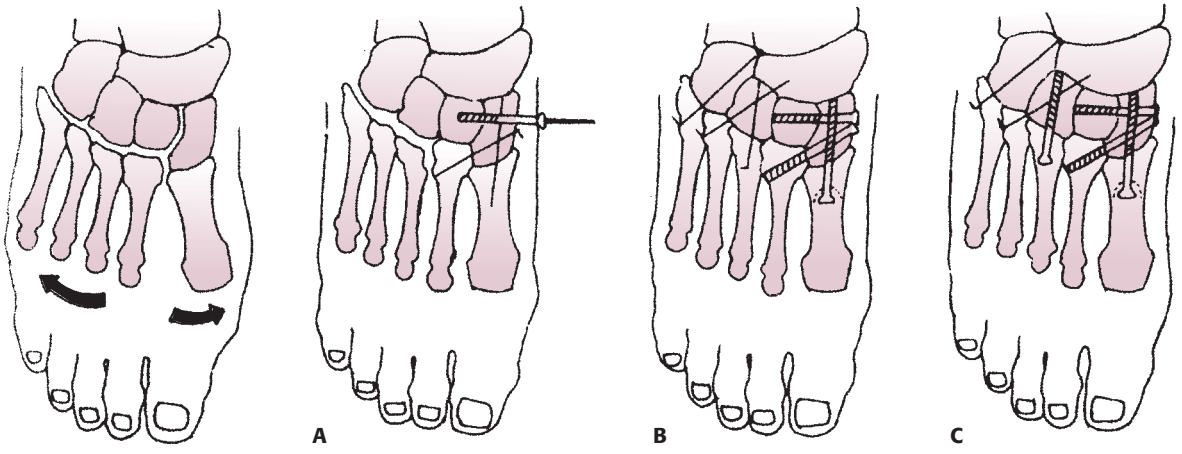

FIGURE 33-32 Sequence of repair for reduction and stabilization of TMT fracture-dislocations. **A:** Stabilization of the first ray by alignment of the metatarsal, medial cuneiform, and navicular. **B:** Stabilization of the Lisfranc ligament by accurate alignment of the second metatarsal to the medial cuneiform, as well as the medial and middle cuneiforms. **C:** Alignment and stabilization of the third through fifth metatarsal rays. Cannulated screws can be used instead of pins as needed for stability and compression. (From Trevino SG, Kodros S. Controversies in tarsometatarsal injuries. *Orthop Clin North Am.* 1995;26:229–238, with permission.)

once pain free weight bearing is achieved to confirm no further displacement.

If the TMT joint is displaced greater than 1 to 2 mm, then the author performs a closed reduction and routinely uses percutaneous K-wire fixation with image intensifier control. Although these injuries can be held with cast immobilization, the author prefers the assurance of knowing the fracture-dislocation is being held internally. This is especially useful when the foot is very swollen and repeated assessments are necessary to rule out compartment syndrome. In the rare circumstance of an open reduction, the author prefers to use temporary screw fixation. These injuries are usually far more severe than a type B dislocation and the TMT joints are very unstable. After open reduction through two longitudinal incisions, 3.5-mm cortical screws are used to hold the reduction taking care to avoid the proximal growth plate of the first metatarsal. These screws are removed usually within a month of cast removal.

Regardless of the way the fracture-dislocation is treated, all these patients must be investigated at outpatient appointments with weight-bearing radiographs to confirm that the ligaments have healed and there is no residual subluxation.

Complications of Tarsometatarsal Injuries

The most common complication following TMT injuries is posttraumatic arthritis. This can often occur because the injury is "missed" and the subtle fracture-dislocation remains displaced. Another cause is a loss of reduction. Lastly, the trauma itself can damage the articular cartilage and, despite an anatomic reduction, arthritis can develop.

Hardcastle et al.[63] showed that the outcomes are poor if the diagnosis is made more than 6 weeks after the injury. Curtis et al.[38] found similar results in athletes who had a delayed diagnosis. This reinforces the importance of making the diagnosis early and treating appropriately.

Posttraumatic arthritis is known to occur after TMT injuries in a significant percentage of adults, and this is best prevented by achieving an anatomic reduction.[120] Wiss et al.[183] performed gait analysis on 11 adult patients with TMT joint fracture-dislocations and found that no patient walked normally after a displaced TMT fracture-dislocation. In Wiley's[180] series of 18 children, none of whom required open reduction, 14 patients were asymptomatic 3 to 8 months postinjury. Four patients had persisting pain of minor severity at the TMT joint 1 year following injury. Two of these patients had residual angulation at the injury site. One patient had an unrecognized dislocation and had not been treated; the other had not had an anatomic reduction because of extensive intra-articular fractures. One 16-year-old patient developed asymptomatic osteonecrosis of the second metatarsal head, and this was attributed to a possible compromise of the blood supply at the time of injury as the nutrient vessel to this area is a terminal branch of the dorsalis pedis. Buoncristiani et al.[22] followed eight children (3 to 10 years old) with indirect TMT joint injuries treated in a below-knee cast and found seven were asymptomatic at an average follow-up of 32 months. The one patient who had midfoot pain had developed early degenerative changes on the plain radiographs.

The treatment for painful TMT joint arthritis is arthrodesis if conservative care has failed. In children this would be extremely unusual. An arthrodesis often requires extensive soft tissue release to allow anatomic reduction of the joint and then rigid internal fixation with screws. It is important not to fuse the lesser TMT joints as mobility here is important for the long-term function of the foot.

Metatarsal Fractures

Fractures of the metatarsals are the most common fractures of the foot in children, accounting for up to 60% of all pediatric

foot fractures.[37,38,125,161] Owen et al.[125] showed in an epidemiologic study that in children younger than 5 years of age, 73% of metatarsal fractures involve the first metatarsal, whereas in children older than 10 years these fractures accounted for only 12%. The most common metatarsal fracture for all 60 patients was a fracture of the fifth metatarsal (45%). Six and a half percent of all the fractures and 20% of first metatarsal fractures were not diagnosed at the initial consultation in their series.

Management of Metatarsal Fractures

Mechanism of Injury

Metatarsal fractures result from either a direct or indirect injury. Direct injuries are usually caused by a heavy load falling on the forefoot or a crush injury (i.e., the foot being run over by a car). The metatarsals can be fractured anywhere along the shaft but typically they are fractured middiaphyseal. Indirect injuries are caused by axial loading or torsional forces and usually produce spiral fractures of the proximal shaft or neck of the metatarsal. Singer et al.[161] found in a recent study of 125 children that if the patient was less than 5 years of age, the primary mechanism was a fall from a height and this usually occurred within the home. In children older than 5 years of age, most injuries occurred while playing sport and occurred on a level playing surface.

Signs and Symptoms of Metatarsal Fractures

Direct injuries can result in significant swelling and bruising of the foot because of the extensive soft tissue injury as well as the metatarsal fractures. Careful evaluation of a compartment syndrome should take place. An indirect injury usually has more subtle clinical findings and careful palpation will usually locate the site of the fracture. The infant with a metatarsal fracture due to an unwitnessed injury may present with minimal swelling but an inability to bear weight.

Associated Injuries with Metatarsal Fractures

Proximal fractures of the metatarsals are often associated with tarsal fractures or fracture-dislocations, and this should be evaluated further with a CT scan. A fracture of the second metatarsal and a cuboid fracture are highly suggestive of a TMT joint dislocation rather than two isolated fractures. Singer et al.[161] found that the first and fifth metatarsals were usually isolated fractures, whereas if multiple metatarsals were fractured, they were always contiguous bones and involved the second, third, and fourth metatarsals.

Imaging Evaluation of Metatarsal Fractures

Radiographic evaluation should consist of AP, lateral, and oblique views of the whole foot. The AP view often gives the impression that the fractures are minimally displaced; however, the lateral view often shows significant plantar or dorsal displacement. Other associated fractures may be apparent on the plain radiographs and if any doubt exists, especially if there has been significant trauma, a CT scan is advised. In a young child, if a fractured metatarsal is suspected but not visible on the initial radiograph, a repeat film can be taken 10 to 14 days later that often shows the fracture line or early callus.

Classification of Metatarsal Fractures

No classification system exists for fractures of the first through fourth metatarsals. Fractures of the fifth metatarsal are classified according to their location along the bone (see section on treatment of the fifth metatarsal below).

Current Treatment Options for Metatarsal Fractures

The majority of metatarsal fractures in children can be treated nonoperatively in a below-knee cast. The child with a displaced fracture often needs to be admitted overnight in the hospital for pain relief and observation for compartment syndrome. The initial treatment includes elevation for the severe swelling that coexists with the fractures. Immobilization may be performed by a well-padded cast, splint, or a Cam walker. Once the swelling subsides, a molded below-knee cast can be applied. Weight bearing can be initiated when pain allows, and the cast can usually be removed at 3 to 4 weeks at which time the patient can be transitioned to a Cam walker.

The amount of angulation or shortening to accept in a child has not been determined. A closed reduction of the central metatarsals is indicated in an adult if there is more than 10 degrees angulation in the dorsal plain or more than 4 mm of translation in any plane.[159] These criteria may be appropriate for an older adolescent whose growth plates had closed but are far too stringent for a skeletally immature patient. If there is severe dorsal angulation of greater than 20 degrees or "tenting" of the skin and shortening of greater than 5 mm, then a closed reduction is indicated. This is best performed under a general anesthetic when the swelling has subsided. Finger traps have been advocated by some surgeons to help with traction while the metatarsals are manipulated. A below-knee cast can be molded with pressure applied to both the dorsal and plantar aspects of the foot; however, the need to allow for swelling suggests implants should be used to hold fracture reduction rather than molding of a cast. To accommodate the swelling and to relax the plantar fascia, the cast can be applied with the ankle in slight equinus and when it is changed 2 weeks later, it can be bought up into a neutral position.

Fractures of the first metatarsal need careful attention especially in the adolescent patient. The first ray is important in maintaining the longitudinal arch of the foot and the position of the first metatarsal head in relation to the lesser metatarsal heads is also vitally important. A closed reduction should be considered if there is greater than 10 degrees of dorsal angulation or any shortening of the first metatarsal. It is unusual to have angulation in the coronal plane if the second metatarsal is intact and transverse displacement is acceptable if there is no shortening.

If a closed reduction is performed, K-wire fixation is at times required. Intramedullary placement is difficult to perform without opening the fracture and passing the wires under direct vision. Small, dorsal, longitudinal incisions are made over the fracture sites and dissection is carefully carried out down to

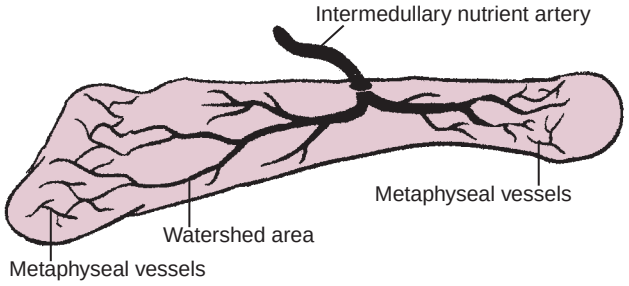

FIGURE 33-33 Blood supply of the proximal fifth metatarsal.

the fracture. The wire is drilled down the distal fragment to exit the plantar skin. The wire is then withdrawn enough to allow the fracture to be reduced, then the wire is driven retrograde across the fracture site and sufficiently far enough into the proximal fragment. Another technique is to hold fracture reduction by placing K-wires across the fractured metatarsal to an adjacent nonfractured metatarsal both proximal and distal to the fracture. The K-wire is cut and bent outside the skin to facilitate removal in the outpatient clinic in 3 to 4 weeks when the patient can be placed in a walking cast for 2 further weeks to allow fracture consolidation. This is the same technique that can be used on the rare occurrence an open reduction is required for an irreducible fracture or when the fracture is open.

Fractures of the Base of the Fifth Metatarsal

Fractures of the fifth metatarsal are the most common metatarsal fracture in children, comprising almost 50% of all metatarsal fractures in some series.[68,125,138,161] Traditionally, treatment has been based on treatment algorithms from the adult literature. Fractures of the base of the fifth metatarsal are discussed separately from the other metatarsal fractures as the anatomy, fracture patterns, and treatment indications are quite different.

Surgical Anatomy

The fifth metatarsal has a number of tendinous insertions at its base. The peroneus brevis tendon inserts on the dorsal aspect of the tubercle and the peroneus tertius attaches on the dorsal aspect of the fifth metatarsal at the metaphyseal–diaphyseal junction. The strong plantar aponeurosis inserts into the plantar aspect of the tubercle at the base.

The nutrient artery enters the shaft of the fifth metatarsal medially at the junction of the proximal and middle thirds of the diaphysis and sends intraosseous branches proximally and distally (Fig. 33-33). Proximally within the bone are the metaphyseal vessels, and the small area where these overlap with the proximal vessels from the nutrient artery is known as the watershed area. This region corresponds with Zone 2 and fractures in this area have a higher rate delayed of union or nonunion in those close to maturity. The proximal apophyseal growth center of the fifth metatarsal can often be confused for a fracture. The apophyseal growth center (os vesalianum) has a longitudinal orientation roughly parallel to the metarsal shaft and generally has smooth contours which distinguish it from a transverse orientated fracture (Fig. 33-34). The os vesalianum usually appears by the age of 9 years and unites with the metaphysis between the ages of 12 and 15 years (Fig. 33-35).

Classification

Fractures of the base of the fifth metatarsal are classified according to their location into one of three zones (Fig. 33-36). Zone 1 is the cancellous tuberosity, which includes the insertion of the peroneus brevis tendon, the abductor digiti minimi tendon, and the strong calcaneometatarsal ligament of the plantar fascia.

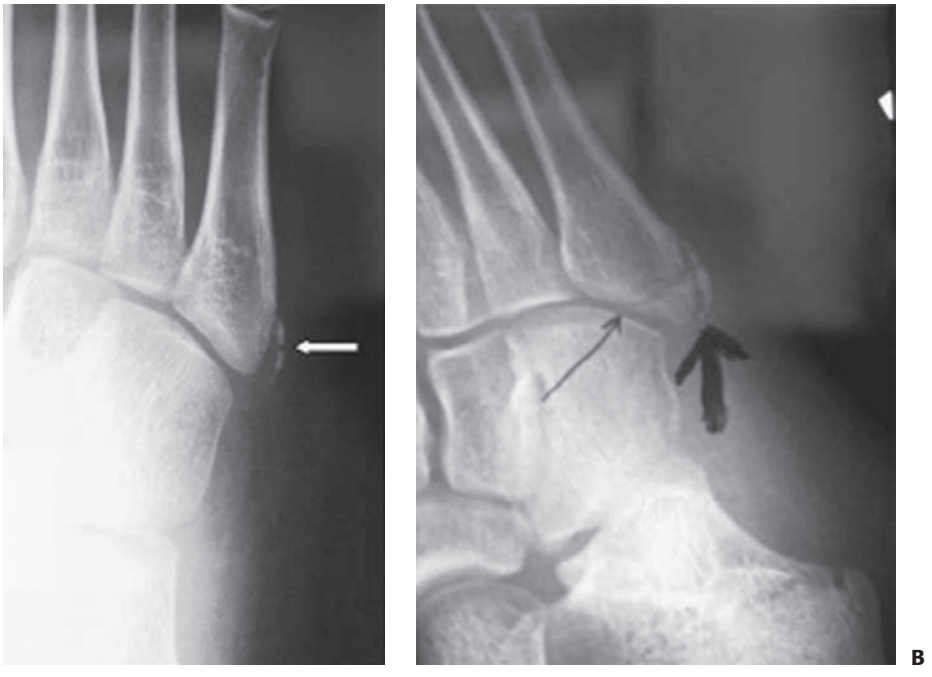

FIGURE 33-34 **A:** A normal apophysis of the base of the fifth metatarsal at the attachment of the peroneus brevis (*arrow*) in a 10-year-old girl. **B:** The *thicker arrow* points to the normal apophysis, which is roughly parallel to the metatarsal. The *thinner arrow* points toward a fracture, which is roughly perpendicular to metatarsal.

FIGURE 33-35 This 11-year-old girl had pain in her proximal fifth metatarsal after twisting her foot during physical education at school. No fracture was visible; however, her secondary ossification center is clearly seen running parallel to the shaft of the metatarsal.

Zone 2 is the distal aspect of the tuberosity where the dorsal and plantar ligamentous attachments to the fourth metatarsal attach to insert. Zone 3 is the region that extends from distal to these ligamentous attachments to approximately the middiaphyseal area. Herrera-Soto et al.[68] tried to define this classification further in their recent review of 103 children with fifth metatarsal fractures. They define a type I fracture as a "fleck" injury. A type II fracture is a tubercle fracture with an intra-articular extension, and a type III fracture represents a fracture at the proximal diaphyseal region (Jones fracture).

Treatment

Traditionally, treatment has been based on treatment algorithms from the adult literature. Treatment of fractures of the base of the fifth metatarsal in children is determined primarily by the zone of the fracture, and somewhat by age.

Zone 1 Fractures. These injuries are usually traction-type injuries where the force from the peroneus brevis tendon and the pull from the plantar aponeurosis result in an avulsion fracture of the fifth metatarsal. Some authors suggest the fracture may be an avulsion at the origin of abductor digiti minimi.[83,143] Treatment involves a weight-bearing below-knee walking cast for 3 to 6 weeks. Herrera-Soto et al.[68] found all 30 of their children with an extra-articular type 1 fracture treated in this way healed with good outcomes even if they were displaced. Undisplaced intra-articular tuberosity fractures also healed well in the series[68]; however, displaced (>2 mm) intra-articular fractures took significantly longer to heal. Radiographic union usually lags behind resolution of symptoms, and most patients are asymptomatic after 3 weeks.[68] This delay in radiographic union should not prevent the child returning to full activities as symptoms allow. Treatment with a Cam walker rather than a cast may be considered. Nonunion can occur but usually is asymptomatic.[39] Although operative fixation of acute tuberosity avulsions rarely is indicated, it may be considered for significant displacement (more than 3 mm) in young active patients who want to return to competitive sports sooner (Fig. 33-37).

Zone 2 Fractures. Zone 2 fractures include the Jones fracture. This is an oblique fracture in the watershed area at the proximal metaphyseal–diaphyseal junction. It typically occurs in adolescents and is thought to be caused by a combination of vertical loading and coronal shear forces at the junction of the stable proximal metaphysis and the mobile fifth metatarsal diaphysis. Frequently, these fractures are stress injuries, usually involving athletic adolescents who present with a traumatic event superimposed on prior symptoms.[24,36,81,82,92,148] A good history is important to determine the duration of symptoms because chronic injuries are unlikely to respond to nonoperative treatment as well as acute fractures. Critical radiographic analysis will also show cortical sclerosis in the chronic injuries.

Acute injuries should be immobilized in a short-leg non–weight-bearing cast for 6 weeks. Serial radiographs and examinations are necessary to determine adequate healing, and further non–weight-bearing immobilization may be necessary if the fracture has not healed clinically and radiographically at 6 weeks. With evidence of callus and diminished tenderness,

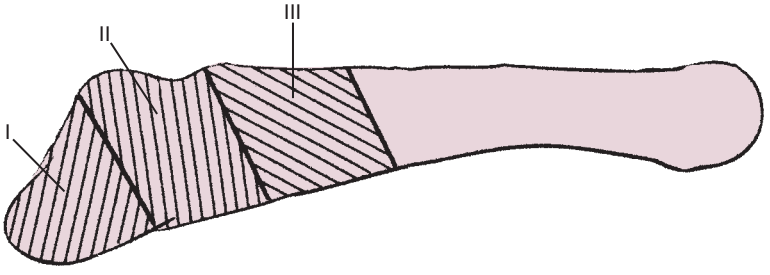

FIGURE 33-36 The three anatomic zones of the proximal fifth metatarsal.

FIGURE 33-37 **A:** A 12-year-old boy who is a professional snowboarder with a displaced, intra-articular fifth metatarsal fracture. **B:** This was reduced open and internally fixed, which allowed him to compete 8 weeks after surgery.

the patient can begin protected weight bearing in a hard-soled shoe or Cam walker for an additional 4 weeks. This protected weight bearing may prevent refracture.[68] In a series of adults, Torg et al.[171] reported successful healing in 14 of 15 patients treated with non–weight-bearing casts, whereas only 4 of 10 who were allowed to bear weight went on to union. Herrera-Soto et al.[68] reported 15 fractures in this zone (type III) and found a higher rate of delayed union and refracture in patients over 13 years of age. They feel that primary internal fixation in this age group may be indicated.

For chronic fractures in zone 2 where the symptoms have been present for more than 3 months, nonoperative management is unlikely to be successful. Nonetheless, it is worthwhile initially trying 6 weeks immobilization in a non–weight-bearing below-knee cast or brace. If this fails, then internal fixation is required. A useful technique is to insert an intramedullary screw from proximal to distal which stabilizes the fracture site. A 4-mm cancellous screw is usually sufficient; however, in an older adolescent with a capacious intramedullary canal, a 6.5-mm cancellous screw may give better fixation and compression. It is beneficial to curette the intramedullary canal and use cancellous bone graft, which can be harvested from the distal tibia (Fig. 33-38).[94]

Zone 3 Fractures. Fractures in zone 3 are usually stress fractures in active athletes. Acute fractures in this zone with no prodromal symptoms can be treated with a below-knee non–weight-bearing cast for 6 weeks followed by protective weight bearing for 4 weeks. In the more common scenario, where the patient complains of pain with activity for several months, this period of casting is often unsuccessful but worth trying in the first instance. The stress fracture may heal clinically with 6 to 12 weeks of immobilization and radiographs will confirm the reconstitution of the medullary canal and less sclerosis at the fracture site. Electrical stimulation may be used. If the chronic stress fracture does not heal, then surgical intervention is required similar to that in a zone 2 fracture outlined above. Some authors advocate a more aggressive open debridement of the fracture site with bone grafting before introducing the intramedullary screw.[137,171]

Complications

The most common complication of treating fractures of the proximal fifth metatarsal is a painful nonunion. This is more common in zone 2 and zone 3 fractures and rarely occurs in zone 1. Herrera-Soto et al.[68] concluded that pediatric fifth metatarsal fractures behaved similarly to adult fractures and can be treated the same. If a symptomatic nonunion develops and surgery is indicated, a thorough debridement of the sclerotic medullary canal should be undertaken, the area bone grafted, and strong compression achieved across the fracture site with the appropriate size intramedullary screw.[58]

Author's Preferred Treatment

Lesser metatarsal fractures are usually treated nonoperatively in a below-knee walking cast for 3 to 4 weeks. Grossly displaced fractures in older children with greater than 20 degrees of dorsiflexion or more than 5 mm of shortening are treated

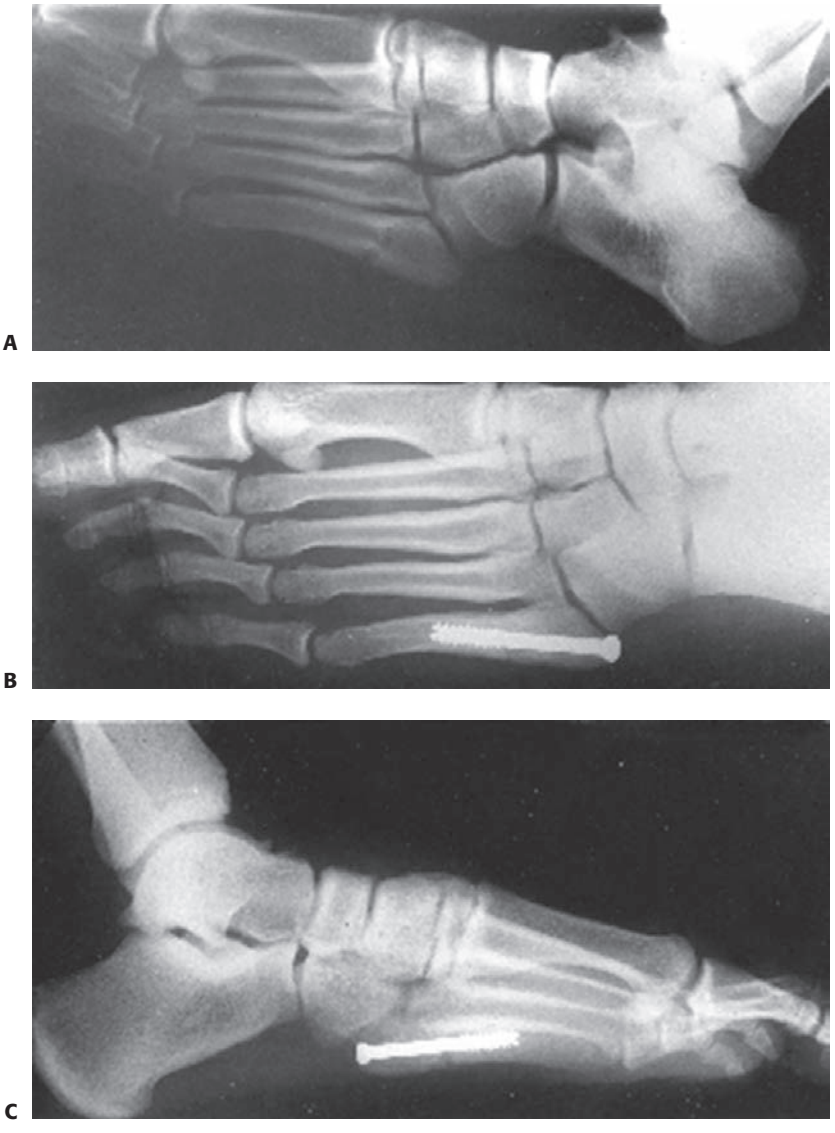

FIGURE 33-38 This 15-year-old high-level basketball player sustained a proximal fifth metatarsal fracture at the metaphyseal–diaphyseal junction. The patient chose intramedullary screw fixation because of his desire to return to sport as promptly as possible, lessen his time in immobilization, and lessen the risk of delayed union or nonunion. **A:** Radiograph at time of injury. **B, C:** After intramedullary screw fixation. (Courtesy of Keith S. Hechtman, MD.)

with closed reduction under a general anesthetic and a well-molded below-knee cast. If the reduction is difficult, percutaneous K-wires are used for supplementary support. Except for open injuries, rarely is an open reduction through longitudinal incisions required.

A shortened or rotated distal fracture of the first or fifth metatarsal is treated by closed reduction and crossed K-wire fixation.

Proximal fifth metatarsal fractures present a more challenging problem. Treatment is determined by the location of the fracture in the bone and the age and activity level of the child. If inadequately treated, they can go on to a delayed or nonunion. For zone 1 fractures that are intra-articular and displaced greater than 3 to 4 mm, the author recommends open reduction and internal fixation with a 3.5-mm partially threaded screw, especially if the child is involved in competitive sports, as this will allow an earlier return to sport. This fixation is perpendicular to the fracture line and gives maximum compression. The screw is inserted through a direct lateral approach. Care must be taken to identify and protect the sural nerve which is usually directly under the incision. The peroneous brevis and peroneous tertius tendons are identified, and the area between them at their insertion into the proximal fifth metatarsal is a good starting point for the screw. The author prefers to insert a bicortical cannulated compression screw, and this can either be a partially threaded cancellous screw or a fully threaded cortical screw. The fracture can usually be indirectly reduced and held with a K-wire. In difficult fracture patterns or in delayed presentations, the fracture line needs to be clearly seen and can be held reduced with a compression clamp.

In zone 2 fractures (Jones fracture), the author treats the patient in a non–weight-bearing cast for 6 weeks and then protected weight bearing in a moon-boot for 2 to 4 weeks as comfort allows. The recent study by Herrera-Soto et al.[68] showing poor results with this treatment in patients over 13 years old may make primary internal fixation a better option in this age group.

Chronic fractures or nonunions should be treated with internal fixation. The author prefers to perform this with

an intramedullary screw which compresses the fracture site. If a 3.5-mm cancellous screw does not achieve adequate internal fixation in the medullary canal, the author increases the diameter of the screw until it does. Often, a 4-mm malleolar screw is used. A small curette is used down the medullary canal to help remove the sclerotic bone. If this is not possible, the fracture site should be debrided open with small osteotomes and rongeurs. Bone grafting is required for these chronic injuries and can be harvested from the distal tibia.

Grossly displaced shaft and distal metaphyseal fractures are treated with closed reduction and cast immobilization for 6 weeks. Occasionally, crossed K-wires are required.

Phalangeal Fractures

Phalangeal fractures are common in children and may account for up to 18% of pediatric foot fractures.[37] Most toe injuries are treated by primary care physicians, so orthopedic surgeons only see the more severe fractures. Phalangeal fractures are the result of direct trauma by a falling object or indirect trauma when the unprotected toe is struck against a hard object (so-called "stubbing"). The proximal phalanx is more commonly injured than the distal phalanges.

The toes must be closely examined for any break in the skin especially at the base of the nail as this may indicate an open Salter–Harris fracture with an associated nail bed injury. These compound injuries require a thorough debridement, repair of the nail bed, and often a single longitudinal K-wire to stabilize the fracture (Fig. 33-39). IV antibiotics should be given for 24 hours followed by 7 days of oral antibiotics. Nail bed injuries should be repaired as meticulously as in the hand. A poorly repaired germinal matrix will cause abnormal nail growth and difficulty with shoe wear long after the fracture has healed.

Closed fractures of the phalanges rarely require reduction and can be treated by simple "buddy strapping" to the adjacent toe and immediate mobilization. A hard-soled shoe or Cam walker may help; however, crowding in the toe box may make this more uncomfortable than bare feet. An angulated toe in both the coronal and sagittal plane usually remodels well if the growth plate is still open. In adolescents, a percutaneous K-wire can be used if the fracture is grossly unstable and unable to be held reduced by strapping alone. This wire can be passed longitudinally through the tip of the affected toe or obliquely across the fracture. It is extremely unusual to get any growth disturbance from a smooth wire crossing the growth plate in the phalanges. These pins can be removed in clinic 4 to 6 weeks later. Laterally angulated fractures of the little toe sometimes need closed reduction before strapping them to the fourth toe.

Nail Bed Injuries

Nail bed injuries to the toes should be treated similarly to those in the fingers (see Chapter 8). Failure to address the nail bed

adequately can lead to abnormal nail growth and problems with shoewear (Table 33-4; Fig. 33-40).

Great Toe Fractures

The great toe is injured by the same mechanisms as the lesser toes. Standard AP and lateral radiographs are taken; however, it is useful to have the patient hold the lesser toes dorsiflexed with a small towel to maximize visualization on the lateral view. Intra-articular fractures of the proximal phalanx are more common in the great toe than the other toes. They are usually Salter–Harris type III or IV fractures (Fig. 33-41). Most of these fractures can be managed with "buddy strapping" to the second toe; however, if greater than 25% of the joint surface is involved and there is displacement of more than 2 to 3 mm of the joint surface, reduction should be performed. Fracture reduction may be held by strapping to the second toe or a percutaneous

TABLE 33-4 Repair of Nail Bed Injury

1. Use sterile tourniquet (glove)
2. Remove the nail
3. Thoroughly clean the nail bed gently
4. Repair the nail bed with fine absorbable suture (6-0 or 7-0 rapid dissolving suture)
5. Replace the nail to protect the eponychial fold with skin glue
6. Cover with sterile dressing and tape
7. Leave dressing intact for 10 days then debulk dressing

K-wire. In the rare occasion that this is not successful, an open reduction can be performed either through a midlateral or dorsal incision. With diaphyseal fractures, axial alignment and rotation both need to be addressed with the closed reduction. Often, the clinical appearance of the toe following the reduction is more useful than the postreduction radiograph as the toe usually looks "fine" even though the radiograph shows malalignment.

Lawnmower and Other Mutilating Injuries

There are approximately 9,400 lawnmower injuries a year in the United States affecting children 20 years or younger with an average age of 10.7 years. This incidence has not changed in 15 years, indicating that new safety regulations have been ineffective.[174] These accidents occur with all types of lawnmowers; however, the most severe injuries are a result of a child being run over by a riding-mower.[103,175] Seventy-two percent of children who have severe lawnmower injuries are bystanders.[46,175] Ross et al.,[146] however, had a higher number of children in their series who fell off the riding-mowers and were run over. Seventy-eight percent of all lawnmower accidents occur in boys.[174] Loder et al.[103] reviewed 235 children who had a traumatic amputation and found that these injuries are more common in the spring and summer. Children under the age of 14 years are most susceptible to injury with those under the age of 6 years having the greatest risk of death.[121] The most common body region injured is the hand (34.6%), followed by the leg (18.9%) and the foot (17.7%) (Fig. 33-42).[174]

Treatment of Lawnmower and Other Mutilating Injuries

The initial treatment for these children is a thorough assessment of the injuries suffered and appropriate resuscitation. Often, a large volume of blood has been lost from the time of the accident to arriving in the emergency department. Once the child is stabilized, a secondary survey can be conducted to assess the extent of the injury to each limb. With regard to the foot, these injuries are mutilating and heavily contaminated with soil and grass. After inspection, the wound should be dressed and a firm bandage applied to prevent further bleeding. Antibiotics need to be administered as soon as possible and include

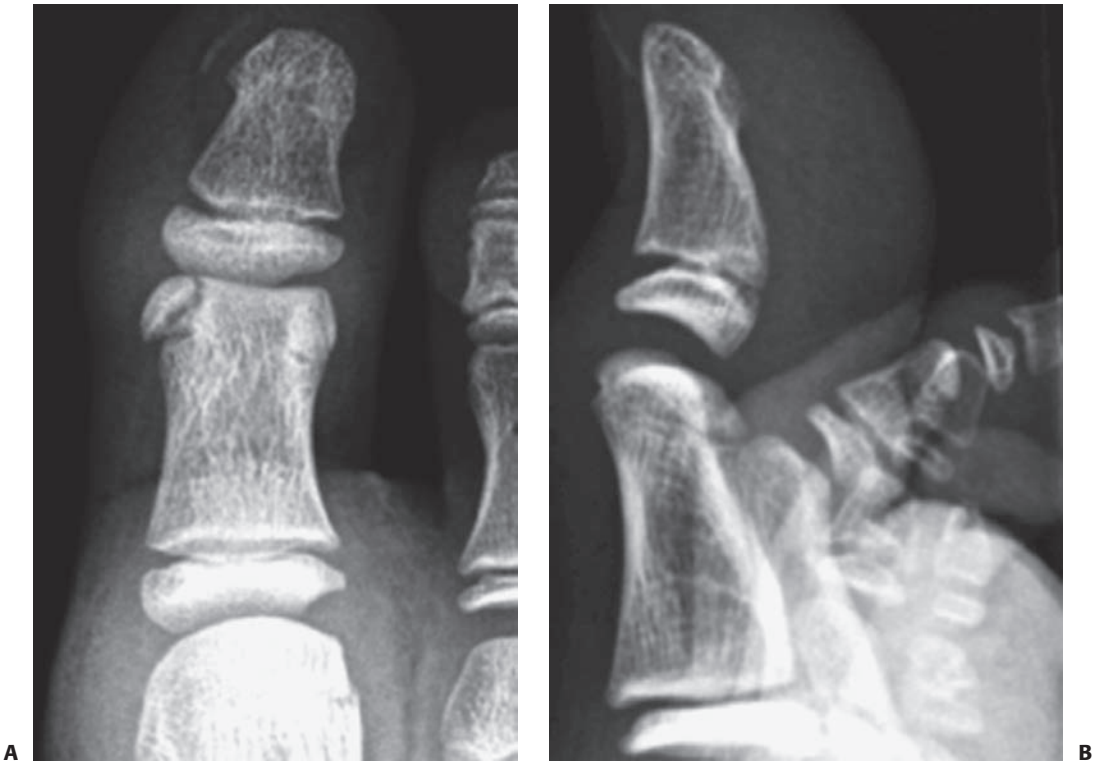

FIGURE 33-41 A: An 11-year-old boy with an intra-articular fracture of the proximal phalanx of the great toe. Successful treatment was achieved with simple buddy strapping. **B:** A lateral radiograph of the great toe is best taken with the lesser toes held flexed with a bandage.

FIGURE 33-42 A 4-year-old boy with a severe lawnmower accident after being run over by the driver. There was extensive soft tissue loss and compound fractures to the foot. Despite multiple debridements, the leg was amputated below the knee.

a cephalosporin, aminoglycoside, and penicillin. The patient's tetanus status should be ascertained and tetanus prophylaxis administered if unknown.

The child then needs to be taken urgently to the operating room for the initial debridement. Considerable time should be spent removing the foreign material as meticulously as possible. A water jet lavage system can be useful, but should be used with care as it can force debris further in to the soft tissue envelopes. Devitalized tissue should be debrided; however, questionable tissue should be left as there will be multiple return trips to the operating room when further debridements can take place. It is useful to involve a plastic surgeon even at this initial surgery so they can see the extent of the damage and start planning for definitive coverage. The child will generally need at least three trips to the operating room and some cases many more.[46] These return trips should be every 24 to 48 hours detreatment and what effect prolonged treatments and hospitalizations will have on the child. Amputation rates vary between 16% and 78% in the literature.[7,46,175] A mangled extremity severity score (MESS) has been developed in adults to help surgeons make these decisions.[80] The MESS score was validated in children by Fagelman et al.[52]; however, they did not include fractures below the ankle. It is useful to ask for a colleague's advice when contemplating an amputation so the advantages and disadvantages can be freely debated. If an amputation is performed, as much length of the bone should be preserved as possible, and transdiaphyseal amputation should generally be avoided to prevent problems with stump overgrowth.[2,104] The functional outcome for these patients is generally satisfactory. Vosburgh et al.[175] reviewed the functional outcome of 21 children with lawnmower accidents and found that patients who had their injury confined to the forefoot had 88% of normal function compared to 72% of normal function in patients who had sustained injuries to the posterior and plantar aspects of their foot pending on the state of the wound. Each debridement is important and should not be left to the most junior member of the surgical team to perform. Every piece of viable skin is vital and may be the difference between a primary closure over an amputation stump or a skin graft or tissue transfer. There is no hurry to close the wound until the soft tissue and bone is completely free of foreign material and the tissues are well perfused. Shilt et al.[160] have found the use of VAC safe and effective in managing these types of lawnmower injuries. Fractures need to be stabilized and initially external fixation is useful. This allows plenty of room for further debridements and does not compromise later internal fixation once the soft tissue coverage has been determined.

Skin grafting or flap coverage of lawnmower injuries is required in approximately 50% of cases.[46] Unlike adults, split-thickness skin grafting can function very well on the weight-bearing surfaces in children.[46,175] When the soft tissue defect is large or there is exposed bone that would be better to preserve than excise, a free tissue transfer is helpful.[50,100] Lin et al.[101] recently reviewed 93 microsurgical reconstructions of soft tissue defects of the pediatric foot. They reported excellent results with free musculocutaneous flaps or skin grafted muscle flaps. For plantar foot reconstructions, the musculocutaneous flaps had better results with fewer tropic ulcers and fewer resurfacing procedures. They also found that reconstruction of the tendons in the immediate setting led to fewer subsequent operations than staged tendon reconstructions.[101]

One of the problems with free flaps is their bulk and the subsequent problems with shoe fitting. An alternative to a free muscle flap is a free fascial flap. A common one used is the temporoparietal fascial flap[33,41,162] This fascia is supplied by the superficial temporal artery which is a terminal branch of the external carotid. The graft can be as large as 12 × 14 cm; however, this varies with the age and size of the child. It is harvested through an incision within the hairline which results in a cosmetic closure (Fig. 33-43A). The fascial flap can then be used to cover exposed bone and tendons in the foot (Fig. 33-43B–D). Split skin can then be grafted onto the fascia and any surrounding areas of full thickness skin loss

One of the most difficult decisions to make while treating these severe injuries is whether to salvage the affected part of the limb or amputate the questionable part. This decision is largely based on what the functional outcome will be with either

Crush Injuries to the Foot

Severe crush injuries to the foot in children are rare but the consequences of not recognizing the degree of injury can be devastating. The commonest cause is the foot being run over by a car tire and there is both a crush and shearing force (Fig. 33-43). An alternative injury would be a very heavy weight falling on the foot.

The child presents with an extremely painful, tight foot usually with the skin intact. If the child was wearing shoes these can be difficult to remove and they may need sedation first. Initial primary and secondary surveys need to be carried out to exclude other injuries and then a thorough assessment of the foot undertaken.

It is important to continually assess the child for compartment syndrome and perform fasciotomies when indicated (see Compartment syndrome below).

Sesamoid Fractures

There are a number of sesamoid bones in the foot; however, the most commonly symptomatic ones are the two within the plantar plate of the first metatarsophalangeal joint and in the flexor hallucis brevis tendons. These medial and lateral sesamoid bones are important both for shock absorption and to provide a fulcrum to improve the biomechanical function of the tendons to the first toe.

A

B

C

D

FIGURE 33-44 **A:** Medial sesamoid of the right foot appears fractured following a great toe injury. A radiograph of the left foot confirms a similar partite sesamoid that is asymptomatic. **B:** Asymptomatic partite patella in the contralateral uninjured foot **C:** Tangential sesamoid views can be useful however in this case the radiograph does not show the transverse partite sesamoid. **D:** An MRI scan of the right foot 5 months after the injury for a different problem shows the partite medial sesamoid.

Acute sesamoid fractures are rare in children and diagnosis is difficult because of the variable anatomy of the medial and lateral sesamoid bones. They can have more than one ossification centre which may or may not unite resulting in a partite sesamoid. The incidence of partite patellas varies between 19% and 31%.[45,85] The incidence of a partite sesamoid is approximately 10 times higher in the medial sesamoid compared to the lateral one. The incidence of bilaterality varies between 25% and 85%.[35,77]

An acute fracture to the sesamoids is usually caused by a fall from a height onto the forefoot which may be associated with a forced dorsiflexion of the first metatarsal. This results in acute pain and swelling under the first metatarsal head and pain on dorsiflexion of the first toe. A more common cause of sesamoid pain is a stress fracture or inflammation of the sesamoid (sesamoiditis). This occurs from repetitive dorsiflexion of the great toe for example in runners and dancers.

Specific radiographs need to be taken to help differentiate whether this is an acute or chronic condition. Anteroposterior and lateral weight-bearing views coned on the sesamoids should be requested. A tangential view is also advisable (Fig. 33-44A–D). An acute fracture will usually be transverse, have a "jagged" appearance, and have sharp corners. It is not widely displaced as the fragments are contained within the plantar plate. Wide displacement would represent a major disruption to the first metatarsophalangeal joint which would be obvious clinically. Another useful tip is that the sum of the fragment sizes should add up to the "normal sesamoid size." Two partite fragments are often much larger when combined than one would normally expect with a fracture. Radiographs of the opposite foot can be helpful for comparison however with the variable incidence of bilaterality mentioned above a definitive diagnosis is not always possible.

Treatment for a closed injury with an intact planter plate is nonoperative. Immobilization in a below-knee plaster cast with a toe plate for 4 to 6 weeks is advisable. Alternatively a moot-boot with a midfoot ridge to unload the forefoot can be used. Transition from the cast into a stiff-soled shoe that continues to prevent dorsiflexion will give symptomatic relief. With stress fractures and sesamoiditis a longer period of immobilization may be necessary.

Surgical intervention is rarely required. If a symptomatic nonunion occurred this can be treated by open reduction and bone grafting which is technically difficult or by excision of the smaller of the two fragments. Either way care needs to be taken to avoid damage to the plantar plate.

Compartment Syndrome

Compartment syndrome of the foot can occur in children with severe soft tissue injuries in the presence or absence of associated fractures. Most commonly, it occurs with severe crush injuries of the forefoot where there are multiple fractures and dislocations; however, it can occur without any fracture, such as the case of a car running over a foot causing crush and shear injury to soft tissue. The symptoms are not as obvious as they are in compartment syndrome of the forearm or leg, and increased pain with passive motion of the toes is not always present. There is significant pain from the injury itself, which often requires considerable amounts of pain relief. Pallor, pain on passive extension, paresthesia, and a dorsalis pedis pulse that is difficult to palpate likewise can all be clinical signs in a large number of foot injuries. The clinician needs to have a high index of suspicion for a compartment syndrome and if any doubt exists, the compartment pressures should be measured or the child taken urgently to the operating room for a decompression of the foot.

Compartment pressure measurements are difficult to perform with invasive catheterization in an awake child with trauma to the foot. Often, the compartments need to be measured under a general anesthetic, so the child and parents need to be warned that the surgeon may proceed to a decompression. There are nine compartments in the foot, and it is difficult to confirm exact compartment location. It is important, however, to measure the pressure in the calcaneal compartment because it appears to be the most sensitive.[109] When a pressure of greater than 30 mm Hg is measured in any compartment, a fasciotomy should be performed.[109,119] It may be more accurate to use a measurement that takes into account the patient's blood pressure. In adults, the threshold is a measured pressure that is less than 30 mm Hg below the patient's diastolic blood pressure.[108]

There are nine fascial compartments in the foot that contain the intrinsic muscles and short plantar flexors. When a decompression is carried out, all the compartments should be released regardless of the clinical findings or compartment measurements. The most thorough way to achieve this is by using the three incision technique described by Myerson (Fig. 33-45).[119] Two dorsal longitudinal incisions are made in line with the second and fourth metatarsals. Dissection is then carried out through the interosseous compartments and fascia to enable decompression of the deep plantar compartments. Puncturing the fascia and spreading with a hemostat is an effective and safe technique. The lateral compartment is decompressed through the incision over the fourth metatarsal by dissecting deep to the fifth metatarsal. A medial incision is made along the arch of the foot as far posterior as the medial malleolus. This incision allows decompression of the medial compartment and a more thorough decompression of the deep compartments. It also allows decompression of the tarsal tunnel. Dissection is carried out on both the dorsal and plantar surfaces of the abductor hallucis muscle, freeing it from both the plantar fascia and bony attachments. Care must be taken to avoid damaging the lateral plantar nerve and vessels which lie on the quadrates plantae muscle. The deep compartments can now be easily released under direct vision. These three incisions are usually well placed to help with fracture reduction and K-wiring to stabilize the foot at the same time as the decompression. The wounds should be left open initially and closed 5 to 7 days later. Often, one of the wounds will require split-skin grafting.

Although uncommon in children, late sequelae of missed compartment syndrome can lead to disability including claw toe deformity, paresthesia, cavus deformity, stiffness, and residual pain.[14,167]

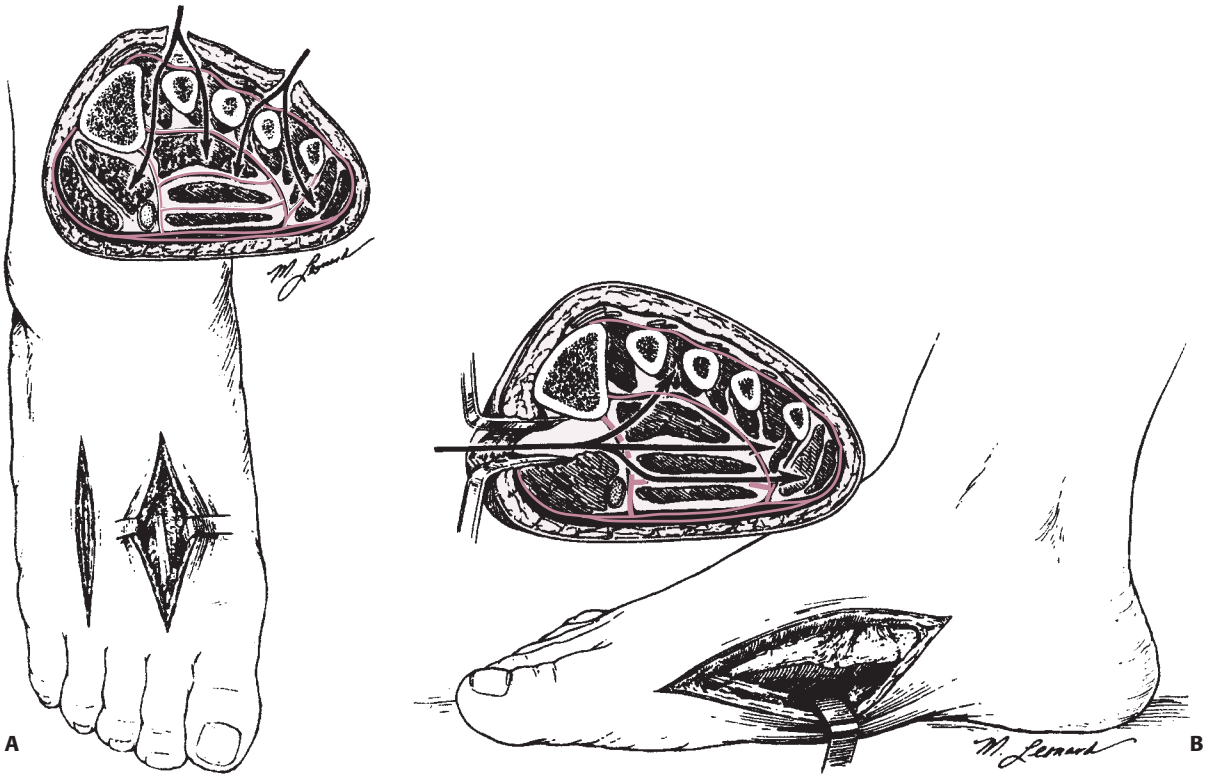

FIGURE 33-45 Surgical approaches for fasciotomy of the foot. **A:** The dorsal approach is made through an incision over the second and fourth metatarsal shafts and is more suitable for injuries of the forefoot or midfoot. **B:** The medial approach is more suitable for injuries of the hindfoot, with the incision extending from the base of the first metatarsal to the medial malleolus. A tarsal tunnel release can be done through this incision. (From Myerson MS. Experimental decompression of the fascial compartments of the foot: The basis for fasciotomy in acute compartment syndromes. *Foot Ankle.* 1988;8:308–314, with permission.)

Puncture Wounds

Puncture wounds to the foot are extremely common in children and frequently treated by primary care physicians or in the emergency department. Most injuries can be treated by simply removing the offending foreign body, irrigating the entry site, giving tetanus prophylaxis if required, and a short course of oral antibiotics. It is important to carefully assess the foreign body that is removed to make sure a small part of it has not been retained in the foot. Often, the patient will bring the offending foreign body with them if it broke off or came out spontaneously. The depth of penetration should also be assessed by looking at the length of the foreign object as well as the point of entry. This may help predict if a joint or tendon sheath has been penetrated. The amount of contamination can also help determine if an open debridement is necessary and the length of administration of antibiotics.

Radiographs are useful in most cases of acute puncture wounds as occasionally a foreign body will be seen. If the foreign body has punctured a joint, air may be seen as well. When a retained foreign body is still suspected but not seen on radiograph, an ultrasound scan can be useful to identify its location. An MRI scan is even more useful at identifying foreign bodies and has the added advantage of showing secondary changes of septic arthritis or osteomyelitis if the puncture wound is more chronic (Fig. 33-46).

If a patient with a treated puncture wound does not rapidly improve clinically, further investigation is required to rule out a retained foreign body, deep soft tissue infection, septic arthritis, or osteomyelitis. Eidelman et al.[48] recommend that patients who have an established infection 24 to 36 hours after a puncture wound should be admitted to hospital for IV antibiotics. In their series of 80 children with puncture wounds, a delay in diagnosis or presentation was associated with deep infection.[48] The most common organism causing deep infections in their study was *Staphylococcus aureus* and Group A *Streptococcus.* A complete blood count, erythrocyte sedimentation rate, and C-reactive protein should be performed, and an MRI scan is the most accurate radiologic investigation.[74,90] The patient can then be treated accordingly with IV antibiotics and open debridement of the entry site and deeper tissues.

Septic arthritis or osteomyelitis should be suspected if a child presents with foot pain and swelling following a puncture wound to the foot with a nail while wearing sneakers. Pseudomonas osteochondritis is thought to occur when the cartilage is damaged at the initial injury.[54] The source of the pseudomonas

FIGURE 33-46 MRI scans are useful following penetrating foot injuries as the extent of the soft tissue or joint involvement can be clearly seen. This 6-year-old boy had pain 4 days after standing on a nail in barefeet, and despite oral antibiotics he had developed a septic arthritis.

is debatable; however, some authors have postulated that it is from the sneakers.[53,91] The patient should be admitted to hospital and a thorough debridement of the affected soft tissues, cartilage, and bone should be carried out. IV antibiotics are administered often for 5 to 7 days or until the infection has clearly resolved.[76,78] The long-term sequelae of pain, growth arrests, chronic osteomyelitis, and recurrence make this an important infection to identify early and treat aggressively.

Stress Fractures

Stress fractures in children are becoming more common because of overtraining in youth athletics and year-round participation in sports.[31] The tibia, fibula, femur, and pars interarticularis are the areas most commonly affected; however, stress fractures in the foot can also occur.[34,43,60,184]

The predominant symptom is "pain with weight bearing," and this usually coincides with the beginning of an intense period of training. The repetitive training results in bone fatigue and eventual partial or complete fracture. The normal cortical bone remodeling is accelerated and resorption occurs at a faster rate than the reparative process resulting in weakening of the bone and inevitable microfracture. Treatment, therefore, is aimed at breaking this cycle by activity modification and protected weight bearing to prevent further fracture and allow the reparative process to "catch up."

Patients with stress fractures in the foot present with pain on weight bearing and often no history of any particular injury that may have been the cause. A thorough history of their training regimen is essential, particularly any increases or changes in technique playing surface or footwear. On examination, there is point tenderness but minimal swelling. Radiographs taken early in the process are often normal but later show periosteal layering of new bone on the cortex and osteolysis at the fracture site. Bone scans are often more sensitive initially and a three-phase technetium bone scan is helpful when the radiographs are normal in the first 2 to 3 weeks after the onset of symptoms.[49] MRI has been shown to identify stress fractures before radiographic changes are evident, and in a prospective study of collegiate basketball players, MRI demonstrated marrow edema even before stress fractures were clinically evident.[107]

As well as concentrating on the fracture itself, the patient should be assessed for any conditions that could predispose them to stress fractures. These conditions include metabolic bone diseases, amenorrhea, eating disorders, and incorrect training techniques. There may have been as simple a cause as a change in footwear that has lead to increased stress in a particular bone in the foot.

The second metatarsal is the most common bone in the foot to get a stress fracture. This usually occurs at the neck of the metatarsal at the junction of the mobile shaft and rigid metaphysis. Treatment involves rest and partial weight bearing in a moon-boot for 4 to 6 weeks. It is best to avoid a cast as during this time the athlete can maintain physical fitness with swimming, deep water running, and exercycling. A gradual return to activity can be restarted when radiographs confirm adequate healing and the symptoms have abated which often takes 8 to 12 weeks. Stress fractures of the navicular are disabling and difficult to treat. They occur most commonly in basketball players, hurdlers, and runners.[115] Bennell and Bruckner[11] reviewed 18 large studies of stress fractures and found that the incidence of navicular stress fractures can range between 0% and 28.6% of injuries among track and field athletes. These fractures are thought to arise because of overuse and the reduced vascularity that can exist in the central third of the navicular. They are difficult to diagnose and one needs to have a high level of suspicion as with any other stress fracture. The fracture is often diagnosed by technetium bone scan, and if this is positive in the region of the navicular, a CT scan is very helpful in delineating the stress response from an acute injury. The fracture line on CT, and if present on radiograph, is vertically orientated in the middle third of the bone. Most of these fractures heal with rest and protective weight bearing; however, some do go on to delayed or nonunion. The treatment for a painful nonunion is open reduction and internal fixation with autogenous bone grafting.[133] The average time for the return to activity following a navicular stress fracture in athletes is 5.6 months.[86] Stress fractures of the base of the fifth metatarsal usually occur in zone 2 or 3 and their treatment is discussed earlier in the chapter under the section fractures of the fifth metatarsal base.

Stress fractures can also occur in the cuboid, calcaneus, and sesamoid bones of the foot.
